www.nationaldiabetesalliance.org, whose members include many of the governmental and physician organizations concerned with diabetes quality-of-care measures.

The major performance measures should assess the ability to meet current standards of care and recognize the minimal treatment goals for glycemia, lipids, and hypertension, and provide targets for monitoring and adjusting pharmacotherapy as discussed in various sections above. Unfortunately, current publicly-reported quality measures often fall short of current guidelines. Glycemic control (percentage of patients with <9% lipid (percentage of patients with LDL <130 mg/dL), and hypertension (percentage of patients with blood pressure <140/90 mm Hg) quality measures are not congruent with the current goals recommended by the American Diabetes Association or American College of Endocrinology/American Association of Clinical Endocrinologists. Glycemic control is paramount in managing type 1 or type 2 DM, but as readily identified from the above discussion, it requires frequent assessment and adjustment in diet, exercise, and pharmacologic therapies. Minimally, HbA_{1c} should be measured twice a year in patients meeting treatment goals on a stable therapeutic regimen. Quarterly assessments are recommended for those whose therapy has changed or who are not meeting glycemic goals. Fasting lipid profiles should be obtained as part of an initial assessment and thereafter at each follow-up visit if not at goal, annually if stable and at goal, or every 2 years if the lipid profile suggests low risk. Documenting regular frequency of foot exams (each visit), urine albumin assessment (annually), dilated ophthalmologic exams (yearly or more frequently with identified abnormalities), and office visits for follow-up are also important. Assessment for pneumococcal vaccine administration, annual administration of influenza vaccine, and routine assessment for and management of other cardiovascular risks (i.e., smoking and antiplatelet therapy) are components of preventive medicine strategies. The multiplicity of assessments for each patient visit are likely to be better facilitated utilizing an integrative computer program, standardized progress note forms, or flow sheets, which assist the clinician in identifying whether the patient has met standards of care in the frequency of monitoring and achievement of defined targets of therapy.

ABBREVIATIONS

ACE: angiotensin-converting enzyme
 ADA: American Diabetes Association
 ALT: alanine aminotransferase
 BMI: body mass index
 CDE: certified diabetes educator
 CHD: coronary heart disease
 CSII: continuous subcutaneous insulin infusion
 CYP450: cytochrome P450
 DCCT: Diabetes Control and Complications Trial
 DM: diabetes mellitus
 FFA: free fatty acid
 GCT: glucose challenge test
 GDM: gestational diabetes mellitus
 HbA_{1c}: hemoglobin A_{1c}
 HDL-C: high-density lipoprotein cholesterol
 IFG: impaired fasting glucose
 IGT: impaired glucose tolerance
 IRS: insulin resistance syndrome
 LADA: latent autoimmune diabetes in adults
 LDL-C: low-density lipoprotein cholesterol

MODY: maturity onset diabetes of youth
 NCEP-ATP: National Cholesterol Education Program Adult Treatment Panel
 NHANES III: The Third National Health and Nutrition Evaluation Survey
 NPH: neutral protamine Hagedorn
 OGTT: oral glucose tolerance test
 PAI-1: activator-1 plasminogen-inhibitor
 PPAR- γ : peroxisome proliferator activator receptor- γ
 SUR: sulfonylurea receptor
 SMBG: self-monitoring of blood glucose
 TZD: thiazolidinedione
 UKPDS: United Kingdom Prospective Diabetes Study
 VAT: visceral adipose tissue

THYROID DISORDERS

Robert L. Talbert

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The molecular biology of the thyroid hormones and their receptors has provided an in-depth understanding of the various mutations that give rise to hyper- and hypothyroidism.
- 2 Thyrotoxicosis is most commonly caused by Graves' disease, which is an autoimmune disorder in which thyroid-stimulating antibody (TSAb) directed against the thyrotropin receptor elicits the same biologic response as thyroid-stimulating hormone (TSH).
- 3 Hyperthyroidism may be treated with antithyroid drugs such as propylthiouracil (PTU) or methimazole (MMI), radioactive iodine (RAI; e.g., ^{131}I), or surgical removal of the thyroid gland; selection of the initial treatment approach is based on patient characteristics such as age, concurrent physiology (e.g., pregnancy), comorbidities (e.g., chronic obstructive lung disease), and convenience.
- 4 PTU and MMI reduce the synthesis of thyroid hormones and are similar in efficacy and adverse effects, but their dosing ranges differ by 10-fold.
- 5 Response to PTU and MMI is seen in 4 to 6 weeks with a maximal response in 4 to 6 months; treatment usually continues for 1 to 2 years and therapy is monitored by clinical signs and symptoms and by measuring the serum concentrations of TSH and free thyroxine (T_4).
- 6 Many patients choose to have ablative therapy with ^{131}I rather than undergo repeated courses of PTU or MMI; most receiving RAI eventually become hypothyroid and require thyroid hormone supplementation.
- 7 Adjunctive therapy with β -blockers controls the adrenergic symptoms of thyrotoxicosis, but does not correct the underlying disorder; iodine may also be used adjunctively in preparation for surgery and acutely for thyroid storm.
- 8 Hypothyroidism is most often due to an autoimmune disorder known as Hashimoto's thyroiditis, and the drug of choice for replacement therapy is T_4 .
- 9 Monitoring of thyroxine replacement therapy is done by clinical signs and symptoms and by measuring the TSH (elevated for underreplacement) and free T_4 (below normal for underreplacement).

Thyroid hormones affect the function of virtually every organ system. In the child, thyroid hormone is critical for normal growth and development. In the adult, the major role of thyroid hormone is to maintain metabolic stability. Substantial reservoirs of thyroid hormone in the thyroid gland and blood provide constant thyroid hormone availability. In addition, the hypothalamic-pituitary-thyroid axis is exquisitely sensitive to small changes in circulating thyroid hormone concentrations, and alterations in thyroid hormone secretion maintain peripheral free thyroid hormone levels within a narrow range. Patients seek medical attention for evaluation of symptoms owing to abnormal thyroid hormone levels or because of diffuse or nodular thyroid enlargement.

THYROID HORMONE PHYSIOLOGY

THYROID HORMONE SYNTHESIS

The thyroid hormones thyroxine (T_4) and triiodothyronine (T_3) are formed on thyroglobulin, a large glycoprotein synthesized within the thyroid cell (Fig. 73–1). Because of the unique tertiary structure of

this glycoprotein, iodinated tyrosine residues present in thyroglobulin are able to bind together to form active thyroid hormones.^{1,2}

Iodide is actively transported via a Na^+/I^- symporter from the extracellular space into the thyroid follicular cell against both electrical and biochemical gradients.³ Structurally related anions such as SCN^- (thiocyanate), ClO_4^- (perchlorate), and TcO_4^- (pertechnetate) are competitive inhibitors of iodine transport.⁴ In addition, bromine, fluorine, and lithium block iodide transport into the thyroid (Table 73–1). Inorganic iodide that enters the thyroid follicular cell is oxidized by thyroid peroxidase and is covalently bound (organified) to tyrosine residues of thyroglobulin (Fig. 73–2). It is interesting that although salivary glands and the gastric mucosa are able to actively transport iodide, they are unable to effectively incorporate iodide into proteins. Similarly, when tyrosine molecules are iodinated on proteins other than thyroglobulin, they lack the proper tertiary structure needed to allow the formation of active thyroid hormones.

The iodinated tyrosine residues monoiodotyrosine (MIT) and diiodotyrosine (DIT) combine to form iodothyronines (Fig. 73–3). Thus, two molecules of DIT combine to form T_4 , whereas MIT and DIT constitute T_3 . In addition to its role in iodine organification,

FIGURE 73-1. Structure of thyroid hormones.

the hemoprotein thyroid peroxidase also catalyzes the formation of iodothyronines (coupling).

Iodine deficiency causes an increase in the ratio of MIT to DIT in thyroglobulin and leads to a relative increase in the production of T₃. Because T₃ is more potent than T₄, the increase in T₃ production in iodine-depleted areas may be beneficial. The thionamide drugs used to treat hyperthyroidism inhibit thyroid peroxidase and thus block thyroid hormone synthesis.

Thyroglobulin is stored in the follicular lumen and must re-enter the cell, where the process of proteolysis liberates thyroid hormone into the bloodstream. Thyroid follicles active in hormone synthesis are identified histologically by columnar epithelial cells lining follicular lumens, which are depleted of colloid. Inactive follicles are lined by cuboidal epithelial cells and are replete with colloid. Both iodide and lithium block the release of preformed thyroid hormone, through poorly understood mechanisms.

T₄ and T₃ are transported in the bloodstream by three proteins: thyroid-binding globulin (TBG), thyroid-binding prealbumin (TBPA), and albumin.⁵ It is estimated that 99.96% of T₄ and 99.5% of T₃ are bound to these proteins. Only the unbound (free) thyroid hormone is able to diffuse into the cell, elicit a biologic effect, and regulate thyroid-stimulating hormone (TSH; also known as thyrotropin) secretion from the pituitary.

Whereas T₄ is secreted solely from the thyroid gland, less than 20% of T₃ is produced in the thyroid. The majority of T₃ is formed from the breakdown of T₄ catalyzed by the enzyme 5'-monodeiodinase found in peripheral tissues. Because T₃ may be five times more active than T₄, the deiodinase enzymes play a pivotal role in determining overall metabolic activity. Three different 5'-monodeiodinase enzymes are present in the body.⁶ Type I enzymes are present in peripheral tissues, whereas type II enzymes are found in the central nervous system, pituitary, and thyroid. Type III en-

TABLE 73-1. Thyroid Hormone Synthesis and Secretion Inhibitors

| Mechanism of Action | Substance |
|---|---|
| Blocks iodide transport into the thyroid | Bromine Fluorine Lithium |
| Impairs organification and coupling of thyroid hormones | Thionamides Sulfonyleureas Sulfonamide(?) Salicylamide(?) Antipyrine(?) |
| Inhibits thyroid hormone secretion | Iodide (large doses) Lithium |

FIGURE 73-2. Thyroid hormone synthesis. Iodide is transported from the plasma, through the cell, to the apical membrane where it is organified and coupled to the thyroglobulin (TG) synthesized within the thyroid cell. Hormone stored as colloid re-enters the cell through endocytosis and moves back toward the basal membrane, where T₄ is secreted.

zymes, found in the placenta, skin, and developing brain, inactivate T₄ and T₃.^{5,7} The principal characteristics of these enzymes are listed in Table 73-2. T₄ may also be acted on by the enzyme 5'-monodeiodinase to form reverse T₃. Reverse T₃ has no known significant biologic activity. T₃ is removed from the body by deiodinative degradation and through the action of sulfotransferase enzyme systems to T₃ sulfate and 3,3'-diiodothyronine sulfates.

The growth and function of the thyroid are stimulated by activation of the thyrotropin receptor by thyroid-stimulating hormone.⁸ This receptor belongs to the family of G-protein-coupled receptors. The thyrotropin receptor is coupled to the α subunit of the stimulatory guanine-nucleotide-binding protein (G_s), activating adenylate cyclase and increasing the accumulation of cyclic adenosine

FIGURE 73-3. Scheme of coupling reactions. After tyrosine is iodinated to form MIT or DIT (organification of the iodine), MIT and DIT combine to form triiodothyronine (T₃), or two molecules of DIT form T₄.

TABLE 73–2. Properties of Iodothyronine 5′-Deiodinase Isoforms

| Property | Type I | Type II | Type III |
|----------------------------|--|--|--|
| Effect of propylthiouracil | Increase | Decrease | Increase |
| Tissue localization | Thyroid, liver, kidney | Pituitary, thyroid, CNS, brown adipose tissue | Placenta, developing brain, skin |
| Preferred substrate | rT ₃ > T ₄ > T ₃ | T ₄ > T ₃ | T ₃ (sulfate) > T ₄ |
| Physiologic role | Extracellular T ₃ production for peripheral tissue | Intracellular T ₃ production, especially for brain in hypothyroidism or iodine deficiency | Inactivation of T ₄ and T ₃ |
| Developmental expression | Expressed latest in development; predominant deiodinase in adult | Expressed second; especially high in brain and brown adipose tissue | Expressed first; high in developing brain; may be important for fetal thyroid hormone metabolism |

rT₃, reverse T₃; T₃, triiodothyronine; T₄, thyroxine.

monophosphate. This regulates the expression of thyroglobulin and thyroid peroxidase genes. A mutation in the receptor that results in chronic stimulation causes diffuse thyroid enlargement and hyperthyroidism (germline mutations) or autonomously functioning thyroid nodules (somatic mutation in an epithelial cell).⁹ Conversely, thyrotropin resistance would result from point mutations, leading to abnormalities in the thyrotropin receptor–adenylate cyclase system.⁸ Individuals with this abnormality have high levels of TSH, but decreased thyroglobulin levels and a normal or small gland.

Thyroid hormone receptors^{10,11} regulate the transcription of target genes in the presence of physiologic concentrations of T₃. Thyroid receptors translocate from the cytoplasm to the nucleus and interact in the nucleus with T₃, and target genes and other proteins required for basal and T₃-dependent gene transcription. Thyroid receptors exist in multiple isoforms such as TRβ2, TRβ1, TRα1, and others in man and animals. There is some evidence that the genes that encode for these receptors, THRA and THRB, may be linked to some human cancers.¹²

The production of thyroid hormone is regulated in two main ways. First, thyroid hormone is regulated by TSH secreted by the anterior pituitary. The secretion of TSH is itself under negative feedback control by the circulating level of free thyroid hormone and the positive influence of hypothalamic thyrotropin-releasing hormone (TRH). Second, extrathyroidal deiodination of T₄ to T₃ is regulated by a variety of factors including nutrition, nonthyroidal hormones, drugs, and illness.

THYROTOXICOSIS

Thyrotoxicosis results when tissues are exposed to excessive levels of T₄, T₃, or both.¹³ In the National Health and Nutrition Examination Survey III, 0.2% of those surveyed who were not taking thyroid medications and had no history of thyroid disease had subclinical hyperthyroidism (TSH <0.1 milli-international units/L; and T₄ normal), and 0.2% had “clinically significant” hyperthyroidism (TSH <0.1 milli-international units/L; and T₄ >13.2 mcg/dL).¹⁴ The prevalence of suppressed TSH peaked in people aged 20 to 39, declined in those 40 to 79, and increased again in those 80 or older. Elevated and suppressed TSH levels were more common among women than among men.

CLINICAL PRESENTATION OF THYROTOXICOSIS

GENERAL

Patients may have symptoms for an extended time period before the diagnosis of hyperthyroidism is made.

SYMPTOMS

The clinical manifestations of thyrotoxicosis include nervousness, anxiety, palpitations, emotional lability, easy fatigability, and heat intolerance. A cardinal sign is loss of weight concurrent with an increased appetite.

SIGNS

A variety of physical signs may be elicited including warm, smooth, moist skin, exophthalmos, pretibial myxedema, and unusually fine hair. Separation of the end of the fingernails from the nail beds (onycholysis) may be noted. Ocular signs that result from thyrotoxicosis include retraction of the eyelids and lagging of the upper lid behind the globe when the patient looks downward (lid lag). Physical signs of a hyperdynamic circulatory state are common and include tachycardia at rest, a widened pulse pressure, and a systolic ejection murmur. Gynecomastia is sometimes noted in men. Neuromuscular examination often reveals a fine tremor of the protruded tongue and outstretched hands. Deep tendon reflexes are generally hyperactive. Thyromegaly is usually present.

DIAGNOSIS

- Elevated free and total T₃ and T₄ serum concentrations. Low thyroid-stimulating hormone (TSH) serum concentration¹⁵
- Elevated radioactive iodine uptake (RAIU) by the thyroid gland

OTHER TESTS

- Thyroid stimulating antibodies (TSAb)
- Thyroglobulin
- Thyrotropin receptor antibodies
- Thyroid biopsy

TABLE 73–3. Differential Diagnosis of Thyrotoxicosis

| Increased RAIU | Decreased RAIU |
|--|--------------------------------------|
| TSH-induced hyperthyroidism | Inflammatory thyroid disease |
| TSH-secreting tumors | Subacute thyroiditis |
| Selective pituitary resistance to T ₄ | Painless thyroid |
| Thyroid stimulators other than TSH ^a | Ectopic thyroid tissue |
| TSAb (Graves' disease) | Struma ovarii |
| hCG (trophoblastic diseases) | Metastatic follicular carcinoma |
| Thyroid autonomy | Exogenous sources of thyroid hormone |
| Toxic adenoma | Medication |
| Multinodular goiter | Food |

hCG, human chorionic gonadotropin; RAIU, radioactive iodine uptake; TSAb, thyroid-stimulating antibodies; TSH, thyroid-stimulating hormone.

^aThe RAIU may be decreased if the patient has been recently exposed to excess iodine.

Adapted from Ingbar SH, Braverman LE, Werner S. *The Thyroid*, 5th ed. Philadelphia, JB Lippincott, 1986, with permission.

In the elderly patient and in the patient with very severe disease, anorexia may be present as well. Elderly patients are also more likely to develop atrial fibrillation with thyrotoxicosis than younger patients. The frequency of bowel movements may increase but frank diarrhea is unusual. Palpitations are a prominent and distressing symptom, particularly in the patient with pre-existing heart disease. Proximal muscle weakness is common and is noted on climbing stairs or in getting up from a sitting position. Women may note their menses are becoming scanty and irregular. Extremely thyrotoxic (thyrotoxic storm) patients may have tachycardia, heart failure, psychosis, hyperpyrexia, and coma.¹³

DIFFERENTIAL DIAGNOSIS

Measurement of the radioactive iodine uptake (RAIU) is critical in the evaluation of the clinically thyrotoxic patient (Table 73–3). The normal 24-hour RAIU ranges from 10% to 30% with some regional variation owing to differences in iodine intake. An elevated RAIU indicates true hyperthyroidism, that is, the patient's thyroid gland is actively overproducing T₄, T₃, or both. Conversely, a low RAIU indicates the excess thyroid hormone is not a consequence of thyroid gland hyperfunction. The importance of differentiating true hyperthyroidism from other causes of thyrotoxicosis lies in the widely different prognosis and treatment of the diseases in these two categories. Therapy of thyrotoxicosis associated with thyroid hyperfunction is mainly directed at decreasing the rate of thyroid hormone synthesis, secretion, or both. Such measures are ineffective in treating thyrotoxicosis that is not the result of true hyperthyroidism, because hormone synthesis and regulated hormone secretion are already at a minimum.

CAUSES OF THYROTOXICOSIS ASSOCIATED WITH ELEVATED RAIU

TSH-INDUCED HYPERTHYROIDISM

To better understand these syndromes we must first review TSH biosynthesis and secretion. TSH is synthesized in the anterior pituitary as separate α - and β -subunit precursors. The α subunits from luteinizing hormone (LH), follicle-stimulating hormone (FSH), human chorionic gonadotropin (hCG), and TSH are similar, whereas the β subunits are unique and confer immunologic and biologic speci-

ficity. Free β subunits are devoid of receptor binding and biologic activity and require combination with an α subunit to express their activity. Criteria for the diagnosis of TSH-induced hyperthyroidism include (1) evidence of peripheral hypermetabolism, (2) diffuse thyroid gland enlargement, (3) elevated free thyroid hormone levels, and (4) elevated serum immunoreactive TSH concentrations. Because the pituitary gland is extremely sensitive to even minimal elevations of free T₄, a detectable TSH level in any thyrotoxic patient indicates the inappropriate production of TSH.

TSH-SECRETING PITUITARY ADENOMAS

TSH-secreting pituitary tumors^{16,17} occur sporadically and release biologically active hormone that is unresponsive to normal feedback control. The mean age at diagnosis is around 40 years, with women being diagnosed more commonly than men (8:7). These tumors may co-secrete prolactin or growth hormone; therefore the patients may present with amenorrhea/galactorrhea or signs of acromegaly. Most patients present with classic symptoms and signs of thyrotoxicosis. Visual-field defects may be present owing to impingement of the optic chiasm by the tumor. Tumor growth and worsening visual-field defects have been reported following treatment of thyrotoxicosis.

Diagnosis of a TSH-secreting adenoma should be made by demonstrating lack of TSH response to TRH stimulation, elevated α -subunit levels, and radiologic imaging. Note that some small tumors are not identified by MRI. Moreover, 10% of "normal" individuals may have pituitary tumors noted on pituitary imaging.¹⁸

Transsphenoidal pituitary surgery is the treatment of choice for TSH-secreting adenomas. Pituitary gland irradiation is often given following surgery to prevent tumor recurrence. Bromocriptine has been used to treat tumors that co-secrete prolactin.

PITUITARY RESISTANCE TO THYROID HORMONE

Pituitary resistance to thyroid hormone (PRTH) refers to selective resistance of the pituitary thyrotrophs to thyroid hormone.^{8,19} About twice as many women as men have been reported with this rare, probably familial syndrome. Multiple abnormalities have been reported in the initial 50 reported cases including schizophrenia (three patients), mental retardation (two patients), short fourth metacarpals (one patient), and Marfanoid habitus (one patient). About 90% of patients studied have an appropriate increase in TSH in response to TRH; conversely, the TSH will be suppressed by T₃ administration.

Patients with PRTH require treatment to reduce their elevated thyroid hormone levels. Determining the appropriate serum T₄ level is difficult because TSH cannot be used to evaluate adequacy of therapy. Any reduction in thyroid hormone carries the risk of inducing thyrotroph hyperplasia. Ideally, agents that suppress TSH secretion could be used to treat these individuals. Glucocorticoid, dopaminergic drugs, somatostatin and its analog, and thyroid hormone analogs with reduced metabolic activity have all been tried. None is ideal.

THYROID STIMULATORS OTHER THAN TSH

GRAVES' DISEASE

Graves' disease^{22–24} is an autoimmune syndrome that may include hyperthyroidism, diffuse thyroid enlargement, exophthalmos, pretibial myxedema, and thyroid acropachy (Figs. 73–4 and 73–5).^{21,22} Graves' disease is the most common cause of hyperthyroidism. The prevalence of Graves' disease is estimated to be 3 per

FIGURE 73-4. A 33-year-old male with Graves' disease manifested by bilateral exophthalmos, acropachy (clubbing), and extensive pretibial myxedema. When this photograph was taken, he already had been treated with radioactive ^{131}I , had become hypothyroid, and was receiving replacement therapy with exogenous L-thyroxine. (Reproduced with permission from Becker KL, ed. *Principles and Practice of Endocrinology and Metabolism*. Philadelphia, Lippincott, 1990.)

1000 population in the United States. Hyperthyroidism results from the action of thyroid-stimulating antibodies (TSAb), which are directed against the thyrotropin receptor on the surface of the thyroid cell. When these immunoglobulin G antibodies bind to the receptor, they activate the enzyme adenylate cyclase in the same manner as

TSH. Autoantibodies that react with orbital muscle and fibroblast tissue in the skin are responsible for the extrathyroidal manifestations of Graves' disease, and these autoantibodies are encoded by the same germline genes that encode for other autoantibodies for striated muscle and thyroid peroxidase. The defect leading to abnormal antibody production may be a genomic point mutation in the extracellular domain of the thyrotropin receptor.⁸ Clinically, the extrathyroidal disorders may not appear at the same time that hyperthyroidism develops.

There is now compelling evidence that heredity and gender both play a role in the development of clinically overt thyroid disease. Several lines of evidence support a role for heredity. First, there is a well-recognized clustering of Graves' disease within some families. Twin studies in Graves' disease have revealed that a monozygotic twin has a 50% likelihood of ultimately developing the disease compared to a 9% likelihood for a dizygotic twin. Second, the occurrence of other autoimmune diseases, including Hashimoto's thyroiditis, is also increased in families of patients with Graves' disease. Third, several studies have demonstrated an increased frequency of certain human leukocyte antigens (HLAs) in patients with Graves' disease. In Whites, HLA-D3 is present in at least one-half of patients, and the presence in an individual of both HLA-B8 and -D3 confers a fourfold greater risk for developing Graves' disease. A role for gender in the emergence of Graves' disease is suggested by the fact that hyperthyroidism is approximately eight times more common in women than men.

The thyroid gland is diffusely enlarged in the majority of patients and is commonly 40 to 60 g (two to three times the normal size). The surface of the gland is smooth and the consistency varies from soft to firm. In patients with severe disease, a thrill may be felt and a systolic bruit may be heard over the gland. The presence of any of the extrathyroidal manifestations of this syndrome including exophthalmos, thyroid acropachy, or pretibial myxedema in a thyrotoxic patient is pathognomonic of Graves' disease (see Fig. 73-4).

FIGURE 73-5. A and B. Different degrees of involvement of tissues with pretibial myxedema. (Reproduced with permission from Becker KL, ed. *Principles and Practice of Endocrinology and Metabolism*. Philadelphia, Lippincott, 1990.)

TABLE 73-4. Thyroid Function Test Results in Different Thyroid Conditions

| | Total T ₄ | Free T ₄ | Total T ₃ | T ₃ Resin Uptake | Free Thyroxine Index | TSH |
|---------------|----------------------|---------------------|----------------------|-----------------------------|----------------------|--------------------------------------|
| Normal | 4.5–12.5 mcg/dL | 0.8–1.5 ng/dL | 80–220 ng/dL | 22% to 34% | 1.0–4.3 units | 0.25–6.7 milli-international units/L |
| Hyperthyroid | ↑↑ | ↑↑ | ↑↑↑ | ↑ | ↑↑↑ | ↓↓ |
| Hypothyroid | ↓↓ | ↓↓ | ↓ | ↓↓ | ↓↓↓ | ↑↑ |
| Increased TBG | ↑ | Normal | ↑ | ↓ | Normal | Normal |

TBG, thyroid-binding globulin; TSH, thyroid-stimulating hormone.

An important clinical feature of Graves' disease is the occurrence of spontaneous remissions. The abnormalities in TSAb production may decrease or disappear over time in many patients.

The results of laboratory tests in thyrotoxic Graves' disease include an increase in the overall hormone production rate with a disproportionate increase in T₃ relative to T₄ (Table 73-4). In an occasional patient, the disproportionate overproduction of T₃ is exaggerated, with the result that only the serum T₃ concentration is increased (T₃ toxicosis). The saturation of thyroid-binding globulin (TBG) is increased owing to the elevated levels of serum T₄ and T₃. This is reflected in elevated values for the T₃ resin uptake. As a result, the concentration of free T₄, free T₃, and the free T₄ and T₃ indices are increased to an even greater extent than are the measured serum total T₄ and T₃ concentrations. The TSH level will be undetectable owing to negative feedback by elevated levels of thyroid hormone at the pituitary.

In the patient with manifest disease, measurement of the serum T₄ concentration, T₃ resin uptake (or free T₄), and the TSH value will confirm the diagnosis of thyrotoxicosis. If the patient is not pregnant, a 24-hour RAIU should be obtained. An increased RAIU documents that the thyroid gland is inappropriately utilizing the iodine to produce more thyroid hormone at a time when the patient is thyrotoxic.

Hypokalemic periodic paralysis is a rare complication of hyperthyroidism commonly observed in Asian and Hispanic populations. It presents as recurrent proximal muscle flaccidity ranging from mild weakness to total paralysis. The paralysis may be asymmetric and usually involves muscle groups that are strenuously exercised before the attack. Cognition and sensory perception are spared, whereas deep tendon reflexes are commonly markedly diminished. Hypokalemia results from a shift of potassium from extracellular to intracellular sites. High carbohydrate loads and exercise provoke the attacks. Treatment includes correcting the hyperthyroid state, potassium administration, spironolactone to conserve potassium, and propranolol to minimize intracellular shifts.²⁵

TROPHOBLASTIC DISEASES

In the past decade several lines of evidence have shown that human chorionic gonadotropin (hCG) is a thyroid stimulator and may cause hyperthyroidism.^{20,26} The basis for the thyrotropic effect of hCG is the structural similarity of hCG to TSH (similar α subunits and unique β subunits). In hyperthyroid patients with very high hCG levels, serum TSH may be inappropriately detectable owing to the weak cross-reactivity of hCG in the radioimmunoassay for TSH. In patients with hyperthyroidism caused by trophoblastic tumors, serum hCG levels usually exceed 300 units/mL and always exceed 100 units/mL. The mean peak hCG level in normal pregnancy is 50 units/mL. On a molar basis, hCG has only 1/10,000 the activity of pituitary TSH in mouse bioassays. Nevertheless, this thyrotropic activity may be very substantial in patients with trophoblastic tumors, whose serum hCG concentrations may reach 2000 units/mL.

THYROID AUTONOMY

TOXIC ADENOMA

An autonomous thyroid nodule is a discrete thyroid mass whose function is independent of pituitary control.^{27,28} The prevalence of toxic adenoma ranges from about 2% to 9% of thyrotoxic patients, and depends on iodine availability and geographic location. Toxic adenomas arise from gain-of-function somatic or germline mutations of the G_s α protein or the TSH receptor; more than a dozen TSH receptor mutations have been described.²⁷ These nodules may be referred to as a toxic adenoma or a "hot" nodule because of their appearance on a radioiodine thyroid scan (Fig. 73-6). The amount of thyroid hormone produced by an autonomous nodule is mass related. Therefore hyperthyroidism usually occurs with larger nodules (i.e., those >4 cm in diameter). Older patients (>60 years) are more likely (up to 60%) to be thyrotoxic from autonomous nodules than are younger patients (12%). There are many reports of isolated elevation of serum T₃ in patients with autonomously functioning nodules. Therefore if the T₄ level is normal, a T₃ level must be measured to rule out T₃ toxicosis. Once a radioiodine scan has demonstrated that the toxic thyroid adenoma would collect more radioiodine than the surrounding tissue, independent function may be documented by a failure of the autonomous nodule to decrease its iodine uptake during exogenous T₃ administration. RAI ablation, subtotal thyroidectomy, thionamides, and percutaneous ethanol injection are treatment options, but since thionamides do not halt the proliferative process in the nodule, definitive therapies are recommended. Because thyroid carcinoma is not a major consideration in an autonomously functioning thyroid nodule, observation is usually recommended for patients with autonomously functioning nodules who are euthyroid.

MULTINODULAR GOITERS

In multinodular goiters (MNGs; Plummer's disease),²⁷ follicles with a very high degree of autonomous function coexist with normal or even nonfunctioning follicles. Thyrotoxicosis in a multinodular goiter occurs when the follicles with a high degree of autonomy generate enough thyroid hormone to exceed the needs of the patient. The pathogenesis of multinodular goiter is thought to be similar to that of toxic adenoma.²⁹ It is not surprising that this type of hyperthyroidism develops insidiously over a period of several years and predominantly affects older individuals with long-standing goiters. Often, elderly women present with subtle signs of hyperthyroidism that are superimposed on underlying heart disease. The patient's complaints of weight loss, depression, anxiety, and insomnia may be attributed to old age. Any unexplained chronic illness in an elderly patient presenting with a multinodular goiter calls for the exclusion of hidden thyrotoxicosis. Third-generation TSH assays and T₃ suppression testing may be useful in detecting subclinical hyperthyroidism.³⁰

A thyroid scan will show patchy areas of autonomously functioning thyroid tissue. The preferred treatment for toxic MNG is RAI or

FIGURE 73-6. *Left.* Autonomously functioning nodule is suppressing the remainder of the thyroid gland. *Right.* Previously suppressed lobes of thyroid gland are visualized 3 months after radioiodine treatment of hyperfunctioning nodule. The “X” is a marker for thyroid cartilage. (Reproduced with permission from Becker KL, ed. *Principles and Practice of Endocrinology and Metabolism*. Philadelphia, Lippincott, 1990.)

surgery. Surgery is usually selected for younger patients and patients in whom large goiters impinge on vital organs. Alternatively, percutaneous injection of 95% ethanol has also been used to destroy single or multinodular adenomas with a 5-year success rate approaching 80%.

CAUSES OF THYROTOXICOSIS ASSOCIATED WITH SUPPRESSED RAIU

INFLAMMATORY THYROID DISEASE

Subacute Thyroiditis

Painful subacute (viral or deQuervain’s) thyroiditis may be caused by viral invasion of thyroid parenchyma. Typically, patients complain of severe pain in the thyroid region, which often extends to the ear on the affected side. With time, the pain may migrate from one side of the gland to the other. Low-grade fever is common. Systemic symptoms owing to thyrotoxicosis are present. On physical examination, the thyroid gland is firm and exquisitely tender. Signs of thyrotoxicosis are present.

Thyroid function tests typically run a triphasic course. Initially, serum thyroxine levels are elevated owing to release of preformed thyroid hormone from disrupted follicles. The 24-hour RAIU during this time is less than 2% owing to thyroid inflammation and TSH suppression by the elevated thyroxine level. As the disease progresses, intrathyroidal hormone stores are depleted and the patient may become mildly hypothyroid with an appropriately elevated TSH level. During the recovery phase thyroid hormone stores are replenished and serum TSH elevation gradually returns to normal. Recovery is generally complete within 2 to 6 months. Most patients remain euthyroid and recurrences of painful thyroiditis are extremely rare. The patient with painful thyroiditis should be reassured that the disease is self-limited and is unlikely to recur. Thyrotoxic symptoms may be relieved with β -blockers. Aspirin (650 mg orally every 6 hours)

will usually relieve the pain. Occasionally, prednisone (20 mg orally three times a day) must be used to suppress the inflammatory process. Antithyroid drugs are not indicated because they do not decrease the release of preformed thyroid hormone.

Painless Thyroiditis

Since its description in 1975, painless (silent, lymphocytic, postpartum) thyroiditis has been recognized as a common cause of thyrotoxicosis and may represent up to 15% of cases of thyrotoxicosis in North America. The etiology is not fully understood and may be heterogeneous. The triphasic course of this illness mimics that of painful thyroiditis. Most patients present with mild thyrotoxic symptoms. Lid retraction and lid lag are present but exophthalmos is absent. The thyroid gland may be diffusely enlarged but thyroid tenderness is absent.

The 24-hour RAIU will be suppressed to less than 2% during the thyrotoxic phase of painless thyroiditis.^{31,32} Antithyroglobulin and antimicrosomal antibody levels are elevated in more than 50% of patients. Painless thyroiditis frequently occurs during the immediate postpartum period, and individual patients may experience recurrence of the disease with subsequent pregnancies. Patients with mild hyperthyroidism and painless thyroiditis should be reassured that they have a self-limited disease. Adrenergic symptoms may be ameliorated with propranolol. Antithyroid drugs are not indicated because they do not decrease the release of preformed thyroid hormone.

ECTOPIC THYROID TISSUE

Struma Ovarii

Struma ovarii is a teratoid tumor of the ovary that is capable of making thyroid hormone. This extremely rare cause of thyrotoxicosis is suggested by the absence of thyroid enlargement in a thyrotoxic patient with a suppressed RAIU. The diagnosis is established by localizing functioning thyroid tissue in the ovary with whole-body radioactive

iodine (^{131}I) scanning. Interestingly, struma ovarii without associated hyperthyroidism is much more common than struma ovarii associated with hyperthyroidism. Because the tissue is neoplastic and potentially malignant, combined surgical and radioiodine treatment of malignant struma ovarii for both monitoring and therapy of relapse is the recommended treatment.³³

Follicular Cancer

In widely metastatic follicular carcinomas with relatively well-preserved function, sufficient thyroid hormone can be synthesized and secreted to produce thyrotoxicosis. In most instances, a previous diagnosis of thyroid malignancy has been made. The diagnosis can be confirmed by whole-body ^{131}I scanning. Treatment with ^{131}I is generally effective at ablating functioning thyroid metastases.

EXOGENOUS SOURCES OF THYROID HORMONE

The term *thyrotoxicosis factitia* denotes hyperthyroidism produced by the ingestion of exogenous thyroid hormone. Obesity is the most common nonthyroidal disorder for which thyroid hormone is used, but thyroid hormone has been used for almost every conceivable problem from menstrual irregularities and infertility to baldness. Because these patients do not benefit from treatment with thyroid hormone, the physician or patient may gradually increase the dose of hormone employed in an attempt to gain the desired effect. Obviously, thyrotoxicosis factitia can also occur when too large a dose of thyroid hormone is employed for conditions in which it is likely to be beneficial, such as hypothyroidism or nontoxic goiter. Rarely, thyrotoxicosis factitia is caused by the purposeful and secretive ingestion of thyroid hormone by disturbed patients (usually with a medical background) who wish to obtain attention or lose weight.

Thyrotoxicosis factitia should be suspected in a thyrotoxic patient without infiltrative ophthalmopathy or thyroid enlargement. The RAIU uptake is at low levels because the patient's thyroid gland func-

tion is suppressed by the exogenous thyroid hormone. Measurement of plasma thyroglobulin (TG) is a valuable laboratory aid in the diagnosis of thyrotoxicosis factitia. TG is normally secreted in small amounts by the thyroid gland; however, when thyroid hormone is taken orally, very low amounts of thyroglobulin are detectable in the plasma. In other entities characterized by a low RAIU, such as silent thyroiditis, leakage of preformed thyroid hormone results in elevated thyroglobulin levels. If a history of thyroid hormone ingestion is elicited or deduced, exogenous thyroid hormone should be withheld for between 4 and 6 weeks and thyroid function tests repeated to document that the euthyroid state has been restored.³⁴

Amiodarone may induce thyrotoxicosis (2% to 3% of patients) or hypothyroidism. Amiodarone contains 37.2% iodine by weight and approximately 6 mg/day of iodine is released for each 200 mg of amiodarone.^{4,35} The recommended daily amount of iodine is 200 mcg/day. Amiodarone interferes with type I 5'-deiodinase, leading to reduced conversion of T_4 to T_3 , and iodide released from the drug owing to deiodination contributes to iodine excess, especially in iodine-deficient areas. Amiodarone also causes a destructive thyroiditis with loss of thyroglobulin and thyroid hormones. Iodine-induced thyroid dysfunction occurs primarily in patients with pre-existing thyroid disease (Graves' disease, nodular goiter, or Hashimoto's thyroiditis) known as type I, or in patients who have apparently normal thyroid glands (type II). The two types may be differentiated using color flow Doppler ultrasonography.³⁶ Type I amiodarone-induced hyperthyroidism responds well to thionamides, whereas type II may require glucocorticoids or iopanoic acid.³⁷ An inflammatory process induced by amiodarone or iodine, which also leads to follicular cell damage and subacute thyroiditis with leakage of thyroid hormones into the circulation, is associated with elevated interleukin-6 levels. The manifestations may be atypical symptoms such as ventricular tachycardia and exacerbation of underlying chronic obstructive pulmonary disease. Prednisone has been reported to normalize interleukin-6 and thyroid hormone values.³⁸

► TREATMENT: Hyperthyroidism

■ DESIRED OUTCOMES

3 Three common treatment modalities are used in the management of hyperthyroidism: surgery, antithyroid medications, and radioactive iodine (RAI) (Table 73–5). The overall therapeutic objectives are to eliminate the excess thyroid hormone and minimize the symptoms and long-term consequences of hyperthyroidism. Therapy must be individualized based on the type and severity of hyperthyroidism, patient age and gender, existence of nonthyroidal conditions, and response to previous therapy.^{20,39,40} Clinical guidelines for the treatment of hyperthyroidism have been published by various groups.^{41–44}

■ NONPHARMACOLOGIC THERAPY

Surgical removal of the hypersecreting thyroid gland became feasible in 1923 when Plummer discovered that iodine reduced the gland's vascularity, making this definitive procedure possible. Surgery should be considered in patients with a large thyroid gland (>80 g), severe ophthalmopathy, and a lack of remission on antithyroid drug treatment. In case of cosmetic or pressure symptoms, the choice in multinodu-

lar goiter stands between surgery, which is still the first choice, and radioiodine if uptake is adequate (hot). In addition to surgery, the solitary nodule, whether hot or cold, can be treated with percutaneous ethanol injection therapy. If hot, radioiodine is the therapy of choice.⁴⁵ Traditional preparation of the patient for thyroidectomy includes propylthiouracil (PTU) or methimazole (MMI) until the patient is biochemically euthyroid (usually 6 to 8 weeks), followed by the addition of iodides (500 mg/day) for 10 to 14 days before surgery to decrease the vascularity of the gland. Levothyroxine may be added to maintain the euthyroid state while the thionamides are continued. Iodine supplementation in iodine-deficient areas of the country may lead to a greater reduction in remnant volume in nontoxic goiter.⁴⁶ Propranolol for several weeks preoperatively and 7 to 10 days after surgery has also been used to maintain a pulse rate of less than 90 beats/min. Combined pretreatment with propranolol and 10 to 14 days of potassium iodide also has been advocated.

The overall morbidity rate with surgery is 2.7%. Hyperthyroidism persists or recurs in 0.6% to 17.9% of patients after thyroidectomy for Graves' disease and is more common in children. The most common complications of surgery include hypothyroidism (up to about 49%), hypoparathyroidism (up to 3.9%), and vocal cord abnormalities (up to 5.4%). The frequent occurrence of hypothyroidism following surgery requires periodic follow-up for identification and treatment of these patients.^{47–49}

TABLE 73–5. Treatments for Hyperthyroidism Caused by Graves' Disease

| Treatment | Advantages | Disadvantages | Comment |
|--|--|---|--|
| Antithyroid drugs | Noninvasive Lower initial cost Low risk of permanent hypothyroidism Possible remissions due to immune effects | Low cure rate (30%–80%; average 40%–50%) Adverse drug reactions Drug compliance | First-line treatment in children, adolescents, and in pregnancy Initial treatment in severe cases or preoperative preparation |
| Radioactive iodine (¹³¹ I) | Cure of hyperthyroidism Most cost effective | Permanent hypothyroidism almost inevitable Might worsen ophthalmopathy Pregnancy must be deferred for 6–12 months; no breast-feeding Small potential risk of exacerbation of hyperthyroidism | Best treatment for toxic nodules and toxic multinodular goiter |
| Surgery | Rapid, effective treatment, especially in patients with large goiters | Most invasive Potential complications (recurrent laryngeal nerve damage, hypoparathyroidism) Most costly Permanent hypothyroidism Pain, scar | Potential in pregnancy if major side-effect from antithyroid Useful when coexisting suspicious nodule present Option for patients who refuse radioiodine |

■ PHARMACOLOGIC THERAPY

■ ANTITHYROID MEDICATIONS

■ Thiourea Drugs

Two drugs within this category, PTU and MMI, are approved for the treatment of hyperthyroidism in the United States.^{50,51} They are classified as thioureylenes (thionamides), which incorporate a N—C—S = N group into their ring structures.

4 ■ Mechanism of Action. PTU and MMI share several mechanisms to inhibit the biosynthesis of thyroid hormone.¹³ These drugs serve as preferential substrates for the iodinating intermediate of thyroid peroxidase and divert iodine away from potential iodination sites in thyroglobulin. This prevents subsequent incorporation of iodine into iodotyrosines and ultimately iodothyronine (“organification”). Second, they inhibit coupling of monoiodotyrosine and diiodotyrosine to form T₄ and T₃. The coupling reaction may be more sensitive to these drugs than the iodination reaction. Experimentally, these drugs exhibit immunosuppressive effects, although the clinical relevance of this finding is unclear. In patients with Graves' disease, antithyroid drug treatment has been associated with lower TSAbs titers and restoration of normal suppressor T-cell function. However, perchlorate, which has a different mechanism of action, also decreases TSAbs, suggesting that normalization of the thyroid hormone level may itself improve the abnormal immune function. PTU inhibits the peripheral conversion of T₄ to T₃. This effect is acutely dose-related and occurs within hours of PTU administration. MMI does not have this effect. Over time, depletion of stored hormone and lack of continuing synthesis of thyroid hormone results in the clinical effects of these drugs.

■ Pharmacokinetics. Both antithyroid drugs are well absorbed (80% to 95%) from the gastrointestinal tract, with peak serum concentrations about 1 hour after ingestion. The plasma half-life ranges of PTU and MMI are 1 to 2.5 hours and 6 to 9 hours, respectively, and are not appreciably affected by thyroid status. Urinary excretion is about 35% for PTU and less than 10% for MMI. These drugs are

actively concentrated in the thyroid gland, which may account for the disparity between their relatively short plasma half-lives and the effectiveness of once-daily dosing regimens even with PTU. Approximately 60% to 80% of PTU is bound to plasma albumin, whereas MMI is not protein-bound. Methimazole readily crosses the placenta and appears in breast milk. Older studies suggested that PTU crosses the placental membranes only one-tenth as well as MMI; however, these studies were done in the course of therapeutic abortion early in pregnancy. Newer studies show little difference between fetal concentrations of PTU and MMI, and both are associated with elevated TSH in about 20% and low T₄ in about 7% of the fetuses.⁵²

5 ■ Dosing and Monitoring. PTU is available as 50-mg tablets and MMI as 5- and 10-mg tablets. MMI is approximately 10 times more potent than PTU. Initial therapy with PTU ranges from 300 to 600 mg daily, usually in three or four divided doses. MMI is given in three divided doses totaling 30 to 60 mg/day. Although the traditional recommendation is for divided doses, evidence exists that both drugs can be given as single daily doses. Patients with severe hyperthyroidism may require larger initial doses, and some may respond better at these larger doses if the dose is divided. The maximal blocking doses of PTU and MMI are 1200 and 120 mg daily, respectively. Once the intrathyroidal pool of thyroid hormone is reduced and new hormone synthesis is sufficiently blocked, clinical improvement should ensue. Usually within 4 to 8 weeks of initiating therapy, symptoms are diminished and circulating thyroid hormone levels are returning to normal. At this time the tapering regimen can be started. Changes in dose for each drug should be made on a monthly basis, because the endogenously produced T₄ will reach a new steady-state concentration in this interval. Typical ranges of daily maintenance doses for PTU and MMI are 50 to 300 mg and 5 to 30 mg, respectively.

If the objective of therapy is to induce a long-term remission, the patient should remain on continuous antithyroid drug therapy for 12 to 24 months. Antithyroid drug therapy induces permanent remission rates of 10% to 98%, with an overall average of about 40% to 50%.⁵³ This is much higher than the remission rate seen with propranolol alone, which is reported to range from 22% to 36%. Patient

characteristics for a favorable outcome include older patients (>40 years), low ratio of T_4 to T_3 (<20), a small goiter (<50 g), short duration of disease (<6 months), no previous history of relapse with antithyroid drugs, duration of therapy 1 to 2 years or longer, and low T_SAb titers at baseline or a reduction with treatment.¹³ It is important that patients be followed every 6 to 12 months after remission occurs.

◀ **6** If a relapse occurs, alternate therapy with RAI is preferred to a second course of antithyroid drugs. Relapses seem to plateau after about 5 years and eventually 5% to 20% of patients will develop spontaneous hypothyroidism.

Concurrent administration of thyroxine with thionamide therapy for thyrotoxicosis and subclinical hyperthyroidism may reduce autoantibodies directed toward the thyroid gland and improve the remission rate; however, these effects have not been consistently observed in all studies.^{53,54} In a Japanese study, adjunctive treatment with thyroxine was associated with a 20-fold reduction in the recurrence rate of Graves' disease compared with the recurrence rate seen in patients treated with antithyroid drugs alone. Attempts to reproduce these results in American and European patients with Graves' disease have failed to show any delay or reduction in the recurrence of Graves' disease with thyroxine administration.⁵⁵

■ **Adverse Effects.** Minor adverse reactions to PTU and MMI have an overall incidence of 5% to 25% depending on the dose and the drug, whereas major adverse effects occur in 1.5% to 4.6% of patients receiving these drugs.^{13,56,57} Pruritic maculopapular rashes (sometimes associated with vasculitis based on skin biopsy), arthralgias, and fevers occur in up to 5% of patients and may occur at greater frequency with higher doses and in children. Rashes often disappear spontaneously, but if persistent, may be managed with antihistamines.

Perhaps one of the most common side effects is a benign transient leukopenia characterized by a white blood cell (WBC) count of less than 4000/mm³. This condition occurs in up to 12% of adults and 25% of children, and sometimes can be confused with mild leukopenia seen in Graves' disease. This mild leukopenia is not a harbinger of the more serious adverse effect of agranulocytosis, so therapy can usually be continued. If a minor adverse reaction occurs with one antithyroid drug, the alternate thiourea may be tried, but cross-sensitivity occurs in about 50% of patients.⁵⁰

Agranulocytosis is the most serious adverse effect of thiourea drug therapy and is characterized by fever, malaise, gingivitis, oropharyngeal infection, and a granulocyte count less than 250/mm³.⁵⁰ These drugs are concentrated in granulocytes and this reaction may represent a direct toxic effect rather than hypersensitivity. This toxic reaction has occurred with both thioureas, and the incidence varies from 0.5% to 6%. It is higher in patients over age 40 receiving a methimazole dose greater than 40 mg/day or the equivalent dose of PTU, and is linked to HLA class II genes containing the DRB1*08032 allele.⁵⁸ Agranulocytosis almost always develops in the first 3 months of therapy. Because the onset is sudden, routine monitoring is not recommended. Colony-stimulating factors have been used with some success to restore cell counts to normal, but it is unclear how effective this form of therapy is to routine supportive care.^{59,60} Peripheral lymphocytes obtained from patients with PTU-induced agranulocytosis undergo transformation in the presence of other thioamides, suggesting that these severe reactions are immunologically mediated and patients should not receive other thionamides. Aplastic anemia has been reported with MMI and may be associated with an inhibitor to colony-forming units. Once antithyroid drugs are discontinued, clinical improvement is seen over several days to weeks. Patients should be counseled to discontinue therapy and contact their physician when flu-like symptoms such as fever, malaise, or sore throat develop.

Arthralgias and a lupus-like syndrome (sometimes in the absence of antinuclear antibodies) have been reported in 4% to 5% of patients. This generally occurs after 6 months of therapy. Uncommonly, polymyositis, presenting as proximal muscle weakness and elevated creatine phosphokinase, has been reported with PTU administration. Gastrointestinal intolerance is also reported to occur in 4% to 5% of patients. Hepatotoxicity, which usually occurs within the first 3 months of therapy, may be seen with both methimazole and PTU with a prevalence of about 1.3%.⁶¹ In mice, MMI undergoes epoxidation of the C-4,5 double bond by cytochrome P450 enzymes, and after being hydrolyzed, the resulting epoxide is decomposed to form N-methylthiourea, a proximate toxicant.⁶² At moderate doses, some authors have found that initial enzyme elevations eventually normalize in most patients with continued therapy.⁶³ High doses of PTU are more likely to produce severe hepatitis and even death. Discontinuation of therapy usually results in complete resolution of hepatitis. Patients receiving interferon products for hepatitis C or other disorders may develop hyper- or hypothyroidism along with liver enzyme abnormalities.⁶⁴ Although older reports suggested that congenital skin defects (aplasia cutis) may be caused by methimazole and carbimazole, a registry review from the Netherlands could not find an association between maternal use of these drugs and skin defects.⁶⁵ Hypoprotrombinemia is a rare complication of thionamide therapy. Patients who have experienced a major adverse reaction to one thiourea drug should not be converted to the alternate drug because of cross-sensitivity.

■ Iodides

Iodide was the first form of drug therapy for Graves' disease. Its mechanism of action is to acutely block thyroid hormone release, inhibit thyroid hormone biosynthesis by interfering with intrathyroidal iodide utilization (the Wolff-Chaikoff effect), and decrease the size and vascularity of the gland. This early inhibitory effect provides symptom improvement within 2 to 7 days of initiating therapy, and serum T_4 and T_3 concentrations may be reduced for a few weeks. Despite the reduced release of T_4 and T_3 , thyroid hormone synthesis continues at an accelerated rate, resulting in a gland rich in stored hormones. The normal and hyperfunctioning thyroid soon escapes from this inhibitory effect within 1 to 2 weeks by decreasing the active transfer of iodide into the gland. Iodides are often used as adjunctive therapy to prepare a patient with Graves' disease for surgery, to acutely inhibit thyroid hormone release and quickly attain the euthyroid state in severely thyrotoxic patients with cardiac decompensation, or to inhibit thyroid hormone release following radioactive iodine therapy. However, large doses of iodine may exacerbate hyperthyroidism or indeed precipitate hyperthyroidism in some previously euthyroid individuals (Jod-Basedow disease).⁶⁶ This Jod-Basedow phenomenon is most common in iodine-deficient areas, particularly in patients with pre-existing nontoxic goiter. Iodide is contraindicated in toxic multinodular goiter.

Potassium iodide is available either as a saturated solution (SSKI), which contains 38 mg of iodide per drop, or as Lugol's solution, which contains 6.3 mg of iodide per drop. The typical starting dose of SSKI is 3 to 10 drops daily (120 to 400 mg) in water or juice. There is no documented advantage to using doses in excess of 6 to 8 mg/day. When used to prepare a patient for surgery, it should be administered 7 to 14 days preoperatively. As an adjunct to RAI, SSKI should not be used before, but rather 3 to 7 days after RAI treatment, so that the radioactive iodide can concentrate in the thyroid. The most frequent toxic effect with iodide therapy is hypersensitivity reactions (skin rashes, drug fever, rhinitis, and conjunctivitis); salivary gland swelling; "iodism" (metallic taste, burning mouth and throat, sore

teeth and gums, symptoms of a head cold, and sometimes stomach upset and diarrhea); and gynecomastia.

Other compounds containing organic iodide have also been used therapeutically for hyperthyroidism. These include various radiologic contrast media that share a triiodo- and monoaminobenzene ring with a propionic acid chain (e.g., iopanoic acid and sodium ipodate). The effect of these compounds is a result of the iodine content inhibiting thyroid hormone release as well as competitive inhibition of 5'-monodeiodinase conversion related to their structures, which resemble thyroid analogs.⁴

■ Adrenergic Blockers

7 Because many of the manifestations of hyperthyroidism are mediated by β -adrenergic receptors, β -blockers (especially propranolol) have been used widely to ameliorate thyrotoxic symptoms such as palpitations, anxiety, tremor, and heat intolerance. Although β -blockers are quite effective for symptom control, they have no effect on the urinary excretion of calcium, phosphorus, hydroxyproline, creatinine, or various amino acids, suggesting a lack of effect on peripheral thyrotoxicosis and protein metabolism. Furthermore, β -blockers do not reduce TSAb nor prevent thyroid storm. Propranolol and nadolol partially block the conversion of T_4 to T_3 , but this contribution to the overall therapeutic effect is small in magnitude. Inhibition of conversion of T_4 to T_3 is mediated by *d*-propranolol, which is devoid of β -blocking activity, and *l*-propranolol, which is responsible for the antiadrenergic effects and has little effect on the conversion.

β -Blockers are usually used as adjunctive therapy with antithyroid drugs, RAI, or iodides when treating Graves' disease or toxic nodules; in preparation for surgery; or in thyroid storm. The only conditions for which β -blockers are primary therapy for thyrotoxicosis are thyroiditis and iodine-induced hyperthyroidism. The dose of propranolol required to relieve adrenergic symptoms is variable, but an initial dose of 20 to 40 mg four times daily is effective (heart rate <90 beats/min) for most patients. Younger or more severely toxic patients may require as much as 240 to 480 mg/day because there seems to be an increased clearance rate in these patients. β -Blockers are contraindicated in patients with decompensated heart failure unless it is caused solely by tachycardia (high output). Nonselective agents and those lacking intrinsic sympathomimetic activity should be used with caution in patients with asthma and bronchospastic chronic obstructive lung disease. β -Blockers that are cardioselective and have intrinsic sympathomimetic activity may have a slight margin of safety in these situations. Other patients in whom contraindications exist are those with sinus bradycardia, those receiving monoamine oxidase inhibitors or tricyclic antidepressants, and those with spontaneous hypoglycemia. β -Blockers may also prolong gestation and labor during pregnancy. Other side effects include nausea, vomiting, anxiety, insomnia, light-headedness, bradycardia, and hematologic disturbances.

Antiadrenergic agents such as centrally acting sympatholytics and calcium channel antagonists may have some role in the symptomatic treatment of hyperthyroidism. These drugs might be useful when contraindications to β -blockade exist. When compared to nadolol 40 mg twice daily, clonidine 150 mcg twice daily reduced plasma catecholamines, whereas nadolol increased both epinephrine and norepinephrine after 1 week of treatment. Diltiazem 120 mg given every 8 hours reduced heart rate by 17%; fewer ventricular extrasystoles were noted after 10 days of therapy, and diltiazem has been shown to be comparable to propranolol in lowering heart rate and blood pressure.

■ Radioactive Iodine

Although other radioisotopes have been used to ablate thyroid tissue, sodium iodide 131 (^{131}I) is considered to be the agent of choice for Graves' disease, toxic autonomous nodules, and toxic multinodular goiters.^{22,67} RAI is administered as a colorless and tasteless liquid that is well absorbed and concentrates in the thyroid. Sodium iodide 131 is a β -emitter with a tissue penetration of 2 mm and a half-life of 8 days. Other organs take up ^{131}I , but the thyroid gland is the only organ in which organification of the absorbed iodine takes place. Initially, RAI disrupts hormone synthesis by incorporating into thyroid hormones and thyroglobulin. Over a period of weeks, follicles that have taken up RAI and surrounding follicles develop evidence of cellular necrosis, breakdown of follicles, development of bizarre cell forms, nuclear pyknosis, and destruction of small vessels within the gland, leading to edema and fibrosis of the interstitial tissue. Pregnancy is an absolute contraindication to the use of RAI.

β -Blockers may be given any time without compromising RAI therapy, accounting for their role as a mainstay of adjunctive therapy to RAI treatment. If iodides are administered, they should be given 3 to 7 days after RAI to prevent interference with the uptake of RAI in the thyroid gland. Because thyroid hormone levels will transiently increase following RAI treatment owing to release of preformed thyroid hormone, patients with cardiac disease and elderly patients are often treated with thionamides prior to RAI ablation. Occasionally, in patients with underlying cardiac disease, it may be necessary to reinstitute antithyroid drug therapy following radioactive iodine ablation. The standard practice is to withdraw the thionamide 4 to 6 days prior to RAI treatment and to reinstitute it 4 days after therapy is concluded. Administering antithyroid drug therapy following RAI treatment may result in a higher rate of posttreatment recurrence or persistent hyperthyroidism.⁶⁷

Corticosteroid administration will blunt and delay the rise in antibodies to the TSH receptor, thyroglobulin, and thyroid peroxidase while reducing T_3 and T_4 concentrations following RAI. Bartalena and associates found no progression in ophthalmopathy in patients receiving prednisone after RAI compared with methimazole (2% to 3% worsened), or no other treatment (5% with persistent worsening).⁶⁸ Theoretically, if shared thyroidal and orbital antigen is involved in the pathogenesis of Graves' ophthalmopathy, antigen released with RAI treatment could aggravate pre-existing eye disease. Note also that thyroid ablation may decrease eye disease in the long term by removing the source of antigen, but it is unclear if RAI differs from surgery or thionamide for the risk of worsening eye disease.⁶⁹

Destruction of the gland attenuates the hyperthyroid state, and hypothyroidism commonly occurs months to years following RAI.⁷⁰ The goal of therapy is to destroy overactive thyroid cells, and a single dose of 4000 to 8000 rads results in a euthyroid state in 60% of patients at 6 months or less. The remaining 40% become euthyroid within 1 year, requiring two or more doses. It is advisable that a second dose of RAI be given 6 months after the first RAI treatment if the patient remains hyperthyroid. Variables that influence the outcome of RAI include gender (men are less likely to develop hypothyroidism), race (blacks are more resistant to ^{131}I), the size of the thyroid, severity of disease, and perhaps the level of TSAb. The acute, short-term side effects of ^{131}I therapy are minimal and include mild thyroidal tenderness and dysphagia. Concern over the development of thyroid carcinoma and leukemia and increased risk of mutations and congenital defects now appears to be unfounded because long-term follow-up studies have not revealed increased risk for these complications.^{50,71} Although RAI is very effective in the treatment of hyperthyroidism, long-term follow-up from Great Britain suggests that among patients

with hyperthyroidism treated with RAI, mortality from all causes and mortality resulting from cardiovascular and cerebrovascular disease and fracture are increased.⁷²

A common approach to Graves' hyperthyroidism is to administer a single dose of 5 to 15 mCi (80 to 120 mCi/g of tissue).^{50,67} The optimal method for determining ¹³¹I treatment doses for Graves' hyperthyroidism is unknown, and techniques have varied from a fixed dose to more elaborate calculations based on gland size, iodine uptake,

and iodine turnover. In a trial of 88 patients with Graves' disease, no difference in outcome was seen among high or low, fixed or adjusted doses.⁷³ Thyroid glands estimated to weigh >80 g may require larger doses of RAI. Larger doses are likely to induce hypothyroidism and are seldom given outside the United States owing to the imposition of stringent safety restrictions. For example, in the United Kingdom, a nursery school teacher is advised to stay out of school for 3 weeks following a 15-mCi dose of ¹³¹I.⁷⁴

EVALUATION OF THERAPEUTIC OUTCOMES: HYPERTHYROIDISM

After therapy (surgery, thionamides, or RAI) for hyperthyroidism has been initiated, patients should be evaluated on a monthly basis until they reach a euthyroid condition. Clinical signs of continuing thyrotoxicosis (tachycardia, weight loss, and heat intolerance, among others) or the development of hypothyroidism (bradycardia, weight gain, and lethargy, among others) should be noted. β -Blockers may be used to control symptoms of thyrotoxicosis until the definitive treatment has returned the patient to a euthyroid state. Once thyroxine replacement is initiated, the goal is to maintain both the free thyroxine level and the TSH concentration in the normal range. Once a stable dose of thyroxine is identified, the patient may be followed-up every 6 to 12 months.

Finally, a common, potentially confusing clinical situation should be mentioned. Why are the TSH concentrations suppressed in some patients who are clinically hypothyroid and who have a low free T₄ level? In patients with long-standing hyperthyroidism, the pituitary thyrotrophs responsible for making TSH become atrophic. The average amount of time required for these cells to resume normal functioning is 6 to 8 weeks.⁷⁵ Therefore if a thyrotoxic patient has his or her free T₄ concentration lowered rapidly, before the thyrotrophs resume normal function, a period of "transient central hypothyroidism" will be observed.

SPECIAL CONDITIONS

GRAVES' DISEASE AND PREGNANCY

Inappropriate production of human chorionic gonadotropin (hCG) is a cause of abnormal thyroid function tests during the first half of pregnancy, and hCG can cause either subclinical (normal T₄, suppressed TSH) or overt hyperthyroidism.^{76–78} This is owing to the homology of hCG and TSH as well as their receptors. Hyperthyroidism during pregnancy is almost solely caused by Graves' disease, with approximately 0.1% to 0.4% of pregnancies affected. Although the increased metabolic rate is usually well tolerated in pregnant women, two symptoms suggestive of hyperthyroidism during pregnancy are failure to gain weight despite good appetite, and persistent tachycardia. There is no increase in maternal mortality or morbidity in well-controlled patients; however, postpartum thyroid storm has been reported in about 20% of untreated individuals. Fetal loss is also more common, owing to the facts that spontaneous abortion and premature delivery are more common in untreated pregnant women, as are low-birth-weight infants and eclampsia. Transplacental passage of thyroid-stimulating antibodies may occur, causing fetal as well as neonatal hyperthyroidism.⁷⁹ An uncommon cause of hyperthyroidism is molar pregnancy; women present with a large-for-dates uterus and evacuation of the uterus is the preferred management approach.^{80–84}

Because RAI is contraindicated in pregnancy and surgery is usually not recommended (especially during the first trimester), antithy-

roid drug therapy is usually the treatment of choice. Methimazole readily crosses the placenta and appears in breast milk.

PTU is considered to be the drug of choice in pregnancy, with the lowest possible doses used to maintain the maternal T₄ level in the high-normal range, but as described previously, there appears to be little difference between PTU and methimazole.⁵² To prevent fetal goiter and suppression of fetal thyroid function, PTU is usually prescribed in daily doses of 300 mg or less and tapered to 50 to 150 mg daily after 4 to 6 weeks. PTU doses of less than 200 mg daily are unlikely to produce fetal goiter.⁸⁵ During the last trimester, TSABs fall spontaneously, and some patients will go into remission so that antithyroid drug doses may be reduced. A rebound in maternal hyperthyroidism occurs in about 10% of women and may require more intensive treatment postpartum than in the last trimester of pregnancy.⁷⁹

NEONATAL AND PEDIATRIC HYPERTHYROIDISM

Following delivery, some babies will be hyperthyroid owing to placental transfer of TSABs, which stimulates thyroid hormone production in utero and postpartum.^{86,87} This is likely if the maternal TSAB titers were quite high. The disease is usually expressed 7 to 10 days postpartum and treatment with antithyroid drugs (PTU 5 to 10 mg/kg per day or methimazole 0.5 to 1 mg/kg per day) may be needed for as long as 8 to 12 weeks until the antibody is cleared (immunoglobulin G half-life is about 2 weeks). Iodide (potassium iodide 1 drop/day or Lugol's solution 1 to 3 drops/day) and sodium ipodate may be used for the first few days to acutely inhibit hormone release.

Childhood hyperthyroidism is usually managed with either PTU or methimazole. Long-term follow-up studies suggest that this form of therapy is quite acceptable, with 25% of a cohort experiencing remission every 2 years.⁸⁸

THYROID STORM

Thyroid storm is a life-threatening medical emergency characterized by severe thyrotoxicosis, high fever (often >103°F), tachycardia, tachypnea, dehydration, delirium, coma, nausea, vomiting, and diarrhea.^{89,90} Precipitating factors for thyroid storm include infection, trauma, surgery, RAI treatment, and withdrawal from antithyroid drugs. It may occur at any age and has an average duration of 72 hours, although symptoms may persist up to 8 days if treatment is not aggressive. With aggressive treatment, the mortality rate has been lowered to 20%. The following therapeutic measures should be instituted promptly: (1) suppression of thyroid hormone formation and secretion, (2) antiadrenergic therapy, (3) administration of corticosteroids, and (4) treatment of associated complications or coexisting factors that may have precipitated the storm. Specific agents used in thyroid storm are outlined in Table 73–6. PTU in large doses is the preferred thionamide because it interferes with the production of thyroid hormones and blocks the peripheral conversion of T₄ to T₃. If patients are unable to take medications orally, the tablets can be crushed into suspension and instilled by gastric tube. Iodides, which

TABLE 73–6. Drug Dosages Used in the Management of Thyroid Storm

| Drug | Regimen |
|---|---|
| Propylthiouracil | 900–1200 mg/day orally in four or six divided doses |
| Methimazole | 90–120 mg/day orally in four or six divided doses |
| Sodium iodide Lugol's solution | Up to 2 g/day IV in single or divided doses 5–10 drops three times a day in water or juice |
| Saturated solution of potassium iodide | 1–2 drops three times a day in water or juice |
| Propranolol | 40–80 mg every 6 h |
| Dexamethasone | 5–20 mg/day orally or IV in divided doses |
| Prednisone | 25–100 mg/day orally in divided doses |
| Methylprednisolone | 20–80 mg/day IV in divided doses |
| Hydrocortisone | 100–400 mg/day IV in divided doses |

rapidly block the release of preformed thyroid hormone, should be administered after PTU is initiated to inhibit iodide utilization by the overactive gland. If iodide is administered first, it could theoretically provide the substrate, permitting the synthesis and storage of a large amount of thyroid hormone in the thyroid gland, which would prolong the duration of hyperthyroidism thereafter.

Antiadrenergic therapy with the short-acting agent esmolol may be used in the patient with pulmonary disease or at risk for cardiac failure because its effects may be rapidly reversed.⁹¹ Corticosteroids are generally recommended, although there is no convincing evidence of adrenocortical insufficiency in thyroid storm, and the benefits derived from steroids may be owing to their antipyretic action and their effect of stabilizing blood pressure.⁹² General supportive measures, including acetaminophen as an antipyretic (do not use aspirin or other nonsteroidal anti-inflammatory agents because they may displace bound thyroid hormone), fluid and electrolyte replacement, sedatives, digitalis, antiarrhythmics, insulin, and antibiotics should be given as indicated. Plasmapheresis and peritoneal dialysis have been used to remove excess hormone when the patient has not responded to more conservative measures, although these measures do not always work.⁹³

HYPOTHYROIDISM

Hypothyroidism is defined as the clinical and biochemical syndrome resulting from decreased thyroid hormone production.⁹⁴ Overt hypothyroidism occurs in 1.5% to 2% of women and 0.2% of men, and its incidence increases with age.^{95–97} In the Third National Health and Nutrition Examination Survey, levels of serum thyroid-stimulating hormone (TSH) and total thyroxine (T_4) were measured in a representative sample of adolescents and adults (age 12 or older). Among 16,533 people who neither were taking thyroid medication nor reported histories of thyroid disease, 3.9% had subclinical hypothyroidism (TSH >4.5 milli-international units/L; and T_4 normal), and 0.2% had “clinically significant” hypothyroidism (TSH >4.5 milli-international units/L; and T_4 <4.5 mcg/dL).¹⁴ The vast majority of hypothyroid patients have thyroid gland failure (primary hypothyroidism). Special populations with higher risk of developing hypothyroidism include postpartum women, individuals with a family history of autoimmune thyroid disorders and patients with previous head and neck or thyroid irradiation or surgery, other autoimmune endocrine conditions (e.g., type 1 diabetes mellitus, adrenal insufficiency, and ovarian failure), some other nonendocrine autoimmune disorders (e.g., celiac disease, vitiligo, pernicious anemia, Sjögren's syndrome, and multiple sclerosis), primary pulmonary hypertension,

and Down's and Turner's syndromes.⁹⁴ Pituitary failure is an uncommon cause of hypothyroidism, but should be suspected in a patient with decreased levels of thyroxine and inappropriately normal or low TSH levels. Most patients with secondary hypothyroidism will have clinical signs of more generalized pituitary insufficiency, such as abnormal menses and decreased libido, or evidence of a pituitary adenoma, such as visual field defects, galactorrhea, or acromegaloid features. Generalized (peripheral and central) resistance to thyroid hormone is extremely rare.

Thyroid hormone is essential for normal growth and development during embryonic life. Thyroid hormone deficiency during fetal and neonatal development results in mental retardation. There is slowing of physical and mental activity, as well as of cardiovascular, gastrointestinal, and neuromuscular function. Depression may result from untreated hypothyroidism.⁹⁸

CLINICAL PRESENTATION OF HYPOTHYROIDISM

GENERAL

Hypothyroidism can lead to a variety of end-organ effects and a wide range of disease severity, from entirely asymptomatic individuals to patients in coma with multisystem failure. In the adult, manifestations of hypothyroidism are varied and nonspecific. In the child, thyroid hormone deficiency may manifest as growth retardation.

SYMPTOMS

Common symptoms of hypothyroidism include dry skin, cold intolerance, weight gain, constipation, and weakness. Complaints of lethargy and fatigue or loss of ambition and energy are also common but are less specific. Muscle cramps, myalgia, and stiffness are frequent complaints of hypothyroid patients.

SIGNS

Objective weakness is common, with proximal muscles being affected more than distal muscles. Slow relaxation of deep tendon reflexes is common. The most common signs of decreased levels of thyroid hormone include coarse skin and hair, cold or dry skin, periorbital puffiness, and bradycardia. Speech is often slow as well as hoarse. Reversible neurologic syndromes such as carpal tunnel syndrome, polyneuropathy, and cerebellar dysfunction may also occur.

DIAGNOSIS

TSH serum concentration should be elevated. Free and/or total T_4 and T_3 serum concentrations should be low.

OTHER TESTS

Antithyroid peroxidase antibodies and antithyroglobulin antibodies are likely to be elevated.

A rise in the TSH level is the first evidence of primary hypothyroidism. Many patients will have a T_4 level within the normal range (compensated hypothyroidism) and few, if any, symptoms of hypothyroidism. As the disease progresses the T_4 concentration will drop below the normal level. Interestingly, the T_3 concentration will often be maintained in the normal range in spite of a low T_4 . The RAIU is not a useful test in the evaluation of a hypothyroid patient.

CAUSES OF HYPOTHYROIDISM

Table 73–7 outlines the causes of hypothyroidism.

TABLE 73–7. Causes of Hypothyroidism

| |
|---------------------------------|
| Primary hypothyroidism |
| Hashimoto's disease |
| Iatrogenic hypothyroidism |
| Others |
| Iodine deficiency |
| Enzyme defects |
| Thyroid hypoplasia |
| Goitrogens |
| Secondary hypothyroidism |
| Pituitary disease |
| Hypothalamic disease |

CHRONIC AUTOIMMUNE THYROIDITIS

8 Autoimmune thyroiditis (Hashimoto's disease) is the most common cause of spontaneous hypothyroidism in the adult. Patients may present with either goitrous thyroid gland enlargement and mild hypothyroidism, or thyroid gland atrophy and more severe thyroid hormone deficiency. Both forms of autoimmune thyroiditis probably result from cell- and antibody-mediated thyroid injury. The bulk of evidence suggests that the presence of specific defects in suppressor T-lymphocyte function leads to the survival of a randomly mutating clone of helper T lymphocytes, which are directed against normally occurring antigens on the thyroid membrane. Once these T lymphocytes interact with thyroid membrane antigen, B lymphocytes are stimulated to produce thyroid antibodies.^{99,100}

Antimicrosomal antibodies are present in virtually all patients with Hashimoto's thyroiditis and appear to be directed against the enzyme thyroid peroxidase, thyroglobulin, and other thyroid cell-membrane antigens. These antibodies are capable of fixing complement and inducing cytotoxic changes in thyroid cells. Antibodies that are capable of stimulating thyroid growth are also present in the goitrous variety of Hashimoto's disease; conversely, antibodies that inhibit the trophic effects of TSH are present in the atrophic type.¹⁰¹

IATROGENIC HYPOTHYROIDISM

Iatrogenic hypothyroidism follows exposure to radiation (radioiodine or external radiation) or surgery. Hypothyroidism occurs within 3 months to a year after ¹³¹I therapy in most patients treated for Graves' disease. Thereafter it occurs at a rate of approximately 2.5% each year. External radiation therapy to the region of the thyroid using doses of greater than 2500 rads for therapy of neck carcinoma also causes hypothyroidism. This effect is dose-dependent, and more than 50% of patients who receive more than 4000 rads to the thyroid bed develop hypothyroidism. Total thyroidectomy causes hypothyroidism within 1 month.

► TREATMENT: Hypothyroidism

■ PHARMACOLOGIC THERAPY

■ DESIRED OUTCOMES

The goals of therapy are to restore normal thyroid hormone concentrations in tissue, provide symptomatic relief, prevent neurologic deficits in newborns and children, and reverse the biochemical abnormalities of hypothyroidism.

OTHER CAUSES OF PRIMARY HYPOTHYROIDISM

Iodine deficiency, enzymatic defects within the thyroid gland, thyroid hypoplasia, and maternal ingestion of goitrogens during fetal development may cause cretinism. Early recognition and treatment of the resultant thyroid hormone deficiency is essential for optimal mental development. Large-scale screening programs in North America, Europe, Japan, and Australia are now in place.^{102,103} The frequency of congenital hypothyroidism in North America and Europe is 1 per 3500 to 4000 live births. In the United States, there are racial differences in the incidence of congenital hypothyroidism, with whites being affected seven times as frequently as blacks.^{104–107}

In the adult, hypothyroidism may rarely be caused by iodine deficiency and goitrogens. Rarely, iodine ingestion in the form of expectorants can lead to hypothyroidism. In sensitive persons, the iodide blocks the synthesis of thyroid hormone, leading to an increased secretion of TSH, which causes thyroid enlargement.⁴ Thus both iodine excess and iodine deficiency can cause decreased secretion of thyroid hormone.

CAUSES OF SECONDARY HYPOTHYROIDISM

Pituitary Disease

TSH is required for normal thyroid secretion. Thyroid atrophy and decreased thyroid secretion follow pituitary failure. Pituitary insufficiency may be caused by destruction of thyrotrophs by either functioning or nonfunctioning pituitary tumors, surgical therapy, external pituitary radiation, postpartum pituitary necrosis (Sheehan's syndrome), infiltrative processes of the pituitary such as metastatic tumors, tuberculosis, histiocytosis, and autoimmune mechanisms. In all these situations, TSH deficiency most often occurs in association with other pituitary hormone deficiencies.

In most hypothyroid patients with pituitary disease, serum TSH concentrations are low or normal. A serum TSH concentration in the normal range is clearly inappropriate if the patient's T₄ is low.

Note that pituitary enlargement in hypothyroidism does not invariably indicate the presence of a primary pituitary tumor. Pituitary enlargement is seen in patients with severe primary hypothyroidism owing to compensatory hyperplasia and hypertrophy of the thyrotrophs. Serum TSH concentrations and pituitary enlargement decline during thyroid hormone replacement therapy, indicating that the TSH secretion is not autonomous. These patients are easily separated from patients with primary pituitary failure by measuring a TSH level.

Hypothalamic Hypothyroidism

TRH deficiency also causes hypothyroidism. In both adults and children it may occur as a result of cranial irradiation, trauma, infiltrative diseases, or neoplastic diseases. Hypothalamic hypothyroidism is rare.

■ GENERAL APPROACH

Any of the commercially available thyroid preparations accomplish this goal (Table 73–8); however, levothyroxine (l-thyroxine) is considered to be drug of choice. The thyroid preparations are either natural (i.e., desiccated thyroid and thyroglobulin) or synthetic (levothyroxine, liothyronine, and liotrix) in origin. The availability of sensitive and specific assays for total and free hormone levels as well as TSH

TABLE 73–8. Thyroid Preparations Used in the Treatment of Hypothyroidism

| Drug/Dosage Form | Content | Relative Dose | Comments/Equivalency |
|---|--|---|--|
| Thyroid USP Armour Thyroid (T ₄ :T ₃ ratio) 9.5 mcg:2.25 mcg, 19 mcg:4.5 mcg, 38 mcg:9 mcg, 57 mcg:13.5 mcg, 76 mcg:18 mcg, 114 mcg:27 mcg, 152 mcg:36 mcg, 190 mcg:45 mcg tablets | Desiccated beef or pork thyroid gland | 1 grain (equivalent to 60 mcg of T ₄) | Unpredictable hormonal stability, inexpensive generic brands may not be bioequivalent |
| Thyroglobulin Proloid 32-mg, 65-mg, 100-mg, 130-mg, 200-mg tablets | Partially purified pork thyroglobulin | 1 grain | Standardized biologically to give T ₄ :T ₃ ratio of 2.5:1; more expensive than thyroid extract; no clinical advantage |
| Levothyroxine Synthroid, Levothroid, and other generics 25-, 50-, 75-, 88-, 100-, 112-, 125-, 137-, 150-, 175-, 200-, 300-mcg tablets; 200- and 500-mcg/vial injection | Synthetic T ₄ | 50–60 mcg | Stable; predictable potency; generics are bioequivalent; when switching from natural thyroid to L-thyroxine, lower dose by 1/2 grain; variable absorption between products; half-life = 7 days, so daily dosing; considered to be drug of choice |
| Levoxyl, Thyro-Tabs, Unithroid Liothyronine Cytomel 5-, 25-, and 50-mcg tablets | Synthetic T ₃ | 15–37.5 mcg | Uniform absorption, rapid onset; half-life = 1.5 days, monitor TSH assays |
| Liotrix Thyrolar 1/4-, 1/2, 1-, 2-, and 3-strength tablets | Synthetic T ₄ :T ₃ in 4:1 ratio | 50–60 mcg T ₄ and 12.5–15 mcg T ₃ | Stable; predictable; expensive; lacks therapeutic rationale because T ₄ is converted to T ₃ peripherally |

TSH, thyroid-stimulating hormone.

now allow more definitive dose titration to allow adequate replacement without inadvertent overdose. The response of TSH to TRH had been advocated for use by some for “fine-tuning” thyroid replacement, but this is not necessary if the sensitive immunoradiometric assays for TSH are used. Minimum clinical guidelines for the treatment of hypothyroidism have been published by the American Thyroid Association.⁴²

■ NATURAL THYROID HORMONES

Desiccated thyroid is derived from hog, beef, or sheep thyroid gland. The United States Pharmacopeia, 23th ed., requires Thyroid USP to contain 38 mcg ($\pm 15\%$) of levothyroxine and 9 mcg ($\pm 10\%$) of liothyronine for each 65 mg (1 grain) of the labeled content of thyroglobulin. Thyroglobulin USP should contain 36 mcg ($\pm 15\%$) of levothyroxine and 12 mcg ($\pm 10\%$) of liothyronine for each 65 mg (1 grain) of the labeled content of thyroglobulin. Not all generic brands may be bioequivalent, and switching among brands in patients stabilized on one product should be discouraged. Thyroid USP, as an animal protein–derived product, may be antigenic in allergic or sensitive patients. Even though desiccated thyroid is inexpensive, its limitations preclude it from being considered as a drug of choice for hypothyroid patients. Thyroglobulin is a purified hog-gland extract, but it has no clinical advantages and is not widely used.

■ SYNTHETIC THYROID HORMONES

Levothyroxine (T₄; l-thyroxine) is the drug of choice for thyroid replacement and suppressive therapy because it is chemically stable,

relatively inexpensive, and free of antigenicity, and has uniform potency. Whereas T₃ and not T₄ is the biologically more active form of thyroid hormone, levothyroxine administration results in a pool of thyroid hormone that is readily and consistently converted to T₃; in this regard levothyroxine may be thought of as a prohormone. The half-life of levothyroxine is approximately 7 days. This long half-life is responsible for a stable pool of prohormone and the need for only once-daily dosing with levothyroxine. Older studies with levothyroxine suggested that bioavailability was low and erratic; however, this product has been reformulated and the average bioavailability is now approximately 80%.^{108–110} The bioavailability of Synthroid, Levoxine, and generic levothyroxine preparations were compared in a blinded, randomized, four-way cross-over trial.¹¹¹ The study was sponsored by the manufacturers of Synthroid, who have challenged the authors’ conclusions that the levothyroxine preparations are bioequivalent and should be interchangeable for the majority of patients. However, because the relationship between T₄ concentration and TSH is not linear, very small changes in T₄ concentration can lead to substantial changes in TSH, which is a more accurate reflection of hormone replacement status. To avoid over- and undertreatment, once a product is selected, therapeutic interchange should be discouraged. Currently, no products are AB rated for Synthroid. The time to maximal absorption is 2 hours, and this should be considered when T₄ and TSH concentrations are determined. Mucosal diseases such as sprue, diabetic diarrhea, and ileal bypass surgery may also reduce absorption. Cholestyramine, calcium carbonate, sucralfate, aluminum hydroxide,¹¹² ferrous sulfate,¹¹³ soybean formula,¹¹⁴ and dietary fiber supplements¹¹⁵ may also impair the absorption of levothyroxine from the gastrointestinal tract. Drugs that increase nondeiodinative T₄ clearance include rifampin, carbamazepine, and possibly phenytoin. Selenium deficiency and amiodarone may block the conversion of T₄ to T₃.

Liothyronine (T_3) is chemically pure with known potency and has a shorter half-life of 1.5 days. Although it is widely used diagnostically in the T_3 -suppression test, T_3 has some clinical disadvantages, including a higher incidence of cardiac adverse effects, higher cost, and difficulty in monitoring with conventional laboratory tests. Liotrix is a combination of synthetic T_4 and T_3 in a 4:1 ratio that attempts to mimic natural hormonal secretion. It is chemically stable and pure and has a predictable potency. The major limitations to this product are high cost and lack of therapeutic rationale, because about 35% of T_4 is peripherally converted T_3 .

Recently a trial comparing levothyroxine alone to a combination of levothyroxine plus partial replacement with liothyronine (triiodothyronine) has been published.¹¹⁶ Patients received a regimen in which 50 mcg of the usual dose of thyroxine was replaced by 12.5 mcg of triiodothyronine. The order in which each patient received the two treatments was randomized. Biochemical, physiologic, and psychological tests were performed at the end of each treatment period. Although lower serum free and total thyroxine concentrations and higher serum total triiodothyronine concentrations after treatment with thyroxine plus triiodothyronine were noted, the TSH concentrations were not significantly different. Cognitive function was higher on some rating scales, but neurophysiologic test scores were similar. In another recent trial of combination therapy, when compared with levothyroxine alone, treatment of primary hypothyroidism with combination levothyroxine plus liothyronine demonstrated no beneficial changes in body weight, serum lipid levels, hypothyroid symptoms as measured by a health-related quality of life questionnaire, and standard measures of cognitive performance.¹¹⁷

■ Dosing and Monitoring

During the mid-1980s the average dose of levothyroxine was about 160 mcg/day. With the advent of more sensitive assay methods for TSH and the reformulation of levothyroxine, it is now apparent that many patients have been treated with excessive amounts of levothyroxine. More recent studies suggest that the average maintenance dose for most adults should be closer to about 125 mcg per day.⁹⁴ Indeed, as many as one-third of patients receiving levothyroxine 150 mcg daily will be overreplaced. There is, however, a wide range of replacement doses, necessitating individualized therapy and appropriate monitoring to determine an adequate but not excessive dose.

The initial dose of levothyroxine is dependent on the patient's age, and the presence of associated disorders, as well as the severity and duration of hypothyroidism.¹¹⁸ In young patients with longstanding disease and patients over age 45 without known cardiac disease, therapy should be initiated with 50 mcg daily of levothyroxine and increased to 100 mcg daily after 1 month. The recommended initial daily dose for older patients or those with known cardiac disease is 25 mcg per day titrated upward in increments of 25 mcg at monthly intervals to prevent stress on the cardiovascular system. Some patients may experience an exacerbation of angina with higher doses of thyroid hormone. Although the TSH is very sensitive for under- or overreplacement, clinicians often fail to alter the dose of T_4 based on TSH clearly outside of the normal range.¹¹⁹

Patients with subclinical hypothyroidism (seen more commonly in the elderly and particularly in women) have no or few signs or symptoms, normal serum T_3 and T_4 concentrations, and an elevated basal TSH concentration.⁹⁷ The prevalence of this disorder is thought to be about 8%, but the reported range is quite wide.^{120,121} Although the treatment of subclinical hypothyroidism is controversial, patients presenting with marked elevations in TSH (>10 milli-international

units/L) and high titers of TSAb or prior treatment with ^{131}I may be most likely to benefit from treatment.¹²² Other patients who may improve with replacement include those with mild symptoms of hypothyroidism and depression. It should be noted that some studies find that only one of four treated patients experienced improvement.¹²¹ Conservative treatment goals in this situation would be to maintain serum T_4 and T_3 levels in the normal range and reduce TSH to a value of 1 milli-international unit/L.

9 Once euthyroidism is attained, the daily maintenance dose of levothyroxine does not fluctuate greatly. As patients age, the dosing requirement may need to be reduced.¹²³ The ability to measure serum TSH concentrations has improved the accuracy with which thyroid hormone replacement can be monitored. Many clinicians now consider serum TSH concentration to be the most sensitive and specific monitoring parameter for adjustment of levothyroxine dose. Plasma TSH concentrations begin to fall within hours and are usually normalized within 2 weeks, but may take up to 6 weeks in some patients, depending on the baseline value. TSH and T_4 concentrations are both used to monitor therapy, and they should be checked every 6 weeks until a euthyroid state is achieved. Serum T_4 concentrations can be useful in detecting noncompliance, malabsorption, or changes in levothyroxine product bioequivalence. An elevated TSH concentration indicates insufficient replacement. The appropriate dose maintains the TSH concentration in the normal range. Thyroxine disposal is accelerated by nephritic syndrome, other severe systemic illnesses, and several antiepileptic medications (phenobarbital, phenytoin, and carbamazepine) and rifampin. Pregnancy increases the thyroxine dose requirement in 75% of women, probably because of increased degradation by the placental deiodinase. Initiating postmenopausal hormone replacement therapy increases the dose needed in 35% of women, perhaps due to an increased circulating thyroxine-binding globulin level. Patient noncompliance with prescribed thyroxine, the most common cause of inadequate treatment, might be suspected in patients with a dose that is higher than expected, variable thyroid function test results that do not correlate well with prescribed doses, and an elevated serum thyrotropin concentration with serum free thyroxine at the upper end of the normal range, which can suggest improved compliance immediately before testing due to a lag in the thyrotropin response. The metabolism of other pharmacologic agents can be altered in patients with hypothyroidism. The mechanism might be decreased expression of hepatic enzymes involved in drug metabolism, as seen in hypothyroid rats. As a result, increased sensitivity to anesthetic and sedative agents, and higher serum levels of phenytoin have been reported. Hypothyroidism can also cause higher serum digoxin values, an effect attributed to a decreased volume of drug distribution. Conversely, hypothyroidism might decrease sensitivity to warfarin due to slowed metabolism of the vitamin K-dependent clotting factors, and restoration of euthyroidism can then increase the warfarin dose requirement.

In patients with hypothyroidism caused by hypothalamic or pituitary failure, alleviation of the clinical syndrome and restoration of serum T_4 to the normal range are the only criteria available for estimating the appropriate replacement dose of levothyroxine. Concurrent use of dopamine, dopaminergic agents (bromocriptine), somatostatin or somatostatin analogs (octreotide), and corticosteroids suppresses TSH concentrations and may confound the interpretation of this monitoring parameter.¹²⁴

TSH-suppressive levothyroxine therapy may also be given to patients with nodular thyroid disease and diffuse goiter, to patients with a history of thyroid irradiation, and to patients with thyroid cancer. The rationale for suppression therapy is to reduce TSH secretion, which promotes growth and function in abnormal thyroid tissue. In

patients with solitary nodules who have not received radiation, TSH should be suppressed to 0.05 to 0.1 milli-international unit/L in premenopausal women and in men <60 years old. A dose of levothyroxine of 100 to 150 mcg per day is usually sufficient. In men over 60 years of age and postmenopausal women, TSH levels should be reduced to 0.1 to 0.3 milli-international unit/L, owing to the risk of more serious adverse effects in this population and reduced clearance of levothyroxine with advanced age. Levothyroxine may be given in nontoxic multinodular goiter to suppress the TSH to low-normal levels of 0.5 to 1 milli-international unit/L if the baseline TSH is >1 milli-international unit/L. Goiter size and thyroid volume may be reduced with suppression therapy. Diffuse goiter associated with autoimmune thyroiditis may also be treated with levothyroxine to reduce goiter size and thyroid volume. In patients with follicular or papillary thyroid cancer, current recommendations are to suppress the TSH to <0.02 milli-international unit/L. Doses of levothyroxine of up to 2.2 to 2.5 mcg/kg may be needed to provide TSH levels of <0.02 milli-international unit/L in this population, and free T₃ and T₄ levels are useful in detecting hyperthyroidism.¹²⁵

Adverse Effects

Serious untoward effects are unusual if dosing is appropriate and the patient is carefully monitored during initial treatment. Levothyroxine replacement in athyrotic hypothyroid patients restores systolic and diastolic left ventricular performance within 2 weeks, and the use of levothyroxine may increase the frequency of atrial premature beats, but not necessarily ventricular premature beats. Excessive doses of

thyroid hormone may lead to heart failure, angina pectoris, and myocardial infarction; rarely, the latter may be caused by coronary artery spasm. Allergic or idiosyncratic reactions can occur with the natural animal-derived products such as desiccated thyroid and thyroglobulin, but these are extremely rare with the synthetic products used today. The 0.05-mg Synthroid tablet is the least allergenic (owing to a lack of dye and few excipients) and should be tried in the patient suspected to be allergic to thyroid hormone.

Hyperremodeling of cortical and trabecular bone due to hyperthyroidism leads to reduced bone density and may increase the risk of fracture. Compared with normal controls, excess exogenous thyroid hormone results in histomorphometric and biochemical changes similar to those observed in osteoporosis and untreated hyperthyroidism; however, at routinely used replacement doses, bone mineral density loss is less than that seen with untreated hyperthyroidism and only slightly greater than in controls.¹²⁶ The risk for this complication of therapy seems to be related to the dose of levothyroxine, patient age, and gender. Markers for bone turnover include urinary cross-linked *N*-telopeptides, pyridinoline of type I collagen, osteocalcin, and bone-specific alkaline phosphatase. When doses of levothyroxine are used to suppress TSH concentrations to below-normal values (less than 0.3 milli-international unit/L) in postmenopausal women, this adverse effect is more likely to be seen. Cortical bone is affected to a greater degree than trabecular bone at suppressive doses of l-thyroxine. In contrast, it appears to be much less likely in men and in premenopausal women. Maintaining the TSH between 0.7 and 1.5 milli-international units/L with approximately 150 mcg/day of levothyroxine does not alter bone mineral density in premenopausal women.

SPECIAL CONDITIONS

MYXEDEMA COMA

Myxedema coma is the end stage of long-standing, uncorrected hypothyroidism.¹²⁷ Clinical features include hypothermia, advanced stages of hypothyroid symptoms, and altered sensorium ranging from delirium to coma. Mortality rates of 60% to 70% necessitate immediate and aggressive therapy with intravenous bolus thyroxine 300 to 500 mcg. Glucocorticoid therapy with intravenous hydrocortisone 100 mg every 8 hours should be given until coexisting adrenal suppression is ruled out. Consciousness, lowered TSH concentrations, and normal vital signs are expected within 24 hours. Maintenance doses are typically 75 to 100 mcg given intravenously until the patient stabilizes and oral therapy is begun. Supportive therapy must be instituted to maintain adequate ventilation, euglycemia, blood pressure, and body temperature. Any underlying disorder, such as sepsis, myocardial infarction, and the like obviously must be diagnosed and treated.

CONGENITAL HYPOTHYROIDISM

In congenital hypothyroidism, full maintenance therapy should be instituted early to improve the prognosis for mental and physical development.¹²⁸ The average maintenance dose in infants and children depends on the age and weight of the child. Several studies demonstrate that aggressive therapy with levothyroxine is important for normal development and current recommendations are for initiation of therapy within 45 days of birth at a dose of 10 to 15 mcg/kg per day.¹²⁹ This dose is used to keep T₄ concentrations at about

10 mcg/dL within 30 days of starting therapy and is associated with improved IQs in treated infants. The dose is progressively decreased to a typical adult dose as the child ages, the adult dose being given in the age range of 11 to 20 years. In utero treatment of fetal goiter and hypothyroidism has been accomplished with the injection of thyroxine into the amniotic fluid.¹³⁰

HYPOTHYROIDISM IN PREGNANCY

Hypothyroidism during pregnancy leads to an increased rate of stillbirths and possibly lower psychological scores in infants born of women who received inadequate replacement during pregnancy.^{131,132} Thyroid hormone is necessary for fetal growth and must come from the maternal side during the first 2 months of gestation. Although liothyronine may cross the placental membrane slightly better than levothyroxine, the latter is considered to be the drug of choice. The objective of treatment is to decrease TSH to 1 unit/mL and maintain free T₄ concentrations in the normal range. Based on elevated TSH levels during pregnancy, it was found that the mean dose of levothyroxine had to be increased by 36 mcg/day to suppress TSH into the normal range. Increased production of binding proteins, a marginal decrease in free hormone concentration, modification of peripheral thyroid hormone metabolism, and increased thyroxine metabolism by the fetal-placental unit also contributes to increased thyroid hormone demand and the need for increased doses decreases after delivery.⁷⁷ Only about 20% of women need to have levothyroxine dose adjustment during pregnancy. After delivery the levothyroxine may need to be reduced based on T₃ concentrations and measurement of TSH.¹³³

EFFECTS OF HYPOTHYROIDISM ON SELECTED MEDICATIONS

Hypothyroidism may affect the metabolism and clinical efficacy of several medications. Digitalis preparations have a decreased volume of distribution in the hypothyroid state, resulting in increased sensitivity to the digitalis effect. Therefore, many hypothyroid patients achieve a therapeutic effect at lower digitalis doses. Insulin degradation may be delayed in hypothyroidism, thereby requiring a lower insulin dose. Hypothyroidism delays the catabolism of clotting factors, and if a patient stabilized on warfarin is made euthyroid with levothyroxine, the patient may become excessively anticoagulated. Respiratory depressants such as barbiturates, phenothiazines, and opioid analgesics should be avoided, because increased sensitivity may increase carbon dioxide retention and precipitate myxedema coma.

RECOMBINANT TSH IN THYROID CANCER

Patients with previously treated thyroid carcinoma require lifelong monitoring for recurrent disease.^{134,135} Two diagnostic tests that play a central role in follow-up of these patients—radioiodine whole body scanning and serum thyroglobulin measurement—are most accurate during thyroid-stimulating hormone (TSH) stimulation. Temporary discontinuation of thyroid hormone therapy was previously the sole effective approach for TSH-stimulated testing. However, hormone withdrawal was associated with the morbidity of hypothyroidism and occasional tumor progression. The introduction of recombinant TSH (rTSH)-stimulated testing offers an alternative therapy. Recent clinical trials have shown that the sensitivity of combined rTSH-stimulated radioiodine scanning and serum thyroglobulin measurement has equivalent sensitivity to testing after thyroid hormone withdrawal. Furthermore, measurement of the rTSH-stimulated thyroglobulin concentration is a more sensitive way to detect residual thyroid cancer or normal tissue than thyroglobulin measurement or thyroid hormone therapy alone.

NONTHYROIDAL ILLNESS

A wide variety of abnormalities of pituitary-thyroid function, serum thyroid hormone binding, and extrathyroidal thyroid hormone metabolism occur in patients with nonthyroidal illness. These abnormalities frequently result in decreased serum T_3 concentrations and less often lead to a decreased serum T_4 concentration. Serum TSH concentrations are usually within the normal range. The presence of coexisting primary hypothyroidism can be recognized in patients who have other illnesses by an elevation in the TSH concentration.

The degree and extent of the abnormality in thyroid function generally correlates with the severity of the nonthyroidal illness. These conditions are frequently referred to as the “euthyroid sick syndrome.” It is likely that these changes represent adaptive forms of hypothyroidism that serve to reduce the availability of thyroid hormones to lessen the impact of the nonthyroidal illness.¹³⁶

Decreased serum T_3 concentrations occur in patients with both acute and chronic illnesses. The fundamental cause of decreased serum T_3 concentrations in these situations is decreased extrathyroidal conversion of T_4 to T_3 . This reaction is normally mediated by T_4 -5'-deiodinase. A circulating inhibitor of this enzyme, perhaps interleukin-6, is present in patients with nonthyroidal illness.¹³⁷ Serum total and free T_4 concentrations are usually normal. The serum reverse

T_3 concentration is characteristically high because the same enzyme, 5'-deiodinase, that is necessary to convert T_4 to T_3 , is necessary to convert reverse T_3 to its breakdown products. Acute respiratory infections and surgery acutely elevate interleukin-6, and T_3 concentration is inversely correlated.¹³⁸

Low serum T_4 is seen in most critically ill patients. This change is caused by diminished serum T_4 binding, resulting either from decreased serum concentrations of thyroid-binding globulin, thyroid-binding prealbumin, or albumin, or from inhibitors of T_4 binding. The free T_4 concentration is generally normal. This more severe degree of hypothyroidism, which occurs in severely ill patients, produces a greater reduction in thyroid hormone availability. The low serum T_4 concentrations in patients with nonthyroidal illness indicates a grave prognosis. In two studies, more than 60% of hospitalized patients with a low serum free T_4 index died. T_4 or T_3 supplementation has been of no benefit in this situation and in fact has increased morbidity.

To confuse matters, some patients with nonthyroidal illness have elevation of their serum T_4 concentration. Most commonly, this is seen in patients with psychiatric disorders during acute psychotic breaks. Thyroid hormone levels return to normal within 2 weeks after successful treatment of the underlying psychiatric disease. The occurrence of these abnormalities requires that care be taken in diagnosing hypothyroidism or hyperthyroidism in patients who have nonthyroidal illnesses.

GOITROUS THYROID DISEASE

Endemic goiter is the major thyroid disease throughout the world, affecting more than 200 million people. Many goitrous glands contain one or more nodules. The introduction of iodide supplementation has eliminated goiter as a major medical problem in developed countries, though it continues to be a problem in developing countries whose geographic position makes them more susceptible to iodide deficiency. In 1924, Marine postulated that periods of iodide deficiency resulted in cyclic hyperplasia and involution of thyroid follicular cells with eventual development of nodular hyperplasia.¹⁰² This hypothesis is still used to explain goiter formation today. Whatever the specific cause, the final common pathway appears to result from an inadequate thyroid hormone secretion with compensatory TSH secretion and eventual thyroid gland enlargement. The essential factor for the conversion of a hyperplastic iodine-deficiency goiter into a colloid goiter appears to be an acute reduction of TSH stimulation; therefore, any situation that would result in a cyclical increase and decrease in TSH secretion might eventually result in the production of a nodular goiter.

There has been an interest in the possibility that growth factors other than TSH play a role in the development of a goiter. Immunoglobulin fractions capable of stimulating thyroid growth have been found in patients with nontoxic goiter and Graves' disease. In these patients, thyroid growth-promoting immunoglobulin titers correlates with goiter size rather than with the thyroid hormone concentration.

Sporadic goiter is defined as a goiter occurring in a nonendemic goiter region. Although a number of known goitrogens and errors in thyroid hormone biosynthesis may cause goiter, the majority of cases of sporadic goiter have no known etiology.

Treatment of all goiters is a trial of thyroid hormone suppression in an effort to eliminate TSH as a possible stimulus for continued thyroid growth. Large, long-standing goiters seldom undergo significant reduction in size. If the patient is symptomatic (with dysphagia

or dyspnea) or there is a question of malignant thyroid involvement, surgery is recommended.

PHARMACOECONOMIC CONSIDERATIONS

Although the initial expense of surgery would seem to make it the most expensive treatment option, the relapse rates for thionamides and RAI are higher and in longer-term follow-up, there is not much difference between treatment options nor patients' opinions concerning treatment preferences.¹³⁹ The cost proportion between the medical and surgical treatment in younger patients is 1:2.5 (1 = \$1126 U.S.) before and 1:1.3 (1 = \$2284 U.S.) after inclusion of the relapse costs. The proportion between the medical, surgical, and ¹³¹I treatment in older patients is 1:2.5:1.6 (1 = \$1164 U.S.) before and 1:1.6:1.4 (1 = \$1972 U.S.) after inclusion of the relapse costs.

CLINICAL CONTROVERSIES

Although the current FDA standards of bioavailability for thyroxine products suggest that several products are bioequivalent, the relationship between T₄ serum concentration and TSH response suggests that the products are not truly bioequivalent. New standards of bioequivalency may need to be developed for drug products like thyroxine.

Combination therapy of T₄ + T₃ for hypothyroidism seems to improve cognitive function over monotherapy with T₄; however, there are not corresponding improvements in biochemical markers of thyroid hormone nor differences in TSH response.

Multiple studies have addressed the role of thyroid supplementation in critically ill patients with cardiac disease, sepsis, pulmonary disease (e.g., acute respiratory distress syndrome), or severe infection, or with burn and trauma patients. In spite of a very large number of published studies, it is very difficult to form clear recommendations for treatment with thyroid hormone in the intensive care unit.

EVALUATION OF THERAPEUTIC OUTCOMES

Patients on optimal thyroid hormone replacement therapy should have TSH and free T₄ serum concentrations in the normal range with idiopathic hypothyroidism and Hashimoto's thyroiditis. Those who are being treated for thyroid cancer should have TSH suppressed to very low levels and thyroglobin should be undetectable. Given the half-life of 7 days of T₄, the appropriate monitoring interval is no more often than 4 weeks. The signs and symptoms of hypothyroidism should be improved or absent (see clinical presentation of hypothyroidism, above), although this may take several months for most to improve.

ABBREVIATIONS

ClO₄⁻: perchlorate
 DIT: diiodotyrosine
 FSH: follicle-stimulating hormone
 G_sα: the α subunit of the stimulatory guanine-nucleotide-binding protein
 hCG: human chorionic gonadotropin
 HLA: human leukocyte antigen
¹³¹I: sodium iodide 131
 l-thyroxine: levothyroxine

LH: luteinizing hormone
 MIT: moniodotyrosine
 MMI: methimazole
 MNG: multinodular goiter
 PRTH: pituitary resistance to thyroid hormone
 PTU: propylthiouracil
 RAI: radioactive iodine
 RAIU: radioactive iodine uptake
 rTSH: recombinant thyroid-stimulating hormone
 SCN⁻: thiocyanate
 SSKI: saturated solution of potassium iodide
 T₃: triiodothyronine
 T₄: thyroxine
 TBG: thyroid-binding globulin
 TBPA: thyroid-binding prealbumin
 TcO₄⁻: pertechnetate
 TG: thyroglobulin
 TRβ2, TRβ1, TRα1: thyroid hormone receptors
 TRH: thyrotropin-releasing hormone
 TSA: thyroid-stimulating antibody
 TSH: thyroid-stimulating hormone

ADRENAL GLAND DISORDERS

John G. Gums and John M. Tovar

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Glucocorticoid secretion from the adrenal cortex is stimulated by corticotropin or adrenocorticotropic hormone (ACTH) that is released from the anterior pituitary in response to hypothalamic-mediated release of corticotropin-releasing hormone (CRH).
- 2 To ensure the proper treatment of Cushing's syndrome, diagnostic procedures should (1) establish the presence of hypercortisolism and (2) discover the underlying etiology of the disease.
- 3 The rationale for treating Cushing's syndrome is to reduce the morbidity and mortality resulting from disorders such as diabetes mellitus, cardiovascular disease, and electrolyte abnormalities.
- 4 The treatment of choice for both ACTH-dependent and ACTH-independent Cushing's syndrome is surgery, whereas pharmacologic agents are reserved for adjunctive therapy, refractory cases, or inoperable disease.
- 5 Pharmacologic agents that may be used to manage the patient with Cushing's syndrome include: steroidogenic inhibitors, adrenolytic agents, neuromodulators of ACTH release, and glucocorticoid-receptor blocking agents.
- 6 Spironolactone, a competitive inhibitor of aldosterone, is the drug of choice in bilateral adrenal hyperplasia (BAH)-dependent hyperaldosteronism.
- 7 Addison's disease (primary adrenal insufficiency) is a deficiency in cortisol, aldosterone, and various androgens resulting from the loss of function of all regions of the adrenal cortex.
- 8 Secondary adrenal insufficiency usually results from exogenous steroid use, leading to hypothalamic-pituitary-adrenal (HPA)-axis suppression followed by a decrease in ACTH release, and low levels of androgens and cortisol.
- 9 Virilism results from the excessive secretion of androgens from the adrenal gland and is usually seen as hirsutism in females.

The adrenal glands were first characterized by Eustachius in 1563. After Addison identified a case of adrenal insufficiency in man, adrenal anatomy and physiology flourished. Most of the work done in the early and mid-1900s centered on the glucocorticoid cortisol. With the discovery of aldosterone by Simpson and Tait in 1952, adrenal pharmacology turned toward the mineralocorticoid. Conn¹ followed with his classical description of primary aldosteronism in 1955, and numerous clinicians and investigators have continued the discovery of the variety of disease processes promoted through the adrenal gland.

PHYSIOLOGY, ANATOMY, AND BIOCHEMISTRY

There are two adrenal glands located extraperitoneally to the upper poles of each kidney (Fig. 74-1). On average, each adrenal gland weighs 4 g and is 2 to 3 cm in width and 4 to 6 cm in length. The gland is fed by small arteries from the abdominal aorta and renal and phrenic arteries. Drainage of the adrenal gland occurs via the renal vein on the left and the inferior vena cava on the right.

The adrenal medulla occupies 10% of the total gland and is responsible for the secretion of catecholamines. The adrenal cortex

accounts for the remaining 90% and is responsible for the secretion of three types of hormones (Fig. 74-2) from three separate zones.²

The zona glomerulosa, 15% of the total adrenal cortex, is responsible for mineralocorticoid production, of which aldosterone is the principal end product. Aldosterone maintains electrolyte and volume homeostasis by altering potassium and magnesium secretion and renal tubular sodium reabsorption. The zona fasciculata, the middle zone, makes up 60% of the cortex, is high in cholesterol, and is responsible for basal and stimulated glucocorticoid production. Glucocorticoids, mainly cortisol, are responsible for the regulation of fat, carbohydrate, and protein metabolism. The zona reticularis occupies 25% of the adrenal cortex, and is responsible for all adrenal androgen production. The androgens, testosterone and estradiol, are the major end products and have influence within the reproductive system as well as affecting primary and secondary sex characteristics.

HORMONE PRODUCTION AND METABOLISM

Cortisol production is accomplished via two successive hydroxylations: the first at the 21-position by 21-hydroxylase (yielding 11-deoxycortisol) and the second at the 11-position by 11-hydroxylase, yielding cortisol or hydrocortisone.

FIGURE 74-1. Anatomy of the adrenal gland.

Aldosterone is a by-product of the 21-hydroxylation of pregnenolone to form deoxycorticosterone. The oxidation of 18-hydroxycorticosterone to aldosterone is a unique feature of the zona glomerulosa, explaining why aldosterone is not affected during disease processes limited to the fasciculata and/or reticularis.

Androgens have a 19-carbon nucleus and serve as precursors to more potent androgens produced in the periphery. The adrenal gland can synthesize estradiol and estrone from testosterone and androstenedione, respectively; however, the quantities are extremely small. The rates of production for the various steroids produced by the adrenal gland are listed in Table 74-1.

Metabolism of glucocorticoids occurs in the liver, and is responsible for converting inactive steroids to active metabolites, as well as deactivating the active steroids to less active or inactive metabolites. Most pharmaceutical steroid products are active; however, in the case of prednisone and cortisone, metabolism is necessary for the conversion to the active prednisolone and cortisol, respectively. Following metabolic conversion, glucocorticoids are excreted renally as less active or inactive metabolites.

After metabolism, glomerular filtration is primarily responsible for the elimination of endogenously produced glucocorticoids. The

TABLE 74-1. Rates of Adrenal Production and Plasma Concentrations of Various Steroids

| Steroid | 24-Hour Secretion (mg) | Plasma Concentration (ng/mL) |
|------------------------|------------------------------|---|
| Aldosterone | 0.15 | 0.15–0.17 |
| Androstenedione | 2.50 (female) 2.20 (male) | 1.80 ± 0.21 (female) 1.14 ± 0.21 (male) |

^bLuteal phase of menstrual cycle

half-life of cortisol is 70 to 120 minutes; with aldosterone, the half-life is only 15 minutes because of an extremely high intrinsic clearance.

Metabolism and conversion of the various steroids can be altered by a variety of disease states and medicinal compounds. Drugs and diseases known to result in enhanced clearance of steroids include phenytoin, phenobarbital, rifampin, mitotane, aminoglutethimide, hyperthyroidism, and renal disease (dexamethasone only). Drugs and diseases known to result in reduced clearance of steroids include estrogens and estrogen-containing oral contraceptives, liver disease, age, pregnancy, hypothyroidism, anorexia nervosa, protein-calorie malnutrition, and renal disease (prednisolone only). Plasma glucocorticoids are bound to one of three plasma proteins in varying degrees. Corticosteroid-binding globulin (CBG), albumin, and α_1 -glycoprotein are capable of binding glucocorticoids, with CBG being the principal binding protein.

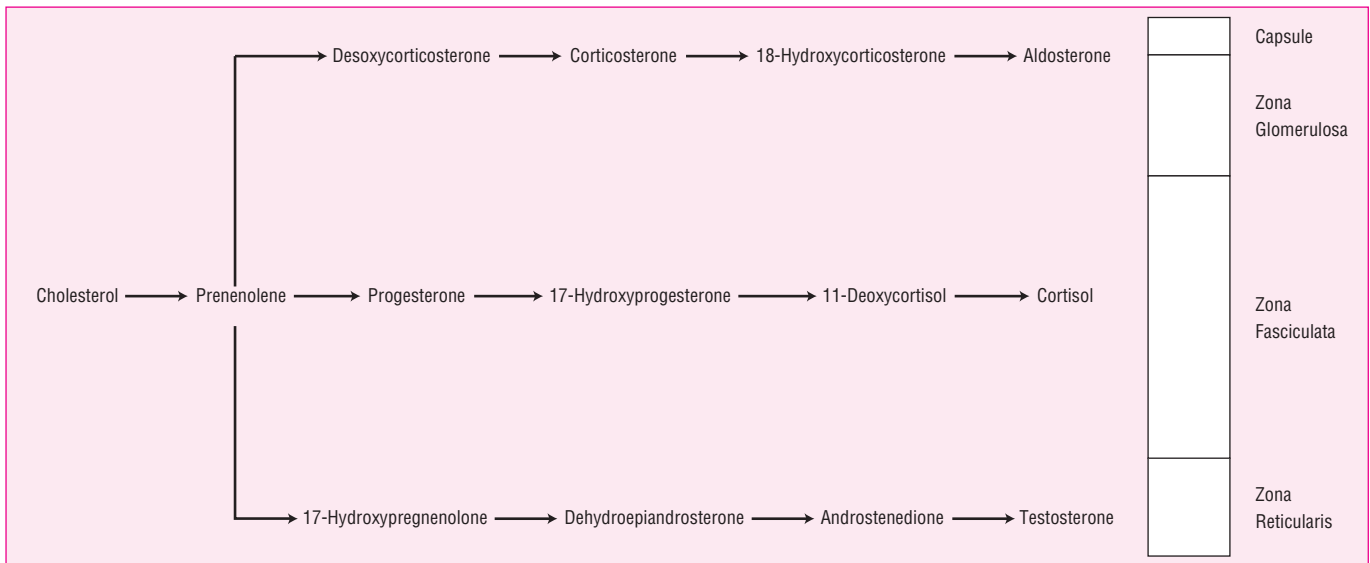

FIGURE 74-2. Hormone synthetic pathways in relation to the zones of the adrenal gland.

The function of steroid binding is to serve as a reservoir of steroids in their inactive state. This binding may change the availability of glucocorticoids to receptor-activating sites. Therefore, a final but important variable in altered plasma concentration of free (active) steroids is concentration of plasma proteins.

REGULATION OF HORMONE SECRETION

▶ The regulation of glucocorticoid secretion is accomplished by the pituitary hormone, adrenocorticotropic hormone (ACTH). Under normal conditions, ACTH is released from the anterior pituitary in response to corticotropin-releasing hormone (CRH), which is secreted by the median eminence of the hypothalamus (Fig. 74–3).

Additionally, histochemical studies have demonstrated that certain neurotransmitters have the unique ability to stimulate production of CRH or ACTH directly. 5-Hydroxytryptamine and norepinephrine have both been shown to increase levels of ACTH. 5-Hydroxytryptamine causes a release of CRH through excitation of a cholinergic intervention. Norepinephrine can cause direct stimulation of ACTH release, although this effect is still controversial. After release, ACTH stimulates the adrenal gland to release cortisol and to a lesser extent aldosterone and androgens. The rising cortisol concentration inhibits the secretion of CRH and ACTH through a negative-feedback mechanism.

Regulation of adrenal androgens is accomplished in a manner similar to cortisol regulation. When plasma androgen reaches sufficient concentrations, production is terminated via a negative-feedback loop. Androgen release is increased during puberty and in women with hirsutism. Adrenal androgen release is decreased in fasting, anorexia nervosa, and aging.

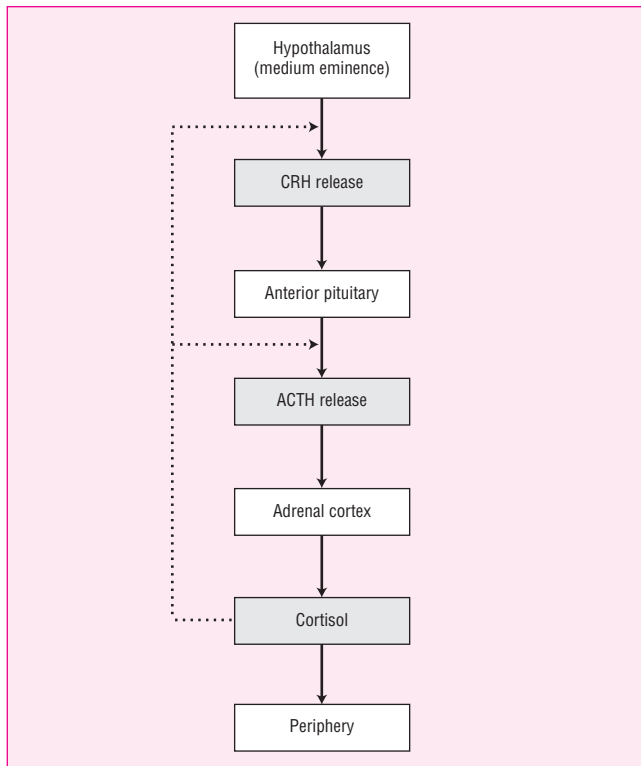

FIGURE 74–3. Negative feedback system involved in the regulation of cortisol secretion under normal conditions. CRH, corticotropin-releasing hormone; ACTH, adrenocorticotropic hormone.

Regulation of aldosterone secretion is considerably more complex. The renin-angiotensin system has the ability to respond to electrolyte and volume changes to increase or decrease aldosterone secretion. Renin production and subsequent aldosterone secretion is stimulated by blood pressure lowering, erect posture, salt depletion, β -adrenergic stimulation, and central nervous system excitation. Renin production is inhibited by salt loading, angiotensin II, vasopressin, potassium, calcium, blood pressure increases, and a variety of drugs. The conversion of renin substrate angiotensinogen to angiotensin I and subsequently to angiotensin II is the initial stimulus for aldosterone synthesis. Angiotensin II is acted on by aminopeptidase and converted to angiotensin III. Angiotensin II and III are both capable of stimulating the zona glomerulosa to secrete aldosterone. Following aldosterone secretion, increases in renal sodium and water retention as well as blood pressure are seen, thereby turning off the stimulus for renin release.

HYPERFUNCTION OF THE ADRENAL GLAND

CUSHING'S SYNDROME

In 1932, Cushing first described a syndrome of pituitary basophilism that attracted national attention. It was not until this time that patients with unexplained central obesity, cutaneous striae, osteoporosis, weakness, hypertension, diabetes mellitus, and congestion had a definite diagnosis. Cushing emphasized that the disease was of pituitary origin. Ten years later, Albright³ focused his attention on the sugar hormone, which he believed originated from the adrenal cortex.

After the development of the method for measuring urinary steroids, Daughaday discovered elevated steroids in the urine of patients with Cushing's disease. Finally, the end product was identified and Cushing's syndrome was correctly explained as an excess of cortisol in the plasma (hypercortisolism).

ETIOLOGY

Cushing's syndrome results from the effects of supraphysiologic levels of glucocorticoids originating either from exogenous administration or from endogenous overproduction by the adrenal glands (ACTH-dependent) or by abnormal adrenocortical tissues (ACTH-independent). ACTH-dependent Cushing's syndrome is usually (~70% of Cushing's cases) caused by overproduction of ACTH by the pituitary gland, causing adrenal hyperplasia (Cushing's disease). Pituitary adenomas account for approximately 85% of these cases. Ectopic ACTH-secreting tumors and nonneoplastic corticotropin hypersecretion, possibly secondary to excess CRH production, are felt to be responsible for the remaining 12% of ACTH-dependent causes. Ectopic ACTH syndrome refers to excessive ACTH production resulting from an endocrine or nonendocrine tumor, usually of the pancreas, thyroid, or lung. Small-cell carcinoma of the lung will lead to ectopic ACTH secretion in 0.5% to 2% of cases. To distinguish between the various etiologies, a careful history and some pertinent laboratory work are required (Table 74–2).

The remaining 18% of Cushing's syndrome cases are ACTH-independent and are almost equally divided between adrenal adenomas and adrenal carcinomas, with rare cases caused by micronodular or macronodular hyperplasia.^{4–5} The majority of adrenal cortex tumors are benign adenomas. Adrenal carcinoma is found more often in children than in adults with Cushing's syndrome.

TABLE 74–2. Various Etiologies of Cushing’s Syndrome and Their Respective Differences

| | Pituitary Dependent | Ectopic ACTH Syndrome | Adrenal Adenoma | Adrenal Carcinoma |
|-----------------------------------|------------------------|--------------------------|--------------------|----------------------|
| Course | Slow | Rapid | Slow | Rapid |
| Symptoms | Mild to moderate | Atypical | Mild to moderate | Severe |
| Dominant sex/age | Female/male | Male | None noted | Children |
| Virilization | + | + | + | +++ |
| Abdominal mass | 0 | 0 | 0 | ++ |
| Plasma ACTH concentration | Slightly elevated | High | 0 | 0 |
| Dexamethasone suppression test | ≥50% Suppression | No suppression | No suppression | No suppression |
| Iodocholesterol scan | Bilateral uptake | Bilateral uptake | Unilateral | None |

ACTH, adrenocorticotropic hormone.

CLINICAL PRESENTATION

The most common findings in patients with Cushing’s syndrome, which are present in 90% of patients, are central obesity and facial rounding. In addition, about 50% of patients will exhibit some peripheral obesity and fat accumulation. Fat accumulation in the dorsocervical area (buffalo hump) can be associated with any major weight gain, whereas increased supraclavicular fat pads are more specific for Cushing’s syndrome.⁵ Striae are usually present along the lower abdomen and take on a red to purple color. Hypertensive complications have traditionally been major contributors to the morbidity and mortality of Cushing’s syndrome. Hypertension is seen in 75% to 85% of patients, with diastolic blood pressures greater than 119 mm Hg noted in over 20% of patients.⁶

DIAGNOSIS

2 The diagnosis of Cushing’s syndrome involves two steps: (1) establishing the presence of hypercortisolism, which is relatively easy, and (2) differentiating between etiologies, which can be quite a challenge (Fig. 74–4).^{4,5,7} The presence of hypercortisolism can be established via the following tests: 24-hour urine free cortisol, midnight plasma cortisol, and/or the low-dose dexamethasone suppression test (DST) (using 1 mg for the overnight test or 0.5 mg/6 h for the classic 2-day study). However, because these tests cannot determine the etiology of Cushing’s syndrome, other tests and procedures subsequently will be employed. They may include any of the following: high-dose DST; plasma ACTH via immunoradiometric assay (IRMA) or radioimmunoassay (RIA); adrenal vein catheterization; metyrapone stimulation test; adrenal, chest, or abdominal computed tomography (CT); CRH stimulation test; inferior petrosal sinus sampling; and pituitary magnetic resonance imaging (MRI). Other possible tests and procedures include insulin-induced hypoglycemia; somatostatin receptor scintigraphy; the desmopressin stimulation test; naloxone CRH stimulation test; loperamide test; the hexarelin stimulation test; and radionuclide imaging.^{4–17} Table 74–3 summarizes some of the tests used to diagnose Cushing’s syndrome.

Elevated urinary free cortisol concentrations are highly suggestive of Cushing’s syndrome. Normal reference values for urinary free cortisol are 20 to 90 mcg per 24-hour period. It is not unusual to detect a twofold or threefold increase in urine cortisol in the patient with hyperfunction of the adrenal gland. Starvation, topical steroid application, hydration from water loading, and acute stress all are capable of elevating the urine cortisol concentrations. Because other pathologic conditions can increase the amount of free cortisol, additional

tests should be performed to confirm the diagnosis, or the diagnostic evaluation should be repeated when the acute stress has resolved. Of all urinary measures, urinary free cortisol is the most useful for assessment of any patient with suspected Cushing’s syndrome.⁷

CLINICAL PRESENTATION: CUSHING’S SYNDROME

GENERAL

The most common findings, which are present in 90% of patients, are central obesity and facial rounding.

SYMPTOMS

About 65% and 58% of patients complain of myopathies and muscular weakness, respectively.

SIGNS

- Peripheral obesity and fat accumulation is found in 50% of patients.
- Facial plethora is caused by an underlying atrophy of the skin and connective tissue and is seen in approximately 84% of patients.
- Patients often are described as having moon facies with a buffalo hump.
- Hypertension is seen in 75% to 85% of patients.
- Psychiatric changes may occur in as many as 55% of patients.
- About 50% to 60% of patients will develop Cushing’s-induced osteoporosis. Of these, 40% will present with back pain and 20% will progress to compression fractures of the spine.
- Gonadal dysfunction is common, with amenorrhea seen in up to 75% of females.
- Excess androgen secretion is responsible for 80% of females presenting with hirsutism.

LABORATORY TESTS

A midnight plasma cortisol, 24-hour urine free cortisol, and/or low-dose DST will establish the presence of hypercortisolism.

OTHER DIAGNOSTIC TESTS

The high-dose DST, plasma ACTH test, metyrapone stimulation test, and CRH stimulation test will help determine the etiology.

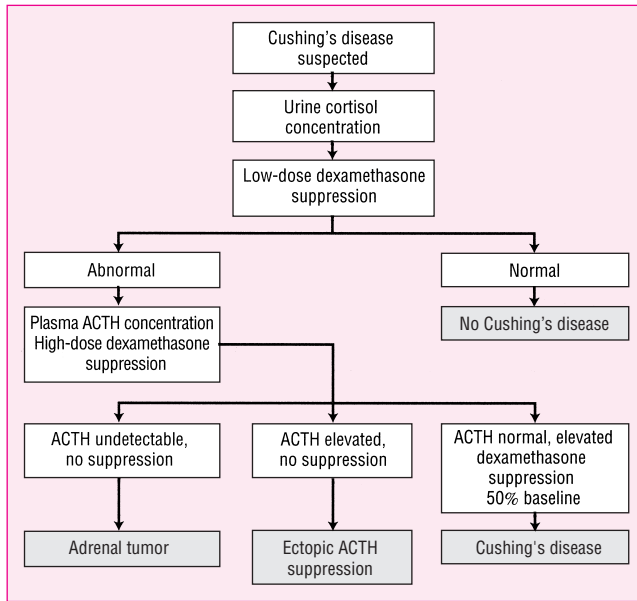

FIGURE 74-4. Algorithm for diagnosing Cushing's syndrome. ACTH, adrenocorticotropic hormone.

The normal circadian rhythm of cortisol will demonstrate a 60% to 80% decline between 8:00 A.M. and 11:00 P.M. This rhythm is lost in the Cushing's syndrome patient. Thus while many patients with Cushing's syndrome will have serum cortisol values in the high normal range if the serum is assayed in the morning, only 3.4% will have normal values if measured late at night.⁷ Thus a midnight serum cortisol greater than 7.5 mcg/dL is a highly sensitive assay for Cushing's. However, this test requires that patients be admitted for more than 48 hours to avoid false-positive responses secondary to the stress of hospitalization. Also if a patient is sleeping, a lower serum cortisol value (>1.8 mcg/dL) should be used. An alternative assay that may prove useful in the future is measurement of salivary cortisol.

In the overnight DST, 1 mg of dexamethasone is administered at 11:00 P.M. The following morning at 8:00 A.M. plasma cortisol is obtained for analysis. The Cushing's syndrome patient will not exhibit a suppressed cortisol concentration via the negative-feedback loop, and the morning cortisol concentration will be elevated above 5 mcg/dL, or as low as 1.8 mcg/dL.^{5,18} The overnight DST is useful only as a screening tool for Cushing's syndrome, because of a high sensitivity, but a rather low specificity. Phenytoin, rifampin, phenobarbital, and other drugs that induce liver enzymes may cause an increase in the clearance rate of the dexamethasone, causing decreased levels leading to a false-positive suppression test.⁷ Plasma dexamethasone measured at the conclusion of this test can clarify results clouded by differences

in metabolism from these drug interactions, individual variability, or patient noncompliance.

The first test used to determine the etiology of Cushing's syndrome is the plasma ACTH test. Plasma ACTH concentrations can be measured via RIA or IRMA.^{7,16} In the ACTH-dependent Cushing's syndromes, ACTH may be normal or elevated. Very high levels of ACTH favor ectopic production. ACTH values are low in ACTH-independent (adrenal) Cushing's syndrome. ACTH levels may appear artificially low in some ectopic ACTH-producing tumors because ACTH can be secreted as an active prohormone that is not detected by the assay.

The high-dose DST operates under the same principle as the low-dose test.^{5,7} The high-dose test has its main application in differentiating the Cushing's disease patient from the patient with another form of hypercortisolism. The Cushing's disease patient will generally demonstrate a 50% reduction in urinary steroids over baseline, whereas the others will generally not suppress. The high-dose test is based on the principle that patients with Cushing's syndrome not caused by adrenal tumors or ectopic ACTH production will suppress their hypothalamic-pituitary axis in the presence of glucocorticoids, but it takes much higher-than-normal doses. An overnight high-dose DST has been developed, whereby the patient has a baseline serum cortisol drawn at 8:00 A.M. and dexamethasone 8 mg is taken at 11:00 P.M. The next morning, at 8:00 A.M., another serum cortisol is drawn.^{7,16} The high-dose test is most useful when the low-dose test and other diagnostic studies have confirmed the diagnosis of Cushing's syndrome. The high-dose DST has been studied in combination with ACTH and metapyrone testing, and results in better specificity than either test alone.

Abnormal adrenal anatomy is effectively identified using high-resolution CT scanning and perhaps MRI. Nodules as small as 1 to 1.5 cm on the adrenal cortex are easily identified by CT. With the use of thin-section scanning, nodules as small as 3 to 5 mm can be visualized.^{7,19,20}

DIFFERENTIAL DIAGNOSIS

Although the diagnosis of Cushing's disease is not a difficult one, at times the clinician will need to differentiate it from syndromes that mimic Cushing's. Pseudo-Cushing's syndrome refers to a group of diseases that can mimic Cushing's disease. Patients with obesity, chronic alcoholism, depression, and acute illness of any type can cloud the diagnosis of Cushing's disease. Depressed patients, though mimicking the urinary steroid abnormalities of Cushing's disease, will not resemble a cushingoid patient in appearance. The chronic alcoholic will have his laboratory panel returned to baseline after he or she stops drinking. The obese patient often will have normal cortisol concentrations on both serum and urinary screening.

TABLE 74-3. Summary of Tests Used to Diagnose Cushing's Syndrome

| Test | Normal | Hyperplasia | Adenoma | Carcinoma |
|------------------------------|--------|-------------|---------|-----------|
| Plasma | | | | |
| Cortisol (mcg/dL, A.M./P.M.) | 170/80 | ↑↑↑ | ↑↑/↑↑ | ↑↑↑/↑↑↑ |
| After low-dose DST | ↓ | ↔ | ↔ | ↔ |
| After high-dose DST | ↓ | ↓/↔ | ↔ | ↔ |
| ACTH (pg/mL) | 10-80 | ↑↑ | ↓ | ↓ |
| Urine | | | | |
| Cortisol (mcg/24 h) | 20-90 | ↑↑ | ↑↑ | ↑↑↑ |

ACTH, adrenocorticotropic hormone; DST, dexamethasone suppression test.

Iatrogenic Cushing’s syndrome, induced by pharmacologic agents, often is indistinguishable from Cushing’s disease. This syndrome can occur from administration of oral, inhaled, intranasal, and topical glucocorticoids, as well as progestins such as medroxyprogesterone

acetate and megestrol acetate.^{21–24} A careful history and serum determination in a basal state can aid the clinician in making the diagnosis. If exogenous glucocorticoids are being taken, plasma cortisol levels may increase, while corticosterone levels remain low.^{7,25}

► **TREATMENT: Cushing’s Syndrome**

3 If left untreated, Cushing’s syndrome is associated with a high percentage of morbidity and mortality owing to associated disorders such as diabetes mellitus, cardiovascular disease, and electrolyte abnormalities. These disorders limit the survival of the Cushing’s disease patient to 4 to 5 years following initial diagnosis. The desired outcomes of treatment are to limit the morbidity and mortality and return the patient to a normal functional state by removing the source of hypercortisolism without causing any pituitary or adrenal deficiencies.

4 Once the etiology of the disease is identified, the treatment of choice for both ACTH-dependent and ACTH-independent Cushing’s syndrome is surgical resection of any offending tumors.²² However, several pharmacologic secondary treatment plans are available, depending on the etiology of the disease (Table 74–4).^{4,5,26}

■ **PHARMACOLOGIC THERAPY**

5 Pharmacotherapy of Cushing’s syndrome (dosing can be found in Table 74–4)^{27,28} can be divided into four categories based on the anatomic site of action of the agent: (1) steroidogenic inhibitors; (2) adrenolytic agents; (3) neuromodulators of ACTH release; and (4) glucocorticoid-receptor blocking agents.^{26,29,30}

Steroidogenic inhibition may be accomplished with the following agents: metyrapone, aminoglutethimide, and ketoconazole. Either metyrapone or aminoglutethimide used alone has limited efficacy, with relapse occurring after discontinuation of therapy. Neither agent should be used after successful surgery. Their use should be restricted to the refractory patient who is not a surgical candidate. Combination therapy with these agents appears more effective than single-agent therapy and may cause fewer side effects.

Metyrapone inhibits 11-hydroxylase activity, resulting in inhibition of cortisol synthesis. Initially, patients may demonstrate an increase in plasma ACTH concentrations because of a sudden drop in cortisol. Metyrapone is biologically active following oral administration. Nausea, vomiting, vertigo, headache, dizziness, abdominal discomfort, and allergic rash have been reported following administration.^{26–30}

Initially, aminoglutethimide was used to treat refractory forms of epilepsy, but it was later discovered to be a potent inhibitor of cortisol synthesis. Aminoglutethimide inhibits the conversion of cholesterol to pregnenolone early in the cortisol pathway.^{26,30,31} Plasma cortisol concentrations are reduced by up to 50% following aminoglutethimide therapy. Side effects include severe sedation, nausea, ataxia, and skin rashes.^{26,31} Most of these reactions are dose-dependent and limit the use of aminoglutethimide in most patients. Aminoglutethimide may decrease the anticoagulant effect of warfarin. As aminoglutethimide can induce the metabolism of exogenous glucocorticoids, careful titration is required with steroid replacement.

Alone, aminoglutethimide is indicated for short-term use in inoperable Cushing’s disease with ectopic ACTH syndrome as the suspected underlying etiology. Aminoglutethimide may be used in combination with metyrapone. Smaller doses of both drugs can be used, thereby minimizing the toxicity associated with either agent. The combination therapy appears effective for various etiologies of Cushing’s disease and is useful in the inoperable patient.

The imidazole derivative antifungal ketoconazole^{26,29,30} is highly effective in lowering cortisol in Cushing’s disease, resulting in normal corticosteroid values in 84% of patients, with an additional 11% of patients reporting improvement. Patients can be maintained successfully for months to years on ketoconazole therapy. In addition to lowering serum cortisol levels, ketoconazole can cause gynecomastia

TABLE 74–4. Possible Treatment Plans in Cushing’s Syndrome Based on Etiology

| Etiology | Nondrug | Generic (Brand) Drug Name | Treatment | | |
|-----------------------|------------------------------------|---|--|---|-------------|
| | | | Initial | Usual | Max |
| Ectopic ACTH syndrome | Surgery, chemotherapy, irradiation | Metyrapone (Metopirone) 250-mg tabs | 1–1.5 g/day, divided every 4–6 h | 1–6 g/day, divided every 4–6 h | 6 g/day |
| | | Aminoglutethimide (Cytadren) 250-mg tabs | 0.5–1 g/day, divided two to four times a day for 2 weeks | 1 g/day, divided every 6 h | 2 g/day |
| Pituitary-dependent | Surgery, irradiation | Cyproheptadine 2 mg/5 mL syrup or 4-mg tabs | 4 mg twice a day | 24–32 mg/day, divided four times a day | 32 mg/day |
| | | Mitotane (Lysodren) 500-mg tabs | 1–6 g/day, increased by 1–2 g/day every 3–7 days | 9–10 g/day, divided three to four times a day | 16 g/day |
| Adrenal adenoma | Surgery, postoperative replacement | Metyrapone | See above | See above | See above |
| | | Ketoconazole (Nizoral) 200-mg tabs | 200 mg once or twice a day | 600–800 mg/day, divided twice a day | 1200 mg/day |
| Adrenal carcinoma | Surgery | Mitotane | See above | See above | See above |

ACTH, adrenocorticotropic hormone.

and lower plasma testosterone values. All of these effects are attributed to its inhibition of a variety of cytochrome P450 enzymes, including 11-hydroxylase and 17-hydroxylase.²⁷ The most common adverse effects are reversible elevation of hepatic transaminases, gynecomastia, and gastrointestinal upset.²⁷

The adrenolytic agent mitotane is a cytotoxic drug that structurally resembles the insecticide dichlorodiphenyltrichloroethane (DDT). Mitotane inhibits the 11-hydroxylation of 11-desoxycortisol and 11-desoxycorticosterone in the cortex. The net result is a reduced synthesis of cortisol and corticosterone. It decreases the cortisol secretion rate, plasma cortisol concentrations, urinary free cortisol, and plasma concentrations of the 17-substituted steroids.²⁷ This drug appears to selectively inhibit adrenocortical function without causing cellular destruction. Degeneration of cells within the zona fasciculata and reticularis occurs with resultant atrophy of the adrenal cortex. The zona glomerulosa is minimally affected during acute therapy, but can become damaged following long-term treatment.^{26,27,30}

Because mitotane can severely reduce cortisol production, the patient should be hospitalized before initiating therapy. Mitotane should be continued as long as clinical benefits occur. Cortisol secretion rate, plasma cortisol concentration, urinary free cortisol, and urinary steroid production should be monitored to assess response to mitotane. If necessary, steroid replacement therapy can be given. Nausea and diarrhea are common adverse effects that occur at doses greater than 2 g/day and may be avoided by gradually increasing the dose and/or administering the agent with food. Approximately 80% of mitotane-treated patients develop lethargy and somnolence, and other central nervous system adverse drug reactions occur in approximately 40% of patients. Furthermore, significant but reversible hypercholesterolemia can result from mitotane use.

Neuromodulatory agents include cyproheptadine, bromocriptine, valproic acid, ritanserin, and octreotide. None of the neuromodulatory agents has demonstrated consistent clinical efficacy in the treatment of Cushing's disease. The existence of a bromocriptine-responsive subset of patients remains controversial.^{26,30}

Cyproheptadine can decrease ACTH secretion in the Cushing's disease patient. Morning plasma cortisol concentrations, as well as 24-hour urinary cortisol (free) concentrations should be monitored. Side effects are minor and include sedation and hyperphagia. Cyproheptadine should be reserved for nonsurgical candidates who fail more conventional therapy. Because the response rate is no more than 30%, patients should be followed closely for relapses.

Glucocorticoid receptor antagonism may be accomplished via RU-486 (mifepristone). RU-486 is a progesterone- and glucocorticoid-receptor antagonist that inhibits dexamethasone suppression and raises endogenous cortisol and ACTH values in normal subjects.^{26,32} Limited clinical experience in Cushing's suggests that RU-486 is highly effective in reversing the manifestation of hypercortisolism. Because of its novel site of action as a receptor antagonist leading to higher cortisol and ACTH levels, the diagnosis of treatment-induced glucocorticoid insufficiency must rest on clinical signs only. The efficacy and long-term effects of RU-486 remain to be determined.

Spirolactone has been used for its competitive antagonism of aldosterone in the treatment of Cushing's syndrome. Spirolactone can provide symptomatic relief of the hypertension and hypokalemia often seen in Cushing's syndrome.

Close monitoring of 24-hour urinary free cortisol levels and serum cortisol levels are essential to monitor for adrenal insufficiency. Steroid secretion should be monitored with all of these drugs and steroid replacement given as needed. Whatever the choice, pharmacologic therapy in pituitary-dependent disease is mainly centered

around patient stabilization prior to surgery or in patients waiting for potential response to other therapies.

■ NONPHARMACOLOGIC THERAPY

■ SURGERY

During the last decade, the treatment of choice for Cushing's disease has been transsphenoidal resection of the pituitary microadenoma.^{4,5,33} The advantages to this procedure include preservation of pituitary function, low complication rate, and high clinical improvement rate. The overall cure rate of histologically proven tumors approaches 90%.

Bilateral adrenalectomy surgery had been the mainstay of therapy for years. It is used now only in patients for whom transsphenoidal surgery and pituitary irradiation have failed or cannot be used.⁵ Bilateral adrenalectomy rapidly reverses hypercortisolism. However, patients may develop Nelson's syndrome, which involves sella turcica enlargement and hyperpigmentation, caused by postoperative hypothalamic stimulation. Therefore if bilateral adrenalectomy is used it should be accompanied by some form of hypothalamic inhibition, such as cyproheptadine.

Irradiation (4000 to 5000 rads) of the pituitary has provided clinical improvement in approximately 50% of patients. Improvement is usually not seen until 6 to 12 months after therapy and can create pituitary-dependent hormone deficiencies. Most clinicians will reserve pituitary irradiation for the patient with a mild case of Cushing's disease or as an adjunct to another therapy.³⁴

■ Adrenal Adenoma

Surgical resection of benign adrenal adenoma is associated with relatively few side effects and a high cure rate (95%). The contralateral gland in the patient with adrenal adenoma is usually atrophic, therefore steroid replacement is needed both perioperatively and postoperatively. Table 74-5 outlines an approach to steroid replacement for three separate routes of hydrocortisone. Therapy should be continued for 6 to 12 months following surgery. Before replacement therapy is discontinued, recovery of the adrenal axis may be assessed by administering ACTH and measuring cortisol response at 30 and 60 minutes. Cortisol levels should exceed 18 mcg/dL before discontinuance of the exogenous steroids.⁴

■ Adrenal Carcinoma

Unlike the benign adenoma patient, patients with adrenal carcinoma have an unpredictable and unfavorable outcome with surgical resection.⁵ Often the complete tumor cannot be excised, leaving the patients with some degree of symptomatology and extra-adrenal involvement. Irradiation can be used if metastases are discovered. In the patient with adrenal carcinoma who is not a surgical candidate, the focus of treatment is on palliative pharmacologic intervention (e.g., mitotane).

Mitotane appears to be the drug of choice in inoperable functional and nonfunctional adrenal carcinoma. Tumor regression is seen in approximately 35% to 50% of patients, with most regression occurring between the second and fourth month of therapy. Seventy-five percent of patients will exhibit a 30% fall in urinary steroids, with 50% of patients showing an improved clinical response after 5 months of

TABLE 74-5. Alternative Steroid Replacement Regimens in the Adrenal Adenoma Patient

| Time | Hydrocortisone Dose (mg) | | |
|--------------------------|--------------------------|--|------------------------------|
| | IV | IM | PO |
| Operation day | 300 | 50 before surgery and 50 after surgery | |
| Postoperative day 1 | 200 | 50 every 12 h | |
| Postoperative day 2 | 150 | 50 every 12 h | |
| Postoperative day 3 | 100 | 50 every 12 h | |
| Postoperative day 4 | | 50 every 12 h | 25 every 6 h |
| Postoperative day 5 | | 25 every 12 h | 25 every 6 h ^a |
| Postoperative day 7 | | | 25 every 6 h |
| Postoperative days 8-10 | | | 25 every 8 h |
| Postoperative days 11-20 | | | 25 every 12 h |
| Postoperative days 21+ | | | 20 at 8 A.M. 10 at 4 P.M. |

^aAdd fludrocortisone 0.05-2 mg orally once daily starting on postoperative day 5. Adjust dose based on blood pressure, body weight, and serum electrolytes.

treatment. Patient survival appears prolonged, although no adequate clinical trials are available to support this assumption.

Metyrapone, aminoglutethimide, and ketoconazole may be given to attempt control of steroid hypersecretion. 5-Fluorouracil has also been used in combination therapy.

Ectopic ACTH Syndrome

In the ectopic ACTH syndrome multiple sites of tumors exist, and locating the ectopic site is essential but often difficult.

Therefore only approximately 10% of patients are cured following surgery, and the remaining 90% receive postoperative medication.

Pharmacologic management with metyrapone is effective and remains the agent of choice in the ectopic ACTH syndrome.³⁵ Aminoglutethimide and ketoconazole are alternative agents.^{4,35,36} Mitotane has been tried in patients with ectopic ACTH syndrome; however, its side-effect profile generally limits its use. RU-486 and the somatostatin analog octreotide have been reported to reduce the clinical signs of the ectopic ACTH syndrome.^{30,35} Further evaluation of these agents is needed.

HYPERALDOSTERONISM

Excess aldosterone is categorized as either primary or secondary hyperaldosteronism.³⁷⁻⁴⁸

PRIMARY ALDOSTERONISM

Etiology

Primary aldosteronism implies that the physiologic abnormality is within the adrenal cortex. The most common causes include a solitary adrenal adenoma (60%) or idiopathic adrenocortical hyperplasia (35% bilateral and 5% unilateral). Other rare causes include adrenal cortex carcinoma, primary adrenocortical hyperplasia, renin-responsive adrenocortical adenoma, and genetic mutations, such as in glucocorticoid-suppressible hyperaldosteronism.^{39,40,42}

Clinical Presentation

The incidence of primary aldosteronism is disputed, with estimates ranging from approximately 0.5% to 9.5% of all hypertensive patients.^{39,49} The disease is more common in women aged 30 to 50 years. Signs and symptoms may include arterial hypertension, muscle weakness, fatigue, and headache, though many patients are asymptomatic.

Diagnosis

The absolute diagnosis is relatively easy based on clinical findings and pertinent laboratory findings. However, as in Cushing's disease, the discovery of the underlying etiology is mandatory to ensure proper treatment. Table 74-6 lists the various abnormalities that must be ruled out when suspicion of hyperaldosteronism is high.

CLINICAL PRESENTATION: PRIMARY HYPERALDOSTERONISM

SYMPTOMS

Patients may complain of muscle weakness, fatigue, paresthesias, and headache.

SIGNS

- Hypertension
- Reduced glucose tolerance is seen in 25% of patients.
- Metabolic alkalosis
- Tetany/paralysis
- Polydipsia/nocturnal polyuria

LABORATORY TESTS

A serum potassium concentration of less than 3.5 mEq/L with a concurrent urinary potassium content greater than 30 mEq per 24 hours is suggestive of primary aldosteronism.

Common laboratory findings include hypokalemia (80% to 90%), suppressed renin activity, elevated plasma aldosterone concentrations, hypernatremia (>142 mEq/L), hypomagnesemia, and elevated bicarbonate concentration (>31 mEq/L).

OTHER DIAGNOSTIC TESTS

A plasma-aldosterone-to-plasma-renin-activity ratio (PA:PRA) greater than 25 is indicative of primary hyperaldosteronism.

A serum potassium concentration of less than 3.5 mEq/L with a concurrent urinary potassium content greater than 30 mEq per

TABLE 74–6. Differential Diagnosis of Primary Aldosteronism

| Disease | Plasma Renin Concentration | Plasma Aldosterone Concentration | Blood Pressure |
|----------------------------------|----------------------------|----------------------------------|----------------|
| Primary aldosteronism | Low | High | High |
| Edematous disorders | High | High | Normal |
| Malignant hypertension | High | High | High |
| Congenital adrenal hyperplasia | Low | Low | High |
| Cushing's syndrome | Low to normal | Low to normal | High |
| Liddle's syndrome | Low | Low | High |
| Bartter's syndrome | High | High | Low to normal |
| Licorice ingestion | Low | Low | High |
| Low-renin essential hypertension | Low | Low to normal | High |

24 hours is suggestive of primary aldosteronism.³⁶ Normokalemia does not exclude the diagnosis of primary aldosteronism. Between 7% and 38% of patients with primary aldosteronism will have serum potassium concentrations greater than 3.6 mEq/L. The diagnosis of primary aldosteronism can be made with a plasma-aldosterone-to-plasma-renin-activity ratio (PA:PRA). Hirohara and colleagues⁴⁴ found a PA:PRA greater than 32% to be 100% sensitive and 61% specific in patients with aldosterone-producing adenomas. However, lower cutoffs of 20 and 25 ng/dL per ng/mL have been proposed to search for primary hyperaldosteronism.^{44–46}

Differentiating between an aldosterone-producing adenoma (APA) and bilateral adrenal hyperplasia (BAH) is imperative to formulate a proper treatment plan. A majority of the adenomas are singular and small, less than 1 cm. The left adrenal gland is affected at a higher rate than the right. Patients with APA generally have more severe hypertension, more profound hypokalemia, and higher plasma and urinary aldosterone levels compared to patients with BAH. CT scanning can usually detect most adenomas, though nonfunctional adenomas may occasionally cause confusion.

The underlying abnormality in BAH remains a mystery, but some investigators believe that a hormone factor stimulates the zona glomerulosa, resulting in increased sensitivity to angiotensin II.³⁴ In contrast to APA patients, patients with BAH are able to maintain control of the renin-angiotensin system, with little effect following doses of ACTH.

Therapeutic Management

6 BAH-Dependent Hyperaldosteronism. Spironolactone, the drug of choice in BAH-dependent hyperaldosteronism, competitively inhibits aldosterone biosynthesis within the adrenal gland, making it extremely useful in overstimulated BAH patients.^{40,41} It is available in oral form, with most patients responding to doses of 25 to 400 mg/day. The clinician should wait 4 to 8 weeks before reassessing the patient for urinary electrolytes and blood pressure control. Adverse effects of spironolactone include gastrointestinal discomfort, impotence, gynecomastia, and menstrual irregularities. Additionally, because salicylates increase the renal secretion of canrenone, the active metabolite, patients should be advised to avoid concomitant therapy with salicylates. Because spironolactone blocks testosterone biosynthesis, it often is not used in men. The drug of choice in men and patients intolerant of spironolactone is amiloride.^{37,39} The usual dose is 5 mg twice a day up to 30 mg/day if necessary. More recently, eplerenone, a new aldosterone antagonist with high affinity for the aldosterone receptor and low affinity for androgen and progesterone receptors, was approved for the treatment of hypertension. It appears to be more beneficial than spironolactone due

to its limited progestational and antiandrogenic side effects. However, its role in the management of hyperaldosteronism has not been established.^{37,41}

Second-line therapy is often required to control the blood pressure of patients with BAH. Agents useful as second-line choices include the calcium channel blockers, angiotensin-converting enzyme inhibitors, and low-dose diuretics such as hydrochlorothiazide.^{38,40,41}

Therapeutic Management

APA-Dependent Hyperaldosteronism. The treatment of choice for APA-dependent aldosteronism remains laparoscopic resection of the adenoma.⁵⁰ If no primary lesion is found, resection of one and a half of the adrenal glands may be attempted, followed by supplemental spironolactone therapy. However, a recent retrospective analysis of patients with aldosterone-producing adenomas who chose medical management instead of surgical resection, revealed medical management to be efficacious in this population and should be considered as an alternative in patients in whom surgery is contraindicated.⁵¹

Summary

The diagnosis of primary aldosteronism is made through the observation of elevated blood pressure, low serum potassium, high urinary potassium, elevated serum and urinary aldosterone, and an elevated PA:PRA (Fig. 74–5). Differentiating between the various etiologies is mandatory. Patients with adrenal adenomas can be distinguished from patients with hyperplasia by CT scan. Treatment depends on the etiology with surgical resection, well accepted as the treatment of choice in adenomas, and spironolactone or amiloride plus second-line agents in patients with hyperplasia.

SECONDARY ALDOSTERONISM

Secondary hyperaldosteronism results from stimulation of the zona glomerulosa by an extra-adrenal factor, usually the renin-angiotensin system. Excessive potassium intake can create a physiologic increase in aldosterone, as can oral contraceptive use, pregnancy (10 times normal by the third trimester), and menses. Congestive heart failure, cirrhosis, renal artery stenosis, and Bartter's syndrome also can lead to elevated aldosterone concentrations.

Treatment of secondary aldosteronism is dictated by etiology. Control or correction of the extra-adrenal stimulation of aldosterone secretion should resolve the disorder. Medical therapy with spironolactone is the mainstay of treatment until an exact etiology can be located.

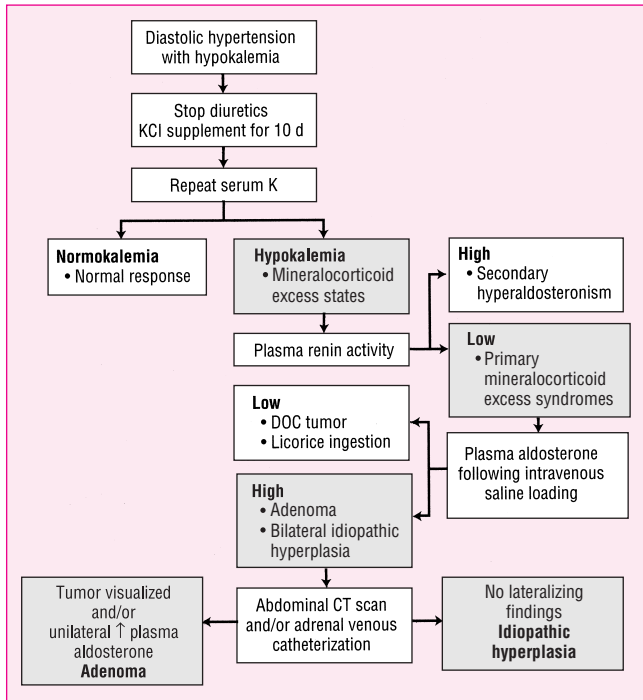

FIGURE 74-5. Algorithm for the diagnosis of primary aldosteronism.

TABLE 74-7. Etiologies of Primary and Secondary Adrenal Insufficiency

| Primary Insufficiency | Secondary Insufficiency |
|---|---|
| <i>Slow onset</i> | |
| Acquired immunodeficiency syndrome | Craniopharyngioma |
| Adrenomyeloneuropathy | Cure of Cushing's syndrome |
| Amyloidosis | Empty sella syndrome |
| Autoimmune adrenalitis ^a | Tumors of the third ventricle |
| Bilateral adrenalectomy | Histiocytosis |
| Congenital adrenal hypoplasia | Hypothalamic tumors |
| Hemochromatosis | Hypopituitarism |
| Isolated glucocorticoid deficiency | Long-term corticosteroid administration |
| Metastatic neoplasia | Lymphocytic hypophysitis |
| Systemic fungal infection | Pituitary surgery, radiation, or tumor |
| Tuberculosis ^b | Sarcoidosis |
| <i>Fast onset</i> | |
| Adrenal thrombosis, hemorrhage, or necrosis | Postpartum pituitary necrosis |
| | Necrotic or bleeding pituitary macroadenoma |
| | Head trauma, lesions of the pituitary stalk |
| | Pituitary or adrenal surgery for Cushing's syndrome |

^aAccounts for approximately 70% of cases.

^bAccounts for approximately 20% of cases.

HYPOFUNCTION OF THE ADRENAL GLAND

7 Primary adrenal insufficiency, or Addison's disease, involves the destruction of all regions of the adrenal cortex. Deficiencies arise in cortisol, aldosterone, and the various androgens. Approximately 40% to 53% of patients with idiopathic primary adrenal insufficiency present with one or more clinical disorders involving multiple endocrine organs. The organs involved can include ovary, thyroid, pancreas, and parathyroid gland. This polyglandular failure syndrome is associated with the idiopathic etiology only and has not been seen with adrenal insufficiency associated with tuberculosis or other invasive diseases.

8 Secondary insufficiency most commonly results from exogenous steroid use, leading to suppression of the hypothalamic-pituitary-adrenal (HPA)-axis and decreased release of ACTH, resulting in impaired androgen and cortisol production. This has been reported from oral, inhaled, intranasal, and topical glucocorticoid administration.⁵²⁻⁵⁴ Other drugs reported to induce secondary adrenal insufficiency include rifampin, ketoconazole, phenytoin, phenobarbital, mirtazapine, and progestins such as medroxyprogesterone acetate and megestrol acetate.⁵⁵⁻⁵⁷ Chronic suppression also can result in atrophy of the anterior pituitary and hypothalamus, impairing recovery of function if the exogenous steroid is reduced. Secondary disease classically presents with normal concentrations of mineralocorticoids.

Approximately 90% of the adrenal cortex must be destroyed before adrenal insufficiency symptoms will occur.⁵⁸ Specific etiologies for both primary and secondary insufficiency are listed in Table 74-7. Adrenal hemorrhage can result from multiple etiologies including traumatic shock, coagulopathies, ischemic disorders, and other situations of severe stress, but septicemia is the most common. Symptoms include truncal pain, fever, shaking, chills, hypotension preceding shock, anorexia, headache, vertigo, vomiting, rash, psychiatric symptoms, abdominal rigidity or rebound, and death in 6 to 48 hours if not treated. The most common organisms found on autopsy are

Streptococcus pneumoniae, *Staphylococcus* spp., and *Haemophilus influenzae*.⁵³

ADDISON'S DISEASE

Distinguishing Addison's disease from secondary insufficiency is difficult; however, the following guidelines may be helpful:

1. Hyperpigmentation usually is not seen in secondary adrenal insufficiency because of low amounts of melanocyte-stimulating hormone. Low amounts of melanocyte-stimulating hormone are present owing to a deficient pituitary secretion of ACTH and β -lipotropin, all of which are synthesized together in a common precursor peptide, pro-opiomelanocortin (POMC).
2. Aldosterone secretion usually is preserved in secondary insufficiency.
3. Weight loss, dehydration, hyponatremia, hyperkalemia, and elevated blood urea nitrogen are common in Addison's disease.
4. Addison's disease will have an abnormal response to the rapid ACTH-stimulation test. Plasma ACTH levels are usually 400 to 2000 pg/mL in primary insufficiency, versus normal to low (0 to 50 pg/mL; see Table 74-3) in secondary insufficiency. A normal cosyntropin-stimulation test does not rule out secondary adrenal insufficiency.

The short cosyntropin-stimulation test can be used to assess patients suspected of hypocortisolism. Patients are given 250 mcg of synthetic ACTH intravenously or intramuscularly, with serum cortisol levels drawn at baseline and 30 to 60 minutes after the injection. An increase to a cortisol level ≥ 18 mcg/dL (500 nmol/L) rules out

adrenal insufficiency.⁵⁹ While this test remains the most commonly used method, in some patients with secondary adrenal insufficiency or mild primary adrenal insufficiency, this test will be normal. This result may be owing to the high dose of corticotropin given. Thus some suggest that higher cutoff values (≥ 22 to 25 mcg/dL) should be used.⁶⁰ Alternatively, studies have demonstrated that equivalent results can be seen using 1 mcg of cosyntropin. The normal response is an increase to a cortisol level ≥ 18 mcg/dL 30 minutes after the injection. Other tests include the insulin hypoglycemia test, the metyrapone test, and the corticotropin-releasing hormone stimulation test.^{59,61,62}

Cortisol levels greater than 18 to 20 mcg/dL 30 minutes after a cosyntropin-stimulation test are not useful in patients who are acutely ill.⁶³ Severe infection, trauma, burns, illnesses, or surgery can increase cortisol production by as much as a factor of six, making the recognition of adrenal insufficiency in this population extremely difficult. In the critically ill, a random cortisol level below 15 mcg/dL is indicative of adrenal insufficiency, while a level greater than 34 mcg/dL suggests that adrenal insufficiency is unlikely.⁶³ For patients who fall between these two values, a poor response to corticotropin (less than 9 mcg/dL increase in plasma cortisol from baseline at 30 or 60 minutes) indicates the possibility of adrenal insufficiency and a need for corticosteroid supplementation.⁶³

Treatment of Addison's disease must include adequate patient education, so that the patient is aware of treatment complications, expected outcome, missed doses, and drug side effects. The agents of choice are prednisone, hydrocortisone, and cortisone, administered twice daily with the treatment objective being the establishment of the lowest effective dose while mimicking the normal diurnal adrenal rhythm.⁵⁹ Usually a twice-daily dosing schedule is adequate with the dose depending on the agent used.

Recent studies^{64,65} indicate that the daily cortisol production varies between 5 and 10 mg/m². Hence, the 12- to 15-mg/m² per day rule for cortisol supplementation, which is roughly equivalent to 15 to 25 mg of hydrocortisone or 25 to 37.5 mg of cortisone acetate daily. A morning dose of cortisone (20 mg), hydrocortisone (15 mg), or prednisone (2.5 mg) followed by an evening dose of the same agent at 33% to 50% of the morning dose is usually sufficient to duplicate the normal circadian rhythm of cortisol production. To replace the mineralocorticoid loss, fludrocortisone acetate can be used. A dose of 0.05 to 0.2 mg by mouth once a day is adequate. If parenteral therapy is needed, 2 to 5 mg of deoxycorticosterone trimethylacetate in oil intramuscularly every 3 to 4 weeks can be used. The main reason for adding the mineralocorticoid is to minimize the development of hyperkalemia. Adverse effects must be monitored closely. Symptoms include gastric upset, edema, hypertension, hypokalemia, insomnia, excitability, and diabetes mellitus. In addition, patient weight, blood pressure, and electrocardiogram should be monitored regularly.⁶¹

Most adrenal crises occur secondary to glucocorticoid dose reduction or lack of stress-related dose adjustments. It is recommended that patients receiving corticosteroid-replacement therapy add 5 to 10 mg hydrocortisone to their normal daily regimen shortly before strenuous activities such as hiking.⁶¹ Likewise, during times of severe physical stress such as febrile illnesses or after accidents, patients should be instructed to double their daily dose until recovery.⁶⁶

The end point of therapy is difficult to assess in most patients, but a reduction in excess pigmentation is a good clinical marker. The development of features of Cushing's syndrome indicates excessive replacement. Treatment of secondary adrenal insufficiency is identical to primary disease treatment with the exception that mineralocorticoid replacement usually is not necessary. Patient education still should be stressed with emphasis placed on establishing an alternate-day regimen.

ACUTE ADRENAL INSUFFICIENCY

Adrenal crisis, or Addisonian crisis, is characterized by an acute adrenocortical insufficiency. Adrenal crisis represents a true endocrine emergency. Anything that increases adrenal requirements dramatically can precipitate an adrenal crisis. Stressful situations, surgery, infection, and trauma all are potential triggering events, especially in the patient with some underlying adrenal or pituitary insufficiency. The most common cause of adrenal crisis is hypothalamic-pituitary-adrenal (HPA)-axis suppression brought on by chronic use of exogenous glucocorticoids and abrupt withdrawal.

Treatment of adrenal crisis involves the administration of parenteral glucocorticoids. Hydrocortisone is the agent of choice owing to its combined mineralocorticoid and glucocorticoid activity. Hydrocortisone is started at 100 mg intravenously through rapid infusion, and followed by a continuous infusion or intermittent bolus of 100 to 200 mg every 24 hours. Intravenous administration is continued for 24 to 48 hours, at which time if the patient is stable, oral hydrocortisone may be started at a dose of 50 mg every 8 hours for another 48 hours. Following oral maintenance therapy, a hydrocortisone taper is initiated until the dosage is 30 to 50 mg/day in divided doses. Fluid replacement often is required and may be accomplished with 5% dextrose and isotonic saline (D₅NS) at a rate to support blood pressure. If hyperkalemia is present after the hydrocortisone maintenance phase, additional mineralocorticoid usually is required. Fludrocortisone acetate in a dose of 0.1 mg by mouth daily is the agent of choice.

Patients with adrenal insufficiency should be instructed to carry a card or wear a bracelet or necklace, such as MedicAlert, that contains information about their condition. Patients should also have easy access to injectable hydrocortisone or glucocorticoid suppositories in case of an emergency or during times of physical stress, such as febrile illness or injury.⁶¹

CLINICAL PRESENTATION: ADRENAL INSUFFICIENCY

SYMPTOMS

- Patients commonly complain of weakness, weight loss, gastrointestinal symptoms, craving for salt, headaches, memory impairment, depression, and postural dizziness.
- Early symptoms of acute adrenal insufficiency also include myalgias, malaise, and anorexia. As the situation progresses, vomiting, fever, hypotension, and shock will develop.

SIGNS

- Increased pigmentation
- Hypotension (postural)
- Fever
- Decreased body hair
- Vitiligo
- Features of hypopituitarism (amenorrhea and cold intolerance)

LABORATORY TESTS

The short cosyntropin stimulation test can be used to assess patients suspected of hypercortisolism.

OTHER DIAGNOSTIC TESTS

Other tests include the insulin hypoglycemia test, the metyrapone test, and the corticotropin-releasing hormone stimulation test.

HYPOALDOSTERONISM

Hypoaldosteronism is rare and usually is associated with low renin status, diabetes, complete heart block, or severe postural hypotension, or it may occur postoperatively following tumor removal.² Hypoaldosteronism may be part of a larger adrenal insufficiency or be the only defect the patient has. In nonselective hypoaldosteronism, the etiology of the low aldosterone is most likely generalized adrenocortical insufficiency (see Addison’s disease). In selective hypoaldosteronism, the etiology is usually a specific defect in the stimulation of adrenal aldosterone secretion (21-hydroxylase deficiency being most common) or a defect in peripheral aldosterone action (decreased aldosterone receptors).

Laboratory analysis reveals low serum sodium and high serum potassium concentrations. Patients often will present with hyperchloremic metabolic acidosis. Because the deficiency is in the mineralocorticoid, replacement with fludrocortisone in a dose of 0.1 to 0.3 mg is usually effective. Patients should be followed for blood pressure response as well as electrolyte status.

CONGENITAL ADRENAL HYPERPLASIA

Because many enzyme systems are needed to complete the complex cholesterol-to-cortisol pathway, enzyme deficiencies may lead to disruptions of the normal cascade of events (see Fig. 74–2). This group of enzyme disorders is known as congenital adrenal hyperplasia, mainly because of the resultant chronic adrenal gland stimulation that occurs following enzyme deficiency.^{67,68} The most frequent is steroid 21-hydroxylase deficiency, accounting for more than 90% of cases. Any enzyme deficiency is capable of affecting any one or all three of the steroid pathways. Therefore treatment should be focused on replacement of the deficient hormone, as well as cessation of the chronic stimulation causing the hyperplasia. In Table 74–8, six of the most common enzyme deficiencies are briefly outlined.

TABLE 74–8. Congenital Adrenal Hyperplasia (CAH)

| Enzyme Deficiency (Disorder) | Symptoms | Lab Tests | Comments |
|---|--|--|---|
| 20-Hydroxylase (nonvirilizing CAH) | Enlarged female genitalia and adrenal gland (due to cholesterol) | All steroids are low in blood and urine | Poor prognosis for infants |
| 17-Hydroxylase (nonvirilizing CAH) | Hypertension usually present | Low concentrations of cortisol and estrogens | Mineralocorticoid replacement not necessary |
| 21-Hydroxylase (virilizing CAH) | Pubertal irregularities (acne, early pubic hair, voice lowering, and increased muscularity); mature normally with replacement | High progesterone, renin, 17-hydroxyprogesterone and ACTH; low cortisol, sodium, and aldosterone | Most common form of CAH (90% of total), incidence of 1/10,000; monitor growth velocity, bone age, renin, and 17-hydroxyprogesterone |
| 11-Hydroxylase (virilizing CAH) | Hypertension secondary to high deoxycortisol and virilism from androgen excess; mistaken for Cushing’s, but no glucose intolerance | Low plasma cortisone and aldosterone; high ACTH and MSH concentrations | Second most common form of CAH (9% of total), incidence of 1/100,000; final step in biosynthesis of corticosterone and cortisol; found only in adrenal cortex |
| 3-Hydroxysteroid dehydrogenase (mixed CAH) | Both cortisol and aldosterone deficiencies | Decreased aldosterone, cortisol, estrogens, and androgens; increased pregnenolone and cholesterol | Defect affects both adrenals and gonads |
| 18-Hydroxysteroid dehydrogenase (corticosterone methyloxidase deficiency) | Hypotension | Restricted to zona glomerulosa; sole aldosterone defect; hyponatremia, hyperkalemia, increased renin | Mineralocorticoid replacement without glucocorticoid replacement |

ADRENAL VIRILISM

Virilism, excessive secretion of androgens from the adrenal gland, is more commonly seen in females, with hirsutism being the dominant feature. Women who present with hirsutism also may have voice deepening, increased muscle mass, menstrual abnormalities, clitoral enlargement, redistribution of body fat and loss of female body contour, breast atrophy, and hair recession and crown balding.⁶⁹ Though virilism may be easy to diagnose based on clinical symptoms, making the diagnosis on a biochemical basis is difficult. The most common etiology of virilism involves one of many possible congenital enzyme defects. Depending on the enzyme deficiency, accumulation of a variety of androgens, notably testosterone, can develop.

Treatment of virilism centers around suppression of the pituitary-adrenal axis with exogenous glucocorticoids. Choice of steroids is variable. In adults, the usual steroids used are dexamethasone (0.25 to 0.5 mg), prednisone (2.5 to 5 mg), or hydrocortisone (10 to 20 mg).⁶⁹ Antiandrogen use may allow lower steroid doses to be used.

HIRSUTISM

Hirsutism (hypertrichosis) is defined as more hair than is cosmetically acceptable. The majority of cases occur in women with some degree of excess androgen production, though certain drugs also may induce hirsutism. Examples of such drugs include minoxidil, phenytoin, cyclosporine, methyl dopa, danazol, metoclopramide, phenothiazines, reserpine, and diazoxide. Androgen excess can be derived from either the ovaries or the adrenal glands, with a small fraction coming from pituitary disorders. Ovarian excess is typically associated with obesity and menstrual abnormalities. In the patient with hirsutism, congenital adrenal hyperplasia, adrenal tumors, and ovarian tumors should be ruled out.^{69,70}

TABLE 74–9. Relative Potencies of Glucocorticoids

| Glucocorticoid | Anti-Inflammatory Potency | Equivalent Potency (mg) | Approximate Half-Life (min) | Sodium-Retaining Potency |
|--------------------|---------------------------|-------------------------|-----------------------------|--------------------------|
| Cortisone | 0.8 | 25 | 30 | 2 |
| Hydrocortisone | 1 | 20 | 90 | 2 |
| Prednisone | 3.5 | 5 | 60 | 1 |
| Prednisolone | 4 | 5 | 200 | 1 |
| Triamcinolone | 5 | 4 | 300 | 0 |
| Methylprednisolone | 5 | 4 | 180 | 0 |
| Betamethasone | 25 | 0.6 | 100–300 | 0 |
| Dexamethasone | 30 | 0.75 | 100–300 | 0 |

Cosmetic approaches are generally tried first, with laser photothermolysis offering the greatest long-term success. Only when cosmetic surgery is ineffective should suppressive therapy be used. Glucocorticoids, such as dexamethasone, can be used if the androgen source is adrenal, but may induce cushingoid symptoms even in doses of 0.5 mg/day. Oral contraceptives can be used in patients who require contraception concurrently. If oral contraceptives are used, a progestin with low androgen activity (norethynodrel or ethynodiol diacetate) should be employed. Gonadotropin-releasing hormone may be an effective adjunct to oral contraceptives if the source of androgen is ovarian. Antiandrogens are often added to the more specific therapies. The most common include spironolactone, flutamide, and finasteride, although none of these is approved by the Food and Drug Administration for the treatment of hirsutism. It can take 4 months for the antiandrogens to alleviate the hirsutism, and duration of therapy is unclear.^{69,70}

CLINICAL CONTROVERSY

Some clinicians believe that the usual starting doses for glucocorticoid supplementation are high and unnecessarily increase a patient's risk for adverse outcomes such as osteoporosis.

PRINCIPLES OF GLUCOCORTICOID ADMINISTRATION

Originally, the term *glucocorticoid* was given to these agents to describe their glucose-regulating properties. However, carbohydrate metabolism is only one of a multitude of effects that steroids can exhibit. The activity produced is a function of the receptor activated (glucocorticoid versus mineralocorticoid) as well as the agent and dose prescribed.

The mechanism of glucocorticoids is complex and not fully known. The glucocorticoid enters the cell through passive diffusion and binds to its specific receptor. There are between 5000 and 100,000 receptors per cell. Steroids exhibit various binding affinities to the vast number of receptors in almost every tissue and therefore elicit a wide variety of biologic effects.

After binding to the receptor, there is a structural change that occurs in the receptor, known as *activation*. After activation, the receptor-steroid complex binds to deoxyribonucleic acid sites in the cell called *glucocorticoid regulatory elements* (GREs). This binding to the GREs stimulates or inhibits transcription of nearby genes.

The pharmacokinetics of the glucocorticoids varies with the agent given and the route of administration. In general, most steroids

given by the oral route are well absorbed. Water-soluble agents are more rapidly absorbed following intramuscular injection than are lipid-soluble agents. Intravenous administration is recommended when a quick onset of action is needed. A summary of the steroids is provided in Table 74–9.

In addition to systemic steroids causing iatrogenic Cushing's syndrome, they also can lead to increased susceptibility to infection, osteoporosis, sodium retention with resultant edema, hypokalemia, hypomagnesemia, cataracts, peptic ulcer disease, seizures, and generalized suppression of the HPA-axis. Long-term complications tend to be insidious and less likely to respond to steroid withdrawal.

Suppression of the HPA-axis is a major concern whenever systemic steroids are tapered or withdrawn. Single doses of glucocorticoids can prevent the axis from responding to major stressors for several hours. In general, the longer the steroid is administered and the higher the dose used, the more suppression of the axis occurs. However, the possibility of suppression occurs any time the patient is exposed to supraphysiologic doses of a steroid.^{62,71} Symptoms of steroid withdrawal resemble those seen in a patient with adrenocortical deficiency.

A variety of recommendations for steroid tapering are available.^{62,72,73} In general, patients who have been on long-term steroid therapy will need to be gradually withdrawn toward physiologic doses over months. On average, the normal adult produces approximately 20 to 30 mg of cortisol per day with the peak concentration occurring around 8:00 A.M. As the steroid or steroid-equivalent dose approaches the 20- to 30-mg level, the taper should be slowed and the patient checked for axis function. The primary mode to test HPA integrity is the ACTH test, either high- or low-dose. A normal ACTH test would indicate that daily steroid maintenance therapy is not needed. More recently, the use of exogenous human CRH was found to be nearly as useful in the assessment of pituitary-adrenal function.⁷⁴ Caution should be used to prevent disease exacerbation during the steroid taper to prevent the need for rebolusing the patient with another course of high-dose steroids. The dilemma of prolonged steroid administration is sometimes lessened by the use of an alternate-day therapy (ADT) regimen.^{72,73} ADT theoretically minimizes the hypothalamic-pituitary suppression as well as some of the adverse effects seen with once-daily therapy. This can be especially important in the treatment of the child and young adult, in whom growth suppression is a major concern. ADT is not recommended for initial management, but rather in the management of the stabilized patient who needs long-term therapy. The patient will be exposed to "on" and "off" days, with the "on" day dose gradually increased with concurrent reduction in the "off" day dose over a period of 14 days. By the fourteenth day, the patient will be consuming medication only on the "on" day. It should be noted that not all patients will have

TABLE 74–10. Factors in Successful Glucocorticoid Therapy

| | |
|---------------------------|--|
| Monitoring | Glucose concentrations (serum and urine) Electrolytes (serum and urine) Ophthalmologic exams Stool tests for occult blood loss |
| Counseling | Growth and development (children and adolescents) Take with food to minimize gastrointestinal discomfort Never discontinue medication on your own; check with your physician; gradual dose reduction is usually necessary Carry or wear medical identification indicating that you are on long-term glucocorticoid therapy Dosage increases may be necessary at times of increased stress (surgery or emergency treatments) Be aware of potential side effects (i.e., visual disturbances, bruising, and delayed wound healing) What to do if you miss a dose: If your dosing schedule is <i>Every other day:</i> Take as soon as possible if remembered that morning. If not remembered until later, skip that day. Take the next morning, then skip the following day. <i>Every day:</i> Take as soon as possible, but skip if almost time for the next dose. Never double doses. |
| Recognizing complications | Early in therapy and essentially unavoidable: insomnia, enhanced appetite, weight gain Common in patients with underlying risk factors: hypertension, diabetes mellitus, peptic ulcer disease Long-term intense treatment: cushingoid habitus, hypothalamic-pituitary-adrenal suppression, impaired wound healing Delayed and insidious: cataracts, atherosclerosis Rare and unpredictable: psychosis, glaucoma, pancreatitis |

equivalent disease control on ADT, and it should be avoided in certain indications.⁷³

EVALUATION OF THERAPEUTIC OUTCOMES

Successful glucocorticoid therapy involves counseling the patient, monitoring the patient, and recognizing complications of therapy (Table 74–10). The risk:benefit ratio of glucocorticoid administration should always be considered, especially with concurrent disease states such as hypertension, diabetes mellitus, peptic ulcer disease, and uncontrolled systemic infections.

CLINICAL CONTROVERSY

Some clinicians believe that twice-daily administration of glucocorticoids in patients with adrenal insufficiency is not as effective as three-times daily. If a twice-daily regimen is used, the second dose should be administered 6 to 8 hours after the first.

ABBREVIATIONS

ACTH: adrenocorticotropic hormone
ADT: alternate-day therapy
APA: aldosterone-producing adenoma
BAH: bilateraladrenalhyperplasia
CBG: corticosteroid-binding globulin
CRH: corticotropin-releasing hormone
CT: computed tomography

D₅NS: 5% dextrose and isotonic saline
DDT: dichlorodiphenyltrichloroethane
DST: dexamethasone suppression test
GRE: glucocorticoid regulatory element
HPA: hypothalamic-pituitary-adrenal
IRMA: immunoradiometric assay
MRI: magnetic resonance imaging
PA:PRA: plasma-aldosterone-to-plasma-renin-activity ratio
RIA: radioimmunoassay
RU-486: mifepristone

PITUITARY GLAND DISORDERS

Amy Heck Sheehan, Jack A. Yanovski, and Karim Anton Calis

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Pharmacologic therapy for acromegaly should be considered when surgery and irradiation are contraindicated, when rapid control of symptoms is needed, or when other treatments have failed to normalize growth hormone (GH) and insulin-like growth factor-I (IGF-I) concentrations.
- 2 Dopamine agonists provide advantages of oral dosing and reduced cost when compared to somatostatin analogs and pegvisomant. However, dopamine agonists effectively normalize IGF-I concentrations in only 10% of patients.
- 3 Octreotide therapy should be initiated using the short-acting subcutaneous formulation. Patients who have been maintained on subcutaneous octreotide for at least 2 weeks, and have shown response to therapy, may be converted to the long-acting depot form of octreotide.
- 4 Blood glucose concentrations should be monitored frequently in the early stages of octreotide therapy in all acromegalic patients.
- 5 Pegvisomant appears to be the most effective agent for normalizing IGF-I concentrations. However, further study is needed to determine the long-term safety and efficacy of this agent for the treatment of acromegaly.
- 6 Recombinant GH is currently considered the mainstay of therapy for the treatment of children with growth-hormone-deficient (GHD) short stature. Prompt diagnosis of GHD and initiation of replacement therapy with recombinant GH is crucial for optimizing final adult heights.
- 7 All GH products are generally considered to be equally efficacious. The recommended dose for treatment of GHD short stature in children is 0.3 mg/kg per week.
- 8 Pharmacologic agents that antagonize dopamine or increase the release of prolactin can induce hyperprolactinemia. Discontinuation of the offending medication and initiation of an appropriate therapeutic alternative usually normalizes serum prolactin concentrations.
- 9 Cabergoline appears to be more effective than bromocriptine for the medical management of prolactinomas and offers the advantage of less-frequent dosing and decreased adverse events.
- 10 Patients receiving cabergoline who plan to become pregnant should discontinue the medication at least 1 month before planned conception.
- 11 Pharmacologic treatment of panhypopituitarism consists of glucocorticoids, thyroid-hormone preparations, sex steroids, and recombinant growth hormone, where appropriate, as lifelong replacement therapy.

In the 1950s Geoffrey Harris and his colleagues uncovered the physiologic importance of pituitary hormones and proposed the theory of neurohormonal regulation of the pituitary by the hypothalamus.¹ Today the pituitary gland is recognized for its essential role in body homeostasis, and for this reason it is often referred to as the “master gland.” The hypothalamus and the pituitary gland are closely connected, and together they provide a means of communication between the brain and many of the body’s endocrine organs. The hypothalamus uses nervous input and metabolic signals from the body to control the secretion of pituitary hormones that regulate growth, thyroid function, adrenal activity, reproduction, lactation, and fluid balance.

ANATOMY AND PHYSIOLOGY

The hypothalamus (Fig. 75–1) is a small region at the base of the brain that receives autonomic nervous input from different areas of the body to regulate limbic functions, food and water intake, body

temperature, cardiovascular function, respiratory function, and diurnal rhythms. In addition, the hypothalamus controls the release of hormones from the anterior and posterior regions of the pituitary gland. Neurons in the hypothalamus produce vasopressin and oxytocin and make many hormone-releasing factors that stimulate or inhibit the release of trophic hormones. At the base of the hypothalamus, a projection known as the *median eminence* is rich with nerve axons and blood vessels and provides both chemical and physical connections between the hypothalamus and the pituitary gland.

The pituitary gland, also referred to as the hypophysis, is located at the base of the brain in a cavity of the sphenoid bone known as the *sella turcica*. The pituitary is separated from the brain by an extension of the dura mater known as the *diaphragma sella*. The pituitary is a very small gland, weighing between 0.4 and 1 g in adults. It is divided into two distinct regions, the anterior lobe, or adenohypophysis, and the posterior lobe, or the neurohypophysis (see Fig. 75–1).

The posterior pituitary gland secretes two major hormones, oxytocin and vasopressin (antidiuretic hormone) (Table 75–1). Oxytocin

FIGURE 75-1. Pituitary gland.

release from the posterior pituitary causes contraction of the smooth muscles in the breast during lactation and also plays a role in uterine contraction during parturition. Vasopressin is essential for proper fluid balance and acts on the renal collecting ducts to conserve water. Oxytocin and vasopressin are synthesized in the paraventricular and supraoptic nuclei of the hypothalamus. The posterior pituitary gland contains the terminal nerve endings of these two nuclei as well as specialized secretory granules that release hormones in response to appropriate signals. Loss of anterior pituitary function does not necessarily affect the release of vasopressin or oxytocin, because these hormones are actually synthesized in the hypothalamus.

Unlike the posterior pituitary, the release of anterior pituitary hormones is not regulated by direct nervous stimulation, but rather is controlled by specific hypothalamic releasing and inhibitory hormones. The median eminence of the hypothalamus contains a large number of capillaries that converge to form a network of veins known as the hypothalamic-hypophysial portal circulation. Inhibiting and releasing hormones synthesized in the neurons of the hypothalamus reach the anterior pituitary via the hypothalamic-hypophysial portal vessels to control release of anterior pituitary hormones. Although there is a direct arterial blood supply to the anterior pituitary lobe, the hypothalamic-hypophysial portal vessels provide the primary blood supply (see Fig. 75-1). In contrast to the posterior pituitary, the anterior pituitary lobe is extremely vascular and has the highest rate of blood flow of all body organs.

The specialized secretory cells of the anterior pituitary lobe secrete six major polypeptide hormones (see Table 75-1). These include growth hormone (GH) or somatotropin, adrenocorticotropic hormone (ACTH) or corticotropin, thyroid-stimulating hormone (TSH) or thyrotropin, prolactin, follicle-stimulating hormone (FSH), and luteinizing hormone (LH). The release of these hormones is regulated primarily by hypothalamic releasing and inhibiting hormones. Thyrotropin-releasing hormone (TRH) stimulates anterior pituitary release of TSH and prolactin, corticotropin-releasing hormone (CRH) stimulates anterior pituitary release of ACTH, growth hormone-releasing hormone (GHRH) stimulates anterior pituitary release of GH, and gonadotropin-releasing hormone (GnRH) stimulates anterior pituitary release of LH and FSH. Hypothalamic release of somatostatin inhibits release of growth hormone, and hypothalamic release

of dopamine (prolactin-inhibiting hormone) inhibits the secretion of prolactin. Prolactin differs from the other anterior lobe hormones in that an inhibiting factor, rather than a stimulating factor, is primarily responsible for controlling its secretion. In the absence of hypothalamic input, an excess of prolactin is produced, whereas a deficiency state of other anterior pituitary hormones results. Physiologic regulation and action of anterior and posterior pituitary hormones are summarized in Table 75-1.²⁻⁴

Destruction of the pituitary gland may result in secondary hypothyroidism, hypogonadism, adrenal insufficiency, growth hormone deficiency, and hypoprolactinemia. The formation of certain types of pituitary tumors may result in pituitary hormone excess. Pituitary tumors may also physically compress the pituitary and prevent the release of the trophic hypothalamic factors that regulate pituitary hormones. In this chapter, the pathophysiology and role of pharmacotherapy in the treatment of acromegaly, short stature, hyperprolactinemia, and panhypopituitarism will be discussed.

GROWTH HORMONE

Growth hormone has direct anti-insulin effects on lipid and carbohydrate metabolism. GH decreases utilization of glucose by peripheral tissues, increases lipolysis, and increases muscle mass. GH also stimulates gluconeogenesis in hepatocytes, impairs tissue glucose uptake, decreases insulin-receptor sensitivity, and impairs postreceptor insulin action. The growth-promoting effects of GH are largely mediated by insulin-like growth factors (IGFs) also known as somatomedins. GH stimulates the formation of IGF-I in the liver, as well as in other peripheral tissues. This anabolic peptide acts as a direct stimulator of cell proliferation and growth. There are two types of insulin-like growth factors, IGF-I and IGF-II. IGF-I regulates growth to some extent before, and largely after, birth. In contrast, IGF-II is thought to primarily regulate growth in utero.⁵ Growth hormone is secreted by the anterior pituitary in a pulsatile fashion with several short bursts that occur mostly at night. Because of the short half-life of growth hormone in the plasma (approximately 30 minutes), measurements of circulating GH concentrations throughout the waking hours are usually very low or undetectable. Daytime GH pulses are most likely to occur after meals, following exercise, or during periods of stress. The greatest amount of GH secretion occurs during the night within the first 1 to 2 hours of slow-wave sleep (stages III or IV). Secretion of growth hormone is lowest during infancy, increases slightly during childhood, reaches its peak during adolescence, and then begins to gradually decline during the middle-age years.³

GROWTH HORMONE EXCESS

Acromegaly is a pathologic condition characterized by excessive production of growth hormone. This is a rare disorder that affects approximately 50 to 70 adults per million.⁶ Gigantism, which is even more rare than acromegaly, is the excess secretion of growth hormone prior to epiphyseal closure in children.⁷ Patients diagnosed with acromegaly are reported to have a two- to threefold increase in mortality, usually related to cardiovascular, respiratory, or neoplastic disease.⁸⁻¹⁰ Most patients are middle-aged at the time of diagnosis, and this disorder does not appear to affect one gender to a greater extent than the other. The most common cause of excess GH secretion in acromegaly, accounting for approximately 98% of all cases, is a growth hormone-secreting pituitary adenoma.⁸ Rarely, acromegaly may be caused by ectopic GH-secreting adenomas, GH cell hyperplasia, excess growth hormone-releasing hormone secretion, or as one of the manifestations of the multiple endocrine neoplasia

TABLE 75–1. Pituitary Hormones

| Hormone | Stimulation | Inhibition | Physiologic Effects |

TABLE 75–2. Clinical Presentation of Acromegaly**General**

The patient will experience slow development of soft-tissue overgrowth affecting many body systems. Signs and symptoms may gradually progress over 10 to 15 years.

Symptoms

The patient may complain of symptoms related to local effects of the growth hormone (GH)-secreting tumor such as headache and visual disturbances. Other symptoms related to elevated GH and insulin-like growth factor-I (IGF-I) concentrations include excessive sweating, neuropathies, joint pain, and paresthesias.

Signs

The patient may exhibit coarsening of facial features, increased hand volume, increased ring size, increased shoe size, an enlarged tongue, and various dermatologic conditions.

Laboratory tests

The patient's GH concentration will be greater than 1 mcg/L following an oral glucose tolerance test (OGTT) and IGF-I serum concentrations will be elevated. Glucose intolerance may be present in up to 50% of patients.

Additional clinical sequelae

- Cardiovascular diseases such as hypertension, coronary heart disease, cardiomyopathy, and left ventricular hypertrophy are common in patients with acromegaly.
- Osteoarthritis and joint damage develops in up to 90% of acromegalic patients.
- Respiratory disorders and sleep apnea occur in up to 60% of acromegalic patients.
- Type 2 diabetes develops in approximately 25% of acromegalic patients.
- Patients with acromegaly may also have an increased risk for the development of esophageal, colon, and stomach cancer.

From Ben-Shlomo et al,⁸ Molitch,⁹ Melmed,¹⁰ Fatti et al,¹¹ Vitale et al,¹² and Webb et al.¹³

syndrome type 1, the McCune-Albright syndrome, or the Carney complex, all very rare hypersecretory endocrinopathies.⁸

The clinical signs and symptoms of acromegaly develop gradually over an extended period of time. In fact, because of the subtle and slowly developing changes in physical appearance that GH excess causes, most patients are not definitively diagnosed with acromegaly until 10 to 15 years after the presumed onset of excessive growth-hormone secretion.⁹ Excessive secretion of GH and IGF-I adversely affects several organ systems. Almost all acromegalic patients will present with physical signs and symptoms of soft-tissue overgrowth. Table 75–2 summarizes the classic clinical presentation of patients with acromegaly.^{8–13} Some patients with acromegaly may present with few of these classic signs and symptoms, making recognition of this disease extremely difficult.

The diagnosis of acromegaly is based on a combination of diagnostic tests and clinical signs and symptoms. Random measures of plasma GH levels are not usually dependable because of the pulsatile pattern of release. The oral glucose tolerance test (OGTT) is commonly used as an important diagnostic tool. Postprandial hyperglycemia inhibits the secretion of growth hormone for at least 1 to

2 hours. Therefore an oral glucose load would be expected to suppress growth-hormone concentrations.

However, patients with acromegaly continue to secrete growth hormone during the OGTT, and GH concentrations remain elevated after oral glucose loads of 50 to 100 g in 80% of acromegalics.¹⁴ Since GH stimulates the production of IGF-I, serum IGF-I concentrations can also be measured to aid in the diagnosis of acromegaly. Circulating IGF-I is cleared from the body at a much slower rate than GH, and measurements can be collected at any time of the day to identify patients with GH excess.¹⁴ Current criteria for the diagnosis of acromegaly include failure of GH suppression below 1 mcg/L following an OGTT in the presence of elevated IGF-I serum concentrations.¹⁴ With the development of more sensitive GH and IGF-I assays, the cut-off value for diagnosis of acromegaly will likely decrease in the future. Insulin-like growth factor-I-binding-protein-3 (IGFBP-3) can also be measured because it is positively regulated by GH and binds to circulating IGF-I with high affinity. This test may be useful in monitoring response to therapy.⁸ Computed tomography and magnetic resonance imaging of the pituitary are important diagnostic tests to confirm the presence of a pituitary adenoma.^{9,14}

► TREATMENT: Acromegaly

The primary treatment goals for patients diagnosed with acromegaly are to reduce GH and IGF-I concentrations, improve the clinical signs and symptoms of the disease, and decrease mortality.^{15–17} Many clinicians define cure of acromegaly as suppression of GH concentrations to lower than 1 mcg/L after a standard OGTT in the presence of normal IGF-I serum concentrations.^{15–18} The treatment of choice for acromegaly is transsphenoidal surgical resection of the growth-hormone secreting adenoma.^{15,17,18} Postsurgical cure rates have been reported to range from 50% to 90%, depending on the type of adenoma and the expertise of the neurosurgeon.^{8,17,18} Complications of transsphenoidal surgery are relatively infrequent and include cerebrospinal fluid leak, meningitis, arachnoiditis, diabetes insipidus, and pituitary failure.⁸ For patients who are poor surgical candidates, those

who have failed surgical interventions, or others who refuse surgical treatment, radiation therapy may be considered. Radiation, however, may take several years to relieve the symptoms of acromegaly.

Because neither radiation therapy nor surgery will cure all patients with acromegaly, adjuvant drug therapy is often needed to control symptoms.^{15,17,18}

■ PHARMACOLOGIC THERAPY

◀ Drug therapy should be considered for acromegalic patients in whom surgery and irradiation are contraindicated, when rapid

control of symptoms is indicated, or when other treatments have failed to normalize GH and IGF-I concentrations. Pharmacologic treatment options include dopamine agonists, somatostatin analogs, and the GH receptor antagonist, pegvisomant. Dopamine agonists such as bromocriptine, pergolide, or cabergoline are effective in a small subset of patients and provide the advantages of oral dosing and reduced cost. Somatostatin analogs are more effective than dopamine agonists, reducing GH concentrations and normalizing IGF-I in approximately 50% to 60% of patients. Pegvisomant is a newly approved GH receptor antagonist that is highly effective, normalizing IGF-I concentrations in up to 97% of patients. However, additional long-term data are needed to establish safety and efficacy of pegvisomant in the management of acromegaly.

■ DOPAMINE AGONISTS

2 In normal healthy adults, dopamine agonists cause an increase in growth hormone production. However, when these agents are given to patients with acromegaly, there is a paradoxical decrease in GH production. Most clinical experience with the use of dopamine agonists in acromegaly is with bromocriptine. Other agents such as pergolide, cabergoline, and lisuride have also been used. Bromocriptine is a semisynthetic ergot alkaloid that acts as a dopamine-receptor agonist. Most trials assessing the efficacy of bromocriptine in the treatment of acromegaly were conducted in the 1970s and early 1980s. It was determined from these studies that certain subsets of acromegalic patients have a favorable response to drug therapy with bromocriptine. These patients include individuals with high circulating concentrations of prolactin and patients who experience GH suppression following a single dose of 2.5 mg of bromocriptine, known as a bromocriptine challenge.¹⁹ A review evaluating 34 studies concluded that therapy with bromocriptine was effective in suppressing mean serum GH levels to less than 5 mcg/L in approximately 20% of patients.²⁰ Only 10% of patients experience normalization of IGF-I concentrations with bromocriptine therapy, but over 50% of patients treated with bromocriptine experience improvement in acromegalic symptoms.^{15,21}

Bromocriptine is commercially available in the United States as 2.5-mg oral tablets and 5-mg oral capsules. In acromegalic patients, significant reductions in growth hormone concentrations are observed within 1 to 2 hours of oral dosing. This effect persists for at least 4 to 5 hours. An overall clinical response in acromegalic patients typically occurs following 4 to 8 weeks of continuous bromocriptine therapy. For the treatment of acromegaly, bromocriptine is initiated at a dose of 1.25 mg at bedtime and is increased by 1.25-mg increments every 3 to 4 days as needed.^{14,19,20} Doses as high as 80 mg per day have been used for the treatment of acromegaly, but clinical studies have shown that dosages greater than 20 or 30 mg daily do not offer additional benefits in the suppression of GH.^{18,20,21} When used for the treatment of acromegaly, the duration of action of bromocriptine is shorter than for the treatment of hyperprolactinemia. Therefore the total daily dose of bromocriptine should be divided into three or four doses.^{18,19,21}

The most common adverse effects of bromocriptine therapy include central nervous system symptoms such as headache, lightheadedness, dizziness, nervousness, and fatigue. Gastrointestinal effects such as nausea, abdominal pain, or diarrhea also are very common. Some patients may need to take bromocriptine with food to decrease the incidence of adverse gastrointestinal effects. Most adverse effects are seen early in the course of therapy and tend to decrease with continued treatment.^{18,21} Bromocriptine may cause thickening of bronchial secretions and nasal congestion. There have been rare cases of psychiatric disturbances, pleural diseases, and an erythromelalgic syndrome

(painful paroxysmal dilation of the blood vessels in the skin of the feet and lower extremities) reported with the use of bromocriptine. These conditions appear to be associated with higher doses and prolonged duration of therapy.^{20,21}

Bromocriptine generally should be discontinued if a woman becomes pregnant while taking the drug. Surveillance of women who took bromocriptine throughout pregnancy do not suggest that bromocriptine is associated with an increased risk of birth defects.²¹ If a woman becomes pregnant while taking bromocriptine, the risks and benefits of therapy should be fully considered. In most cases, the benefits of successful therapy outweigh the risks, and bromocriptine therapy should be continued if it is effective in improving symptoms and reducing the elevated GH concentrations.

Other dopamine agonists that have been used to treat acromegaly include pergolide, cabergoline, lisuride, and quinagolide. Cabergoline may be especially useful in patients with pituitary tumors that secrete both prolactin and growth hormone.^{21,22} Quinagolide, a dopamine agonist available in Europe, has been shown to be more effective than both bromocriptine and cabergoline in normalizing GH and IGF-I values in acromegalic patients.¹⁹ Because of the potential cost advantages and convenience of oral administration, dopamine agonists are often considered for the treatment of acromegaly prior to initiation of somatostatin analogs. However, the recent development of long-acting somatostatin analogs has made these agents more attractive for first-line treatment of acromegaly.

■ SOMATOSTATIN ANALOGS

Octreotide is a long-acting somatostatin analog that is approximately 40 times more potent in inhibiting GH secretion than endogenous somatostatin.^{23,24} It also suppresses the LH response to GnRH; decreases splanchnic blood flow; and inhibits the secretion of insulin, vasoactive intestinal peptide (VIP), gastrin, secretin, motilin, serotonin, and pancreatic polypeptide. Lanreotide is another somatostatin analog, currently not available in the United States, which is a slow-release depot formulation administered twice monthly.²³

Octreotide (Sandostatin) injection is commercially available in the United States for subcutaneous or intravenous administration. A long-acting intramuscular formulation of octreotide (Sandostatin LAR) is also available for monthly administration. In addition to the treatment of acromegaly, octreotide has many other therapeutic uses, including the treatment of carcinoid tumors, vasoactive intestinal peptide tumors (VIPomas), gastrointestinal fistulas, variceal bleeding, diarrheal states, and irritable bowel syndrome.

The efficacy of octreotide for the treatment of acromegaly has been determined by two major multicenter trials.^{25,26} These studies determined that drug therapy with octreotide suppresses mean serum GH concentrations to less than 5 mcg/L and normalizes serum IGF-I concentrations in 50% to 60% of acromegalic patients. Octreotide is also beneficial in reducing the clinical signs and symptoms of acromegaly. In a 6-month multicenter trial, 70% of patients experienced significant relief of headaches.²⁶ In some patients, relief of headache symptoms occurred within minutes of octreotide administration. In addition, middle-finger circumference was reduced significantly, and 50% to 75% of the patients experienced improvement in symptoms of excessive perspiration, fatigue, joint pain, and cystic acne. A 2-year follow-up of 103 patients treated with octreotide showed that octreotide therapy is safe and effective for long-term use in acromegalic patients.²⁷ Several small studies have shown that octreotide improves the cardiovascular manifestations of acromegaly; it decreased left-ventricular mass, decreased heart rate, and increased exercise capacity.^{28–30} Octreotide also improves oxygen desaturation,

sleep quality, and subjective symptoms of sleepiness in acromegalic patients suffering from sleep apnea.³¹ Data from two major multicenter trials indicate that pituitary tumor growth is halted during octreotide treatment, and a small number of patients experience tumor regression.^{25,26} A more recent study determined that the growth of pituitary tumors during octreotide therapy is suppressed by approximately 83%.³²

The pharmacodynamic effects of long-acting octreotide are similar to those of subcutaneously administered octreotide. Single monthly doses of long-acting octreotide have been shown to be at least as effective as daily doses of 300 or 600 mcg of subcutaneous octreotide administered in divided doses three times daily in normalizing IGF-I levels and maintaining suppression of mean serum GH concentrations.³³ A large multicenter trial evaluating the efficacy of long-acting octreotide in acromegalic patients who had previously responded to subcutaneously administered octreotide reported suppression of GH concentrations to below 5 mcg/L in 94% of patients and normalization of IGF-I in 66% of patients following 1 year of therapy.³⁴

Response to long-term therapy with octreotide is related to the presence and increased quantity of functioning somatostatin receptors located in the pituitary adenoma.^{26,27} Identification of patients who will most likely respond to octreotide, prior to the initiation of therapy, is important when considering the high cost of this medication and the inconvenience of subcutaneous or intramuscular drug administration. Suppression of serum GH concentrations after a single 50-mcg dose of octreotide has been used to predict a favorable long-term response (GH concentrations <1 mcg/L after a standard OGTT in the presence of normal IGF-I serum concentrations) to octreotide therapy. Somatostatin-receptor imaging and serum GH concentrations after short-term (1 month) administration of octreotide appear to be even more accurate in predicting which patients will respond to long-term octreotide therapy than acute suppression of GH by a single dose of octreotide.³⁵

3 The initial dose of octreotide for the treatment of acromegaly is 100 mcg administered every 8 hours.^{17,20,24} Some clinicians recommend a starting dose of 50 mcg every 8 hours, then increasing the dose to 100 mcg every 8 hours after 1 week, to improve the patient's tolerance of the adverse gastrointestinal effects.^{14,18} The dose may be increased by increments of 50 mcg every 1 to 2 weeks based on mean serum GH and IGF-I concentrations. Patients who experience a significant rise in GH prior to the end of the 8-hour dosing interval may benefit from decreasing the dosing interval to every 4 to 6 hours. Although doses as high as 1500 mcg per day have been used, doses above 600 mcg daily generally do not offer additional benefits, and most patients are adequately managed with 100 to 200 mcg three times daily.^{18,25–27} Patients who have been maintained on subcutaneous octreotide for at least 2 weeks and have shown response to therapy, may be converted to the long-acting depot form of octreotide. The initial dose of long-acting octreotide is 20 mg administered intramuscularly in the gluteal region every 28 days. Steady-state serum concentrations are not obtained until after 3 months of therapy. Therefore dosage adjustments for long-acting octreotide should not be considered until after this time. Some patients may require additional subcutaneous injections during the initial dose-titration phase in order to control symptoms. Long-acting octreotide doses higher than 30 mg every 4 weeks have not been studied.

The most common adverse effects of octreotide therapy are gastrointestinal disturbances such as diarrhea, nausea, abdominal cramps, malabsorption of fat, and flatulence.^{17,18,23} These effects are dose dependent and can be seen within a few hours of the first octreotide injection. Gastrointestinal adverse effects occur in approx-

imately 75% of patients, but usually subside within 10 to 14 days of continued treatment.^{17,18,23} Octreotide has also been reported to cause injection-site pain (4% to 31%), conduction abnormalities and arrhythmias (9%), biochemical hypothyroidism (2% to 12%), biliary tract disorders (4% to 50%), and abnormalities in glucose metabolism (2% to 18%).^{20,23}

Octreotide also inhibits cholecystokinin release and gallbladder motility, predisposing patients to the development of cholelithiasis.^{17,18,23} The development of gallstones is a long-term adverse effect of octreotide use and is largely dependent on geographic factors, dietary habits, and length of therapy.^{14,20,24} The incidence of gallstones in acromegalic patients receiving octreotide increases with length of therapy and has been reported to range from 20% to 50%.^{14,24–27} Most patients, however, are asymptomatic, and the diagnosis of cholelithiasis is usually made following an ultrasonographic study that is not prompted by patient symptoms. It has been estimated that only 1% of patients will develop symptomatic gallstones during 1 year of octreotide treatment.^{14,24} Because octreotide-induced gallstones are usually present without clinical symptoms, the latest U.S. Acromegaly Therapy Consensus Development Panel recommended that treatment of octreotide-induced gallstones be the same as that for gallstones in the general population.¹⁵ Prophylactic cholecystectomy or medical therapy with ursodeoxycholic acid for acromegalic patients with asymptomatic gallstones are usually not recommended. However, limited data suggest that concomitant therapy with ursodeoxycholic acid may reverse the formation of sludge and gallstones in acromegalic patients receiving octreotide.³⁶ A small number of studies have suggested that the incidence of gallstone development may be lower with long-acting octreotide as compared to subcutaneous octreotide.^{33,34} However, further studies are needed to confirm this observation.

4 The effect of octreotide on glucose metabolism in patients with acromegaly is multifactorial. Decreases in serum GH concentrations induced by octreotide should result in decreased hepatic gluconeogenesis and increased insulin-receptor sensitivity. However, octreotide also decreases insulin secretion and increases IGFBP-1, which is known to inhibit the insulin-like effects of IGF-I. In addition, octreotide delays the gastrointestinal absorption of glucose, which may further alter glucose metabolism in acromegalic patients. Small studies conducted in acromegalic patients with glucose intolerance have reported improvement in insulin sensitivity associated with octreotide therapy.^{37,38} However, one study of 90 acromegalics reported that 11 (12%) patients developed impaired glucose tolerance and 16 (18%) patients developed frank diabetes mellitus while receiving octreotide.³⁹ In the same study, 27% of subjects who were diabetic at the beginning of the trial experienced an improvement in their glycemic control by the end of the 6-month study period. Risk factors associated with worsening glucose tolerance included female gender and elevated baseline insulin values. Although octreotide appears to have a beneficial effect on glucose tolerance in most patients, glucose determinations should be obtained frequently in the early stages of octreotide therapy in all acromegalic patients.

■ DOPAMINE AGONIST AND SOMATOSTATIN ANALOG COMBINATION THERAPY

Somatostatin analogs are more effective than dopamine agonists in reducing mean serum GH concentrations and normalizing IGF-I in patients with acromegaly.^{14,15,17,18,20} However, several small studies have suggested that combination therapy with octreotide and bromocriptine or cabergoline may be more beneficial than either drug

alone.^{20,23,40} Because of the potential for additive adverse effects, combination therapy should be considered as a therapeutic option only for refractory patients who have not fully responded to either therapy alone.

GH RECEPTOR ANTAGONIST

5 Pegvisomant (Somavert) is a new genetically engineered GH derivative that binds to GH receptors in the liver and inhibits IGF-I. This agent is different from other medications used in the management of acromegaly because it does not inhibit GH production, but rather blocks the physiologic effects of GH on target tissues. Therefore GH concentrations remain elevated during therapy, and response to treatment is evidenced by a reduction in IGF-I concentrations. Unlike somatostatin analogs, the pharmacologic activity of pegvisomant does not depend on the presence and quantity of somatostatin receptors in the pituitary tumor.⁴¹

Studies evaluating the clinical efficacy of pegvisomant in acromegalic patients have reported a dose-dependent normalization of IGF-I concentrations in 54% to 89% of patients after 12 weeks of therapy, and in 97% of patients after 1 year of therapy.^{42,43} Significant improvements in the clinical signs and symptoms of acromegaly were also reported and persisted throughout the 1-year treatment period.⁴³ Adverse effects appeared to be minimal and included injection-site pain, gastrointestinal complaints such as nausea and diarrhea, and flu-like symptoms. Significant elevations in hepatic aminotransferase concentrations, which were reversible upon discontinuation of the drug, were reported in two patients.⁴² As a result, hepatic function tests should be monitored very closely during therapy as outlined in the product labeling, and the drug should be used with caution in patients with baseline elevations in hepatic aminotransferase con-

centrations. Growth hormone concentrations increased significantly during the first 6 months of therapy. Although tumor size did not change significantly during clinical trials, there are theoretical concerns that persistently elevated GH concentrations may stimulate tumor growth or result in other unfavorable long-term effects.

Pegvisomant is commercially available in the United States for daily subcutaneous use. The first dose should be administered under the supervision of a physician as a 40-mg loading dose. Subsequent doses are self-administered by the patient starting at a dose of 10 mg daily. The dose can be adjusted in 5-mg increments based on serum IGF-I concentrations every 4 to 6 weeks, up to a maximum daily dose of 30 mg.⁴⁴

Based on the available data, pegvisomant appears to be among the most effective agents for normalizing IGF-I serum concentrations. However, given the limited clinical data, further study is needed to determine the long-term safety and efficacy of pegvisomant in the treatment of acromegaly.

PHARMACOECONOMIC CONSIDERATIONS

Cost-effectiveness comparisons of the various treatment options for patients with acromegaly have not been performed. Considering that approximately 40% of patients are not completely cured after transsphenoidal surgery, pharmacologic treatment often becomes necessary. Bromocriptine and cabergoline are considerably less expensive than octreotide and pegvisomant. However, these agents are not effective in the majority of patients. Long-acting octreotide offers a convenient method of octreotide administration for acromegalic patients. Although this formulation is approximately two times the cost of subcutaneous octreotide, it may result in improved patient

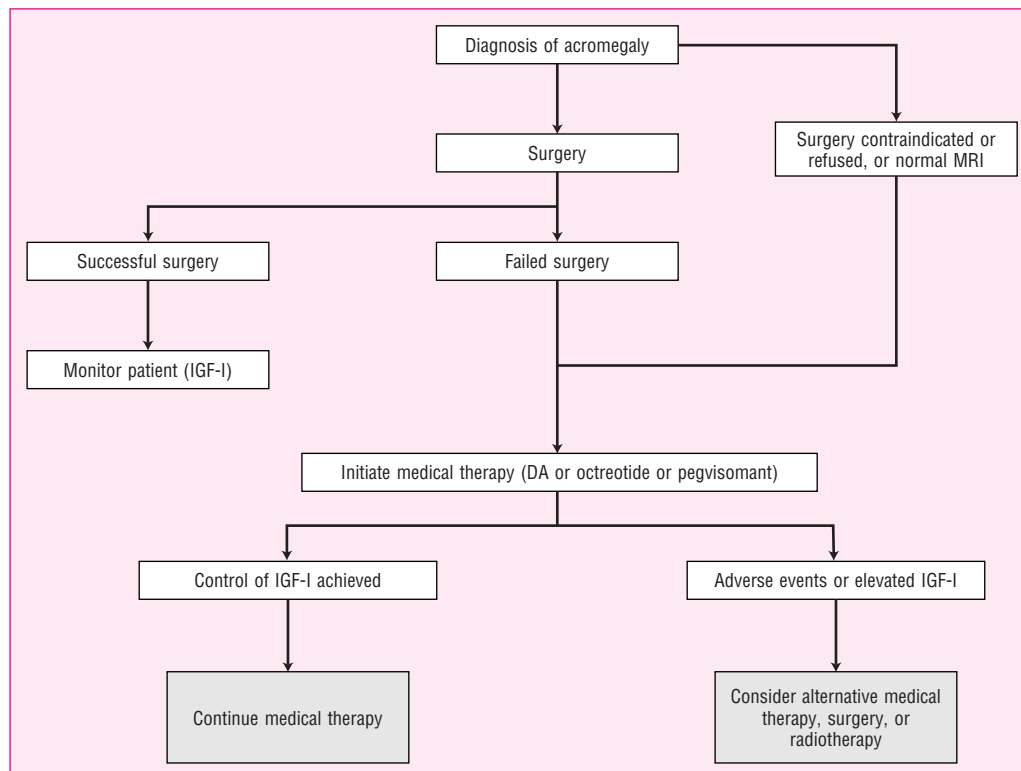

FIGURE 75-2. Treatment algorithm for acromegaly. DA, dopamine agonist; MRI, magnetic resonance imaging; IGF-I, insulin-like growth factor type I. (Reprinted with permission from Clemmons et al.⁴¹)

compliance, quality of life, and overall disease management. Pegvisomant appears to be the most effective agent for normalizing IGF-I concentrations, and may be useful in patients who are intolerant to or have failed therapy with dopamine agonists or somatostatin analogues. However, pegvisomant is significantly more expensive than long-acting octreotide and requires daily subcutaneous injections. Long-term studies evaluating the safety of pegvisomant are needed to clearly define its role in the management of acromegaly. The drug therapy of choice for an acromegalic patient should be determined

CLINICAL CONTROVERSY

Some clinicians advocate the use of somatostatin analogues for primary therapy of acromegaly in place of surgery. However, others believe that sufficient long-term safety and efficacy data are lacking.

by careful consideration of several patient-specific factors including clinical response, compliance, tolerability, and cost of therapy.

CONCLUSIONS

Acromegaly is a chronic debilitating disease characterized by excess growth hormone secretion most commonly caused by a GH-secreting pituitary adenoma. Transsphenoidal surgical resection of the adenoma is the current treatment of choice for patients with acromegaly. Patients who are poor surgical candidates may receive radiation therapy or long-term pharmacologic therapy. Drug therapy options within the U.S. for acromegaly include dopamine agonists, the somatostatin analog octreotide, and pegvisomant. Figure 75–2 illustrates a treatment algorithm for the management of acromegaly.⁴¹

GROWTH HORMONE DEFICIENCY

Short stature is a condition that is commonly defined by a physical height that is more than two standard deviations below the population mean and lower than the third percentile for height in a specific age group.^{45–47} It has been estimated that more than 1.8 million children in the United States can be characterized as having short stature.⁴⁷ Short stature is a very broad term describing a condition that may be the result of many different causes. A true lack of GH is among the least common causes and is known as growth-hormone-deficient (GHD) short stature. Absolute GH deficiency is a congenital disorder that can result from various genetic abnormalities such as GHRH deficiency, GH gene deletion, or developmental disorders including pituitary aplasia or hypoplasia.^{45,46} GH insufficiency is an acquired condition that can result secondary to hypothalamic or pituitary tumors, cranial irradiation, head trauma, pituitary infarction, and various types of CNS infections. In addition, psychosocial deprivation; hypothyroidism; poorly controlled diabetes mellitus; treatment of precocious puberty with LHRH agonists; and pharmacologic agents such as glucocorticoids, methylphenidate, and dextroamphetamine may induce transient GH insufficiency.^{45,48}

Short stature also occurs with several conditions that are not associated with a true GH deficiency or insufficiency. These conditions include intrauterine growth restriction; constitutional growth delay; malnutrition; malabsorption of nutrients associated with inflammatory bowel disease, celiac disease, and cystic fibrosis; chronic renal failure; skeletal and cartilage dysplasia; and genetic syndromes

such as Turner's syndrome.^{45,46,48} In addition, many children are diagnosed with idiopathic or normal variant short stature. These patients have heights that are significantly lower than the third percentile, but present with normal GH serum concentrations and no specific underlying explanation for short stature.⁴⁷

Children with GHD short stature are usually born with an average birth weight. Decreases in growth velocity generally become evident between the age of 6 months and 3 years.^{45,48} In contrast, GH insufficiency may arise at any age during growth and development. The clinical characteristics of GH-deficient or GH-insufficient children are presented in Table 75–3.^{45,46}

Several factors must be considered in the diagnosis of GH deficiency or insufficiency. Standard epidemiologic growth charts developed by the National Center for Health Statistics are typically used to determine the percentile of anthropometric measurements such as height, weight, and head circumference. Pubertal stage is typically determined using the Tanner method. The bone age is determined according to published standards, and growth velocity is calculated to determine the patient's height velocity percentile using standard growth-velocity charts.^{45,46,48} Growth hormone deficiency is rarely seen in the absence of delayed skeletal maturation and decreased growth velocity. In addition, several different provocative stimuli that induce GH secretion are used diagnostically to determine GH status. Common provocative pharmacologic GH stimuli include insulin-induced hypoglycemia, clonidine, L-dopa, arginine, glucagon, and growth hormone-releasing hormone.⁴⁶ A subnormal GH response is arbitrarily defined as a peak GH serum concentration

TABLE 75–3. Clinical Presentation of Short Stature^{45,46}

General

The patient will have a physical height that is greater than two standard deviations below the population mean for a given age and gender.

Signs

- The patient will present with reduced growth velocity and delayed skeletal maturation.
- Children with growth hormone (GH)-deficient or GH-insufficient short stature may also present with central obesity, prominence of the forehead, and immaturity of the face.

Laboratory tests

- The patient will exhibit a peak GH concentration <10 mcg/L following a GH provocation test. Reduced insulin-like growth factor-I and insulin-like growth factor-I-binding-protein-3 concentrations may also be present.
- Because GH deficiency may be accompanied by the loss of other pituitary hormones, hypoglycemia and hypothyroidism may also be noted.

From Hindmarsh et al⁴⁵ and American Association of Endocrinologists.⁴⁶

of <10 mcg/L during a 2-hour period after administration of one of these agents.⁴⁶ However, this maximum may be lower, depending on the specific assay and GH reference product used. Assessment of IGF-I and IGFBP-3 serum concentrations should also be made, with measurements exceeding two standard deviations below the standard reference range strongly suggestive of GH deficiency.⁴⁶ The three generally accepted criteria for the definitive diagnosis of GH deficiency are a subnormal growth velocity, a delayed bone age, and a subnormal GH response to at least two provocative stimuli.⁴⁹ For prepubertal and early-pubertal patients (Tanner stage less than III), priming with sex hormones to improve the specificity of GH provocation tests is often considered. Some patients may exhibit clinical

signs of GH deficiency, subnormal growth velocity, and delayed bone age, despite GH levels that are within normal limits after provocative testing. This makes diagnosis in this group of patients very difficult. Diagnosis based on GH stimulation tests becomes further complicated because of the paucity of data reporting the normal range of GH concentrations after provocative testing in healthy children and the fact that commercial GH assays currently available may not be equivalent. One study comparing several different GH assays found a significant variation between measured GH serum concentrations.⁴⁹ Because of these limitations, careful consideration of multiple factors by a pediatric endocrinology specialist is required to diagnose growth hormone deficiency correctly.

▶ TREATMENT: Growth Hormone Deficiency

■ PHARMACOLOGIC THERAPY

The treatment of growth hormone deficiency with pituitary-derived human growth hormone was first reported in the late 1950s. The National Hormone and Pituitary Program was founded by the National Institutes of Health in 1963 to coordinate the collection of human pituitary glands and purification of GH for administration to children with GH deficiency. In 1985, three deaths linked to Creutzfeldt-Jakob disease (CJD) were identified in young individuals who were previously treated with human pituitary growth hormone. An evaluation of National Hormone and Pituitary Program data identified 26 cases of fatal CJD in a cohort of 6,107 patients who received treatment with human pituitary-derived growth hormone in the United States between 1963 and 1985.⁵⁰ Human pituitary growth hormone was withdrawn from the U.S. market because of the strong likelihood that the CJD was transmitted through contaminated human pituitary-derived growth hormone. Shortly after the withdrawal of human pituitary growth hormone, the U.S. Food and Drug Administration approved the first recombinant DNA-derived growth hormone for the treatment of GH insufficiency. Prior to the introduction of recombinant growth hormone, the number of individuals who received treatment for GH insufficiency was relatively small owing to the limited availability of human pituitary tissue for GH extraction. Currently, with the widespread availability of recombinant growth hormone products, a large number of children can receive growth hormone replacement therapy at higher doses. Unfortunately, human pituitary-derived growth hormone continues to be used today in some underdeveloped countries.

6 Recombinant GH is currently considered the mainstay of therapy for the treatment of GHD short stature. GH replacement therapy in children with documented GHD short stature produces a significant improvement in growth velocity within the first year of therapy and significantly improves final adult height.^{51–54} The initial increase in growth velocity is often referred to as catch-up growth. Most of the initial studies evaluating the efficacy of GH therapy in GHD children were conducted for short periods of time in small numbers of patients, and until recently, information about the long-term outcome of GH therapy was limited. Initial data suggested that final adult height is not substantially improved, with an average final adult height reported to be two standard deviations below the population mean.^{55–58} Although these results were disappointing, it is important to note that a substantial percentage of patients included in these studies had initially received human pituitary growth hormone in relatively low doses because of its limited availability. In addition, current growth hormone dosing regimens have changed with regard to frequency of administration, making these data difficult to inter-

pret and apply to patients who are receiving GH replacement therapy today. Recent studies evaluating the adult height of children who received only recombinant GH therapy with currently recommended dosing regimens suggest that current recombinant GH therapy has a greater impact on final adult height than was previously reported.^{51–54} These studies have reported average final adult heights ranging from 0.5 to 1.7 standard deviations below the population mean. Initiation of therapy at an early chronologic age, prior to the onset of puberty, is associated with a more favorable increase in final height.^{46,52,53} Therefore prompt diagnosis of growth hormone deficiency and early initiation of replacement therapy with recombinant GH are crucial factors in optimizing the final adult height of children with GH deficiency.

Recombinant growth hormone has also been shown to increase the short-term growth rate in patients with chronic renal insufficiency, intrauterine growth restriction, Turner's syndrome, idiopathic short stature, and Prader-Willi syndrome, and is approved by the FDA for treatment of growth failure associated with these conditions.⁴⁶ GH is also FDA approved for the treatment of adult growth hormone deficiency and the acquired immunodeficiency syndrome wasting syndrome. Long-term GH therapy in growth-hormone-deficient adults significantly decreases body fat, increases muscle mass, and improves exercise capacity.⁴⁶ GH therapy in adults has been shown to improve the cardiac risk profile, bone mineral density, and psychological well being.^{59–61} In addition, GH is currently being investigated for a variety of disorders, including infertility, chronic fatigue, obesity, and natural aging.⁴⁶ Use of GH as an anabolic agent for management of acute catabolism is not recommended.⁴⁶

The majority of short children in the United States do not have an identifiable medical cause for their condition, but with widespread availability of several recombinant growth hormone formulations, many children have received GH therapy regardless of the underlying etiology of their short stature.⁶² The use of recombinant growth hormone therapy in children with non-growth-hormone-deficient short stature, also referred to as idiopathic short stature, has been studied by several investigators. Of note, a recent meta-analysis of 38 clinical studies evaluating the efficacy of GH treatment in non-growth-hormone-deficient children reported average increases in final adult height of 4 to 5 cm (1.6 to 2 inches) following a mean duration of therapy of 4.7 years.⁶³ This corresponded to an increase above the predicted final adult height of 0.56 to 0.63 standard deviations of the population mean. Given the significant cost of growth hormone therapy, the authors estimated a cost of \$35,000 per inch of height gained.⁶² Humatrope was recently approved by the FDA for management of idiopathic short stature. However, the use of GH therapy in this patient population remains controversial.

CLINICAL CONTROVERSY

Most pediatric endocrinologists in the U.S. believe that GH therapy is an appropriate treatment in certain patients with non-GHD short stature. However, given the high cost of therapy and small increases in height, use of GH in this patient population remains controversial.

▶ Nine different recombinant growth hormone products are currently available for use in the United States. Somatrem (Protropin) was the first recombinant GH product developed and used for the treatment of GH deficiency. This formulation contains the same 191-amino-acid sequence as human pituitary growth hormone, with the exception of the terminal addition of a methionine amino acid group.

The remaining GH formulations (Genotropin, Norditropin, Nutropin, Nutropin AQ, Nutropin Depot, Humatrope, Serostim, and Saizen) contain somatotropin. Somatotropin is composed of the same amino-acid sequence as human pituitary GH. Recombinant GH formulations must be administered by intramuscular or subcutaneous injection. Nutropin AQ is the only GH product that is available as a liquid formulation. The remaining products are formulated as lyophilized powders for injection, and patients must be instructed regarding proper reconstitution, storage, and administration. A newly formulated long-acting depot form of growth hormone, Nutropin Depot, is also available for once- or twice-monthly subcutaneous injection. This product may be particularly useful for patients who are noncompliant or experience significant adverse effects from frequent injections. The potency of GH products is expressed as international units per milligram (international units/mg) with 1 mg containing approximately 2.6 international units of growth hormone. Direct comparisons between the different recombinant growth hormone products have not been published. However, all GH products are generally considered to be equally efficacious. The recommended dose for treatment of GHD short stature in children is 0.3 mg/kg per week.⁴⁶ Recombinant GH may be administered daily or in equal doses six times per week, depending on the specific GH product used.⁴⁶ Dosing regimens with greater frequency of administration have been shown to provide more favorable short-term growth responses.⁴⁶ Growth hormone replacement therapy should be initiated as early as possible after diagnosis of GH insufficiency and continued until a desirable height is reached or growth velocity has decreased to less than 2.5 cm per year after the pubertal growth spurt. However, the suitable time point for discontinuation of therapy with growth-promoting doses remains controversial. Glucocorticoids may inhibit the growth-promoting effects of recombinant GH, and concomitant administration of androgens, estrogens, thyroid hormones, or anabolic steroids may accelerate epiphyseal closure and compromise final height.

Three large databases, the National Cooperative Growth Study, the Kabi International Growth Study, and the Australian and New Zealand growth database (OZGROW), have been developed to collect postmarketing adverse effect data or reports associated with recombinant growth hormone. Development of these databases was prompted by the unexpected and tragic cases of CJD reported in patients treated with human pituitary growth hormone. These databases are maintained by pharmaceutical companies that manufacture GH products.⁶⁴ Recombinant GH is generally well tolerated in children, and adverse effects are relatively uncommon.^{64,65} A small number of patients may complain of injection-site pain or arthralgias. Idiopathic intracranial hypertension, also known as pseudotumor cerebri, has been reported in a very small number of children receiving GH therapy. This condi-

tion usually develops within the first 8 to 12 of weeks of treatment and presents with symptoms such as headache, blurred vision, diplopia, nausea, and vomiting.⁶⁴ The symptoms of idiopathic intracranial hypertension usually resolve after discontinuation of GH therapy, and long-term complications are rare. Cases of slipped capital femoral epiphysis have been reported in children with growth-hormone deficiency who are receiving GH therapy.⁶⁴ This condition is thought to occur as a result of the increased width of the femoral plate during GH treatment, but it has also been reported in GH-deficient children who are not receiving GH replacement. Patients with this condition typically complain of hip or knee pain. Slipped capital femoral epiphysis can be managed by an orthopedic surgeon, and GH therapy does not need to be withdrawn. Because growth hormone is known to cause decreased insulin sensitivity, hyperglycemia and diabetes mellitus may develop.⁶⁶ Patients who have specific predisposing risk factors for diabetes mellitus are at greatest risk for this adverse effect.^{64–66} Glycosylated hemoglobin concentrations should be monitored in all patients receiving GH products.⁴⁶ GH may promote the growth of various types of neoplasms and increase tumor recurrence rates in patients with a history of malignancy.^{46,64,65} For this reason, GH should not be administered to patients with an active malignant tumor or a history of recurrent tumor growth. In 1988, a Japanese report indicated that children receiving GH therapy were twice as likely to develop leukemia as children who were not receiving the hormone.⁶⁷ A more recent analysis of all collected reports of leukemia associated with GH therapy determined that these children had other leukemia risk factors (Fanconi anemia, Bloom's syndrome, or a prior history of cancer).⁶⁸ GH therapy in children without these risk factors does not appear to predispose children to develop leukemia.^{64,65,68} Some patients may develop antibodies to recombinant GH. The development of antibodies during replacement therapy with recombinant-GH products has been reported to be relatively low, affecting approximately 15% to 20% of patients.^{69,70} More importantly, the presence of GH antibodies has not been shown to adversely affect growth response and appears to be clinically insignificant except in patients with GH gene deletions. Finally, recent postmarketing reports suggest an increased risk of death associated with long-term GH treatment in children with Prader-Willi syndrome who are severely obese or have severe respiratory impairment. GH treatment is contraindicated in patients with Prader-Willi syndrome who have any of these risk factors.

■ GROWTH HORMONE-RELEASING HORMONE

A synthetic growth hormone-releasing hormone (GHRH) product known as sermorelin (Geref) is currently FDA approved for the treatment of idiopathic growth hormone deficiency in children. Sermorelin [GH-RH (1-29)-NH₂] is composed of 29 amino acid residues that are identical to the amino-terminal segment of human GHRH. Although not as effective as recombinant GH therapy, sermorelin has been shown to increase short-term growth velocity in children with idiopathic growth hormone deficiency.⁷¹ This product has also been shown to increase growth velocity in children who have GH deficiency secondary to hypothalamic damage rather than pituitary abnormalities, as is observed with radiation-induced GH deficiency.⁷² In most cases of radiation-induced GH deficiency, pituitary somatotropes are capable of secreting endogenous GH, and stimulation of these cells by exogenously administered GHRH may restore the natural pulsatile secretion of GH and result in increased growth rate.

The recommended dose of sermorelin is 0.03 mg/kg administered daily by subcutaneous injection. No serious adverse events have

been identified. The most common adverse effect reported by patients receiving sermorelin therapy is pain at the site of injection. Because normal pituitary function is needed for sermorelin to stimulate GH secretion, children should not receive GHRH therapy with sermorelin unless adequate capacity to secrete GH is documented by provocative GH-stimulation testing. Sermorelin may prove to be a beneficial therapeutic option in the treatment of various types of non-GHD short stature. However, owing to its mechanism of action, sermorelin does not have a role in the treatment of true GHD short stature.

EVALUATION OF THERAPEUTIC OUTCOMES

Appropriate monitoring of therapy for GHD and non-GHD short stature includes regular assessments of height, weight, growth velocity, serum alkaline phosphatase, and bone age every 6 to 12 months. Additional laboratory tests to monitor for potential adverse effects include serum glucose and thyroid function. The dose of GH will periodically need to be increased as weight increases in growing children.

PHARMACOECONOMIC CONSIDERATIONS

The treatment of short stature with recombinant GH is very expensive. Despite the prohibitive cost, recombinant GH remains the mainstay of therapy for children with GHD short stature. However, treatment of

non-GHD short stature with recombinant GH is not widely accepted. The benefits in final adult height and increases in growth velocity, particularly in children with true GH deficiency, are associated with significant psychosocial benefits. Many clinicians believe that GH therapy can improve quality of life and should be made available to all children with short stature, regardless of whether or not they are GH deficient.⁷³ Until studies using recombinant GH more definitively demonstrate improvements in both final adult height and quality of life, the cost-effectiveness of GH, particularly for non-GHD short stature, remains uncertain.

CONCLUSIONS

Growth hormone deficiency during childhood results in short stature. Replacement with recombinant GH is considered the mainstay of therapy for patients with GHD short stature, but its use for the treatment of non-GHD short stature remains controversial, albeit such treatment is FDA approved. Recombinant GH has proven to be safe for use in children and is associated with very few adverse effects. New therapeutic agents such as the synthetic growth hormone-releasing hormone sermorelin, and other growth hormone-releasing peptides may provide benefit for patients with non-GHD short stature. Growth hormone regimens can be particularly demanding and inconvenient for pediatric patients because they must be administered by subcutaneous injection. Knowledge of the long-term benefits and risks is critical to the development of rational, cost-effective treatments for patients with short stature.

PROLACTIN

PHYSIOLOGIC EFFECTS

Prolactin is secreted in a pulsatile fashion by the lactotroph cells of the anterior pituitary, with the highest peak concentrations observed during sleep.⁴ The secretion of prolactin is regulated primarily by tonic hypothalamic inhibitory effects of dopamine. As described earlier in this chapter and listed in Table 75–1, many factors can affect prolactin secretion. During pregnancy, prolactin serum concentrations rise substantially above normal. All other conditions characterized by excess prolactin serum concentrations, known as hyperprolactinemia, are considered pathologic.

HYPERPROLACTINEMIA

Hyperprolactinemia is a state of persistent serum prolactin elevation. Prolactin concentrations greater than 20 mcg/L observed on multiple occasions are generally considered indicative of hyperprolactinemia.^{74,75} Hyperprolactinemia usually affects women of reproductive age.⁷⁴ The incidence of hyperprolactinemia in the general population is reported to be less than 1%.⁷⁵

Hyperprolactinemia has several etiologies. The most common causes are benign prolactin-secreting pituitary tumors, known as prolactinomas, and various medications. Prolactinomas are classified according to size. Prolactin-secreting microadenomas are less than 10 mm in diameter and often do not increase in size.^{4,75,76} In contrast, macroadenomas are tumors with a diameter greater than 10 mm that continue to grow and can cause invasion of surrounding tissues.^{4,75,76} In the presence of a prolactinoma, prolactin serum concentrations

may remain normal or may be markedly elevated to thousands of micrograms per liter.

8 Any pharmacologic agent that antagonizes dopamine or increases the release of prolactin can induce hyperprolactinemia (Table 75–4). Serotonin is a strong stimulator of prolactin secretion, and selective serotonin reuptake inhibitors (SSRIs) such as

TABLE 75–4. Drug-Induced Hyperprolactinemia

Dopamine antagonists

- Antipsychotics
- Phenothiazines
- Metoclopramide
- Domperidone

Prolactin stimulators

- Tricyclic antidepressants
- Monoamine oxidase inhibitors
- H₂-Receptor antagonists
- Opioids

Other

- Verapamil

From Molitch,⁴ Mah et al,⁷⁵ Molitch,⁷⁶ and Davies.⁷⁷

TABLE 75–5. Clinical Presentation of Hyperprolactinemia**General**

Hyperprolactinemia most commonly affects women and is very rare in men.

Signs and symptoms

- The patient may complain of symptoms related to local effects of the prolactin-secreting tumor, such as headache and visual disturbances, that result from tumor compression of the optic chiasm.
- Female patients experience oligomenorrhea, amenorrhea, galactorrhea, infertility, decreased libido, hirsutism, and acne.
- Male patients experience decreased libido, erectile dysfunction, infertility, reduced muscle mass, galactorrhea, and gynecomastia.

Laboratory tests

Prolactin serum concentrations at rest will be >20 mcg/L on multiple occasions.

Additional clinical sequelae

- The prolonged suppression of estrogen in premenopausal women with hyperprolactinemia leads to decreases in bone mineral density and significant risk for the development of osteoporosis.
- Risk for ischemic heart disease may be increased with untreated hyperprolactinemia.

From Molitch,⁴ Schlechte,⁷⁴ Mah et al,⁷⁵ and Molitch.⁷⁶

fluoxetine, paroxetine, sertraline, and fluvoxamine are the medications most frequently associated with hyperprolactinemia.⁷⁷ Prior to the increased use of SSRIs, antipsychotic medications with potent dopamine-receptor blockade, such as the phenothiazine derivatives and haloperidol, were most often identified as the cause of drug-induced hyperprolactinemia.⁷⁸ Metoclopramide and domperidone, an antiemetic available in Europe, are potent dopamine-receptor antagonists reported to induce hyperprolactinemia.⁷⁷ Hormones such as estrogen and progesterone, commonly prescribed as oral contraceptives, can stimulate lactotroph growth to promote prolactin secretion and have been implicated in drug-induced hyperprolactinemia. Although the exact mechanism of action remains to be determined, the calcium-channel-blocking agent verapamil has been associated with cases of hyperprolactinemia.^{4,77} Methyl dopa and reserpine, although not used frequently in clinical practice today, are antihypertensive agents that can stimulate prolactin secretion.⁷⁷ Prolactin concentrations may increase with the administration of gonadotropin-releasing hormone analogs like leuprolide or goserelin.⁷⁷ Other medications rarely reported to cause hyperprolactinemia include H₂-receptor blocking agents, benzodiazepines, tricyclic antidepressants, dexfenfluramine, opioids, protease inhibitors, and monoamine oxidase inhibitors.^{4,75–77} Prolactin levels do not typically rise to greater than 150 mcg/L in cases of drug-induced hyperprolactinemia. Measurement of serum prolactin concentrations prior to the initiation of therapy with medications known to cause prolactin elevation may obviate the need for extensive examination of pituitary function and aid with the appropriate diagnosis of drug-induced hyperprolactinemia.

Less common etiologies include central nervous system lesions that physically compress the pituitary stalk and interrupt tonic hypothalamic dopamine secretion, resulting in hyperprolactinemia.^{75,76} Increased thyroid-releasing hormone (TRH) concentrations in hypothyroidism can stimulate prolactin secretion and cause hyperprolactinemia. During conditions of renal or liver compromise, the

clearance of prolactin is decreased, resulting in elevated prolactin concentrations.⁴ Despite vigorous diagnostic effort, the cause of hyperprolactinemia cannot always be determined. This is known as idiopathic hyperprolactinemia and is most likely a result of the presence of very small tumors that are not detected by standard imaging techniques.⁷⁴ It should be noted that many physiologic factors, such as stress (including the stress of phlebotomy), sleep, exercise, coitus, and eating can also induce transiently elevated prolactin levels.^{4,74} This emphasizes the importance of obtaining multiple prolactin measurements to confirm the diagnosis. Ideally, after an intravenous line is placed in the patient's arm, the patient should rest in a supine position or in a chair for 2 hours before prolactin samples are collected.

Elevated prolactin serum concentrations inhibit gonadotropin secretion and sex-steroid synthesis.⁷⁴ Because prolactin concentrations higher than 60 mcg/L are associated with anovulation, women with hyperprolactinemia typically present with menstrual irregularities such as oligomenorrhea or amenorrhea and infertility.^{7,74,75} In addition, approximately 40% to 80% of women with hyperprolactinemia will have galactorrhea.^{74,75} The clinical presentation of patients with hyperprolactinemia is summarized in Table 75–5.^{4,74–76}

The diagnosis of hyperprolactinemia, as defined by multiple prolactin serum concentrations above 20 mcg/L, is relatively simple. However, identifying the underlying cause of this abnormality may be more challenging. Patients with modest prolactin elevations should have multiple prolactin serum determinations to minimize the potential for detecting only transient increases in prolactin. A careful medication history is essential, and the presence of hypothyroidism, renal failure, or hepatic dysfunction should be evaluated. If the cause of hyperprolactinemia remains ambiguous, a computed tomography scan or magnetic resonance imaging study should be performed to determine the presence of a pituitary tumor.^{74,75} If an underlying cause of elevated prolactin serum concentration is not determined, the hyperprolactinemia is considered to be idiopathic.

► TREATMENT: Hyperprolactinemia

The treatment of hyperprolactinemia depends on the underlying cause of the abnormality. In cases of drug-induced hyperprolactinemia, discontinuation of the offending medication and initiation of an appropriate therapeutic alternative usually normalizes serum prolactin concentrations.⁷⁷ In cases for which an appropriate therapeutic alternative does not exist, medical therapy with dopamine agonists is

warranted. Sex-steroid replacement should also be considered.⁷⁵ Treatment options for the management of prolactinomas include clinical observation, medical therapy with dopamine agonists, radiation therapy, and transsphenoidal surgical removal of the tumor.^{4,74–76} Because prolactin-secreting microadenomas are very small and typically do not increase in size, treatment of these tumors is primarily directed

toward alleviating symptoms.^{74–76} The goal of therapy is to normalize prolactin serum concentrations and re-establish gonadotropin secretion to restore fertility and reduce the risk of osteoporosis. In patients with asymptomatic elevations in serum prolactin, observation and close follow-up are appropriate.^{74–76} Treatment goals are more aggressive in patients with prolactin-secreting macroadenomas because these tumors are larger and can cause invasion of local tissues with significant visual defects.⁷⁶ Therefore in addition to normalizing prolactin concentrations, tumor shrinkage and correction of visual defects are primary goals of treatment.

Medical therapy with dopamine agonists is usually more effective than transsphenoidal surgery for both types of pituitary prolactinomas.^{4,74–76} Postsurgical cure rates differ depending on tumor type and expertise of the neurosurgeon. Long-term cure rates are reported to be approximately 60% for microprolactinomas and only 25% for macroprolactinomas.⁴ Transsphenoidal surgery for the removal of prolactinomas is usually reserved for patients who are refractory to or cannot tolerate therapy with dopamine agonists, and for patients with very large tumors that cause severe compression of adjacent tissues.^{4,74–76} Radiation therapy may require several years for effective tumor shrinkage and reduction in serum prolactin concentrations, and is usually used only in conjunction with surgery.⁴

■ PHARMACOLOGIC THERAPY

Medical therapy with dopamine agonists has proven to be very effective in normalizing prolactin serum concentrations, restoring menstruation, and reducing tumor size in approximately 80% to 90% of patients within 3 to 6 months of therapy.^{4,75} Bromocriptine has been the mainstay of therapy since the 1970s, and pergolide has been used as an effective alternative in patients who are intolerant of the adverse effects associated with bromocriptine. Cabergoline is a new long-acting dopamine agonist that offers the advantage of less-frequent dosing. In recent years cabergoline has replaced bromocriptine as the agent of choice for the medical management of prolactinomas.

■ BROMOCRIPTINE

Bromocriptine was the first D₂-receptor agonist to be used in the treatment of hyperprolactinemia and has been the mainstay of therapy for over 20 years. It inhibits the release of prolactin by directly stimulating postsynaptic dopamine receptors in the hypothalamus. Hypothalamic release of dopamine (prolactin-inhibitory hormone) inhibits the release of prolactin. Decreases in serum prolactin concentrations occur within 2 hours of oral administration with maximal suppression occurring after 8 hours, and suppressive effects persisting for up to 24 hours. Medical therapy with bromocriptine normalizes prolactin serum concentrations, restores gonadotropin production, and shrinks tumor size in approximately 90% of patients with prolactinomas.⁷⁶

For the management of hyperprolactinemia, bromocriptine therapy is typically initiated at a dose of 1.25 to 2.5 mg once daily at bedtime to minimize adverse effects.^{74,75} The dose can be gradually increased by 1.25-mg increments every week to obtain desirable serum prolactin concentrations. Usual therapeutic doses of bromocriptine range from 2.5 to 15 mg per day, although some patients may require doses as high as 40 mg per day.⁷⁵ Bromocriptine is usually administered in two or three divided doses, but once-daily dosing has also been shown to be effective.⁷⁹

The most common adverse effects associated with bromocriptine therapy include central nervous system symptoms such as headache, lightheadedness, dizziness, nervousness, and fatigue. Gastrointestinal effects such as nausea, abdominal pain, and diarrhea are also common. Bromocriptine should be administered with food to decrease the incidence of adverse gastrointestinal effects. Although most of these adverse effects diminish with continued treatment, about 12% of patients will not tolerate the adverse effects associated with bromocriptine therapy.⁷⁹ Vaginal preparations of bromocriptine have been studied in an effort to decrease the incidence of adverse effects associated with oral dosage forms.^{4,75,80}

Because most patients with hyperprolactinemia are women with a principal complaint of infertility, the safety of bromocriptine in pregnancy must be considered. One report of over 2000 pregnancies in women who received bromocriptine during part or all of their gestation did not detect an increase in the risk for spontaneous abortion or incidence of congenital anomalies.⁷⁹ Although bromocriptine does not appear to be teratogenic, most clinicians discontinue therapy as soon as pregnancy is detected because the effects of in utero exposure to bromocriptine on gonadal function and fertility of the offspring remain unknown.^{4,74–76} In patients with macroprolactinomas undergoing rapid tumor expansion, bromocriptine therapy may need to be continued throughout pregnancy.

■ PERGOLIDE

Pergolide is a dopamine-receptor agonist with affinity for both D₁- and D₂-receptors. This agent is 10 to 1000 times more potent than bromocriptine on a per milligram basis. In the United States, pergolide is not FDA-approved for the treatment of hyperprolactinemia and is most commonly prescribed for the treatment of parkinsonism. However, pergolide has been used for many years as a safe and effective alternative to bromocriptine in the management of patients with hyperprolactinemia and offers the advantage of once-daily dosing.^{4,76}

For the treatment of hyperprolactinemia, pergolide therapy is initiated at a dose of 25 mcg given once daily at bedtime. The average dose that achieves optimal suppression of prolactin serum concentrations is 50 mcg/day given as a single dose.⁷⁶ Adverse effects of pergolide are similar to those of bromocriptine and include nausea, headache, vomiting, and dizziness in about 30% of patients. A few cases of cardiac valvulopathy have been reported during pergolide therapy. Pathologic assessment suggests that the valvulopathy associated with pergolide appears to be similar to that reported with other ergot alkaloids. In addition, a small number of patients receiving pergolide have recently reported abruptly falling asleep while performing activities of daily living. This adverse effect has been reported up to 1 year after initiation of therapy. Therefore patients should be made aware of this potentially dangerous adverse effect. The use of pergolide during pregnancy has not been as extensively evaluated as bromocriptine, and should be avoided until additional data become available.

■ CABERGOLINE

9 Cabergoline is a long-acting dopamine agonist with high selectivity and affinity for dopamine D₂-receptors. This agent is approved for the treatment of hyperprolactinemia and has been shown to effectively reduce serum prolactin concentrations in 80% to 90% of hyperprolactinemic patients.^{81–83} Cabergoline also effectively reduces tumor size in patients with both micro- and macroprolactinomas.^{81,84} In a multicenter randomized trial comparing

the efficacy of cabergoline and bromocriptine, serum prolactin levels were normalized in 83% of patients receiving cabergoline and 58% of patients receiving bromocriptine after 6 months of therapy.⁸⁵ Cabergoline has also proved effective in patients who are intolerant of or resistant to bromocriptine, and recent data suggest that cabergoline is as effective in men as it is in women with micro- and macroprolactinomas.^{86–88}

Cabergoline is commercially available as 0.5-mg oral tablets. The initial dose of cabergoline for the treatment of hyperprolactinemia is 0.5 mg once weekly or in divided doses twice weekly. This dose may be increased by increments of 0.5 mg at 4-week intervals based on serum prolactin concentrations. The usual dose is 1 to 2 mg weekly; however, doses as high as 4.5 mg weekly have been used.⁸⁹ Recent studies have also evaluated the efficacy of a vaginal dosage form of cabergoline to reduce the adverse effects associated with oral therapy.⁹⁰

Following oral administration, peak serum concentrations are obtained within 2 hours, and food does not affect absorption. Data from animal studies indicate that cabergoline is widely distributed to well-perfused organs, including the pituitary gland.⁸⁹ The elimination of cabergoline from the pituitary appears to be very slow; this rate may explain the long duration of action. Cabergoline is extensively metabolized in the liver by hydrolysis, and the dose should be reduced in patients with severe hepatic failure. This drug is eliminated primarily in the feces, and the elimination half-life ranges from 79 to 155 hours in hyperprolactinemic patients.⁸⁹

The most common adverse effects reported with the use of cabergoline are nausea, vomiting, headache, and dizziness.^{81,84,89} These are similar to the adverse effects reported with bromocriptine and pergolide. However, in a large comparative study evaluating bromocriptine and cabergoline, fewer patients receiving cabergoline reported adverse effects than patients receiving bromocriptine, and only 3% of the patients in the cabergoline group withdrew from the study because of adverse effects, versus 12% of patients taking bromocriptine.⁸⁵ Other adverse events associated with the use of cabergoline include gastrointestinal complaints, drowsiness, fatigue, paresthesias, dyspnea, suffocation sensation, and epistaxis.^{85,89} As with other dopamine agonists, adverse events usually occur early in therapy and subside with continued treatment. However, in one study 15% to 20% of patients receiving cabergoline experienced a recurrence of early symptoms or an onset of new symptoms after several weeks of treatment.⁸⁵ Mild to moderate decreases in blood pressure have been observed in up to 50% of patients taking cabergoline; however, the incidence of symptomatic orthostatic hypotension has not been significant.^{81,82,85} Transient increases in serum alkaline phosphatase, bilirubin, and aminotransferases have been reported in small numbers of patients receiving cabergoline.⁸⁵ Pleuropulmonary disease has been reported with cabergoline, but only with larger doses used in the treatment of Parkinson's disease.⁸⁷

10 The use of cabergoline in pregnancy has not been extensively studied. However, several case reports of women who received cabergoline therapy during the first and second trimesters of pregnancy have not documented an increased risk of spontaneous abortion, congenital abnormalities, or tubal pregnancy.⁸⁹ However, prospective data in large numbers of pregnancies is lacking. Owing to the long half-life and limited data on cabergoline use in pregnancy, most clinicians recommend that women receiving cabergoline therapy who plan to become pregnant should discontinue the medication 1 month before planned conception.⁹¹

Other dopamine agonists that have been used in the treatment of hyperprolactinemia but are not commercially available in the United States include lisuride, terguride, metergoline, dihydroergocristine,

and quinagolide.⁷⁹ Quinagolide is a D₂-receptor agonist used frequently in Europe which is dosed once daily. Quinagolide has been shown to be as effective as bromocriptine for the management of hyperprolactinemia and may also be effective in the treatment of patients who are resistant to or intolerant of bromocriptine.⁷⁹

EVALUATION OF THERAPEUTIC OUTCOMES

Prolactin serum concentrations should be monitored every 3 to 4 weeks after the initiation of any dopamine-agonist therapy to assess efficacy and appropriately titrate medication dosage.⁷⁴ In addition, symptoms such as headache, visual disturbances, menstrual cycles in women, and sexual function in men should be evaluated to assess clinical response to therapy. Once prolactin concentrations have normalized and clinical symptoms of hyperprolactinemia have resolved with dopamine-agonist therapy, prolactin serum concentrations should be monitored every 6 to 12 months. In patients receiving long-term treatment, the dose of the dopamine agonist can be gradually reduced or discontinued in some patients. For patients with microprolactinomas who have normal serum prolactin concentrations and at least a 50% reduction in tumor size, medical therapy may be withdrawn every 2 to 5 years to assess if remission has been achieved. In the case of macroprolactinomas, the dose of the dopamine agonist can be gradually reduced in some cases, but complete drug discontinuation should be attempted only if careful monitoring for renewed tumor growth can be ensured.^{74,75,92}

PHARMACOECONOMIC CONSIDERATIONS

Medical therapy with dopamine agonists is more effective than transsphenoidal surgery or radiation for the management of hyperprolactinemia. Because most patients receive therapy for long periods of time, the medical management of hyperprolactinemia may result in considerable cost. Although bromocriptine has been frequently used to manage hyperprolactinemia, therapy with pergolide, which has been shown to be equally effective, costs considerably less and offers the advantage of once-daily dosing. Cabergoline has been shown to be more effective than bromocriptine and offers additional advantages such as a decreased incidence of adverse effects and improved patient compliance. Most clinicians agree that cabergoline is the most efficacious dopamine agonist currently available. However, the cost of cabergoline therapy is approximately two times greater than that of bromocriptine. Pharmacoeconomic studies are needed to assess whether the higher cost of cabergoline therapy is balanced by the potential added benefits.

CONCLUSIONS

Hyperprolactinemia is a common disorder that can have a significant impact on fertility. Hyperprolactinemia is most commonly caused by the presence of prolactin-secreting pituitary tumors and various medications that antagonize dopamine or increase the secretion of prolactin. Available treatment options for this disorder include medical therapy with dopamine agonists, radiation therapy, and transsphenoidal surgery. In most cases, medical therapy with dopamine agonists

is considered the most effective treatment. Cabergoline has replaced bromocriptine as the mainstay of medical therapy, as it appears to be better tolerated and more effective. However, due to limited data

regarding the safety of cabergoline during pregnancy, bromocriptine remains the preferred agent when fertility is the primary purpose for treatment.

PANHYPOPITUITARISM

11 Panhypopituitarism is a condition of complete or partial loss of anterior and posterior pituitary function resulting in a complex disorder characterized by multiple pituitary-hormone deficiencies. Patients with panhypopituitarism may have ACTH deficiency, gonadotropin deficiency, growth hormone deficiency, hypothyroidism, and hyperprolactinemia. Panhypopituitarism can be classified as either primary or secondary depending on the etiology. Primary panhypopituitarism involves an abnormality within the secretory cells of the pituitary, whereas secondary panhypopituitarism is caused by a lack of proper external stimulation needed for normal release of pituitary hormones. Some of the most common causes of panhypopituitarism include primary pituitary tumors, ischemic necrosis of the pituitary, surgical trauma, irradiation, and various types of central nervous system infections. Pharmacologic treatment of panhypopituitarism is essential and consists of replacement of specific pituitary hormones after careful assessment of individual deficiencies. Replacement most often consists of glucocorticoids, thyroid-hormone preparations, and sex steroids. The administration of recombinant growth hormone also may be necessary. Patients with panhypopituitarism will need lifelong replacement therapy and constant monitoring of multiple homeostatic functions.

ABBREVIATIONS

ACTH: adrenocorticotropic hormone
 CJD: Creutzfeldt-Jakob disease
 CRH: corticotropin-releasing hormone
 FSH: follicle-stimulating hormone
 GH: growth hormone
 GHD: growth-hormone-deficient
 GnRH: gonadotropin-releasing hormone
 GHRH: growth hormone-releasing hormone
 IGFBP-3: Insulin-like growth factor-I-binding-protein-3
 IGF: insulin-like growth factor
 IHH: idiopathic intracranial hypertension
 LH: luteinizing hormone
 OGTT: oral glucose tolerance test
 SSRI: selective serotonin reuptake inhibitor
 TRH: thyrotropin-releasing hormone
 TSH: thyroid-stimulating hormone
 VIP: vasoactive intestinal peptide

PREGNANCY AND LACTATION: THERAPEUTIC CONSIDERATIONS

Denise L. Walbrandt Pigarelli, Connie K. Kraus, and Beth E. Potter

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Altered drug pharmacokinetics during pregnancy can influence drug selection and dosing. Physiologic changes during pregnancy typically result in changes in absorption, protein binding, distribution, and elimination.
- 2 Although drug-induced teratogenicity is a serious concern during pregnancy, most drugs required by pregnant women can be used safely. Informed selection of drug therapy is essential.
- 3 Health care practitioners must know where to find and how to evaluate evidence related to the safety of drugs used during pregnancy.
- 4 Pregnancy-influenced health issues such as constipation, gastroesophageal reflux disease, and nausea/vomiting of pregnancy (and others) for many years have been treated safely and effectively with carefully selected drug therapy. Some acute and chronic illnesses may pose special risks during pregnancy, and they should be treated with appropriately selected and monitored drug therapies to avoid harm to both the woman and the fetus.
- 5 Understanding the physiology of lactation and pharmacokinetic factors affecting drug distribution, metabolism, and elimination can assist the clinician with more appropriate and safe use of medications during lactation.

Drug use in pregnancy and lactation is a critically important topic that is underemphasized in the education of health professions. Interestingly, the subject encompasses a dichotomous discussion of the benefits of drug therapy for the mother and the potential risks for the embryo/fetus. Drug use in pregnancy and lactation is a controversial and emotionally charged area because of medicolegal and ethical implications.

It is the clinician's responsibility to ensure safe and effective therapy before conception, during pregnancy, and after delivery, and the patient's active participation is essential. Both acute and chronic illnesses must be managed during pregnancy, and optimal treatments sometimes are different from those in the nonpregnant patient. Pharmacotherapeutic issues also apply to selection of drugs during parturition and the postpartum period. Principles of drug use during lactation, although similar, are not the same as those applicable during pregnancy.

In many instances, medication dosing recommendations for acute or chronic illness treatment in pregnant women are the same as for the general population. On the other hand, there are some instances where dosing or selection of medications in pregnancy is quite different from that in the general population. We have sought to highlight unique dosing and drug selection considerations in this chapter.

NATURAL COURSE OF PREGNANCY

PHYSIOLOGY

Because of the complexity of fertilization and subsequent pregnancy events, approximately 50% of embryos do not survive.¹ Most of these losses occur in the first 2 weeks after fertilization, and many women may not realize that they were pregnant. About 15% of the pregnancies that survive the first 2 weeks of gestation will be lost spontaneously later in the course of the pregnancy.¹

Fertilization occurs when a sperm joins to an egg by attaching to a receptor on the outer protein layer of the egg, the zona pellucida.¹ Immediately, the egg becomes unresponsive to other sperm. The attached sperm releases enzymes that cause the egg's chromosomes to mature and also allow the sperm to fully penetrate the zona pellucida and contact the egg's cell membrane. The membranes of the sperm and egg are then fused to create a new, single cell. Male and female chromosomes join in the new cell, fuse to create a single nucleus, and organize to set the stage for cell division.¹

Fertilization usually occurs in the fallopian tube.¹ Cell division continues for the first 2 days while the fertilized egg travels down the fallopian tube, reaching the uterine cavity on the third day. Cell division continues for 2 to 3 more days in the uterine cavity before

implantation begins.¹ Approximately 6 days after fertilization, the cell mass is termed a *blastocyst*.¹ Human chorionic gonadotropin is now produced in amounts that may be detected in commercial laboratories. The blastocyst sloughs the zona pellucida and rests directly on the endometrium, which now responds to the denuded blastocyst by allowing it to begin to grow into the endometrial wall. After 6 days of this growth, the blastocyst lies implanted under the endometrium's surface and begins to receive nutrition from maternal blood.¹ It is now called an *embryo*.²

The embryonic period lasts from approximately 2 weeks after fertilization until 8 weeks after fertilization, when the conceptus is renamed a *fetus*.² Most body structures are formed during the embryonic period, and they continue to grow and mature during the fetal period. The fetal period continues until the pregnancy reaches term, approximately 40 weeks after the last menstrual period.²

Gravidity refers to the number of times that a woman experiences pregnancy.² A multiple birth is counted as a single pregnancy. *Parity* refers to the number of a woman's pregnancies that exceeded 20 weeks of gestation and also relates information regarding the outcome of each pregnancy. In sequence, the numbers reflect (1) term deliveries, (2) premature deliveries, (3) aborted and/or ectopic pregnancies, and (4) number of living children. A woman who has been pregnant four times; has experienced two term deliveries, one premature delivery, and one ectopic pregnancy; and has three living children would be designated by G₄P₂₁₁₃.²

PREGNANCY DATING

Approximately 280 days (about 40 weeks or 9 months) constitute the duration of a pregnancy; this time period extends from the first day of the last menstrual period to birth.² *Gestational age* or *menstrual age* refers to the age of the embryo or fetus beginning with the first day of the last menstrual period, which is about 2 weeks prior to fertilization. To calculate an approximate pregnancy due date, the clinician adds 7 days to the first day of the last menstrual period and subtracts 3 months.²

For simple description purposes, pregnancy is divided into three periods of 3 calendar months, and each period of 3 months is called a *trimester*.

PREGNANCY SIGNS AND SYMPTOMS

The early symptoms of pregnancy include fatigue and increased frequency of urination.³ At approximately 6 weeks' gestation, the pregnant woman may experience nausea and vomiting; this is commonly known as *morning sickness* but may occur at any time of the day. Nausea and vomiting usually resolve at 12 to 18 weeks' gestation. Fetal movement is detected in the woman's lower abdomen at 16 to 20 weeks of gestation.³

Signs of pregnancy may include sudden cessation of menses, changes in consistency of the cervical mucus, a bluish discoloration of the vaginal mucosa, increased skin pigmentation, and anatomic breast changes.³

MATERNAL PHARMACOKINETIC CHANGES IN PREGNANCY

During pregnancy, a woman's reduced gastrointestinal motility, increased gastric pH, and increased pulmonary alveolar drug uptake affect drug absorption.⁴ Drug distribution in pregnancy may change because maternal plasma volume increases by 50%. Of the approximately 8-L increase in total-body water during pregnancy,

40% is distributed to maternal compartments, and 60% is distributed to the amniotic fluid, placenta, and fetus. Serum albumin binding capacity is decreased during pregnancy, which results in increased unbound drug. However, decreased amounts of ingested drug per kilogram of body weight and increased hepatic and renal elimination of drugs result in a net impact on drug distribution of unaltered free drug serum concentration for many (but not all) drugs.⁴

Pregnancy also affects drug elimination. The maternal hormones progesterone and estradiol affect hepatic drug metabolism in various ways; they enhance the hepatic metabolism of some drugs (e.g., phenytoin) but inhibit the metabolism of others (e.g., theophylline).⁴ In addition, the clearance of drugs excreted into the biliary system may slow because estrogen can cause cholestasis. Renal drug clearance may be affected by an increased renal blood flow of 25% to 50% and an increased glomerular filtration rate of 50%. Fortunately, these changes usually do not result in a need for altered drug dosing.⁴

TRANSPLACENTAL DRUG TRANSFER

Although once thought to be a barrier to drug transfer, the placenta is fundamentally the organ of exchange for a number of substances, including drugs, between the mother and fetus.⁵ The placenta functions fully for such transport by the fifth week after conception. Most drugs move across the membranes by passive diffusion, both to the fetus from the mother and from the fetus to the mother, as maternal serum levels decline. Such considerations as maternal dose, route of administration, maternal pharmacokinetic handling of the ingested substance, and maternal plasma protein binding may influence the actual amount of drug that reaches the fetus. Characteristics of the ingested substance also influence the degree of transfer. High lipophilicity, low ionization, low maternal protein binding, and low molecular weight all enhance the degree of transfer.⁵

The degree to which exposure to a drug influences the embryo/fetus also may be a function of the timing of the exposure. It is generally thought that drug exposure during the embryonic period has the greatest potential influence on organ development.^{5,6} Indeed, the most obvious teratogenic effects occur during this period.⁵ Teratogenic effects may include loss of pregnancy, structural abnormalities, growth impairment, and functional loss.⁶ However, more subtle changes in function or behavior may be associated with drug exposure at other times during pregnancy.⁵

DRUG SELECTION DURING PREGNANCY

The greatest concern regarding the use of medications in pregnant women is the potential risk of abnormal development in the child. Although some drugs have the potential to cause teratogenic effects, most medications required by pregnant women can be used safely. There are many misconceptions related to the role medications play in causing birth defects.

The vast majority of children are born healthy. The overall incidence of congenital malformations is approximately 3% to 5%.^{7,8} Although many people assume that medications play a large role in causing birth defects, it is estimated that medication exposure accounts for less than 1% of all birth defects.⁸ Genetic causes are responsible for 15% to 25%, other environmental issues (e.g., maternal conditions, infection, and mechanical deformations) account for 10%, and the remaining 65% to 75% of congenital malformations result from unknown causes.⁸

Despite the greater potential of harm with certain drugs, not every exposure will result in a birth defect. Factors such as the stage of

pregnancy when the exposure occurred, the route of administration, and dose all can influence outcomes.⁷ In the first 2 weeks after conception, exposure to a teratogen may result in an “all or nothing” effect, which could either destroy the embryo or cause no problems. The period from 18 to 60 days postconception (organogenesis) is the time when organ systems are developing, and teratogenic exposures may result in structural anomalies. In the remainder of the pregnancy, exposure to teratogenic agents may result in retardation of growth, central nervous system (CNS) abnormalities, or death. Examples of medications associated with teratogenic effects in the period of organogenesis include chemotherapy drugs (e.g., methotrexate, cyclophosphamide), sex hormones (e.g., diethylstilbesterol), lithium, retinoids, thalidomide, certain antiepileptic drugs, and coumarin derivatives. Medications such as angiotensin-converting enzyme inhibitors, nonsteroidal anti-inflammatory agents, and tetracycline derivatives are more likely to exhibit effects in the second or third trimesters.⁷

Finally, there is a growing interest in discovering the role that genetic susceptibility plays in whether an exposure to a medication will result in a birth defect. Maternal and fetal genotypes may influence the effect a drug might have on the fetus by influencing the absorption, metabolism, distribution, and binding of a drug.⁷ There is some evidence that certain unique anomalies associated with maternal smoking may be more likely in people with specific genetic variants.⁹

In summary, a small number of medications are associated with the potential to cause congenital malformations. Many of these agents can be avoided easily during pregnancy. In situations where a drug may be harmful to the developing child but is necessary for maternal care, considerations related to route of administration and dosing may lessen the risk of congenital malformations.

METHODS OF DETERMINING SAFETY OF DRUGS IN PREGNANCY

3 Even though most medications are likely to be safe during pregnancy, clinicians will struggle to make decisions about choosing therapy. Information about medication safety in pregnancy comes from a variety of sources. One of the most important questions for the clinician is how to evaluate the quality of the evidence related to the safety of medications used in pregnancy.

Although randomized, controlled trials form the basis for some of the most reliable assessments of drug safety, pregnant women usually are not eligible for participation in clinical trials. Other types of data often are used to estimate the risk associated with medication use during pregnancy, such as animal studies, case reports, case-control studies, prospective cohort studies, historical cohort studies, and voluntary reporting systems.

Although animal studies are a required component of drug testing, extrapolation of the results of such testing to humans is not always accurate. One example is thalidomide, which was found to be safe in some animal models but proved to have teratogenic effects in human offspring.¹⁰

Case reports may be of limited value because an isolated occurrence of a birth defect in the infant of a woman who used a medication during her pregnancy may have occurred by chance.¹⁰ Because most pregnant women use drugs infrequently, and the overall risk of drug-related teratogenic effects is low, it would take a very large number of exposures to appreciate an increased risk. The few instances in which case reports have been helpful in establishing teratogenic risk were situations in which a drug was used infrequently but was associated with a high rate of birth defects (isotretinoin); or it was used widely and caused reproducible malformations (thalidomide).¹¹

Case-control studies identify an outcome (congenital anomaly), match subjects with and without that outcome, and report how often there was exposure to a suspected agent.¹⁰ The concern with this type of study is recall bias, because a woman with an affected pregnancy may be more likely to recall drugs used during the course of pregnancy than would a woman who had a normal pregnancy outcome.¹⁰

Cohort studies look at the intervention (use of a particular drug) in a group of persons and compare outcomes in a similar group of subjects without the intervention.¹⁰ The fact that the study is prospective eliminates some of the problems with recall bias. This approach has several potential disadvantages, however, such as the need for large numbers of participants, time involved, and potential loss to follow-up. Despite these disadvantages, cohort studies are used often for evaluating the effects of a drug exposure on pregnancy outcomes.¹⁰

An example of a cohort study is the Michigan Medicaid study, which consisted of data collected from 229,101 pregnancies over 7 years.¹⁰ Teratology information services provide pregnant women with information about potential exposures during pregnancy and, in turn, follow these women throughout the pregnancy to assess the outcomes of the pregnancy. These services may report pooled data to facilitate information sharing about medications used in pregnancy. In addition, some pharmaceutical companies have organized voluntary reporting systems for drugs used in pregnancy. One such example is the Acyclovir in Pregnancy Registry.¹⁰

RESOURCES

3 Unfortunately, there is no one place for the clinician to collect information regarding the safety of a medication for pregnant patients. Computerized databases (e.g., the Canadian database, www.motherisk.org) and textbooks with information from large cohorts of treated women offer valuable assistance. New information regarding drug use in pregnancy also may be obtained from searches of the primary literature for cohort and case studies.

One commonly used source of information about drug safety is the category system of the Food and Drug Administration (FDA). The FDA created drug categories to provide guidance regarding the risk versus benefit for drug use during pregnancy.¹¹ The reliability of this resource has been of concern for several reasons.^{11,12} When compared with two other risk classification systems from other countries, only 61 of 236 drugs (26%) in common to all three systems were ranked in the same risk category.¹² The FDA ranks very few drugs as considered safe during pregnancy (category A) because it has a requirement for a controlled trial to establish safety. Therefore, the impression from this source would be that few drugs are safe. Another concern about use of the FDA categories involves the difficulty of changing a drug's classification when new information becomes available.¹¹ An example of this issue is that oral contraceptives are classified by the FDA as category X drugs (studies in animals or pregnant women demonstrated evidence of fetal abnormality), but there is little current evidence that such exposure results in congenital abnormalities.^{11,12} In contrast, the Swedish and Australian classification systems do not categorize oral contraceptives as teratogenic agents.¹²

GENERAL RECOMMENDATIONS FOR SELECTION OF MEDICATIONS IN PREGNANCY

2 Several principles may be helpful in selecting medications for use during pregnancy. The first is to consider selecting drugs that have been used for the longest periods of time with safety.¹¹ Whenever possible, the amount of drug administered should be at the lower

end of the dosing range to minimize fetal exposure. Finally, patients should be discouraged from self-medicating during pregnancy and encouraged to consult their clinician for advice.¹¹

PRECONCEPTION PLANNING

There are approximately 4 million births in the United States each year,¹³ and almost 50% of these are unplanned.¹⁴ In addition, many women may not seek health care for pregnancy until after the first trimester.¹³ Given the dynamic changes that occur during the first trimester, there is growing effort to encourage preconception planning. Not only would such planning assist the prospective mother in identifying areas of risk for pregnancy, but it also would provide education and interventions to improve birth outcomes.¹³ Several preconception interventions have been shown to improve pregnancy outcomes significantly. One of the interventions with strong scientific evidence for benefit is the ingestion of folic acid to reduce the risk for neural tube defects,¹³ which affect approximately 4000 pregnancies in the United States each year.^{14,15} Of these pregnancies, one-third are aborted spontaneously or electively.¹⁵ Controlled clinical trials have shown that folic acid supplementation prior to and during the early stages of pregnancy can reduce the incidence of neural tube defects by 50%. Because the neural tube closes within the first 4 weeks of pregnancy, and because so many pregnancies are unplanned and unrecognized until after this time, it is necessary to encourage women of childbearing potential either to consume folate-enriched foods or to use supplements prior to pregnancy.¹⁵

The American Academy of Pediatrics Committee on Genetics endorses the recommendation from the U.S. Public Health Service that all women of childbearing age ingest 400 mcg of folic acid daily to reduce the risk of neural tube defects in their potential offspring.¹⁵ Because the consumption of food naturally containing folic acid is variable from day to day, and because folate from these sources is less well absorbed, it is suggested that women fulfill the daily requirement for folic acid through either folate-enriched foods or supplements.¹⁴ Women who have had a pregnancy affected by a neural tube defect or who use certain seizure medications should receive 4000 mcg (4 mg) of folic acid daily beginning 1 to 3 months prior to conception and continuing throughout the first trimester.¹⁵ These higher doses of folic acid require the use of supplements. Although folic acid supplementation potentially may mask the hematologic effects of vitamin B₁₂ deficiency, the risk of this occurring in women of childbearing potential is rare. In contrast, the level of evidence of reduction in birth defects with supplementation of other vitamins and nutrients prior to pregnancy is weaker than that for supplementation of folic acid.¹³

Other preconception interventions with evidence of improving pregnancy outcomes include screening and immunization for rubella and varicella.¹³ Influenza vaccine is also recommended for women who will be in the second or third trimester during the influenza season.¹⁶ Pregnant women who contract influenza may have greater morbidity and mortality owing to the risk of pneumonia.¹⁶

Another important component of preconception and early pregnancy care involves the assessment and reduction of risks associated with the use of tobacco.¹³ Cigarette smoking is said to be the most significant modifiable cause of adverse events in pregnancy.¹⁷ It is estimated that up to 20% of women smoke during pregnancy.¹⁸ Smoking during pregnancy commonly results in fetal growth retardation.¹⁷ Preterm delivery, perinatal mortality, and sudden infant death syndrome are also associated with the use of tobacco during pregnancy.^{17,18} One strategy to reduce the number of women who

smoke during pregnancy is to encourage young women not to begin smoking.¹⁷ This is important because even though women are more likely to quit smoking when they become pregnant than at any other time, many will restart smoking before delivery or soon thereafter.¹⁷

Behavioral therapy is considered the intervention of first choice to assist pregnant women with smoking cessation.¹⁸ As little as a single 5- to 15-minute counseling session by a provider has resulted in a doubling of the rate of pregnant women who stop smoking versus no counseling (20% versus 5% to 10%). Some pregnant women may be unable to quit smoking with behavioral interventions alone,¹⁹ especially those who use a greater number of cigarettes per day.¹⁷ Use of nicotine replacement in pregnant women who are unable to quit may be helpful.¹⁷ Nicotine has been shown to cause CNS toxicity in fetal animal studies.¹⁹ Cigarette smoking, however, delivers over 3000 chemicals in addition to nicotine. One of these chemicals, carbon monoxide, is a factor in reducing fetal growth. Thus, although there are potential risks with nicotine replacement in the pregnant patient, these risks may be more than offset by the benefits if the patient can stop smoking. Some authors recommend intermittently used products (such as gum) to decrease the total daily dose of nicotine or suggest removal of patches at bedtime to allow a drug-free interval. The dose of nicotine initially should be selected to be comparable with that obtained from smoking.¹⁹

Health care providers can use many different types of encounters with young women of reproductive age to share information about improving their personal health, as well as the future health of their children. Pharmacotherapeutic interventions may include recommendations about folic acid supplementation, appropriate immunizations, and strategies to stop smoking.

PREGNANCY-INFLUENCED ISSUES

4 Pregnant women commonly experience health issues that are either caused by or exacerbated by the pregnant state. Constipation, gastroesophageal reflux, hemorrhoids, and nausea and vomiting may affect many women during pregnancy. Gestational diabetes, gestational hypertension, and venous thromboembolism have the potential to cause adverse pregnancy consequences. Gestational thyrotoxicosis is usually a self-limiting condition.

GASTROINTESTINAL TRACT

Constipation occurs commonly in pregnancy. Contributing factors may include changes in dietary habits, fluid intake, and physical activity; delayed intestinal transit (most likely because of hormonal changes during pregnancy); and possibly obstruction.²⁰ Therapy for the constipation of pregnancy should be instituted first with nondrug modalities, such as education, physical exercise, biofeedback, and increased intake of dietary fiber and fluid. If additional therapy is warranted, the use of supplemental fiber and/or a stool softener such as docusate is appropriate. Lactulose, sorbitol, and bisacodyl are acceptable treatments for constipation in pregnancy but should be reserved for occasional rather than routine use. Senna also may be used occasionally. Castor oil should be avoided in pregnancy because it can cause uterine contractions; mineral oil can reduce the absorption of fat-soluble vitamins, such as vitamin K, and the decreased serum levels can lead to neonatal hemorrhage.²⁰

Gastroesophageal reflux disease occurs in approximately 50% to 80% of pregnant women, and decreased lower esophageal sphincter pressure (due to estrogen and progesterone causing smooth muscle relaxation) and increased intragastric pressure (due to the gravid uterus)

are the most likely etiologic factors.²¹ Therapy for gastroesophageal reflux disease in pregnancy includes lifestyle and dietary modifications (e.g., small, frequent meals, caffeine avoidance, food avoidance 3 hours before bedtime, elevation of the head of the bed) just as for nonpregnant patients and pharmacologic therapy for pregnant patients who do not receive adequate relief from nondrug therapies.²¹ Drug therapy for gastrointestinal reflux disease in pregnancy may be initiated with aluminum, calcium, or magnesium antacid preparations, although the use of sodium bicarbonate should be avoided because of the potential for causing electrolyte and fluid abnormalities in the mother and fetus. Magnesium trisilicate probably should be avoided as well because fetal renal, respiratory, cardiovascular, and muscular problems may occur with long-term, high-dose exposure. Sucralfate is another option for gastroesophageal reflux disease in pregnancy. Evidence also supports the use of ranitidine and cimetidine, but little literature is available regarding the use of famotidine and nizatidine in pregnancy.²¹ Combination antacids and nonprescription ranitidine have been shown in one small trial to be effective in patients unresponsive to antacids alone.²² If a patient does not respond to histamine-2 receptor blockers, lansoprazole and metoclopramide are also viable options for pregnant patients.²¹

The exact prevalence of hemorrhoids during pregnancy is unknown. Pathophysiologic causes of hemorrhoids during pregnancy may include constipation, venous dilation and engorgement due to pregnancy, and laxity of pelvic connective tissue.²⁰ Therapy of hemorrhoids during pregnancy is generally conservative; high intake of dietary fiber, adequate oral fluid intake, and use of sitz baths are helpful. Topical anesthetics, skin protectants, and astringents also may be used. Other options for refractory hemorrhoids include rubber band ligation, sclerotherapy, and surgery.²⁰

Nausea and vomiting affect up to 80% of pregnant women; however, hyperemesis gravidarum (i.e., severe nausea and vomiting requiring hospitalization for hydration and nutrition) occurs in only about 0.5% of pregnant women.²³ Possible causes of nausea and vomiting in pregnancy include elevated serum concentrations of human chorionic gonadotropin, estrogens and progesterone, prostaglandin E₂, *Helicobacter pylori* seropositivity, abnormal autonomic nervous system function and resulting abnormal peristalsis, elevated serum concentrations of thyroid hormones, and psychosocial factors. Dietary modifications such as eating frequent, small meals and avoiding fatty and fibrous foods may be helpful; acupressure and acustimulation also may be beneficial.²³

A number of pharmacotherapeutic approaches have been tried for the treatment of nausea and vomiting in pregnancy.^{23,24} Pyridoxine (vitamin B₆) and cyanocobalamin (vitamin B₁₂) also have shown efficacy.²⁵ Antihistamines (including doxylamine) have not been proved to be toxic during pregnancy and have shown efficacy in treating this disorder.²⁴ The anticholinergic agents dicyclomine and scopolamine have not been shown to increase fetal malformation rates above those expected in the general population; however, dicyclomine has no proven efficacy, and no trials exist that evaluate the effects of scopolamine for this disorder.²⁴ Phenothiazines, with the exception of one study, have not been shown to increase the risk of fetal malformation, and this drug class has demonstrated efficacy in treating nausea and vomiting in pregnancy. Metoclopramide has been used widely for nausea and vomiting in pregnancy, although no randomized clinical trials support its use; the drug has not been linked to an increased risk of malformations.²⁴ Limited efficacy and safety information is available regarding ondansetron use in pregnancy.²⁴ Ginger has shown efficacy for hyperemesis in a small trial and probably is safe to use for nausea and vomiting in pregnancy.²³ Corticosteroids (dexamethasone and prednisolone) have shown efficacy for

hyperemesis gravidarum, but a small increase in the risk of oral clefts may be associated with first-trimester use.²⁴

GESTATIONAL DIABETES

About 7% of pregnant women develop gestational diabetes, although the prevalence may range from 1% to 14% depending on the study population and tests used for diagnosis.²⁶ Whether or not to screen for gestational diabetes is an issue of significant controversy. The U.S. Preventative Services Task Force Independent Expert Panel has concluded that there is a lack of evidence to prove that screening for gestational diabetes decreases adverse maternal and fetal outcomes.²⁷ The American Diabetes Association, however, favors screening a woman who has risk factors for developing gestational diabetes mellitus (e.g., obesity, history of the condition, glycosuria, or a strong family history of diabetes) at her first prenatal visit.²⁶ If this screen is normal, testing should be repeated between weeks 24 and 28 of gestation. Pregnant women without these risk factors should undergo screening for gestational diabetes mellitus between weeks 24 and 28 of gestation unless they are considered low risk. To be low risk, a woman must fulfill *all* the following criteria: (1) age younger than 25 years, (2) normal prepregnancy weight, (3) no known diabetes in first-degree relatives, (4) not a member of an ethnic group with a high prevalence of gestational diabetes mellitus, (5) no history of abnormal glucose tolerance, and (6) no history of abnormal obstetric outcome.²⁶

Screening for gestational diabetes mellitus uses the oral glucose challenge test.²⁶ Initial screening involves measuring plasma glucose concentrations 1 hour after a 50-g oral glucose load; if the results are abnormal, a diagnostic 100-g oral glucose tolerance test should be completed. Of women with gestational diabetes mellitus, 80% will be identified if the glucose threshold value is more than 140 mg/dL; 90% will be identified if the glucose threshold value is more than 130 mg/dL.²⁶

According to the American Diabetes Association, first-line therapy for gestational diabetes mellitus includes nutritional and exercise interventions for all women and caloric restriction for obese women.²⁶ Daily self-monitoring of blood glucose levels is necessary for all women with this condition. If nutritional and exercise interventions fail to result in a fasting whole-blood glucose concentration equal to or less than 95 mg/dL and a 2-hour postprandial whole-blood glucose level equal to or less than 120 mg/dL, insulin therapy with recombinant human insulin should be instituted²⁶; glyburide may be considered after 11 weeks of gestation.²⁸ Women who require insulin therapy also should continue to monitor their glucose levels postprandially. Goals for self-monitored blood glucose levels while on insulin therapy are as follows: preprandial plasma glucose level, 80–110 mg/dL; 2-hour postprandial plasma glucose level, <155 mg/dL.²⁹

In contrast to the American Diabetes Association dietary recommendations, a Cochrane Review revealed that there is insufficient evidence to recommend dietary interventions for women with abnormal glucose tolerance in pregnancy.³⁰ Neither large-birth-weight deliveries nor need for cesarean delivery was influenced by adherence to dietary interventions for gestational diabetes.³⁰

CLINICAL CONTROVERSY

Despite a lack of evidence for benefit of screening for gestational diabetes or for implementation of dietary interventions as a therapy for gestational diabetes, many clinicians offer screening and dietary guidelines for women with impaired glucose tolerance results.

HYPERTENSION

In pregnancy, the spectrum of hypertension includes chronic hypertension, gestational hypertension, preeclampsia-eclampsia, and preeclampsia superimposed on chronic hypertension.³¹ Chronic hypertension is hypertension present either before pregnancy or before 20 weeks' gestation; gestational hypertension is blood pressure more than 140 mm Hg systolic or more than 90 mm Hg diastolic after 20 weeks' gestation. Preeclampsia-eclampsia is a syndrome consisting of gestational blood pressure elevation with proteinuria (i.e., ≥ 300 mg in a 24-hour urine collection). The syndrome is also suspected if proteinuria is absent, but the woman has gestational blood pressure elevation with symptoms of blurred vision, abdominal pain, headache, thrombocytopenia (platelet count $< 100,000$ cells/mm³), or elevated liver enzymes (alanine aminotransferase or aspartate aminotransferase or both). Edema is no longer part of the definition for preeclampsia. Eclampsia is defined as preeclampsia with seizures.³¹

A recent meta-analysis including 12,416 women at high-risk for preeclampsia (i.e., history of preeclampsia, chronic hypertension, diabetes, or kidney disease) revealed that 50 to 150 mg aspirin daily significantly reduced rates of perinatal death and preeclampsia.³² Rates of spontaneous preterm birth were decreased and mean birth weight increased by 215 g with aspirin therapy.³² No evidence exists for aspirin benefit for women at low risk for preeclampsia. Similar findings exist for calcium supplementation during pregnancy. An evidence-based review suggests that calcium may be beneficial in women at high risk of developing preeclampsia and in those who have low dietary calcium intake.³³

Non-drug therapeutic approaches for hypertension in pregnancy traditionally have focused on activity restriction, psychosocial therapy, and biofeedback. There is currently no evidence that any of these approaches improves pregnancy outcome, and prolonged bed rest may increase a pregnant woman's risk of venous thromboembolic disease.

Antihypertensive drug therapy for women with gestational hypertension or preeclampsia has not been shown to improve fetal outcomes.³¹ If antihypertensive drug therapy is required during pregnancy, methyldopa is preferred because of its established efficacy and safety for mother and fetus.³¹ Other alternatives include labetalol, β -blockers (except atenolol), prazosin, nifedipine, isradipine, hydralazine, clonidine, and diuretics.^{31,34} The cure for preeclampsia is delivery of the fetus if the pregnancy is at term. Preeclampsia may progress rapidly to eclampsia, a medical emergency, so weight, edema, and blood pressure must be monitored studiously in patients with preeclampsia. For acute severe hypertension in preeclampsia, parenteral hydralazine and labetalol in addition to oral nifedipine for hypertension control and magnesium sulfate for seizure prevention are standard therapy.³¹

THYROID ABNORMALITIES

Human chorionic gonadotropin may stimulate the thyroid gland because the structure of human chorionic gonadotropin is similar to that of thyrotropin.³⁵ Pregnant patients with excessive thyroid gland stimulation by this mechanism have gestational thyrotoxicosis. Thyrotoxic patients usually present with vomiting, which can be severe; an increased serum level of free thyroxine; and a depressed thyrotropin level. The degree of the thyroxine and thyrotropin abnormalities correlates with the severity of the vomiting, and no other findings are present to support the diagnosis of true thyrotoxicosis. Gestational thyrotoxicosis resolves with declining human chorionic gonadotropin concentrations at the completion of the first trimester.³⁵ Nausea and

vomiting may be treated as for patients without this pseudohyperthyroid state.

Within 3 to 6 months postpartum, women may experience either hypothyroidism or hyperthyroidism owing to thyroiditis secondary to autoimmune factors.^{35,36} The thyroiditis is usually self-limiting. This disorder is thought to occur in about 5% of postpartum women without a prior history of thyroid abnormalities. If women are asymptomatic, treatment is not indicated. Women who have hyperthyroid symptoms should undergo further testing to determine the cause of the disorder. If thyroiditis is suspected, only symptomatic treatment of hyperthyroid symptoms is indicated, although the patient should be monitored carefully because transient hypothyroidism may follow. Women who have both symptoms and laboratory evidence of hypothyroidism may be treated with thyroxine therapy, although the decision to initiate therapy depends on the degree of abnormality and symptoms. Again, careful monitoring is required because the condition usually resolves, and thyroxine therapy may be discontinued.^{35,36}

THROMBOEMBOLISM

The incidence of venous thromboembolism during pregnancy varies with age. In women younger than 35 years of age, the rate of thromboembolism is 6.15 events per 10,000 pregnancies; in women older than age 35, the rate is 12.16 events per 10,000 pregnancies.³⁷ Other major risk factors for thromboembolism during pregnancy include history of thromboembolism, hypercoagulable conditions, operative vaginal delivery or cesarean section, obesity, and a family history of thrombosis that suggests an inheritable hypercoagulable condition.³⁷

4 Therapy to prevent or treat venous thromboembolism during pregnancy must not include warfarin after the first 6 weeks of gestation because this drug may cause fetal bleeding, malformations of the nose, stippled epiphyses, or CNS anomalies.^{37,38} Low-molecular-weight heparins are the preferred agents for prophylaxis or treatment of venous thromboembolism during pregnancy. Unfractionated heparin also may be used but is associated with a higher incidence of heparin-induced thrombocytopenia and a lower lumbar spine bone mineral density than are the low-molecular-weight heparins.^{37,38} Dextran and hirudin should not be used in pregnancy.³⁷ Aspirin may offer some benefit in prevention of thromboembolism, but it is likely to be less effective than heparin. Compression stockings are recommended for prevention and treatment of venous thromboembolism.³⁷

CONCLUSIONS

Many women with pregnancy-influenced gastrointestinal issues can be treated safely with lifestyle modification or medications, many of them nonprescription. Gestational diabetes, hypertension, and thyrotoxicosis may or may not require drug therapy; venous thromboembolism usually will require therapy with a low-molecular-weight heparin and compression stockings.

ACUTE CARE ISSUES IN PREGNANCY

4 Acute illnesses that occur in pregnant women may present challenges for providers. In some cases, the risks associated with the illness may be magnified during pregnancy, and early screening and treatment become critical. Such is the case for asymptomatic bacteriuria, where the risk of progression to pyelonephritis may have profound effects on the health of both the mother and the infant. In other cases, such as in the treatment of certain sexually transmitted diseases, the urgency regarding treatment comes from an increased

likelihood of infection leading to preterm labor. Occasionally, common acute care issues, such as migraine headache, actually may improve during pregnancy. In all cases, it is important to select therapies that are effective and safe for the pregnant patient.

URINARY TRACT INFECTION

4 With an estimated incidence of 8%, urinary tract infections are common in pregnancy.³⁹ The American College of Obstetrics and Gynecology recommends a urine culture both at the initial prenatal visit and during the third trimester to screen pregnant women for such infections.⁴⁰ In contrast, the U.S. Preventive Task Force recommends a urine culture between 12 and 16 weeks' gestation. A urine culture is the preferred method for screening because other methods, such as dipsticks that measure leukocytes and esterase, may fail to identify as many as 50% of patients with asymptomatic bacteriuria.⁴⁰

As with the general population, *Escherichia coli* is the principal infecting organism, present in 80% to 90% of infections.⁴⁰ Other gram-negative rods, such as *Proteus mirabilis* and *Klebsiella pneumoniae*, also account for some infections. Group B *Streptococcus* bacteriuria is sometimes discovered in pregnant women and is associated with preterm delivery.⁴¹ The presence of group B *Streptococcus* in the urine also may correspond to heavy colonization of the genitourinary tract, increasing the risk for group B *Streptococcus* infection in the newborn. Treatment of group B *Streptococcus* bacteriuria at the time of discovery reduces the rate of preterm delivery from this infection. Additionally, women with group B *Streptococcus* bacteriuria also should receive antibiotics at the time of delivery to prevent infection in the newborn.⁴¹ (Please refer to group B *Streptococcus* under "Labor and Delivery" below.)

In general, urinary tract infections during pregnancy may occur as asymptomatic bacteriuria, acute cystitis, or pyelonephritis. Asymptomatic bacteriuria may be present in 2% to 7% of pregnant women.⁴³ The most worrisome aspect of asymptomatic bacteriuria is that approximately 25% of untreated pregnant women will develop a pyelonephritis, compared with only 3% to 4% of women who receive treatment. Other adverse effects of asymptomatic bacteriuria include increased risk for preterm labor and low birth weight. These adverse effects in both mothers and infants underscore the need for screening and treatment in the pregnant population.⁴³

Even though ampicillin and amoxicillin are considered safe medications for the treatment of asymptomatic bacteriuria, the incidence of *E. coli* resistance to these drugs may be 20% to 30%.^{39,40} Nitrofurantoin is considered safe and effective for use in pregnancy; cephalexin is also considered a good alternative. Sulfa-containing drugs may increase the risk for kernicterus in the newborn, and they should be avoided during the third trimester. Folate antagonists, such as trimethoprim, are relatively contraindicated during the first trimester of pregnancy. Fluoroquinolones and tetracyclines are contraindicated in pregnancy. The optimal duration of therapy for urinary tract infection in pregnancy has not been determined. Courses of 7 to 10 days are common, but some studies have demonstrated that shorter courses may be sufficient. A repeat culture to confirm cure is recommended.^{39,40}

Acute cystitis occurs in 0.3% to 1.3% of pregnancies.³⁹ In addition to having significant amounts of bacteria in the urine, women with acute cystitis complain of urinary frequency and pain.⁴⁰ The risks of low birth weight and preterm labor associated with acute cystitis have not been defined. Treatment for acute cystitis is the same as described for asymptomatic bacteriuria.⁴⁰

Acute pyelonephritis complicates 1% to 2% of pregnancies,³⁹ sometimes leading to maternal sepsis and preterm labor and

delivery.⁴⁰ Patients usually present with bacteriuria and systemic symptoms of fever, flank pain, nausea, and vomiting. Hospitalization often is necessary for pregnant women with pyelonephritis.⁴⁰ Inpatient therapy for pyelonephritis has included intravenous administration of cephalosporins (e.g., cefazolin) and ampicillin with gentamicin or the intramuscular administration of ceftriaxone. Outpatient antibiotic therapy for pyelonephritis may be considered if the woman is able to take medications orally and is not exhibiting symptoms of sepsis or preterm labor; cephalexin has been used for this purpose. The total duration of antibiotic therapy for acute pyelonephritis is 10 to 14 days.³⁹ This course may be followed by bedtime prophylaxis with nitrofurantoin for the duration of the pregnancy.³⁹

In summary, the early recognition of asymptomatic bacteriuria in pregnant women is an important primary prevention strategy in reducing morbidity and mortality from severe renal infections. Treatment of pregnant women requires careful consideration of medications with good efficacy and also low likelihood of risks to the infant. The aminopenicillins, cephalosporins, and nitrofurantoin often are viewed as first-line agents for most indications.

SEXUALLY TRANSMITTED DISEASES

4 Sexually transmitted diseases in pregnant women range from infections that may be transmitted across the placenta and infect the infant prenatally (e.g., syphilis) to organisms that may be transmitted during birth and cause neonatal infection (e.g., *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, or herpes simplex virus) to infections that pose a threat for preterm labor (e.g., bacterial vaginosis). In the case of bacterial infections, treatment will cure the infection. For viral infections, such as herpes, the goal is not cure but control of outbreaks at the time of delivery. Screening is essential for early detection of most sexually transmitted diseases but may not be beneficial in other instances (bacterial vaginosis in low-risk patients). Medications used to treat sexually transmitted diseases in pregnant women should be chosen to decrease risks to the fetus. In women with certain infections (e.g., syphilis, *N. gonorrhoeae*, *C. trachomatis*), sexual partners also will require treatment to prevent recurrence of infection.

SYPHILIS

It is recommended that all pregnant women be screened for syphilis at the first prenatal visit.⁴⁴ Additional testing may be warranted in areas where the prevalence of syphilis is high. Penicillin is the drug of choice for the treatment of syphilis during pregnancy and is effective in preventing transmission to the fetus as well as treating the fetus, if already infected. The dose and route of administration are determined by the stage of syphilis and are the same for pregnant women as for other patients. One special consideration is the issue that no alternatives for penicillin are acceptable for pregnant women allergic to penicillin. Erythromycin does not cross the placenta well enough to treat an infected fetus adequately. Penicillin skin testing and penicillin desensitization are required for the penicillin-allergic pregnant woman requiring treatment for syphilis.⁴⁴

N. GONORRHOEAE

N. gonorrhoeae cervicitis is a risk factor for preterm delivery, and treatment has been associated with a reduction of risk.⁴¹ Coinfection with *C. trachomatis* is common, and treatment of most *N. gonorrhoeae* infections also includes treatment for *C. trachomatis*. The treatment of choice for *N. gonorrhoeae* cervical infection during pregnancy is

ceftriaxone 125 mg intramuscularly as a single dose.⁴⁴ For women unable to use a cephalosporin, spectinomycin 2 g intramuscularly as a single dose is appropriate. The quinolones should be avoided in pregnant women.⁴⁴ (Please note that although the guidelines include cefixime as a treatment option, the drug is no longer manufactured.)

C. TRACHOMATIS

C. trachomatis is thought to be the most common sexually transmitted organism.⁴¹ The prevalence of infection with this organism in pregnant patients ranges from 5% to 26%. Transmission of *Chlamydia* at the time of delivery represents a risk of 10% to 20% for neonatal pneumonitis and 20% to 50% for conjunctivitis.⁴⁵ There is conflicting evidence for the association of *C. trachomatis* with an increased risk for preterm labor. The recommended treatment for *C. trachomatis* cervicitis is erythromycin base 500 mg four times daily for 7 days.⁴⁴ Erythromycin estolate should be avoided in pregnant women owing to an increased risk of hepatitis. Amoxicillin also may be used as an alternative treatment at a dose of 500 mg three times daily for 7 days. Azithromycin 1 g as a single dose also appears to be a safe and effective alternative treatment⁴⁴ (Table 76-1).

GENITAL HERPES

4 It is estimated that approximately one of every four women in the United States over the age of 12 is infected with genital herpes simplex virus 2.⁴⁶ A smaller number of people have infections caused by herpes simplex virus 1, which is more commonly associated with orolabial infections.⁴⁶

Primary infection in the mother occurs approximately 2 to 14 days after exposure.⁴⁶ Patients with a primary infection may be asymptomatic or may have vaginal discharge, pain, malaise, and other systemic symptoms. Recurrence of symptoms is common with people infected with herpes simplex virus 2, although subsequent outbreaks may be milder.⁴⁶

Infants born of infected women may come in contact with the virus as they move down the birth canal, and this may result in a severe or even life-threatening neonatal infection.⁴⁶ It is estimated that 1 in 350 infants is delivered vaginally during viral shedding, but the incidence of severe herpetic infection in the newborn is approximately 1 in 20,000.⁴⁶

Several factors may affect transmission from mother to infant.⁴⁶ The risk of transmission for an infant born to a mother with a primary infection is 30% to 50%. Conversely, the risk of transmission is less than 1% in women with a history of recurrent herpes at the time of delivery or in women who became infected during the first half of pregnancy.⁴⁴

TABLE 76–1. Recommended Regimens for Treatment of Cervical Infections Due to *Chlamydia* in Pregnancy

First-Line Treatment

Erythromycin base 500 mg orally four times a day for 7 days or
Amoxicillin 500 mg orally three times daily for 7 days.

Alternative Regimens

Erythromycin base 250 mg orally four times a day for 14 days or
Erythromycin ethylsuccinate 800 mg orally four times a day for 7 days or
Erythromycin ethylsuccinate 400 mg orally four times a day for
14 days or
Azithromycin 1 g orally, single dose

Ref. 44.

The goal for treating women with a history of genital herpes during pregnancy is to avoid exposure of the infant to infected lesions during the process of birth.⁴⁴

Women who have no signs or symptoms of an outbreak may deliver vaginally. Many physicians will recommend cesarean sections for women with outbreaks at the time of delivery. For women who newly acquire herpes near the end of their pregnancy, some specialist clinicians will recommend antiviral therapy, some will recommend cesarean section, and some will recommend both.⁴⁴

Of the agents available for treatment, acyclovir has had the longest period of use and has not demonstrated an increased risk of birth defects with first-trimester use.⁴⁴ More data will need to be collected to strengthen the safety data. Both valacyclovir and famciclovir are newer, and data on safety are more limited. Most women will receive oral acyclovir therapy for first episodes of genital herpes or with recurrence. Intravenous acyclovir can be used for severe infections.

CLINICAL CONTROVERSY

Some practitioners provide prophylaxis late in pregnancy with acyclovir for patients with a history of recurrent herpes. At the present time, it is unknown if this practice reduces the need for cesarean section.

BACTERIAL VAGINOSIS

Although not a sexually transmitted disease, bacterial vaginosis during pregnancy is a risk factor for premature rupture of membranes, preterm labor, preterm birth, and spontaneous abortion.⁴⁷ It is found in 9% to 23% of pregnant women.⁴⁷

Pregnant women with a history of preterm delivery should undergo screening for bacterial vaginosis at the first prenatal visit.⁴⁴ If the infection is present, the recommended regimen is metronidazole 250 mg three times a day for 7 days or clindamycin 300 mg twice a day for 7 days.⁴⁴

Conflicting data exist with regard to treating pregnant women at low risk for preterm labor.⁴⁴ Symptomatic women should be treated using the preceding metronidazole or clindamycin regimen. Vaginal creams have not been found to be effective in reducing the risk of adverse pregnancy outcomes associated with bacterial vaginosis.⁴⁴

CONCLUSIONS

One of the unifying themes in this section is the importance of treating genital infections in the pregnant mother not only for her care but also to reduce risks to the developing infant. Genital infections may infect the developing child in utero, may infect the developing child during birth, or may lead to preterm labor and its consequences. Drugs selected for use in pregnant women with genital infections are chosen to lessen risks to the developing child. Ironically, erythromycin may not be used to treat syphilis because it does not cross the placenta well, but it is the drug of choice for *Chlamydia* and is safe because it does not pass to the fetus. Tetracyclines are not used for pregnant women with *Chlamydia*, but other choices are available, including amoxicillin, which generally is not used in the general population as treatment for this condition.

HEADACHE

4 Headaches are common, acute care conditions reported by more than 80% of women of childbearing age.⁴⁸ Headaches in pregnant women can be classified into three different types: tension,

migraine, or secondary to an underlying disorder. Migraine and tension headaches are the most common types.⁴⁸

In more than 70% of pregnant women with a history of migraine headaches, symptoms will either improve or go into remission during pregnancy.⁴⁸ One explanation for this observation is that hormone levels stay consistently elevated during pregnancy. (The improvement in symptoms is more likely to occur in women whose migraine headaches are associated with hormone fluctuations during the menstrual cycle.) Migraines often have a tendency to worsen at the time of delivery and in the early postpartum period. New onset of migraines during pregnancy is rare.⁴⁸

Tension headaches have been less studied during pregnancy.⁴⁸ Some women have increases in tension headaches during pregnancy, whereas 25% report improvement. Since psychological and musculoskeletal stresses play a key role in tension headaches, nonpharmacological interventions serve as the treatment mainstay.⁴⁸

Acetaminophen is the drug of first choice for pain relief from migraine and tension headaches.⁴⁸ Nonsteroidal anti-inflammatory agents may be used during early pregnancy but generally are contraindicated after 37 weeks' gestation. Narcotics may be used for refractory migraine headaches. The use of sumatriptan in pregnant women is controversial, but some clinicians choose to continue use in women who have tried other agents for migraine headaches without success. Patients with nausea associated with migraine headaches may be treated with metoclopramide. Both ergotamine and dihydroergotamine should be avoided during pregnancy.⁴⁸

CHRONIC ILLNESSES IN PREGNANCY

4 Pharmacotherapeutic considerations in pregnant women with chronic conditions pose unique challenges. For the majority of women and their health care providers, pregnancy will be a new consideration for a previously diagnosed health condition. Medications used to treat the chronic illness potentially may be used throughout the pregnancy and during breast-feeding.

ALLERGIC RHINITIS, ASTHMA

4 Asthma and rhinitis represent two of the most common chronic illnesses in pregnant women. Although rhinitis itself is unlikely to cause harm to the mother or fetus, untreated rhinitis may be associated with a diminished quality of life. Asthma control may change during pregnancy, and worsening asthma may have significant health consequences to both the mother and the developing fetus. Use of medications is an integral part of providing care to pregnant women with these conditions.

It is estimated that asthma affects up to 4% of pregnant women.⁴⁹ Asthma severity can change during pregnancy, with an almost equal proportion of patients having their symptoms worsen, improve, or remain unchanged. Typically, asthma symptoms may exacerbate during the early part of the third trimester (weeks 24–36), but it is less common to see worsening of symptoms closer to the time of delivery.⁴⁹

Appropriate treatment of asthma is critical to the health of mother and infant.⁴⁹ Undertreated asthma in the mother is associated with preterm labor, gestational hypertension, preeclampsia, and uterine hemorrhage.⁵⁰ In the infant, intrauterine growth retardation, low birth weight, and congenital malformations may result from poor asthma control.

The goals for care of the pregnant woman with asthma are (1) birth of a healthy baby, (2) achievement of normal or near-normal pulmonary function, (3) lack of adverse effects of treatment, (4) control of symptoms without nighttime awakenings, (5) ability to

continue normal activities, (6) ability to exercise, and (7) avoidance of acute exacerbations.⁵¹ It is critical that the pregnant woman avoid things that may exacerbate asthma. Reducing exposure to allergens and irritants, such as cigarette smoke, are important nonpharmacologic interventions.⁵¹

The American College of Allergy, Asthma, and Immunology and the American College of Obstetrics and Gynecology published guidelines for the medical management of asthma during pregnancy in 2000.⁵¹ Anti-inflammatory therapy is the cornerstone of chronic asthma care. For pregnant women who need to add anti-inflammatory therapy to their regimen, inhaled cromolyn is recommended because of low toxicity and extensive clinical experience. For asthma unresponsive to cromolyn, inhaled budesonide or beclomethasone is recommended, again because of the clinical experience using these agents in pregnancy. For women using other inhaled corticosteroids effectively at the time they become pregnant, the guidelines suggest that continuation of current therapy is reasonable. Rescue medications, the inhaled β -agonists (e.g., terbutaline, metaproterenol, and albuterol), are considered safe in pregnancy. Oral theophylline has a long history of use and may be considered as add-on therapy to inhaled corticosteroids for moderate or severe persistent asthma, or alternatively, the inhaled long-acting β -agonist salmeterol may be used.⁵¹ Leukotriene antagonists may be continued if required prior to pregnancy to control asthma, but these agents are not considered drugs of choice in patients who have not used them prior to pregnancy. Oral corticosteroids are essential therapy for the treatment of severe, acute asthma and appear to be safe.⁵¹

The various forms of rhinitis—allergic, vasomotor, drug-induced, and bacterial sinusitis—are seen in more than 20% of pregnant women.⁴⁹ Vasomotor rhinitis of pregnancy is a unique condition caused by increased blood flow to the nasal turbinates. This condition peaks in the second trimester and generally resolves shortly after delivery. As with asthma, the first approach to treatment of rhinitis is avoidance of exacerbating factors, such as allergens, cigarette smoke, or strong odors. Irrigation of the nose with nasal saline also may be helpful. Occasional use of nasal decongestants, such as oxymetazoline, may be warranted, but frequent use may lead to rebound congestion.

Cromolyn nasal spray is considered a drug of first choice for treatment of chronic allergic rhinitis. Antihistamines also may be used during pregnancy. Chlorpheniramine and triproleamine have a long history of safety in pregnancy, but the nonsedating antihistamines loratadine or cetirizine also could be considered if the older drugs are not tolerated. Pseudoephedrine may be used as a decongestant, although a very rare gastrointestinal birth defect has been linked to its use. Nasal corticosteroids may be considered for pregnant women who do not respond to other therapies. As with asthma care, budesonide and beclomethasone nasal sprays are recommended as first-line choices because of longer clinical experience in the treatment of pregnant women. If the pregnant woman is receiving immunotherapy before pregnancy, it may be continued. Escalation of therapy or initiation of new therapy is not recommended during pregnancy.⁴⁹

CLINICAL CONTROVERSY

Selection of first-line therapy for allergic rhinitis and asthma and pregnancy is controversial. Topical corticosteroids are a well-established treatment in the general population as drugs of first choice for both conditions; corticosteroids also appear safe to use in pregnancy. However, guidelines still provide advice about use of less effective treatments that have a longer history of use in pregnancy for these conditions.

DERMATOLOGIC CONDITIONS

4 The treatment of dermatologic conditions during pregnancy often may be delayed until after the delivery. Sometimes, however, it is necessary to implement treatment during pregnancy. The major categories of medications used in dermatology are antiacne agents, antibiotics, antiviral agents, antihistamines, and antifungal agents.⁵² Of all the dermatologic agents used commonly during pregnancy, only topical nystatin has been shown to have no fetal risk in controlled studies. Recommended topical agents with minimal pregnancy risk include bacitracin, benzoyl peroxide, ciclopirox, clindamycin, erythromycin, metronidazole, mupirocin, permethrin, and terbinafine, among others. Topical corticosteroids are also thought to be safe for use in pregnancy. Systemic agents that may be used safely in pregnancy for dermatologic conditions include acyclovir, amoxicillin, azithromycin, cephalosporins, chlorpheniramine, cyproheptadine hydrochloride, dicloxacillin, diphenhydramine, erythromycin (except estolates), nystatin, and penicillin. Lidocaine and lidocaine with epinephrine may be used safely topically during pregnancy.⁵²

DIABETES

4 The American Diabetes Association recommends that women with diabetes defer pregnancy until the condition is under control with medication and lifestyle interventions.²⁹ This recommendation is based on knowledge of increased fetal loss and malformations resulting from suboptimally controlled diabetes. In addition, it is known that diabetic retinopathy may worsen, hypertension may develop, and renal function may deteriorate during pregnancy in diabetic patients. Enhanced monitoring for these target-organ problems is essential during pregnancy.²⁹

Insulin is the drug treatment of choice for patients with both type 1 and type 2 diabetes during pregnancy.²⁹ However, it may be acceptable to use glyburide after the eleventh week of gestation in patients with type 2 diabetes.²⁸ Medical nutrition therapy and supervised physical activity programs should be continued throughout pregnancy as well.²⁹ Goals for self-monitored blood glucose are as follows: preprandial plasma glucose level, 80 to 110 mg/dL; 2-hour postprandial plasma glucose level, <155 mg/dL.²⁹ These goals are the same as for gestational diabetes.

EPILEPSY

4 Maternal epilepsy is present in about 1% of all pregnancies.⁵³ About 35% of women with epilepsy experience an increase in seizure frequency during pregnancy, and approximately 65% of women experience no change or a decrease in seizure frequency. Seizures may become more frequent because of hormonal changes in pregnancy, sleep deprivation, and medication adherence problems⁵³ because of a perceived teratogenic risk of antiepileptic drug therapy. In addition, free serum concentrations of the antiepileptic drug may change during pregnancy as a result of maternal increased volume of distribution, decreased protein binding because of hypoalbuminemia, increased hepatic drug metabolism, and increased renal drug clearance.⁵³ A woman's clinical condition rather than solely the free serum concentrations of antiepileptic drug should be the basis for any adjustments in dosage. Postpartum concentrations also must be monitored because drug requirements probably will decrease as pregnancy-induced pharmacokinetic changes resolve. If a woman chooses to breast-feed, her antiepileptic drug requirements will not change until breast-feeding stops.⁵³

Major malformations occur in 4% to 6% of the offspring of epileptic women taking benzodiazepines, carbamazepine, phenobar-

bital, phenytoin, and valproic acid.⁵³ Minor malformations occur in 6% to 20% of pregnancies affected by epilepsy, which is twice the rate in the general population.⁵³ The malformations are considered a result of fetal exposure to antiepileptic drug therapy rather than a result of maternal epilepsy.⁵⁴ Combination regimens of antiepileptic drugs are associated with higher malformation rates.⁵⁴

For the management of pregnant women with epilepsy, the American Academy of Neurology has recommended the use of antiepileptic drug monotherapy, if possible, and optimization of any drug therapy prior to conception.⁵⁵ Medication change exclusively to minimize teratogenic risk, such as the prior recommendation to switch to phenobarbital from other antiepileptic drugs, is *no longer* recommended. If drug withdrawal is planned, it should be attempted at least 6 months before conception is attempted. In addition, all women with epilepsy should take folic acid supplementation of 0.4 to 5 mg daily.^{53,55} To correct vitamin K deficiency in newborns, 10 mg oral vitamin K₁ should be supplemented daily in the mother during the last month of gestation.⁵⁵

For women who remain on carbamazepine, divalproex sodium, or valproic acid, an α -fetoprotein check at 14 to 16 weeks' gestation and a level II ultrasound at 16 to 20 weeks' gestation are recommended to screen for neural tube defects.⁵⁵

HUMAN IMMUNODEFICIENCY VIRUS (HIV) INFECTION

4 Zidovudine is the mainstay of antiretroviral therapy and is recommended for use during pregnancy, labor, and delivery, as well as the postpartum period.⁵⁶ During pregnancy, the continuation of any other therapies that the woman may be taking, except for efavirenz and hydroxyurea, should be strongly considered. Additionally, inclusion of zidovudine is recommended after 14 weeks' gestation, whether it is added to the other agents or replaces another nucleoside analog. The current zidovudine dosing recommendation during pregnancy is 100 mg five times daily, 200 mg three times daily, or 300 mg two times daily; zidovudine should be initiated at 14 to 34 weeks' gestation and continued for the duration of the pregnancy. Intravenous zidovudine is recommended during labor, and the infant should receive the drug beginning 8 to 12 hours after birth and continued for the first 6 weeks of life.⁵⁶

A single dose of oral nevirapine administered to women at the beginning of labor and to newborns at 72 hours after birth may be an alternative to zidovudine, especially in developing countries.⁵⁷

HYPERTENSION

4 For women with stage 1 or 2 chronic hypertension (blood pressure 140 to 179 mm Hg systolic or 90 to 109 mm Hg diastolic), the decision of whether to continue or stop antihypertensive therapy during pregnancy is controversial because most of the increase in adverse fetal and maternal outcomes is due to preeclampsia superimposed on chronic hypertension.³¹ If medication is discontinued and women are monitored closely, therapy should be restarted if blood pressure exceeds 150 to 160 mm Hg systolic or 100 to 110 mm Hg diastolic or if target-organ damage is present. Alternatively, antihypertensive drugs may be continued during pregnancy (except for angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers) at the lowest effective dose. Use of diuretics is controversial, but the Working Group on High Blood Pressure in Pregnancy has determined that diuretic use is acceptable in women with chronic hypertension. When considering drug therapy in the treatment of chronic hypertension during pregnancy, the clinician and patient must

jointly assess the risks and benefits of any therapy. For women with severe hypertension (diastolic blood pressure ≥ 100 mm Hg), the benefit of drug therapy may outweigh the risks.³¹

No evidence exists for superior efficacy of one agent versus another for blood pressure reduction during pregnancy.³⁴ Occasionally, it may be necessary to consider changing from one agent to another prior to or during pregnancy, such as switching from an angiotensin-converting enzyme inhibitor before beginning the second trimester of pregnancy in order to reduce teratogenic risk.³⁴ However, some women may not tolerate medications other than those found to be efficacious prior to pregnancy, or the other drugs may not be as effective. In such cases, the risks and benefits of changing to a different agent solely for the purpose of avoiding teratogenicity must be considered carefully.

MENTAL HEALTH CONDITIONS

4 Nonpharmacologic and pharmacologic treatments for chronic mental health conditions during pregnancy are important for the health of mother and baby. Misunderstandings regarding the safety of certain psychotropic medications may result in undertreatment of pregnant women, resulting in potential harm to both mother and developing infant.

This point is clearly illustrated by a review of pregnant women who consulted the Motherisk Program, a counseling service for pregnant women and health providers, between 1996 and 1997.⁵⁸ All these women had decided to stop taking benzodiazepines or antidepressants when they learned they were pregnant. They were followed throughout the course of their pregnancies. Of the 44 women who agreed to be followed, 4 were lost to follow-up, and 3 others did not become pregnant during the study period. Thirty-four women stopped medications abruptly, and 3 used tapering methods. Nearly one-third of the women reported thinking about suicide for unbearable symptoms, and 4 needed to be hospitalized. One woman had a therapeutic abortion because of how she felt, and one woman used alcohol to deal with benzodiazepine withdrawal symptoms. Most women who discontinued medication did so with the advice of their health care provider. After consultation with Motherisk, approximately 60% of patients resumed medication. Two of these women experienced spontaneous abortions, one had a therapeutic abortion, and there were 35 live births (two sets of twins). All babies were reported to be healthy and normal. Two babies appeared to have mild medication (paroxetine and amitriptyline) withdrawal symptoms that did not require intervention.⁵⁸

DEPRESSION

The prevalence of depression in pregnant women is estimated to be approximately 10%.⁵⁹ Of these, one-third represent a new onset of the illness. Concerns about the safety of medications used to treat depression are common among health practitioners. However, untreated depression may, by itself, have adverse effects on the developing fetus, including preterm birth, low birth weight, small head circumference, and low Apgar scores. Nonpharmacologic approaches are an important component of care. Psychotherapy may be helpful alone or in conjunction with pharmacotherapy. Electroconvulsant therapy may be considered as an alternative to long-term use of medications or for women who fail to respond to pharmacotherapy. Safety of electroconvulsant therapy has been established in pregnancy.

Pharmacotherapy is required frequently by pregnant women for optimal treatment of depression. Potential fetal risks from medications used during pregnancy include (1) teratogenic effects from use early in pregnancy, (2) withdrawal symptoms after birth, and

(3) long-term neurologic consequences.⁵⁹ Tricyclic antidepressants have a long history of use in pregnant women. Both prospective and retrospective studies have found these agents to be safe for use in pregnancy. Desipramine and nortriptyline are recommended frequently for use because of fewer anticholinergic side effects (constipation) and less likelihood of orthostasis. Although less information is available with respect to the use of selective serotonin reuptake inhibitors (SSRIs), they are emerging as first-line agents in treating depression during pregnancy.⁶⁰ The largest body of information exists for fluoxetine and does not suggest an increased rate of major malformations.⁵⁹ Less information is available about other SSRIs, but a small prospective study of mostly users of citalopram and a retrospective review of a small group of users of paroxetine did not demonstrate an increase in risk for birth defects.

Decisions about the use of antidepressants during pregnancy need to be made jointly among the patient, her partner, and her health care practitioners.⁵⁹ For pregnant women with mild depression, it may be possible to discontinue drug therapy and continue psychotherapy. For women who relapse or have more severe forms of depression, it is reasonable to continue medications in conjunction with psychotherapy. Consideration may be given to switching medications to those with a better-understood safety profile. In a situation where a woman has tried several agents to find the optimal selection, it may be of value to continue that agent. Finally, although it is generally recommended that medications be used at the lowest dosage possible during pregnancy, it is very likely that doses of antidepressants actually may need to be increased during pregnancy to maintain therapeutic effect owing to changes in plasma volume, liver metabolism, and renal clearance.

Many of the selective serotonin reuptake inhibitors are well tolerated by breast-fed infants.⁶⁰ Fluoxetine has resulted in some reports of gastrointestinal problems, irritability, and insomnia.⁶⁰

MOOD DISORDERS

It is commonplace for women diagnosed with bipolar disorder to receive mixed messages from health care providers about the advisability of becoming pregnant or maintaining a pregnancy while under treatment for their psychiatric condition.⁶¹ Most of the medications used to treat mood disorders have known potential toxicities for the developing fetus. Patients require well-researched information from their providers to make informed decisions about the care they will need to optimize their own health and the health of their infants during pregnancy.

Bipolar disorder has a lifetime prevalence of approximately 1%.⁶¹ During pregnancy, untreated bipolar disorder may result in hospitalization, suicidal ideation, violence, loss of employment, malnutrition, and an increased risk of postpartum psychosis.⁶² It does not appear that pregnancy provides protection for the risk of recurrence of symptoms.⁶¹ Women who discontinue the use of mood stabilizing drugs abruptly before conception or who have had four or more episodes of recurrence of symptoms have a substantial risk for recurrence during pregnancy. Risk for recurrence in the first 3 to 6 months postpartum has been estimated at 20% up to 80%. Postpartum psychosis may occur in 10% to 20% of women with bipolar disorder.

A number of strategies have been used to optimize the use of medications in treating bipolar disorder in pregnancy.⁶¹ Patients who have had a single episode of mania with good recovery may be able to taper medication before conception. Those with multiple and frequent recurrences of symptoms (depression or mania) could attempt to discontinue medications before conception or wait until the pregnancy is diagnosed and then taper medications. Medications could be resumed if symptoms occur or after the first trimester to decrease the

risk of recurrence. For women who opt to discontinue medications and stay symptom-free throughout the pregnancy, postpartum prophylaxis with a drug such as lithium should be considered. Women with more severe forms of bipolar disorder may benefit most from continuing medications throughout the pregnancy.

The most commonly used mood-stabilizing medications used for the treatment of bipolar disorder include lithium, valproic acid, and carbamazepine. Each of these agents has unique therapeutic profiles to consider in the context of treatment of pregnant and lactating women.

Lithium

Lithium is currently considered the first-line medication for the treatment of bipolar disorder during pregnancy.⁶¹ Lithium's place in therapy has been controversial because of past concerns about cardiovascular anomalies, especially Epstein's anomaly, in exposed infants. With more recent reviews of epidemiologic data, the risk of Epstein's anomaly is estimated to be 0.05% to 0.1% in infants exposed during the first trimester. Other reported side effects in the newborn include cases of muscular hypotonia with impaired breathing and cyanosis ("floppy baby syndrome"), neonatal hypothyroidism, nephrogenic diabetes insipidus, atrial flutter, tricuspid regurgitation, and congestive heart failure.^{61,62} Long-term (5-year) behavioral follow-up in 60 children exposed to lithium during pregnancy did not reveal significant behavioral problems.⁶¹ Lithium concentrations in breast milk may be up to 40% of the serum concentration in the mother.⁶² Several case reports describe adverse effects in infants thought to be due to lithium use by lactating mothers. It is recommended that breastfeeding be partially or totally discontinued in mothers using lithium.⁶² The American Academy of Pediatrics considers lithium incompatible with breast-feeding.⁶¹

Valproic Acid

Valproic acid is associated with a 2- to 3-fold increase in the frequency of congenital anomalies.⁶² A 10- to 20-fold increase in the risk of spina bifida in infants born to women treated with valproic acid compared with the general population has been reported. The absolute risk of spina bifida in exposed infants appears to be 1% to 2%. Other problems associated with use in pregnancy include intrauterine growth retardation, hypoglycemia, and coagulopathy. Some investigators have reported developmental delays in up to 90% of children with prenatal exposure to valproic acid.⁶²

Strategies to reduce the risk of adverse reactions to valproic acid include using divided doses to minimize peak concentrations, recommending folic acid 4 mg to be started before conception and continuing until the twelfth week of pregnancy, prescribing 10 to 20 mg daily of vitamin K to the mother during the last month of pregnancy, and ensuring that the infant receives 1 mg vitamin K intramuscularly at birth to prevent hemorrhage. Valproic acid is excreted into the breast milk in concentrations ranging 2% to 8% of the serum levels of the mother. Several case reports of side effects in nursing infants have been reported, including anemia, thrombocytopenia, and hepatotoxicity. These reports are rare, and valproic acid is considered compatible with breast-feeding.

Carbamazepine

As with valproic acid, a 2- to 3-fold increase in the frequency of congenital malformations has been attributed to the use of carbamazepine.⁶² A 10-fold increase in the risk of spina bifida compared with the general population or an absolute risk of 1% has been described. Other birth defects reported from either monotherapy or combination therapy with other agents include facial roundness, nasal bridge defects, nail defects, and other head anomalies. Developmental

delay has been reported in up to 20% of children in prospective studies. Carbamazepine has been associated with vitamin K deficiency. Vitamin K and folate supplementation should be provided at doses similar to that with valproic acid. Carbamazepine use appears to be compatible with breast-feeding because it is found in breast milk in only very small quantity.

THYROID DISORDERS

4 Untreated hypothyroidism during pregnancy may result in significant cognitive and other neurologic deficits in the fetus. It also increases the risk of preeclampsia, premature birth, and low birth weight.^{35,36} The causes of hypothyroidism during pregnancy include autoimmune diseases such as Hashimoto's thyroiditis, iodine deficiency (uncommon in the United States), and thyroid dysfunction following surgery or ablative therapy for Graves' disease. Thyroid replacement therapy should be instituted if hypothyroidism is diagnosed during pregnancy; the goal is to attain normal thyrotropin concentrations. Women who receive thyroid replacement therapy prior to pregnancy can expect an increased dosage requirement of 25% to 50% during pregnancy. After delivery, maternal thyroid supplementation requirements decrease.^{35,36}

Hyperthyroidism during pregnancy may precipitate outcomes of fetal death, low birth weight, malformations, and maternal heart failure.^{35,36} Graves' disease is the most common cause of hyperthyroidism in pregnancy. Therapy for hyperthyroidism in pregnancy includes thioamides (e.g., propylthiouracil, methimazole) and surgery.^{35,36} Propylthiouracil historically was the preferred agent because it was thought to cross the placenta less readily and was less likely to cause fetal malformations; recent evidence does not support these tenets.³⁶ Iodine-131 is contraindicated in pregnancy owing to the risk of thyroid damage in the fetus.³⁶ The goal of therapy for hyperthyroidism in pregnancy is to attain free thyroxine index concentrations or free thyroxine concentrations in the upper end of the normal range; this allows for minimization of the thioamide dose.^{35,36} An additional factor that allows a reduction in the propylthiouracil dose is partial disease resolution as a result of the natural course of Graves' disease during pregnancy.³⁵

LABOR AND DELIVERY

The mechanism of labor onset has been elucidated in mammalian and nonhuman primate systems, but the sequence in humans is still unclear.⁶³ The transition from phase 0 (quiescence) to phase 1 (activation) may be explained by the loss of inhibition of uterine activity mediators, such as progesterone, prostacyclin, and others. Once activation occurs, oxytocin, prostaglandin E₂, and prostaglandin F_{2α} increase and stimulate contractions of the uterus.⁶³

PRETERM LABOR

Preterm labor is defined as cervical changes and uterine contractions that occur before 37 weeks' gestation.^{63,64} In the United States, the incidence of preterm births is 11% despite a strong national effort to decrease the incidence of preterm labor.⁶⁵ Accounting for 35% of health care spending on infants, preterm labor is the leading cause of infant morbidity and mortality.^{63,65} Risk factors for preterm delivery include previous preterm delivery, infections (e.g., bacterial vaginosis, upper and lower urinary tract infections, and sexually transmitted infections), multiple gestation, poverty, nonwhite race, maternal complication factors (e.g., smoking and use of illicit drugs or

alcohol), uterine functional causes (e.g., incompetent cervix and uterine septum), and fetal causes (e.g., congenital anomalies and growth retardation).⁶³

Despite knowledge of the risk factors for preterm labor, there have not been good tests to monitor and prevent preterm labor. No evidence supports the use of routine cervical assessments or home monitoring of uterine activity to improve outcomes.^{63,64} The presence of fetal fibronectin, an extracellular protein in cervical and vaginal secretions, in the cervix or vagina after 20 weeks is associated with a threefold risk of preterm delivery.⁶⁴ Also, a cervical length of <30 mm is associated with increased risk of preterm delivery. However, fetal fibronectin determinations and cervical ultrasonography have not helped to prevent preterm labor but have been more useful for their negative predictive value.⁶⁶

TOCOLYTIC THERAPY

The management of preterm labor has centered on the use of tocolytic drugs. The goal of tocolytic therapy is to postpone delivery long enough to reduce the incidence of problems associated with prematurity. Tocolytics have not been shown to reduce the number of premature deliveries, but they may allow sufficient time for the administration of antenatal corticosteroids to improve pulmonary maturity and for transportation of the mother to a facility equipped to deal with high-risk deliveries.^{63,64}

Tocolytic therapy should not be used in cases of intrauterine infection, fetal distress, severe preeclampsia, vaginal bleeding, and maternal hemodynamic instability.⁶⁴ The criteria for starting tocolysis are regular uterine contractions with cervical change. In women with cervical dilatation >3 cm, tocolytic therapy is less effective.⁶⁴

There are five classes of tocolytic therapy: β -adrenergic agents, calcium channel blockers, magnesium, nonsteroidal anti-inflammatory agents, and ethanol.⁶⁵ The first four therapies are similar in effectiveness for prolonging pregnancy from 48 hours to 1 week. Ethanol has not been shown to be effective in prolonging pregnancy.⁶⁵

The β -adrenergic agents terbutaline and ritodrine have been the first-line in tocolytic therapy.^{64,65} (Of the two, only ritodrine has FDA approval for this use, but it was withdrawn from the market in 1997 and 1998 because the manufacturers were no longer interested in producing the drug.⁶⁵) These drugs reduce intracellular calcium levels and reduce the sensitivity of the contractile unit to calcium.⁶⁴ Relative to other agents, β -agonists have a higher incidence of maternal side effects, including hyperkalemia, arrhythmias, hyperglycemia, hypotension, and pulmonary edema. Recommended terbutaline doses range from 250 to 500 mcg subcutaneously every 3 to 4 hours.⁶⁴

Magnesium sulfate may be used in an intravenous infusion as a tocolytic agent. Its mechanism of action is to suppress nerve impulses to the uterine smooth muscles by antagonizing intracellular calcium.⁶⁴ Maternal side effects are rare but can include pulmonary edema. At toxic levels, hypotension, muscle paralysis, tetany, cardiac arrest, and respiratory depression may occur.⁶⁴

Nifedipine is associated with fewer side effects than magnesium or β -agonist therapy.^{64,65} A few studies have suggested that calcium channel blockers are better at prolonging labor than β -agonists.⁶⁵ One of the concerns regarding the use of nifedipine is the potential negative effect on blood flow between the placenta and the uterus. However, a meta-analysis has not shown increased harm to infants in the calcium channel blocker group.⁶⁵ With the initial diagnosis of preterm labor, 5 to 10 mg nifedipine may be administered sublingually every 15 to 20 minutes for three doses. Once the patient is stabilized and there is no evidence of continuing cervical dilatation, 10 to 20 mg

nifedipine may be administered by mouth every 4 to 6 hours for preterm contractions.⁶⁴

Nonsteroidal anti-inflammatory agents such as indomethacin also have been used for tocolysis. The mechanism of action is to inhibit cervical prostaglandin activity.⁶⁴ The drug is first given orally or rectally in a dose of 50 to 100 mg, followed by an oral dose of 25 to 50 mg every 6 hours.⁶⁴ An increased rate of premature constriction of the ductus arteriosus has been noted in infants.⁶⁵

Because infection has been thought to play a role in the etiology of preterm labor, antibiotics have been used, in addition to tocolytics and corticosteroids, to improve the outcome of preterm labor.⁶⁷ Most studies of antibiotic use in preterm labor do not demonstrate a reduction in the incidence of preterm delivery, and a meta-analysis shows a trend toward neonatal mortality in those who receive antibiotics.⁶⁷ Routine use of antibiotics therefore is not recommended.

CLINICAL CONTROVERSY

After acute tocolysis has been achieved, continuation of tocolytic therapy is controversial. Maintenance therapy with tocolytics has not been shown to be of value.⁶⁵ However, some clinicians will use maintenance tocolytics such as β -agonists or nifedipine to treat patients who experience frequent contractions without cervical change.⁶⁵

ANTENATAL CORTICOSTEROIDS

4 A number of clinical trials have demonstrated the benefit of administering antenatal corticosteroids for the prevention of respiratory distress syndrome, intraventricular hemorrhage, and death in infants delivered prematurely.⁶⁸ The current clinical recommendation is to administer betamethasone 12 mg intramuscularly every 24 hours for two doses or dexamethasone 6 mg intramuscularly every 12 hours for four doses to pregnant women between 24 and 34 weeks' gestation who are at risk for preterm delivery within the next 7 days.⁶⁸ Benefits from antenatal corticosteroids are believed to begin within 24 hours. It has been found that repeat corticosteroid administration does not produce any improvement in outcomes for infants and may trend toward harm.⁶⁹

GROUP B STREPTOCOCCUS INFECTION

4 Maternal infection with group B *Streptococcus* is associated with invasive disease in the newborn.⁷⁰ Women colonized with group B *Streptococcus* during pregnancy have an increased risk of premature delivery and transmission of the bacteria to the infant during delivery. Between 10% and 30% of pregnant women are colonized with group B *Streptococcus*.⁷⁰

With active prevention efforts in the 1990s, the incidence of early-onset disease is now 0.5 cases per 1000 births, decreased from 1.8 cases per 1000 births.⁷⁰ There has not been any change in the incidence of late-onset group B *Streptococcus* disease, which remains consistent at 0.35 cases per 1000 births.⁷⁰ The consequences of neonatal infections include bacteremia, pneumonia, and meningitis in the newborn. The case-fatality rate is approximately 4%.⁷⁰

In 2002, the Centers for Disease Control and Prevention revised the recommendations for the prevention of group B *Streptococcus* infection.⁷⁰ Instead of the risk-based screening strategy that was developed in 1996, the Centers for Disease Control and Prevention now recommends universal prenatal screening for group B *Streptococcus* colonization of all pregnant women at 35 to 37 weeks' gestation. Vaginal and rectal cultures should be obtained at 35 to 37 weeks'

gestation. If the cultures are positive, if the woman had a previous infant with invasive group B *Streptococcus* disease, or if the woman had group B *Streptococcus* bacteriuria, antibiotics are given. If negative, no antibiotics are given. If a woman presents for delivery and no screening information is available, antibiotics are given for fever of 100.4°F or greater, for membrane rupture of 18 or more hours, or if less than 37 weeks' gestation.⁷⁰

The currently recommended regimen for group B *Streptococcus* disease is penicillin G 5 million units given intravenously, followed by 2.5 million units given every 4 hours until delivery.⁷⁰ Alternatively, ampicillin 2 g may be given intravenously, followed by 1 g every 4 hours. If the patient is penicillin-allergic and not at risk for anaphylaxis, cefazolin 2 g intravenously, followed by 1 g every 8 hours, should be used. In patients at high risk for anaphylaxis, clindamycin 900 mg intravenously every 8 hours or erythromycin 500 mg intravenously every 6 hours should be used. In the case of penicillin-allergic women, the group B *Streptococcus* cultures should be sent for sensitivities. If the group B *Streptococcus* is resistant to clindamycin or erythromycin, the woman should receive vancomycin 1 g intravenously every 12 hours until delivery.⁷⁰

CERVICAL RIPENING AND LABOR INDUCTION

Throughout most of pregnancy, the cervix is closed and firm.⁷¹ During the last few weeks of pregnancy, the cervix becomes softer and thinner to facilitate labor. This process is mediated by hormonal changes, including final mediation by prostaglandins E₂ and F_{2α}, which cause an increase in the collagenase activity in the cervix leading to thinning and dilatation.⁷¹

The rate of pregnancy induction ranges from 9.5% to 33.5%.⁷¹ The most common reason for induction is postdatism (>42 weeks), which occurs in 10% of all pregnancies.⁷² Other reasons for induction include suspected fetal growth retardation, maternal hypertension, premature rupture of membranes with no active onset of labor, or social factors. Contraindications for induction include placenta previa, oblique or transverse lie, pelvic structure abnormality, prolapsed umbilical cord, and active herpes. The concerns associated with induction of labor are that the labor may be ineffective or that side effects such as uterine hyperstimulation may adversely affect the infant, increasing the likelihood of cesarean section.

A scoring system has been used to determine the likelihood of successful labor induction. The most commonly used system is the Bishop scoring system, which was based originally on the labor patterns of multiparous women. The score is based on five parameters: cervical dilatation, cervical effacement (thinning), station of the baby's head, consistency of the cervix, and position of the cervix. A Bishop score of less than 6 means that a patient requires cervical ripening, and a score of greater than 8 means that the patient most likely will have a successful vaginal delivery.⁷¹

There are a number of nonpharmacologic methods for cervical ripening. Castor oil, hot baths, sexual intercourse, and nipple stimulation all have been recommended for labor induction. However, there is minimal evidence to support the efficacy of these methods.⁷¹ The use of a Foley catheter placed in an unfavorable cervix for ripening has been found as effective as prostaglandin E₂. A safe and inexpensive method, membrane stripping, is particularly of value.⁷¹

Herbal supplements also have been used to induce labor. The most commonly mentioned agents are evening primrose oil, black haw, black and blue cohosh, and red raspberry leaves.⁷¹ Midwives have been the most common group of clinicians using these agents. Currently, there is no evidence to support the safety and efficacy of herbal agents.⁷¹

Prostaglandin E₂ analogs (e.g., dinoprostone, Prepidil, and Cervidil) are commonly used pharmacologic agents for cervical ripening. Prepidil gel is administered intracervically in a dose of 500 mcg. This may be repeated after 6 hours with up to three doses in 24 hours.⁷¹ After administration, the patient remains supine for 30 minutes. Cervidil, a vaginal insert, contains 10 mg dinoprostone with a slower, more constant release of medication than the gel. The insert may be removed when labor begins or after a maximum of 24 hours. Patients must be on a fetal heart rate monitor for the duration of the use of Cervidil and for 15 minutes after its removal.⁷¹

Misoprostol, a prostaglandin E₁ analog, is an effective and inexpensive method for cervical ripening and labor induction.⁷³ Misoprostol is not approved by the FDA for cervical ripening, and the manufacturer has no interest in pursuing this indication. Because labor induction is not an indicated use of this agent, and because of its association with uterine rupture, some hospitals have discontinued its use as an induction agent. Intravaginal administration of 25 mcg misoprostol every 4 hours for up to six doses is more effective than other prostaglandin agents and results in a shorter time to delivery. The most commonly encountered side effects are uterine hyperstimulation and meconium-stained amniotic fluid. The use of misoprostol is contraindicated in women with a previous uterine scar because of its association with uterine rupture, a catastrophic medical event.⁷³

Mifepristone is an antiprogesterone agent that is currently being studied as an induction agent.⁷¹ Preliminary studies show that mifepristone compared with placebo results in a shorter time to delivery and fewer cesarean sections.⁷⁴ There is little information on fetal and maternal outcomes because of the small sample sizes.⁷⁴

Oxytocin is the most commonly used agent for labor induction after cervical ripening. At the end of pregnancy, the number of oxytocin receptors has increased by 300-fold.⁷¹ A solution of 10 milliunits/mL is used for infusion. Oxytocin has been shown to be effective in both low-dose (physiologic) and high-dose (pharmacologic) regimens.⁷¹

LABOR ANALGESIA

During the first phase of labor, women perceive a visceral pain associated with uterine contractions; during the second phase, the pain is associated with perineal stretching.^{75,76} Pain perception is variable from woman to woman as a result of physiologic, psychosocial, cultural, and environmental influences.⁷⁵

NONPHARMACOLOGIC APPROACHES TO ANALGESIA

A number of nonpharmacologic strategies have been used to reduce the pain of childbirth. Women who receive continuous support from a doula, a laywoman trained in labor support, have a decrease in operative vaginal deliveries, cesarean deliveries, and requests for pain medication.⁷⁵ Intermittent support from a caregiver and continuous support from nursing staff have not been shown to affect birth outcomes.⁷⁵ Warm water baths provide temporary pain relief but have not been shown to decrease the use of pharmacologic pain treatments.⁷⁵ Intradermal injections of sterile water in the sacral area have been shown to decrease back pain during labor for 45 to 90 minutes. However, there was no decrease in requests for pain medication.⁷⁵

PHARMACOLOGIC APPROACHES TO LABOR PAIN

In 2000, the American College of Obstetrics and Gynecology, along with the American Society of Anesthesiologists, published a joint

position statement on pain in labor. They stated that labor results in severe pain and that if a woman requests pain medications, it is a medical indication to receive pain relief.⁷⁷ Two main types of pharmacologic methods exist in the United States: parenteral opioids and epidural analgesia.

Between 39% and 56% of women in the United States receive parenteral narcotics to alleviate labor pain.⁷⁷ Meperidine, morphine, and fentanyl are the most commonly used agents. In comparison with epidural analgesia, parenteral opioids have lower rates of oxytocin augmentation, result in shorter stages of labor, and require fewer instrumental deliveries.⁷⁷ However, women are less satisfied with their pain relief with parenteral opioids than with epidural analgesia.⁷⁷

Approximately 60% of women choose an epidural for pain relief during labor.⁷⁶ Epidural analgesia involves introducing a catheter into the epidural space and administering a drug (e.g., bupivacaine or fentanyl) to provide pain relief during labor. Another method is the combined spinal-epidural, in which a single bolus of an opioid is injected into the subarachnoid space, providing instant pain relief, and placement of an epidural catheter with a local anesthetic. Women who receive epidural anesthesia report better pain relief than those with other modalities.^{76,77} Epidural analgesia is associated with prolongation of the first and second stages of labor, higher numbers of instrumental deliveries, and maternal fever.^{76,77} A rare complication of epidural anesthesia is a puncture of the subarachnoid space leading to a severe headache. This occurs in approximately 2% of women.⁷⁶ Other complications include hypotension, nausea, vomiting, itching, and urinary retention. Low back pain has not been shown to be associated with the use of epidural analgesia.⁷⁶

Paracervical blocks using local anesthesia may decrease pain associated with the first phase of labor.⁷⁷ However, these types of blocks have been associated with fetal bradycardia and are used rarely in clinical practice.

Finally, nitrous oxide is not used in the United States but is a common analgesic in many developed countries.⁷⁷ A 50-50 blend of nitrous oxide and oxygen is the most commonly used mixture. Women can self-administer the medication or receive it continuously under medical supervision. Women report significant pain relief.⁷⁷ The side effects include nausea, vomiting, and poor recall of labor.⁷⁷

CLINICAL CONTROVERSY

Many clinicians believe that epidural analgesia is associated with a higher number of cesarean deliveries. However, two systematic reviews have not substantiated an increased rate of cesarean delivery with epidural analgesia compared with parenteral opioids. One of the reviews, however, cautioned that there may not be sufficient data to rule out such an association.⁷⁷

POSTPARTUM ISSUES

DRUG USE DURING LACTATION

5 Although most drugs will diffuse into breast milk, there are very few instances where breast-feeding has to be discontinued. Health care providers should encourage breast-feeding women who need to use medications to continue breast-feeding whenever possible. Medications that require the mother to pump and discard milk are few.

There is strong evidence for the benefits associated with breast-feeding. Breast milk has the perfect composition of nutrients, growth factors, enzymes, immune factors, and hormones for infants.⁷⁸

Breast-fed infants have fewer respiratory illnesses, allergies, otitis media, lymphoma, and gastroenteritis than do bottle-fed infants. There also may be improved neurologic development in breast-fed infants.⁷⁸

There are also benefits for the nursing mother.⁷⁸ Women who breast-feed infants lose the weight gained during pregnancy more quickly, postpone resumption of their menstrual periods, and have a decreased risk of ovarian cancer, premenopausal breast cancer, and osteoporosis.⁷⁸

Nursing mothers typically produce 600 to 1000 mL per day of milk for their infants.⁷⁹ The transfer of medication ingested by the mother into the breast milk occurs by passive diffusion of nonionized and non-protein-bound medication.⁸⁰ The higher the concentration of drug in the mother's serum, the higher the concentration will be in the breast milk. Drugs with higher molecular weights, lower lipid solubility, or higher protein binding are less likely to cross into the breast milk. As mother's serum concentration drops from metabolism and excretion of drug, the concentration of drug in the breast milk may redistribute back into the mother's bloodstream.⁸⁰

Several factors influence the amount of drug an infant will receive through breast-feeding.⁷⁸ The amount of milk produced, the composition of the milk (mature milk versus colostrum), the concentration of the medication, and the extent to which the breast was emptied during a previous feeding session will influence the amount of drug the infant ingests.⁷⁸

Infants also may vary in their ability to absorb, metabolize, and excrete ingested medication.⁷⁸ Premature and full-term infants may not have optimal liver function for the first 2 weeks of life.⁷⁹ Kidney function in full-term infants does not reach maturity until 2 to 4 months of age. Older infants may receive calories from other sources besides breast milk and actually ingest less total drug.⁷⁸

Safety of a drug in pregnancy does not always ensure safety for breast-feeding, but the converse also may be true.⁸⁰ Fortunately, most of the medications listed in the position statement from the American Academy of Pediatrics are compatible with breast-feeding.⁸⁰

Strategies to reduce the amount of drug transferred to the infant may include selection of medicines that also would be considered safe to use in the infant and use of topical medications, if possible.⁸⁰ Medications that have shorter half-lives tend to accumulate less, and those which are more protein bound do not cross into breast milk as well. Drugs with lower oral bioavailability and lower lipid solubility are also good choices. If the mother is using a once-daily medication, administration at bedtime may be advised to increase the interval to the next feeding. For medications taken multiple times per day, administration of medication immediately after a breast-feeding session also will give the longest interval to allow backdiffusion of drug from the breast milk as the mother's serum concentration decreases.⁸⁰

MASTITIS

Women who experience mastitis often will feel fatigued initially, note breast tenderness, and complain of flulike symptoms.⁸¹ Often the breast tenderness affects one breast only and generally is localized to the upper outer quadrant. The highest incidence of mastitis occurs within 1 to 2 weeks of beginning breast-feeding.⁸² The risk of developing mastitis may be higher in situations where the feeding pattern has been altered, the number of feedings per day has decreased, the first breast is not emptied before switching to the other side, the infant is latching on poorly, the mother is overproducing milk, or the child or mother is ill.

Staphylococcus aureus is the most common organism associated with mastitis.⁸² Antibiotics that are used for treatment of mastitis include penicillinase-resistant penicillins (e.g., cloxacillin,

dicloxacillin, and oxacillin) and cephalosporins (e.g., cephalexin). Antibiotics are often given for 10 to 14 days. Anti-inflammatory agents, such as ibuprofen, also may be considered for pain. Prevention of recurrence includes strategies to transfer milk such as frequent feedings or pumping and reduction of breast inflammation.⁸²

POSTPARTUM DEPRESSION

Postpartum major depression has been reported to affect 12% to 16% of women; the incidence may be up to 26% in adolescent women.⁸³ The actual incidence of postpartum major depression varies in reports and may depend on the time after delivery that depression screening is conducted.

Both nondrug and drug options exist for the treatment of postpartum depression. Nondrug therapies include emotional support from family and friends, education about the condition, and psychotherapy. Bright-light therapy (effective for seasonal affective disorder and non-seasonal depression) also may provide benefit.⁸⁴ Pharmacologic therapy may need to be initiated because untreated depression may have negative effects on the mother's care of and relationship with the infant.⁸³ Guidelines for postpartum antidepressant use include (1) careful drug selection taking into account patient factors and available literature related to potential adverse effects in breast-feeding infants, (2) continual monitoring of drug dosage needs as related to efficacy and potential toxicity of the drug, (3) use of an agent that is known to result in limited infant exposure, (4) use of a single agent whenever possible, (5) continual assessment of possible infant toxicity from a drug, and (6) attention to pharmacokinetics of an agent as related to administration of the agent in relation to breast-feeding as well as selection of an agent with few or no active metabolites.⁸³ The most common medications used to treat postpartum major depression include selective serotonin reuptake inhibitors and tricyclic antidepressants. The small number of case reports and studies published to date suggest the relative safety of these agents for breast-feeding infants.⁸³

RELACTATION

Declining serum prolactin concentrations cause a decrease in or cessation of lactation, and this can be problematic, as well as distressing, for mothers who desire to breast-feed their infants. Relactation is the process of increasing the breast milk supply for such women.⁸⁵ Lactation also can be induced in women who have not recently delivered a baby, such as adoptive mothers. The mainstay of therapy for this condition involves nipple stimulation either by the infant's nursing or by pumping of the breast with a mechanical pump or the hand.⁸⁵ One small study showed that a substance in beer and nonalcoholic beer can stimulate prolactin secretion and thus increase milk production.⁸⁶

Recommended pharmacologic therapy in the United States for relactation is metoclopramide, which should be used only if nondrug therapy is ineffective.⁸⁵ The most commonly used dose is 10 mg taken orally three times daily for 7 to 14 days. Breast milk production can be increased up to 100% or more in women who are 1 month postpartum or less; in mothers who are 8 to 12 weeks postpartum, milk production may be increased up to 40%. Breast milk production may decrease after metoclopramide therapy is discontinued, but if lactation has been established successfully, it will continue.⁸⁵

CONCLUSIONS

Providing pharmacologic care to women during pregnancy can be rewarding and, at times, difficult. Many women perceive a high inherent

risk of birth defects with drug exposure during pregnancy. This perception, linked with a high rate of unplanned pregnancies, may create anxiety because of drug exposure prior to the discovery of pregnancy.

Some medications are considered to be safe for use in pregnancy because of frequent use with no apparent increase in the rate of congenital problems. Women using these medications should be reassured that these choices are unlikely to increase the risk of birth defects. In some cases, medications that have been associated with a higher risk of adverse effects to the fetus will need to be selected or continued to ensure the health of the mother and, in some instances, the fetus. In these instances, realistic information about types and likelihood of adverse effects will aid the patient and her family in making decisions.

Health care providers who care for pregnant women need to work in collaboration to seek, evaluate, and present the most contemporary information to their patients. Use of technology to access evidence-based resources, databases related to drug use in pregnancy, and primary literature may assist health care practitioners in accessing relevant medication information to manage drug therapy needs during pregnancy and lactation.

CONTRACEPTION

Lori M. Dickerson and Kathryn K. Bucci

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The attitude of both the patient and the sexual partner toward various contraceptive methods, the reliability of the patient in using it correctly (which may affect the effectiveness of the method), and the patient's ability to pay must be considered carefully when selecting a contraceptive method.
- 2 Patient-specific factors (e.g., frequency of intercourse, age, smoking status, and concomitant diseases, conditions, or medications) that may prove to be a consideration or precaution for use of a specific method must be evaluated when selecting a contraceptive method.
- 3 Side effects or difficulties using the chosen method should be monitored carefully and managed in consideration of patient-specific factors.
- 4 The utility and satisfaction of the patient and partner(s) with a contraceptive method must be reevaluated periodically.
- 5 Many practitioners recommend progestin-only contraceptives for breast-feeding women because progestins provide effective contraception without diminishing the amount of breast milk produced.
- 6 Accurate and timely counseling on the optimal use of the contraceptive method and strategies to minimize sexually transmitted diseases must be provided to all patients when contraceptive pharmacotherapy is initiated and on an ongoing basis.
- 7 Certain oral contraceptives in high doses can be used as emergency contraception to prevent pregnancy after unprotected intercourse. Administration must occur within 72 hours of unprotected intercourse with a follow-up dose 12 hours after the first.

Unintended pregnancy is a significant public health problem with economic, health, personal, and social consequences. The most recent data reveal that 49% of pregnancies are unintended and that 54% of unintended pregnancies end in abortion. Between 1987 and 1994, the unintended pregnancy rate dropped by 16%, from 54 to 45 per 1000 women of reproductive age.¹ Slightly more than half these unintended pregnancies occurred in the 94% of sexually active couples who claimed to use some method of contraception.² If the goal of contraception is that pregnancies are planned and desired, education about the use and efficacy of contraceptive methods must be improved.

ETIOLOGY AND PATHOPHYSIOLOGY

Comprehension of the hormonal regulation of the normal menstrual cycle is essential to understanding contraception in women. The cycle of menstruation begins with menarche, usually around age 12, and continues to occur in nonpregnant women until menopause; usually around age 50.^{3,4} The cycle includes the vaginal discharge of sloughed endometrium called *menses* or *menstrual flow*. Three phases comprise the menstrual cycle: the follicular (or preovulatory), the ovulatory, and the luteal (or postovulatory).^{3,4}

THE MENSTRUAL CYCLE

The first day of menses is referred to as *day 1 of the menstrual cycle* and marks the beginning of the follicular phase.^{3,4} This continues until

ovulation, which typically occurs on day 14. The time after ovulation is referred to as the *luteal phase*, which lasts until the beginning of the next menstrual cycle. The median menstrual cycle length is 28 days, but it can range from 21 to 40 days. Generally, variation is greatest and follicular and luteal phases are longest in the years immediately after menarche and before menopause, when anovulatory cycles are more common.⁵

The menstrual cycle is influenced by the hormonal relationships between the hypothalamus, anterior pituitary, and ovaries³ (Fig. 77-1). In response to epinephrine and norepinephrine stimulation, the hypothalamus secretes gonadotropin-releasing hormone (GnRH) in a pulsatile fashion every 60 to 90 minutes.^{3,4} These GnRH bursts stimulate the anterior pituitary to secrete bursts of gonadotropins, follicle-stimulating hormone (FSH), and luteinizing hormone (LH). These gonadotropins, FSH, and LH direct events in the ovarian follicles that result in the production of a fertile ovum.

FOLLICULAR PHASE

In the first 4 days of the menstrual cycle, FSH levels rise and allow the recruitment of a small group of follicles for continued growth and development^{3,4} (Fig. 77-2). Between days 5 and 7, one becomes the dominant follicle, which will later rupture and release the oocyte. The dominant follicle develops increasing amounts of estradiol and inhibin, which cause a negative feedback on the hypothalamic secretion of GnRH and pituitary secretion of FSH, causing atresia of the remaining follicles recruited during the cycle.

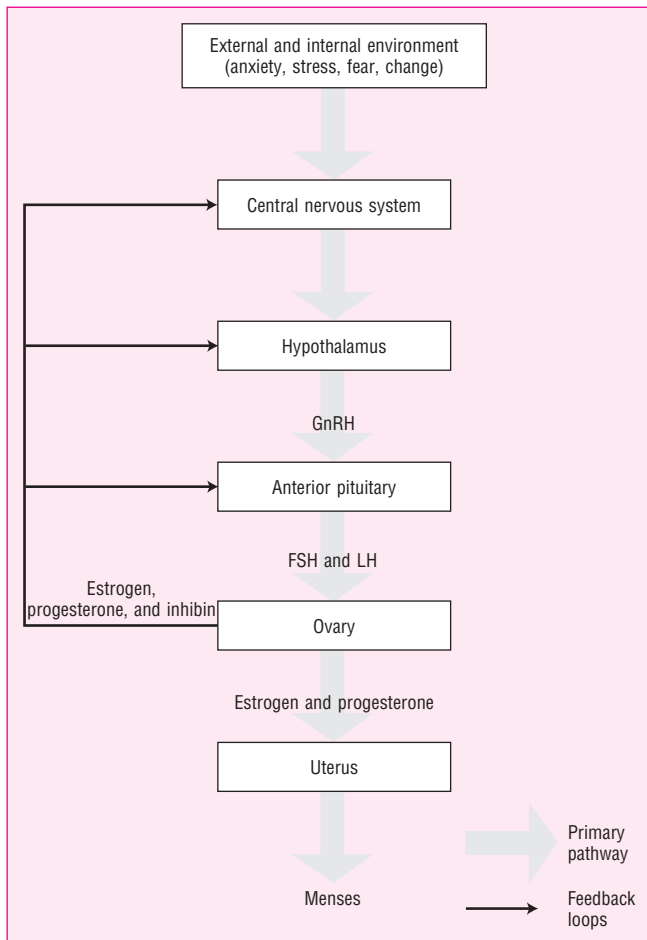

FIGURE 77-1. Regulation of the menstrual cycle. Primary hormone pathways in the reproductive system are modulated by both negative and positive feedback loops. Prostaglandins, secreted by the ovary and by uterine endometrial cells, also play a role in ovulation and may modulate hypothalamic function as well. (Reproduced courtesy of Hatcher RA, Nelson AL, Ziemann M, et al. *A Pocket Guide to Managing Contraception*. Tiger, GA, Bridging the Gap Foundation, 2003:1–146. This figure may be reproduced at no cost to the reader.)

Once the follicle has received FSH stimulation, it must have continued FSH stimulation or it will die.^{3,4} Gonadotropin-dependent growth allows the follicle to enlarge, produce other layers of receptors for FSH and LH, and synthesize estradiol, progesterone, and androgen. Estradiol serves to stop the menstrual flow from the previous cycle, thickening the endometrial lining of the uterus to prepare it for embryonic implantation. Estrogen is also responsible for the increased production of thin, watery cervical mucus, which will enhance sperm transport during fertilization. FSH also regulates the aromatase enzymes that convert androgens to estrogens in the follicle. If a follicle has insufficient aromatase, androgen will accumulate, and the follicle will not survive. Therefore, follicles with the most FSH stimulation have the lowest androgen-estrogen ratios.

OVULATION

When estradiol levels remain elevated for a sustained period of time (200 pg for at least 50 hours), the pituitary releases a midcycle LH

surge^{3,4} (see Fig. 77-2). This LH surge stimulates the final stages of follicular maturation and ovulation (follicular rupture and release of the oocyte). On average, ovulation occurs 24 to 36 hours after estradiol peak and 10 to 16 hours after the LH peak. The LH surge, occurring 28 to 32 hours before a follicle ruptures, is the most clinically useful predictor of approaching ovulation. After ovulation, the oocyte is released and travels to the fallopian tube, where it can be fertilized and transported to the uterus for embryonic implantation. Conception is most successful when intercourse takes place from 2 days before ovulation to the day of ovulation.

LUTEAL PHASE

After rupture of the follicle and release of the ovum, the remaining luteinized follicles become the corpus luteum, which synthesizes androgen, estrogen, and progesterone^{3,4} (see Fig. 77-2). Progesterone helps to maintain the endometrial lining, which sustains the implanted embryo and maintains the pregnancy. It also inhibits GnRH and gonadotropin release, preventing the development of new follicles. If pregnancy occurs, human chorionic gonadotropin (hCG) prevents regression of the corpus luteum and stimulates continued production of estrogen and progesterone secretion to maintain the pregnancy until the placenta is able to fulfill this role (usually 6 to 8 weeks' gestation).

If fertilization or implantation does not occur, the corpus luteum degenerates, and progesterone production declines.^{3,4} The life span of the corpus luteum depends on the continuous presence of small amounts of LH, and its average duration of function is 9 to 11 days. As the progesterone levels decline, endometrial shedding (menstruation) occurs, and a new menstrual cycle begins. At the end of the luteal phase, with low estrogen and progesterone levels, FSH levels start to rise, and follicular recruitment for the next cycle begins.

EPIDEMIOLOGY

Contraception generally implies the prevention of pregnancy following sexual intercourse by inhibiting viable sperm from coming into contact with a mature ovum (i.e., methods that act as barriers or prevent ovulation) or by preventing a fertilized ovum from implanting successfully in the endometrium (i.e., mechanisms that create an unfavorable uterine environment).

Commonly used methods of reversible contraception include oral and transdermal contraceptives, long-acting injectable estrogens and progestins, implantable progestins, condoms, spermicides, withdrawal, the diaphragm, periodic abstinence, and the intrauterine device. These methods differ in their relative effectiveness, safety, and patient acceptability.^{4,6}

The actual effectiveness of any contraceptive method is difficult to determine because many factors affect contraceptive failure. A failure inherent to the proper use of the contraceptive alone is considered a method failure or perfect-use failure. User failure or typical use failure takes into account the user's ability to follow directions correctly and consistently^{4,6} (Table 77-1). In a survey of women having abortions in 2000–2001, 46% had not used a contraceptive method in the month they conceived owing to a perceived low risk of pregnancy (33%) and concerns about the use of contraceptives (32%). The male condom was the most commonly used method (28%), from which inconsistent use was the cited cause of pregnancy in 49% of cases. Oral

FIGURE 77-2. Menstrual cycle events—idealized 28-day cycle. FSH = follicle-stimulating hormone, HCG = human chorionic gonadotropin, LH = luteinizing hormone. (Reproduced courtesy of Hatcher RA, Nelson AL, Ziemann M, et al. *A Pocket Guide to Managing Contraception*. Tiger, GA, Bridging the Gap Foundation, 2003:1–146. This figure may be reproduced at no cost to the reader.)

contraceptives (OCs) were used by 14% of women, 76% of whom reported inconsistent use resulting in pregnancy.⁷

CLINICAL PRESENTATION

For many young women, a major reason for visiting a clinician is to seek contraception. Clinicians may use this opportunity to provide health maintenance/disease prevention by counseling about reproductive health and sexually transmitted diseases. It always has been tradition that hormonal contraception is provided with clinical breast and pelvic examinations. However, the need for the physical

examination may delay access to contraception, resulting in unintended pregnancies and other health risks. In addition, requiring the breast and pelvic examination prior to the prescription of hormonal contraception reinforces the incorrect perception that these methods of pregnancy prevention are harmful or dangerous. Therefore, recent recommendations from the American College of Obstetrics and Gynecology (ACOG) and other national organizations have changed to allow provision of hormonal contraception after a simple medical history and blood pressure measurement.⁸ Other preventive measures, such as pelvic and breast examinations, screening for cervical neoplasia, and counseling for prevention of sexually transmitted diseases, can be done during routine annual office visits.

TABLE 77-1. Comparison of Reversible Methods of Contraception

| Method | Absolute Contraindications | Advantages | Disadvantages | Percent of Women With Pregnancy ^a | |
|---------------------------------------|---|---|--|--|-----------------------------|
| | | | | Lowest Expected | Typical Use |
| Episodic Contraceptive Methods | | | | | |
| Spermicides alone | Allergy to spermicide | Inexpensive No office visit required Some protection against STDs | High user failure rate Must be reapplied before each act of intercourse May cause local irritation in either partner May enhance HIV transmission | 3 | 21 |
| Condoms, male | Allergy to latex or rubber | Inexpensive Readily available No office visit required STD protection, including HIV (latex only) | High user failure rate Poor acceptance Possibility of breakage Efficacy decreased by oil-based lubricants Possible-allergic reactions to latex in either partner | 2 | 12 |
| Condoms, female (Reality) | Allergy to polyurethane History of toxic shock syndrome | Can be inserted just before intercourse or ahead of time; provides protection for 8 hours STD protection, including HIV | High user failure rate Dislike ring hanging outside vagina Cumbersome | 5.0 | 21.0 |
| Diaphragm with spermicide | Allergy to latex, rubber, or spermicide Recurrent UTIs History of toxic shock syndrome Abnormal gynecologic anatomy | Low cost Decreased incidence of cervical neoplasia Some protection against STDs Can be inserted for up to 6 hours before intercourse | High user failure rate Office visit required Decreased efficacy with increased frequency of intercourse Must be refitted after significant change in weight (+/-10 pounds) Increased incidence of vaginal yeast and UTIs Increased incidence of toxic shock syndrome Efficacy affected by oil-based lubricants | 6 | 18 |
| Cervical cap (Prentif) | Allergy to rubber or spermicide Recurrent UTIs History of toxic shock syndrome Abnormal gynecologic anatomy Abnormal Papanicolaou smear | Low cost Some protection against STDs Can be inserted just before or ahead of time; provides protection for 48 hours | High user failure rate Office visit required May be difficult for patient to use correctly Decreased efficacy with parity Cannot be used during menses | 6 | 18 |
| Sponge (Today) | Allergy to spermicide Recurrent UTIs History of toxic shock syndrome Abnormal gynecologic anatomy | Inexpensive No office visit required Some protection against STDs Can be inserted just before or ahead of time; provides protection for 24 hours | High user failure rate Problems removing the sponge due to vaginal dryness Cannot be used during menses Not yet available in U.S. | Parous 9 Nulliparous 6 | Parous 28 Nulliparous 18 |
| Hormonal Methods | | | | | |
| Oral contraceptives | Hepatic adenomas Thromboembolic disorders or history thereof Cerebrovascular or coronary artery disease | Decreased risk of PID, ovarian and endometrial cancer Improvement in endometriosis (probably) Fewer functional ovarian cysts (possibly) | Office visit required Increased risk of benign hepatocellular adenomas Mild increased risk of thromboembolism and stroke May elevate blood pressure | 0.1 | 3 |

TABLE 77-1. (Continued)

| Method | Absolute Contraindications | Advantages | Disadvantages | Percent of Women With Pregnancy ^a | |
|--|---|---|---|--|-------------------------|
| | | | | Lowest Expected | Typical Use |
| | Known or suspected breast cancer Undiagnosed abnormal gynecologic bleeding Jaundice with pregnancy or previous pill use | Less salpingitis and ectopic pregnancy Prevention of benign breast disease (fibroadenoma and fibrocystic changes) Less rheumatoid arthritis (possibly) Increased bone density (possibly) Improvement in acne/hirsutism Significant improvement in menstruation-related problems: fewer cramps, less flow for fewer days, less iron deficiency anemia, more predictable menses, elimination of mittelschmerz, less dysmenorrhea and premenstrual syndrome | No protection against most STDs Estrogenic side effects (nausea, breast tenderness, fluid retention) Progestin side effects (acne, increased appetite, depression) Increased risk of myocardial infarction in older women, smokers | | |
| Progestin-only oral contraceptives | Undiagnosed abnormal gynecologic bleeding | May be used by lactating women and women with cardiovascular risk Allows avoidance of estrogen-related side effects Protection against PID, iron deficiency anemia, and dysmenorrhea | Frequent spotting and amenorrhea Increased risk of ectopic pregnancy Must take every day at the same time | 0.5 | 3 |
| Transdermal contraceptives (Ortho-Evra) | Same as above for oral contraceptives | Same as above for oral contraceptives Convenience of weekly application | Same as above for oral contraceptives | 1 | Up to 9 in women >90 kg |
| Contraceptive rings (NuvaRing) | Same as above for oral contraceptives | Same as above for oral contraceptives Convenience of monthly insertion | Same as above for oral contraceptives | 1 | ? |
| Progestin implants: levonorgestrel (Norplant and Norplant II, ^b Jadelle, ^b Capronor ^b), 3 ketodesogestrel (Implanon ^b), nomegestrol acetate (uniplant ^b) | Pregnancy Undiagnosed abnormal gynecologic bleeding Acute liver disease Benign or malignant liver tumors Known or suspected breast cancers Active thrombophlebitis or thromboembolic disease | Passive contraception Duration of efficacy varies; effective up to 5 years with Norplant in women <154 pounds Effects are quickly reversible Less menstrual cramping and mittelschmerz pain No suppression of lactation No metabolic disturbances Can be considered for use in women who have diabetes, hypertension, gall bladder disease, history of cardiovascular or thromboembolic disease and in women who are smokers or lactating | Requires outpatient surgical procedure Irregular menstrual bleeding, headaches, weight gain, acne Progestin side effects Local infection or bruising on insertion; removal may be difficult Expensive initially High discontinuation rate Unacceptable in patients using some anticonvulsants | 0.3 | 0.3 |

(continued)

TABLE 77-1. (Continued)

| Method | Absolute Contraindications | Advantages | Disadvantages | Percent of Women With Pregnancy ^a | |
|--|--|--|---|--|-------------|
| | | | | Lowest Expected | Typical Use |
| Depo-Provera | Pregnancy Undiagnosed abnormal gynecologic bleeding Known or suspected breast cancers Liver disease (relative contraindication) Severe depression (relative contraindication) Severe cardiovascular disease (relative contraindication) | Passive contraception No suppression of lactation No increased risk of thromboembolism May decrease seizure frequency Effective for 3 months Can be considered for use in women who have seizure disorders, diabetes, hypertension, gall bladder disease, history of cardiovascular or thromboembolic disease and in women who are smokers or lactating | Office visit required every 3 months Irregular menstrual bleeding, headache, weight gain, acne Delayed return of fertility Possible increased risk of breast cancer in younger users Decreased HDL Progestin side effects Decreased bone density in long-term users | 0.3 | 0.3 |
| Lunelle | Pregnancy Undiagnosed abnormal gynecologic bleeding Known or suspected breast cancers Thromboembolic disorders or history thereof Cerebrovascular or coronary artery disease Jaundice of pregnancy or with prior pill use | Effects quickly reversible Less menstrual cramping and mittelschmerz pain Less menstrual irregularity than other injectable or implantable methods | Office visit required monthly Progestin side effects Estrogen side effects | 0.1 | 0.1 |
| Intrauterine Devices (Hormonal and Nonhormonal) | | | | | |
| Copper-T 380A (ParaGard) | Multiple sexual partners or partner with multiple partners (high risk for STDs) History of PID or ectopic pregnancy, acute pelvic infection Abnormal uterine cavity/pelvic surgery/undiagnosed gynecologic bleeding Uterine or cervical cancer Wilson's disease Allergy to copper | Passive contraception Long-term contraception (can remain in place for up to 10 years) Less expensive per year and easier for some patients No delay in return of fertility after removal | Increased heavy bleeding Spotting between periods Increased cramping and dysmenorrhea Increased risk of ectopic pregnancy Office visit required Rarely, uterine perforation | 0.8 | 3 |
| Progesterone T (Progestasert) | Postpartum endometritis or infected abortion in previous 3 months Acute cervicitis or vaginitis (including BV) until infection controlled | Remains in place for 1 year Decreased cramping and dysmenorrhea Decrease in menstrual blood loss No delay in return of fertility after removal | Office visit required Must be changed each year Increased risk of ectopic pregnancy Rarely, uterine perforation | 1.5 | 2 |

TABLE 77-1. (Continued)

| Method | Absolute Contraindications | Advantages | Disadvantages | Percent of Women With Pregnancy ^a | |
|-----------------------------|---|--|--|--|-------------|
| | | | | Lowest Expected | Typical Use |
| Levonorgestrel IUD (Mirena) | Conditions associated with increased susceptibility to infections, including leukemia, AIDS, IV drug abuse, and corticosteroid use Valvular heart disease (relative contraindication) Nulliparity (relative contraindication) Genital actinomycetes Wilson's disease Allergy to copper | Constant rate of hormone release for 5 years Possibly the single most effective reversible contraceptive method over 5-year period Decreased cramping, dysmenorrhea, menorrhagia Combines benefits of Norplant and Copper-T | Office visit required Irregular menstrual bleeding Rarely, uterine perforation | 0.1 | 0.1 |

STD, sexually transmitted disease; HIV, human immunodeficiency virus; UTI, urinary tract infection; PID, pelvic inflammatory disease; HDL, high-density lipoprotein cholesterol; BV, bacterial vaginosis; AIDS, acquired immunodeficiency syndrome; IV, intravenous.

▶ TREATMENT: Contraception

■ DESIRED OUTCOME

The obvious goal of treatment with all methods of contraception is to avoid pregnancy. However, there are many health benefits associated with contraceptive methods, including prevention of sexually transmitted diseases (condoms), improvements in menstrual cycle regularity (hormonal contraceptives), prevention of malignancies and other health conditions (OCs), and management of perimenopause.⁹

■ NONPHARMACOLOGIC THERAPY

■ PERIODIC ABSTINENCE

1 2 Highly motivated couples may use the abstinence (rhythm) method of contraception, avoiding sexual intercourse during the days of the menstrual cycle when conception is likely to occur. These women rely on physiologic changes, such as the basal body temperature and cervical mucus, during each cycle to determine the fertile period. The major reasons for the lack of acceptance are the relatively high pregnancy rates among users and the need to avoid intercourse for several days during each menstrual cycle. To overcome these drawbacks, many women use barrier methods or spermicides during the fertile period.^{4,6}

■ BARRIER TECHNIQUES

The effectiveness of barrier methods and spermicides depends almost exclusively on a couple's motivation to use them consistently and correctly. These methods include the diaphragm, cervical cap,

sponge, condom, and spermicides. Besides contraception, an advantage to using these methods is that they can reduce the rate of sexually transmitted disease (STD) transmission.^{4,6}

The diaphragm, a reusable dome-shaped rubber cap with a flexible rim that is inserted vaginally, fits over the cervix in order to decrease access of sperm to the ovum. The diaphragm is available in 11 sizes and requires a prescription from a physician who has fitted the patient for the correct size.^{4,6} The effectiveness of the diaphragm depends on its function as a barrier and on the spermicidal cream or jelly placed in the diaphragm before insertion. The diaphragm may be inserted as long as 6 hours before intercourse and must be left in place for at least 6 hours after intercourse. If intercourse occurs more than once within 6 hours, the patient must not remove the diaphragm but rather should insert more spermicide and wear the diaphragm for 6 hours after subsequent acts of intercourse or use a condom. Contraindications to the diaphragm are listed in Table 77-1. Users of diaphragms appear to have a lower incidence of cervical neoplasia, which may be attributed to the adjunctive spermicide and the diaphragm's barrier effect against the human papilloma virus. Diaphragm use also has been associated with an increased incidence of urinary tract and yeast infections.

The Prentif cervical cap is a soft, deep, rubber cup with a firm round rim that is smaller than a diaphragm and fits over the cervix like a thimble.^{4,6} Spermicide is used to fill the cap one-third full prior to insertion and is held in place against the cervix until the cap is removed. The cap remains effective for more than one episode (up to 48 hours) of intercourse without adding more spermicide; thus it is less messy to use than a diaphragm. However, because of the limited number of sizes, it may not be possible to fit some women with this device. It is recommended that women not wear the cap for longer than 48 hours to reduce the risk of toxic shock syndrome. A recent review by the Cochrane Library found that the Prentif cap was as effective as

the diaphragm in preventing pregnancy and was less often associated with vaginal ulcerations or lacerations.¹⁰

Condoms are devices that create a mechanical barrier, preventing direct contact of the vagina with semen, genital lesions and discharges, and infectious secretions.^{4,6} Most condoms made in the United States are made of latex rubber, which is impermeable to viruses; the small proportion (5%) made from young lamb intestine is not, however. Condoms are used worldwide as protection from STDs. When used in conjunction with any other barrier methods, their effectiveness theoretically approaches 95%. Spillage of semen or perforation and tearing of the condom can occur, but proper use minimizes these problems.⁴ Mineral oil–based vaginal drug formulations (e.g., Cleocin vaginal cream, Premarin vaginal cream, Vagistat 1, Femstat, and Monistat Vaginal suppositories), lotions, or lubricants can decrease the barrier strength of latex by 90% in just 60 seconds, thus making water-soluble lubricants preferable if they are to come in contact with latex condoms.⁴

The female condom (Reality) appears to be as effective as the diaphragm in preventing pregnancy.³ The female condom is a pre-lubricated, soft, loose-fitting polyurethane sheath, closed at one end, with flexible rings at both ends. Properly positioned, the ring at the closed end covers the cervix, and the sheath lines the walls of the vagina. The outer ring remains outside the vagina, covering the labia; this may make it more effective than the male condom in preventing transmission of diseases such as herpes because it protects the labia from contact with the base of the penis. The pregnancy rate is reported to be 26% per year, based on a 6-month follow-up study of 200 women.³

■ PHARMACOLOGIC THERAPY

■ SPERMICIDES

1 2 Spermicides, most of which contain nonoxynol-9, are chemical surfactants that destroy sperm cell walls and offer some protection against STDs and cervical cancer.⁴ They are available as foams, creams, suppositories, jellies, and film.⁴ Spermicidal tablets or suppositories require 10 to 30 minutes to dissolve. Spermicides can cause local irritation in both men and women. Additional spermicide must be used each time intercourse is repeated.

■ SPERMICIDE-IMPLANTED BARRIER TECHNIQUES

The vaginal contraceptive sponge (Today) is pillow shaped and contains 1 g of the spermicide nonoxynol-9.^{4,11} It has a concave dimple on one side (to fit over the cervix and decrease the risk of dislodgement during intercourse) and a loop on the other side (to facilitate removal). After being moistened with tap water, the sponge is inserted into the vagina up to 6 hours before intercourse. The sponge provides protection for 24 hours, regardless of the frequency of intercourse during this time. After intercourse, the sponge must be left in place for at least 6 hours before removal. Sponges should not be left in place for more than 24 to 30 hours in order to reduce the risk of toxic shock syndrome. After use, sponges should be discarded (they are not effective for reuse). The sponge comes in one size and will soon be available over the counter. Production of the sponge was discontinued temporarily in 1995, and it is now being reviewed by the Food and Drug Administration (FDA) for rerelease in the United States.^{4,11} The sponge is currently available in Canada, Europe, and the United Kingdom.

■ ORAL CONTRACEPTIVES

1 2 OCs are highly effective^{4,6,12} (see Table 77–1). When used correctly, their effectiveness approaches that of surgical sterilization.

■ Composition and Formulations

The currently available OCs contain either a combination of a synthetic estrogen and synthetic progestin or a progestin alone. Estrogens suppress FSH and thus prevent the development of a dominant follicle. Estrogens also potentiate the action of the progestin component, which suppresses the LH surge. As a result, even if the estrogenic component does not blunt follicular growth adequately, the action of the progestin blocks ovulation. Estrogen also serves to stabilize the endometrial lining (bleeding cycle control), whereas the progestin contributes to other contraceptive effects on cervical mucus (thickened/impermeable) and the endometrium (involution/atrophy).^{4,6,12}

The low-dose combination OCs that are currently available are modifications of the original products introduced in 1960; these modified products contain approximately one-third to one-fourth the estrogen and one-tenth the progestin dose found in the earlier pills.³ Over the past decade, combination multiphasic (biphasic and triphasic) formulations have further lowered the total monthly hormonal dose without clearly demonstrating a significant clinical advantage.^{3,4,6} Also introduced in 1960, the progestin-only “minipills” (28 days of active hormone per cycle) are still available. Containing even lower doses of progestin than found in combination OCs and lacking the contribution of estrogen, minipills tend to be less effective than combination OCs with typical use and generally are reserved for women who must avoid estrogen.^{3,4,6}

■ Components

Two synthetic estrogens commonly used in OCs in the United States, ethinyl estradiol (EE) and mestranol, differ only by the presence of a methyl group attached to mestranol at the C-3 site. Mestranol, which must be converted by the liver to ethinyl estradiol before it is pharmacologically active, is estimated to be 50% less potent than EE.^{4,6,13}

Progestins currently used in OCs include drospirenone, ethynodiol diacetate, desogestrel, gestodene (not available in the United States), norgestimate, norethindrone, norethindrone acetate, norethynodrel, norgestrel, and norgestrel’s active isomer levonorgestrel. Progestins vary in their progestational activity and differ with respect to inherent estrogenic, antiestrogenic, and androgenic effects.^{4,6,13–15} Estrogenic and antiestrogenic properties are secondary to the extent of progestins’ metabolism to estrogenic substances, whereas androgenic activity results from the structural similarity of the progestin to testosterone (receptor binding and activity) and the ability to affect free testosterone concentrations through impact on sex hormone–binding globulin, a major carrier protein for testosterone.^{13,14}

Third-generation OCs contain newer progestins (e.g., desogestrel, drospirenone, gestodene, and norgestimate). These progestins are potent progestational agents that appear to have no estrogenic effects and are less androgenic when compared with levonorgestrel on a weight basis. Therefore, these agents are thought to be more effective in improving mild to moderate acne.¹⁶ Drospirenone also has antiminerocorticoid or antialdosterone activities, which may result in less weight gain when compared with OCs containing levonorgestrel.¹⁵

TABLE 77–2. Composition of Commonly Prescribed Oral Contraceptives

| Product | Estrogen | mcg | Progestin | mg | Spotting and BTB |

^a OK; products approved but not yet available.

^b 91-day regimen.

Compiled from refs.13 and 14.

Unfortunately, clinical trials comparing the differences between OCs are few, and sample size is small, so the actual relevance of these purported improvements in progestational selectivity and lower androgenic activity remains unknown.^{12,14} For example, a recent review by the Cochrane Library concluded that there was no evidence supporting a causal association between combination OCs or combination skin patches and weight gain.¹⁷ Table 77–2 lists available OCs products by brand name and specifies hormonal composition.

Considerations with Oral Contraceptive Use

2 3 Oral contraceptives, when used properly, are extremely safe.⁹ Numerous noncontraceptive benefits, including relief from menstruation-related problems (e.g., decreased menstrual cramps, decreased ovulatory pain [mittelschmerz], and decreased menstrual blood loss) and prevention of several diseases (e.g., ovarian and endometrial cancer, ovarian cysts, ectopic pregnancy, pelvic

inflammatory disease [PID], and benign breast disease) have been attributed to the use of OCs (see Table 77–1). A complete medical history and blood pressure measurement should be obtained before a patient begins using OCs, and the risks and precautions associated with OC use warrant careful consideration.^{4,6,7,12,13} The World Health Organization (WHO) has developed a graded list of precautions for clinicians to consider when they are providing OCs, and these precautions have replaced the traditional absolute and relative contraindications to the use of OCs. Many patient-specific characteristics and concomitant disease states increase the patient's risk for adverse effects relating to OC use^{4,6,18} (Table 77–3).

■ **Women Over 35 Years of Age.** Generally, OCs are an acceptable form of birth control for nonsmoking women up to the time of menopause, with women over 35 using the lowest-dose estrogen products.^{4,6,13,18} An ex-smoker for at least 1 year can be regarded as a nonsmoker.⁶ A recent case-controlled study of healthy, nonsmoking women over age 35 years indicated that the use of OCs increased the risk of myocardial infarction (MI) and stroke.^{19,20} As women approach the perimenopausal stage, OCs confer a benefit with respect to bone mineral density and vasomotor symptoms.²¹ If women choose to use hormone therapy, they should switch from OCs in the perimenopausal period.^{18,22}

■ **Smoking.** Women who smoke more than 20 cigarettes per day and are over age 35 should not use OCs containing estrogen. Those who smoke fewer than 20 cigarettes per day and are over age 35 should use them only with caution.^{4,10,18,23} If smoking women use OCs, the 20-mcg estrogen formulation should be used.^{23,24} This extremely low dose of OC does not appear to have an impact on clotting factors and platelet activation, even in smokers.²⁵ Progestin-only pills generally are acceptable for women in whom an estrogen is contraindicated.²⁶ In smoking women older than age 35, the risk of using OCs is likely to exceed the risk of pregnancy.¹⁸

■ **Hypertension.** Combination OCs, even those containing less than 35 mcg estrogen, can cause small increases in blood pressure, although clinically significant increases are rare with low-dose agents.^{4,6,26} If an OC-related increase in blood pressure occurs, discontinuing the OC usually restores blood pressure to pretreatment values within 3 to 6 months.^{4,6} The use of low-dose OCs is acceptable in women with well-controlled and well-monitored hypertension.¹⁸ However, hypertensive women who have end-organ vascular disease (e.g., coronary artery disease, congestive heart failure, or cerebrovascular disease) or who smoke should not use combination OCs.¹⁸ Women with hypertension taking potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, angiotensin-receptor blockers, or aldosterone antagonists may see an increase in serum potassium concentration if they are also using an OC containing drospirenone (e.g., Yasmin), which has antialdosterone properties.¹⁵

■ **Diabetes.** Oral contraceptives appear to affect carbohydrate and lipid metabolism, possibly through the progestin component.^{4,26,27} With the exception of some levonorgestrel-containing products, formulations containing low doses of progestins do not significantly alter insulin, glucose, or glucagon release after a glucose load in healthy women or in those with a history of gestational diabetes.^{4,27} The new progestins are believed to have little, if any, effect on carbohydrate metabolism.^{4,27} Studies of women with type 1 diabetes did not find any association between blood glucose control and the use of OCs.²⁸ In the Nurses' Health Study, women using OCs did not demonstrate any increased risk of developing type 2 diabetes.²⁹ Nonsmoking women

with diabetes but no associated vascular disease can use OCs safely.¹⁸ However, diabetic women with vascular disease (e.g., hypertension, nephropathy, retinopathy, or neuropathy) should not use OCs.¹⁸

■ **Dyslipidemia.** Generally, synthetic progestins adversely affect lipid metabolism by decreasing the level of high-density lipoprotein (HDL) and increasing the level of low-density lipoprotein (LDL). Estrogens tend to have more beneficial effects by increasing the removal of LDL from the circulation and increasing the level of HDL through increases in ApoA₁. Estrogens also may alter the composition of very low density lipoprotein (VLDL) and increase the level of triglycerides.²⁷ Most low-dose combination OCs, with the possible exception of monophasic levonorgestrel (0.15 mg) pills, have no significant impact on HDL, LDL, triglycerides, or total cholesterol.^{6,14,26,27}

Although the lipid effects of OCs theoretically can influence cardiovascular risk, the mechanism of the increased incidence of cardiovascular disease in OC users is believed to be secondary to thromboembolic and thrombotic changes, not atherosclerosis. Numerous epidemiologic studies have failed to find an association between OC use and cardiovascular disease.^{18,30} Women with controlled dyslipidemia can use low-dose OCs, although they need frequent monitoring by means of a fasting lipid panel after they begin using these agents.¹⁸ Women with uncontrolled dyslipidemia (LDL > 160 mg/dL, HDL < 35 mg/dL, triglycerides > 250 mg/dL) and additional risk factors (e.g., coronary artery disease, diabetes, hypertension, smoking, or a positive family history) should use an alternative method of contraception.¹⁸

■ **Thromboembolism.** Estrogens play a dose-related role in the development of venous thromboembolism (VTE) and consequent pulmonary embolism, especially in women who smoke or have other underlying inherited conditions (e.g., deficiencies in antithrombin III, protein C, and protein S levels or factor V Leiden mutation) or acquired conditions (e.g., immobility, trauma, surgery, and certain malignancies) that predispose them to coagulation abnormalities.^{4,6,31} Early observational studies reported the incidence of VTE to be much higher in OC users than in nonusers, but a recent reevaluation of these data suggest that the risk of VTE is much less with non-third-generation OCs (less than a threefold increase in relative risk) than originally thought.^{15,32,33} In addition, the absolute risk is low (15 cases per 100,000 woman-years). The increased risk of VTE and pulmonary embolism appears to be limited to current users, with disappearance of the risk within 3 months after the use of the OC ceases.^{6,15,34} The 20-mcg EE formulations do not appear to have an effect on clotting parameters, even in smokers, but whether these products lower the risk of thrombotic events has not been studied.^{26,35}

European studies of third-generation OCs reported a possible relationship between these agents and the procoagulant effects of OCs. In early studies, researchers found that users of third-generation agents containing gestodene or desogestrel had a twofold greater risk of nonfatal VTE than women using the older low-dose combination OCs.^{3,4,6} More recent data have shown a small increase in the risk of VTE but do not establish a cause-and-effect relationship.^{35,36} There also have been reports of VTE in patients receiving OCs containing drospirenone.¹⁵ Some clinicians argue that this difference reflects preferential prescribing of the newer, and perceived safer, progestin products for women at greater risk for VTE.^{13,24,37–39} The FDA has concluded that this evidence is not persuasive enough to support any changes in current prescribing patterns or to recommend discontinuation of third-generation OCs.^{12,24}

Currently, OCs are contraindicated in any woman with a history of VTE or pulmonary embolism (see Table 77–3). Women who

TABLE 77-3. Precautions in the Provision of Combined Oral Contraceptives (OCs)

| Precautions | Rationale/Discussion |
|--|--|
| <p>World Health Organization Category #4: Refrain from providing combined oral contraceptives for women with the following diagnoses.</p> <ul style="list-style-type: none"> • Deep vein thrombosis or pulmonary embolism, or a history thereof • Cerebrovascular accident (stroke), coronary artery or ischemic heart disease, or a history thereof • Structural heart disease, complicated by pulmonary hypertension, atrial fibrillation, or history of subacute bacterial endocarditis • Diabetes with nephropathy, retinopathy, neuropathy, or other vascular disease; diabetes of more than 20 years' duration • Breast cancer • Pregnancy • Lactation (<6 weeks postpartum) • Liver problems: benign hepatic adenoma or liver cancer, or a history thereof; • Headaches, including migraine (with aura), with focal neurologic symptoms • Active viral hepatitis; severe cirrhosis • Major surgery with prolonged immobilization or any surgery on the legs • Over 35 years old and currently a heavy smoker (20 or more cigarettes a day) • Hypertension, 160+ mmHg/100+ mmHg or with vascular disease | <ul style="list-style-type: none"> • Estrogens promote blood clotting. Thromboembolic events related to known trauma or an intravenous needle are not necessarily a reason to avoid use of pills. • Estrogens promote blood clotting. • Estrogens promote blood clotting. • Estrogens promote blood clotting. • Estrogens promote blood clotting. • Breast cancer is a hormonally sensitive tumor. In theory, the hormones in OCs might cause some masses to grow. • Current data do not show that hormonal contraceptives taken during pregnancy cause any significant risk of birth defects. However, hormonal contraceptives should not be given to pregnant women. • There is some theoretical concern that the neonate may be at risk owing to exposure to steroid hormones during the first 6 weeks postpartum. OCs can diminish the volume of breast milk. • OCs are metabolized by the liver, and their use may adversely affect prognosis of existing disease. • Focal neurologic symptoms such as blurred vision, seeing flashing lights or zigzag lines, or trouble speaking or moving may be an indication of an increased risk of stroke. • Risk for deep vein thrombosis and pulmonary embolism is increased. • Smoking increases the risk for cardiovascular disease. • Hypertension is an important risk factor for cardiovascular disease. |
| <p>World Health Organization Category #3: Exercise caution if combined oral contraceptives are used or considered in the following situations and carefully monitor for adverse effects.</p> <ul style="list-style-type: none"> • Postpartum <21 days • Lactation (6 weeks to 6 months) • Undiagnosed abnormal vaginal/uterine bleeding • Over 35 years of age and light smoker (fewer than 20 cigarettes/day) • Past history of breast cancer, but no evidence of recurrence for 5 years • Use of drugs that affect liver enzymes (rifampicin, rifabutin and griseofulvin); anticonvulsants (phenytoin, carbamazepine, barbiturates, topiramate, and primidone) • Gallbladder disease: medically treated and current biliary tract disease and history of OC-related cholestasis <p>World Health Organization Category #2: Advantages generally outweigh theoretical or proven disadvantages and generally can be provided without restrictions in these conditions.</p> <ul style="list-style-type: none"> • Severe headaches that definitely start after initiation of OCs; migraine headaches without focal neurologic symptoms (without aura) • Diabetes mellitus: gestational diabetes or diabetes without vascular disease • Major surgery without prolonged immobilization • Sickle cell disease or sickle C disease | <ul style="list-style-type: none"> • There is some theoretical concern regarding the association between OC use up to 3 weeks postpartum and risk of thrombosis. • In the first 6 months postpartum, use of OCs during breastfeeding diminishes the quantity of breast milk and may adversely affect the health of the infant. • Although OCs are often used to manage heavy bleeding, clinicians should be sure that the cause of the bleeding is known before prescribing OCs. • Smoking increases the risk for cardiovascular disease. All smokers should be warned of this risk and should be encouraged and advised to stop smoking. • Breast cancer is a hormonally sensitive tumor. • OCs are metabolized by the liver. Drugs that affect liver enzymes could reduce the contraceptive effectiveness of OCs. • Recent reports show that OCs may be weakly associated with the development of gallbladder disease. There is also concern that OCs may worsen existing gallbladder disease. • Migraine headaches with focal neurologic symptoms have been associated with an increased risk of stroke; any headaches clearly starting after initiation of pills may be related to pill use. • Women with diabetes are at increased risk of heart disease and stroke, particularly if the woman smokes. Estrogens and progestins may slightly decrease glucose tolerance, but this is unlikely to happen with low-dose OCs. • With the current low-dose pills, the problems associated with pill use and elective surgery have decreased. • Women with sickle cell disease are predisposed to occlusion of the microvasculature (because of abnormal, inflexible red blood cells). Studies of women with sickle cell disease have shown no significant differences between OC users and non-users with regard to coagulation studies, blood viscosity measurements, or incidence or severity of painful sickle cell crisis. |

(continued)

| Precautions | Rationale/Discussion |
|--|--|
| <ul style="list-style-type: none"> • Moderate blood pressure (140–159 mmHg/100–109 mmHg) • Undiagnosed breast mass • Cervical cancer awaiting treatment and cervical intraepithelial neoplasia • Over 50 years of age • Conditions likely to make it very difficult for a woman to take OCs consistently and correctly • Family history of hyperlipidemia • Family history of death of a parent or sibling due to myocardial infarction before age 50 | <ul style="list-style-type: none"> • Monitor blood pressure periodically. Hypertension is an important risk factor for cardiovascular disease. • Some clinicians and clinical protocols suggest that women found to have a breast mass should not be provided combined OCs until cancer of the breast has been ruled out. Other clinicians are comfortable prescribing pills while the cause of the breast mass is being evaluated. • The risk of cervical cancer appears to be increased slightly in OC users. OC users may get Papanicolaou smears more regularly so that early dysplasia is more likely to be recognized. They also tend to have more sexual partners. Pill use may also alter susceptibility to infection with human papilloma virus a known risk factor for cancer of the cervix. • Women over 50 are at increased risk for heart and cerebrovascular disease. • Mental retardation, major psychiatric illness, alcoholism, or other chemical abuse, and/or a history of repeatedly taking OCs or other medications incorrectly, make compliance with OC regimens difficult. • Some types of hyperlipidemia increase a woman's risk for heart disease. Routine screening is not recommended by WHO because of the rarity of the conditions and the high cost of screening. • Myocardial infarction in a mother or sister is especially significant and suggests a need for lipid evaluation. |
| <p>World Health Organization Category #1: Do not restrict use of combined oral contraceptives for the following conditions.</p> | |
| <ul style="list-style-type: none"> • Postpartum ≥ 21 days • Postabortion after first or second trimester or immediately after postseptic abortion • History of gestational diabetes • Varicose veins • Mild headaches • Irregular vaginal bleeding patterns, without or with heavy or prolonged bleeding and not anemia • Past history of pelvic inflammatory disease (PID) • Current or recent history of (within last 3 months) PID • Current or recent history of (within last 3 months) sexually transmitted infection (STI) • Vaginitis without purulent cervicitis • Increased risk of STI (i.e., multiple partners or partner who has multiple partners) • Infection with human immunodeficiency virus (HIV), high risk or HIV or acquired immunodeficiency syndrome (AIDS) • Benign breast disease • Family history of breast cancer • Cervical ectropion • Endometrial or ovarian cancer • Viral hepatitis carrier • Uterine fibroids • Past ectopic pregnancy • Obesity • Thyroid conditions: simple goiter, hyperthyroidism, hypothyroidism • Benign or malignant gestational trophoblastic disease • Iron deficiency anemia • Epilepsy • Schistosomiasis (uncomplicated or with fibrosis of the liver) • Malaria • Current use of antibiotics • Nulliparity or parity • Severe dysmenorrhea • Tuberculosis, including pelvic • Endometriosis • Benign ovarian tumors • Prior pelvic surgery | |

Compiled from refs. 4 and 18.

develop thrombotic complications while taking a low-dose OCs should have an examination for an underlying coagulation disorder.^{4,6,13,18} Some experts support the use of OCs in women with coagulation disorders *who have been properly anticoagulated*, citing the potential advantages of lowering the risk of fetal exposure to warfarin, bleeding corpus luteum cysts, and excessive blood loss during menses.^{4,6,18}

■ **Cerebrovascular Disease.** Both thrombotic and hemorrhagic stroke have been associated with the use of OCs. However, early studies used higher-dose products and did not take into account independent risk factors for vascular disease (e.g., smoking, hypertension, and advancing age). Recent studies evaluating low-dose OCs found the risk for stroke to be extremely low in healthy young women.^{19,20,40,41} These results suggest that the effect of smoking in women younger than 35 years of age is minimal in the absence of hypertension and that hypertension may be the major risk factor for stroke.^{13,42,43} Cerebrovascular accidents often are preceded by persistent headaches (for weeks or months) and/or by temporary hemiparesis. Patients should be screened carefully and counseled to recognize warning signs of cerebrovascular accidents in order to decrease risk.

■ **Migraine Headaches.** Women in their reproductive years frequently experience headaches, ranging in variety from tension headache to simple (without aura) and classic migraine (with aura).¹⁸ OCs usually decrease the frequency of migraine headaches, but they exacerbate symptoms in some women; headaches may even occur during the hormone-free interval (during menses). There is some evidence that migraine headaches are a risk factor for stroke and that classic migraine (with aura) may increase the risk of stroke more than simple migraine (without aura) does.^{18,44} The absolute risk of stroke in women using OCs who experience simple migraines is relatively low, but the risk of stroke among those with classic migraines is still undetermined. Combination OCs may be used in young (less than 35 years of age), healthy, nonsmoking women with migraine headaches if they do not have focal neurologic signs.¹⁸

■ **Myocardial Infarction.** Generally, myocardial infarction (MI) in OC users occurs primarily in those older than 35 years of age who have additional risk factors for cardiovascular disease (e.g., smoking, diabetes, hypertension, and obesity).^{4,6,13} These risk factors, in particular smoking, appear to act synergistically with OCs to increase the risk of cardiovascular disease.¹³ A large British study found a 21-fold increase in MI among women taking OCs who smoke more than 15 cigarettes daily but no apparent increased risk in healthy, nonsmoking women regardless of age.⁴⁵ Since the FDA lifted its restrictions on OC use in healthy, nonsmoking women over 40 years of age in 1989, OCs containing 30 mcg estrogen or less are being used more frequently in these women up to the age of menopause without evidence of significantly increased risk of cardiovascular events.^{4,6,13,43} Recent data suggest that the use of low-dose OCs containing third-generation progestins may reduce the incidence of MI to a rate that is similar to that of MI in nonusers.^{43,46} Therefore, healthy, nonsmoking women can use OCs safely without an increased risk of MI. Women with a history of coronary artery disease and those who smoke and have other risk factors for MI should not use combined OCs but rather should use progestin-only or nonhormonal methods of contraception.¹⁸

■ **Cancer.** The risk for ovarian and endometrial cancer decreases by 40% to 50% with OC use, and the beneficial effect is believed to persist for at least 15 years after the use ceases.^{4,6,9,23,24} The relationship between OCs and other cancers is controversial. OCs increase cervical ectopy, but the association with cervical cancer is unclear.

Worldwide epidemiologic data from 54 studies in 25 countries (many of which studied high-dose OCs) were reanalyzed recently to assess the relationship between the use of OCs and the risk of breast cancer.^{47,48} Researchers concluded that women who began to use these agents before age 20 had a higher relative risk compared with users who began at later ages. They also found that women currently taking OCs and those within 10 years of ceasing to take them have a small increase in the risk of breast cancer, but these cancers were less clinically advanced than in women who had never used OCs.^{21,47,48} Prospective data from the Nurses' Health Study cohort showed no overall relationship between the duration of OC use and breast cancer, even in long-term users (>10 years), and researchers concluded that long-term past use, either overall or prior to a full-term pregnancy, did not increase the risk of breast cancer in women over 40 years of age.⁴⁹ This was confirmed by a recent case-control study that demonstrated that former or current OC use was not associated with an increased risk of breast cancer in women 35 to 64 years of age.⁵⁰ It will take many years to discover what, if any, impact the low-dose OCs will have on breast cancer risk. The current recommendation is that a positive family history of breast cancer in a mother or sister, or both, or a history of benign breast disease should not be regarded as a contraindication to OC use.¹⁸

■ **Systemic Lupus Erythematosus.** The use of hormonal contraception is important in women with systemic lupus erythematosus (SLE) because the risk associated with pregnancy is high in this population. It has been thought that hormonal contraception may exacerbate the symptoms of SLE.^{18,51} Retrospective studies have not found an association between combined OCs and disease flare-ups in these patients, but there does appear to be an association between VTE and OC use in women with SLE and antiphospholipid antibodies.^{18,51} Progestin-only contraceptives should be used in women with SLE and in women with a history of vascular disease or antiphospholipid antibodies, and combination OCs should be avoided.^{18,51}

■ Choice of an Oral Contraceptive

❖ ❖ Before prescribing an OC, the clinician must ask and answer several questions. Are there any precautions to consider in the use of OCs (see Table 77–3)? Does this form of contraception fit the patient's lifestyle, and will the patient be compliant? The clinician should discuss the advantages and disadvantages of all available forms of contraception with the patient to ensure that she can make an informed choice (see Table 77–1).

Progestin-only pills (minipills) tend to be less effective than combination OCs with typical use and are associated with irregular and unpredictable menstrual bleeding, as well as an increased frequency of functional ovarian cysts.^{4,6,13} Irregular menstrual cycles indicate that ovulation has been inhibited; however, this is one of the most frequent reasons for the discontinuation of the minipill. Unlike combination OCs, minipills are always begun on the first day of menses and must be taken every day at approximately the same time to maintain contraceptive efficacy. Since minipills may not block ovulation (nearly 40% of women continue to ovulate normally), the risk of ectopic pregnancy is higher with their use than with the use of other hormonal contraceptives.

All combined OCs (monophasic and multiphasic) are similarly effective in preventing pregnancy (see Table 77–1). Although multiphasic pills have a lower total hormone dose per cycle, there is no convincing evidence that they provide any advantage or cause fewer side effects than monophasic pills. In addition, some women find monophasic pills to be simpler to take. A reasonable first choice of an

TABLE 77-4. Symptoms of a Serious or Potentially Serious Nature Associated With Oral Contraceptives (OCs)

| Symptom | Possible Cause |
|--|--|
| Serious: OCs Should Be Stopped Immediately | |
| Loss of vision, proptosis, diplopia, papilledema | Retinal artery thrombosis |
| Unilateral numbness, weakness, or tingling | Hemorrhagic or thrombotic stroke |
| Severe pains in chest, left arm, or neck | Myocardial infarction |
| Hemoptysis | Pulmonary embolism |
| Severe pains, tenderness or swelling, warmth, or palpable cord in legs | Thrombophlebitis |
| Slurring of speech | Hemorrhagic or thrombotic stroke |
| Hepatic mass or tenderness | Liver neoplasm |
| Potentially Serious: OCs May Be Continued With Caution While Patient Is Being Evaluated | |
| Absence of menses | Pregnancy |
| Spotting or breakthrough bleeding | Cervical, endometrial, or vaginal cancer |
| Breast mass, pain, or swelling | Breast cancer |
| Right upper-quadrant pain | Cholecystitis, cholelithiasis, or liver neoplasm |
| Midepigastric pain | Thrombosis of abdominal artery or vein, myocardial infarction, or pulmonary embolism |
| Migraine (vascular or throbbing) headache | Vascular spasm which may precede thrombosis |
| Severe nonvascular headache | Hypertension, vascular spasm |
| Galactorrhea | Pituitary adenoma |
| Jaundice, pruritus | Cholestatic jaundice |
| Depression | Vitamin B ₆ deficiency |
| Uterine size increase | Leiomyomata, adenomyosis, pregnancy |

OC is a monophasic pill containing 30 to 35 mcg EE^{3,4,6,24} (see Table 77-2). This strategy is based on evidence that the most serious side effects of combination OCs (i.e., thromboembolic events, stroke, or MI) result from excessive estrogen content.^{4,6,13,24}

Products containing 20 mcg EE may cause less bloating and breast tenderness, and women over 40 years of age may prefer them. However, these low-estrogen OCs lead to more breakthrough bleeding and an increased risk of contraceptive failure if doses are missed.^{3,4,6,13} Because all combined OCs raise sex hormone-binding globulin and decrease free testosterone levels, women may experience an improvement in acne symptoms.⁵² Norgestimate-containing OCs also have been shown to improve acne symptoms, and Ortho Tri-Cyclen and Estrostep are specifically approved by the FDA for this indication⁵³⁻⁵⁵ (see Table 77-2).

Many symptoms occurring in the first cycle of OC use (e.g., breakthrough bleeding and side effects related to estrogen excess) improve spontaneously by the second or third cycle of use as the body adjusts to the altered hormone level.^{6,13} Therefore, initial OC use should be reevaluated during the first 3 to 6 months of therapy to

determine if the patient is experiencing any adverse effects and if the patient wishes to continue medication.

If the patient complains of symptoms related to the use of the OC, it is necessary to determine if the symptom indicates the presence or potential development of a serious illness^{4,13} (Tables 77-4 and 77-5). Nearly all OC-induced side effects parallel the symptoms and physiologic changes of pregnancy (hormone excess) or the perimenopausal period (hormone deficiency). In some cases, symptoms relating to the hormonal imbalance may improve with adjustments in the specific combination of estrogen and progestin because progestins can contribute to estrogenic and antiestrogenic activity. However, the clinically significant differences between the low-dose OCs used today are difficult to distinguish. Several useful handbooks and articles are available to the practitioner in managing side effects associated with OCs.^{3,4,6,12,13}

For example, women who continue to experience nausea after 3 months of OC use may benefit from a change to a pill with lower estrogenic activity. In addition, taking the OC with food or at bedtime also has been recommended.

TABLE 77-5. Symptoms That May Be Warnings of Serious Trouble^a

| Five Signals | Possible Problem |
|--|--|
| Abdominal pain (severe) | Gallbladder disease, hepatic adenoma, blood clot, pancreatitis |
| Chest pain (severe), shortness of breath, or coughing up blood | Blood clot in lungs or myocardial infarction (heart attack) |
| Headaches (severe) | Stroke, hypertension, or migraine headache |
| Eye problems: blurred vision, flashing lights, or blindness | Stroke, hypertension, or temporary vascular problem of many possible sites |
| Severe leg pain (calf or thigh) | Blood clot in legs |

^a See your clinician if you have any of these problems, or if you develop depression, yellow jaundice, or a breast lump. From ref. 4, with permission.

CLINICAL CONTROVERSY

There is a widely held belief that antibiotics reduce the efficacy of OCs, increasing the risk of pregnancy. However, there are little data to support this drug interaction with most antibiotics, with the exception of rifampin. Because of this potential risk, and considering the fact that OCs are not 100% effective, many practitioners still counsel patients about this issue. The Council on Scientific Affairs at the American Medical Association recommends that women be informed about the small

risk of interactions with antibiotics and, if desired, provided with additional nonhormonal contraceptive agents.

Drug Interactions

3 The effectiveness of an OC is sometimes limited by drug interactions that interfere with gastrointestinal absorption, increase intestinal motility by altering gut bacteriologic flora, and alter the metabolism, excretion, or binding of the OC^{4,12,13,18,24,57} (Table 77–6).

TABLE 77–6. Interactions of Oral Contraceptives (OCs) With Other Drugs

| Interacting Drugs | Adverse Effects (Probable Mechanism) | Comments and Recommendation |
|--|--|--|
| Acetaminophen (Tylenol and others) | Possible decreased pain-relieving effect (increased metabolism) | Monitor pain-relieving response |
| Alcohol | Possible increased effect of alcohol | Use with caution |
| Ampicillin | Decreased contraceptive effect | Low but unpredictable incidence; use backup method of contraception |
| Anticoagulants (oral) | Decreased anticoagulant effect | Use with caution, monitor INR |
| Anticonvulsants (barbiturates, including phenobarbital and primidone; carbamazepine; felbamate; phenytoin; topiramate; vigabatrin) | Possible decreased contraceptive effect | Avoid simultaneous use; use alternative contraceptive (DMPA) for patients with seizure disorder |
| Antidepressants (Elavil, Norpramin, Tofranil, and others) | Possible increased antidepressant pharmacologic effect | Monitor for adverse effects |
| Benzodiazepine tranquilizers (Ativan, Librium, Serax, Tranxene, Valium, Xanax, and others) | Possible increased or decreased tranquilizer effects including psychomotor impairment | Use with caution; greatest impairment during drug-free week in oral contraceptive dosage |
| β -Blockers (Corgard, Inderal, Lopressor, Tenormin) | Possible increased β -blocker pharmacologic effect | Monitor cardiovascular status |
| Corticosteroids (cortisone) | Possible increased corticosteroid toxicity | Clinical significance not established |
| Griseofulvin (Fulvicin, Grifulvin V, and others) | Decreased contraceptive effect | Use backup method of contraception |
| Hypoglycemics (Tolbutamide, Diabinese, Orinase, Tolinase) | Possible decreased hypoglycemic effect | Monitor blood glucose |
| Methyldopa (Aldoclor, Aldomet, and others) | Possible decreased antihypertensive effect, especially with high-dose OCs | Monitor blood pressure |
| Non-nucleoside reverse transcriptase inhibitors (Sustiva, Viramune) | Decreased contraceptive effect (Viramune), possible decreased contraceptive effect (Sustiva) | Use alternative method of contraception |
| Phenytoin (Dilantin) | Decreased contraceptive effect, possible increased phenytoin effect | Use alternative contraceptive (DMPA); monitor phenytoin concentration |
| Pioglitazone (Actos) | Decreased contraceptive effect documented with previous thiazolidinedione, troglitazone (Rezulin); no documented interaction with rosiglitazone (Avandia); interaction with pioglitazone (Actos) not studied | Use alternative method of contraception |
| Protease inhibitors (Agenerase, Crixivan, Norvir, Viracept) | Decreased contraceptive effect (Agenerase, Norvir, Viracept), possible decreased contraceptive effect (Crixivan) | Use alternative method of contraception |
| Rifampin | Decreased contraceptive effect | Use backup method of contraception; use alternate method if planned concomitant use is long term |
| Sulfonamides | Decreased contraceptive effect | Use backup method of contraception |
| Tetracycline | Decreased contraceptive effect | Use backup method of contraception |
| Theophylline (Bronkotabs, Marx, Primatene, Quibron, Tedral, TheoDur, and others) | Decreased contraceptive effect, increased theophylline effect | Monitor theophylline concentration |
| Troleandomycin (TAO) | Jaundice (additive) | Avoid simultaneous use |
| Vitamin C | Increased serum concentration and possible increased adverse effects of estrogens with 1 g or more per day of vitamin C | Avoid high dose of vitamin C |

INR, International Normalized Ratio; DMPA, depomedroxyprogesterone acetate.
Compiled from refs. 4, 12, 13, 18, 24, and 56.

The lower the dose of hormone in the OC, the greater is the risk that a drug interaction will compromise its efficacy. Women should be instructed to use an alternative method of contraception (e.g., condoms) if there is a possibility of a drug interacting altering the efficacy of the OC.⁴ Several recent reviews of the interaction between antibiotics and OCs have documented a true pharmacokinetic interaction with rifampin in which the efficacy of OCs is impaired. Pharmacokinetic studies of other antibiotics have not shown any consistent interaction, but case reports of individual patients have shown a reduction in EE levels when taken with tetracyclines and penicillin derivatives.^{57,58} The Council on Scientific Affairs at the American Medical Association recommends that women taking rifampin should be counseled about the risk of OC failure and advised to use an additional nonhormonal contraceptive agent during the course of rifampin therapy. The council also recommends that women should be informed about the small risk of interactions with other antibiotics, and if desired, appropriate additional nonhormonal contraceptive agents should be considered. In addition, women who develop breakthrough bleeding during concomitant use of antibiotics and OCs should be advised to use an alternate method of contraception during the period of concomitant use.⁵⁷

Women receiving anticonvulsants for a seizure disorder require special attention with regard to hormonal contraception. Giving a hormonal contraceptive concomitantly with phenobarbital, carbamazepine, or phenytoin reduces the contraceptive's efficacy, and many anticonvulsants (e.g., phenytoin) are known teratogens. The use of condoms in conjunction with high-estrogen OCs, injectable progestin-only contraceptives, or intrauterine devices may be considered for these women.¹⁸

■ Patient Instructions

1 **4** **6** Many women who take OCs are poorly informed about the proper use of these medications. The patient first should be given the package insert that accompanies all estrogen products and instructed to read it carefully. The written information in the package insert should be supplemented with verbal information describing the way in which the medication works (primarily by stopping release of the egg from the ovary), both common and serious side effects, and the management of those side effects. Although there often are several transient self-limiting side effects (e.g., breast tenderness, bloating, breakthrough bleeding, spotting, and nausea), the patient should be aware of the danger signals (see Table 77–5) that require immediate medical attention^{3,4,6} (see Table 77–4). Also, the benefits and risks should be discussed in terms that the patient can understand, including the fact that OCs provide no physical barrier to the transmission of STDs, including the human immunodeficiency virus (HIV). Detailed instructions for when to start taking the medication should be provided. Patients can either start taking the OC on the first Sunday after menses (which provides for period-free weekends) or on the first day of the next menses—either option is appropriate. Patients should be told the importance of routine daily administration to ensure consistent plasma concentrations and improve compliance, and specific instructions should be given regarding what to do if a pill is not taken. Important drug interactions should be discussed.

The patient taking combination OCs should expect her menses to start within 1 to 3 days after taking the last active pill. She should start another pack of pills immediately after finishing a 28-day pack (no days between) or 1 week after finishing the previous 21-day pack, even if her menses is not completed.^{4,6,13} The use of an additional contraceptive method is advisable while the patient is taking the first

pack of pills (especially if she began 5 days or more after the start of her menses), if she misses more than one pill per cycle, or if she experiences severe diarrhea or vomiting for several days. Patients taking progestin-only pills should be advised to use a backup method for 48 hours if they are 3 or more hours late in taking their daily progestin dose.

There is increasing interest in the use of continuous OCs to eliminate monthly withdrawal bleeding. Several prospective studies have assessed the efficacy of continuous OCs in preventing withdrawal bleeding and have found monophasic OCs to be most useful for this purpose. Although patients may experience increased breakthrough bleeding and spotting, there may be a decrease in headache and other menstruation-associated symptoms. With continued use for 1 year, there have not been any significant changes in blood pressure, weight, or hemoglobin when compared with cyclic users. However, long-term studies have not been done to assess the risk of cancer, VTE, or changes in fertility.^{59,60} As an alternative to continuous OCs, a product has been approved recently by the FDA that will produce four menstrual periods per year.⁶¹ This OC pill will provide 12 weeks (84 days) of active EE and levonorgestrel and then 1 week of inactive pills. Therefore, it will allow for one menstrual period per season and is marketed as Seasonale. However, reports from clinical trials demonstrated more breakthrough bleeding and spotting, particularly in the first few cycles, than in women taking a conventional 28-day-cycle OC.

■ Discontinuation of the Oral Contraceptive, Return of Fertility, and Breast-Feeding

Women who have used OCs may take longer to return to their baseline fertility than women who have used barrier contraception methods. Eventually, the percentage of women who conceive after discontinuing the use of OCs becomes the same as for barrier method users.^{4,6,13}

Traditionally, women are counseled to allow two to three normal menstrual periods before becoming pregnant to permit the reestablishment of menses and ovulation.^{4,6,13} However, in several large cohort and case-controlled studies, the infants conceived in the first month after an oral contraceptive was discontinued had no greater chance of miscarriage or being born with a birth defect than those born in the general population.¹³

CLINICAL CONTROVERSY

Existing randomized, controlled trials are insufficient to establish an effect of hormonal contraception, if any, on milk quality and quantity. Current recommendations are to avoid combined OCs in the first 6 weeks postpartum and to use them with caution during the 6-month postpartum period.

It is acceptable to begin any method of hormonal contraception immediately after first- or second-trimester termination of pregnancy (spontaneous or induced). Following third-trimester childbirth, ovulation usually does not begin again for 3 weeks (even in a non-breast-feeding woman), and the risk of maternal thromboembolic disease is increased for approximately the same time period.^{4,6,62,63} Ideally, therefore, estrogen-containing contraceptives are withheld until the third week after delivery, but progestin-only formulations can be initiated immediately.^{4,6,24}

5 Because the hormones in OCs are excreted into breast milk, breast-feeding generally is regarded as a relative contraindication to OC use. This contraindication was based on earlier formulations containing higher doses of hormones and probably does not

apply to current formulations.⁶³ Another concern is that estrogens inhibit the action of prolactin at breast tissue receptors, resulting in decreased milk production and protein content.^{3,4,6,13} Although this is not a particular problem in well-nourished lactating women, many practitioners recommend progestin-only contraceptives because progestins do not diminish the amount of breast milk and provide highly effective contraception in breast-feeding women.^{4,6,13,18,64}

A recent review by the Cochrane Library indicated that existing randomized, controlled trials are insufficient to establish an effect of hormonal contraception, if any, on milk quality and quantity.⁶⁴ Furthermore, the review stated that current recommendations are for breast-feeding women to avoid combined OCs in the first 6 weeks postpartum and to use them with caution in the 6-month postpartum period.⁶⁴

CLINICAL CONTROVERSY

Emergency contraception is likely to be available over the counter because prescription use is thought to limit access, leading to unintended pregnancies. Prior to this change, some states allowed pharmacists to dispense emergency contraception without a prescription, and others were considering collaborative practice agreements to increase pharmacists' ability to provide emergency contraception and counsel women receiving this regimen. Regardless of prescription status, the pharmacist can play an important role in assisting women to use this method correctly.

EMERGENCY CONTRACEPTION

High doses of estrogens can inhibit ovulation, in addition to causing a rapid shedding of the endometrium and preventing implantation of the fertilized ovum.^{3,4,12,65} OCs in one-time high doses are safe and effective as emergency contraception (EC) to prevent pregnancy after unprotected intercourse (e.g., condom breakage, diaphragm dislodging, or sexual assault). The FDA has approved two hormonal contraceptive products (Preven and Plan B) specifically packaged for this use. In most states, EC is available by prescription only. This is viewed as a public health problem, leading to more unintended pregnancies by limiting access to the regimen. Some states allow pharmacists to dispense EC without a physician's prescription, and many others are considering this legislation.^{66,67} Several organizations (AMA, ACOG) support over-the-counter availability of EC and are lobbying the FDA to change this policy.^{66–68}

The Preven Emergency Contraceptive Kit contains four blue tablets, each containing 50 mcg EE and 0.25 mg levonorgestrel (similar to four tablets of Ovral, also known as the Yuzpe regimen). The kit also contains a patient education booklet and a urine pregnancy test to determine if the woman is already pregnant. Plan B contains two white tablets, each containing 0.75 mg levonorgestrel (similar to two 10-tablet doses of Ovrette). The first dose of each of these regimens is to be taken within 72 hours of unprotected intercourse (although the sooner, the more effective); the second dose, 12 hours later.^{3,4,12,65} One study found single-dose Plan B (1.5 mg levonorgestrel) to be as effective as two-dose Plan B or mifepristone, but this regimen is not yet approved by the FDA.⁶⁹

Despite the availability of the new products, it is still permissible to use regular contraceptives for EC. Specifically, the FDA has declared the following regimens safe and effective methods of EC: Ovral (2 tablets/dose); Nordette, Levlen, Levora, Lo/Ovral, Triphasil, Tri-Levlen, or Trivora (4 tablets/dose); and Alesse or

Levlite (5 tablets/dose).^{3,4,13} In addition, progestin-only pills can be used as EC, but a large number of tablets must be taken: Ovrette (20 tablets/dose).^{3,4,13} When these regular contraceptives are used, the first dose should be taken within 72 hours of unprotected intercourse, with a follow-up dose 12 hours after the first.^{3,4,13}

The efficacy of any of the regimens for EC declines if they begin more than 72 hours after intercourse.^{3,4,13} Treatment is totally ineffective by 7 days, when implantation usually occurs. Patients may experience nausea, vomiting, and breast tenderness with this regimen. Although some clinicians prescribe antiemetics prophylactically, others recommend simply repeating the dose if the patient vomits within an hour of taking the pills.

TRANSDERMAL CONTRACEPTIVES

A new combination contraceptive is available as a transdermal patch (Ortho Evra), which includes 0.75 mg EE and 6 mg norelgestromin, the active metabolite of norgestimate.^{70,71} In comparative trials, it has been shown to be as effective as combined OCs. Of the 15 pregnancies reported with the patch, 5 were among women with a baseline weight of greater than 90 kg, so efficacy may be compromised as weight increases. Some patients experience application-site reactions, but other side effects are similar to OCs (i.e., breast discomfort, headache, nausea, and menstrual cramps).

The patch should be applied to the abdomen, buttocks, upper torso, or upper outer arm at the beginning of the menstrual cycle and replaced every week for 3 weeks (the fourth week is patch-free).^{70,71} About 5% of patches will need to be replaced because they become partly detached or fall off all together, so single replacements are also available. Two trials have demonstrated greater compliance with the patch than with an OC, but it remains to be seen if this results in reduced pregnancy rates or safety advantages.

CONTRACEPTIVE RINGS

Hormonal contraception also can be delivered through a vaginal ring. In 2002, the first vaginal ring (NuvaRing) was approved for contraception by the FDA, containing EE and etonogestrel, a progestin.⁷² The ring releases approximately 15 mcg/day EE and 120 mcg/day etonogestrel over a 3 week period of time, thus preventing pregnancy. On first use, the ring should be inserted on or prior to the fifth day of the menstrual cycle, remain in place for 3 weeks, then be removed for 1 week to allow for withdrawal bleeding. The new ring should be inserted on the same day of the week as it was during the last cycle, similar to starting a new OC pack on the same day of the week. A second form of contraception should be used for the first 7 days of ring use or if the ring has been expelled accidentally for more than 3 hours.⁷²

Side effects, precautions, and contraindications for the hormonal ring are similar to those for combined OCs. The most common reported reasons for discontinuation of use were device-related issues, such as foreign-body sensation, device expulsion, and vaginal symptoms. Cycle control with the vaginal ring appears to be as good as or better than with combined OCs, with a low incidence of breakthrough bleeding and spotting after the second cycle of use.^{72,73}

LONG-ACTING INJECTABLE AND IMPLANTABLE CONTRACEPTIVES

Steroid hormones provide long-term contraception when injected or implanted into the skin. The most commonly used steroids for

injectable or implantable contraception are progestins, either alone or in combination with estrogen.^{4,6} Sustained progestin exposure blocks the LH surge, thus preventing ovulation; should ovulation occur, progestins reduce ovum motility in the fallopian tubes; and even if fertilization occurs, progestins thin the endometrium, reducing the chance of implantation. Progestins also thicken the cervical mucus, producing a barrier to sperm penetration. However, FSH is not intensely suppressed by progestin-only contraception; therefore, follicular growth and estrogen concentrations, although lower than normal at times, are maintained.

Women who particularly benefit from progestin-only methods, including minipills, are those who are breast-feeding, those who are intolerant to estrogens (i.e., have a history of estrogen-related headache, breast tenderness, or nausea), those with concomitant medical conditions in which estrogen is not preferred (i.e., have a history of uncontrolled hypertension or dyslipidemia, history of VTE, or history of SLE); and those who smoke and are older than 35 years of age.^{4,6} Pregnancy failure rates with long-acting progestin contraception are comparable with that of female sterilization. Previous reports stated an increased risk of ectopic pregnancy in pregnancies occurring while using one of the progestin-only methods, but a recent study did not find an increase in ectopic pregnancies or fetal anomalies in the 0.42 pregnancies per 1000 women using injectable progestin-only contraception each year. These long-acting methods of contraception do not offer protection from STDs, but the thickened cervical mucus may help to prohibit the entry of bacteria into the upper pelvic region, thus preventing pelvic inflammatory disease.

■ INJECTABLE PROGESTINS

Medroxyprogesterone acetate is similar in structure to naturally occurring progesterone. Depomedroxyprogesterone acetate 150 mg administered by deep intramuscular injection in the gluteal or deltoid muscle within 5 days of the onset of menstrual bleeding inhibits ovulation for more than 3 months.^{4,74} Although this injection may inhibit ovulation for up to 14 weeks, the dose should be repeated every 3 months (12 weeks) to ensure continuous contraception. The manufacturer recommends excluding pregnancy in women more than 1 week late for repeat injection. Depo-Provera is available as a 150 mg/mL injection.⁵⁶

Depomedroxyprogesterone acetate can be used in lactating women, and it may increase the length of time that a woman can breast-feed.⁶ Although depomedroxyprogesterone acetate is safe postpartum and no adverse effects have occurred in infants exposed to depomedroxyprogesterone acetate through breast milk, the manufacturer recommends initiating depomedroxyprogesterone acetate at 6 weeks postpartum in women who are breast-feeding. Depomedroxyprogesterone acetate does not alter blood pressure or increase the risk of VTE. It may be used in women with seizure disorders; not only do anticonvulsant drugs have less effect on depomedroxyprogesterone acetate's efficacy, but also it may decrease the frequency of seizures independently.^{4,75} Noncontraceptive benefits observed in women using depomedroxyprogesterone acetate include reducing the risk of anemia because less menstrual blood is lost and decreasing the incidence of menstrual cramps and pain at ovulation. The incidence of *Candida* vulvovaginitis, ectopic pregnancy, and pelvic inflammatory disease, as well as endometrial and ovarian cancer, is decreased in women using depomedroxyprogesterone acetate for contraception compared with women using no contraception.

Return of fertility may be delayed after discontinuation of depomedroxyprogesterone acetate. The median time to conception from

the first omitted dose is 10 months. Sixty-eight percent of women will be able to conceive within 12 months, 83% within 15 months, and 93% within 18 months of the last injection.⁵⁶

Menstrual irregularities, including irregular, unpredictable spotting or, more rarely, continuous heavy bleeding, are the most frequent adverse effects of depomedroxyprogesterone acetate. In some cases, bleeding may be severe enough to cause a significant drop in hemoglobin. Women who cannot tolerate prolonged bleeding may benefit from a short course of estrogen (e.g., 7 days of 2 mg estradiol or 1.25 mg conjugated estrogen given orally).⁷⁴ The incidence of irregular bleeding decreases from 30% in the first year to 10% thereafter (such that most women are amenorrheic after the first year). After 12 months of therapy, 57% of women report amenorrhea, with the incidence increasing to 68% after 2 years.⁵⁶

Because estrogen concentrations may be lower than normal in women using depomedroxyprogesterone acetate, women can lose bone density. The clinical significance of this bone loss is unknown; it has not resulted in an increase in fracture rates.^{74,76} Breast tenderness, weight gain, and depression occur less commonly (<5%). Weight gain averages 1 kg annually and may not resolve until 6 to 8 months after the last injection. Whether weight gain can be attributed directly to depomedroxyprogesterone acetate is debatable.^{74,76} Minor alterations in total, LDL, and HDL cholesterol have been noted after depomedroxyprogesterone acetate exposure. A decrease in glucose tolerance has been observed in some patients. Clotting factors VII, VIII, IX, and X may be increased. The clinical significance of these minor alterations in metabolism is unknown.^{56,74}

Although used in developing countries for decades, depomedroxyprogesterone acetate was not approved as a contraceptive in the U.S. market until 1992 because of a concern about a possible increased incidence of breast cancer. Overall, the risk of breast cancer in women who have used depomedroxyprogesterone acetate is not increased.^{4,74} However, two studies suggest that the risk may be increased in some groups. One study from the WHO found a very slight increased risk in the first 4 years of use, but the risk did not increase with a longer duration of use.^{77,78} Another study found a possible increased risk in women initiating use at an early age.⁷⁹ These studies suggest that if any effect exists at all, medroxyprogesterone may enhance the growth of already existing tumors. Depomedroxyprogesterone acetate was approved for use in the United States as a contraceptive because worldwide data in millions of women showed benefit on maternal mortality and demonstrated other noncontraceptive benefits, outweighing any possible increased risk of breast cancer.

■ INJECTABLE ESTROGEN/PROGESTINS

1 2 Lunelle is a new once-a-month injectable contraceptive agent containing 5 mg estradiol cypionate and 25 mg medroxyprogesterone acetate.⁸⁰ Like Depo-Provera, it acts by suppressing ovulation. The addition of estrogen has minimal impact on contraceptive efficacy but promotes regular bleeding patterns.⁸¹ Lunelle is administered by an intramuscular injection given every 23 to 32 days. Its efficacy is similar to that of other injectable/implantable contraceptives, and body weight does not appear to affect it.^{81,82} It is a reversible form of contraception, and fertility returns as early as 1 month after discontinuation.⁸³

Most women using Lunelle have regular monthly menstrual cycles, similar to women using nonhormonal contraceptive methods. Menstrual irregularities, such as breakthrough bleeding and spotting, are more common in the first three cycles of use, and less than 1% of women experience amenorrhea.⁸¹ Other adverse events associated

with Lunelle include headache, breast tenderness, weight gain, and acne. Precautions and drug interactions associated with Lunelle are similar to those for other estrogen- and progestin-containing contraceptive methods.

■ SUBDERMAL PROGESTIN IMPLANTS

1 2 Norplant, developed by the Population Council, became the first subdermal progestin implant approved for use in the United States in 1990.⁴ The Norplant contraceptive system is currently a set of six implantable, nonbiodegradable, soft silicone rubber capsules, each filled with 36 mg crystalline levonorgestrel. Capsules are inserted just under the skin to provide continuous contraception for up to 5 years. Early clinical trials included implants with a hard capsule, but they resulted in higher contraceptive failure rates.⁴ Because the cumulative pregnancy rate in all groups of women using Norplant increases significantly during the sixth year, Norplant should be replaced after 5 years. Even with the softer capsules currently available in the United States, failure rates may be unacceptable during the fourth and fifth years of use in women weighing more than 154 pounds. Replacement after 3 years in heavier women helps to ensure effectiveness.^{4,84}

A new system can be inserted immediately after removal of the old system. Removal of a Norplant system often becomes complicated as a result of poor insertion technique, broken capsules, or impedance by fibrous tissue. A U technique of Norplant removal using a 4-mm incision located parallel to the third and fourth implant appears to be an improvement over the manufacturer-recommended technique, especially for personnel who are not highly experienced in this procedure.^{84,85} Norplant II or Jadelle, a levonorgestrel two-rod, 150-mg implant system that provides 3 years of contraception, may prove to be easier to insert and remove than the older system.^{86–88} Implanon is the newest contraceptive implant system, a single rod containing 68 mg 3-keto-desogestrel, that lasts for 3 years. However, none of these products is available currently in the United States.⁸⁹ Other progestin implants, some of which are biodegradable, are under development.⁸⁶

As with other progestin-only methods, the most common side effect of subdermal progestin implants is irregular menstrual bleeding. Approximately 60% to 70% of women using Norplant experience irregular bleeding during the first year of insertion. Prolonged bleeding can be treated with a short course of estrogen (e.g., 2 mg estradiol or 1.25 mg conjugated estrogen daily for 7 to 10 days).^{4,6} Spotting and bleeding decrease in amount and duration with time, but adding several cycles of a low-dose combined

OC can resolve repeated monthly menstrual bleeding.⁴ However, by the fifth year of use, regular bleeding cycles may resume in more than 60% of users. Regular cyclic bleeding in a woman who is using Norplant indicates return of ovulation and a higher risk of method failure.⁸⁴

Fertility returns quickly after the removal of Norplant. Most women return to baseline ovulatory patterns within the first month after removal of the system. Other progesterone-related adverse effects that usually occur in the first year include headache (common), dizziness, breast tenderness, nervousness, nausea, acne, breast discharge, and weight gain. Because of the extremely low concentrations of levonorgestrel released from the Norplant system, drugs that significantly increase hepatic enzymes, including most antiepileptic medications (e.g., phenobarbital, carbamazepine, and phenytoin) and rifampin, lower the efficacy of the contraceptive. Ovarian cysts may occur but usually regress spontaneously within 1 month of detection.^{4,6}

The noncontraceptive benefits of Norplant are similar to those of Depo-Provera, and no clinically significant adverse effects have been observed on carbohydrate metabolism in nondiabetic women, on bone density, on blood coagulation, or on lipid metabolism.^{4,56,90,91}

■ INTRAUTERINE DEVICES

1 2 The low-grade intrauterine inflammation and increased prostaglandin formation caused by intrauterine devices (IUDs) appear to be primarily spermicidal, although interference with implantation is a backup mechanism. The IUD has several contraindications (see Table 77–1). The risk of pelvic inflammatory disease among IUD users ranges from 1% to 2.5%. Because the increase in the risk of infection appears to be related to the introduction of bacteria into the genital tract during IUD insertion, the risk is highest during the first 20 days after the procedure.⁹² Ideal patients for IUD use include parous, monogamous women who are not at risk for STDs or pelvic inflammatory disease. Three IUDs are currently marketed in the United States; all are shaped like a T and are medicated, one with copper (ParaGard), one with progesterone (Progestasert), and the newest one with levonorgestrel (Mirena). ParaGard provides better contraceptive effectiveness than previous copper devices and can be left in place for 10 years. A disadvantage of Progestasert is that it must be replaced annually, but it has been associated with less blood loss during menstruation and less dysmenorrhea. Mirena releases levonorgestrel over a period of 5 years and appears to lead to less systemic levonorgestrel absorption than the levonorgestrel implants (Norplant).⁹³

PHARMACOECONOMIC CONSIDERATIONS

More than half of all pregnancies in the United States are unintended.^{4,6} Not all unintended pregnancies are unwanted; many are just “mis-timed.” Nevertheless, the United States has a higher rate of induced abortions than most other industrialized Western nations. Whatever method is used, preventing unintended pregnancy is highly cost-effective. With regard to the acquisition cost of reversible contraception, spermicides alone are the least expensive method, followed by use with condoms. Depo-Provera is slightly less expensive than Norplant and IUDs. Implantable and injectable methods carry a higher initial cost that can be prohibitive for some women, and the annual cost

is greater if they are removed prior to their expiration. The diaphragm and cervical cap (with spermicide) are midrange in cost, with the female condom being slightly more expensive than the other female barrier methods. OCs, the contraceptive patch, and the vaginal ring are the most expensive forms of reversible contraception. These cost estimates are based on the assumption of 100 acts of intercourse annually. However, with regard to direct medical costs (i.e., method use, side effects, and unintended pregnancies) over 5 years, the copper IUD, vasectomy, Norplant, and Depo-Provera are the most cost-effective. Oral contraceptives are more cost-effective than methods with high failure rates (i.e., barrier methods, spermicides, withdrawal, and periodic abstinence), but even these methods are more cost-effective than no method.⁹⁴

EVALUATION OF THERAPEUTIC OUTCOMES

4 Patients should receive both verbal and written instructions concerning the chosen method of contraception. Follow-up appointments can increase compliance, allow time for the patient to ask questions, and provide opportunities to address other health maintenance issues (e.g., self-breast examination, Papanicolaou smears, STD risk).⁴

At least annual blood pressure monitoring is recommended in all users of OCs. When a patient with a history of glucose intolerance or overt diabetes mellitus begins or discontinues the use of an OC, it is necessary to monitor the glucose level closely for deterioration of the condition. OC users should receive at least annual (more frequent if they are at risk for STDs) cytologic screening. Finally, OC users should undergo examination for clinical problems possibly relating to the OC (e.g., breakthrough bleeding, amenorrhea, weight gain, and acne).

Women using Norplant should be monitored for menstrual cycle disturbances, weight gain, local inflammation or infection at the implant site, acne, breast tenderness, headaches, and hair loss. Women using depomedroxyprogesterone acetate should be asked at 3-month follow-up visits about weight gain, any problems or concerns they may have, menstrual cycle disturbances, and STD risks. Patients on depomedroxyprogesterone acetate also should be weighed and have their blood pressure checked and receive annual examinations (e.g., complete physical examination, Papanicolaou smear, and mammogram) as indicated based on the patient's age.

Choosing a contraceptive method most suited to the patient's needs will reduce the chance of unintended pregnancy significantly. Typical failure rates for some of the commonly used methods of reversible contraception are listed in Table 77-1. A medical and sexual history and a thorough physical examination are essential when evaluating the various methods available. Understanding the risks and precautions associated with the methods available is essential for both the patient and the prescriber (see Tables 77-1 and 77-3).

ABBREVIATIONS

MENSTRUATION-RELATED DISORDERS

Martha P. Fankhauser and Marlene P. Freeman

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Menstruation-related disorders occur commonly during the reproductive years and are characterized by cyclic, somatic, and/or psychological symptoms during the late luteal phase of the menstrual cycle, and often symptoms become more episodic and severe prior to menopause.
- 2 Approximately 90% of women experience symptoms of premenstrual syndrome (PMS), and more than 80% of women report that psychological and physical symptoms worsen during the perimenopause phase. Up to 3% to 5% of menstruating women experience severe mood and anxiety symptoms and meet criteria for the diagnosis of premenstrual dysphoric disorder (PMDD).
- 3 Menstruation-related disorders are the result of a complex interaction between genetic predisposition and cyclic changes in ovarian steroids, neurotransmitters, neurohormones, and neuropeptides.
- 4 A correct diagnosis of dysmenorrhea, PMS, PMDD, and perimenopause is essential. An evaluation and careful work-up should rule out other possible causes of the symptoms.
- 5 Premenstrual and perimenopausal syndromes can manifest with a wide variety of symptoms, including depression, mood lability, irritability, anxiety, insomnia, fatigue, abdominal pain, breast tenderness, muscle aches, headaches, hot flashes, decreased libido, and concentration difficulties. Although some degree of these symptoms may be a normal phenomenon, up to 10% of women have significant impairment in social and/or occupational functioning and require treatment.
- 6 The goals of treatment are to ameliorate or eliminate symptoms, to improve or restore social and occupational functioning, and to minimize adverse effects.
- 7 There are no specific laboratory tests that are diagnostic for PMS or PMDD. A prospective self-rated symptom diary with severity ratings is most helpful in diagnosing and monitoring menstruation-related disorders.
- 8 A stepwise approach is recommended, starting with lifestyle changes and nonpharmacologic treatments, then first-line pharmacologic agents, and finally, second-line agents that may have more adverse effects. After a 3-month trial, nonpharmacologic and/or pharmacologic treatments should be evaluated for efficacy and adverse effects. Combination therapies may be needed for refractory or severe symptoms, if monotherapy is ineffective, and if multiple symptoms persist.
- 9 Perimenopausal women should be evaluated for hormone-replacement therapy (HRT) because deficiency states may cause physical, psychological, and cognitive symptoms. Although hormone concentrations (e.g., 17β -estradiol, inhibin, testosterone, and follicle-stimulating hormone) are diagnostic for menopause, these tests may not be accurate during the perimenopause phase because of erratic and fluctuating hormone levels secondary to changes in ovarian function. Estradiol-replacement therapy has been identified as a successful treatment for perimenopausal women with vasomotor and depressive symptoms. Testosterone-replacement therapy has been reported to improve mood, well-being, and sexual functioning in perimenopausal women. Assessment of the risks versus benefits of HRT should be done regularly during treatment.
- 10 Education, psychotherapy, well-balanced meals and snacks, regular exercise, dietary changes (e.g., limiting caffeine, alcohol, and salt), relaxation therapy, stress reduction, and sleep hygiene are first-line nonpharmacologic approaches for menstruation-related disorders.
- 11 Serotonin (5-hydroxytryptamine, 5-HT)-augmenting antidepressants are effective for treating premenstrual and perimenopausal mood and anxiety symptoms. Serotonin reuptake inhibitors (SRIs) may be given continuously or intermittently during the luteal phase of the menstrual cycle for PMDD.
- 12 Nonsteroidal anti-inflammatory agents (NSAIDs) are the treatment of choice for dysmenorrhea, muscle aches, and headaches. Diuretics such as spironolactone may provide some relief for bloating and fluid retention if sodium restriction is not effective. Vitamin E supplementation may reduce fibrocystic breast changes if caffeine restriction is not helpful.
- 13 Ovulation suppression (e.g., oral contraceptives, danazol, gonadotropin-releasing hormone agonists) should be used before resorting to surgical therapy in women with severe PMDD.

1 During their reproductive years, women are vulnerable to mood and physical changes secondary to hormonal triggers associated with the menstrual cycle.^{1–3} *Dysmenorrhea* is the most common menstrual problem in adolescents. *Premenstrual molimina* describes the mild physical symptoms of breast tenderness and bloating that occur premenstrually. *Premenstrual headache* or *migraine* occurs during the late luteal phase of the menstrual cycle and subsides after the onset of menses.⁴ *Mastalgia* or *mastodynia* is breast pain that is associated with premenstrual syndrome and fibrocystic breast disease. *Premenstrual tension* or *premenstrual syndrome* (PMS) is the cyclic recurrence of a combination of psychological, behavioral, and physical symptoms that occur during the luteal phase of ovulatory menstrual cycles and resolve with menopause.³ A more severe subtype of premenstrual syndrome, previously called *late luteal phase dysphoric disorder* and later renamed *premenstrual dysphoric disorder* (PMDD), is associated with significant mood and anxiety symptoms and an impairment in functioning.^{3,5,6}

Premenopause describes years preceding menopause when women still have regular menstrual cycles but can experience a worsening of mood, sleep, and cognition.^{7,8} The *perimenopausal phase* reflects the transition to menopause and includes the 3 to 5 years before and 1 year after the cessation of menstrual flow. Perimenopause is associated with irregular menstrual cycles, reduced fertility, decreased 17 β -estradiol production, a worsening of premenstrual symptoms (e.g., sleep disturbances, irritability, anxiety, depression, fatigue, mood swings, and cognitive changes), and vasomotor complaints (e.g., hot flashes and night sweats).^{7,8}

Depression is often associated with declining levels of ovarian hormones (i.e., depression is worse prior to menses, immediately after pregnancy, and prior to menopause).^{8,9} Women also have more sleep problems compared with men, and sleep disruption (and deprivation) has a negative impact on mood, energy level, and cognition.¹⁰ Menstruation-associated sleep complaints are secondary to cyclic changes in the levels of reproductive hormones, vasomotor symptoms, and an increase in sleep disorders (e.g., sleep apnea and periodic leg movements) in peri- and postmenopausal women.¹¹

EPIDEMIOLOGY

2 Up to 90% of women experience one or more mood or somatic symptoms just before or during menses in ovulatory cycles.^{1,3,5,12} Common symptoms include dysphoric mood, irritability, anxiety, sleep disturbances, changes in appetite, poor concentration, fluid retention, breast tenderness, and various types of pain syndromes.^{1,13} After menarche, the type and severity of symptoms may change during the reproductive age span.⁶

The prevalence of *dysmenorrhea* increases from early to late adolescence and decreases after age 30 to 35 years. Approximately 40% to 50% of women have painful menstrual cramps, and up to 10% have impaired functioning for 1 to 3 days per month, such as missing work or school, because of pain.¹⁴ Up to 75% of women younger than age 55 experience premenstrual breast pain, and 11% to 30% have moderate to severe *mastalgia* for at least 5 days or more each month that interferes with their daily functioning.^{15,16} Menstruation-related *migraine* affects approximately a third of women at menarche, and peak incidence occurs during adolescence.⁴ Approximately 60% of women complain of menstrual migraine attacks, and 8% to 14% experience only premenstrual migraines.⁴ Migraines often are associated with other somatic complaints (e.g., headache, cramps, nausea, and breast tenderness). Although migraine prevalence decreases with

advancing age, migraines can recur and worsen during menopause, with hormone-replacement therapy, and with oral contraceptive (OC) use.⁴ *Fibromyalgia* (a syndrome of chronic musculoskeletal pain, tenderness over trigger points, fatigue, and sleep disturbances) is more common in women, the incidence increases with age, and the syndrome can cause significant disability.¹⁷

Premenstrual syndrome (variably defined with over 100 possible symptoms) typically begins between the ages of 25 and 35 years.¹⁸ Point-prevalence studies report that up to 50% of menstruating women have PMS (defined as a luteal phase onset of symptoms that resolve midmenses). Approximately 5% to 10% of women have symptoms severe enough to impair their daily functioning during the week prior to and during menses.^{1,4–6,12,18} An estimated 3% to 5% of women have severe affective symptoms and meet criteria for PMDD⁶ (Table 78–1).

Approximately 50% of women with premenstrual complaints have an exacerbation of an underlying psychiatric or medical disorder.^{1,3,6,19} Women with a history of anxiety disorders, dysthymia, major depressive disorder, bipolar disorder, postpartum depression, and mood changes induced by OCs and a family history of mood disorders or premenstrual depression have an increased risk for developing PMDD.^{6,19} Compared with controls, women with PMDD are at higher risk for developing other affective disorders, have lower parity rates, and have higher rates of alcohol and drug use.² Women with PMDD have an increased risk of experiencing depression during pregnancy and the postpartum period (e.g., 10% to 16% develop a major depression during pregnancy, and up to 70% experience depressive symptoms postpartum).²⁰ For more information regarding mood disorders occurring during pregnancy and postpartum, see Chap. 76.

More than 80% of women report that psychological and physical symptoms worsen during the perimenopausal phase.^{6,21} The menopausal transition (when hot flashes begin and there are changes in bleeding patterns) usually begins in the middle to late 40s, and the last menses occurs in the early 50s.² Hot flashes or flushes are one of the most common complaints associated with perimenopause, along with sleep disruption, mood disturbance, and cognitive difficulties.²² Up to 85% of women have vasomotor symptoms during the year preceding and following menopause. Approximately 25% of women report that hot flashes and night sweats are severe enough to impair their sleep and social functioning and will seek treatment from health care providers.^{22–24} Perimenopausal women with vasomotor symptoms are reported to be 4.4 times more likely to be depressed than those without vasomotor symptoms.^{22,25} It is estimated that as many as 80% of perimenopausal women develop mood symptoms, and these individuals have higher prevalence rates of major depression (16% to 20%) during the climacteric.² Perimenopausal women with a previous history of depression, PMDD, or postpartum depression are at increased risk of a recurrent major depressive episode during the climacteric.²

ETIOLOGY

3 Several biologic, cognitive, genetic, psychological, environmental, and social theories have been proposed for menstruation-related disorders, but there are no definite conclusions regarding the etiology.^{2,10,26} The menstrual cycle is a rapidly changing biologic process that involves the hypothalamic-pituitary-gonadal (HPG) axis with input from gonadotropin-releasing hormones (GnRHs), gonadotropins, ovarian hormones, endogenous opioids, neurotransmitters, and neuropeptides.^{8,27–29} The hormonal feedback

TABLE 78–1. Assessment and Diagnosis of Premenstrual Dysphoric Disorder**Assessment**

Interview

- Retrospective history of premenstrual syndrome
- Psychiatric and medical evaluation (past and current history)
- Medication and over-the-counter drug use (including alternative/complementary therapies)
- Exercise, sleep, and nutritional evaluation

Medical review

- Complete physical examination
- Laboratory testing (e.g., thyroid function, anemia, gonadal hormones)

Daily charting

- Prospective daily self-rating of symptoms for two menstrual cycles (e.g., Prospective Record of the Impact and Severity of Menstruation [PRISM], the Calendar of Premenstrual Experiences [COPE], Menstrual Distress Questionnaire [MDQ], Visual Analogue Scale [VAS])

Diagnostic Criteria for Premenstrual Dysphoric Disorder

A 1-year duration of symptoms that are present for the majority of cycles (occurs during the luteal phase and remits during the follicular phase)

Five of the following symptoms (with at least one of the symptoms marked with an asterisk) must occur during the week before menses and remit within days of menses:

- Irritability*
- Affective lability* (sudden mood swings)
- Depressed mood or hopelessness*
- Tension or anxiety*
- Decreased interest in activities
- Difficulty concentrating
- Lack of energy
- Change in appetite, e.g., food cravings
- Change in sleep
- Feeling out of control or overwhelmed
- Other physical symptoms, e.g., breast tenderness, bloating, headaches

Seriously interferes with work, social activities, relationships

Not an exacerbation of another psychiatric disorder

Confirmed by prospective daily charting/ratings during a minimum of two consecutive symptomatic menstrual cycles

Compiled from refs. 6 and 19.

system that controls neuroendocrine functioning is extremely complex and vulnerable to familial factors, psychosocial and environmental stresses, circadian rhythms, and the normal aging process.^{2,5} A circadian rhythm dysregulation theory has been suggested as a possible link between mood disorders and the reproductive cycle.^{2,30}

PATHOPHYSIOLOGY

4 Because medical conditions, emotional/behavioral symptoms, and physiologic indices change during the premenstrual and perimenopause phases, it is important to rule out other disorders that may contribute to mood fluctuations or pain syndromes^{1,13} (Table 78–2). For example, dysmenorrhea may be “primary,” which occurs during ovulatory cycles, or “secondary,” which relates to pelvic pathology (e.g., infection caused by the placement of intrauterine devices, endometriosis, pelvic inflammatory disease, ovarian cyst, endometrial cancer, adhesions, and benign uterine tumors).

PREMENSTRUAL PAIN SYNDROMES

Primary dysmenorrhea is a prostaglandin-mediated hypertonicity of the uterine smooth muscle that constricts uterine blood vessels and leads to ischemia and menstrual pain.¹⁴ At menstruation, the shedding of the uterine lining releases arachidonate and stimulates

prostaglandin synthesis that cause uterine and gastrointestinal smooth muscle contraction and ischemia. Women with PMDD have lower β -endorphin levels in the luteal phase and report greater premenstrual pain, suggesting that endogenous opioids may be involved in the pathophysiology of pain sensitivity.³¹

Mastalgia frequently coexists with fibrocystic breast disease and is commonly a benign condition that occurs during ovulatory cycles.¹⁶ The association between caffeine consumption and mastalgia is unclear, but the reduction or elimination of methylxanthines appears to reduce fibrocystic changes.¹⁵ The cause of premenstrual mastalgia is unknown, but theories include estrogen dominance, an augmented response to prolactin during the luteal phase, high dietary fat intake, and abnormalities in fatty acid metabolism.^{15,16}

PREMENSTRUAL SYNDROME (PMS)

The HPG axis is responsible for the cyclic hormone secretion that regulates and controls ovulation and plays a major role in menstruation-related disorders.^{7,12,27} The menstrual cycle is characterized by cyclic alterations in the production of gonadal hormones (estradiol and progesterone), pituitary hormones (gonadotropins, prolactin, growth hormone), melatonin, and cortisol and in temperature rhythms. Menstruation-related disorders are likely the result of a complex interaction between ovarian steroids and central neurotransmitters, neurohormones, and neuropeptides.^{5,8,12} The occurrence of physical

TABLE 78–2. Conditions and Symptoms that Change or Worsen Premenstrually

| | |
|---|---|
| Medical Conditions | Physical Symptoms |
| Acute porphyria | Abdominal bloating |
| Adrenal disorders | Acne |

Compiled from refs. 1, 13, and 53.

and psychological symptoms is closely linked to the rise and fall of gonadotropins, ovarian hormones, 5-hydroxytryptamine (5-HT), endorphins, and prostaglandins.^{2,7,12,26} The hypothesis that ovarian hormones are important for the pathophysiology of reproductive-related physical and mood disorders is supported by the fact that the onset and disappearance of symptoms are linked to ovulatory menstrual cycles and with the administration of progesterone and estrogen products.¹² Symptoms decline during pregnancy, after drug-induced inhibition of ovulation, with surgical ovariectomy, and after menopause.

Ovarian hormones are potent modulators of neurotransmitters in the brain. Although no differences in plasma levels of 17 β -estradiol and progesterone have been found between women with PMS and controls, these ovarian steroids have an important role in the development and severity of symptoms.^{12,32} Gonadal hormones such as 17 β -estradiol, inhibin, progesterone, and testosterone are the most potent peripherally generated chemical signals in the central nervous system (CNS) that affect neurotransmitter synthesis, release, reuptake, and enzymatic inactivation.^{12,27} 17 β -Estradiol has been shown to affect 5-HT synthesis, levels, and receptors (e.g., promotes tryptophan hydroxylase, the rate-limiting enzyme in the synthesis of 5-HT; reduces 5-HT reuptake transporter activity; and increases the

density of the 5-HT_{2A} receptor in the brain regions associated with mood).^{8,26}

PREMENSTRUAL DYSPHORIC DISORDER (PMDD)

Central serotonergic system dysfunction has been one of the leading theories for the pathogenesis of premenstrual and perimenopausal anxiety and mood changes.^{5,12,28} Women with premenstrual dysphoria have been found to have reduced platelet [³H]paroxetine binding sites compared with controls, which may reflect abnormalities with brain serotonergic transmission at the presynaptic reuptake pumps.³³ Further evaluation of 5-HT transporter gene polymorphism was not associated with the decreased platelet 5-HT transporter density in women with PMDD.³³ A premenstrual reduction in protein intake has been reported in overweight women with PMS that could decrease the availability of L-tryptophan and its conversion to 5-HT.³⁴

5-HT is converted to melatonin in the pineal gland under the influence of darkness, and its production is controlled by a circadian temperature rhythm and synchronized by the light-dark cycle. Several studies have reported reduced and earlier secretion of

nocturnal melatonin in women with PMDD.³⁵ The pineal gland secretes melatonin under the influence of darkness, and the suprachiasmatic nuclei of the hypothalamus controls its release through β -adrenergic receptors. β -Adrenergic blockers such as propranolol suppress melatonin production and may cause insomnia, whereas tryptophan- and 5-HT-augmenting agents increase melatonin levels.

The GABAergic system appears to be involved in the pathophysiology of PMDD.³⁶ γ -Aminobutyric acid (GABA) neuronal function is modulated by gonadal steroids, and brain levels have been found to fluctuate across the menstrual cycle.³⁶ Plasma GABA levels have been reported to be lower across the menstrual cycle in women with PMDD compared with controls.³⁷ Cortical levels of GABA were found to decrease across the menstrual cycle in healthy women, whereas there was an increase in levels from the follicular phase to the midluteal and late luteal phase in women with PMDD compared with the controls.³⁶ Plasma allopregnanolone levels, a metabolite of progesterone that binds to the GABA_A receptor, were reported to be higher in untreated women with PMDD³⁸ and lower in women with PMDD who responded to antidepressant treatment compared with controls.³²

A genetic factor has been proposed for PMDD because several twin studies have found higher concordance rates in monozygotic twins than in dizygotic twins. Premenstrual mood symptoms and postpartum depression also may be linked genetically. During the postpartum period, hormonal changes are more extreme and sustained than they are in the normal menstrual cycle; thus women are particularly vulnerable to the development or exacerbation of anxiety and mood disorders during these times.²⁶ PMDD and seasonal affective disorder (SAD) may share a genetic vulnerability based on a study of polymorphism in the 5-HT transporter-promoter gene (i.e., women with PMDD and SAD were heterozygous for the 5-HTTLPR *l* and *s* alleles).³⁹ Women with severe PMDD have been found to have a higher prevalence of SAD compared with controls.⁴⁰

PERIMENOPAUSE

Perimenopause is associated with erratic ovarian function that causes variation in the amount or duration of menstrual flow, change in the length of the menstrual cycle, and skipped menstrual periods.^{7,21} The number of ovarian follicles diminishes gradually during a woman's reproductive life, but by the fortieth year, the decline becomes more rapid; by menopause, only a few follicles remain. Menopause generally occurs between the ages of 47 and 53 years, and 90% of women experience menopause by age 55.⁷ In natural menopause, the ovaries continue to secrete the precursor to testosterone, androstenedione, which can be converted to estrone and estradiol, both weak estrogens. The deficiency of testosterone and its conversion to 17β -estradiol, the primary active estrogen, is associated with causing physical and cognitive changes. Surgical menopause occurs when the ovaries are removed and results in an abrupt and complete loss of the ovarian secretion of testosterone, 17β -estradiol, and progesterone. After menopause, there is an absence of ovarian steroids as well as decreased serotonergic functioning.^{8,41}

Compared with controls, perimenopausal women with depression have lower follicular phase plasma 17β -estradiol levels and higher luteinizing hormone (LH) levels.⁴² Women with a lifetime history of major depression may have an earlier decline in ovarian function and onset of perimenopause (e.g., higher follicle-stimulating hormone [FSH] and LH levels and lower 17β -estradiol levels).⁴³ The perimenopausal transition is a time of increased vulnerability for depressive episodes, particularly in women with a history of mood disorders.⁴³

CLINICAL PRESENTATION

PREMENSTRUAL SYNDROME (PMS)

5 Premenstrual symptoms begin at menarche and are absent during anovulatory cycles, pregnancy, and after menopause. Sequential hormone replacement with estrogen and progestogen products can produce the same symptoms associated with hormone fluctuations.²⁹ Although some women experience positive premenstrual changes, such as increased energy and productivity, most women experience negative changes in mood, appetite, sleep, and energy.¹ Women with PMS usually rank anxiety, irritability, mood lability, and fatigue as the most distressing symptoms.⁴⁴ Common emotional and behavioral symptoms include sadness, anhedonia, feelings of insecurity, low self-esteem, anger attacks, oversensitivity, crying episodes, decreased concentration, and food cravings. Physical changes (e.g., back pain, breast tenderness, headaches, water retention, and bloating sensations) may be better tolerated and cause less dysfunction than mood or behavioral changes do.⁴⁴ Cystic mastalgia is a common problem with PMS and is usually bilateral and nonlocalized (with no sign of pathology on mammographic testing).^{14,16} Breast pain can be severe and often interferes with social and occupational functioning and sexual activity; thus women often seek medical care for the problem.¹⁴

PREMENSTRUAL DYSPHORIC DISORDER (PMDD)

PMDD is listed as an example of a category called *depressive disorder not otherwise specified* in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* (see Table 78–1 for diagnostic criteria).⁶ In order to confirm a diagnosis of PMDD, women must chart symptoms for at least two cycles using standardized prospective instruments.⁴⁵ The onset of PMDD typically occurs during the late teens to twenties (average age of onset is about 26 years), and the symptoms usually peak in the third or fourth decade.² During the perimenopause phase (up to 10 years prior to menopause), PMDD may become more severe and refractory to standard 5-HT-augmenting treatments secondary to the decline in the ovarian production of estradiol.⁴³ Common negative outcomes of PMDD include marital discord, physical and verbal abuse of others, difficulties in parenting, criminal behavior, poor work or school performance, work absenteeism, social isolation, accidents, hospitalizations, and suicide ideation.^{1,2,19,46}

PERIMENOPAUSE

In the climacteric phase preceding menopause, women report trouble sleeping, hot flashes, anxiety attacks, nervous tension, depression, irritability, mood swings, short-term memory loss, and decreased libido.^{7,21} Hot flashes and night sweats may disrupt sleep, which can cause irritability, fatigue, and poor concentration.² Irregular menstrual periods, vaginal dryness, urogenital atrophy, and urinary incontinence are caused by declining 17β -estradiol levels. A self-reported symptom checklist can be used to determine menopause-related symptoms over three dimensions—psychological, somatic, and vasomotor symptoms.⁴⁷ Women with a past history of mood disorders, premenstrual and postpartum depression, and a lengthy and symptomatic menopause transition may be at risk for major depressive episodes.^{2,7,21,43} Predictors of an earlier age of perimenopause and menopause include an early age at menarche, cigarette smoking, a hysterectomy, a family history of early menopause, and a lifetime history of depression.^{21,42,43}

▶ TREATMENT: Menstruation-Related Disorders

■ DESIRED OUTCOME

6 The goals of treating menstruation-related disorders are to minimize symptoms and to improve functioning and well-being without causing adverse effects.

■ GENERAL APPROACH TO TREATMENT

7 Before a diagnosis of a menstruation-related disorder is made, other medical or psychiatric conditions should be excluded (see Table 78–2). Mood and anxiety disorders often first occur during childbearing years and may require standard pharmacologic approaches. Effective treatment depends on an accurate diagnosis, identification and avoidance of triggers, and the development of a treatment plan that reduces the impact of the most disturbing symptoms.¹⁹ A self-rated daily diary or calendar helps to establish a relationship between symptoms and the menstrual cycle and to monitor changes with different treatment approaches. Women should prospectively rate themselves daily for at least two menstrual cycles to determine baseline severity ratings so that treatments can be tailored to the most bothersome symptoms.^{2,19} Women with severe PMDD may require immediate pharmacologic interventions because of the disruption in their lives.

8 It is recommended that the clinician follow a stepwise approach beginning with lifestyle modifications and nondrug therapies before resorting to pharmacologic treatments.³ The weighing of risk versus benefit of pharmacologic interventions is important because some medications cause significant adverse effects and may have teratogenic properties.

In general, five different treatment strategies are used for menstruation-related disorders: (1) lifestyle changes to minimize precipitants, (2) physical and behavioral symptom relief, (3) modification of neurotransmitter/hormonal imbalances, (4) suppression of ovulation, and (5) removal of ovaries.

CLINICAL CONTROVERSY

Laboratory tests such as FSH and 17β -estradiol determinations are used frequently to diagnose perimenopause. The value and accuracy of these levels are controversial because levels fluctuate considerably each month depending on whether ovulation has occurred. No one symptom or laboratory test is accurate by itself to diagnosis perimenopause or PDD.

9 Perimenopausal women have varying degrees of severity of their symptoms (i.e., psychological, somatic, and vasomotor) that fluctuate based on hormonal changes in the late reproductive phase. Longitudinal monitoring of perimenopausal symptoms using a standardized rating scale is helpful to assess the severity and fluctuations during this period.^{3,47,48} The use of serum hormone concentrations for diagnosing perimenopause may not be accurate because hormone levels vary widely from woman to woman, and levels change during the day and month based on ovarian functioning. In early perimenopause, there are reduced inhibin B levels (owing to fewer follicles) and a rise in FSH levels, with no significant change in 17β -estradiol or inhibin A levels.²¹ FSH levels fluctuate considerably depending on whether

ovulation has occurred, and 17β -estradiol levels may be normal or elevated depending on the activity of the ovaries. Thus laboratory tests may not be reflective of perimenopause.²¹ An elevated serum FSH level (>25 IU/L), in conjunction with a low free 17β -estradiol level (<40 pg/mL) measured on day 2 or 3 after the onset of menses and a low inhibin B level (<30 ng/L), is suggestive of perimenopause.²¹ At menopause, FSH levels are usually higher than 40 IU/L, 17β -estradiol levels are under 25 pg/mL, and both inhibin A and inhibin B levels are reduced.

Middle-aged women with somatic and mood symptoms should undergo evaluation for perimenopausal depression. Transdermal 17β -estradiol replacement can reduce vasomotor symptoms significantly; improve mood, sleep, and cognition; and decrease the risk of osteoporosis.^{49–51} Transdermal testosterone therapy has been shown to improve mood, well-being, and sexual functioning in perimenopausal women.⁵²

Hormonal fluctuations during the menstrual cycle, postpartum period, and peri- and postmenopause phases may cause differences in the pharmacokinetics and pharmacodynamics of drugs (e.g., changes in drug absorption, distribution, metabolism, and excretion). Thus clinicians must be aware of gender differences when prescribing medications.^{53–55}

■ NONPHARMACOLOGIC THERAPY

10 A great number of lifestyle changes and nonpharmacologic treatments are promoted for menstruation-related disorders without evidence-based studies.^{1,3,5,14,19,24,56–61} Examples of lifestyle modifications and nondrug remedies recommended for menstruation-related disorders are listed in Table 78–3.

■ PHARMACOLOGIC THERAPY

After women have tried lifestyle changes, nutritional supplements, and nonpharmacologic treatment approaches, some may require pharmacologic therapies if there is limited response. Women with severe PMS generally self-treat headaches and cramps with aspirin, acetaminophen, and nonsteroidal anti-inflammatory drugs (NSAIDs). NSAIDs, such as naproxen and ibuprofen, are the treatments of choice for dysmenorrhea, menstrual headaches or migraines, and mastalgia.

For PMDD, the first-line strategy is to augment serotonergic neurotransmission, and the second-line strategy is to induce an anovulatory state using different types of hormonal treatments. For the perimenopause syndrome, augmentation of 5-HT neurotransmission and hormone-replacement therapy are the most common treatment strategies. Clinical studies have reported that 17β -estradiol replacement improves mood in perimenopausal and postmenopausal women with no or mild depression.⁸ In postmenopausal women, 17β -estradiol therapy alone or in combination with antidepressants may be used to treat a major depressive episode.

■ DRUG TREATMENTS OF FIRST CHOICE

■ Published Guidelines or Treatment Protocols

There are no published consensus guidelines for the treatment of menstruation-related disorders.^{3,19} Information about pharmacologic

TABLE 78–3. Nonpharmacologic Treatments for Menstruation-Related Disorders

- Education about the symptoms, treatment approaches, and strategies to reduce target behaviors
- Daily charting for two menstrual cycles to identify target symptoms
- Reduction or discontinuation of alcohol, caffeine, nicotine, and drugs of abuse
- Regular conditioning or aerobic exercise at least three times a week (with an increase in the daily workout routine by 30 minutes during the premenstrual week) and weight-bearing exercises to prevent osteoporosis
- Bright, white morning light (and possibly evening light) for 1 week premenstrually for seasonal worsening of premenstrual syndrome
- Regular, well-balanced, scheduled meals with adequate fiber, protein, essential fatty acids, complex carbohydrates, vitamins, calcium, and minerals
- Reduced intake of salt, fat, and simple sugars
- Increased intake of phytoestrogen-rich foods (soybean products) and tryptophan-containing foods (fish, poultry, and dairy products)
- Reduce weight to obtain a normal body mass index
- Adequate rest and a regular sleep cycle in a cool, dark room
- Dress in layers, consume cool foods and drinks, and use a fan for hot flashes
- Stress management, relaxation training, yoga, massage, biofeedback, and self-hypnosis
- Acupuncture, electroacupuncture, or acupressure treatment for dysmenorrhea, headaches, and pain symptoms
- Low-level topical heat for dysmenorrhea
- Individual, group, or family therapy, cognitive behavioral therapy, support groups, anger management, and assertiveness training

Compiled from refs. 1, 3, 5, 14, 19, 24, 56–61, and 96.

treatments and nonprescription remedies used for specific symptoms appears in Table 78–4. Examples of treatment approaches for different menstruation-related disorders are found in Table 78–5. An example of an algorithm for the diagnosis and management of PMDD is given in Fig. 78–1.

■ General Information Regarding Efficacy and Safety

PMDD should first be treated with 5-HT-augmenting antidepressants.^{5,28,58,62–64} Fluoxetine, sertraline, and paroxetine are the only agents currently approved by the Food and Drug Administration (FDA) to treat PMDD, but other serotonin reuptake inhibitors (SRIs) are also effective.⁶⁵ These agents work by blocking presynaptic 5-HT transporter pumps, and their efficacy depends on 5-HT synthesis and release from the neuron. Patients should be reminded that adequate and regular intake of L-tryptophan (e.g., animal-derived protein such as dairy products, eggs, poultry, fish, and other meat sources) is important for the synthesis and storage of 5-HT in the brain and for the efficacy of SRIs.^{28,34} Although benzodiazepines may be useful in the treatment of acute anxiety and intermittent insomnia, these agents should be used only as adjuncts to 5-HT-augmenting antidepressants because they do not alleviate the core symptoms of depression.

For women with premenstrual exacerbation of an underlying depression, severe PMDD, or climacteric depression, a 6- to 12-month course of an antidepressant is recommended. Some women benefit from continuous antidepressant dosing with an intermittent increase in dose prior to the onset of symptoms and a reduction in dose at the onset of menses. Varying the antidepressant dosage and adding supplemental medications based on menstruation-related symptoms have been shown empirically to be helpful. It may be necessary to try several different treatments to find an acceptable therapy.

Perimenopausal symptoms often respond to transdermal 17 β -estradiol replacement therapy, along with a 5-HT-augmenting antidepressant if severe mood or anxiety symptoms are present.^{26,41,49–51,66} Equine conjugated estrogens may not be effective because of the low content of 17 β -estradiol in the product and

the high content of other estrogen components that are not bioidentical to human estradiol metabolites.⁶⁷ Perimenopausal depression should be treated with standard antidepressant therapy such as 5-HT and norepinephrine (NE) reuptake inhibitors. Synthetic progestogens (e.g., medroxyprogesterone) may increase depressive symptoms and reduce the beneficial effects of estradiol.^{2,26}

CLINICAL CONTROVERSY

Women often seek relief for premenstrual and perimenopausal symptoms from alternative or nontraditional treatments without consulting their health care providers. Herbal therapies, phytoestrogens, progesterone creams, megavitamins, folk remedies, and homeopathy are marketed to women without scientific evidence of efficacy or safety. Clinicians should ask women if they use alternative/complementary therapies and become familiar with the products (e.g., mechanism of action, efficacy, dosing, side effects, monitoring, and drug-herb and herb-herb interactions).

■ ALTERNATIVE DRUG TREATMENTS

■ Vitamin, Mineral, Herbal, Nutritional, and Hormonal Therapies

Complementary (or alternative) medical approaches are used widely by women to treat menstruation-related disorders.^{23,24,56–61,67,68} Daily supplementation of vitamins, minerals, and calcium, along with a well-balanced diet, is the first-line therapy for all menstruation-related disorders and helps to reduce deficiency states, particularly in peri- and postmenopausal women.⁶⁸ Vitamin E supplementation in doses of 300 and 400 IU/day may be effective in relieving some premenstrual symptoms based on a few controlled studies.¹⁴ Over-the-counter products that contain megadoses of vitamins, as well as minerals and trace elements, have been marketed for PMS without clinical trials to document their effectiveness or safety. There are several brands of products for PMS (e.g., a combination preparation of a mild diuretic,

TABLE 78-4. Pharmacologic Treatments and Nonprescription Remedies for Menstruation-Related Disorders

| | |
|--|--|
| Vitamins and Minerals | |
| <i>Supplementation</i> | |
| Pyridoxine | 50–100 mg/day (>200 mg/day associated with risk of peripheral neuropathy) |
| Calcium | 1200–1600 mg/day in divided doses 2–4 times/day (minimum of 1000 mg/day for ages 19–50 and 1200 mg/day for ages >51 years) plus adequate vitamin D intake (e.g., 200–600 IU/day) |
| Magnesium | 100–360 mg/day in divided doses during the luteal phase |
| Over-the-Counter/Herbal Products | |
| <i>Hot flashes</i> | |
| Black cohosh | Various products (e.g., tablets, drops) and dosages used; 27-deoxyactein content 1 mg per 20-mg tablet for Remifemin product |
| Dietary isoflavones | Soy-derived isoflavones (40–80 mg/day); red clover-derived isoflavones (40–80 mg/day) |
| Vitamin E | 400–800 IU/day |
| <i>Mastalgia</i> | |
| Evening primrose oil | 500 mg/day to 1000 mg three times daily on days 16–28 of menstrual cycle |
| Chaste tree or chasteberry | 30–40 mg/day on days 16–28 of menstrual cycle |
| Vitamin E | 400–800 IU/day |
| <i>Insomnia</i> | |
| Melatonin | 0.1–1 mg at bedtime |
| Valerian | 400–900 mg at bedtime |
| <i>Depressive/anxiety symptoms (mild)</i> | |
| St. John's wort | 300 mg (standardized to 0.3% hypericum) three times daily |
| Diuretics | |
| <i>Fluid retention/swelling</i> | |
| Spironolactone | 50–100 mg/day in divided doses starting on days 12–16 until onset of menses |
| Nonsteroidal Anti-Inflammatory Drugs | |
| <i>Headache, backache, dysmenorrhea, and mastalgia</i> | |
| Ibuprofen | 200–400 mg every 4–6 hours or 600 mg twice daily starting 1 week before menses and during first few days of bleeding |
| Mefenamic acid | 250–500 mg three times daily starting as early as day 16 of cycle or at start of symptoms |
| Naproxen sodium | 550 mg and then 275–550 mg twice daily starting 1 week before menses and during first few days of bleeding |
| Anxiolytics | |
| <i>Anxiety symptoms:</i> Treat only during the luteal phase and only if serotonin reuptake inhibitors are ineffective. | |
| Alprazolam | 0.25–1.5 mg/day in divided doses during the luteal phase to reduce the risk of dependence |
| Buspirone | 16–60 mg/day in divided doses continuously or on days 16–28 of menstrual cycle |
| Antidepressants | |
| <i>Affective symptoms:</i> Use serotonin reuptake inhibitors only during the luteal phase (e.g., 7–14 days premenstrual) for a 2-month trial. Switch to continuous daily administration if response is inadequate and increase dose 7–14 days premenstrually if needed. A discontinuation syndrome may occur if using higher doses without tapering dose down gradually over several days. | |
| Citalopram | 10–40 mg/day |
| Escitalopram | 5–20 mg/day |
| Fluoxetine | 10–40 mg/day |
| Fluvoxamine | 50–200 mg/day (may require tapering off) |
| Paroxetine | 10–30 mg/day (may require tapering off) |
| Sertraline | 50–150 mg/day |
| Venlafaxine | 75–375 mg/day in divided doses (may require tapering on and off) |
| Dopamine Agonist | |
| <i>Mastalgia</i> | |
| Bromocriptine | 2.5 mg twice daily on days 10–28 of menstrual cycle |
| Hormonal Therapies | |
| <i>Perimenopausal symptoms (vasomotor symptoms, atrophic vaginitis, emotional symptoms, sexual dysfunction)</i> | |
| 17 β -Estradiol | 25–200 mcg transdermal patch (once-weekly patch or twice-weekly patch replacement); vaginal cream, ring, and tablets used primarily for vaginal atrophy and urogenital symptoms |
| Micronized progesterone | 100–200 mg/day orally on days 17–28 or continuous (with intact uterus); progesterone topical products may not provide adequate serum progesterone levels to prevent estrogen-induced endometrial hyperplasia |
| Testosterone | 150 mcg/day transdermal patch twice weekly (for low libido) |
| <i>Suppression of ovulation (severe premenstrual syndrome or premenstrual dysphoric disorder)</i> | |
| Oral contraceptives | Estradiol + progesterone/progestogen (monophasic products on a continuous basis; biphasic products may cause more mood changes) |
| Estradiol | 100–200 mcg transdermal patch every 3–7 days with add-back progesterone |
| Danazol | 200–400 mg/day in divided doses at onset of breast pain until first day of menses (for mastalgia or premenstrual migraines) |
| Leuprolide | 3.75–7.5 mg intramuscular injection monthly plus add-back estradiol and progesterone |
| Buserelin | 400–900 mcg/day intranasal plus add-back estradiol and progesterone |
| Goserelin | 3.6 mg subcutaneous injection monthly plus add-back estradiol and progesterone |

Compiled from refs. 12, 13, 18, 19, 68, 77, and 96.

TABLE 78–5. Treatment Approaches for Menstruation-Related Disorders**First-Line Treatment Approaches***Lifestyle changes*

- Regular, frequent, and small balanced meals with complete proteins, essential fatty acids, and complex carbohydrates
- Low dietary intake of fat and sodium
- Caffeine restriction
- Regular exercise
- Smoking cessation
- Alcohol restriction
- Regular sleep

Nonpharmacologic treatments

- Patient education about the cause, diagnosis, and treatment
- Stress reduction and management
- Anger management
- Self-help support group
- Individual and couples therapy
- Cognitive-behavioral therapy
- Light therapy with 10,000-lx cool-white florescent light (morning or evening)
- Acupuncture

Nutritional supplements

- Multiple vitamin with minerals once daily
- Essential fatty acids (omega-3 fatty acids), various products and dosages
- Pyridoxine up to 100 mg/day
- Vitamin E up to 800 IU/day
- Calcium carbonate up to 2000 mg/day
- Magnesium up to 400 mg/day

Second- and Third-Line Treatment Approaches*Dysmenorrhea*

- Nonsteroidal anti-inflammatory drugs: ibuprofen, ketoprofen, naproxen sodium
- Alternative: mefenamic acid, acupuncture

Bloating/fluid retention

- Sodium reduction/restriction
- Spironolactone
- Alternative: amiloride, metolozone, hydrochlorothiazide, triamterene

Mastalgia

- Caffeine restriction (for fibrocystic breast disease)
- Evening primrose oil
- Chasteberry (minimal evidence for efficacy)
- Vitamin E (for fibrocystic breast disease)
- Nonsteroidal anti-inflammatory drugs: ibuprofen, ketoprofen, naproxen sodium
- Alternative: bromocriptine, danazol, oral contraceptives, gonadotropin releasing hormone agonist ± estradiol/progesterone add-back therapy

Migraines

- Caffeine restriction
- Nonsteroidal anti-inflammatory drugs: ibuprofen, ketoprofen, naproxen sodium
- Alternative: mefenamic acid, cyclooxygenase-2 inhibitors, acupuncture, oral contraceptives, triptans, intermittent 17 β -estradiol, gonadotropin-releasing hormone agonist ± estradiol/progesterone add-back therapy

Insomnia

- Caffeine restriction
- Melatonin or valerian
- Alternative: trazodone, short-acting benzodiazepine, zaleplon, zolpidem (short-term use only)

Anxiety

- Caffeine restriction
- Serotonin reuptake inhibitor (intermittent during luteal phase)
- Alternative: buspirone (intermittent during luteal phase), alprazolam (short-term use only)

Depression

- Serotonin reuptake inhibitor (intermittent luteal phase therapy or continuous)
- Alternative: St. John's wort (mild symptoms only)

Severe premenstrual dysphoric disorder (multiple severe symptoms)

- Serotonin reuptake inhibitor (intermittent or continuous with increase in dose during luteal phase)
- Alternative: danazol or gonadotropin-releasing hormone agonist for 2–3 cycles (if longer treatment, estradiol ± progesterone add-back therapy may be required)

Perimenopausal symptoms (hot flashes, sleep disturbances, mood and cognitive changes)

- 17 β -transdermal estradiol (with progesterone if intact uterus)
- Alternative: serotonin reuptake inhibitors; gabapentin for hot flashes only

Compiled from refs. 1, 2, 7, 18, 20, 68, 77, and 96.

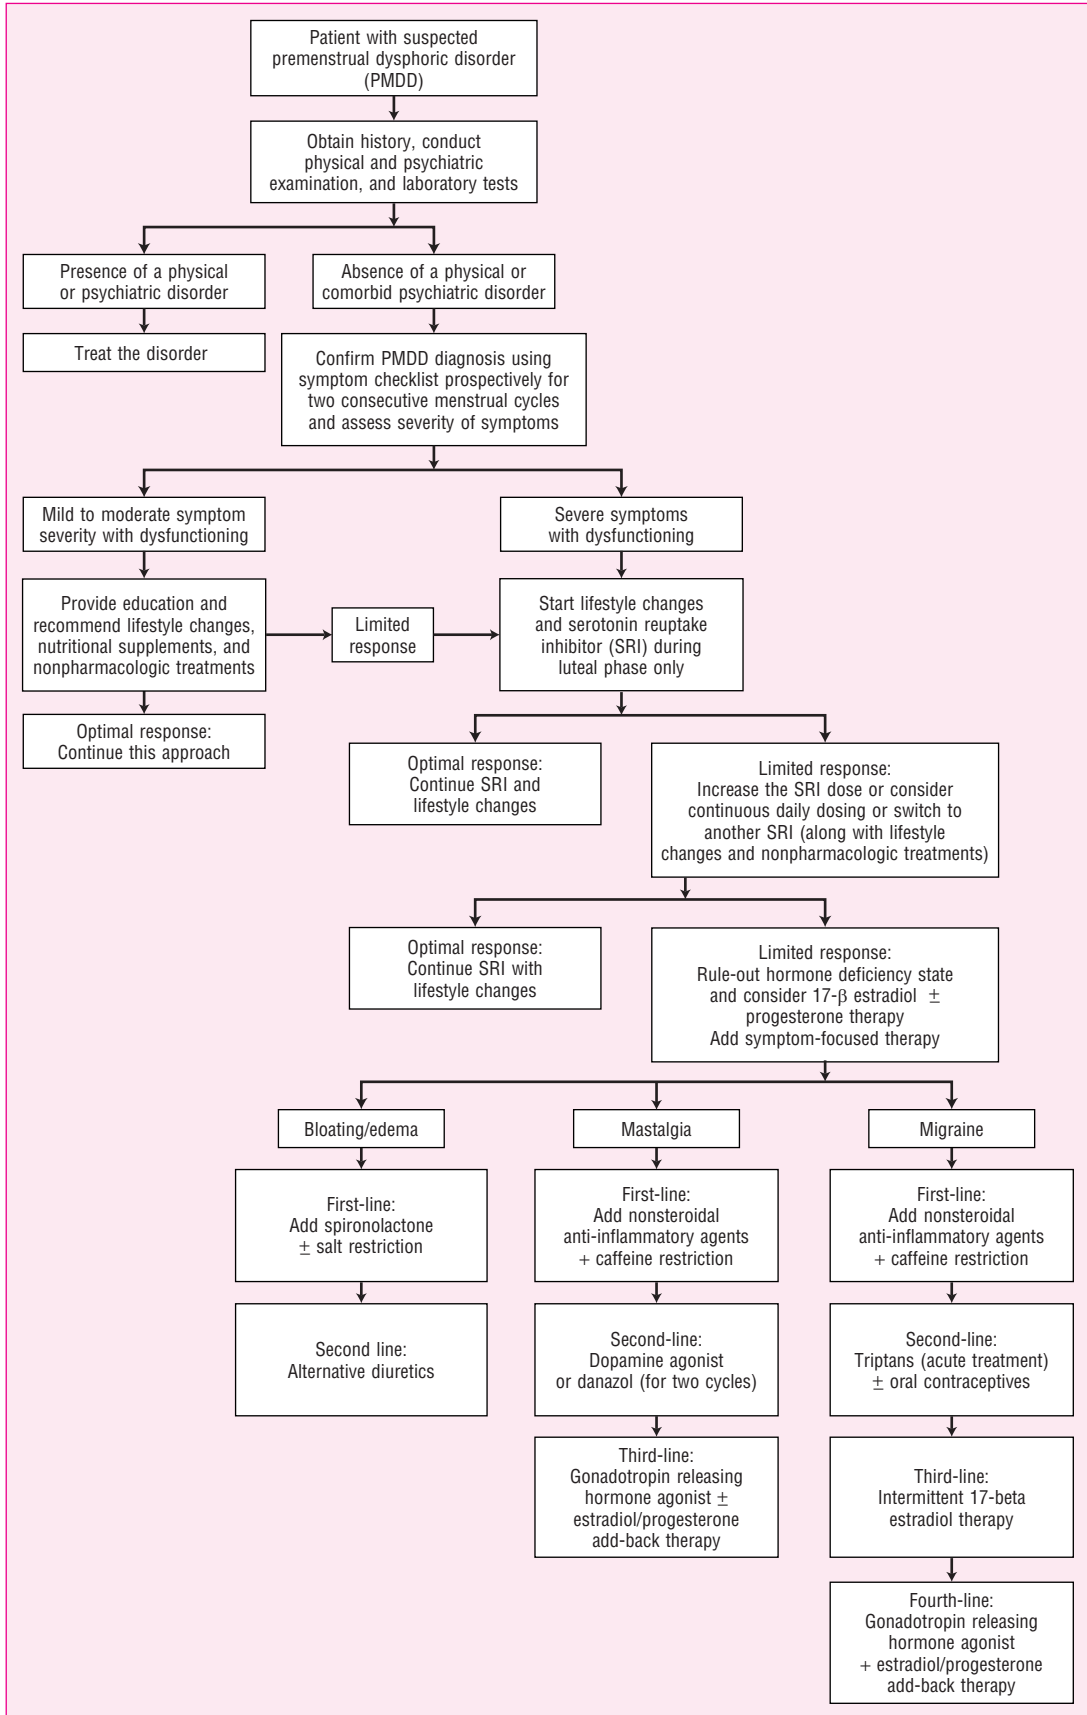

FIGURE 78-1. Algorithm for the treatment of premenstrual dysphoric disorder (PMDD).

an analgesic, and an antihistamine), but no efficacy data are available for these products.

Although pyridoxine (vitamin B₆) is used commonly as a treatment for PMS in doses of 50–100 mg/day, there is no evidence that women have a premenstrual pyridoxine deficiency. Pyridoxine has been reported to reduce the severity of premenstrual depression, fatigue, irritability, headache, and edema, but controlled studies have provided little support for its efficacy in PMS.^{14,68} After a meta-analysis of nine published studies with pyridoxine, the authors suggested that doses of 50–100 mg/day pyridoxine may be beneficial in relieving premenstrual symptoms despite the lack of randomized, controlled studies.⁶⁹ Pyridoxine has been reported to cause peripheral neuropathy in excessive doses (e.g., 2000–6000 mg/day), and a reversible peripheral neuropathy has occurred with daily dosages of 200 mg.^{14,69}

Magnesium is involved with many neuromuscular activities and cellular pathways that may affect PMS.⁶⁸ Low intracellular magnesium levels have been reported in women with PMS compared with controls.⁷⁰ It has been suggested that PMS may be related to an increased serum calcium-to-magnesium ratio.⁷¹ Daily or luteal magnesium supplementation of 200–360 mg/day was reported to be minimally helpful in reducing premenstrual fluid retention in women with PMS.^{18,72} A daily supplementation of 200 mg magnesium and 50 mg pyridoxine was found to reduce anxiety-related premenstrual symptoms in women with PMS compared with placebo.⁷³

Abnormalities in calcium or parathyroid hormone homeostasis may be a factor in depression.⁶¹ Significant fluctuations in calcitonin, a calcium-regulating hormone, and low plasma calcium levels during the menstrual cycle may play a part in the etiology of PMS.^{74,75} Calcium influx into brain cells is involved with the release of many neurotransmitters. Calcium supplementation (e.g., 1200–1600 mg/day of calcium carbonate in two divided doses) has been shown to reduce premenstrual symptoms such as anxiety, depression, irritability, mood swings, headache, fluid retention, and cramps.^{14,68,74–76} Calcium supplementation may help to prevent osteoporosis later in life, and it is a relatively safe and inexpensive treatment.⁷⁶

Although herbal products and nutritional supplements are promoted for PMS and menopause, little is known about their dosing, efficacy, or safety.^{23,24,57,60,61,77,78} Up to 80% of peri- and postmenopausal women have reported using botanical dietary supplements (e.g., soy, green tea, chamomile, ginkgo, ginseng, echinacea, St. John's wort, black cohosh, garlic, red clover, kava, valerian, evening primrose, and ephedra).^{23,24} Because the FDA does not regulate herbal preparations and dietary supplements, active ingredients may vary from brand to brand.

St. John's wort (*Hypericum perforatum*), the most popular herbal remedy for mild depression, was reported to have efficacy in randomized, controlled trials and in one open-label PMS trial.^{14,57,79} For the treatment of menopausal symptoms, only one observational study has reported that women had substantial improvement in physical and psychological symptoms.^{14,80} The usual dose recommended for mild depression is 300 mg three times daily of a standardized product (hypericum 0.3%).⁵⁷ Several in vitro and human studies suggest that St. John's wort induces the hepatic cytochrome P450 3A4 enzymes and may decrease the efficacy of OCs and should not be combined with SRIs because of the potential risk of a 5-HT syndrome.^{77,78,81}

Ginkgo biloba is marketed for improving memory and is often added to combination products to help relieve depression, anxiety, and memory impairment in menopausal women despite the lack of scientific evidence.^{14,24} For PMS, *Ginkgo biloba* has been shown to improve mood and reduce breast tenderness and fluid retention when taken at 80 mg twice daily during the luteal phase.⁵⁷ Ginkgo inhibits platelet-activating factors and may increase bleeding in some

people. Ginkgo also interacts at the cytochrome 450 enzymes in the liver and may cause drug interactions when combined with multiple medications.⁵⁷

Dong quai (*Angelica sinensis*) is used widely in China for menstrual cramps and irregular menses and often is mixed with other herbs.²⁴ Chaste tree or chasteberry (*Vitex agnus castus*) has been used for PMS, mastodynia, and menstrual irregularities.^{14,57,77,82} Three double-blind, placebo-controlled trials suggest that chasteberry may be effective in relieving premenstrual symptoms.⁵⁸ Black cohosh (*Actaea racemosa*) has been used for the treatment of dysmenorrhea and menopausal hot flashes, and blue cohosh has been used for menstrual cramps and stimulation of menstrual flow.^{14,77,83} A review of clinical studies and drug surveillance reports of black cohosh products suggests that its side effects are mild and reversible.⁸³ Other herbal products that women often take are valerian, an herbal sleep aid; chamomile, a sedative, antispasmodic, antipyretic, and anti-inflammatory agent; and kava (*Piper methysicum*), an agent used to relieve pain and treat mild anxiety and insomnia.^{14,24,57,77,78} Because of recent medical reports of kava causing hepatotoxicity, clinicians should monitor liver function tests if patients use kava.⁵⁷

Products promoted for perimenopausal symptoms without scientific testing include dehydroepiandrosterone, a steroid hormone produced by the adrenal glands and ovaries that is a precursor in the steroid hormone synthesis pathway for testosterone; passion flower for insomnia, pain, and climacteric complaints; wild yam root, which contains diosgenin, a precursor to progesterone; and phytoestrogens, plant-based hormones found in soybean products such as tofu that promote estrogenic effects.^{14,77,84} Phytoestrogens have a similar structure to 17 β -estradiol but are 100 to 1000 times weaker at estrogen receptors.¹⁴ The results of using soy isoflavones for vasomotor symptoms in peri- and postmenopausal women have been mixed (e.g., no differences in the number and severity of hot flashes compared with placebo treatment).^{14,24,85} Controlled studies suggest that standard doses of soy isoflavone extracts (e.g., genistein and daidzein) may not be an effective treatment for vasomotor symptoms.^{24,85} Women treated with soy protein also have a high discontinuation rate because the products cause a bad taste, gastrointestinal upset, gas, cramps, and stomach pains.²⁴ Consumption of soy protein instead of animal protein may decrease the serum concentrations of triglycerides, total cholesterol, and low-density lipoproteins, which may help to decrease cardiovascular risks.¹⁴

Various progesterone-like skin creams derived from extracts of the Mexican wild yam are available from health food stores. There is controversy as to whether diosgenin, the plant steroid, can be absorbed through the human skin and be converted to a biologically active progestogen.⁸⁶ When natural progesterone is added to creams or gels and applied topically, the circulating progesterone levels are low and may not induce a biologic change in the endometrium compared with orally administered micronized progesterone.^{24,86,87}

■ SYMPTOM-BASED APPROACHES: SPECIAL POPULATIONS AND DRUG CLASS INFORMATION

■ Dysmenorrhea and Cramps

12 Dietary supplements such as thiamine, calcium, magnesium, omega-3 fatty acids, and herbal products have been reported to be effective in the treatment of both premenstrual and menstrual pain syndromes, but few have been evaluated for the treatment of dysmenorrhea.¹⁴ Other modes of therapy for menstrual pain include biofeedback, transcutaneous electrical nerve stimulation, spinal manipulation, and application of local heat.¹⁴ Acupuncture has been

used for over 2500 years for pain syndromes and may be efficacious in the management of menstrual pain based on initial randomized studies.^{14,88}

Prostaglandin inhibitors are effective in treating dysmenorrhea, headaches, and other pain syndromes.⁵⁸ NSAIDs inhibit prostaglandin synthesis and exhibit anti-inflammatory, analgesic, and antipyretic activity. Mefenamic acid has been reported to be effective in reducing menstrual pain, as well as breast tenderness, bloating, irritability, and depression. Agents such as ibuprofen, ketoprofen, and naproxen are also effective for dysmenorrhea and menstrual migraine. A comparison of nonprescription doses of naproxen (400 mg) and naproxen/naproxen sodium (200/220 mg) indicated that these agents were more effective than acetaminophen (1000 mg), ibuprofen (200 mg), or placebo in the treatment of dysmenorrhea.⁸⁹

NSAIDs may cause gastrointestinal side effects and are contraindicated in patients with aspirin sensitivity, peptic ulcer disease, gastritis, bleeding disorders, and renal insufficiency. NSAIDs should be prescribed for short-term use only and in the lowest effective dosages (e.g., 1 week before the onset of menses and continued through the first few days of bleeding).⁵⁸ If primary dysmenorrhea does not respond to first-line agents, OCs (e.g., low-dose ethinyl estradiol combined with desogestrel) may be tried as an alternative approach for menstrual pain.⁹⁰

■ Headaches and Migraines

◀¹² The first-line acute treatment approach for menstrual migraines is NSAIDs.⁴ If migraines do not respond to these agents, 5-HT_{1D} agonists (triptans) can be used for abortive migraine therapy; however, these agonists should not be combined with 5-HT-augmenting antidepressants such as SRIs or monoamine oxidase inhibitors (MAOIs).⁴ For more information on the treatment of acute migraines, see Chap. 59.

Low-dose intermittent estradiol therapy (oral or transdermal patch) started on days 24 to 26 and continued for 7 days through menstruation may help an “estradiol withdrawal” migraine.⁴ If a woman experiences a worsening of migraines with cyclic estradiol therapy, the dose can be lowered or changed to continuous transdermal therapy.⁴ Estradiol-replacement therapy (alone or in combination with progestogens) is used frequently to treat menopausal migraines.⁴ Selective estrogen receptor modulators such as raloxifene may be an option for menopausal women who cannot tolerate or take standard estrogen therapies.⁴

Other preventative treatments for menstrual migraine include the use of β -adrenergic blockers, calcium channel blockers, tricyclic antidepressants, and valproate. Agents that suppress ovulation, such as OCs, estrogen implants, danazol, and gonadotropin-releasing hormone agonists (GnRH-As), have been used for menstrual migraines that are refractory to standard migraine therapies.⁴

■ Bloating and Fluid Retention

◀¹² Women with premenstrual syndrome commonly complain of bloating, swelling, and weight gain despite little evidence that they actually retain fluid. Dietary salt restriction should be the first-line treatment. If sodium restriction is not effective and there is a documented weight gain of 5 lb or more, diuretic therapy may be indicated. Spironolactone, an aldosterone receptor antagonist with potassium-sparing properties, is the only diuretic recommended for premenstrual weight gain and bloating.¹⁸ Spironolactone has antian-

drogenic effects, and women should not use it during pregnancy and lactation. Other diuretics (e.g., hydrochlorothiazide, metolazone, and triamterene) have been used in treating premenstrual fluid retention, but there is no conclusive evidence that these agents are beneficial for women with PMS.¹⁸ Magnesium supplements have been reported to reduce premenstrual fluid retention after 2 months of treatment.⁷²

■ Mastalgia

◀¹² Mastalgia, or mastodynia, is a common premenstrual problem and frequently coexists with fibrocystic breast disease.^{14–16} Vitamin E (α -tocopherol) has been reported to decrease breast tenderness and swelling and is recommended often for fibrocystic breast disease despite a lack of randomized, controlled studies.¹⁴ Caffeine restriction may not reduce breast pain, but it may be helpful for reducing fibrocystic breast changes.¹⁵ Analgesics, evening primrose oil, chaste tree, and flaxseed have been advocated as therapies for breast pain based on a few open-label and randomized, controlled trials.¹⁴ Diuretics, pyridoxine, and vitamin E have not been shown to be more effective than placebo for mastalgia.¹⁶ A low-fat diet may be helpful because a high intake of saturated fatty acids has been implicated in causing breast pain.^{15,16} Acupuncture and physical support (a well-fitted bra) are alternative modes of therapy for mastodynia.¹⁴

A deficiency of prostaglandin E₁ has been proposed to cause breast pain on the rationale that low levels may increase prolactin's effect on breast tissue and cause mastodynia.¹⁸ *cis*-Linolenic acid, an essential fatty acid contained in vegetable oils, is converted to γ -linolenic acid, the precursor to prostaglandin E₁. *cis*-Linolenic acid, magnesium, pyridoxine, zinc, and vitamin C are all involved in the synthesis of prostaglandin E₁. Products that promote the synthesis of prostaglandin E₁ (e.g., evening primrose oil, which contains γ -linolenic acid) have been used for breast pain, but a meta-analysis of placebo-controlled studies concluded that evening primrose oil was not effective.^{14,91} Although the oil may have little value in treating the other symptoms of PMS, it is used widely as a nutritional supplement for breast tenderness at doses of 500 mg three times daily during the luteal phase.^{13,24,57,58}

Dopamine agonists bromocriptine and lisuride have been used to inhibit prolactin secretion and to significantly reduce breast swelling, engorgement, and tenderness in premenstrual women with mastalgia.^{16,92} OCs also have demonstrated a reduction in premenstrual breast pain.¹² Antiestrogenic agents that inhibit ovulation (such as danazol and tamoxifen) have been used to treat endometriosis and cystic mastitis.¹⁶ Danazol in doses of 100 mg twice daily was reported to be highly effective for the relief of premenstrual mastalgia when given during the luteal phase only but was less effective in treating the general symptoms of PMS.⁹³ Danazol has androgenic adverse effects at higher doses (e.g., increased lipids, acne, vocal changes, and negative mood) and should be reserved for the short-term treatment of breast pain or for co-occurring endometriosis and cystic mastitis.¹²

■ Insomnia

Histamine-1 receptor antagonists (e.g., diphenhydramine) and antidepressants with high histamine-1 blockade (e.g., doxepin and amitriptyline) have been used for acute sleep disturbances but may cause anticholinergic side effects, daytime sedation, and weight gain. Trazodone, a serotonin-2A and α_1 -adrenergic antagonist, has sedative properties at lower doses and may be useful to promote sleep. The chronic use of benzodiazepines is not recommended for insomnia

because such use may lead to tolerance and physical dependence. If benzodiazepines are used for the acute treatment of insomnia, agents with shorter half-lives should be used (e.g., lorazepam or temazepam). Ultra-short-acting hypnotic benzodiazepines (e.g., triazolam) are less likely to cause daytime sedation but have an increased risk of causing anterograde amnesia, early-morning insomnia, delirium, and withdrawal reactions. Zolpidem and zaleplon, nonbenzodiazepines that bind to the benzodiazepine omega-1 receptor subtype, are alternative agents for the treatment of premenstrual insomnia but should be used only for short-term or intermittent therapy.

Melatonin has been used to regulate the sleep-wake cycle and is used often to treat insomnia. It is not recommended during pregnancy and breast-feeding because of a lack of information about its safety.⁹⁴ Lower doses of melatonin (e.g., 0.1–1 mg at bedtime) are effective in initiating sleep; higher doses may not improve the hypnotic effect.⁹⁴ The reduction in daytime sunlight, which increases melatonin secretion, may exacerbate PMS in the winter; this type of seasonal mood disorder may respond to phototherapy.⁵⁹ Early sleep deprivation also may help to correct circadian rhythm disturbances in PMDD.⁹⁵

Hot Flashes, Vasomotor Symptoms, and Night Sweats

9 17β -Estradiol therapy (preferably transdermal patches) is an effective treatment for moderate to severe vasomotor symptoms. Although venlafaxine, paroxetine, and fluoxetine have been used for hot flashes in postmenopausal women with a contraindication or intolerance to estrogen therapy, the role of 5-HT- and NE-augmenting antidepressants has not been established in perimenopausal women with hot flashes.^{22,96} Gabapentin, an anticonvulsant used in several pain syndromes, was found to reduce hot flashes in doses of up to 1200 mg/day in uncontrolled studies with women who were unwilling to take or who had a contraindication to estrogen exposure.⁹⁷ Gabapentin at 900 mg/day was reported to be more effective than placebo treatment in reducing hot flashes in postmenopausal women.⁹⁸

The North American Menopause Society position statement for treatment of mild menopause-associated vasomotor symptoms recommends first trying lifestyle changes, either alone or in combination with nonprescription remedies such as dietary isoflavones, black cohosh, or vitamin E.^{14,23,24,96} Studies suggest that there is a modest reduction in vasomotor symptoms with soy supplementation and that higher doses of soy isoflavones may be needed.^{85,99} Black cohosh does not have phytoestrogenic effects, and the evidence of its efficacy for menopausal symptoms is weak.^{14,22,57,83,100} Dong quai, a traditional Chinese medicine used for a wide range of gynecologic problems, was reported to have some estrogenic-like properties (i.e., it stimulates cell proliferation of a human breast cancer cell line).^{24,100} To date, there are no controlled efficacy or safety studies with dong quai for perimenopausal women.^{24,100} Vitamin E has been promoted as being effective for vasomotor symptoms and vaginal dryness, but placebo-controlled studies have shown no effect on hot flashes.¹⁴ Although chaste tree (*Vitex agnus-castus*), licorice (*Glycyrrhiza glabra*), and wild yam (*Dioscorea villosa*) have been promoted to help with hot flashes and vaginal dryness, no controlled studies have supported their efficacy.¹⁴

Anxiety

Before the advent of 5-HT-augmenting antidepressants, the treatment of premenstrual anxiety symptoms commonly included benzodiazepines. Although benzodiazepines have the advantage of acting

quickly to reduce anxiety symptoms and promote sleep, they have the disadvantage of causing sedation, cognitive and motor impairment, tolerance, dependence, and withdrawal reactions. Alprazolam, a triazolobenzodiazepine marketed for the treatment of generalized anxiety and panic disorder, has been evaluated for the treatment of PMDD in six double-blind, placebo-controlled studies. Four of these studies reported that alprazolam was more effective than placebo.⁶⁸ Intermittent dosing (e.g., 0.75–4 mg/day in divided doses 8 to 12 days before menses and gradually tapered down at menses by no more than 25% per day) and continuous dosing of alprazolam (e.g., 0.25 mg three times per day) reduced anxiety, irritability, tension, and feelings of being out of control in comparison with placebo. Because of the potential for dependency and worsening of mood, benzodiazepines should be used only for short-term treatment of menstruation-related mood disorders and should be avoided in dependency-prone patients.

Bupirone, a partial 5-HT_{1A} agonist, has anxiolytic properties without causing sedation, cognitive impairment, or muscle relaxation. Bupirone is administered chronically for the treatment of generalized anxiety disorder, but some studies used intermittent dosing (for 12 days before menstruation). Bupirone has minimal side effects and has the advantage over benzodiazepines of not causing dependence or a withdrawal syndrome after abrupt discontinuation. Comparative efficacy studies of bupirone and SRIs for PMDD are lacking.

Depression

11 5-HT deficiency or dysregulation (secondary to low levels of estradiol, high levels of MAO, or tryptophan depletion) during the premenstrual and perimenopausal phases may be a cause of anxiety, depression, and irritability.^{5,28,50,62} Controlled studies using 5-HT-augmenting antidepressants (either continuous or intermittent dosing) have reported positive benefits in reducing dysphoria, irritability, and tension.^{5,28,35,63–65,101} In addition, SRI antidepressants increase the bioavailability of 5-HT in the synapse and have been effective in reducing a premenstrual exacerbation of major depression.

Nortriptyline and clomipramine, TCAs that inhibit the reuptake of 5-HT and NE, have been effective in the treatment of PMDD.⁶⁴ Nefazodone, a 5-HT_{2A} antagonist with weak 5-HT reuptake inhibition, was reported to improve symptoms significantly in a preliminary study, but a recent comparison study with bupirone reported that nefazodone was not superior to placebo treatment.¹⁰² Venlafaxine, a 5-HT and NE reuptake inhibitor, was reported to be superior to placebo treatment in the treatment of PMDD^{64,103,104} and may have efficacy in alleviating pain associated with fibromyalgia.¹⁰⁵ L-Tryptophan (the essential amino acid precursor for 5-HT) is currently not available as a dietary supplement, but it has been reported to be beneficial in PMDD.¹⁰⁵ NE-augmenting antidepressants such as bupropion, desipramine, and maprotiline are less effective than serotonergic agents in the treatment of PMDD.^{5,28,62}

Compared with other classes of antidepressants, SRIs have a more favorable side-effect profile and better efficacy data.⁶² A review of randomized, controlled trials with SRIs for the treatment of PMDD reported that the agents were well tolerated and effective in treating physical as well as behavioral symptoms with either intermittent or continuous dosing.^{63,64,101} Citalopram, fluoxetine, paroxetine, sertraline, and venlafaxine all have been effective in PMDD placebo-controlled trials (60% to 90% efficacy rates with almost complete relief of symptoms).^{63,64} For fluvoxamine, there are mixed results because one controlled study reported that it had similar efficacy to placebo treatment in PMDD.⁶⁴ Although antidepressants usually take

3 weeks or more to relieve the symptoms of major depression, the 5-HT-augmenting agents work more quickly in PMDD to relieve premenstrual anxiety, depression, irritability, food cravings, overeating, and weight gain. Side effects usually are dose-related and are worse during the first few weeks of therapy (e.g., tiredness, sedation, upset stomach, nausea, decreased appetite, headache, dizziness, sweating, nervousness, insomnia, and difficulty concentrating). A common long-term adverse effect is sexual dysfunction (e.g., decreased libido and delayed orgasm). SRIs have the advantage of not causing the significant weight gain, drowsiness, cardiovascular changes, and anticholinergic side effects compared with TCAs. Further, SRIs appear to have minimal teratogenic risk when used in recommended doses during pregnancy.^{106,107}

SRIs may be effective in the treatment of PMDD at lower daily dosages than those required in major depression (e.g., fluoxetine 10 mg/day, sertraline 50 mg/day).⁶⁵ Doses should be increased gradually if the agent's effectiveness erodes after several months of treatment.³⁵ If one SRI is not effective or not tolerated, others should be tried until one is found to be effective.¹⁰⁸ The use of intermittent dosing during the luteal phase is gaining popularity because the SRIs work rapidly to attenuate depressive symptoms. The issue of a 5-HT discontinuation syndrome (e.g., sensory disturbances, flulike symptoms, sleep disturbances, or irritability) needs to be monitored when the agents are used intermittently.^{65,109}

Intermittent dosing with fluoxetine 20 mg/day (during the 2 weeks before the onset of menses) has been approved for the treatment of PMDD.¹¹⁰ Recent studies suggest that fluoxetine is also effective at 10 mg/day during the luteal phase or at 90 mg/day administered weekly at 2 and 1 weeks prior to menses.^{65,111} The intermittent administration of citalopram (10–30 mg/day) during the luteal phase was reported to be more effective than continuous or semi-intermittent administration.¹¹² Controlled studies with intermittent luteal phase administration of clomipramine (25–75 mg/day) and sertraline (50–100 mg/day) reported a 1- to 2-day onset of effects with an improvement in the quality of life and functioning outcomes. A study comparing full- or half-cycle sertraline treatment (50–150 mg/day) reported that both regimens were effective and that side effects were similar for both groups.¹¹³ With luteal phase administration, SRIs may improve mood symptoms more than the physical discomforts. Intermittent therapy with 5-HT-augmenting agents should be recommended before continuous daily dosing in the treatment of PMDD.⁶³

For perimenopausal depression, antidepressants usually are dosed daily at standard dosages for major depression, although some women may respond to lower doses. Estradiol deficiency may decrease the activity of 5-HT and decrease the efficacy of antidepressants.⁵⁵ Two open-label studies have reported that citalopram in doses of 20–60 mg/day was effective in treating depression in peri- and postmenopausal women and had augmenting effects in depressed subjects who were still symptomatic after treatment with transdermal estradiol (i.e., improved symptoms of anxiety and somatic complaints).¹¹⁴

■ HORMONAL THERAPIES

By inducing anovulation with various hormonal therapies, the cyclicality of PMS disappears. Anovulation can be induced by estradiol implants, high doses of progestones, OCs, GnRH-As, and danazol.¹² For the perimenopausal syndrome, the replacement of hormones such as 17 β -estradiol, progesterone (if the uterus is intact), and testosterone is used to stabilize the deficiency and fluctuations in hormone levels.

■ Estradiol

9 17 β -Estradiol, the active estrogen produced by the ovaries, is effective for menstrual migraines and to control perimenopausal symptomatology (i.e., vasomotor symptoms, vaginal dryness, and cognitive function). Given sublingually or transdermally, 17 β -estradiol may be helpful for postpartum depression and psychosis.^{20,26} Estradiol implants (subcutaneous pellets) and transdermal estradiol patches (two \times 100 mcg) have been used to suppress ovulation in controlled studies in women with PMS.¹² Both routes of administration of estradiol were beneficial in reducing premenstrual mental and physical symptoms.

Transdermal administration of 17 β -estradiol (combined with the cyclic or continuous administration of progestogens if the uterus is present) is recommended in perimenopausal women with significant mood and physical symptoms. Estradiol-replacement therapy has been beneficial in treating perimenopausal depression as well as in reducing hot flashes and sleep disturbances.^{115,116} Preliminary studies suggest that transdermal 17 β -estradiol can enhance the efficacy of serotonergic antidepressants in perimenopausal women.¹¹⁷ Soy-based isoflavone extracts (genistein and daidzein) have been tried as an alternative therapy to estrogen replacement, but they are not a functional equivalent to 17 β -estradiol, and long-term safety and efficacy studies are needed in peri- and postmenopausal women.¹⁴

Available estradiol products include a micronized and an ethinyl estradiol tablet, a cypionate and a valerate estradiol parenteral oil injection, a transdermal 17 β -estradiol topical system, topical estradiol gel and emulsion, a vaginal estradiol cream and ring, and several oral and transdermal combination products with progestins (e.g., norgestimate and norethindrone).¹¹⁰ The transdermal 17 β -estradiol patches may cause skin irritation and should be replaced at a new application site every 3 to 7 days depending on the product formulation. With oral administration, 17 β -estradiol is rapidly metabolized to estrone, which is not as active biologically and is less likely to help with mood and cognitive symptoms. Oral equine conjugated estrogens should not be used because of the very low content of 17 β -estradiol (i.e., approximately 0.005 mg per 0.625-mg tablet), and the product is not bioidentical to human hormone.⁶⁷

Unopposed estrogen therapy increases the risk for endometrial hyperplasia and adenocarcinoma; thus the use of cyclic, intermittent, or continuous progestogen therapy is recommended in women with an intact uterus.¹¹⁸ Progestins decrease cellular proliferation and synthesis of estradiol receptors in the endometrium and increase the conversion of estradiol to estrone, which has a lower affinity for estrogen receptors. Estradiol with intermittent progestogen therapy (e.g., norethisterone 5 mg/day for 7 days each month to induce regular menses) may cause premenstrual-like side effects.¹² Chronic estrogen-only therapy has certain risks (e.g., increasing risk of endometrial, ovarian, and breast cancer and gallbladder disease).⁶⁶ Contraindications to the use of estrogens include breast cancer (relative contraindication), estrogen-dependent cancer, thrombophlebitis or thromboembolic disorders, undiagnosed abnormal uterine bleeding, and pregnancy.⁶⁶

CLINICAL CONTROVERSY

Progesterone therapy has long been advocated for the treatment of PMS, but it is the most controversial treatment. Placebo-controlled trials do not support the use of progesterone or progestogen products in the management of premenstrual or perimenopausal syndrome.

■ Progesterone

A progesterone-deficiency theory had been proposed as causing PMS; thus for many years the administration of progesterone products during the luteal phase was a common hormonal treatment.¹² A meta-analysis of double-blind, placebo-controlled studies of different progesterone therapies in the management of PMS reported that these products are no better than placebo and that progestogens can induce negative mood changes.¹¹⁹ Because of its questionable efficacy and risk of adverse effects, progesterone or progestin-only therapy is not recommended as a treatment in premenstrual syndromes.

During the perimenopausal phase, progesterone therapy is indicated if a woman has an intact uterus and is placed on estrogen-replacement therapy. An oral micronized form of natural progesterone is better absorbed but is metabolized rapidly by enzymes in the gut and liver to 5α and 5β reduced metabolites that have anxiolytic and hypnotic effects.¹¹⁸ Oral administration of progesterone is associated with irregular and variable plasma levels, and transdermal progesterone creams do not achieve adequate plasma levels of progesterone; thus synthetic progestogens usually are added to hormonal regimens for OCs and for menopausal therapy.⁸⁷ Progesterone metabolites (especially allopregnanolone) are neuroactive and have benzodiazepine-like effects.^{12,32,38} Very high doses of progesterone have been shown to cause confusion, memory impairment, and fatigue.¹¹⁸ Vaginal administration and possibly topical administration decrease progesterone's conversion to allopregnanolone and may reduce CNS side effects.¹¹⁸ Progestogens should be used with caution in certain medical conditions (e.g., migraine, seizure disorders, asthma, and cardiac or renal disease). Progestogens are contraindicated in patients with thrombophlebitis and thromboembolic disorders.

■ Estrogen-Progestin Combinations

OCs cause anovulation and may reduce dysmenorrhea, depression, and irritability in approximately 30% of women with PMS. Most women with PMS taking OCs continue to have cyclic mood changes, although the physical symptoms such as breast tenderness and menstrual pain may improve.¹² Differences in OC products (e.g., monophasic, biphasic, or triphasic and the type of estrogen and progestin) may result in variations in efficacy and adverse effects. Monophasic OCs appear to cause fewer mood changes than triphasic products, whereas monophasic products may result in more fluid retention.¹²

Placebo-controlled studies with drospirenone (a spironolactone-like progestin with antiandrogenic and antimineralocorticoid activity) along with ethinyl estradiol have been disappointing in reducing mood-associated symptoms in women with PMDD, although the product did decrease acne, appetite, and food cravings.^{12,120,121} OCs high in progestin or progestin-only contraceptive agents may produce breakthrough bleeding and/or spotting, amenorrhea, acne, hirsutism, increased appetite and food cravings, fatigue, and depression. Pyridoxine-replacement therapy at 50 mg/day is recommended for women who become depressed while taking OCs. Because of the progestogen effects, estrogen-progestin combinations have an increased risk of causing thrombophlebitis, pulmonary embolism, and cerebral thrombosis.

■ Testosterone

◀² Testosterone-replacement therapy, combined with 17β -estradiol-replacement therapy, has been used in peri- and postmenopausal women and after surgically induced menopause

to increase libido, decrease fatigue, and improve well-being.^{52,122} Testosterone products have been marketed primarily for male andropause, impotence, hypogonadism, delayed puberty, and palliative treatment of metastatic breast cancer in women. Testosterone is available as a transdermal patch, topical gel, buccal product, an intramuscular injection, and a subcutaneous pellet for implantation for men. A testosterone patch for female sexual dysfunction is under investigation for women with decreased libido after their ovaries have been removed. Methyltestosterone, a synthetic androgenic anabolic steroid, is available as an oral product and as a combination oral product with esterified estrogens for women.

Special testosterone formulations for women (e.g., troches, creams, and gels) with lower doses and in combination with estradiol are compounded frequently by pharmacists. When using testosterone products in perimenopausal women for decreased libido, the lowest effective dose should be used, serum testosterone levels should be monitored, and adverse effects should be assessed regularly.¹²² Adverse effects of testosterone include acne, edema, hirsutism, hoarseness, clitoral enlargement, menstrual irregularities, abnormal liver function tests, irritability, anxiety, mental depression, and insomnia. Absolute contraindications include pregnancy and lactation.

■ Gonadotropin-Releasing Hormone Agonists (GnRH-As)

◀³ Because of their downregulation of pituitary gonadotropin secretion, GnRH-As (e.g., buserelin, goserelin, leuprolide, nafarelin, and triptorelin) cause a “medical ovariectomy” or pseudomenopausal state.^{12,123} These agents are used for the management of endometriosis, dysfunctional uterine bleeding, uterine leiomyomata (fibroids), and severe PMDD.¹²³ GnRH-As can be administered subcutaneously, intranasally, by implants, or by intramuscular depot injections. The initial administration stimulates the release of FSH and LH from the pituitary, and then a downregulation of the pituitary decreases ovarian stimulation to release 17β -estradiol and progesterone.¹²³ Initially, some women report a “flare” in symptoms during the first few weeks of treatment, which is followed by a reduction in the physical and behavioral symptoms.

GnRH-As may improve cyclic mood changes and migraines during short-term therapy, but the chronic effects of suppressing ovarian hormone secretion could result in significant antiestrogen effects (osteoporosis and cardiovascular disease) and worsening of mood without hormone-replacement therapy.¹² GnRH-As therapy alone should not continue for longer than 6 to 9 months because of the risk of osteoporosis.¹² The use of a combination of a GnRH-As plus an “add back” of 17β -estradiol/progesterone may help to reverse antiestrogen and antiprogestosterone effects but may decrease the effectiveness of GnRH-As. Low and ultralow dosages of GnRH-As (e.g., buserelin 400- and 100-mcg nasal spray once daily) have reduced cyclic mood changes in women with severe PMDD.¹² Until the long-term safety is established, GnRH-As should be used only for the most severe cases of PMS.

CLINICAL CONTROVERSY

Surgical treatment such as bilateral ovariectomy is controversial because it is irreversible and is associated with severe hormonal deficiency states unless there is add-back therapy. In addition, a tubal ligation or a partial hysterectomy is not effective for menstrual-related disorders. Clinicians usually reserve a complete hysterectomy as a last-resort treatment in severely affected patients who do not respond to standard therapies.

SURGICAL THERAPY

13 Surgical ablation of the ovaries (oophorectomy or bilateral ovariectomy) should be reserved as the last resort for the treatment of severe PMDD.¹² Before radical surgery, a 3- to 6-month trial of a GnRH-As or danazol is recommended to determine if anovula-

tion is effective because the ovariectomy is not reversible. A hysterectomy without an ovariectomy is not effective for PMS.¹² A woman who has an ovariectomy without a hysterectomy needs both estradiol- and progesterone-replacement therapy. Women who have both the ovariectomy and hysterectomy can receive continuous estradiol without intermittent progesterone therapy because there is no risk for endometrial cancer.

PHARMACOECONOMIC CONSIDERATIONS

Few studies have prospectively documented the degree of functional impairment before or after specific treatments or have evaluated the pharmacoeconomic differences in treatments for premenstrual and perimenopausal disorders. Data on the economic burden (i.e., health care utilization, related costs, and the loss of productivity) from different menstrual-related disorders are still lacking.¹²⁴ Several PMDD studies have reported greater improvement in psychosocial functioning and work capacity with SRIs compared with placebo.^{125,126} In all studies, the degree of functional impairment was substantial at baseline and similar to that seen in studies of major depression. The functional improvement correlated with the improvement in premenstrual symptoms and was evident by the second cycle of treatment.

The peri- and postmenopausal periods are associated with significant physical and psychosocial changes in women's lives that can affect quality of life (e.g., occupational, health, emotional, and sexual).^{47,48} Untreated depression may contribute to the development of a chronic and refractory mood disorder that significantly impairs psychosocial functioning. More studies are needed because severe menstruation-related disorders are disabling; prompt diagnosis and efficacious treatments are essential to improve functioning, to reduce morbidity and mortality, and to decrease the negative impact on women and their families.

EVALUATION OF THERAPEUTIC OUTCOMES

A trial of at least three menstrual cycles is needed to determine the treatment efficacy of one therapy and to adjust dosing before resorting to another therapy. Self-rating of prominent symptoms using a severity rating scale helps to monitor the efficacy of different treatment approaches.^{1,45} A reduction of baseline premenstrual ratings (the average score for 5 to 7 days prior to menses) by 50% should be the minimum goal of therapy. Ideally, relief would be complete when premenstrual ratings are similar to postmenstrual ratings 5 to 7 days after the cessation of menses for several menstrual cycles.

MONITORING OF THE PHARMACOTHERAPEUTIC CARE PLAN

Patients who are undergoing therapy for menstruation-related disorders should have a monthly examination by a clinician to assess efficacy and adverse effects and adjust dosing, if needed. If first-line treatment approaches are not effective after several months, then alternative or combination therapies should be considered. Perimenopausal women should be monitored every 1 to 2 months to determine the effectiveness of treatment. Once a patient is stable and responding to the treatment plan, monitoring may be extended to every 3 to 6 months. Peri- and postmenopausal women should be monitored regularly because of the increased risk of osteoporosis, cardiovascular disease, and dementia. Throughout therapy, patients should be

encouraged to eat well-balanced meals, to engage in regular exercise, to limit caffeine, to avoid drinking excessive alcohol or using drugs of abuse, to practice good sleep hygiene, and to take medications as prescribed to maximize treatment outcomes.

Menstruation-related disorders are common and cause significant disability and impairment in functioning if not treated properly. Therapeutic strategies should be individualized and targeted to the most distressing symptoms. If possible, medications should not be prescribed unless nonpharmacologic approaches have failed or unless symptoms disrupt the patient's functioning. The regular assessment and monitoring of menstruation-related disorders are necessary throughout a woman's reproductive years.

ABBREVIATIONS

DA: dopamine
 FDA: Food and Drug Administration
 FSH: follicle-stimulating hormone
 GABA: γ -aminobutyric acid
 GnRH: gonadotropin-releasing hormone
 GnRH-A: gonadotropin-releasing hormone agonist
 HPG axis: hypothalamic-pituitary-gonadal axis
 5-HT: 5-hydroxytryptamine, serotonin
 LH: luteinizing hormone

ENDOMETRIOSIS

Deborah A. Sturpe and Alkesh D. Patel

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The etiology of endometriosis is likely multifactorial, with no single theory satisfactory to explain all cases. Retrograde menstruation is the most widely accepted proposed mechanism.
- 2 Endometriosis should be suspected in any woman of reproductive age, including adolescents, with recurring cyclic or acyclic pelvic pain and/or subfertility.
- 3 There are no physical examination findings or laboratory tests that are considered diagnostic for endometriosis. A definitive diagnosis can be made only via surgical visualization of lesions. Confirmation of diagnosis is not necessary in all cases.
- 4 Treatment goals of endometriosis include improvement of painful symptoms and maintenance or improvement of fertility. Therapy is considered successful based on resolution of the patient's symptoms or achievement of pregnancy.
- 5 All medical therapies (nonsteroidal anti-inflammatory drugs, oral contraceptives, progestins, danazol, or gonadotropin-releasing hormone agonists) are equally efficacious in treating endometriosis-related pain based on available evidence. Choice among agents is determined primarily by side-effect profile, cost, and individual patient response.
- 6 Endometriosis-related pain may be treated by medical or surgical therapy. Empirical medical therapy is likely more cost-effective and is recommended based on consensus guidelines.
- 7 Recurrence rates of endometriosis-related pain are high after both medical and surgical therapies. Extended use of medical therapy or postoperative use of medical therapy may be needed to maintain efficacy.
- 8 Endometriosis-related infertility is unresponsive to medical therapy. Conservative surgical therapy is the preferred treatment.

Endometriosis is a common cause of chronic pelvic pain in women and is also associated with infertility. Characterized by the presence of endometrial tissue outside the uterus, endometriosis is a chronic, recurring disease. Therapy is targeted at relieving symptoms and improving fertility.

EPIDEMIOLOGY

Endometriosis is the cause of pelvic pain (dysmenorrhea, dyspareunia) and infertility in more than 35% of women of reproductive age, but the exact prevalence of the disease is unknown because surgical visualization is necessary to make a definitive diagnosis. In the general population, prevalence is estimated at approximately 10% of women.¹ An estimated 71% to 87% of women presenting with chronic pelvic pain have endometriosis, and approximately 38% of women with infertility have the disorder.¹ The disease typically presents during the reproductive years but has been documented over a wide age range of 8 to 76 years, with some cases occurring prior to menarche.^{2,3} In the adolescent population, 45% to 70% of chronic pelvic pain and dysmenorrhea cases are thought to be secondary to endometriosis, and symptoms are often more severe than in the adult population.^{3,4} Endometriosis progression generally is slow, and the disease may remain stable or regress in 50% of women.⁵

ETIOLOGY

- 1 The etiology of endometriosis is unknown. The mechanism for development of these lesions is likely to be multifactorial and includes theories of retrograde menstrual flow, coelomic metaplasia, lymphatic and vascular spread, and immunologic abnormalities.^{1,3,6–8} Retrograde menstruation is the most popular theory of endometriosis development. It proposes that endometrial tissue flows back through the fallopian tubes with subsequent implantation into the peritoneal cavity. However, a low percentage of women with retrograde menstrual flow develop endometriosis, thus supporting other mechanisms of pathogenesis. One of the mechanisms gaining increasing recognition is the involvement of immune system factors in the development and progression of endometriosis. This theory is supported by abnormal B- and T-cell function, decreased apoptosis, and altered levels of prostanoids, cytokines, growth factors, and interleukins found in endometrial lesions and peritoneal fluid of affected women.^{8,9} Based on these findings, it has been hypothesized that an underlying immunologic disorder is responsible for endometriosis development in most women.⁸

Several causal associations have been identified in the development of endometriosis despite the uncertainty regarding etiology. Factors associated with endometriosis include obstruction of menstrual flow, frequent or heavy menstruation, genital tract abnormalities,

high estrogen levels, and elevated peripheral body fat.^{1,7,10,11} Genetic predisposition also has been identified as a contributing factor, with the disease being linked between first-degree female relatives and monozygotic twins.^{3,8} The decreased estrogen levels associated with oral contraceptive use, menopause, exercise, and smoking appear to protect against the development of endometriosis.^{1,11}

PATHOPHYSIOLOGY

PELVIC PAIN

Endometriosis-associated pain is secondary to structural and/or inflammatory causes. The lesions may cause pain by compression of nerve fibers.^{8,12} Increased pressure within endometriomas (cysts within the ovary) has been linked to dyspareunia.¹² Endometrial lesions also generate local inflammation with prostaglandin release and increase the risk of developing adhesions.^{8,12} Endometrial lesions contain estrogen and progesterone receptors, and symptoms may correlate with the cyclic release of hormones during the menstrual cycle.

INFERTILITY

In severe endometriosis, infertility likely results from distortion of the pelvic structure secondary to endometrial lesions, inflammation, and adhesions.^{8,12,13} In milder disease, the cause-effect relationship is more controversial. Decreased oocyte viability and/or production resulting from the altered uterine environment may be a contributing factor.¹²

CLINICAL PRESENTATION

2 3 Endometriosis should be suspected in women with subfertility, dysmenorrhea, dyspareunia, or chronic pelvic pain. A definitive diagnosis can be made only by direct surgical visualization of endometrial lesions. Lesions typically are found in the pelvis

▶ TREATMENT: Endometriosis

■ DESIRED OUTCOME

4 Treatment goals for endometriosis depend on patient presentation. Women with endometriosis may be asymptomatic, or they may present with pain, infertility, or a combination of both. Depending on the primary complaint, goals of endometriosis treatment include (1) minimization or removal of endometrial deposits, (2) prevention of disease progression, (3) minimization of associated pain, and (4) prevention or correction of associated infertility.

■ GENERAL APPROACH TO TREATMENT

5 The treatment for an asymptomatic patient with endometriosis consists of expectant management (watchful waiting) only because therapy is not indicated unless symptoms develop. For symptomatic patients, the foundation of therapy includes medical treatment, surgical treatment, or both. To date, no studies have compared medical and surgical treatment directly as first-line therapy. Furthermore,

TABLE 79–1. Clinical Presentation of Endometriosis

| |
|--|
| Symptoms |
| Asymptomatic |
| Dysmenorrhea |
| Dyspareunia |
| Chronic pelvic pain (cyclic or acyclic) |
| Premenstrual spotting |
| Gastrointestinal disturbances |
| Urinary disturbances (dysuria, hematuria) |
| Low back pain |
| Painful defecation (dyschezia) |

Compiled from refs. 1, 3, 8, and 12.

but also have been described in the bowel, lung, bladder, and ureter.⁸ The American Association of Reproductive Medicine has developed a staging system for endometriosis ranging from stage I (mild) to stage IV (severe) disease. In stage I endometriosis, lesions are scattered and superficial, and adhesions or scarring typically has not yet developed. Conversely, in stage IV endometriosis, large ovarian endometriomas, adhesions, obstruction, and lesions in nonpelvic areas develop. Unfortunately, this staging system is not useful in clinical practice because the size, location, and number of lesions do not correlate with painful symptoms, nor does the staging system predict pregnancy rates.^{1,8} Characteristics of the clinical presentation are shown in Table 79–1.

determining the optimal medical or surgical approach is difficult secondary to a paucity of well designed, randomized, controlled trials. Medical therapy relieves endometriosis-related pain by regressing lesions via induction of a pseudopregnancy or pseudomenopausal state but does not eradicate lesions or improve fertility. Choice of initial therapy therefore depends on multiple factors such as the patient’s primary complaint, location and extent of the disease, desire for future fertility, cost of therapy, contraindications to therapy, and potential side effects or complications of therapy.

6 Consensus recommendations for the treatment of chronic pelvic pain suspected to be secondary to endometriosis advocate empirical medical therapy with nonsteroidal anti-inflammatory drugs (NSAIDs), oral contraceptives (OCs), progestins, danazol, or gonadotropin-releasing hormone agonists (GnRH-a).⁵ Conservative surgical therapy is also recommended to treat painful symptoms in women who fail or have contraindications to medical therapy or in instances in which other compelling reasons exist for surgery. Of note, 7 30% to 70% of women will experience recurrence of pain within 6 to 18 months after initial treatment with either medical or surgical means, and extended use of medical therapy or postoperative adjunctive medical therapy may be necessary.^{8,14} Definitive treatment for

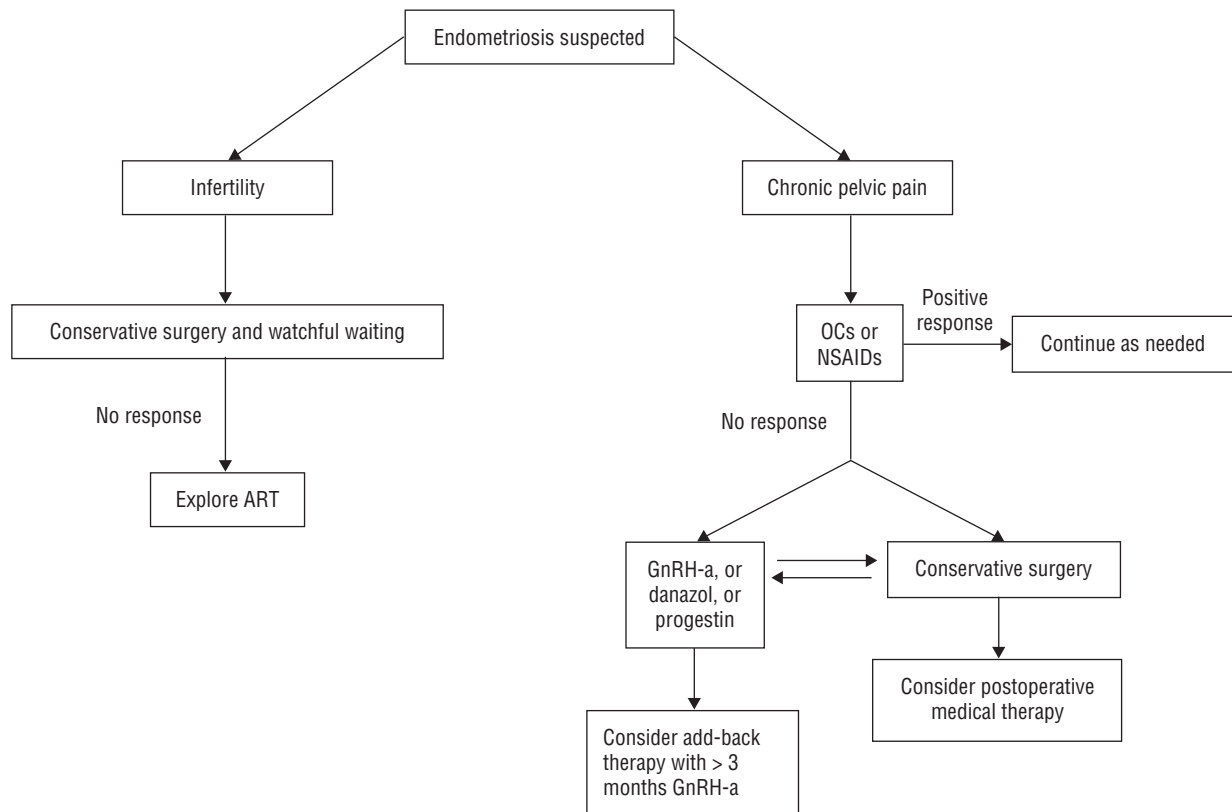

FIGURE 79–1. General treatment algorithm for endometriosis-related problems.

endometriosis involves nonconservative surgical therapy via bilateral salpingo-oophorectomy, with or without hysterectomy. This therapy should be reserved for women not desiring future fertility who accept the potential complications of surgically induced menopause.

8 For women presenting with infertility as a primary complaint, first-line therapy involves surgical resection of the lesions to restore normal anatomy followed by watchful waiting.¹⁵ Medical therapy is ineffective for endometriosis-related infertility and should be avoided.^{12,15–18} For women in whom surgical intervention does not result in pregnancy within 6 months, controlled ovarian stimulation with intrauterine insemination or in vitro fertilization is commonly employed.¹⁹ Pretreatment with GnRH-a prior to in vitro fertilization cycles may increase success rates.^{19,20} No clear guidelines or recommendations exist to guide the choice of one therapy or technique over another. A general treatment algorithm for endometriosis-related pain and infertility is shown in Fig. 79–1.

NONPHARMACOLOGIC THERAPY

SURGERY

8 Surgical intervention in endometriosis may be used as both a diagnostic and a therapeutic tool. Goals of conservative surgical therapy include destruction of endometrial implants, removal of lesions, and restoration of normal pelvic structure to treat associated pain and infertility.¹² Although considered the only “definitive” therapy for endometriosis, radical surgery to remove the uterus and ovaries should be considered only in women not desiring future fertility.

Laparoscopic procedures (versus laparotomy) have become the primary standard of care for endometriosis surgery because of lower

complication rates, a lower incidence of postoperative adhesions, and more rapid patient recovery.^{1,8} One form of laparoscopic procedure cannot be recommended over another because no studies exist that compare these types of interventions directly. Ultimately, the choice of surgical intervention should be guided by the patient’s desire for future fertility, the extent and location of disease, and the expertise and experience of the surgeon.⁵

A systematic review concluded that conservative laparoscopic procedures are superior to watchful waiting in treating the pain of minimal, mild, and moderate endometriosis.²² Approximately 60% to 100% of affected women will obtain relief of pain from surgery, but up to 44% of women will experience recurrence of symptoms at 1 year.^{1,8,14} This recurrence is due to failure to visualize and remove all endometrial lesions and to regrowth of endometrial tissue. Use of adjunctive medical therapy postoperatively may extend the pain-free interval, but routine use of such therapy remains controversial because the small amount of available data show conflicting efficacy results.^{1,20} Regimens studied for adjunctive medical therapy include 6 months of treatment with danazol (with or without OCs), medroxyprogesterone, and GnRH-a.^{1,5,14,20} Choice of agent depends primarily on patient preference and prior response to medical therapy.⁵

Conservative surgical therapy is a primary treatment for endometriosis-associated infertility. Data support efficacy of surgery at all stages of disease but are limited by lack of well-designed, randomized trials. Patients with advanced disease causing distortion of the pelvic structure may benefit most from surgical intervention. Pregnancy rates in this population are nearly 0 percent, and uncontrolled studies consistently support efficacy of surgery to improve pregnancy rates.²⁰ For women with mild to moderate disease, spontaneous conception occurs at a rate of approximately 20%; this makes evaluation of surgical efficacy more difficult.¹³ A systematic review highlights

the inconsistent treatment efficacy from surgery in this population with milder disease. Results suggest that the number needed to treat to achieve one pregnancy ranges from 3 to 100 women with mild to moderate endometriosis.¹³

Surgical therapy is not without risk. Potential complications include uterine prolapse, adhesion development with subsequent reduced fertility, and damage to or denervation of the pelvic structure.¹⁶ Risks and benefits of surgery therefore should be discussed on an individual patient basis.

■ PHARMACOLOGIC THERAPY

■ DRUG TREATMENTS OF FIRST CHOICE

5 First-line therapy for endometriosis-associated pain includes NSAIDs, OCs, or a combination of both.⁵ These drug classes are considered effective and less costly than other endometriosis treatments. Choice of agent depends on patient characteristics such as desire for contraception, pain patterns, and contraindications. Long-term maintenance therapy with these agents may be considered for women achieving a good therapeutic response.

Efficacy of NSAIDs in patients with endometriosis has not been evaluated in controlled trials. However, NSAIDs have proven efficacy in treating primary dysmenorrhea and are likely to have benefit in endometriosis as well.⁵

Use of OCs to treat endometriosis pain is desirable because of the potential for long-term use without significant side effects. A low-dose OC administered cyclically was compared with a GnRH-a in a randomized trial.²³ Both groups showed overall improvement in dyspareunia, nonmenstrual pain, and dysmenorrhea at 6 months. The rate of recurrent symptoms 6 months after cessation of therapy was equal between groups.

■ ALTERNATIVE DRUG TREATMENTS

6 Chronic pelvic pain not responding to NSAIDs or OCs should be treated with either advanced medical therapy or conservative surgery according to consensus recommendations.⁵ Choice of medical versus surgical therapy should include consideration of patient preference, potential for adverse reactions, cost, and impact on future fertility.

Agents that may be used as advanced medical therapy include progestins, danazol, or GnRH-a.⁵ Systematic reviews have concluded that all three classes of agents are effective choices, and no one agent has been proven superior to another.^{20,24–26} The primary difference between treatments is the side-effect profile and available dosage forms; choice of agent, therefore, depends on patient preference and tolerance of side effects. A 2-month trial of the agent should be employed, and treatment should be continued for a minimum of 6 months if relief is obtained.⁵ For women treated with GnRH-a, add-back therapy with estrogens or progestins should be considered to minimize vasomotor side effects and bone mineral density loss.⁵ Surgical therapy should be considered in women failing to respond to advanced medical therapy, in women with contraindications to medical therapy, or in women unable to tolerate side effects caused by medical therapy.⁵

■ SPECIAL POPULATIONS: ADOLESCENTS

4 Treatment goals for endometriosis in the adolescent patient are focused on management of pain.²⁷ Medical therapy is preferred

over surgical therapy in this population in order to minimize adhesion development from repeated surgeries.²⁷ Most experts recommend first-line therapy with OCs in adolescents secondary to the minimal side-effect profile and ability to continue treatment indefinitely.^{2,27} Progestins are also likely to be well tolerated, although the long-term effects on bone mineral density and lipid profile are still not clearly defined.²⁷ Danazol is not likely to be well tolerated by the adolescent population and generally is not recommended for use.^{2,27} Therapy with a GnRH-a is efficacious, but effects on bone mineral density are of concern in young women who have not achieved peak bone mass. If a GnRH-a is used, add-back therapy should be included.^{2,27}

■ DRUG CLASS INFORMATION

■ Nonsteroidal Anti-Inflammatory Drugs

NSAIDs treat the painful symptoms of endometriosis by interfering with prostaglandin production but do not affect the structure of the endometrial lesions directly.⁸ Long-term use of these agents may be limited by gastrointestinal or renal toxicity. They also may aggravate reactive airways disease and should be used with caution in such patients. The most commonly used NSAIDs in treatment of gynecologic pain are ibuprofen and naproxen.¹⁴ Dosing may be intermittent or continuous depending on whether the pain is cyclic or acyclic.⁵ Specific dosing information can be found in Table 79–2.

■ Oral Contraceptives

OCs treat the pain of endometriosis by decreasing menstrual flow and regressing endometrial implants.²⁸ The OCs are likely equal in efficacy to GnRH-a and medroxyprogesterone for relieving endometrial pain.²⁹ OCs are also effective in preventing recurrence of pain after surgical intervention for endometriosis.³⁰ There is no evidence to suggest that one OC is superior to another.

Side effects of these agents are typically mild and may include nausea, bloating, headache, and breakthrough bleeding. Because of this favorable side-effect profile, OCs are the drug of choice in adolescents with endometriosis. OCs do carry a risk of thromboembolism and should not be used in women with a history of thromboembolism or in smokers over the age of 35.

Administration of OCs may be cyclic or continuous. Although no studies have compared the two methods directly, continuous administration is more likely to induce amenorrhea and therefore may be more beneficial in treating dysmenorrhea.^{14,20}

■ Progestins

Multiple progestins have been studied in the treatment of endometriosis. Agents available in the United States include oral and depot medroxyprogesterone, megestrol, norethindrone, and the levonorgestrel-releasing intrauterine device. The progestins treat endometriosis via atrophy and decidualization of endometrial tissue. They tend to be less expensive and better tolerated than other endometriosis treatments. Most studies have examined use of medroxyprogesterone. A systematic review concluded that continuous medroxyprogesterone (oral or depot) is no more or less effective than other therapies.²⁶ Overall, 80% to 90% of women report improvement of endometriosis-related pain when using medroxyprogesterone.¹⁴

TABLE 79–2. Medical Therapy for Endometriosis-Associated Pain

| Drug | Dose | Comments |
|----------------------|---|---|
| OCs (various) | 1 orally daily | Continuous administration may lessen dysmenorrhea Contraindicated in women with history of thromboembolism and in women greater than age 35 years old who smoke |
| NSAIDs | | |
| Ibuprofen | 400 mg orally every 4–6 hours | Use with caution in women with reactive airways disease, renal disease, or history of gastrointestinal ulcer |
| Naproxen | 250 mg orally every 6–8 hours | |
| Progestins | | |
| MPA | 30–100 mg orally daily 150 mg IM every 3 months | Generally well-tolerated and less costly than GnRH-as or danazol |
| NE | 15 mg orally daily (5 mg daily × 2 weeks, then titrate by 2.5 mg daily every 2 weeks) | May delay return of fertility |
| Megestrol | 40 mg orally daily 3.75 mg IM monthly | |
| GnRH-a | | |
| Leuprolide | 11.25 mg IM every 3 months | Vasomotor symptoms and bone loss may limit use Add-back therapy improves side effects and reduces bone loss Not preferred in adolescent patients secondary to bone loss |
| Goserelin | 3.6 mg SQ monthly | |
| Nafarelin | 200 mcg (one spray) intranasally twice daily | |
| Other | | |
| Danazol | 600–800 mg orally daily in divided doses | Androgenic side effects limit use; not preferred in adolescent patients secondary to side-effect profile |

Abbreviations: OCs = oral contraceptives; MPA = medroxyprogesterone acetate; IM = intramuscular; NE = norethindrone; GnRH-a = gonadotropin-releasing hormone agonists; SQ = subcutaneous; mcg = micrograms; NSAIDs = nonsteroidal anti-inflammatory drugs.

Common side effects of progestins include breakthrough bleeding, weight gain, fluid retention, and mood swings. Also of concern are the unknown long-term effects on bone mineral density and lipid profile. For women desiring immediate future fertility, progestins may not be optimal secondary to prolonged amenorrhea and anovulation after cessation of therapy. This effect has been noted specifically with the depot form of medroxyprogesterone. Specific progestin dosing information can be found in Table 79–2.

■ Gonadotropin-Releasing Hormone Agonists

The GnRH-a create a functional oophorectomy via inhibition of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) secretion. This, in turn, diminishes endometrial implants. When first initiated, the GnRH-a create an initial gonadotropin flare prior to receptor downregulation that may cause a temporary increase in pain. Initiating therapy during the midluteal phase may minimize such effects.

Therapy with GnRH-a is superior to placebo and comparable with danazol for relief of endometriosis-associated pain.²⁵ Response rates are approximately 85% to 100% after 6 months of therapy, but recurrence rates at 5 years are 53%.^{1,20,25,29} Although typically taken for 6 months' duration, one comparative study has shown equivalent efficacy and recurrence rates between 3 and 6 months of GnRH-a therapy.³¹ Therapy also may need to be extended beyond 6 months to maintain efficacy, although data are limited regarding such extended usage.

Three GnRH-a are currently available in the United States: goserelin, leuprolide, and nafarelin. These agents differ primarily by

route of administration. Choice of therapy, therefore, depends on patient preference. Specific dosing information for the GnRH-a can be found in Table 79–2.

Side effects are the primary limitation of GnRH-a use. The pharmacologically induced hypoestrogenic environment results in bone loss and vasomotor symptoms such as hot flashes, vaginal dryness, and insomnia. Loss of bone mineral density is estimated at 4% to 6% over 6 months of GnRH-a therapy, but this loss is recoverable on cessation of the drug.³² Bone loss is progressive as use of the drugs is extended beyond 6 months, and it is unknown if reversibility is maintained after such longer treatment periods.³³ Add-back therapy with estrogens, progestins, or bisphosphonates has been studied as a way to treat vasomotor symptoms and prevent bone loss while maintaining efficacy of the drug.

The theory behind use of add-back therapy centers on the idea that the level of estrogen needed to prevent GnRH-a side effects is less than the estrogen level that allows growth of endometrial implants.¹⁴ Multiple add-back regimens have been studied, but only three have consistently prevented bone mineral density loss, treated vasomotor symptoms, and maintained efficacy of the GnRH-a. These include norethindrone plus etidronate, norethindrone alone, and low-dose conjugated equine estrogens plus norethindrone.³² Specific dosing information for add-back therapy regimens can be found in Table 79–3.

The optimal time to initiate add-back therapy remains controversial. The cost of the regimen must be balanced against the potential benefit. Add-back therapy is not recommended for GnRH-a regimens of less than 3 months' duration.^{1,32} Use of add-back therapy for GnRH-a regimens of 3 to 6 months' duration is for the primary purpose of relief of vasomotor symptoms and improved adherence

TABLE 79–3. Add-Back Therapy for GnRH Agonists

| Drug(s) | Dose | Comments |
|-----------------|--|--------------------------------|
| NE | 5 mg orally daily | Recommend supplemental calcium |
| NE + CEE | 5 mg orally daily (NE) + 0.625 mg orally daily (CEE) | |
| NE + etidronate | 2.5 mg orally daily (NE) + 400 mg orally daily × 14 days cycled every 8 weeks (etidronate) | |

NE = norethindrone; CEE = conjugated equine estrogens.

because the bone loss sustained at 6 months is recoverable.³² For GnRH-a therapy lasting longer than 6 months, add-back therapy should be used for the purpose of preventing bone loss along with preventing vasomotor symptoms.³² In all instances, supplemental calcium should be recommended.

Danazol

Danazol is a synthetic steroid analogue of 17α-ethinyl testosterone. It induces anovulation, amenorrhea, and endometrial atrophy through pituitary suppression of the midcycle LH and FSH surge and induction of a high-androgen, low-estrogen environment. The drug also has immunosuppressive activity that may contribute to its efficacy. Formerly the “gold standard” of endometriosis treatment, danazol’s popularity has decreased as agents with more favorable side-effect profiles have been developed.

Danazol has been proven effective as empirical therapy as well as postoperative therapy. Symptomatic improvement has been reported in up to 80% to 90% of women using the drug, with the best results seen in women achieving amenorrhea.¹⁴ A systematic review concluded that 6 months of danazol therapy is superior to placebo in relieving painful symptoms.²⁴ Therapy for only 3 months has not been as successful, especially when used postoperatively.^{1,5,14}

The primary limitation of danazol therapy is the high occurrence of androgenic side effects, including weight gain, acne, hot flashes, decreased breast size, hirsutism, and increased low-density lipoprotein cholesterol. Lowering the dose of danazol may alleviate some of these side effects, but drug efficacy is also compromised.¹⁴ Danazol should not be initiated in women with hyperlipidemia or liver disease. Danazol is also teratogenic, and barrier forms of contraception must be used. The dose of danazol ranges from 200–800 mg/day, but most studies used doses of 600–800 mg. Specific dosing information can be found in Table 79–2.

PHARMACOECONOMIC CONSIDERATIONS

Several cost considerations must be made when choosing endometriosis therapy. Costs of medical therapy must be weighed against the cost of surgical therapy, and the costs of each type of medical therapy must be weighed against another.

6 Two studies have determined that empirical pain therapy with GnRH-a is less expensive than empirical surgical therapy by laparotomy. Cost savings estimates from these studies range from \$1000 to \$2500 per treated patient, although the results of these studies are limited by the lack of consideration of the cost of add-back therapy and/or postoperative medical therapy.^{34–36} Because the rate of recurrence of symptoms is high for both conservative surgical therapy and medical therapy, empirical medical therapy appears to be the most reasonable option. Generally speaking, the GnRH-a are the most expensive agents, and OCs and progestins are the least expensive. For add-back therapy, norethindrone monotherapy is likely to be most cost-effective.

CLINICAL CONTROVERSIES

Treating endometriosis-related pain by medical therapy versus surgical therapy is controversial. In the past, surgical diagnosis was deemed necessary prior to starting therapy, and surgical intervention, therefore, seemed logical. More recently, evidence supports empirically starting medical therapy and awaiting symptomatic improvement.

Add-back therapy alleviates the vasomotor symptoms and bone density loss associated with GnRH-a. Controversy

exists as to when to initiate such therapy. Some practitioners believe that add-back therapy should be prescribed only after 6 months of GnRH-a treatment because bone loss until this point is reversible. Other clinicians recommend immediate use of add-back therapy to minimize side effects and improve adherence.

Recurrence of endometriosis-related pain is frequent after conservative surgery. Some experts therefore recommend routine use of postoperative medical therapy to delay return to symptoms. Data supporting the efficacy of this practice is conflicting, and the cost of such therapy may not be warranted.

EVALUATION OF THERAPEUTIC OUTCOMES

4 Monitoring of endometriosis therapy is focused on subjective relief of symptoms.^{5,14} Although objective confirmation of lesion regression by laparotomy is feasible, the results typically are misleading because the number and size of lesions do not correlate well with patient symptoms.¹⁴

Endometriosis-related pain should be relieved within 2 months of initiating medical therapy. If symptoms persist, consideration should be given to different medical and/or surgical therapy. For endometriosis-related infertility, most experts recommend 6 months of watchful waiting after surgical intervention. If pregnancy is not achieved within that time, assisted reproductive techniques can be considered.

ABBREVIATIONS

ART: assisted reproductive technology
 FSH: follicle-stimulating hormone
 GnRH: gonadotropin-releasing hormone
 GnRH-a: gonadotropin-releasing hormone agonist
 LH: leuteinizing hormone
 NSAIDs: nonsteroidal anti-inflammatory drugs
 OC: oral contraceptive

HORMONE THERAPY IN WOMEN

Sophia N. Kalantaridou, Susan R. Davis, and Karim Anton Calis

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Estrogen-based postmenopausal hormone therapy should be used for the treatment of menopausal symptoms (i.e., vasomotor and urogenital symptoms) and, when specifically indicated, for osteoporosis prevention.
- 2 A progestogen should be added for endometrial protection when estrogen therapy is prescribed. Thus women with an intact uterus should not receive unopposed estrogen, whereas women who have undergone hysterectomy always should receive estrogen alone.
- 3 Lower doses of hormone therapy than previously used should be considered as standard initial therapy. Clinicians should prescribe hormone therapy at the lowest effective dose for the shortest duration, carefully and individually weighing treatment goals and risks for each woman.
- 4 The major indication for estrogen-containing hormone therapy is the relief of menopausal symptoms, and the benefits of short-term perimenopausal and postmenopausal hormone therapy for the relief of severe menopausal symptoms outweigh the risks in many women.
- 5 Osteoporosis prevention remains an approved indication for estrogen-based hormone therapy, but alternative strategies are available and should be considered as first-line agents for asymptomatic women. Vitamin D deficiency should be excluded before any other treatment is prescribed for the prevention or treatment of bone loss, and adequate calcium intake should be ensured.
- 6 Postmenopausal hormone treatment with oral combined estrogen plus progestogen has no benefit for cardiovascular disease prevention and increases the risk of breast cancer, coronary heart disease events, stroke, and venous thromboembolic events. However, it reduced the rates of hip fracture and colorectal cancer.
- 7 Hormone therapy improves mood and well-being primarily in women with hot flashes, night sweats, and sleep disturbance, but it does not improve gross quality-of-life measures in postmenopausal women who do not experience vasomotor symptoms.
- 8 Evaluation of each individual woman is essential in determining the appropriateness of perimenopausal and postmenopausal hormone therapy, and collaboration between a woman and her primary care provider in the decision-making process is essential. The benefits and risks of hormone therapy should be reassessed annually.
- 9 Results from randomized trials of hormone therapy in postmenopausal women cannot be extrapolated to premenopausal women with ovarian dysfunction. Women with premature ovarian failure (i.e., those younger than 40 years of age) need exogenous sex steroids to compensate for the decreased production by their ovaries.

Menopause is the permanent cessation of menses following the loss of ovarian follicular activity.¹ By definition, it is a physiologic event that occurs after 12 consecutive months of amenorrhea—so the time of the final menses is determined retrospectively. Women who have undergone hysterectomy must rely on their symptoms to estimate the actual time of menopause.

Many women seek therapy for alleviation of symptoms that arise from loss of ovarian function at the time of menopause. However, the use of hormone therapy (estrogen \pm progestogen) for the prevention of diseases of aging has attracted considerable public attention since the premature termination of the estrogen-progestogen arm of the Women's Health Initiative (WHI) in 2002.² The estrogen-alone arm of the trial also was discontinued recently after 7 years of follow-up because it was found that estrogen alone did not affect (either increase or decrease) heart disease.³ Breast cancer risk was not increased during the study period.³

The median age at the onset of menopause in the United States is 51 years, whereas the average life expectancy for women is 81 years. Thus American women can expect to be postmenopausal for more than one-third of their lives.

Although the age at menarche has declined steadily throughout the centuries, probably a result of improved nutrition, the age at menopause onset appears to be relatively stable. However, on average, cigarette smokers experience menopause 2 years earlier than nonsmokers. Women who have undergone hysterectomy also are more likely to have an earlier menopause despite preservation of their ovaries. Approximately 1% of women develop ovarian failure before the age of 40 years (premature menopause or premature ovarian failure).⁴

Prior to publication of the WHI results, about 38% of postmenopausal women in the United States took hormone therapy.⁵ Approved indications of postmenopausal hormone therapy include

treatment of menopausal symptoms (i.e., hot flashes, night sweats, and urogenital atrophy) and osteoporosis prevention.⁶

Results from recent randomized clinical trials evaluating the effects of hormone therapy have differed substantially from previous observational studies. These trials showed that the risks of hormone therapy exceed the potential benefits for chronic disease prevention in postmenopausal women.^{2,3,6a} Weighing the risks and benefits, the Food and Drug Administration (FDA) recently mandated the addition of new safety warnings to the labels of all systemic estrogens (regardless of route or dosage form), including estrogen-only and combined estrogen-progestogen products. The labels now caution that use of estrogen-containing hormone therapy regimens by postmenopausal women may be associated with an increased risk of myocardial infarction, stroke, breast cancer, and thromboembolism. Nonetheless, hormone therapy remains the most effective therapy for the management of hot flashes and vaginal atrophy in the postmenopausal woman.^{6a}

MENOPAUSE AND PERI- AND POSTMENOPAUSAL HORMONE THERAPY

PHYSIOLOGY

Characteristics of the human menstrual cycle throughout reproductive life have been well described.⁷ A woman is born with approximately two million primordial follicles in her ovaries. During a normal reproductive life span, she ovulates less than 500 times. The vast majority of follicles undergo atresia.

The hypothalamic-pituitary-ovarian axis dynamically controls reproductive physiology throughout the reproductive years. The pituitary is regulated by pulsatile secretion of gonadotropin-releasing hormone (GnRH) from the hypothalamus. Follicle-stimulating hormone (FSH) and luteinizing hormone (LH), produced by the pituitary in response to GnRH, regulate ovarian function. These gonadotropins also are influenced by negative feedback from estradiol and progesterone. Ovarian follicular activity is reflected by the circulating concentrations of sex steroids and by peptide hormones (such as inhibin and activin). The sex steroids include estradiol, produced by the dominant follicle; progesterone, produced by the corpus luteum after maturation of the dominant ovarian follicle; and androgens, primarily testosterone and androstenedione, secreted by the ovarian stroma. Sex steroids are important for the healthy functioning of many organs, including the bones, brain, skin, and reproductive and urogenital tracts. They act primarily by regulating gene expression.

Pathophysiologic changes associated with menopause are caused by the loss of ovarian follicular activity.¹ Ovarian primordial follicle numbers decrease with advancing age, and at the time of the menopause, few follicles remain in the ovary. Hence the postmenopausal ovary is no longer the primary site of estradiol or progesterone synthesis. The postmenopausal ovary secretes primarily androstenedione and testosterone. In contrast to the acute fall in circulating estrogen at the time of menopause, the decline in circulating androgens commences in the decade leading up to the average age of natural menopause and closely parallels increasing age.⁸ Androgens are secreted by both the ovaries and the adrenal glands. Following menopause, direct ovarian androgen secretion appears to account for as much as 50% of testosterone production, with the adrenal gland being a less important source. Hypertrophy of the ovarian stroma may develop after menopause, probably secondary to high LH concentrations, thereby resulting in increased ovarian testosterone production.

Alternatively, the ovaries may become fibrotic and a poor source of sex steroids.

No endocrine event clearly signals the time just prior to final menses.⁹ Nonetheless, as women age, a progressive rise in circulating FSH¹⁰ and a concomitant decline in ovarian inhibin⁹ are observed. In women who continue to experience menstrual bleeding, FSH determinations on day 2 or 3 of the menstrual cycle are considered elevated when concentrations exceed 10–12 IU/L, an indication of diminished ovarian reserve. Clear elevations in serum FSH are seen in women around the age of 40.⁹ When ovarian function has ceased, serum FSH concentrations are greater than 40 IU/L.

The perimenopause is the period immediately prior to the menopause and the first year after menopause. The menopausal transition is the period of time when the endocrinologic, biologic, and clinical features of the approaching menopause commence.⁹ The menopausal transition usually begins approximately 4 years prior to menopause and is characterized by menstrual cycle irregularity caused by increased frequency of anovulatory cycles. Vasomotor symptoms (hot flashes and night sweats), psychological symptoms (anxiety, mood swings, and depression), and disturbances of sexuality are increased markedly in the perimenopause. Menopause is characterized by a 10- to 15-fold increase in circulating FSH concentrations as compared with concentrations of FSH in the follicular phase of the cycle, a four- to fivefold increase in LH, and a more than 90% decrease in circulating estradiol concentrations.⁹ During the perimenopause, FSH concentrations may rise to the postmenopausal range during some cycles but return to premenopausal levels during subsequent cycles. Thus high concentrations of FSH should not be used to diagnose menopause in perimenopausal women. However, vasomotor symptoms in perimenopausal women may require treatment despite the presence of menstrual bleeding. Abnormal thyroid function and other conditions that may cause similar symptomatology should be excluded first. Dysfunctional uterine bleeding may occur during the perimenopausal years because of anovulatory cycles, but other gynecologic causes also should be considered. Treatment options for dysfunctional uterine bleeding include progestins or low-dose oral contraceptives.

An observational study of more than 9000 postmenopausal women examined the relationship between endogenous estrogens and bone mineral density, bone loss, fractures, and breast cancer.^{11–14} Women with detectable serum estradiol concentrations (5–25 pg/mL) had a 6% to 7% higher bone mineral density at the total hip and spine as compared with women with undetectable levels (less than 5 pg/mL).¹¹ They also had significantly less bone loss at the hip than women with undetectable levels.¹² Women with undetectable serum estradiol concentrations had a relative risk of 2.5 for subsequent hip and vertebral fractures.¹³ However, women with the highest estradiol serum concentrations had the greatest risk of developing breast cancer.¹⁴

CLINICAL PRESENTATION OF PERIMENOPAUSE AND MENOPAUSE

SYMPTOMS

- Vasomotor symptoms (hot flashes and night sweats)
- Sleep disturbances
- Mood changes
- Sexual dysfunction
- Problems with concentration and memory
- Vaginal dryness and dyspareunia

SIGNS

- *Perimenopause*: Dysfunctional uterine bleeding owing to anovulatory cycles (other gynecologic disorders should be excluded)
- *Menopause*: Signs of urogenital atrophy

LABORATORY TESTS

- *Perimenopause*: FSH on day 2 or 3 of the menstrual cycle greater than 10–12 IU/L
- *Menopause*: FSH greater than 40 IU/L

OTHER RELEVANT DIAGNOSTIC TESTS

- Thyroid function tests
- Iron stores

CLINICAL PRESENTATION OF MENOPAUSE

Vasomotor symptoms, hot flashes, and night sweats are common symptoms of estrogen withdrawal. Hot flashes are the classic sign of menopause and the major clinical complaint of American women during the perimenopausal and early menopausal years. Hot flashes are

a sensation of warmth, frequently accompanied by skin flushing and perspiration. A chill may follow as the core body temperature drops. Hot flashes may occur in women of any age who experience acute estrogen withdrawal. They can be occasional or frequent, last from seconds to an hour, and are characterized by symptoms ranging from mild warmth to profuse sweating. For some women, hot flashes are a minor nuisance, but for others, they can be a disturbing symptom that disrupts their sense of well-being and causes problems in their social and professional lives. They usually occur spontaneously but often are increased in frequency or severity in hot or humid weather or after ingestion of caffeine, alcohol, or spicy foods. The prevalence of hot flashes is higher in the first two postmenopausal years. Women who have undergone surgical menopause tend to have more intense menopausal symptoms than those who experience a natural menopause.

Vaginal dryness is also directly related to estrogen insufficiency, but some women can find adequate relief from nonestrogenic vaginal creams. Most women with significant vaginal dryness, however, require local or systemic estrogen therapy to replenish moisture.

Although some would accept a range of other symptoms to be typical of estrogen deficiency (e.g., mood swings, tiredness, poor concentration, depression, insomnia, migraines, formication, arthralgia, myalgia, and urinary frequency), the relationship between these symptoms and the absolute decline in estrogen is more controversial. Many women, nonetheless, experience relief of such symptoms with estrogen therapy.

► TREATMENT: Menopause

Postmenopausal hormone therapy is a subject of major interest in the field of women's health. Treatment of menopausal symptoms can be managed effectively in some women with lifestyle modifications, including exercise, weight control, smoking cessation, and a healthful diet. More recently, however, dietary supplements and nonpharmacologic therapies have been promoted as “complementary medicine” alternatives to hormone therapy. To date, there is little to support the use of such nonprescription products, which include various herbal remedies and soy-based supplements.

■ PHYTOESTROGENS

Phytoestrogens have physiologic effects in humans¹⁵; they are plant compounds with estrogen-like biologic activity and relatively weak estrogen-receptor-binding properties. Epidemiologic studies suggest that consumption of a phytoestrogen-rich diet, as seen in traditional Asiatic societies, is associated with a lower risk of breast cancer.¹⁶

The biologic potencies of phytoestrogens vary, and most of these compounds are nonsteroidal in structure and less potent than the synthetic estrogens. There are three main classes of phytoestrogens: isoflavones, lignans, and coumestans, all of which are found in plants or their seeds.¹⁵ The most commonly studied phytoestrogen is the isoflavone class. Genistein and daidzein are the most abundant active components of isoflavones. Of note, the concentration of isoflavones per gram of soy protein varies considerably among preparations. Also, a single plant often contains more than one class of phytoestrogen. Common food sources of phytoestrogens include soybeans (isoflavones), cereals, oilseeds such as flaxseed (lignans), and alfalfa sprouts (coumestans).

Mild estrogenic effects have been seen in postmenopausal women,¹⁵ but current data suggest that phytoestrogen supplementa-

tion is no more effective than placebo in relieving hot flashes or other symptoms of menopause in postmenopausal women.¹⁷

Phytoestrogens decrease low-density lipoprotein (LDL) cholesterol and triglyceride concentrations with no significant change in high-density lipoprotein (HDL) cholesterol concentrations.¹⁸ Furthermore, phytoestrogens have the ability to inhibit LDL oxidation and normalize vascular reactivity in estrogen-deprived primates.¹⁸ In addition, bone density may be improved by phytoestrogens.¹⁵ Common adverse effects include constipation, bloating, and nausea.¹⁹

Larger, long-term studies are needed to document the effects of phytoestrogens on the breast, bone, and endometrium. Furthermore, differences among classes of phytoestrogens must be identified clearly, including dosing and biologic activity, before phytoestrogens can be considered an alternative to conventional hormone therapy in postmenopausal women.

Black cohosh (*Cimicifuga racemosa*) is used widely and has been shown to be an effective alternative for the relief of vasomotor symptoms in some randomized, controlled trials.²⁰ It does not appear to have strong intrinsic estrogenic properties but rather may act through the serotonergic system.

■ HORMONAL REGIMENS

Approved indications of hormone therapy include treatment of menopausal symptoms and osteoporosis prevention. Therapy directed at menopausal symptoms, such as hot flashes, is often short term. However, therapy directed at prevention of osteoporosis should be long term. For osteoporosis prevention, the advantages of hormone therapy must be weighed against risks, including thrombosis and the increased incidence of cardiovascular disease and breast cancer,² and consideration should be given to approved nonestrogen alternatives.

In women with an intact uterus, hormone therapy consists of an estrogen plus a progestogen. In women who have undergone hysterectomy, estrogen therapy is given unopposed by a progestogen.

The continuous combined oral estrogen-progestogen arm of the randomized Women’s Health Initiative (WHI) study was terminated prematurely. This arm included 16,608 relatively healthy postmenopausal women aged 50 to 79 years at enrollment (mean age 63.2 years). The primary outcome was coronary heart disease events, defined as nonfatal myocardial infarction and coronary artery disease death, with invasive breast cancer as the primary adverse outcome.² The study also examined secondary outcomes, including stroke, thromboembolic disease, fractures, colon cancer, and endometrial cancer.² After a mean of 5.2 years of follow-up (planned duration was 8.5 years), the Data and Safety Monitoring Board recommended stopping this arm of the trial because of the occurrence of a prespecified level of invasive breast cancer. That is, women receiving the active drug had an increased risk of invasive breast cancer (hazard ratio [HR] 1.26, 95% confidence interval [CI] 1–1.59), and the overall risks exceeded benefits.² The study also found increased coronary disease events (HR 1.29, 95% CI 1.02–1.63), stroke (HR 1.41, 95% CI 1.07–1.85), and pulmonary embolism (HR 2.13, 95% CI 1.39–3.25). Beneficial effects included decreases in hip fracture (HR 0.66, 95% CI 0.45–0.98) and colorectal cancer (HR 0.63, 95% CI 0.43–0.92).² Results from this study indicated that short-term use (less than 1 year) has risks for coronary heart disease and thromboembolic disease events. The number of deaths was similar among the groups.

After a mean of 7 years of follow-up, the Data and Safety Monitoring Board also recommended stopping the oral estrogen-alone arm of the study. This arm consisted of 10,739 women who had undergone hysterectomy. Estrogen-only therapy had no effect on coronary heart disease risk and no increased breast cancer risk.³

Among women in the estrogen-progestogen arm, there was one serious adverse event for every 100 women treated for 5 years. Specifically, it suggested that for every 10,000 women taking combined hormone therapy, there would be 8 more cases of breast cancer, 7 more cases of myocardial infarctions, 8 more cases of stroke, and 8 more cases of pulmonary embolism. However, 6 fewer colorectal cancers

and 5 fewer hip fractures would be expected.² For the majority of women who had never used hormone therapy before enrolling in the study (6280 treated with estrogen-progestogen and 6024 treated with placebo), the hazard ratio for breast cancer was 1.06 (95% CI 0.81–1.38), indicating that the burden of risk for breast cancer was from hormone therapy use beyond 5 years. Subsequently, a large epidemiologic study reported a greater risk estimate for combined estrogen-progestogen use, as well as increased risk for estrogen-only therapy and tibolone.²¹ However, interpretation of these findings is limited by selection bias because the women who used hormone therapy were significantly different from nonusers in their risk profiles.²¹ It is unclear if the type of estrogen compound or the dose, route, or administration method could at least in part be responsible for the risks observed in the WHI trial.

■ ESTROGEN AND PROGESTOGEN TREATMENT

■ Estrogens

◀ The primary accepted indication for estrogen-based hormone therapy is the relief of vasomotor symptoms, and the initial dose should be the lowest effective dose for symptom control. Estrogens are naturally occurring hormones or synthetic steroidal or nonsteroidal compounds with estrogenic activity. Various systemically administered estrogens (typically oral and transdermal) are suitable for replacement therapy (Table 80–1). Estrogens can be administered orally, transdermally (patches and other topical products), intravaginally (creams, tablets, or rings), intranasally, intramuscularly, and even in the form of subcutaneously implanted pellets. The choice of estrogen delivery (product, route, and method) should be determined in consultation with the patient to ensure acceptability and enhance compliance. In general, the oral and transdermal routes are used most frequently, with oral conjugated equine estrogens (CEEs) being particularly popular in the United States. There is no evidence that one estrogen compound is more effective than another in relieving menopausal symptoms or preventing osteoporosis.

TABLE 80–1. Systemic Estrogen Products^{a,b}

| Estrogen | Dosage Strength | Comments |
|--|---|---|
| Oral estrogens | | |
| Conjugated equine estrogens | 0.3, 0.45, 0.625, 0.9, 1.25 mg | Orally administered estrogens stimulate the synthesis of hepatic proteins and increase the circulating concentrations of sex hormone-binding globulin, which, in turn, may compromise the bioavailability of androgens and estrogens. |
| Synthetic conjugated estrogens | 0.3, 0.45, 0.625, 0.9, 1.25 mg | |
| Esterified estrogens | 0.3, 0.625, 1.25, 2.5 mg | |
| Estropipate (piperazine estrone sulfate) | 0.625, 1.5, 2.5 mg | |
| Micronized estradiol | 0.5, 1, 1.5, 2 mg | |
| Parenteral estrogens | | |
| Transdermal 17β-estradiol (patch) | 14, 25, 37.5, 50, 75, 100 mcg per 24 h | Women with elevated triglyceride concentrations or significant liver function abnormalities may benefit from parenteral therapy |
| Estradiol vaginal ring | 0.05, 0.1 mg per 24 h (replaced every 3 months) | |
| Estradiol topical emulsion | 4.35 mg of estradiol hemihydrate | |
| Estradiol topical gel | 0.75 mg of estradiol | |
| Intranasal estradiol ^c | One spray per nostril delivers 150 mcg | |

^aSystemic oral and transdermal estrogen and progestogen combination products are available in the United States.

^bSystemic oral estrogen and androgen combination products are available in the United States.

^cNot available in the United States.

■ **Oral Estrogen.** Oral CEE has been available for more than 50 years. CEE is prepared from the urine of pregnant mares and is composed of estrone sulfate (50% to 60%) and multiple other equine estrogens such as equilin and 17α -dihydroequilin.²²

Estradiol is the predominant and most active form of endogenous estrogens. A micronized form of estradiol (produced by a technique that yields extremely small particles of the pure hormone) is readily absorbed from the small intestines.²² When given orally, estradiol is metabolized by the intestinal mucosa and the liver during the first hepatic passage, and only 10% reaches the circulation as free estradiol. Metabolism of estrogen is partly mediated by the cytochrome P-450 3A4 isoenzyme. Gut and liver metabolism converts a large proportion of estradiol to the less potent estrone. Thus measurement of serum estradiol is not useful for monitoring oral estrogen replacement. The principal metabolites of micronized estradiol are estrone and estrone sulfate. Administration of estradiol via the oral route results in estrone concentrations that are three to six times those of estradiol. Ethinyl estradiol is a highly potent semisynthetic estrogen that has similar activity following administration by the oral or parenteral routes.

Orally administered estrogens stimulate the synthesis of hepatic proteins and increase the circulating concentrations of sex hormone-binding globulin, which, in turn, may compromise the bioavailability of androgens and estrogens.

■ **Other Routes.** Parenteral estrogens (including transdermal, intranasal, and vaginal) bypass the gastrointestinal tract and thereby avoid first-pass liver metabolism. Parenteral routes of estrogen delivery result in a more physiologic estradiol-to-estrone ratio (estradiol concentrations greater than estrone concentrations), as seen in the normal premenopausal state. Parenteral estrogen therapy also is less likely to affect sex hormone-binding globulin as compared with oral therapy. Parenteral regimens produce little or no change in circulating lipids, coagulation parameters, or C-reactive protein levels.²³

Transdermal estrogens share the advantages of other parenteral estrogen routes. Transdermal systems have the added advantage of delivering estradiol to the general venous circulation at a continuous rate. Reactions at the application site occur in about 10% of women who use reservoir (alcohol-based) patches. The newer matrix systems (estrogen in adhesive) generally are better tolerated, and fewer than 5% of women experience skin reactions.²⁴ The incidence of skin irritation diminishes when the application site is rotated. Topical

anti-inflammatory products can be applied for managing the rashes, and switching to another transdermal patch is often a viable option.

Percutaneous preparations (gels, creams, and emulsions) are convenient, but variability in drug absorption is common. This form of estrogen is used for systemic therapy. Topical emulsion and gel formulations were approved for use recently in the United States.

Estradiol pellets (implants) containing pure crystalline 17β -estradiol have been available for more than 50 years. They are inserted subcutaneously into the anterior abdominal wall or buttock. Pellets are difficult to remove and may continue to release estradiol for a long time after insertion. Implantation should not be repeated until serum estradiol concentrations have fallen to values similar to those at the midfollicular phase of the menstrual cycle. Estradiol pellets have not gained popularity in the United States.

Intranasal 17β -estradiol spray, which enables single-daily or twice-daily dosing, has been shown to have clinical therapeutic equivalence to oral and transdermal estradiol and is associated with significantly lower reporting of mastalgia.²⁵

Vaginal creams, tablets, and rings are used for the treatment of urogenital (vulval and vaginal) atrophy. However, this route of administration can have more than just a local effect. Systemic estrogen absorption is lower with the vaginal tablets and rings (specifically Estring) when compared with the vaginal creams. Nonetheless, local application of the cream at low doses can reverse atrophic vaginal changes and avoid significant systemic exposure. Nonestrogen vaginal moisturizers and lubricants also may provide local symptom relief. These products can be used alone or in combination with locally acting vaginal estrogens. Vaginal rings are a sustained-release delivery system composed of a biologically inert liquid polymer matrix with pure crystalline estradiol that can maintain adequate estradiol concentrations. One such vaginal ring product (Femring) is designed to achieve systemic concentrations of estrogen and is indicated for the treatment of moderate to severe vasomotor symptoms.

The standard dose of estrogen previously believed to be effective in alleviating vasomotor symptoms is equivalent to 0.625 mg CEE,²⁶ but new evidence indicates that lower doses of estrogen are also effective in controlling postmenopausal symptoms and reducing bone loss^{27–30} (Table 80–2). Surprisingly, even ultralow doses of 17β -estradiol delivered by a vaginal ring (Estring) improved the serum lipid profiles and prevented bone loss in elderly women.³¹ In general, if adverse effects such as breast tenderness occur with initial

TABLE 80–2. Estrogen for the Treatment of Menopausal Symptoms and Osteoporosis Prevention

| Regimen | Standard Dose | Low Dose | Route | Frequency |
|--|-------------------------------------|----------------|----------------------------------|----------------------|
| Conjugated equine estrogens | 0.625 mg | 0.3 or 0.45 mg | Oral | Once daily |
| Synthetic conjugated estrogens | 0.625 mg | 0.3 mg | Oral | Once daily |
| Esterified estrogens | 0.625 mg | 0.3 mg | Oral | Once daily |
| Estropipate (piperazine estrone sulfate) | 1.5 mg | 0.625 mg | Oral | Once daily |
| Ethinyl estradiol | 5 mcg | 2.5 mcg | Oral | Once daily |
| Micronized 17β -estradiol | 1–2 mg | 0.25–0.5 mg | Oral | Once daily |
| Transdermal 17β -estradiol | 50 mcg | 25 mcg | Transdermal (patch) | Once or twice weekly |
| Intranasal 17β -estradiol ^a | 150 mcg, per nostril | — | Intranasally | Once daily |
| Implanted 17β -estradiol | 50–100 mg pellets | 25-mg pellets | Pellets implanted subcutaneously | Every 6 months |
| Percutaneous 17β -estradiol | 0.04 mg (gel) 0.05 mg (emulsion) | | Transdermal (emulsion, gel) | Once daily |

^aNot available in the United States.

doses, lowering the dose may resolve the problem and improve patient compliance. Alternatively, if vasomotor symptoms are not controlled adequately with a lower-dose regimen, increasing the estrogen dose may be a reasonable option.

Adverse Effects. Common adverse effects of estrogen include nausea, headache, breast tenderness, and heavy bleeding. More serious adverse effects include increased risk for coronary heart disease, stroke, venous thromboembolism, breast cancer, and gallbladder disease.

Initiating therapy with low doses of estrogen often will minimize breast tenderness, unscheduled bleeding, and potentially other adverse effects. Transdermal estrogen is less likely than oral estrogen to cause nausea and headache. Also, transdermal estrogen is associated with a lower incidence of breast tenderness and deep vein thrombosis than oral estrogen.^{32,33} Changing from one estrogen regimen to another in many cases can alleviate certain adverse effects.

Progestogens

Because of the increased risk of endometrial hyperplasia and endometrial cancer with estrogen monotherapy (unopposed estrogen), women who have not undergone hysterectomy should be treated concurrently with a progestogen in addition to the estrogen.³⁴ Progestogens reduce nuclear estradiol receptor concentrations, suppress DNA synthesis, and decrease estrogen bioavailability by increasing the activity of endometrial 17-hydroxysteroid dehydrogenase, an enzyme responsible for the conversion of estradiol to estrone.³⁵

Several progestogen regimens designed to prevent endometrial hyperplasia are available (Table 80–3). Progestogens must be taken for a sufficient period of time during each cycle. A minimum of 12 to 14 days of progestin therapy each month is required for complete protection against estrogen-induced endometrial hyperplasia.³⁶ It should be noted that even use of low-dose estrogen, including some vaginal preparations, requires progestogen coadministration for endometrial protection in women with an intact uterus.³⁷ However, rarely is there a need for progestogen administration in women who have undergone hysterectomy.

Four combination estrogen and progestogen regimens are currently in use: continuous-cyclic (sequential), continuous-combined, continuous long-cycle (or cyclic withdrawal), and intermittent-combined (or continuous-pulsed) hormone therapy.³⁸ The latter two have been introduced recently. Sequential hormone therapy results in

TABLE 80–3. Progestogen Doses for Endometrial Protection (Oral Cyclic Administration)

| Progestogen | Dose |
|-----------------------------|---|
| Dydrogesterone ^a | 10–20 mg for 12 to 14 days per calendar month |
| Medroxyprogesterone acetate | 5–10 mg for 12 to 14 days per calendar month |
| Micronized progesterone | 200 mg for 12 to 14 days per calendar month |
| Norethisterone ^a | 0.7–1 mg for 12 to 14 days per calendar month |
| Norethindrone acetate | 5 mg for 12 to 14 days per calendar month |
| Norgestrel | 0.15 mg for 12 to 14 days per calendar month |
| Levonorgestrel ^a | 150 mcg for 12 to 14 days per calendar month |

^aNot available in the United States in a progestogen-only oral dosage form.

scheduled vaginal withdrawal bleeding, although in older women this is often scant or completely absent. For many women, the scheduled withdrawal bleeding is one of the main reasons for avoiding or discontinuing hormone therapy. Because there is no physiologic need for bleeding, new hormone therapy regimens that reduce monthly bleeding (such as continuous long-cycle regimens) or prevent monthly bleeding (such as continuous-combined and intermittent-combined regimens) have been developed. Various hormone therapy regimens that combine an estrogen and a progestogen are available (Table 80–4).

The first generation of progestogens included the C-19 androgenic progestogens norethisterone, norgestrel, and levonorgestrel. More recent preparations have included the C-21 progestogens dydrogesterone and medroxyprogesterone acetate, which are less androgenic. Micronized progesterone also has become available for use in postmenopausal women. The most commonly used oral progestogens are medroxyprogesterone acetate, micronized progesterone, and norethisterone acetate. The latter also can now be administered transdermally in the form of a combined estrogen-progestogen patch.

Adverse Effects. Common adverse effects of progestogens include irritability, depression, and headache. Changing from a cyclic to a continuous-combined regimen or changing from one progestogen to another may decrease the incidence or severity of these

TABLE 80–4. Common Combination Postmenopausal Hormone Therapy Regimens

| Regimen | Doses |
|---|--|
| Oral Continuous-Cyclic Regimens CEE + MPA ^a | 0.625 mg + 5 mg; 0.625 mg + 10 mg |
| Oral Continuous-Combined Regimens CEE + MPA 17β-Estradiol + NETA Ethinyl estradiol + NETA | 0.625 mg + 2.5 mg; 0.625 mg + 5 mg; 0.45 mg + 2.5 mg; 0.3 mg + 1.5 mg/day 1 mg + 0.1 mg; 1 mg + 0.25 mg; 1 mg + 0.5 mg/day 1 mcg + 0.2 mg; 2.5 mcg + 0.5 mg; 5 mcg + 1 mg; 10 mcg + 1.0 mg/day |

untoward effects. Adverse effects of progestogens are difficult to evaluate and can vary with the agent administered. Some women experience “premenstrual-like” symptoms, such as mood swings, bloating, fluid retention, and sleep disturbance. New methods and routes of progestogen delivery (e.g., parenterally by an intranasal spray or locally by an intrauterine device that releases levonorgestrel or a progesterone-containing bioadhesive vaginal gel) may be associated with fewer adverse effects. Women who are unable to tolerate a progestogen may be given unopposed estrogen if they are informed of the significant increased risk for endometrial cancer and have endometrial biopsy annually or whenever breakthrough vaginal bleeding occurs.

■ Methods of Estrogen and Progestogen Administration

■ **Continuous Cyclic Estrogen/Progestogen Treatment.** Estrogen typically is administered continuously (daily). A progestogen is coadministered with the estrogen for at least 12 to 14 days of a 28-day cycle.³⁶ The progestogen causes scheduled withdrawal bleeding in approximately 90% of women. With this regimen, bleeding usually begins 1 to 2 days after the last progestin dose. Occasionally, however, bleeding can begin during the latter phase of progestogen administration.

■ **Continuous-Combined Estrogen/Progestogen Treatment.** Continuous-combined estrogen-progestogen administration results in endometrial atrophy and the absence of vaginal bleeding. However, initially it causes unpredictable spotting or bleeding, which usually resolves within 6 to 12 months. Decreasing the estrogen dose or increasing the progestin dose usually decreases or stops the spotting. Occasionally, a drug-free period of 1 or 2 weeks may be useful to stop the bleeding.

Women who have undergone menopause recently have a higher risk for excessive, unpredictable bleeding while receiving continuous therapy; thus this regimen is best reserved for women who are at least 2 years postmenopause. Continuous-combined hormone therapy is more acceptable than traditional cyclic therapy.

■ **Continuous Long-Cycle Estrogen/Progestogen Treatment.** To decrease the incidence of uterine bleeding, a modified sequential regimen has been developed.³⁸ In the continuous long-cycle (or cyclic-withdrawal) estrogen-progestogen regimen, estrogen is given daily, and progestogen is given six times a year, every other month for 12 to 14 days, resulting in six periods a year. Bleeding episodes may be heavier and last for more days than withdrawal bleeding with continuous-cyclic regimens. The effect of continuous long-cycle estrogen-progestogen treatment on endometrial protection is unclear.

■ **Intermittent-Combined Estrogen/Progestogen Treatment.** The intermittent combined estrogen-progestogen regimen, also called continuous-pulsed estrogen-progestogen or pulsed-progestogen, consists of 3 days of estrogen therapy alone, followed by 3 days of combined estrogen and progestogen, which is then repeated without interruption.³⁸ This regimen is designed to lower the incidence of uterine bleeding. It is based on the assumption that pulsed progestogen administration will prevent downregulation of progesterone receptors that continuous-combined regimens can produce. The lower progestogen dose induces fewer side effects and can be better tolerated. The long-term effect of intermittent-combined regimens in endometrial protection is undetermined.

CLINICAL CONTROVERSY

Although some clinicians believe that estrogen can be used safely at lower doses to treat postmenopausal women with severe and protracted vasomotor symptoms, others caution that such long-term therapy even with lower doses of estrogen may be associated with unacceptable risks.

■ Low-Dose Hormone Therapy

3 Increasingly, it has become recognized that use of hormone therapy at doses lower than prescribed historically is effective in the management of menopausal symptoms (see Table 80–2). The Women’s Health, Osteoporosis, Progestin/Estrogen (HOPE) trial demonstrated equivalent symptom relief and bone density preservation without an increase in endometrial hyperplasia using lower doses of hormone therapy (CEE 0.45 mg and medroxyprogesterone acetate 1.5 mg/day).^{27–31} Whether lower doses of estrogen will be safer (lower incidence of venous thromboembolism and breast cancer) remains to be proven. Nonetheless, recent evidence of harm associated with a standard dose of hormone therapy has prompted many patients to either discontinue such therapy or taper to lower doses.

■ ANDROGENS

The therapeutic use of testosterone in women, although controversial, is becoming more widespread.³⁹ Data to support this practice are limited; however, several randomized trials of transdermal testosterone therapy have been conducted and provide evidence for benefits in selected women. There is a cluster of symptoms that appears to characterize androgen insufficiency in women: loss of sexual desire, diminished well-being, loss of energy, and over time, decreased bone mass and reduced muscle strength.³⁹ There is evidence that androgen therapy, usually in the form of testosterone, is effective in alleviating these physical and psychological symptoms of androgen insufficiency. Symptoms are more pronounced in women who have undergone surgical menopause because of the abrupt cessation of testosterone production by the ovaries. Following oophorectomy, testosterone and androstenedione serum concentrations decrease by about 50%. Testosterone therapy generally is accepted for women who have undergone surgical menopause but also should be considered for naturally menopausal women and those who have experienced premature ovarian failure.

In women, androgens may act directly via the androgen receptor or indirectly after conversion to estrogen. Androgens are the precursor hormones for estrogen production in the ovaries, as well as in extragonadal sites, including bone, adipose tissue, and the brain.

Although estrogen therapy improves vaginal dryness, vasomotor symptoms, and general well-being, it has minimal effect on libido. Estrogen combined with androgen significantly improves sexual activity, satisfaction, and pleasure more than that reported with estrogen monotherapy. In addition, estrogen combined with androgen increases bone density sooner and to a greater degree than estrogen therapy,^{40,41} but data confirming a reduction in fracture rate are lacking.

Testosterone therapy appears to be effective and safe when given in doses that achieve circulating serum free testosterone concentrations within the physiologic range for young reproductive women. The goal is to produce beneficial effects on well-being and quality of life without incurring undesirable virilizing adverse effects.³⁹

TABLE 80–5. Androgen Regimens Used for Women

| Regimen | Dose | Frequency | Route |
|--|-----------------|---------------------|--------------------------|
| Methyltestosterone in combination with esterified estrogen | 1.25–2.5 mg | Daily | Oral |
| Mixed testosterone esters | 50–100 mg | Every 4 to 6 weeks | Intramuscular |
| Testosterone pellets | 50 mg | Every 6 months | Subcutaneous (implanted) |
| Transdermal testosterone system ^a | 150–300 mcg/day | Every 3 to 4 days | Transdermal patch |
| Nandrolone decanoate | 50 mg | Every 8 to 12 weeks | Intramuscular |

^aUndergoing clinical trials in the United States.

Nonetheless, oral testosterone therapy can decrease HDL cholesterol and apolipoprotein A₁ and also can lower triglycerides.⁴⁰ However, exogenous testosterone therapy increases brachial artery flow-mediated vasodilation and the vasodilation induced by glyceryl trinitrate in postmenopausal women stabilized on hormone therapy.⁴¹

There are no data regarding the effects of exogenous androgen therapy on the incidence of breast cancer. However, androgen receptors are found in approximately 50% of mammary tumors, and their presence is associated with longer survival in women with operable breast cancer.³⁹

Testosterone is available as oral methyltestosterone in the United States and as testosterone implants in the United Kingdom. Of the available oral preparations, methyltestosterone in combination with esterified estrogen (either 0.625 mg esterified estrogen plus 1.25 mg methyltestosterone or 1.25 mg esterified estrogen plus 2.5 mg methyltestosterone) is the most widely studied.

Relative contraindications to testosterone therapy include moderate to severe acne, clinical hirsutism, and androgenic alopecia. Absolute contraindications to androgen replacement include pregnancy or lactation and known or suspected androgen-dependent neoplasia.

Adverse effects from excessive dosage include virilization, fluid retention, and potentially adverse lipoprotein lipid effects, which are more likely with oral administration.

Testosterone replacement for women is now available in a variety of formulations³⁹ (Table 80–5). The recent development of a transdermal testosterone matrix patch specifically for use in women may provide a new option for women requiring testosterone replacement.^{43,44} Testosterone treatment should not be administered to postmenopausal women who are not receiving concurrent estrogen therapy.

SELECTIVE ESTROGEN-RECEPTOR MODULATORS

Selective estrogen-receptor modulators (SERMs), such as raloxifene, prevent bone loss and spinal fractures. Raloxifene does not alleviate vasomotor symptoms, and it may even exacerbate them. The effects of SERMs on the cardiovascular system are currently being evaluated.

SERMs, a new type of nonhormonal therapy, bind to estrogen receptors and function as tissue-specific estrogen antagonists or agonists. The ideal SERM would protect against osteoporosis and decrease the incidence of breast, endometrial, and colorectal cancer and coronary heart disease without exacerbating menopausal symptoms or increasing the risk of venous thromboembolism or gallbladder disease. To date, no SERM meets these ideals. Tamoxifen, the first-generation SERM, has estrogen antagonist activity on the breast and estrogen-like agonist activity on bone and endometrium.⁴⁵ The second generation of SERMs, most notably raloxifene (a non-

steroidal benzothiophene derivative), recently became available for the prevention of osteoporosis. Raloxifene decreases bone loss in recently menopausal women without affecting the endometrium and has estrogen-like actions on lipid metabolism.^{46,47} The Multiple Outcomes of Raloxifene Evaluation (MORE) study, a multicenter randomized, blinded, placebo-controlled trial, showed that raloxifene increases bone mineral density in the spine and femoral neck and reduces the risk of vertebral fractures.⁴⁶ More important, the same study⁴⁸ and the Continuing Outcomes Relevant to Evista (CORE) trial^{48a} suggest that raloxifene use is associated with a lower incidence of breast cancer compared with placebo. Nonetheless, raloxifene use increases the risk of venous thromboembolism to a degree similar to that of oral estrogen.⁴⁶ The Study of Tamoxifen and Raloxifene (STAR) is currently evaluating the ability of these SERMs to reduce breast cancer incidence in high-risk postmenopausal women.

Raloxifene generally is well tolerated. Its adverse effects include leg cramps and hot flashes. Raloxifene is used specifically to reduce the risk of osteoporosis in postmenopausal women.

TIBOLONE

Tibolone is a gonadomimetic synthetic steroid in the norpregnane family with combined estrogenic, progestogenic, and androgenic activity.⁴⁹ Tibolone has been used for almost two decades in Europe for the treatment of menopausal symptoms and prevention of osteoporosis. Approval of Organon's new drug application for tibolone (Xyvion) in the United States is expected in 2004. The hormonal effects of this synthetic steroid depend on its metabolism and activation in peripheral tissues. The parent compound has been described as a prodrug that is metabolized quickly in the gastrointestinal tract. It has several active metabolites, including a $\Delta 4$ -isomer and 3α -OH and 3β -OH compounds.⁴⁹ The $\Delta 4$ -isomer metabolite confers significant progestogenic and androgenic properties. Tibolone has beneficial effects on mood and libido and improves menopausal symptoms and vaginal atrophy. Tibolone protects against bone loss, and its effect on fracture rates is currently being evaluated.⁵⁰ In addition, it causes endometrial atrophy and, therefore, does not usually cause withdrawal bleeding when used in women who have had amenorrhea for at least 1 year. Tibolone is not recommended during perimenopause because it may cause irregular bleeding. Its use is associated with a low rate of bleeding, ranging from 10% to 15%, during the initial months of treatment to about 4% after 6 months of treatment.²²

Tibolone reduces concentrations of total cholesterol, triglycerides, and lipoprotein(a) but significantly decreases HDL cholesterol and thus may increase overall cardiovascular risk.²² Tibolone increases fibrinolysis parameters without significantly altering

coagulation parameters.⁵¹ Long-term safety data are lacking. The Million Women Study, a cohort study, showed that current users of tibolone may be at increased risk for breast cancer (adjusted relative risk 1.45, 95% CI 1.25–1.68).²¹ The major adverse effects of tibolone include weight gain and bloating. Further studies are necessary to identify the true risk-benefit ratio of tibolone with respect to its overall effect on coronary artery disease and breast cancer.

■ TREATMENT CONSIDERATIONS

Hormone therapy is contraindicated in women with endometrial cancer, breast cancer, undiagnosed vaginal bleeding, thromboembolism (including a recent spontaneous thrombosis or in the presence of a thrombophilia), or active liver disease.⁵² Relative contraindications include uterine leiomyoma, migraine headaches, and seizure disorder.⁵³ In addition, oral estrogen should be avoided in women with hypertriglyceridemia, liver disease, and gallbladder disease. For these women, transdermal administration is a safer approach. The main reasons for discontinuing hormone therapy are side effects such as bleeding, breast tenderness, bloating, and “premenstrual-like symptoms.” Reducing the dose or changing the regimen or the route of administration can minimize these effects.

■ Pretreatment Assessment

The initial visit of a perimenopausal or postmenopausal woman is the most appropriate time to obtain a complete medical history, perform a physical examination, and educate the patient.⁵³ Medical history should include determination of a personal or family history of thrombotic problems. The physical examination should include a complete cardiovascular examination, clinical assessment of thyroid status, and breast and pelvic examinations. Papanicolaou cervical cytologic examination and screening mammography negative for malignancy are required before initiating hormone therapy. Thyroid function tests and lipoprotein lipid profile also should be performed at the discretion of the clinician.

Each patient should be evaluated for the presence of indications (i.e., menopausal symptoms such as hot flashes or vaginal dryness) and possible contraindications. The risks and benefits of hormone therapy should be discussed with the patient so that she can weigh the risks and benefits versus alternatives and make a rational decision about whether to use hormone therapy.

■ BENEFITS OF HORMONE THERAPY

■ Relief of Menopausal Symptoms

4 ■ *Vasomotor Symptoms.* The major indication for postmenopausal hormone therapy is the management of vasomotor symptoms. Most women with vasomotor symptoms require hormone treatment for less than 5 years, and thus the risk appears to be small.

Fewer than 25% of women experience a menopausal transition without symptoms, whereas over 25% suffer severe menopausal symptoms, most commonly hot flashes and night sweats.⁵⁴

Without treatment, hot flashes in most women typically disappear within 1 to 2 years, but in some untreated women they continue for more than 20 years.³² Women with mild vasomotor symptoms often experience relief by lifestyle modification (e.g., wear layered clothing that can be removed or added as necessary); reduction in intake of hot spicy foods, caffeine, and hot beverages; exercise; and other good general health practices. At least 25% of women in clinical trials report significant improvement in their vasomotor symptoms when taking placebo. However, no therapy has been shown to be as effective as estrogen therapy in alleviating significant vasomotor symptoms. Estrogens diminish hot flashes in most women, and all types and routes of administration of estrogen are equally effective.⁵⁵ A dose-dependent relationship between estrogen administration and suppression of hot flashes is well established. Some women, especially younger women, may require a higher than average dose of estrogen to suppress symptoms. On the other hand, many women with hot flashes at the time of menopause require lower dose of estrogen. Hormone therapy for menopausal symptoms can be stopped about 2 or 3 years after starting. If treatment can be tapered and stopped within 5 years, there is no evidence of increased risk of breast cancer.²

Alternatives to estrogen for the treatment of hot flashes include tibolone, selective serotonin reuptake inhibitors (e.g., paroxetine, fluoxetine), venlafaxine, medroxyprogesterone acetate, megestrol acetate, clonidine, and gabapentin⁵⁶ (Table 80–6). Progestogens alone may be an option for some women (e.g., those with a history of breast cancer or venous thrombosis), but weight gain, vaginal bleeding, and other adverse effects often limit their use. Selective serotonin reuptake inhibitors and venlafaxine are considered by some to be a first-line therapy for the treatment of hot flashes in women for whom hormone therapy is contraindicated.^{56–59} Clonidine often is effective for symptom control, but it is not always well tolerated by women.

To date, randomized, placebo-controlled trials of non-hormonal therapies have been equivocal and have not established the safety and

TABLE 80–6. Alternatives to Estrogen for Treatment of Hot Flashes

| Drug | Dose (Oral) | Interval | Comments |
|-------------------|-------------|------------------------------|--|
| Tibolone | 2.5–5 mg | Once daily | Tibolone is not recommended during the perimenopause because it may cause irregular bleeding |
| Venlafaxine | 37.5–150 mg | Once daily | Side effects include dry mouth, decreased appetite, nausea, and constipation |
| Paroxetine | 12.5–25 mg | Once daily | 12.5 mg is an adequate and well-tolerated starting dose for most women; adverse effects include headache, nausea, and insomnia |
| Fluoxetine | 20 mg | Once daily | Modest improvement seen in hot flashes |
| Megestrol acetate | 20–40 mg | Once daily | Progesterone may be linked to breast cancer etiology; also, there is concern regarding the safety of progestational agents in women with preexisting breast cancer |
| Clonidine | 0.1 mg | Once daily | Can be administered orally or transdermally; drowsiness and dry mouth can occur, especially with higher doses |
| Gabapentin | 900 mg | Divided in three daily doses | Adverse effects include somnolence and dizziness; these symptoms often can be obviated with a gradual increase in dosing |

efficacy of herbal remedies, homeopathic treatments, or acupuncture for the prevention or treatment of hot flushes.

■ **Vaginal Atrophy.** Estrogen receptors have been demonstrated in the lower genitourinary tract, and at least 50% of postmenopausal women suffer symptoms of urogenital atrophy caused by estrogen deficiency.⁶⁰ Atrophy of the vaginal mucosa results in vaginal dryness and dyspareunia. Lower urinary tract symptoms include urethritis, recurrent urinary tract infection, urinary urgency, and frequency. Most women with significant vaginal dryness because of vaginal atrophy require the use of local or systemic estrogen therapy for symptom relief. Such treatment also reduces the risk of recurrent urinary tract infections, possibly by modifying the vaginal flora.⁶¹ Vaginal dryness and dyspareunia can be treated with a topical estrogen cream, tablet, or vaginal ring. In clinical trials, topical estrogen appears to be better than systemic estrogen for relieving these symptoms and avoids high levels of circulating estrogen. Concomitant progestogen therapy generally is unnecessary if women are using low-dose micronized 17β-estradiol. However, the regular use of CEE vaginal creams and other products that potentially promote endometrial proliferation in women with an intact uterus requires intermittent progestogen challenges (i.e., for 10 days every 12 weeks). This is an important caveat because vaginal atrophy requires long-term estrogen treatment.⁶¹

Urinary incontinence, which becomes more prevalent with increasing age, usually is not improved by estrogen therapy, and in one large clinical trial, estrogen-progestogen therapy actually increased incontinence.⁶²

■ **Osteoporosis Prevention**

◀ Postmenopausal osteoporosis is a serious age-related disease that affects millions of women throughout the world. The WHI randomized trial was the first study to demonstrate that hormone therapy reduces the risk of fractures at the hip, spine, and wrist.^{2,63} Hip and clinical vertebral fractures are reduced by 34%, and total osteoporotic fractures are reduced by 24%.⁶³ These findings are in agreement with observational data and several meta-analyses regarding

the efficacy of hormone therapy in reduction of fractures in postmenopausal women.⁶⁴

Menopause is accompanied by accelerated bone loss, and the central role of estrogen deficiency in postmenopausal osteoporosis is well established. Osteoporosis is characterized by reduced bone mass associated with architectural deterioration of the skeleton and increased risk for fracture.⁶⁵ Estrogen deficiency results in bone loss through its actions in accelerating bone turnover and uncoupling bone formation from resorption. In fact, annual decrements in bone mass of 3% to 5% are common in the years soon after the menopause, and 0.5% to 1% decrements are seen after 65 years of age.⁶⁶ Estrogen therapy reduces bone turnover and increases bone density in postmenopausal women of all ages. Nonetheless, the protective effect persists as long as the treatment is maintained. With cessation of therapy, postmenopausal bone loss resumes at the same rate as that in untreated women. The standard bone-sparing daily estrogen dose is equivalent to 0.625 mg CEE²⁶ (see Table 80–2). Even low doses of estrogen may increase bone mass when they are supplemented with adequate calcium intake.²⁶

Osteoporosis prevention remains an indicated use of estrogen products; however, nonestrogen products, such as raloxifene and bisphosphonates, are as effective as hormone therapy for preventing osteoporosis (Table 80–7). The FDA has withdrawn the “osteoporosis treatment” indication from estrogen products.

Raloxifene decreases the risk of vertebral fracture by 30% to 50%, although it has not been shown to decrease the risk of hip fracture.⁴⁶ The bisphosphonates reduce the risk of both hip and vertebral fractures by 30% to 50%.⁶⁵ Bisphosphonates are analogues of pyrophosphate that inhibit bone resorption. Drugs in this class include alendronate, etidronate, pamidronate, risedronate, tiludronate, and zoledronate. Bisphosphonates have no known impact on the incidence of cardiovascular disease or breast or endometrial cancer. Adverse effects include upper gastrointestinal side effects, especially if not taken properly. A few trials have shown improved bone density over single therapy when a bisphosphonate is combined with estrogen or raloxifene, but there are no fracture data.⁶⁷

Tibolone can prevent bone loss in early postmenopausal women.⁵⁰ A placebo-controlled study investigating the effects of tibolone on fractures is currently ongoing.

TABLE 80–7. Alternatives to Hormone Therapy for Osteoporosis Prevention

| Drug | Dose | Comments |
|-----------------|--|--|
| Raloxifene | 60 mg/day | Raloxifene reduces the risk of vertebral fractures. Adverse effects include hot flushes and leg cramps. Slowly increasing the dose of raloxifene may help reduce the incidence and severity of hot flushes. |
| Tibolone | 1.25 mg or 2.5 mg/day | Tibolone prevents bone loss. No data are yet available regarding fracture rates. |
| Alendronate | 5 mg/day or 35 mg/week | A 50% reduction in the risk of fractures is observed in women with osteoporosis. In younger postmenopausal women without osteoporosis, therapy with alendronate protected all women from bone loss for up to 4 years. Side effects include upper gastrointestinal symptoms, especially if the drug is not taken as directed. |
| Risedronate | 5 mg/day or 35 mg/week | A 40% reduction in vertebral and nonvertebral fractures is observed in women with osteoporosis. In postmenopausal women without osteoporosis, risedronate increases bone mineral density over 2 years. Significant side effects were not observed. |
| Etidronate | Intermittent administration of 400 mg/day (in 2-week cycles); dose repeated every 3 months | Calcium is taken between the cycles of etidronate. Continuous daily use may cause abnormalities in bone mineralization. A 37% reduction is observed in the risk of vertebral fractures (but not nonvertebral fractures) in women with osteoporosis. Therapy in women without osteoporosis prevents bone loss over 2 years. Side effects include diarrhea and nausea. |
| Zoledronic acid | 4 mg as a single intravenous infusion once yearly | Effects on bone turnover and bone density were similar to those with daily oral bisphosphonates. Efficacy against fractures has not yet been established. Adverse effects include myalgia and pyrexia. |

General protective measures, such as adequate calcium intake (1200 mg/day),⁶⁸ regular weight-bearing exercise, and the avoidance of detrimental lifestyle habits such as smoking and alcohol abuse, are appropriate for all women. Most women require calcium supplementation to their dietary intake. Also, adequate exposure to sunlight is believed to protect against vitamin D deficiency, but many Western women are deficient in this vitamin. The current recommended dietary intake for vitamin D is 400 IU/day for women aged 51 to 70 years and 600 IU/day for women older than age 70.⁶⁸

Low bone density is the most important risk factor for osteoporosis. According to the World Health Organization, a woman with a bone mineral density greater than 2.5 standard deviations below the mean peak density has osteoporosis.⁶⁵ The rates of osteoporosis vary with ethnicity; it is more common in whites and those of Asian descent and less common in blacks.⁶⁵ In the United States, approximately 20% of white women aged 50 years or older have osteoporosis.⁶⁵

Bone mass measurement accurately determines the bone density in the spine and hip. The current “gold standard” method of bone density testing is dual-energy x-ray absorptiometry (DEXA).⁶⁵ Bone density testing is recommended in the United States for all women with medical causes of bone loss and for all women aged 65 years or older. Bone density testing should be assessed in conjunction with clinical risk profile evaluation. For women at high fracture risk (i.e., T-score <2, previous nonspine fracture, family history of hip or spine fracture, and low body weight), bisphosphonates are the treatment of choice because of the demonstrated fracture protection.⁶⁵ There are no clear indications for treating women at low risk for fracture (T-score >2), but raloxifene, tibolone, and bisphosphonates may be used. Long-term hormone therapy is no longer an appropriate first-choice option for osteoporosis prevention because of the risks associated with its long-term use. Therefore, hormone therapy should be considered for osteoporosis prevention only in women at significant risk for osteoporosis who cannot take nonestrogen regimens.

■ Colon Cancer Risk Reduction

Colorectal cancer is the fourth most common cancer and the second leading cause of cancer death in the United States (see Chap. 127). The WHI was the first randomized, controlled trial to confirm that hormone therapy reduces colon cancer risk. Compared with placebo, 6 fewer colorectal cancers are reported per year in every 10,000 women taking hormone therapy.²

■ Other

■ **Diabetes.** In healthy postmenopausal women, hormone therapy appears to have a beneficial effect on fasting glucose level among women with elevated fasting insulin concentrations.⁶⁹ Also, in women with coronary artery disease, hormone therapy reduces the incidence of diabetes by 35%.⁷⁰ These findings provide important insights into the metabolic effects of hormone therapy but are insufficient to recommend the long-term use of hormone therapy in women with diabetes.

■ **Body Weight.** A meta-analysis of randomized, controlled trials showed that unopposed estrogen or estrogen combined with a progestin has no effect on body weight, suggesting that hormone therapy does not cause weight gain in excess of that normally observed at the time of menopause.⁷¹

■ RISKS OF HORMONE THERAPY

■ Cardiovascular Disease

◀ Cardiovascular disease, including coronary artery disease, stroke, and peripheral vascular disease, is the leading cause of death among women. The American Heart Association recommends that postmenopausal hormone therapy should not be used for reducing the risk of coronary heart disease.⁷²

In the last decade, an expectation of coronary benefit had been a major reason for postmenopausal hormone use because observational studies indicated that women who use hormone therapy have a 35% to 50% lower risk of coronary heart disease than nonusers.⁷³ In addition, previous studies have shown that estrogen exerts protective effects on the cardiovascular system, including lipid-lowering,⁷⁴ antioxidant,⁷⁵ and vasodilating effects.⁷⁶ Nevertheless, recent randomized clinical trials have provided no evidence of cardiovascular disease protection and even some evidence of harm with hormone therapy^{2,77–82} (Table 80–8).

The primary findings of the WHI trial showed an overall increase in the risk of coronary heart disease (HR 1.24, 95% CI 1–1.54) among healthy postmenopausal women 50 to 79 years of age receiving combined estrogen-progestogen hormone therapy compared with those receiving placebo.^{2,82} New findings from the Women’s Health Initiative, in women taking estrogen alone, showed no effect (either increase or decrease) in the risk of coronary heart disease.³

In the estrogen-progestogen arm of the WHI trial, the elevation in coronary heart disease risk was most apparent at 1 year (HR 1.81, 95% CI 1.09–3.01). The increased risk for stroke and venous thromboembolism continued throughout the 5 years of therapy.² Increased risk was observed only for ischemic stroke and not for hemorrhagic stroke.⁸³ In the estrogen-alone arm of the study, a similar increased risk for stroke was observed. The lack of cardiac protection observed in the WHI trial is consistent with recent findings from randomized trials of postmenopausal hormone therapy in women with coronary heart disease. In the Heart Estrogen/Progestin Replacement Study (HERS), combined hormone therapy had no overall effect on the risk of recurrent coronary events after 4.1⁷⁷ and 6.8 years⁸⁴ of follow-up. Similar to the WHI, the elevated risk of coronary heart disease was largely limited to the first year of therapy. The Estrogen Replacement in Atherosclerosis (ERA) trial found that neither unopposed estrogen nor estrogen plus progestin slowed the progression of atherosclerosis, measured by quantitative angiography, among women with preexisting coronary heart disease.⁷⁸ The Papworth trial,⁸¹ which tested transdermal 17 β -estradiol with or without norethindrone, and the ESPRIT trial,⁸⁰ which tested estradiol valerate without progestin in women with a history of myocardial infarction, also demonstrated no cardiac protection with hormone therapy. Finally, the Women’s Estrogen for Stroke Trial (WEST), which tested oral 17 β -estradiol (without progestin), found no overall effect in the risk of coronary events and stroke and an increased risk of stroke in the first 6 months of treatment.⁷⁹

Raloxifene therapy for 4 years in osteoporotic postmenopausal women did not significantly affect the risk of cardiovascular events (myocardial infarction, unstable angina, coronary ischemia, stroke, or transient ischemic attack).⁸⁵ Among women at high risk of coronary heart disease, those receiving raloxifene had statistically significant reductions in the risk of cardiovascular events.⁸⁵ These findings must be evaluated by a randomized trial designed specifically to assess cardiovascular events.

Hormone therapy should not be initiated or continued for the prevention of cardiovascular disease. Adherence to a healthful lifestyle

TABLE 80–8. Randomized Clinical Trials of Cardiovascular Disease and Postmenopausal Hormone Therapy

| Trial | Population | Medication | Results | Comments |
|---|--|---|--|--|
| WHI (estrogen/progestogen arm) ² | 16,608 apparently healthy postmenopausal women | Conjugated estrogen 0.625 mg plus medroxyprogesterone acetate 2.5 mg daily or placebo | 29% increased risk of coronary heart disease among women taking hormone therapy | The trial was planned to last for 8.5 years but was stopped after 5.2 years owing to increased risk of breast cancer after 5 years of treatment. |
| WHI (estrogen-alone arm) ³ | 10,739 apparently healthy postmenopausal women with prior hysterectomy | Conjugated estrogen 0.625 mg daily or placebo | No effect on cardiovascular disease risk among women taking estrogen therapy | The trial was stopped after 6.8 years because of an increased risk of stroke (hazard ratio 1.39, 95% CI 1.10–1.77) |
| HERS ⁷⁷ | 2,763 postmenopausal women with coronary heart disease | Conjugated estrogen 0.625 mg plus medroxyprogesterone acetate 2.5 mg daily or placebo | No difference in risk of coronary heart disease events (myocardial infarction or coronary heart disease death) among women in the two groups | A 50% increased risk of coronary heart disease events was observed among women in the hormone therapy group in the first year of treatment. |
| ERA ⁷⁸ | 309 postmenopausal women with coronary heart disease | Conjugated estrogen 0.625 mg plus medroxyprogesterone acetate 2.5 mg daily or placebo | No difference in changes in coronary diameter in either group after 3 years of treatment | Atherosclerosis progression was measured by quantitative angiography. |
| PAPWORTH ⁸¹ | 255 postmenopausal women with coronary heart disease | Transdermal 17 β -estradiol 80 mcg/day alone for women with hysterectomy; transdermal 17 β -estradiol, 80 mcg/day plus cyclic transdermal norethisterone 120 mcg/day for 14 days or placebo | No reduction in the incidence of acute coronary events (coronary disease death, myocardial infarction, unstable angina) among women in the hormone therapy group | During the first 2 years of follow-up, the hormone-therapy group had a higher acute coronary event rate than the control group. |
| WEST ⁷⁹ | 664 postmenopausal women with recent stroke or transient ischemic attack | Oral 17 β -estradiol, 1 mg/day or placebo | No reduction in risk of stroke, death, or coronary events among women in the hormone therapy group during 2.8 years of treatment | In the first 6 months of treatment, a 2.3-fold increase in the risk of stroke was observed among women in the hormone therapy group. |
| ESPRIT ⁸⁰ | 1017 postmenopausal women with previous myocardial infarction | Oral estradiol valerate 2 mg or placebo | No reduction in the incidence of acute coronary events (coronary disease death, myocardial infarction) among women in the estrogen group | In the estradiol group, there were slightly more nonfatal myocardial infarctions but fewer cardiac deaths. |

WHI, Women's Health Initiative; HERS, Heart and Estrogen/Progestin Replacement Study; ERA, Estrogen Replacement in Atherosclerosis; WEST, Women's Estrogen for Stroke Trial; ESPRIT, Estrogen in the Prevention of Reinfarction.

(cessation of smoking, regular exercise, healthy diet, and body mass index less than 25) may prevent the onset of cardiovascular disease in postmenopausal women.^{86,87}

■ Breast Cancer

The WHI trial found that combined estrogen-progestin therapy has an increased risk of invasive breast cancer (HR 1.26, 95% CI 1.0–1.59) and a trend toward increasing risk with increasing duration of therapy.² The estrogen-only arm of the WHI found no increased risk for breast cancer during the 7-year follow-up period.³ In the estrogen-progestogen arm, the increased breast cancer risk did not appear until after 3 years of study participation² (Table 80–9). The breast cancers diagnosed in women in the hormone therapy group had similar histology and grade but were more likely to have advanced stage compared with women in the placebo

group.⁸⁸ In an unselected postmenopausal population, the Million Women Study found that current use of hormone therapy increased breast cancer risk and breast cancer mortality (relative risk 1.66 and 1.22, respectively). Increased incidence was observed for estrogen-only use (relative risk 1.30), for estrogen-progestin (relative risk 2), and for tibolone (relative risk 1.45).²¹

The lifetime risk of developing breast cancer in the United States is approximately one in eight women,⁸⁹ and the greatest incidence occurs in women over the age of 60 years (see Chap. 125). In a collaborative reanalysis of data from 51 studies evaluating over 52,000 women with breast cancer and 108,000 controls, less than 5 years of therapy with estrogen combined with progestogen was associated with a 15% increase in the risk of breast cancer, and the increase was greater with longer duration (relative risk of 1.53 after 5 or more years of use).⁹⁰ However, 5 years after discontinuing hormone-replacement therapy, the risk of breast cancer was no longer increased.⁹⁰

TABLE 80–9. Randomized Clinical Trials of Postmenopausal Hormone Therapy and Breast Cancer

| Trial | Population | Medication | Results | Comments |
|---|--|---|--|--|
| WHI (estrogen/progestogen arm) ² | 16,608 healthy postmenopausal women | Conjugated estrogen 0.625 mg plus medroxyprogesterone acetate 2.5 mg daily or placebo | 26% increased risk of breast cancer | The increased risk did not appear until 5 years of study. There was a trend toward increasing risk over time. |
| WHI (estrogen-alone arm) ³ | 10,739 apparently healthy postmenopausal women with prior hysterectomy | Conjugated estrogen 0.625 mg daily or placebo | No increased risk for breast cancer | The possible reduction in breast cancer risk requires further investigation (hazard ratio 0.77, 95% CI 0.59–1.01) |
| MORE ⁴⁸ | 7705 postmenopausal women with osteoporosis | Raloxifene 60 or 120 mg/day or placebo | 76% lower risk of estrogen receptor-positive breast cancer after 4 years of raloxifene therapy | Raloxifene can cause or exacerbate hot flashes. Also, it increases the risk of venous thromboembolism by about 2-fold. |
| CORE ^{48a} | 5213 postmenopausal women with osteoporosis | Raloxifene 60 mg daily or placebo | 76% lower risk of estrogen receptor-positive breast cancer after 8 years of raloxifene therapy | No new safety concerns were identified during the CORE study. The risk of venous thromboembolism remained increased by about 2-fold. |

WHI, Women's Health Initiative; MORE, Multiple Outcomes of Raloxifene Evaluation; CORE, Continuing Outcomes Relevant to Evista.

Addition of progestogens to estrogen may increase breast cancer risk beyond that observed with estrogen alone.⁹¹ The Iowa Women's Health Study showed that exposure to hormone therapy is associated with an increased risk of breast cancer that has a favorable prognosis.⁹² These findings have been attributed to an increased use of breast cancer screening in women taking hormone therapy. A study of the effects of hormone therapy in women with a family history of breast cancer found that those who were current users had approximately the same increased relative risk compared with those who did not have a family history.⁹³ The overall mortality for women with a family history of breast cancer from all causes was reduced significantly among hormone therapy users.⁹³ These data suggest that hormone therapy use in women with a family history of breast cancer is not associated with a significantly increased incidence of the disease.

Sex steroid deficiency during menopause results in lipomatous involution of the breast that is reflected by decreased mammographic breast density and markedly improved radiotransparency of breast tissue. Thus mammographic changes indicating breast cancer can be recognized more easily and earlier after the menopause. Conversely, combination hormone therapy results in increased mammographic breast density,⁹⁴ and increased density on mammography has been associated with higher breast cancer risk.⁹⁵ Of note, increased mammographic density is not observed with estrogen-only therapy.⁹⁴

Although raloxifene is not approved for prevention or treatment of breast cancer, a 4-year trial of raloxifene in women with osteoporosis (not at increased risk for breast cancer) showed a 76% risk reduction for estrogen-receptor-positive breast cancer⁴⁸ (relative risk 0.24, 95% CI 0.13–0.44). Furthermore, the CORE trial, a study evaluating the efficacy of an additional 4 years of raloxifene therapy in women with osteoporosis, showed that the reduction in estrogen-receptor positive breast cancer incidence continues for up to 8 years^{48a} (hazard ratio 0.24, 95% CI 0.15–0.40) (see Table 80–9). Raloxifene does not increase breast density.⁹⁶ A trial comparing raloxifene with tamoxifen is underway.

■ Endometrial Cancer

The WHI trial suggests that combined hormone therapy does not increase endometrial cancer risk compared with placebo (HR 0.81, 95%

CI 0.48–1.36).⁹⁷ Estrogen given alone to women with an intact uterus significantly increases uterine cancer risk.³⁵ With unopposed estrogen therapy, the risk of endometrial cancer increases within 2 years.³⁵ The excess risk increases with dose and duration of estrogen (10 years of unopposed estrogen increases the risk 10-fold), is apparent within 2 years of the start of treatment, and persists for many years after estrogen replacement is discontinued. Estrogen-induced endometrial cancer is usually of a low stage and grade at the time of diagnosis,³² and it can be prevented almost entirely by progestogen coadministration. The sequential addition of progestin to estrogen for at least 10 days of the treatment cycle or continuous combined estrogen-progestogen does not increase the risk of endometrial cancer.⁹⁸

Also, lower doses of estrogen may be associated with a lower risk of endometrial hyperplasia.⁹⁹ Raloxifene does not result in endometrial hyperplasia, has no effect on endometrial thickness, is not associated with polyp formation, and has virtually no proliferative effect on the endometrium.¹⁰⁰ A 4-year trial of raloxifene in women with osteoporosis showed no increased risk of endometrial cancer.⁴⁸

■ Ovarian Cancer

Lifetime risk of ovarian cancer is low (1.7%). The WHI trial suggests that combined hormone therapy may increase the risk of ovarian cancer (HR 1.58, 95% CI 0.77–3.24).⁹⁷ However, a recent study reported an increased risk of ovarian cancer in women taking postmenopausal estrogen therapy for more than 10 years (relative risk 1.8, 95% CI 1.1–3.0) but no increased risk of ovarian cancer among women receiving combination estrogen-progestin therapy.¹⁰¹ Additional large, controlled studies are needed to confirm these findings.

■ Venous Thromboembolism

Venous thromboembolism, including thrombosis of the deep veins of the legs and embolism to the pulmonary arteries, is uncommon in the general population. The absolute risk of venous thromboembolism in non-hormone therapy users is approximately 1 in 10,000 women.¹⁰² Women taking hormone therapy have a twofold increase in risk for thromboembolic events, with the highest risk occurring in the first

year of use.¹⁰³ The absolute increase in risk is small, with 1.5 venous thromboembolic events per 10,000 women in 1 year.¹⁰³ Lower doses of estrogen are associated with a decreased risk for thromboembolism as compared with higher doses.¹⁰²

Currently, there is no indication for thrombophilia screening before initiating hormone therapy. However, hormone therapy should be avoided in women at high risk for thromboembolic events.

Gallbladder Disease

Gallbladder disease is a commonly cited complication of oral estrogen use.¹⁰⁴ The Nurses' Health Study showed that the age-adjusted relative risk of cholecystectomy is 2.2 for women currently taking 0.625 mg CEE.¹⁰⁴ In this study, the risk of cholecystectomy increased with duration of hormone therapy use and did not resolve after discontinuation.¹⁰⁴ Transdermal estrogen is an alternative to oral therapy for women at high risk for cholelithiasis.

CLINICAL CONTROVERSY

Some clinicians believe that hormone therapy may improve well-being and quality of life of postmenopausal women, whereas others believe that hormone therapy, at best, has no effect. Hormone therapy improves mood and well-being mainly in women with vasomotor symptoms and sleep disturbance.

OTHER EFFECTS OF HORMONE THERAPY

Quality of Life, Mood, Cognition, and Dementia

7 Hormone therapy improves depressive symptoms in symptomatic menopausal women most probably by relieving flushing and improving sleep.^{105,106} Women with vasomotor symptoms receiving hormone therapy have improved mental health and fewer depressive symptoms compared with those receiving placebo; however, hormone therapy may worsen quality of life in women without flushes.¹⁰⁷

There is no evidence that hormone therapy improves quality of life or cognition in older, asymptomatic women.¹⁰⁷⁻¹¹⁰ Postmenopausal hormone therapy should not be used for treatment of major depression.¹¹¹

More than 33% of women aged 65 years or older will develop dementia during their lifetime.¹¹² Several observational studies have suggested that estrogen therapy may be protective against Alzheimer's disease (see Chap. 63). The WHI Memory Study, an ancillary study of WHI including 4532 women aged 65 years or older, evaluated the effect of combined hormone therapy on dementia and cognition.¹⁰⁹ The study found that postmenopausal women aged 65 years or older taking estrogen plus progestogen therapy had twice the rate of dementia, including Alzheimer disease, of women taking placebo¹⁰⁹ (HR 2.05, 95% CI 1.21-3.48). In addition, in these women, estrogen plus progestogen therapy did not prevent mild cognitive impairment, a cognitive and functional state between normal aging and dementia

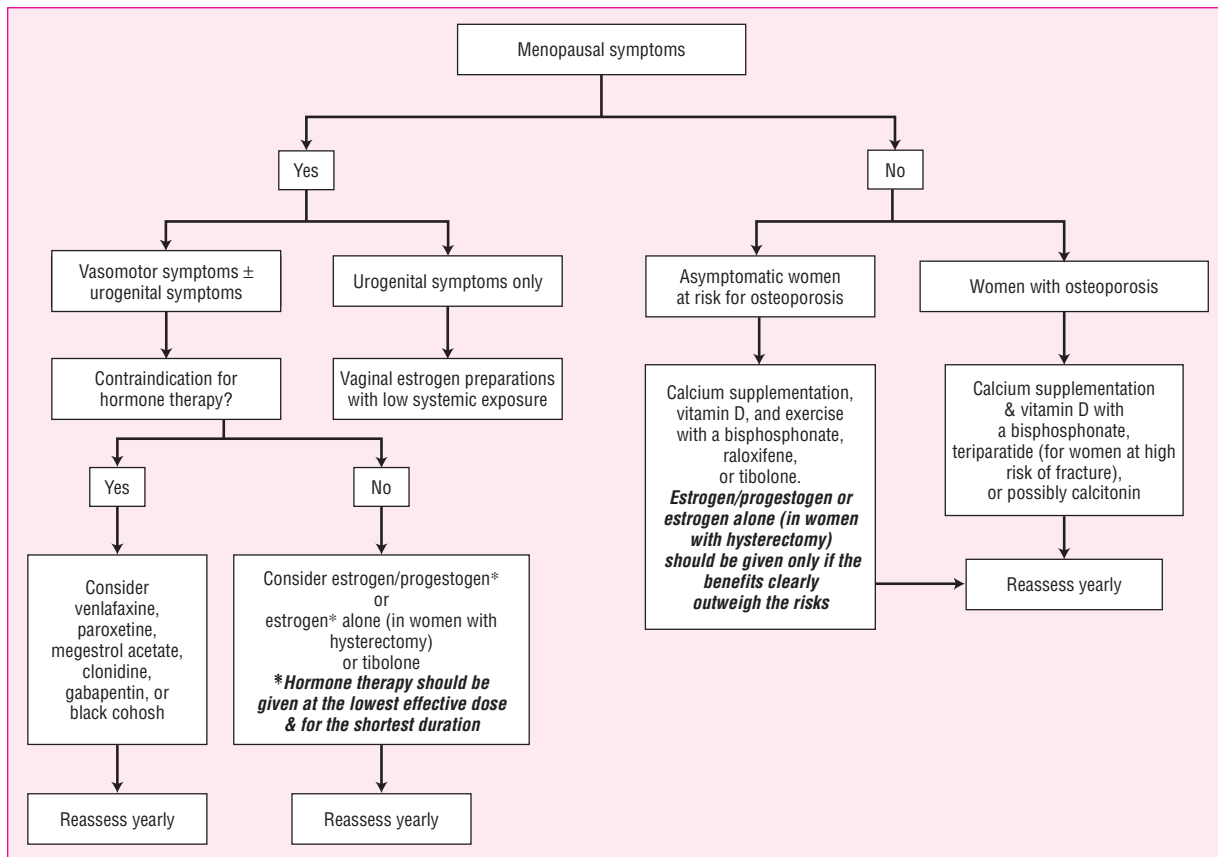

FIGURE 80-1. Treatment algorithm for postmenopausal women. Tibolone is currently not yet approved for use in the United States.

that frequently progresses to dementia.¹⁰⁹ The estrogen-alone arm of the WHI study showed similar findings.^{110a,110b}

Raloxifene does not have a significant effect on cognitive function; however, there is a trend toward a smaller decline in verbal memory and attention scores among women receiving raloxifene.¹¹³

Hormone therapy improves mood and well-being mainly in postmenopausal women with vasomotor symptoms and sleep disturbance, whereas it does not improve quality of life in postmenopausal women without vasomotor symptoms. Hormone therapy does not improve cognitive function when compared with placebo, and more important, a small increased risk of clinically meaningful cognitive decline occurs among women aged 65 years or older taking hormone therapy.^{110,110a,110b}

INDIVIDUALIZING HORMONE THERAPY

8 Menopause is a natural life event, not a disease. The decision to take hormone therapy must be individualized and based on several parameters, including menopausal symptoms, osteoporosis risk, coronary artery disease risk, breast cancer risk, and thromboem-

bolism risk. Recommendations should be specific to each woman and her background. Thus the menopausal treatment should be based on each woman's clinical profile and concerns. Approved indications of hormone therapy include treatment of vasomotor symptoms and urogenital atrophy and prevention of osteoporosis. Weighing risks and benefits, the FDA determined that the indication for vasomotor symptoms (hot flashes and night sweats) should remain unchanged, but the other two indications for hormone therapy should be revised. For the treatment of vasomotor symptoms, systemic hormone therapy remains the most effective pharmacologic intervention (Fig. 80–1). For symptoms of urogenital atrophy, such as vaginal dryness, topical products should be considered. In addition, although prevention of postmenopausal osteoporosis remains an indicated use of hormone therapy, consideration should be given to approved nonestrogen products, such as raloxifene and bisphosphonates (see Fig. 80–1). Clinicians should prescribe the lowest effective dose of hormone therapy for the shortest duration, weighing the potential benefits and risks for the individual woman. Furthermore, measures to reduce the risks of cardiovascular disease (such as treating hypertension and avoid smoking) and osteoporosis (such as taking calcium supplements and vitamin D, changing diet, and performing weight-bearing exercise) should be addressed.

EVALUATION OF THERAPEUTIC OUTCOMES

After the menopausal woman begins hormone therapy, a brief follow-up visit 6 weeks later may be useful to discuss patient concerns about hormone therapy and to evaluate the patient for symptom relief, adverse effects, and patterns of withdrawal bleeding. The FDA recommends that women who choose estrogen-based therapy should have yearly breast examinations, perform monthly breast self-examinations, and receive periodic mammograms (to be scheduled based on their age and risk factors). Also, women receiving hormone therapy should undergo annual monitoring, including a medical history and physical examination, pelvic examination, blood pressure measurement, and routine endometrial cancer surveillance, as indicated. Additional follow-up should be determined based on the patient's initial response to therapy and the need for any modification of the regimen. Endometrial biopsy should be considered in women taking cyclic hormone therapy if vaginal bleeding occurs at any time other than the expected time of withdrawal bleeding or when heavier or more prolonged withdrawal bleeding occurs. In women taking continuous combined hormone therapy, endometrial evaluation should be considered when irregular bleeding persists for more than 6 months after initiating therapy. Endovaginal ultrasonography also has been used in the evaluation of abnormal uterine bleeding in women receiving hormone therapy. However, there is no universal agreement that endovaginal ultrasonography is adequate to exclude endometrial pathology.

The main indication for hormone therapy is the relief of menopausal symptoms, and hormone therapy should be used only as long as symptom control is necessary (typically for about 2 to 3 years). When used under such conditions, the absolute risk of harm to an individual woman is very small.²

Many women have no difficulty stopping hormone therapy abruptly; others develop vasomotor symptoms after discontinuation. Although these symptoms are usually mild and resolve over a few months, in some women they may be severe and intolerable. Slowly tapering the hormone therapy over several months—reducing the

frequency of administration, the dose, or both—may ameliorate the symptoms.¹¹⁴

Women older than 65 years of age or younger with risk factors for osteoporosis should have their bone mineral density measured. Although bone densitometry has been shown to predict fractures, at present there are no guidelines for follow-up bone mineral density testing. However, in women with significant bone loss, repeat testing should be performed as clinically indicated.

PHARMACOECONOMIC CONSIDERATIONS

Estrogens and progestogens used for postmenopausal hormone therapy still are prescribed commonly in the United States, especially for the management of menopausal vasomotor symptoms. Even before publication of the WHI findings, only a fraction of women filled their hormone therapy prescriptions, and only 25% to 40% continued to take postmenopausal hormone therapy for more than 1 year.¹¹⁵ This may be due to women's attitudes toward hormone therapy or a result of fear about adverse effects and associated risks. Hormone therapy use in the United States declined substantially after dissemination of the WHI study results.^{115a}

Use of hormone therapy for the management of vasomotor symptoms is cost-effective, and data to support the use of nonhormonal alternatives are limited. The cost of hormone therapy can vary depending on the route and method of delivery. Transdermal preparations are about twice as expensive as their equivalent oral preparations.¹¹⁶ Women who have undergone hysterectomy use hormone therapy more frequently than do women with an intact uterus (58.7% versus 19.6%).⁵

Raloxifene adversely affects hot flashes, but it is likely to be used for osteoporosis prevention. For women with a history of breast cancer or thromboembolic disease, alternative means of reducing the risk of osteoporosis, such as bisphosphonates, should be considered.

The results of randomized trials suggest that hormone therapy should not be used for cardiovascular disease prevention. Women with

coronary disease risk factors (e.g., hypertension, lipid abnormalities) can benefit from reduction of these risk factors through interventions such as weight loss, lipid lowering, use of aspirin, use of antioxidants, and physical activity.

CONCLUSIONS

During the past decade, postmenopausal hormone therapy became one of the most frequently prescribed therapies in the United States. Menopause is a natural life event, not a disease. Therefore, the decision to use hormone therapy must be individualized based on the severity of menopausal symptoms, risk of osteoporosis, and consideration of such factors as coronary artery disease, breast cancer, and thromboembolism.

Recent large prospective, randomized trials have shown that postmenopausal hormone therapy prescribed for disease prevention may cause more harm than good.^{2,77} The WHI study reported increased risk of cardiovascular disease, breast cancer, stroke, and thromboembolic disease among women using continuous-combined therapy with CEE plus medroxyprogesterone acetate compared with placebo.² In the estrogen-alone arm of the study, CEE had no effect on cardiovascular disease or breast cancer risk compared to placebo, but an increased risk of stroke and thromboembolic disease was noted in those who received estrogen.³ The WHI study also demonstrated that quality of life¹⁰⁸ and cognition^{109,110,110a,110b} are no better in the group receiving hormone therapy than in the placebo group.

Postmenopausal symptoms, such as hot flashes and vaginal dryness, remain a valid indication for hormone therapy in the absence of contraindications. For short-term use of hormone therapy for the relief of menopausal symptoms, the benefits for many women generally outweigh the risks. For symptoms of genital atrophy alone, local estrogen and/or nonhormonal lubricants should be considered.

Long-term use of hormone therapy cannot be recommended routinely for osteoporosis prevention given the availability of alternative therapies, such as raloxifene and the bisphosphonates. For long-term hormone therapy use, the potential harm (cardiovascular disease, breast cancer, and thromboembolism) outweighs the potential benefits.

PREMATURE OVARIAN FAILURE AND PREMENOPAUSAL HORMONE REPLACEMENT

PATHOPHYSIOLOGY

Premature ovarian failure is a condition characterized by sex-steroid deficiency, amenorrhea, and infertility in women younger than 40 years of age. At one time, premature ovarian failure was considered irreversible and was described as “premature menopause.” Premature ovarian failure is not an early natural menopause. Normal menopause results from ovarian follicle depletion, whereas premature ovarian failure is characterized by intermittent ovarian function in one-half of affected women.¹¹⁷ These women produce estrogen intermittently and may ovulate despite the presence of high gonadotropin concentrations. Pregnancies have occurred in 5% to 10% of women after the diagnosis of premature ovarian failure—even in women with no follicles observed on ovarian biopsy.

Premature ovarian failure may occur on the basis of ovarian follicle dysfunction or ovarian follicle depletion and may present as either primary amenorrhea (absence of menses in a girl who has reached the age of 16) or secondary amenorrhea (cessation of menses in a woman previously menstruating for 6 months or more).

TABLE 80–10. Etiology of Premature Ovarian Failure

Idiopathic: karyotypically normal spontaneous premature ovarian failure

Autoimmunity: (a) isolated autoimmune premature ovarian failure or (b) as a component of an autoimmune polyglandular syndrome in association with Addison’s disease, hypothyroidism, hypoparathyroidism, or mucocutaneous candidiasis

Iatrogenic: (chemotherapy, radiation, extensive ovarian surgery)

X-chromosome abnormalities

Gonadotropin and gonadotropin-receptor abnormalities: signal defects
Enzyme deficiencies: cholesterol desmolase, 17 α -hydroxylase, 17, 20-desmolase

Galactosemia

Blepharophimosis, ptosis, and epicanthus inversus syndrome type 1: rare autosomal dominant syndrome in which premature ovarian failure is the predominant syndrome

Perrault’s syndrome: familial autosomal recessive premature ovarian failure in association with deafness

In most cases, the etiology cannot be identified (Table 80–10). In the majority of patients, ovarian failure develops after the establishment of regular menses. Young women with premature ovarian failure who develop ovarian dysfunction before they achieve peak adult bone mass sustain sex steroid deficiency for more years than do naturally menopausal women. This deficiency can result in a significantly higher risk for osteoporosis¹¹⁸ and cardiovascular disease.^{119,119a} Importantly, a survey of more than 19,000 women between the ages of 25 and 100 years suggests that ovarian failure occurring before 40 years of age is associated with significantly increased mortality, with the age-adjusted odds ratio for all-cause mortality being 2.14 (95% CI 1.15–3.99).¹²⁰

CLINICAL PRESENTATION OF PREMATURE OVARIAN FAILURE

SYMPTOMS

- **Primary amenorrhea:** No symptoms of estrogen deficiency
- **Secondary amenorrhea:** Vasomotor symptoms (hot flashes and night sweats), sleep disturbances, mood changes, sexual dysfunction, problems with concentration and memory, vaginal dryness, and dyspareunia

SIGNS

- **Primary amenorrhea:** Incomplete development of secondary sex characteristics
- **Secondary amenorrhea:** Normal development of secondary sex characteristics, signs of urogenital atrophy

LABORATORY TESTS

- FSH greater than 40 IU/L
- Other relevant diagnostic tests
- Thyroid function tests and fasting glucose

CLINICAL PRESENTATION

There is no characteristic menstrual pattern or history that precedes premature ovarian failure. Approximately 50% of patients with this condition have a history of oligomenorrhea or dysfunctional uterine

bleeding (prodromal premature ovarian failure), and about 25% develop amenorrhea acutely. Some patients develop amenorrhea postpartum, whereas others experience it after discontinuing oral contraceptives. Primary amenorrhea is not associated with symptoms of estrogen deficiency. In cases of secondary amenorrhea, symptoms may include hot flashes, night sweats, fatigue, and mood changes. Prodromal premature ovarian failure may present with hot flashes even in women who menstruate regularly. Incomplete development of secondary sex characteristics may occur in women with primary amenorrhea, whereas these characteristics are typically normal in women with secondary amenorrhea. In general, women with premature ovarian failure have normal fertility before the disorder develops.

Approximately 50% of women with premature ovarian failure have been found to have documented ovarian follicle function.¹¹⁷

Premature ovarian failure is defined by the presence of at least 4 months of amenorrhea and at least two serum FSH concentrations measuring greater than 40 IU/L (obtained at least 1 month apart) in women younger than 40 years of age. A complete history should be taken regarding other factors that can affect ovarian function such as prior ovarian surgery, chemotherapy, radiation, and autoimmune disorders. In patients with primary amenorrhea, particular attention should be paid to breast and pubic hair development according to

Tanner stages. Short stature, stigmata of Turner's syndrome, and other dysmorphic features of gonadal dysgenesis should be considered. Ideally, a pelvic examination should be performed, but this is not always clinically appropriate. Alternatively, transabdominal ultrasonography can be performed in primary amenorrhea to confirm the presence of normal anatomic structures. In the majority of cases, physical examination is completely normal. A karyotype should be performed in all patients experiencing premature ovarian failure. Women with ovarian failure and a karyotype containing a Y chromosome should undergo bilateral gonadectomy because there is a substantial risk for gonadal germ cell neoplasia.¹²¹ Ovarian biopsy and antiovarian antibody testing are investigational procedures with no proven clinical benefit in premature ovarian failure. As clinically indicated, the workup should include tests for the diagnosis of other possible associated autoimmune disorders such as hypothyroidism, diabetes mellitus, and Addison's disease.

Young women find the diagnosis of premature ovarian failure particularly traumatic and frequently need extensive emotional and psychological support. While most of these women will, in fact, be infertile, it is important to emphasize that premature ovarian failure can be transient and that spontaneous pregnancies have occurred even years after diagnosis.

► TREATMENT: Premature Ovarian Failure

9 Postmenopausal women who take hormone therapy prolong their exposure to estrogen beyond the average age of completion of their reproductive phase. In contrast, women with premature ovarian failure need exogenous sex steroids to compensate for the decreased production by their ovaries. Importantly, 47% of young women with premature ovarian failure have significantly reduced bone mineral density within 1.5 years of their diagnosis despite taking standard hormone therapy.¹¹⁸

The goal of therapy in young women with premature ovarian failure is to provide a hormone-replacement regimen that maintains sex steroid status as effectively as the normal, functioning ovary. This usually requires the administration of estrogen at a dose greater than the standard dose given to older women experiencing natural menopause.

■ PHARMACOLOGIC THERAPY: HORMONAL REGIMENS

Optimal hormone therapy depends on whether the patient has primary or secondary amenorrhea. Young women with primary amenorrhea in whom secondary sex characteristics have failed to develop should be exposed initially to very low doses of estrogen in an attempt to mimic the gradual pubertal maturation process. A typical regimen is as follows: 0.3 mg CEE unopposed (i.e., no progestogen) daily for 6 months with incremental dose increases at 6-month intervals until the required maintenance dose is achieved. Gradual dose escalation often results in optimal breast development and allows time for the young woman to adjust psychologically to her physical maturation. Cyclic progestogen therapy, given 12 to 14 days per month, should be instituted toward the end of the second year of treatment.

Women with secondary amenorrhea who have been estrogen deficient for 12 months or longer also should be given low-dose estrogen replacement initially to avoid adverse effects such as mastalgia and nausea. However, the dose can be titrated up to maintenance levels over a 6-month period, and progestin therapy can be instituted with the initiation of estrogen therapy. Women with a brief history of sec-

ondary amenorrhea are less likely to experience undesired effects from hormone therapy if they are given a reduced dose for the first month of therapy followed by a full dose from the second month onward.

An estrogen dose equivalent to at least 1.25 mg CEE (or 100 mcg transdermal estradiol) is needed to achieve adequate estrogen replacement in young women. A progestin should be given for 12 to 14 days per calendar month to prevent endometrial hyperplasia (Table 80–11). Estrogens given in usual replacement doses do not suppress spontaneous follicular activity or ovulation. Because women with premature ovarian failure can have spontaneous pregnancies, hormone therapy should produce regular, predictable menstrual flow patterns (i.e., only cyclic regimens should be used). If these patients miss an expected menses, they should be tested for pregnancy and should discontinue hormone therapy. Because most young women negatively associate hormone therapy with menopause in older women, some clinicians prefer to prescribe oral contraceptives for hormone replacement in premenopausal women with hypogonadism. Oral contraceptives, however, may not inhibit ovulation or effectively prevent pregnancy in young women with elevated gonadotropins.

Androgen replacement also should be considered for women with premature ovarian failure experiencing persistent fatigue, poor well-being, and low libido despite adequate estrogen replacement. In these young women, testosterone replacement may be important for the development and maintenance of normal muscle mass and preservation of bone mineral content. An ongoing study at the National Institutes of Health is evaluating the effectiveness of long-term testosterone supplementation, in addition to standard hormone replacement, in protecting women with premature ovarian failure from bone loss. This study employs a transdermal system that delivers the equivalent of the normal daily ovarian testosterone production (150 mcg/day).

Importantly, all women with premature ovarian failure should understand that hormone therapy must be continued at least until the average age of natural menopause and that long-term follow-up is necessary.

TABLE 80–11. Premenopausal Hormone-Replacement Therapy for Young Women with Premature Ovarian Failure

| Regimen | Dose | Frequency | Route |
|--|--------------|---|-------------|
| Estrogen Therapy | | | |
| Conjugated equine estrogen | 1.25 mg | Daily | Oral |
| Piperazine estrone sulphate | 2.5 mg | Daily | Oral |
| Micronized 17β-estradiol | 4.0 mg | Daily | Oral |
| Transdermal estrogen system | 100 mcg/24 h | Once or twice weekly | Transdermal |
| Progestogen Therapy | | | |
| Medroxyprogesterone acetate | 10 mg | 12–14 days ^a | Oral |
| Dydrogesterone ^b | 20 mg | 12–14 days ^a | Oral |
| Norethindrone acetate | 10 mg | 12–14 days ^a | Oral |
| Norethisterone ^b | 1 mg | 12–14 days ^a | Oral |
| Micronized progesterone | 200 mg | 12–14 days ^a | Oral |
| Transdermal norethindrone ^c | 250 mcg/24 h | Twice weekly for 14 days per calendar month | Transdermal |

^aPer calendar month.

^bNot available in the United States in a progestogen-only oral dosage form.

^cAvailable only in combination with estradiol.

EVALUATION OF THERAPEUTIC OUTCOMES

Young women with premature ovarian failure should be monitored annually for their response to treatment, and their compliance with hormone therapy should be assessed regularly. These patients also should be evaluated continuously for the presence of signs and symptoms of associated autoimmune endocrine disorders, such as hypothyroidism, adrenal insufficiency, and diabetes mellitus. Baseline bone mineral density testing should be performed in all women with premature ovarian failure. Mammography should be performed annually after the age of 40 years in accordance with accepted guidelines. Additional mammography screening in premenopausal women younger than age 40 years who are receiving physiologic hormone therapy is not warranted. Other tests should be performed as clinically indicated.

CONCLUSIONS

Approximately 1% of women spontaneously develop ovarian failure before the age of 40 years.⁵ Premature ovarian failure is not an early natural menopause. Most affected women produce estrogen intermittently and may ovulate despite the presence of high gonadotropin concentrations. However, these women sustain sex steroid deficiency for more years than do naturally menopausal women, resulting in a significantly higher risk for osteoporosis¹¹⁸ and cardiovascular disease.¹¹⁹

Women with premature ovarian failure need exogenous sex steroids to compensate for the decreased production by their ovaries. Thus premenopausal hormone therapy is required at least until these women reach the age of “natural menopause.”

The goal of therapy is to provide a hormone-replacement regimen that maintains sex steroid status as effectively as the normal, functioning ovary. This usually requires the administration of estrogen at a dose greater than the standard dose given to older women experiencing natural menopause.

Because women with premature ovarian failure can have spontaneous pregnancies, the hormone therapy should produce regular, predictable menstrual flow patterns. If these patients miss an expected menses, they should be tested for pregnancy and promptly discontinue the hormone treatment.

Annual follow-up should include assessment of hormone therapy compliance and evaluation for signs and symptoms of associated endocrine disorders.¹¹⁷

ERECTILE DYSFUNCTION

Mary Lee

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The incidence of erectile dysfunction is low in men less than 40 years of age. It increases as men age, likely as a result of concurrent medical conditions that impair the vascular, neurologic, psychogenic, and hormonal systems necessary for a normal penile erection.
- 2 Many commonly used drugs have sympatholytic, anticholinergic, sedative, or antiandrogenic effects that may exacerbate or contribute to the development of erectile dysfunction. Clinicians should be familiar with these agents and be prepared to make adjustments in drug regimens to minimize adverse effects of these drugs on a patient's erectile function.
- 3 Specific treatments for erectile dysfunction include medical devices, pharmacologic treatments, psychotherapy, and surgery.
- 4 The ideal treatment for erectile dysfunction should have a fast onset, be effective, be convenient to administer, be cost-effective, have a low incidence of serious adverse effects, and be free of serious drug interactions. Currently, no ideal treatment for erectile dysfunction exists.
- 5 Specific treatment is first initiated with least invasive forms of treatment, including vacuum erection devices and oral phosphodiesterase inhibitors, followed by intracavernosal injections or intraurethral inserts, and finally by surgical insertion of a penile prosthesis.
- 6 Vacuum erection devices have a slow onset of action (30 minutes) and therefore are most effective in elderly couples in a stable relationship.
- 7 Although phosphodiesterase inhibitors are convenient and effective regardless of the etiology of erectile dysfunction, they fail in 30% to 40% of patients. Also, phosphodiesterase inhibitors are contraindicated in patients taking any form of nitrate, including topical nitrates.
- 8 Testosterone supplementation can improve erectile function in patients who have decreased libido secondary to primary or secondary hypogonadism. Testosterone supplementation should not be used in patients with erectile dysfunction who have normal serum testosterone levels.
- 9 Although intracavernosal alprostadil injections are effective independent of the etiology for erectile dysfunction, these fail in one-third of patients. Also, they should be used cautiously in patients at risk of priapism, which includes those with sickle cell disease or lymphoproliferative disorders.

The National Institutes of Health Consensus Development Panel on Impotence defines erectile dysfunction as the failure to achieve a penile erection suitable for sexual intercourse.¹ Patients may refer to it as impotence.

Erectile dysfunction must be distinguished from disorders of libido, ejaculatory disorders, or infertility, which are caused by different pathophysiologic mechanisms and are treated with alternative agents (Table 81-1). A patient may suffer from one or more disorders of sexual dysfunction. For example, an elderly man with primary hypogonadism may suffer from decreased libido and erectile dysfunction. Diagnosis of the type of sexual disorder that a patient has is a key to initiating the most appropriate treatment.

EPIDEMIOLOGY

- 1 The incidence of erectile dysfunction is low in men younger than 40 years of age, but it increases as men age.²⁻⁴ The Massachusetts Male Aging Study, a cross-sectional survey of a random sample of 1290 men in the Boston area, was conducted during the period from 1987 to 1989. It reported an overall prevalence of 52% for any degree of erectile dysfunction in men aged 40 to 70 years, with a 40% prevalence in men aged 40 years, and a 67% prevalence in men aged 70 years.^{1,2} In the most recent Health Professional Follow-Up Study of more than 31,000 male health professionals aged 53 to 90 years, the prevalence of erectile dysfunction was 33%.³

TABLE 81-1. Types of Sexual Dysfunction in Men

| Type of Dysfunction | Definition |
|----------------------------------|---|
| Decreased libido | Decreased sexual drive or desire |
| Increased libido | Precocious puberty. Inappropriate and excessive sexual drive or desire |
| Erectile dysfunction (impotence) | Failure to achieve a penile erection suitable for sexual intercourse |
| Delayed ejaculation | Commonly referred to as “dry sex”; ejaculation is delayed or absent |
| Retrograde ejaculation | Ejaculate passes retrograde into the bladder, instead of toward the anterior urethra (antegrade) and out of the penis |
| Infertility | Sperm are insufficient in number or have inadequate motility and fail to fertilize the ovum |

Although erectile dysfunction is sometimes assumed to be a symptom of the aging process in men, it is unclear if the incidence is directly related to increasing patient age. Erectile dysfunction more likely results from concurrent medical conditions of the patient (e.g., hypertension, arteriosclerosis, hyperlipidemia, diabetes mellitus, or psychiatric disorders) or from medications that patients may be taking for these diseases.²⁻⁵ For example, up to 50% of patients with diabetes mellitus develop erectile dysfunction, and medications such as β -blockers are associated with a high incidence of erectile dysfunction.

PHYSIOLOGY OF A NORMAL PENILE ERECTION

A normal penile erection requires the full functioning of several physiologic systems: vascular, nervous, and hormonal. The patient must also be psychologically receptive to sexual stimuli.

VASCULAR SYSTEM

The penis comprises two corpora cavernosa on the dorsal side and one corpus spongiosum on the ventral side. The corpus spongiosum surrounds the urethra and forms the glans penis. The corpora are composed of multiple interconnected sinuses, which can fill with blood to produce an erection. The corpora are encased by the tunica albuginea, a fibrous tissue membrane, which has limited distensibility. In the flaccid state, arterial flow into and venous outflow from the corpora are balanced. During the erectile phase, arterial blood flow increases and blood fills the sinusoids within the corpora, which causes penile swelling and elongation. The erection is prolonged by a decrease in venous outflow from the corpora, which is caused by compression of subtunical venules by the swollen corpora (Fig. 81-1).

Arterial flow into the corpora is enhanced by acetylcholine-mediated vasodilation. Acetylcholine does not directly enhance arterial flow to the corpora or increase sinusoidal filling of the corporal tissue. Rather, acetylcholine is a co-neurotransmitter, which works along with other nonpeptidinerigic intracellular neurotransmitters—including cyclic guanosine monophosphate (cGMP), cyclic adenosine monophosphate (cAMP), or vasoactive intestinal polypeptide—to produce vasodilation.

Acetylcholine probably works through two different pathways to produce an erection. In the presence of sexual stimulation to genital tissue, acetylcholine through one pathway enhances the production

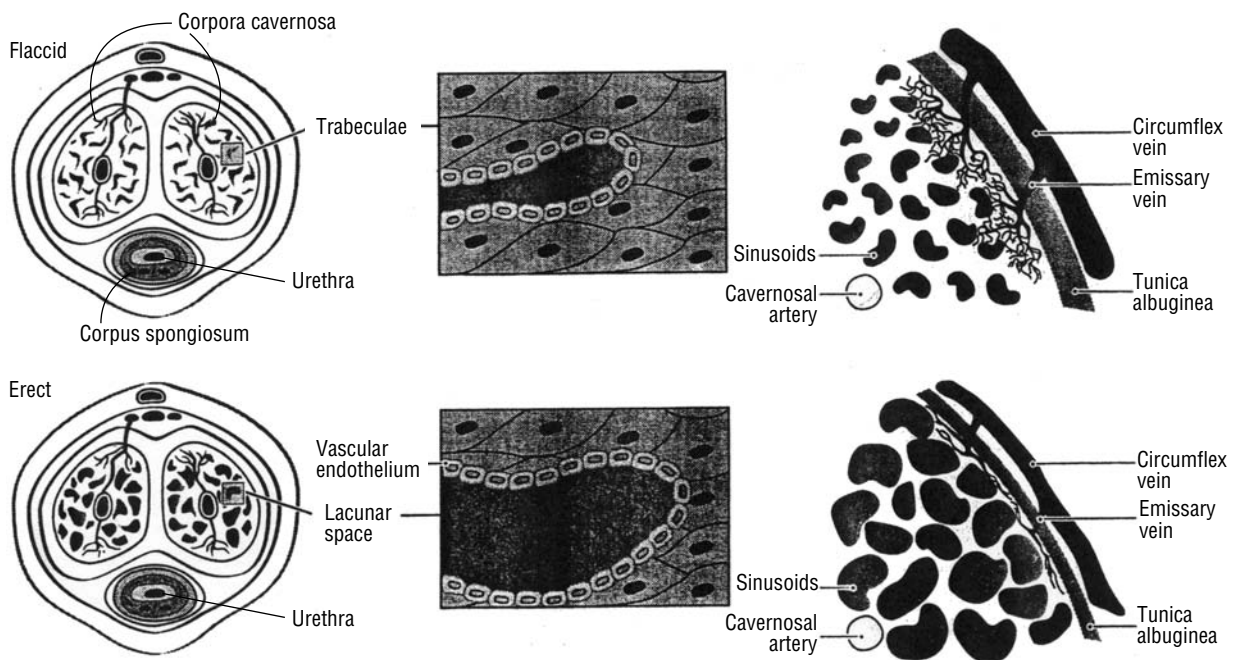

FIGURE 81-1. Microanatomy of and vascular changes in the penis in flaccid and erect states. In the flaccid state, arterial flow into and venous outflow from the corpora are balanced. During the erectile phase, arterial blood flow increases and blood fills the sinusoids within the corpora, which causes penile swelling and elongation. The erection is prolonged by a decrease in venous outflow from the corpora, which is caused by compression of subtunical venules by the swollen corpora. (Adapted from Korenman.²²)

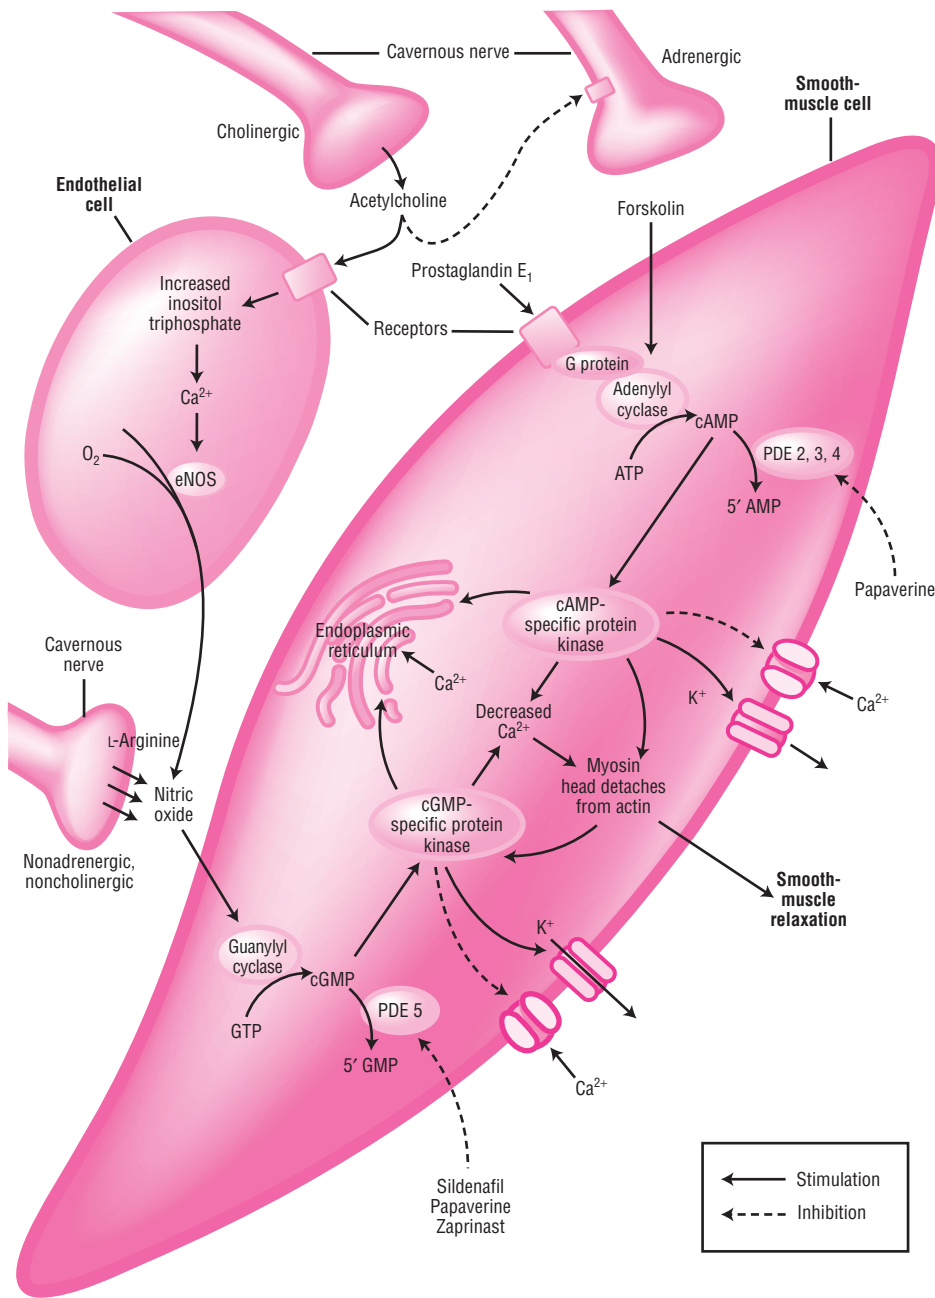

FIGURE 81–2. Molecular mechanism of penile smooth muscle relaxation. cAMP and cGMP, the intracellular second messengers mediating smooth-muscle relaxation, activate their specific protein kinases, which phosphorylate certain proteins to cause opening of potassium channels, closing of calcium channels, and sequestration of intracellular calcium by the endoplasmic reticulum. The resultant fall in intracellular calcium leads to smooth muscle relaxation. Sildenafil inhibits the action of phosphodiesterase (PDE) type 5, thus increasing the intracellular concentration of cGMP. Papaverine is a nonspecific inhibitor. GTP, guanosine triphosphate; eNOS, endothelial nitric oxide synthetase. (Adapted with permission from Lue.⁶)

of nitric oxide by endothelial cells and nonadrenergic-noncholinergic neurons. Nitric oxide enhances the activity of guanylate cyclase, which increases the conversion of cyclic guanosine triphosphate to cGMP. cGMP decreases intracellular calcium concentrations in smooth-muscle cells of penile arteries and cavernosal sinuses. As a result, smooth-muscle relaxation occurs, which enhances arterial blood flow to and blood filling of the corpora.⁵ An erection results (Fig. 81–2).

In an alternative pathway, acetylcholine stimulates a smooth-muscle cell-membrane receptor to enhance the activity of adenylyl cyclase. Adenylyl cyclase increases the conversion of cyclic adenosine triphosphate to cAMP, a potent muscle relaxant. Similarly to cGMP, cAMP decreases intracellular calcium concentrations to produce smooth-muscle relaxation in cells of the arteries and cavernosal sinuses. Arterial blood flow to and blood filling of the corpora are enhanced, and a penile erection results (see Fig. 81–2).⁶

NERVOUS SYSTEM AND PSYCHOGENIC STIMULI

Some erections are mediated by a sacral nerve reflex arc (e.g., erections can occur while the patient is sleeping). However, in the conscious patient, sensory sexual stimulation mediates erections via the central nervous system. That is, when a patient sees an attractive partner, hears sweet words, smells a particular scent, or tastes or touches a pleasant object, this can result in an erection. In this case, the patient’s brain processes this information and the nervous impulse is carried down the spinal cord to peripheral cholinergic nerves that innervate the vascular supply to the corpora, resulting in an erection.

The medial preoptic area of the hypothalamus is thought to be that portion of the brain responsible for integrating external stimuli. Here dopamine exerts a proerectogenic effect, whereas, α_2 -adrenergic stimulation causes the penis to become and/or remain flaccid. After moving down the spinal cord, nerve impulses travel to the penis by efferent peripheral nerves, including inhibitory sympathetic

TABLE 81–2. Medication Classes That Can Cause Erectile Dysfunction⁷

| Drug Class | Proposed Mechanism by Which Drug Causes Erectile Dysfunction | Special Notes |
|---|--|--|
| Anticholinergic agents: antihistamines, antiparkinsonian agents, tricyclic antidepressants, phenothiazines | Anticholinergic activity | <ul style="list-style-type: none"> • Second-generation nonsedating antihistamines (e.g., loratadine) are not associated with erectile dysfunction. • Selective serotonin reuptake inhibitor antidepressants can be substituted for tricyclic antidepressants if erectile dysfunction is a problem. • Phenothiazines with less anticholinergic effect (e.g., chlorpromazine) can be substituted in some patients if erectile dysfunction is a problem. |
| Dopamine agonists (e.g., metoclopramide, phenothiazines) | Inhibit prolactin inhibitory factor, thereby increasing prolactin levels | Increased prolactin levels are associated with blocking testosterone production from the testes. Depressed libido results. |
| Estrogens, antiandrogens (e.g., luteinizing hormone–releasing hormone superagonists, digoxin, spironolactone, ketoconazole, cimetidine) | Suppress testosterone-mediated stimulation of libido | In the face of a decreased libido, a secondary erectile dysfunction develops. |
| Central nervous system depressants (e.g., barbiturates, narcotics, benzodiazepines, short-term use of large doses of alcohol) | Suppress perception of psychogenic stimuli | |
| Agents that decrease penile blood flow (e.g., diuretics, peripheral β -adrenergic antagonists, or central sympatholytics (methyldopa, clonidine, guanethidine)) | Reduce arteriolar flow to corpora | <ul style="list-style-type: none"> • Any diuretic that produces a significant decrease in intravascular volume can decrease penile arteriolar flow. • Safer antihypertensives include angiotensin-converting enzyme inhibitors, postsynaptic α_1-adrenergic antagonists (terazosin, doxazosin), calcium-channel blockers, and angiotensin II receptor antagonists. |

neurons (T₁₁ through L₂), proerectogenic parasympathetic neurons (S₂ through S₄), and proerectogenic somatic neurons (S₂ through S₄).

In summary, acetylcholine produces an erection by working along with other co-neurotransmitters, including cGMP and cAMP, as described earlier. Thus an erection is initiated by the action of nerves, maintained by arterial blood filling of the corpora, and sustained by occlusion of venous outflow from the corpora.

Detumescence, or the progression of an erect penis to a flaccid state, results from the actions of norepinephrine, which contracts vascular smooth muscle to decrease arterial inflow to the corpora and contracts sinusoidal tissue in the corpora. As a result, venous outflow from the corpora increases.

HORMONAL SYSTEM

Testosterone stimulates libido or sexual drive in males. Within the normal physiologic serum concentration range (normal, 300 to 1100 ng/dL), sexual drive is normal. Approximately one-third of men older than 50 years of age have hypogonadism, which is characterized by subphysiologic serum testosterone levels. Such patients complain of loss of energy, loss of muscle strength, depressive mood, and decreased libido.

When libido is decreased, a patient may not develop erections. The relationship between erectile dysfunction and serum testosterone levels is a complicated one. Patients with normal serum testosterone levels may have erectile dysfunction, and patients with subnormal serum testosterone levels may have normal sexual function.⁷

PATHOPHYSIOLOGY

Erectile dysfunction can result from any single abnormality or combination of abnormalities of the four systems necessary for a normal penile erection. Vascular, neurologic, or hormonal etiologies of erectile dysfunction are collectively referred to as *organic erectile dysfunction*. About 80% of patients with erectile dysfunction have the organic type. Patients who fail to respond to psychogenic stimuli have *psychogenic erectile dysfunction*.

Diseases that compromise vascular flow to the corpora cavernosum (e.g., peripheral vascular disease, arteriosclerosis, and essential hypertension) are associated with an increased incidence of erectile dysfunction. Diseases that impair nerve conduction to the brain (e.g., spinal cord injury or stroke) or conditions that impair peripheral nerve conduction to the penile vasculature (e.g., diabetes mellitus) can result in erectile dysfunction.

Diseases associated with hypogonadism, primary or secondary, result in subphysiologic levels of testosterone, which cause diminished sexual drive (decreased libido) and secondary erectile dysfunction. Primary hypogonadism can be associated with the normal aging process in men or surgical removal of the testes for the treatment of prostate or testicular cancer. Secondary hypogonadism may result from hypothalamic or pituitary disorders of luteinizing hormone–releasing hormone or luteinizing hormone, respectively; or elevated prolactin levels, which can result from pituitary tumors or can occur in patients with chronic renal failure.

| Questions | Response options |
|--|---|
| 1. How often were you able to get an erection during sexual activity? 2. When you had erections with sexual stimulation, how often were your erections hard enough for penetration? | 0 = No sexual activity 1 = Almost never/never 2 = A few times (much less than half the time) 3 = Sometimes (about half the time) 4 = Most times (much more than half the time) 5 = Almost always/always |
| 3. When you attempted sexual intercourse, how often were you able to penetrate (enter) your partner? 4. During sexual intercourse, how often were you able to maintain your erection after you had penetrated (entered) your partner? | 0 = Did not attempt intercourse 1 = Almost never/never 2 = A few times (much less than half the time) 3 = Sometimes (about half the time) 4 = Most times (much more than half the time) 5 = Almost always/always |
| 5. During sexual intercourse, how difficult was it to maintain your erection to completion of intercourse? | 0 = Did not attempt intercourse 1 = Extremely difficult 2 = Very difficult 3 = Difficult 4 = Slightly difficult 5 = Not difficult |
| 6. How many times have you attempted sexual intercourse? | 0 = No attempts 1 = One to two attempts 2 = Three to four attempts 3 = Five to six attempts 4 = Seven to ten attempts 5 = Eleven plus attempts |
| 7. When you attempted sexual intercourse, how often was it satisfactory for you? | 0 = Did not attempt intercourse 1 = Almost never/never 2 = A few times (much less than half the time) 3 = Sometimes (about half the time) 4 = Most times (much more than half the time) 5 = Almost always/always |
| 8. How much have you enjoyed sexual intercourse? | 0 = No intercourse 1 = No enjoyment 2 = Not very enjoyable 3 = Fairly enjoyable 4 = Highly enjoyable 5 = Very highly enjoyable |
| 9. When you had sexual stimulation or intercourse, how often did you ejaculate? 10. When you had sexual stimulation or intercourse, how often did you have the feeling of orgasm or climax? | 0 = No sexual stimulation/intercourse 1 = Almost never/never 2 = A few times (much less than half the time) 3 = Sometimes (about half the time) 4 = Most times (much more than half the time) 5 = Almost always/always |
| 11. How often have you felt sexual desire? | 1 = Almost never/ never 2 = A few times (much less than half the time) 3 = Sometimes (about half the time) 4 = Most times (much more than half the time) 5 = Almost always/always |
| 12. How would you rate your level of sexual desire? | 1 = Very low/none at all 2 = Low 3 = Moderate 4 = High 5 = Very high |
| 13. How satisfied have you been with your overall sex life? 14. How satisfied have you been with your sexual relationship with your partner? | 1 = Very dissatisfied 2 = Moderately dissatisfied 3 = About equally satisfied and dissatisfied 4 = Moderately satisfied 5 = Very satisfied |
| 15. How do you rate your confidence that you can get and keep an erection? | 1 = Very low 2 = Low 3 = Moderate 4 = High 5 = Very high |

FIGURE 81-3. International Index of Erectile Function Questionnaire. All questions are preceded by the phrase, "Over the past 4 weeks." (Reprinted with permission from Kirby R, Carson C, Goldstein I. *Erectile Dysfunction, A Clinical Guide*. Oxford, England, ISIS Medical Media, 1999:30-31.)

Finally, patients must be in the proper mental frame of mind to be receptive to sexual stimuli. Patients who suffer from malaise, have reactive depression or performance anxiety, are sedated, have Alzheimer's disease, have hypothyroidism, or have mental disorders, commonly complain of erectile dysfunction. In most studies, patients with psychogenic erectile dysfunction generally exhibit a higher response rate to various interventions than do patients with organic erectile dysfunction, as their disease is often less severe.

Social habits of patients have also been linked to erectile dysfunction. The vasoconstrictor effect of cigarette smoking may compromise blood flow to the corpora and decrease cavernosal filling. Excessive ethanol intake may lead to androgen deficiency, peripheral neuropathy, or chronic liver disease, all of which can contribute to erectile dysfunction.

2 Medications may cause erectile dysfunction through similar pathophysiologic mechanisms (Table 81–2).^{8–13} Medications are estimated to be responsible for approximately 10% to 25% of cases of erectile dysfunction. An excellent review of medication-induced erectile dysfunction is available.⁸

CLINICAL PRESENTATION: ERECTILE DYSFUNCTION

Affects men emotionally in many different ways (e.g., depression, performance anxiety, or embarrassment).

Marital difficulties and avoidance of sexual intimacy; patients are often brought to a physician by their mates.

Nonadherence to medications patient believes are causing erectile dysfunction may be a problem.

DIAGNOSIS

With the availability in the late 1990s of effective medications for erectile dysfunction independent of the etiology, diagnostic evaluation of erectile dysfunction became streamlined.^{14,15} Key assessments include a description of the severity of the erectile dysfunction, a medical history, a review of concurrent medications, a physical examination, and selected clinical laboratory tests.¹⁶

► TREATMENT: Erectile Dysfunction

■ MANAGEMENT OPTIONS

3 The goal of treatment is an improvement in the quantity and quality of penile erections suitable for intercourse. Simple as this may sound, health care providers need to ensure that patients have reasonable expectations for any therapies that are initiated. Furthermore, only patients with erectile dysfunction should be treated. Patients who have normal sexual function should not seek—or be encouraged to seek—treatment in an effort to enhance sexual function or enable increased activity.

■ GENERAL APPROACH TO TREATMENT

The first step in clinical management of erectile dysfunction is to identify, and if possible to reverse, underlying causes. Risk factors for erectile dysfunction, including hypertension, diabetes mellitus, smoking, or chronic ethanol abuse, should be addressed and mini-

To assess the severity of the erectile dysfunction, the patient should be asked about onset and frequency. A standardized questionnaire, such as the International Index of Erectile Dysfunction, is often used. It includes 15 questions about the quality of erectile function and sexual intercourse (Fig. 81–3).¹⁷ The physician should carefully assess the patient's expectations and motivations for erectile function to ensure that they are reasonable.

A medical history should be obtained to identify concurrent medical illnesses that are risk factors for organic or psychogenic erectile dysfunction. If these underlying diseases are not optimally responding to treatment, this should be addressed before specific treatment for erectile dysfunction is initiated. Also, if the patient smokes cigarettes, drinks excessive amounts of ethanol, or uses recreational drugs, these social habits should be discontinued before specific treatment for erectile dysfunction is started.

A complete listing of the patient's prescription and over-the-counter medications should be reviewed by the clinician, who should identify drugs that may be contributing to erectile dysfunction. If possible, causative agents should be discontinued or the dose should be reduced.

A physical examination of the patient should include a check for hypogonadism (i.e., signs of gynecomastia, small testicles, and decreased body hair). The penis should also be evaluated for diseases associated with penile curvature (e.g., Peyronie's disease), which are also associated with erectile dysfunction. Femoral and lower extremity pulses should be assessed to provide an indication of vascular supply to the genitals. Anal sphincter tone and other genital reflexes should be checked to provide an indication of the integrity of the nerve supply to the penis.

Selected laboratory tests should be obtained to identify the presence of underlying diseases that could cause erectile dysfunction. These include a serum blood glucose, lipid profile, and thyroxine level. Serum testosterone levels should be checked in patients older than 50 years of age and in younger patients who complain of decreased sexual drive. Serum testosterone levels follow a circadian pattern of secretion, with the highest levels occurring during the morning hours. To interpret serum testosterone levels properly, serum samples should be obtained in the mornings. At least two serial serum testosterone levels are needed to confirm the presence of hypogonadism.¹⁸

mized. Patients should have heart-healthy lifestyles, which includes physical fitness, weight loss to achieve a normal body mass index, low-cholesterol diets, and no smoking. In some cases, these types of interventions are sufficient to restore erectile function. However, if erectile dysfunction fails to respond to these measures, specific treatment is indicated.

For patients with psychogenic erectile dysfunction, psychotherapy may be used as monotherapy, or as an adjunct to specific treatments for the disorder. To enhance the relevance of psychotherapy, both the patient and his partner should be included in the counseling sessions. Also, treatment should be individualized and should address those immediate factors that may be causing performance anxiety or depression, rather than the remote, deep-seated reasons for psychological disorders.¹⁹ The effectiveness of psychotherapy is generally low, and long-term psychotherapy is often necessary.

4 5 Specific treatments for erectile dysfunction include medical devices, pharmacologic treatments, and surgery. The ideal treatment for this disorder should have a fast onset, be effective, be convenient to administer, be cost-effective, have a low incidence of serious adverse effects, and be free of serious drug interactions.

TABLE 81–3. Dosing Regimens for Selected Drug Treatments for Erectile Dysfunction

| Route of Administration | Generic Name (Brand Name) | Dosage Form | Common Dosing Regimen |
|------------------------------------|---|---|---|
| Oral | Yohimbine (Aphrodyne, Yocon, Yohimex) | 5.4-mg tablet or capsule | 5.4 mg three times a day |
| | Sildenafil (Viagra) | 25-mg, 50-mg, 100-mg tablets | 25–100 mg 1 hour before intercourse |
| | Apomorphine (Uprima) ^a | Sublingual tablets | |
| | Methyltestosterone (Oreton, Android) | 10-mg, 25-mg tablets and capsules | 10–40 mg daily |
| | Fluoxymesterone (Halotestin) | 2-mg, 5-mg, 10-mg tablets | 5–20 mg daily |
| | Trazodone (Desyrel) ^b | 50-mg, 100-mg, 150-mg, 300-mg tablet | 50–150 mg daily |
| | Phentolamine (Spontane, Vasomax) ^a | Oral or buccal tablets | |
| | Vardenafil (Levitra) | 2.5-mg, 5-mg, 10-mg, 20-mg tablets | 5–10 mg 1 hour before intercourse |
| | Tadalafil (Cialis) | 5-mg, 10-mg, 20-mg tablets | 5–20 mg prior to intercourse |
| | Topical | Testosterone patch (Testoderm) | 4 mg/patch, 6 mg/patch |
| Testosterone patch (Testoderm TTS) | | 4 mg/patch, 6 mg/patch | 4–6 mg/day; apply to arm, buttock, back |
| Testosterone patch (Androderm) | | 2.5 mg/patch | 2.5–5 mg/day; apply to arm, back, abdomen, thigh |
| Testosterone gel (AndroGel 1%) | | 5 g/pkt, 10 g/pkt | 5–10 g/day; apply to shoulders, upper arms, abdomen |
| Intramuscular | Testosterone cypionate (Depo-Testosterone) | 100 mg/mL, 200 mg/mL | 200–400 mg every 2 to 4 weeks |
| | Testosterone enanthate (Delatestryl) | 100 mg/mL, 200 mg/mL | 200–400 mg every 2 to 4 weeks |
| | Testosterone propionate | 100 mg/mL | 25–50 mg two to three times a week |
| Intraurethral | Alprostadil (MUSE) | 125-mcg, 250-mcg, 500-mcg, 1000-mcg pellets | 125–1000 mcg 5 to 10 minutes before intercourse |
| Intracavernosal | Alprostadil (Caverject) | 5 mcg, 10 mcg, 20 mcg injection | 2.5–60 mcg 5 to 10 minutes before intercourse |
| | Alprostadil (Edex) | 5 mcg, 20 mcg, 20 mcg, 40 mcg injection | 2.5–60 mcg 5 to 10 minutes before intercourse |
| | Papaverine ^b | 30 mg/mL injection | Variable, usually used in combination |
| | Phentolamine ^b | 2.5 mg/mL injection | Variable, usually used in combination |

^aNot yet commercially available in the United States at the time this chapter was written.

^bNot FDA-approved for this use.

Currently no treatment for erectile dysfunction is ideal (Table 81–3). Generally, when choosing among treatment approaches, those that are least invasive are chosen first, while more invasive therapies are reserved for patients who fail to respond to first-line agents. A sample algorithm that guides selection of treatment is shown in Fig. 81–4.

VACUUM ERECTION DEVICES

A vacuum erection device (VED) has three parts: a pump to generate a negative vacuum pressure; a cylinder, which is closed at one end and into which the penis is inserted; and tubing to connect the pump to the cylinder. The patient inserts his penis into the cylinder, which is then pushed up flush against his lower abdomen to create a vacuum chamber. Then the patient activates the pump to produce vacuum pressure, which draws arteriolar blood into the corpora cavernosa. To prolong the erection, the patient may also use constriction bands or tension rings, which are placed at the base of the penis, to keep the arteriolar blood in and to reduce venous outflow from the penis. With the assistance of loading cones to protect the glans, these bands or rings can be rolled over the glans penis and up the shaft. Alternatively, they can be first threaded onto the plastic cylinder before the penis is inserted. Once the penis is erect, the band or ring can be rolled off the cylinder onto the base of the penis (Fig. 81–5).

The VED's onset of action is comparatively slow (30 minutes), which requires patience from both the patient and his sexual partner. For this reason, VEDs appear to work best in older patients who are married or have stable sexual relationships. In this group, VEDs are considered first-line therapy, and the overall satisfaction rate is 60% to 80%.^{20–22} However, 6% to 11% of patients' partners complain that the penis is cool to the touch or is discolored (bluish) in appearance.

VEDs may also be used as second-line therapy in patients who fail oral or injectable drug treatments for erectile dysfunction. The combination of VED with intracavernosal²³ or intraurethral²⁴ alprostadil is associated with a higher rate of efficacy than use of the VED alone. As a result, combination therapy may sometimes be attempted before surgery is considered in the patient who fails VED monotherapy.

VEDs are available with manual or battery-operated pumps. The latter offer greater convenience, particularly in patients with arthritis of the hands, who find the pumps to be too difficult and tiring to operate. The American Urological Association recommends the use of commercially available VEDs by prescription only.²⁵

Pain or injury from VEDs most often is caused by the rubber rings or tension bands used to sustain an erection. Because these rings trap blood in the corpora and reduce arteriolar flow into the penis, the penile shaft may feel cold and numb. If the rings or bands are applied for longer than 30 to 60 minutes, the penile shaft may turn bluish and hurt. Patients may complain that a hinge-like erection is produced in

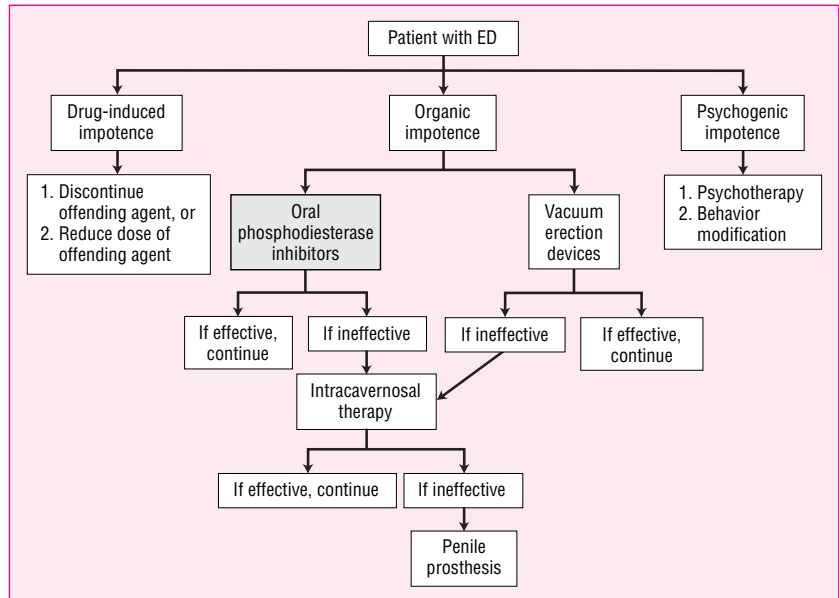

FIGURE 81-4. Algorithm for selecting treatment for erectile dysfunction.

that the penis pivots on the rubber ring or tension band. Patients may also sometimes fail to ejaculate.

VEDs are contraindicated in patients with sickle cell disease. These patients are prone to priapism, which can be exacerbated by the use of rubber rings or tension bands with VEDs. The devices should also be used cautiously in patients on oral anticoagulants. This is also because warfarin, through a poorly understood and idiosyncratic mechanism, can cause priapism.

PHOSPHODIESTERASE INHIBITORS

MECHANISM

In the presence of sexual stimulation, nitric oxide is released by neurons or endothelial cells in penile tissue, thereby enhancing the activity of guanylate cyclase, the enzyme responsible for the conversion of guanylate triphosphate to cGMP (Fig. 81-6).²⁶ cGMP is a vasodilatory neurotransmitter in corporal tissue. Catabolism of cGMP is mediated by phosphodiesterase.

Three highly selective inhibitors of the phosphodiesterase isoenzyme type 5 found in genital tissue have been marketed in the United States (Table 84-4). These decrease catabolism of cGMP. However, phosphodiesterase isoenzyme type-5 is also found in peripheral vascular tissue, tracheal smooth muscle, and platelets. Inhibition of phosphodiesterase in these nongenital tissues can produce adverse effects.

The three marketed phosphodiesterase inhibitors differ in their pharmacokinetic profiles, drug-food interactions, and adverse effects, and precautions are necessary in patients with cardiovascular disease (Table 81-5). Because sildenafil has been marketed longer and is better studied, it is emphasized in this section, with important differences among the three drugs highlighted as appropriate.

EFFICACY

Because of their apparent effectiveness, convenient route of administration, and comparatively low incidence of serious adverse effects, phosphodiesterase inhibitors are considered first-line therapy for erectile dysfunction, particularly in younger patients.

FIGURE 81-5. Technique for using a vacuum erection device with tension band or rubber constriction ring. **A.** The patient inserts his penis into the cylinder, which is then pushed up flush against his lower abdomen to create a vacuum chamber. Then the patient activates the pump to produce a vacuum pressure, which draws arteriolar blood into the corpora cavernosa. **B.** To prolong the erection, the patient may also use constriction bands or tension rings, which are placed at the base of the penis. FIGURE 81–6. Nitric oxide (NO)-cyclic guanosine monophosphate (cGMP) mechanism of penile erection and the NO-enhancing effect of the phosphodiesterase type 5 (PDE5) inhibitor sildenafil. GTP, guanosine triphosphate; NANC, nonadrenergic-noncholinergic neurons. (Adapted with permission from Zusman RM. Cardiovascular data on sildenafil citrate: Introduction. *Am J Cardiol* 1999;83(5A):2C.)

In the presence of sexual stimulation and in doses of 25 to 100 mg, sildenafil produces satisfactory erections in 56% to 82% of patients, independent of the etiology of erectile dysfunction. Similar values are documented in the product labeling for the other two agents in this class (65% to 80% for vardenafil and 62% to 77% for tadalafil). Response rates for sildenafil in the lower range have been documented in patients following radical prostatectomy, probably due to postoperative nerve damage.²⁷ The drugs' effectiveness appears to be dose related.^{28–30}

Approximately 30% to 40% of patients fail to respond to the phosphodiesterase inhibitors. For sildenafil, approximately 55% of

nonresponders can be salvaged with education on proper use of the drugs, and this will likely prove true for the other agents. Education of patients should include these points: (1) patients must engage in sexual stimulation (foreplay) for the best response; (2) sildenafil should be taken on an empty stomach, at least 2 hours before meals, for the fastest response, but the other two agents may be taken without regard to meals; (3) taking sildenafil or vardenafil with a fatty meal can decrease absorption, but tadalafil's absorption is not affected by this; (4) a patient who does not respond to the first dose should continue with the phosphodiesterase inhibitor for at least five to eight doses before failure is declared; and (5) some patients may require dosage

TABLE 81–4. Pharmacodynamics and Pharmacokinetics of Phosphodiesterase Inhibitors

| | Sildenafil ^a | Vardenafil ^a | Tadalafil ^a |
|---|-------------------------|----------------------------|------------------------|
| Trade name | Viagra | Levitra | Cialis |
| Inhibits PDE-5 | Yes | Yes | Yes |
| Inhibits PDE-6 | Yes | Minimally | No |
| Inhibits PDE-11 | No | No | Yes |
| Time to peak plasma level (h) | 0.5–1 | 0.7–0.9 | 2 |
| Fatty meal decreases rate of oral absorption? | Yes | Yes | No |
| Mean plasma half-life (h) | 3.7 | 4.4–4.8 | 18 |
| Percentage of dose excreted in feces | 80 | 91–95 | 61 |
| Percentage of dose excreted in urine | 13 | 2–6 | 36 |
| Duration (h) | 4 | 4 | 24–36 |

| Daily dose in mild hepatic impairment (mg) | 25–100 | 5–20 | 10 |
| Daily dose in moderate hepatic impairment (mg) | 25–100 | 5–10 | 10 |
| Daily dose in severe hepatic impairment (mg) | 25 | Not evaluated | Not recommended |
| Dose in patients taking cytochrome P450 3A4 inhibitors ^a | 25 mg daily | 2.5–5 mg every 24–72 hours | 10 mg every 72 hours |

^aSildenafil doses should be decreased when any potent cytochrome P450 3A4 inhibitor is used (e.g., cimetidine, erythromycin, clarithromycin, ketoconazole, itraconazole, ritonavir, and saquinavir). Vardenafil doses vary according to which agent is used (2.5 mg every 72 hours for ritonavir, 2.5 mg every 24 hours for indinavir, ketoconazole 400 mg daily, and itraconazole 400 mg daily; and 5 mg every 24 hours for ketoconazole 200 mg daily, itraconazole 200 mg daily, and erythromycin). Tadalafil doses are reduced only when it is used with the most potent cytochrome P450 3A4 inhibitors (e.g., ketoconazole or ritonavir).

titration up to 100 mg of sildenafil, 20 mg of vardenafil, or 20 mg of tadalafil for a response.^{31,32}

The phosphodiesterase inhibitors should not be used in patients with normal erectile function. Also, according to FDA-approved labeling, the drugs should not be used in combination with other forms of therapy for erectile dysfunction, as prolonged erections may result.³³

■ PHARMACOKINETICS

Pharmacokinetic parameters of the phosphodiesterase inhibitors are presented in Table 84–4.

Vardenafil and sildenafil are similar in their pharmacokinetic profiles. Both drugs share a similar 1-hour onset of action, short duration of action, and oral absorption that is significantly delayed when the drug is taken within 2 hours of a fatty meal. In contrast, tadalafil has a delayed onset of action of 2 hours, a prolonged duration of action up to 36 hours, and food does not affect its rate of absorption. Thus tadalafil offers greater spontaneity for patients, as one dose can last through an entire weekend.^{34–37}

All three phosphodiesterase inhibitors are hepatically catabolized by the cytochrome P450 3A4 microsomal isoenzyme as well as by other P450 isoenzymes (minor routes) and/or other hepatic enzymes. The drugs and their metabolites (some of which are active) are excreted primarily in the feces, but also in the urine to varying degrees (see Table 84–4).

■ DOSING

The usual oral doses of the phosphodiesterase inhibitors are listed in Table 84–4. The agents vary as to whether doses must be adjusted for elderly patients (over age 65) and compromised hepatic or renal func-

tion. Patients should be advised to take no more than what is prescribed and to use only one dose per day (or less often in the case of some patients taking tadalafil). Doses greater than those recommended have not consistently produced improved erectile responses.²⁶

■ ADVERSE EFFECTS

Most adverse effects of the phosphodiesterase inhibitors are mild or moderate and self-limited, rarely requiring treatment discontinuation. In usual doses the most common adverse effects are headache, facial flushing, dyspepsia, nasal congestion, and dizziness, all of which result from inhibition of phosphodiesterase isoenzyme type 5 in extra-genital tissues.²⁶

Sildenafil produces an 8- to 10-mm decrease in systolic and a 5- to 6-mm decrease in diastolic blood pressure starting about 1 hour after a dose and lasting for 4 hours, and vardenafil has similar vasodilatory actions. Although most patients are asymptomatic as a result of these blood pressure changes, some patients, particularly those taking multiple antihypertensives or nitrates, or those with baseline hypotension, may develop adverse effects as a consequence of these peripheral vascular effects.^{26,38} Tadalafil does not produce decreases in blood pressure, but it too must be used with caution in patients with cardiovascular disease, given the cardiac risk inherent in sexual activity. A management approach for such patients, developed based on an analysis of deaths in men who were using sildenafil, and commonly referred to as the recommendations of the Princeton Consensus Panel, can be applied to all the phosphodiesterase inhibitors (see Table 81–5).^{39–42}

Sildenafil causes increased sensitivity to light, blurred vision, or loss of blue-green color discrimination in 3% to 10% of patients. This results from the agent's inhibition of phosphodiesterase type 6 in the photoreceptor cells in the retina, particularly at doses larger than

100 mg.^{43,44} Although this adverse effect is mild and reversible, caution is recommended in airplane pilots, who rely on green and blue lights for landing planes. Sildenafil is contraindicated in patients at risk of ophthalmologic problems (e.g., retinitis pigmentosa, a genetic disease associated with phosphodiesterase deficiency).³³

Visual adverse effects occur less frequently with vardenafil when compared with sildenafil (less than 0.1% versus 10%, respectively). Tadalafil has minimal to no inhibitory activity against type 6 phosphodiesterase, and no visual adverse effects have been reported.

Unlike the other two marketed phosphodiesterase inhibitors, tadalafil does inhibit type 11 phosphodiesterase, which is found in skeletal muscle. It is believed that this is linked to back and muscle pain, which occurs in a dose-related fashion in 7% to 30% of patients treated with doses of 10 to 100 mg.³⁴

Sildenafil inhibits phosphodiesterase isoenzyme type 5 in platelets, which theoretically could inhibit platelet aggregation. Although sildenafil has not caused bleeding in healthy subjects, it should be used cautiously in patients taking aspirin or other antiplatelet agents and in patients with bleeding tendencies.

Priapism is a rare adverse effect of phosphodiesterase inhibitors, particularly sildenafil and vardenafil, which have shorter plasma half-lives than tadalafil. When priapism has occurred, this has been associated with excessive doses of the phosphodiesterase inhibitor or concomitant therapy involving other erectogenic drugs.

■ DRUG INTERACTIONS

Patients taking organic nitrates may develop severe hypotension if used with phosphodiesterase inhibitors. This is a result of two major factors: (1) organic nitrates on their own produce hypotension and (2) organic nitrates supply extra nitric oxide, which can stimulate the activity of guanylate cyclase and increase tissue levels of cGMP. For this reason, use of any of the three phosphodiesterase inhibitors is contraindicated in patients taking nitrates given by any route at scheduled times or intermittently.^{38,39}

If severe hypotension occurs after exposure to nitrates and a phosphodiesterase inhibitor, the patient should be placed in a Trendelenburg position and aggressive fluid administration should be initiated. If severe hypotension continues, parenteral α -adrenergic agonists (e.g., dopamine, levarterenol, or epinephrine) should be cautiously administered.

Interestingly, dietary sources of nitrates, nitrites, or L-arginine (a precursor for nitrates) do not interact with the phosphodiesterase inhibitors. This is because these dietary sources do not increase circulating levels of nitric oxide in humans.³⁸

Sildenafil does not appear to interact with antihypertensive medications. In one retrospective analysis of patients taking sildenafil in combination with α -adrenergic blocking agents, β -adrenergic blocking agents, diuretics, angiotensin-converting enzyme inhibitors, or calcium channel blockers, the incidence of hypotension was similar to that reported in patients taking sildenafil alone.⁴⁵ This has been confirmed by a retrospective analysis of pooled data on more than 4800 patients in 35 clinical trials.³³

However, largely because of postmarketing data showing small decreases in blood pressure with symptomatic hypotension in patients taking sildenafil and α -adrenergic blocking agents, manufacturers of phosphodiesterase inhibitors include a caution to allow a 4-hour interval between doses of these drugs when concomitantly prescribed in the same patient.

The hepatic metabolism of all three phosphodiesterase inhibitors can be inhibited by cytochrome P450 hepatic microsomal enzyme

inhibitors of CYP 3A4, including cimetidine, erythromycin, clarithromycin, ketoconazole, itraconazole, ritonavir, and saquinavir.^{46,47} In these patients, lower starting doses should be used (see Table 84–4).^{26,42}

CLINICAL CONTROVERSY

Some clinicians believe that tachyphylaxis may develop with continuous use of sildenafil, but others believe that a lack of responsiveness may be due to worsening of underlying diseases that may be contributing to the development of erectile dysfunction.

■ TESTOSTERONE REPLACEMENT REGIMENS

■ MECHANISM

8 Testosterone replacement regimens supply exogenous testosterone and restore serum testosterone levels to the normal range (300 to 1100 ng/dL). In so doing, testosterone replacement regimens correct symptoms of hypogonadism, which include malaise, loss of muscle strength, depressed mood, and decreased libido. Testosterone can directly stimulate androgen receptors in the central nervous system and is thought to be responsible for maintaining normal sexual drive.

■ INDICATIONS

Testosterone replacement regimens are indicated in symptomatic patients with primary or secondary hypogonadism, as confirmed by the presence of a decreased libido and low serum concentrations of testosterone.⁴⁸ Simultaneous serum luteinizing hormone levels help to distinguish patients with primary hypogonadism, who have elevated luteinizing hormone levels, from those with secondary hypogonadism, who have decreased luteinizing hormone levels.

Testosterone replacement regimens should never be administered to men with normal serum testosterone levels.

■ EFFICACY

Testosterone replacement regimens restore muscle strength and sexual drive and improve mood in patients with hypogonadism. Improvements are generally observed within days or weeks of the start of testosterone replacement. Administration of testosterone will correct the serum testosterone level to the normal range. No additional benefit has been demonstrated for large doses of testosterone, which increase the serum testosterone level from the low end to the upper end of the normal range, or to the above-normal range.⁷ Testosterone replacement regimens do not directly correct erectile dysfunction; instead, they improve libido, thereby correcting secondary erectile dysfunction.

Testosterone replacement regimens can be administered orally, parenterally, and topically (see Table 81–3). Injectable testosterone replacement regimens are preferred for treatment of symptomatic patients with primary or secondary hypogonadism because they are effective, inexpensive, and not associated with the bioavailability problems or hepatotoxic adverse effects of oral androgens.^{6,48} Although convenient for the patient, testosterone patches and gels are much more expensive than other forms of androgen replacement; therefore

they should be reserved for those patients who refuse injectable testosterone.⁴⁹

■ PHARMACOKINETICS

Natural testosterone has poor oral bioavailability because of extensive first-pass hepatic metabolism, and large doses must therefore be taken. To improve oral bioavailability, alkylated derivatives were formulated. Of these, methyltestosterone and fluoxymesterone are more resistant to hepatic catabolism, and can be taken in smaller daily doses, which are potentially safer. However, oral alkylated derivatives of testosterone are associated with a higher incidence of serious hepatotoxicity, and therefore are not preferred for management of sexual dysfunction.

Several testosterone esters have been formulated for intramuscular injection, with different durations of action (see Table 81–3). The shorter-acting testosterone propionate, which requires dosing three times a week, has largely been replaced with testosterone cypionate or enanthate, as they can be dosed every 2, 4, or 6 weeks in most patients. However, these testosterone salts produce suprapharmacologic patterns of serum testosterone during the dosing interval, which have been linked to mood swings in some patients.

Topical testosterone replacement regimens can be delivered as once-daily patches or gel. Testosterone patches increase serum testosterone levels into the normal range in 2 to 6 hours. Serum testosterone levels return to baseline 24 hours after patch administration. However, unlike oral or injectable supplements, topical testosterone products, usually applied each morning, produce physiologic patterns of serum testosterone levels throughout the day. The clinical importance of this biochemical effect is unknown.⁵⁰

The original Testoderm brand patch was formulated for scrotal application. Scrotal skin is thinner and has a richer vascular supply than does the skin on the arms or thighs. Therefore application of Testoderm patches produced excellent absorption of the hormone. However, the patch could fall off when the scrotum became damp or moist, when the patient exercised, or if the scrotum was excessively hairy.

For improved convenience, Androderm and Testoderm TTS patches were formulated for application to the arms, buttocks, or back; Androderm can also be applied to the thighs. The addition of absorption enhancers and different adhesives has been linked to a higher incidence of contact dermatitis with Androderm patches, as compared with the original Testoderm scrotal patch.⁵¹

Testosterone gel 1% formulation (AndroGel) is applied in much larger doses—5 or 10 g each day—to the skin of the shoulders, upper arms, or abdomen. The hormone is absorbed quickly, within 30 minutes, but it may take several hours for complete absorption of the dose. For this reason, the patient should be reminded to wait at least 5 to 6 hours after application before showering. To prevent inadvertent transfer of testosterone gel to others, the patient should thoroughly wash his hands with soap and water after administration of a dose.

■ DOSING

Table 81–3 lists the usual doses for testosterone replacement regimens. An adequate treatment trial with a particular dose is considered to be 2 to 3 months. Thus a dose should not be increased until the patient has used one particular dose for at least this time period.⁵²

Before initiating any testosterone replacement regimen in patients 40 years of age or older, the patient should be screened for the

presence of benign prostatic hyperplasia and prostate cancer. Both of these diseases are testosterone-dependent conditions and theoretically could be worsened by the exogenous administration of testosterone. Prostate cancer is a contraindication to androgen supplementation.

■ ADVERSE EFFECTS

Testosterone replacement regimens can cause sodium retention, which can cause weight gain, or exacerbate hypertension, congestive heart failure, and edema. Gynecomastia can also occur as a result of conversion of testosterone to estrogen in peripheral tissues. This has most often been reported in patients with liver cirrhosis.

Deleterious serum lipoprotein changes have also been reported, including decreasing high-density lipoprotein cholesterol levels. However, no cases of cardiovascular disease have been reported with testosterone replacement regimens.

Large doses of testosterone can stimulate erythropoiesis, and polycythemia may result.⁵³ Thus patients on long-term testosterone replacement regimens must undergo clinical laboratory testing for serum testosterone, a lipid profile, and a hematocrit every 6 to 12 months.⁵³ Repeated serum testosterone levels that exceed the normal range require a dosage reduction or increased interval between drug doses. An abnormal lipid profile may require lifestyle and dietary modification, and if necessary, antihyperlipidemic drug therapy. If the hematocrit exceeds 55%, the testosterone replacement regimen should be withheld temporarily.

Oral testosterone replacement regimens have caused hepatotoxicity, which has ranged from mild elevations of hepatic transaminases to serious liver diseases, including peliosis hepatis (hemorrhagic liver cysts), hepatocellular and intrahepatic cholestasis, and benign or malignant tumors. For this reason, parenteral testosterone replacement regimens are preferred.

Topical testosterone patches may cause contact dermatitis, which responds well to topical corticosteroids.

■ ALPROSTADIL

■ MECHANISM

Alprostadil, also known as prostaglandin E₁, stimulates adenylyl cyclase, resulting in increased production of cAMP, a neurotransmitter that causes smooth-muscle relaxation of the arterial blood vessels to and sinusoidal tissues in the corpora. This results in enhanced blood flow to and blood filling of the corpora (see Fig. 81–1).

Alprostadil is commercially available as an intracavernosal injection (Caverject and Edex) and as an intraurethral insert (medicated urethral system for erection; MUSE).

■ INDICATIONS

Both commercially available formulations of alprostadil are FDA-approved as monotherapy for the management of erectile dysfunction. Alprostadil is more effective by the intracavernosal than by the intraurethral route.^{54,55}

The enhanced efficacy of the intracavernosal injection may be related to the excellent bioavailability of the drug when injected directly into the corpora cavernosum. In contrast, intraurethral alprostadil doses generally are several hundred times larger than intracavernosal doses. Intraurethral alprostadil must be absorbed from the urethra,

through the corpus spongiosum, and into the corpus cavernosum, where it exerts its full proerectogenic effect.

Although many other agents, including papaverine and phen-tolamine, have been used off-label for intracavernosal therapy, al-prostadil is preferentially prescribed. This is because the FDA has approved intracavernosal alprostadil for erectile dysfunction, and because it has a low potential for causing prolonged erections and priapism.

Both formulations of alprostadil are considered more invasive than VEDs or phosphodiesterase inhibitors. For this reason, intra-cavernosal alprostadil is generally prescribed after patients fail to respond to or cannot use the less invasive interventions. Intracaver-nosal alprostadil is preferred over intraurethral alprostadil because the former is more effective than the latter. Also, intracavernosal al-prostadil may be preferred in patients with diabetes mellitus, who are accustomed to injectable drug therapy and may suffer from peripheral neuropathies, which decreases the patient's perception of pain upon injection. Intraurethral alprostadil is generally reserved as a treatment of last resort for patients who fail other less invasive and more effective forms of therapy and also refuse surgery.

■ INTRACAVERNOSAL ALPROSTADIL

■ Efficacy

In various controlled and uncontrolled studies, the overall efficacy of intracavernosal alprostadil is 70% to 90%.^{6,56,57} In a large parallel design, double-blind, multicenter study, Linet and associates⁵⁶ docu-mented three relevant characteristics of intracavernosal alprostadil:

1. The effectiveness of alprostadil is dose related over the range of 2.5 to 20 mcg. The mean duration of erection is directly related to the dose of alprostadil administered and ranges from 12 to 44 minutes.
2. The median effective dose ranged from 3 mcg to 5 mcg. A higher percentage of patients with psychogenic and neurogenic erectile dysfunction responded to alprostadil and at a lower dose when compared to patients with vasculogenic erectile dysfunction.

3. Tolerance does not appear to develop with continued use of intracavernosal alprostadil at home.

9 Although 70% to 75% of patients respond to intracavernosal alprostadil, a high proportion of patients elect to discontinue its use over time. Depending on the study and the length of observation, 30% to 50% of patients voluntarily discontinue therapy, usually during the first 6 to 12 months. Common reasons for this include lack of perceived effectiveness; inconvenience of administration; an unnatu-ral, nonspontaneous erection; needle phobia; loss of interest; and cost of therapy.^{6,58}

Approximately one-third of patients will not respond to usual doses of intracavernosal alprostadil. In these patients, intracavernosal alprostadil has been used successfully along with VEDs. Such com-bination therapy may be tried in patients before transitioning to more invasive surgical procedures.²³ Alternatively, intracavernosal injec-tions of synergistic combinations of vasoactive agents that act by different mechanisms have been used.⁵⁹ Table 81–6 lists examples of such mixtures. Intracavernosal drug combinations typically produce an erection that lasts longer than an erection produced by any one of the agents in the mixture. In addition, because of the low dosage of each agent in the combination, fewer systemic and local fibrotic adverse effects develop compared with high-dose monotherapy. For example, when used in low-dose combination regimens, papaverine is less likely to induce hypotension and liver dysfunction, and phen-tolamine is less likely to induce tachycardia and hypotension.⁶⁵

■ Pharmacokinetics

Intracavernosal injection should be made into one corpus cavernosum only. From this injection site, the drug will reach the other corpus cav-ernosum through vascular communications between the two corpora. Alprostadil acts rapidly, with an onset in 5 to 15 minutes. The duration is directly related to the dose, and within the usual dosage range of 2.5 to 20 mcg, the duration of the erection lasts no more than 1 hour. Local enzymes in the corpora cavernosum quickly metabolize al-prostadil. Any alprostadil that escapes into the systemic circulation is deactivated on first passage through the lungs.^{6,56,57} Hence the plasma half-life of alprostadil is approximately 1 minute. Also, dose modifi-cation is not necessary in patients with renal or hepatic diseases.

Dosing

The usual dose of intracavernosal alprostadil is 10 to 20 mcg, with a maximum recommended dose of 60 mcg. Doses greater than 60 mcg have not produced any greater improvement in penile erection, but they may cause prolonged erections lasting more than 1 hour or systemic hypotension.^{6,56,57} The dose should be administered 5 to 10 minutes before intercourse. The manufacturer recommends that patients be slowly titrated up to the minimally effective dosage. Under a physician's supervision, patients should be started with a 1.25-mcg dose, and this can be increased in increments of 1.25 to 2.50 mcg at 30-minute intervals up to the lowest dose that produces a firm erection for 1 hour and does not produce adverse effects. In clinical practice, this is rarely done because it is time-consuming. Thus many physicians start the patient on 10 mcg and move quickly up the dosage range to identify the best dose for the patient. To avoid adverse effects patients should receive no more than one injection per day and not more than three injections per week.⁵⁷

Intracavernosal injections should be performed using a 0.5-inch, 27- or 30-gauge needle. Also, a tuberculin syringe or a syringe pre-filled with diluent as supplied by the manufacturer should be used to ensure precise measurement of doses. Patients with needle phobia, poor vision, or poor manual dexterity can use commercially available autoinjectors (e.g., PenInject) to facilitate the administration of intracavernosal alprostadil.

Intracavernosal injections require that the patient or his sexual partner practice good aseptic technique (to avoid infection), have good manual skills and visual ability, and be comfortable with injection techniques. When practicing self-injection, the patient should use one hand to firmly hold the glans penis against his thigh to expose the lateral surface of the shaft. The injection should be made at right angles into one of the lateral surfaces of the proximal third of the penis. The injection should never be made into the dorsal or ventral surface of the penis. This will prevent inadvertent injection of the drug into arteries on the dorsal surface or the urethra on the ventral surface, respectively. After the injection, the penis should be massaged to help distribute the drug into the opposite corpus cavernosum. Injection sites should be rotated with each dose. Finally, manual pressure should be applied to the injection site for 5 minutes to reduce the likelihood of hematoma formation (Fig. 81-7).⁵⁷

Once the optimal dosage of intracavernosal alprostadil is established, the patient should return for routine medical follow-up every 3 to 6 months. Some patients may subsequently require dosage adjustment, and this is largely attributed to worsening of the underlying disease that is contributing to the erectile dysfunction.

Adverse Effects

Intracavernosal alprostadil is most commonly associated with local adverse effects, which occur most often during the first year of therapy. However, improved administration technique with continued use is believed to account for the lower frequency of adverse effects during subsequent treatment periods.

Intracavernosal injections are associated with several local adverse effects. Cavernosal plaques or areas of fibrosis at injection sites form in approximately 2% to 12% of patients. When these occur, the patient should suspend further injections until the plaques resolve.⁶⁶ These plaques may cause penile curvature, similar to Peyronie's disease, which make sexual intercourse difficult or impossible. The cause for corporal fibrosis and plaque formation is unknown. This adverse effect may be caused by poor injection technique^{67,68} or by

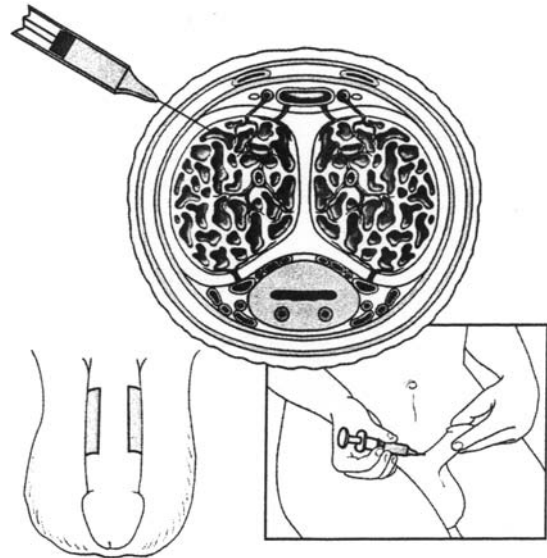

FIGURE 81-7. Technique for administration of intracavernosal injections. (Reprinted with permission from Kirby R, Carson C, Goldstein I. *Erectile Dysfunction, A Clinical Guide*. Oxford, England, ISIS Medical Media, 1999:58.)

alprostadil itself. Although patients have developed corporal fibrosis, alprostadil may be less likely to cause this adverse effect as compared to other intracavernosal drug combinations, such as phentolamine or papaverine.⁶⁹ Unlike cavernosal fibrosis associated with large doses and repeated administration of papaverine, penile scarring secondary to alprostadil appears to be unpredictable.

Alprostadil causes penile pain in approximately 10% to 44% of patients.^{57,70-72} This has been described as a burning discomfort or dull pain near the injection site or during the erection, which generally does not persist after the penis becomes flaccid. The pain is usually mild, generally does not require discontinuation of therapy, and often abates even with continued treatment. However, 2% to 5% of patients require discontinuation of alprostadil because of severe pain. The pain may be managed by oral analgesics (e.g., acetaminophen), if necessary. One investigator has recommended adding procaine to intracavernosal alprostadil, but this may mask the signs of more serious adverse effects of the drug or of penile injury during intercourse, and it is not recommended.⁷⁰ The mechanism of this adverse reaction is poorly understood. Alprostadil may intrinsically produce pain.⁷² Also, this may be a result of the pH of the parenteral solution. Alprostadil is acidic and the commercially available Caverject formulation is buffered with sodium citrate, a weak base, to reduce pain on injection.⁷¹

Priapism, a prolonged, painful erection lasting more than 1 hour, occurs in 1% to 15% of treated patients.⁵⁷ It most often occurs during the dose titration period and is rare thereafter. Blood sludging in the corpora can lead to tissue hypoxia and cavernosal fibrosis and scarring, particularly if priapism develops. The risk for this is greatest for erections that persist beyond 4 hours. Patients are advised to seek medical attention immediately when drug-induced erections last more than 1 hour, as this is considered a urologic emergency. Its management includes supportive care, including analgesics for pain and sedatives for anxiety. In addition, needle aspiration of sludged blood in the corpora or intracavernosal injection of α -adrenergic agonists (e.g., phenylephrine) has been used.⁷² These procedures facilitate venous drainage of the corpora, allowing the venous outflow to "catch up" with arterial inflow.

The likelihood of prolonged erections with intracavernosal alprostadil is dose-related. Therefore to prevent this adverse effect, the lowest effective dose should be used, and the dose should be titrated to ensure that the duration of the erection is no more than 1 hour.

Other local adverse effects include injection site hematomas and bruising. These are largely the result of unskillful injection techniques. To minimize the risk of injection site hematomas, patients should be advised to apply pressure to the injection site for 5 minutes following each dose. Similarly, infection at the injection site has been reported. Meticulous aseptic technique is recommended to avoid this complication.

Intracavernosal alprostadil rarely causes systemic adverse effects, owing to the agent's localized injection and rapid catabolism. However, large doses greater than 20 mcg are associated with dizziness and hypotension in some patients. This is one reason why such large doses are not commonly used.

Intracavernosal injection therapy should be used cautiously in patients at risk of priapism, which includes patients with sickle cell disease or lymphoproliferative disorders. It should also be used cautiously in patients who may develop bleeding complications secondary to injections, including patients with thrombocytopenia or those on anticoagulants. It should also be used cautiously in patients who may use poor-quality injection technique, including patients with psychiatric disorders, obese patients (who may not be able to reach or see the penile injection site), patients who are blind, and patients with severe arthritis.

■ INTRAURETHRAL ALPROSTADIL

■ Efficacy

Intraurethral alprostadil inserts are marketed as MUSE, which contains a pellet inside a prefilled urethral applicator. Multiple studies show this product to have an overall effectiveness rate of 43% to 60%,^{54–55} as compared with 70% to 90% for intracavernosal alprostadil. Its decreased effectiveness and inconvenient administration method have resulted in this product being considered a second-line treatment option for patients with erectile dysfunction. However, some patients respond to intraurethral alprostadil even when intracavernosal alprostadil did not work for them.⁷³

To improve treatment response to intraurethral alprostadil, it has been combined with an adjustable penile constriction band.⁷⁴

■ Pharmacokinetics

Following intraurethral instillation, alprostadil is absorbed quickly through the urethra, into the corpus spongiosum, and into the corpora cavernosum. As much as 90% of each dose is absorbed by the urethra and corpus spongiosum in less than 10 minutes, with peak absorption occurring in 20 to 25 minutes. An estimated 20% of each dose is delivered to the corpora cavernosum. As with intracavernosal injections of alprostadil, any drug absorbed into the systemic circulation is rapidly metabolized on first pass through the lungs.

The onset after intraurethral insertion is similar to that of intracavernosal injection, 5 to 10 minutes.

■ Dosing

The usual dose for intraurethral alprostadil is 125 to 1000 mcg. The dose should be administered 5 to 10 minutes before sexual intercourse.

No more than one dose per day is recommended. Before administration, the patient should be advised to empty his bladder, voiding completely.

Similarly to intracavernosal injection treatments, intraurethral insertion of alprostadil requires good manual and visual skills to minimize the risk of urethral injuries. Intraurethral alprostadil is supplied in a prefilled intraurethral applicator. With one hand the patient holds the glans penis, and with the other hand the patient inserts the intraurethral applicator 0.5-inch into the urethra. The drug pellet is then pushed into the urethra. The penis should then be massaged to enhance drug absorption (Fig. 81–8).

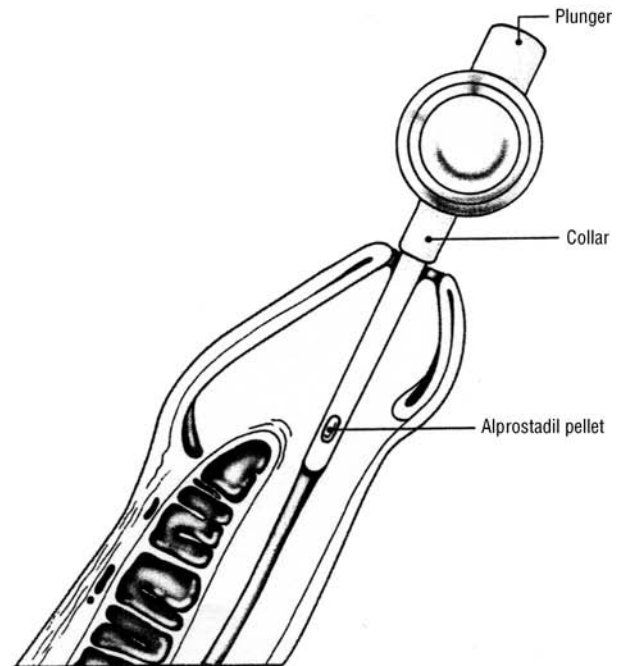

FIGURE 81–8. Technique for administration of intraurethral alprostadil with a MUSE applicator. (Reprinted with permission from Kirby R, Carson C, Goldstein I. *Erectile Dysfunction, A Clinical Guide*. Oxford, England, ISIS Medical Media, 1999:62.)

■ Adverse Effects

The urethra can be injured because of improper administration technique. Injuries can lead to urethral stricture and difficulty in voiding. Patients should receive complete education about optimal administration procedures before the start of treatment.

Urethral pain has been reported in 24% to 32% of patients. Usually it is mild and does not require discontinuation of treatment. Female sexual partners may experience vaginal burning, itching, or pain, which is probably related to transfer of alprostadil from the man's urethra to the woman's vagina during intercourse. However, the resumption of sexual intercourse could also produce such symptoms.

Prolonged painful erections (priapisms) have been rarely reported.^{6,57}

Also, syncope and dizziness have been reported rarely, in only 2% to 3% of patients, and these are likely related to excessively large doses.

CLINICAL CONTROVERSY

Although combinations of proerectogenic drugs may be used in some patients (e.g., sildenafil plus alprostadil intracavernosal injection), such combinations are not recommended by the FDA and may lead to prolonged erections and priapism.

■ UNAPPROVED AGENTS

A variety of other commercially available and investigational agents have been used for management of erectile dysfunction. Although it is beyond the scope of this chapter to discuss all of them, some of the more commonly used agents are presented.

■ TRAZODONE

The mechanism by which trazodone produces an erection is not clear. It likely acts peripherally to antagonize α -adrenergic receptors. As a result, a predominant cholinergic effect results, which causes peripheral arteriolar vasodilation and relaxation of cavernosal tissues, which enhances blood filling of the corpora. Intracavernosal injection of trazodone in experimental studies supports this likely mechanism.⁷⁵

Although initial studies suggested that trazodone 50 to 200 mg by mouth daily might be effective in the management of erectile dysfunction, these trials were generally poorly controlled, were nonrandomized, included small samples, and did not include validated objective parameters of response.^{76,77} More recent well-controlled studies show that trazodone 50 mg⁷⁸ or 150 mg⁷⁹ by mouth daily is no more effective than placebo in most patients with erectile dysfunction.

The adverse effects of trazodone, when used for erectile dysfunction, are similar to those reported with trazodone when used to treat depression (see Chap. 67).

■ YOHIMBINE

Yohimbine, a tree-bark derivative also known as yohimbe, is widely used as an aphrodisiac. This can be explained by yohimbine's central α_2 -adrenergic antagonistic effects, which increase catecholamines and improves mood. However, some investigators believe that yohimbine has peripheral proerectogenic effects. It has been postulated that

yohimbine may reduce peripheral α -adrenergic tone, thereby permitting a predominant cholinergic tone. This could result in a vasodilatory response.⁶

The usual oral dose is 5.4 mg three times a day.

A controlled clinical trial has shown high-dose yohimbine (100 mg daily) to be no more effective than placebo.⁸⁰ Based on a meta-analysis of published studies that came to the same conclusion, the American Urological Association has cautioned against the use of yohimbine.²⁵ In addition, yohimbine can cause many systemic adverse effects, including anxiety, insomnia, tachycardia, and hypertension.

■ PAPAVERINE

Papaverine inhibits cavernosal phosphodiesterase, thereby decreasing metabolic catabolism of cAMP in cavernosal tissue. As a result of the enhanced tissue levels of cAMP, smooth-muscle relaxation occurs. Cavernosal sinusoids fill with blood and a penile erection results.^{6,81}

Papaverine is not FDA approved for erectile dysfunction. Intracavernosal papaverine alone is not commonly used for management of erectile dysfunction because large doses are required, and these produce dose-related adverse effects: priapism, corporal fibrosis, hypotension, and hepatotoxicity.^{82,83} Papaverine is more often administered in lower doses combined with phentolamine and/or alprostadil. A variety of formulae have been used, but no one mixture has been proven better than other mixtures (see Table 81-6). Combination formulations are considered to be safer and associated with the potential for fewer serious adverse effects than high doses of any one of these agents.^{82,83}

A portion of each papaverine dose is systemically absorbed, and its prolonged plasma half-life of 1 hour contributes to adverse effects. The usual dose of papaverine is 7.5 to 60 mg when used as a single agent for intracavernosal injection. When used in combination, the dose decreases to 0.5 to 20 mg (see Table 81-6).

If treated with papaverine, patients with a history of underlying liver disease or alcohol abuse should have liver function tests routinely checked at baseline and every 6 to 12 months during continued treatment.⁸²

■ PHENTOLAMINE

Phentolamine is a competitive nonselective α -adrenergic blocking agent. It reduces peripheral adrenergic tone and enhances cholinergic tone. As a result, it improves cavernosal filling and is proerectogenic.

Phentolamine has most often been administered as an intracavernosal injection. Monotherapy is avoided, as large doses are required for an erection, and at these doses systemic hypotensive adverse effects would be prevalent. Most often, phentolamine has been used in combination with other vasoactive agents for intracavernosal administration. A ratio of 30 mg papaverine to 0.5 to 1 mg phentolamine is typical, and the usual dose ranges from 0.1 mL to 1 mL of the mixture. Such a mixture promotes local effects of phentolamine and minimizes systemic hypotensive adverse effects (see Table 81-6).⁶

Hypotension is the most common adverse effect of intracavernosal phentolamine. It is more common and more severe with large doses or in patients with poor injection technique who have injected into a vein (rather than the cavernosa). Prolonged erections have also been reported in patients who used excessive doses of combination intracavernosal therapy.

PENILE PROSTHESES

Surgical insertion of a penile prosthesis is the most invasive treatment for erectile dysfunction. It is reserved for those patients who fail to respond to or who are not candidates for less invasive oral or injectable treatments.

Prosthesis insertion requires anesthesia and skilled urologists. Two prostheses are widely used: malleable and inflatable. Malleable prostheses consist of two bendable rods that are inserted into the corpora cavernosa. The patient appears to have a permanent erection after the procedure; the patient is able to bend the penis into position at the time of intercourse.

The inflatable prosthesis has several parts, including two inflatable rods and a pump-reservoir mechanism. When activated, the device pumps saline solution from the reservoir into the rods, causing inflation. The inflatable prosthesis produces a more natural erection, in that the patient only develops an erection when the device is activated. Some newer advances in inflatable prosthesis technology have resulted in devices with the pump, reservoir, and rods all in one unit, and these can be placed during shorter surgical procedures and are less likely to malfunction (Fig. 81–9).

Penile prostheses provide penile rigidity suitable for vaginal intercourse and are associated with a greater than 90% patient satisfaction rate. The surgical success rate after insertion is 82% to 98%.⁶

Adverse effects of prosthesis insertion can occur early or late after the surgical procedure. The most common early complication is infection. Late complications include mechanical failure of the prosthesis, particularly when inflatable prostheses have been inserted. With improved technology, the mechanical failure rate has decreased to 5%.⁶ Other late complications include erosion of the rods through

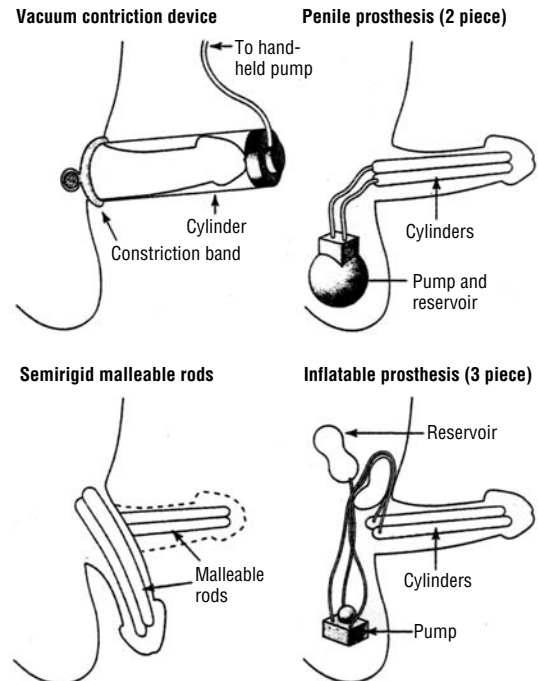

FIGURE 81–9. Devices and prostheses for surgical implantation in patients with erectile dysfunction. (Adapted with permission from Wagner G, de Tegada IS. Update on male erectile dysfunction. *BMJ* 1998;316:681.)

the penis or late-onset infection. Although some salvage procedures have been devised, in many cases the prosthesis may require removal.

EVALUATION OF THERAPEUTIC OUTCOMES

The primary therapeutic outcomes of specific treatments for erectile dysfunction include (1) improvement in the quantity and quality of penile erections suitable for intercourse and (2) avoidance of adverse drug reactions and drug interactions.

At baseline and after the patient has completed a clinical trial period of 1 to 3 weeks with a specific treatment for erectile dysfunction, the physician should conduct assessments to determine whether the quality and quantity of penile erections has improved. It should be noted that a patient's level of satisfaction is highly individualized depending on his lifestyle and expectations. Therefore a patient who has successful intercourse once a week might be completely satisfied; another patient might judge this to be unsatisfactory. Patients with unrealistic expectations in this regard need to be identified and counseled by their physicians to avoid adverse effects of excessive use of proerectogenic agents.

Failure to improve the quality and quantity of penile erections suitable for intercourse after an appropriate clinical trial period with a specific treatment for erectile dysfunction occurs in a significant percentage of patients, as previously described. In this case, physicians generally take these steps in this order:

1. Ensure that the patient has been prescribed a maximum tolerated dose and has an adequate clinical trial of a specific treatment before discarding it as ineffective.
2. Switch to another drug, usually one with a greater potential for adverse effects and complications than the first drug initiated (see Fig. 81–4).

3. Reserve surgical treatment for patients who fail to respond to drug treatment.

CONCLUSIONS

Erectile dysfunction is a common disorder of aging men. Its incidence is higher in patients with underlying medical disorders that compromise the vascular, neurologic, hormonal, or psychogenic systems necessary for a normal penile erection. Medications are common causes of erectile dysfunction. By correcting the underlying etiology, erectile dysfunction can often be reversed without the use of specific treatments.

When treatments for erectile dysfunction are needed, the least invasive forms of treatment should be used first, as they produce the lowest incidence of serious adverse effects. VEDs or phosphodiesterase inhibitors are therefore considered first-line treatments. If these fail, intracavernosal alprostadil injection therapy can be initiated. If this fails, the patient can be tried on a combination of intracavernosal alprostadil plus VED, combination intracavernosal therapy, or intraurethral alprostadil. If this fails, the patient may require insertion of a penile prosthesis.

Some insurance companies do not reimburse for drug treatments for erectile dysfunction; therefore cost is an important issue for some patients.

Clinicians should provide clear and simple advice. Patient confidentiality and privacy, which are extremely important to men with erectile dysfunction, should be maintained at all times.

MANAGEMENT OF BENIGN PROSTATIC HYPERPLASIA

Mary Lee

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Although benign prostatic hyperplasia (BPH) is rare in men younger than 50 years of age, it is very common in men 60 years of age and older as a result of androgen-driven growth in the size of the prostate. Symptoms commonly result from both static factors and dynamic factors.
- 2 While most elderly men have hyperplasia of the prostate, only about 50% of men have symptoms.
- 3 BPH symptoms may be caused by medications, including antihistamines, phenothiazines, tricyclic antidepressants, or anticholinergic agents. In this case discontinuing the causative agent can ameliorate symptoms.
- 4 Specific treatments for BPH include watchful waiting, drug therapy, and surgery.
- 5 No therapy is needed for men with no or few symptoms. They should be managed with watchful waiting, which includes return visits to the physician at 6- to 12-month intervals for reassessment.
- 6 If symptoms progress to moderate severity, drug therapy or surgery is indicated, as waiting longer will not avoid the need for prostatectomy. Drug therapy is an interim measure which delays symptom progression.
- 7 By interfering with testosterone's stimulatory effect on prostate gland enlargement, 5 α -reductase inhibitors reduce the static factor. By relaxing prostatic smooth muscle, the α_1 -adrenergic antagonists reduce the dynamic factor.
- 8 The drugs of choice are α -adrenergic antagonists. These are all equally effective in relieving BPH symptoms. Older second-generation α -adrenergic antagonists (i.e., terazosin or doxazosin) can cause adverse cardiovascular effects, chiefly hypotension and dizziness. In patients who cannot tolerate hypotensive effects of α -adrenergic agents, the third-generation, pharmacologically uroselective agent tamsulosin is a good alternative. An extended-release formulation of alfuzosin, a second-generation functionally uroselective agent, has fewer cardiovascular adverse effects than terazosin or doxazosin; however, it is unclear if alfuzosin has the same cardiovascular safety profile as tamsulosin.
- 9 5 α -Reductase inhibitors are useful primarily in patients with large prostates who wish to avoid surgery and cannot tolerate the side effects of α -adrenergic antagonists.
- 10 Surgery is the gold standard of treatment, as it is the only intervention that relieves symptoms in the greatest number of men with BPH. However, the two most widely used techniques are associated with the highest rates of complications, including retrograde ejaculation and erectile dysfunction.
- 11 Although widely used in Europe for BPH, phytotherapy should be avoided. Studies of these herbal medicines are inconclusive, and the purity of available products is questionable.

Benign prostatic hyperplasia (BPH) is the most common benign neoplasm of American men. A nearly ubiquitous condition among elderly men, BPH is of major societal concern, given the large number of men affected, the long-term nature of the condition, and the health care costs associated with it.

This chapter discusses BPH and its available treatments: "watchful waiting," 5 α -reductase inhibitors, α -adrenergic antagonists, and surgery.

EPIDEMIOLOGY

- 1 About 80% of elderly men develop microscopic evidence of BPH, according to the results of autopsy studies. About one-half of the patients with microscopic changes develop an enlarged prostate gland, and as a result have difficulty emptying the contents of the urinary bladder. About one-half of symptomatic patients eventually require treatment.

The peak incidence of clinical BPH occurs at 63 to 65 years of age. Symptomatic disease is uncommon in men younger than 50 years of age, but some urinary voiding symptoms are present by the time men turn 60 years of age. The Boston Area Normative Aging Study estimated that the cumulative incidence of clinical BPH was 78% in patients at age 80 years.¹ Similarly, the Baltimore Longitudinal Study of Aging projected that approximately 60% of men of at least 60 years of age develop clinical BPH.²

NORMAL PROSTATE PHYSIOLOGY

Located anterior to the rectum, the prostate is a small heart-shaped, chestnut-sized gland located below the urinary bladder. It surrounds the proximal urethra like a doughnut.

Round, soft, symmetric, and mobile on palpation, a normal prostate gland in an adult man weighs 4 to 20 g. Physical examination of the prostate must be done by digital rectal examination (i.e., the prostate is manually palpated by inserting a finger into the rectum). Thus the prostate is examined through the rectal mucosa.

The prostate has two major functions: (1) to secrete fluids that make up a portion (20% to 40%) of the ejaculate volume; and (2) to provide secretions with possible antibacterial effect related to a high concentration of zinc.³

At birth, the prostate is pea-sized and weighs approximately 1 g. The prostate stays that size until the boy reaches puberty. At that time, the prostate undergoes its first growth spurt, growing to its normal adult size of 15 to 20 g by the time the young man is 25 to 30 years of age. The prostate remains this size until the patient reaches age 40, when a second growth spurt begins and continues until the man is 70 to 80. During this period, the prostate can double or triple in size. At surgery, patients with severely symptomatic BPH can have prostates that can exceed 100 g.

The prostate gland comprises three types of tissue: epithelial tissue, stromal tissue, and the capsule. Epithelial tissue, also known as glandular tissue, produces prostatic secretions. These secretions are delivered into the urethra during ejaculation and contribute to the ultimate ejaculate volume. Epithelial tissue is under androgen control (i.e., androgens stimulate epithelial tissue growth). Stromal tissue, also known as smooth muscle tissue, is embedded with α_1 -adrenergic receptors. Stimulation of these receptors by norepinephrine causes smooth-muscle contraction, which results in an extrinsic compression of the urethra, reduction of the urethral lumen, and decreased urinary bladder emptying. The normal prostate is composed of a higher amount of stromal tissue than epithelial tissue, as reflected by a stromal-to-epithelial tissue ratio of 2:1. This ratio is further exaggerated to 5:1 in patients with BPH, which explains why α_1 -adrenergic antagonists are quickly effective in symptomatic management, and why 5α -reductase inhibitors only reduce an enlarged prostate gland by 25%.^{3,4} The capsule, or outer shell of the prostate, is composed of fibrous connective tissue and smooth muscle, which is also embedded with α_1 -adrenergic receptors. When stimulated with norepinephrine, the capsule also contracts around the urethra (Fig. 82-1).

Testosterone is the principal testicular androgen in males, whereas androstenedione is the principal adrenal androgen. These two hormones are responsible for penile and scrotal enlargement, increased muscle mass, and maintenance of the normal male libido. These androgens are converted by 5α -reductase in target cells to dihydrotestosterone (DHT), an active metabolite. Two types of 5α -reductase exist. Type I enzyme is localized to hair follicles, sebaceous glands in the frontal scalp, liver, and skin. DHT produced at these target tissues causes acne, increased body and facial hair, and

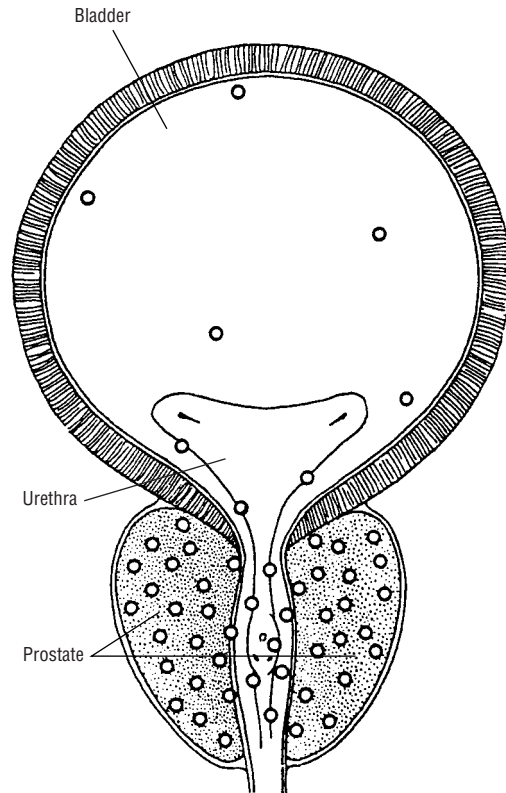

FIGURE 82-1. Representation of the anatomy of and α -adrenergic receptor distribution in the prostate, urethra, and bladder. (Reproduced with permission from the *Western Journal of Medicine* 1994;161:501.)

male pattern baldness. Type II enzyme is localized to the prostate, genital tissue, and scalp. In these target tissues, DHT causes prostate enlargement and prostate growth (Table 82-1).³

In prostate cells, DHT has greater affinity for intraprostatic androgen receptors than testosterone, and DHT forms a more stable complex with the androgen receptor. Thus DHT is considered a more potent androgen than testosterone. It is largely responsible for the normal growth of the prostate during the first growth spurt, as well as the development of BPH during the second growth spurt. It should also be noted that despite the decrease in testicular androgen production in the aging male, intracellular DHT levels in the prostate remain normal. This is probably due to increased activity of intraprostatic 5α -reductase.

Estrogen, a product of peripheral metabolism of androgens, is believed to stimulate the growth of the stromal portion of the prostate gland. Estrogens are produced when testosterone and androstenedione are converted by aromatase enzymes in adipose tissues. In addition, estrogens may induce the androgen receptor.⁵ As men age, the ratio of serum levels of testosterone to estrogen decreases as a result of a decline in testosterone production by the testes and also increased adipose tissue conversion of androgen to estrogen.

PATHOPHYSIOLOGY

While the precise pathophysiologic mechanisms that cause BPH remain unclear, the role of intraprostatic DHT and type II 5α -reductase in the development of BPH is evidenced by several observations:

- BPH does not develop in men who are castrated before puberty.
- Castration causes an enlarged prostate to shrink.

TABLE 82–1. Characteristics of 5 α -Reductase Isoenzymes in Various Target Tissues

| Characteristics | Type I | Type II |
|--|--|---|
| Localized sites | Scalp, skin (all over the body), sebaceous glands, and liver | Prostate, scalp, liver, genital skin |
| Clinical manifestations of the presence of the hormone | Acne; increased body and facial hair | Male pattern baldness; BPH; virilization of the fetus |
| Clinical manifestations of the absence of the hormone | Unknown at this time | Involution of the prostate, ambiguous genitalia in newborns even though the patient is genetically a male (also referred to as pseudohermaphroditism) |
| Inhibited by finasteride | + | +++ |

- Patients with type II 5 α -reductase enzyme deficiency do not develop BPH.
- Administration of testosterone to orchietomized dogs of advanced age produces BPH.

The pathogenesis of BPH is often described as resulting from both static and dynamic factors. Static factors relate to anatomic enlargement of the prostate gland, which produces a physical block at the bladder neck and thereby obstructs urinary outflow. Enlargement of the gland depends on androgen stimulation of epithelial tissue and estrogen stimulation of stromal tissue in the prostate. Dynamic factors relate to excessive α -adrenergic tone of the stromal component of the prostate gland, bladder neck, and posterior urethra, which results in contraction of the prostate gland around the urethra and narrowing of the urethral lumen.

Symptoms of BPH disease may result from static and/or dynamic factors, and this must be recognized when drug therapy is considered. For instance, some patients may present with obstructive voiding symptoms but have prostates of normal size. In these patients, dynamic factors are likely responsible for the symptoms. But in patients with enlarged prostate glands, static and dynamic factors are likely working in concert to produce the observed symptoms.

Static factors may be accentuated by environmental factors. Patients who are stressed or in pain may experience an exacerbation of voiding difficulty. In these situations, increased α -adrenergic tone may precipitate excessive contraction of prostatic stromal tissue. When the stressful event resolves, voiding symptoms often disappear.⁶

MEDICATION-RELATED SYMPTOMS

3 Medications in several pharmacologic categories should be avoided in patients with BPH, as they may exacerbate symptoms. Testosterone replacement regimens, used to treat primary or secondary hypogonadism, deliver additional substrate that can be metabolized to DHT by the prostate. Although no cases of BPH have been reported as a result of exogenous testosterone administration, cautious use is advised in patients with prostatic enlargement. α -Adrenergic agonists, used as oral or intranasal decongestants (e.g., pseudoephedrine, ephedrine, or phenylephrine), can stimulate α -adrenergic receptors in the prostate, resulting in muscle contraction. By decreasing the caliber of the urethral lumen, bladder emptying may be compromised. Also, drugs with significant anticholinergic adverse effects (e.g., antihistamines, phenothiazines, tricyclic antidepressants, or anticholinergic drugs used as antispasmodics or to treat Parkinson's disease) may

decrease (urinary bladder) detrusor muscle contractility. For patients with BPH, who have a narrowed urethral lumen, the loss of effective detrusor contraction could result in acute urinary retention. Diuretics, particularly large doses, can produce polyuria, which may present as urinary frequency, similar to that experienced in patients with BPH.

CLINICAL PRESENTATION

Patients with BPH can present with a variety of symptoms and signs of disease. All symptoms of BPH can be divided into two categories: obstructive and irritative.

CLINICAL PRESENTATION OF BENIGN PROSTATIC HYPERPLASIA

GENERAL

Patient is in no acute distress unless he has severe complications of the BPH.

SYMPTOMS

Urinary frequency, urgency, intermittency, nocturia, decreased force of stream, hesitancy, and straining

SIGNS

Digital rectal examination reveals an enlarged prostate (>20 g)

LABORATORY TESTS

Increased BUN and serum creatinine, elevated PSA

OTHER DIAGNOSTIC TESTS

Increased AUA Symptom Score and decreased urinary flow rate (<10 mL/s), and increased postvoid residual urine volume

Obstructive symptoms, also known as prostatism or bladder outlet obstruction, result when dynamic and/or static factors reduce bladder emptying. The force of the urinary stream becomes diminished, urinary flow rate decreases, and bladder emptying is incomplete or takes a longer time. Patients report urinary hesitancy and straining and a weak urine stream. Urine dribbles out of their penis, and their bladder always feels full, even after they have voided. Some patients state that they need to press on their bladder to force urine out. In severe cases, patients may go into urinary retention when bladder

emptying is not possible. In these cases, suprapubic pain can result from bladder overdistension.

About 50% to 80% of patients have irritative voiding symptoms, which typically occur late in the disease course. Irritative voiding symptoms result from long-standing obstruction at the bladder neck. To compensate, the bladder muscle undergoes hypertrophy so that it can generate a greater contractile force to empty urine past the anatomic obstruction at the bladder neck. Although initially helpful, decompensation eventually occurs, and the hypertrophied bladder muscle is no longer able to generate adequate contractile force, as it becomes hypersensitive and ineffective in storing urine. As a result, small amounts of urine irritate the bladder and initiate a bladder emptying response. Patients complain of urinary frequency and urgency. Bedwetting or clothes wetting occurs. Patients report waking up every 1 to 2 hours at night to void (nocturia), which significantly reduces quality of life.

Symptoms of BPH vary over time. Symptoms may improve, remain stable, or worsen spontaneously. Thus BPH is not necessarily a progressive disease; in fact, some patients experience symptom regression. Between one-third and two-thirds of men with mild disease stabilize or improve without treatment over 2.5 to 5 years.^{6,7} However, other patients experience a slow progression of disease.

Obstructive and irritative voiding symptoms are collectively referred to as lower urinary tract symptoms (LUTS). However, LUTS are not pathognomonic for BPH and LUTS may be caused by other diseases.⁸

Another characteristic of BPH is that some men suffer from silent prostatism. While they have obstructive or irritative voiding symptoms, they adapt to them and do not voluntarily complain about them. Such patients do not present for medical treatment until complications of BPH disease arise.

Complications of untreated BPH include:

- Chronic renal failure from long-standing bladder outlet obstruction
- Gross hematuria when tissue growth exceeds its blood supply
- Overflow urinary incontinence or unstable bladder
- Recurrent urinary tract infection that results from urinary stasis
- Bladder diverticula
- Bladder stones

All of these complications can be potentially serious and life-threatening. Approximately 20% of patients with symptomatic BPH require treatment because of disease complications.⁵ Symptoms, signs, and complications of BPH (both obstructive and irritative voiding symptoms, decreasing peak urinary flow rate, and acute urinary retention) generally worsen in severity over time, with symptom severity greatest in older men. Prostate size also increases with age, at a rate approximating 0.6 g/y. Older men with prostates greater than 40 g were three times as likely to have severe symptoms or suffer from acute urinary retention, and require prostatectomy.^{9–11}

DIAGNOSTIC EVALUATION

Because the common obstructive and irritative voiding symptoms associated with BPH are not unique to the disease and can be presenting symptoms of other genitourinary tract disorders, including prostate or bladder cancer, neurogenic bladder, prostatic calculi, or urinary tract infection, the patient presenting with signs and symptoms of BPH must be thoroughly evaluated.

A careful medical history should be taken to ensure that a complete listing of symptoms is collected, as well as to identify concomitant disorders that may be contributing to voiding symptoms. The medical history should be followed by a thorough medication history, including all prescription and nonprescription medications and dietary supplements that the patient is taking. Any drugs that could be causing the patient's symptoms should be identified. If possible, the suspected drugs should be discontinued or the dosing regimen modified to ameliorate the voiding symptoms.

The patient should also undergo a physical examination, including a digital rectal examination, although the size of the prostate gland does not always correspond to symptoms. BPH usually presents as an enlarged, soft, smooth, symmetric gland, greater than 20 g in size. Some patients have only a slightly enlarged gland and yet have bothersome or even serious voiding difficulties, usually the result of dynamic factors. Other patients have an intravesical enlargement of the prostate gland (i.e., the gland grows into the urinary bladder and produces a ball-valve blockage of the bladder neck). This type of prostate enlargement is not palpable on manual examination.

The patient's perception of the severity of BPH symptoms guides development of a therapeutic plan. To evaluate perceptions objectively, validated instruments, such as the American Urological Association (AUA) Symptom Index, are commonly used. Using the AUA index, the patient rates the "bothersomeness" of seven obstructive and irritative voiding symptoms.^{2,9,12} Each item is rated for severity on a scale of 1 to 5 such that 35 is the maximum score and is consistent with the most severe symptoms.

Objective measures of bladder emptying include peak and average urinary flow rate (normal is at least 10 to 15 mL/s). This is determined using a uroflowmeter, which literally checks the rate of urine flow out of the bladder. This is a quick noninvasive outpatient procedure in which the patient's urinary flow is clocked during voiding. A low urinary flow rate implies failure of bladder emptying, but the degree of bladder outlet obstruction correlates poorly with peak urinary flow rate.

Another objective measure is postvoid residual (PVR) urine volume (normal is 0 mL). This is a simple outpatient procedure and is determined after the patient has attempted to empty his bladder. A straight catheter is inserted to drain any urine remaining in the bladder. A high PVR urine volume (more than 25 to 30 mL) implies failure of bladder emptying and a predisposition for urinary tract infections. Because there is a weak correlation among voiding symptoms, prostate size, and urinary flow rate, most physicians use a combination of measures, including the patient's assessment of symptoms along with objective evaluation of urinary outflow and presence of complications of BPH, to determine the need for treatment.

Clinical laboratory tests can also be helpful in evaluating the patient with possible BPH. Elevated serum blood urea nitrogen (BUN) and creatinine values can indicate development of renal insufficiency caused by long-standing bladder outlet obstruction. Abnormal urinalysis results may be caused by hematuria or urinary tract infection, which can cause voiding symptoms. Prostate-specific antigen (PSA) is used in combination with digital rectal examination of the prostate to screen for prostate cancer, which can also cause voiding difficulty.

Many other tests can be performed if additional information is needed to assess the severity of BPH disease and its complications, or assist in the preoperative assessment of the patient, including a voiding cystometrogram, transrectal ultrasound of the prostate, intravenous pyelogram, renal ultrasound, and prostate biopsy.

► TREATMENT: Benign Prostatic Hyperplasia

As a disease of symptoms, BPH is treated by relieving manifestations that are bothering the patient. Patients are usually stratified into three severity groups for assessing the need for treatment (Table 82–2). However, recent literature about the natural history of BPH and the significant risk of disease complications suggests that physicians should also consider prevention of serious complications of BPH as a goal of treatment in selected patients. This is a controversial topic, which is complicated by many issues, including the variable costs of treatment options, the inability to clearly distinguish patients who experience spontaneous regression or disease stabilization from those in whom symptoms progress, and the potential benefit that may occur in a comparatively small number of treated patients.

Management options include watchful waiting, drug treatment, or surgical intervention. The most definitive recommendation for BPH treatment is the 2003 American Urological Association Guideline on Management of BPH (Fig. 82–2).¹³ This guideline supersedes the older 1994 Guideline on BPH: Diagnosis and Treatment published by the Agency for Health Care Policy and Research.¹² The primary change in the 2003 Guideline is that treatment selection should be based on the patient’s perception of the bothersomeness of symptoms, which may not correlate with the AUA Symptom Index Score, but may be more related to the patient’s perception of the impact of LUTS on their quality of life.^{13,14}

■ NONPHARMACOLOGIC THERAPY

4 **5** Patients with mild disease are asymptomatic or have mildly bothersome symptoms and have no complications of BPH disease. In these patients, no specific treatment is indicated. These patients can be managed with “watchful waiting,” which entails having the patient return for reassessment at regular 6- to 12-month intervals.

At each return visit, the patient should complete a standardized, validated survey tool to assess severity of symptoms. A digital rectal examination, urinary flow rate, postvoid residual urine volume, and routine laboratory tests (BUN and serum creatinine)

TABLE 82–2. Categories of BPH Disease Severity Based on Symptoms and Signs

| Disease Severity | AUA Symptom Score | Typical Symptoms and Signs |
|------------------|-------------------|--|
| Mild | ≤7 | Asymptomatic Peak urinary flow rate <10 mL/s Postvoid residual urine volume >25–50 mL |
| Moderate | 8–19 | Increased BUN and serum creatinine All of the above signs plus obstructive voiding symptoms and irritative voiding symptoms (signs of detrusor instability) |
| Severe | ≥20 | All of the above plus one or more complications of BPH |

AUA, American Urological Association; BUN, blood urea nitrogen.

should be obtained. Watchful waiting also includes thorough patient education about the disease and behavior modification to avoid practices that exacerbate voiding symptoms. Behavior modification includes fluid restriction close to bedtime, avoiding caffeine and alcohol intake, frequent emptying of the bladder during waking hours (to avoid overflow incontinence and urgency), and avoiding drugs that could exacerbate voiding symptoms.

If symptoms progress to moderate or severe severity or the patient perceives his symptoms to be bothersome, the patient should be offered specific treatment. In these patients, watchful waiting delays—but does not decrease—the need for prostatectomy. In symptomatic patients, watchful waiting can lead to intractable urinary retention, increased PVR urine volumes, and significant voiding symptoms. Therefore watchful waiting is not recommended for symptomatic patients.¹⁵ For patients with BPH of moderate or severe severity, treatment options include drug therapy and surgery.

6 Patients with serious complications of BPH should be offered surgical correction (i.e., prostatectomy). Drug therapy is considered an interim measure in such patients, as it likely only delays worsening of complications and the need for surgical intervention.¹⁵

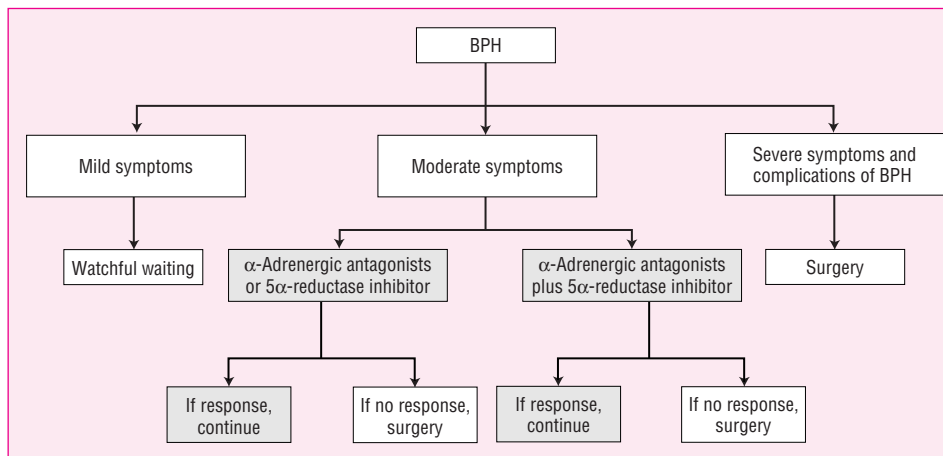

FIGURE 82–2. Management algorithm for benign prostatic hyperplasia.

TABLE 82–3. Summary of Medical Treatment Options for BPH

| Category | Mechanism | Drug (Brand Name) | Daily Dose |
|------------------------|--|---|--|
| Reduces static factor | Blocks 5 α -reductase enzyme | Finasteride (Proscar) | 5 mg by mouth daily |
| | | Dutasteride (Avodart) | 0.5 mg by mouth daily |
| | Blocks dihydrotestosterone at its intracellular receptor | Bicalutamide (Casodex) | 50 mg by mouth daily |
| | | Flutamide (Eulexin) | 100–250 mg by mouth three times daily |
| | Blocks pituitary release of luteinizing hormone | Leuprolide (Lupron) | 7.5 mg intramuscularly monthly or 22.5 mg intramuscularly every 3 months |
| Nafarelin | | 400 mcg subcutaneously daily | |
| Reduces dynamic factor | Blocks pituitary release of luteinizing hormone and blocks androgen receptor | Megestrol acetate | 40–250 mg by mouth three times daily |
| | | Blocks α_1 -adrenergic receptors in prostatic stromal tissue | Prazosin (Minipress) |
| | Alfuzosin (UroXatral) | | 10 mg by mouth daily |
| | Terazosin (Hytrin) | | 1–10 mg by mouth daily |
| | Blocks α_{1A} receptors in the prostate | Doxazosin (Cardura) | 1–8 mg by mouth daily |
| Tamsulosin (Flomax) | | 0.4–0.8 mg by mouth daily | |

PHARMACOLOGIC THERAPY

Drug therapy for BPH can be categorized into three types: agents that interfere with testosterone's stimulatory effect on prostate gland enlargement (reducing the static factor), agents that relax prostatic smooth muscle (reducing the dynamic factor; Table 82–3), and combination therapy with a 5 α -reductase inhibitor plus an α_1 -adrenergic antagonist. Of the agents that interfere with testosterone's stimulatory effect on prostate gland size, the only agents approved by the U.S. Food and Drug Administration (FDA) are 5 α -reductase inhibitors (e.g., finasteride or dutasteride). Other agents that interfere with androgen stimulation of the prostate have not been popular in the United States because of the many adverse effects associated with their use. The luteinizing hormone-releasing hormone superagonists leuprolide and goserelin produce decreased libido, erectile dysfunction, gynecomastia, and hot flashes. Antiandrogens (e.g., bicalutamide and flutamide) produce nausea, diarrhea, and hepatotoxicity.¹⁶

Of the agents that relax prostatic smooth muscle, second- and third-generation α_1 -adrenergic antagonists have been most widely used. These agents relax the intrinsic urethral sphincter and prostatic smooth muscle, thereby enhancing urinary outflow from the bladder. α_1 -Adrenergic antagonists do not reduce prostate size.

Selection of a particular agent for a patient should be determined on a case-by-case basis after a patient-provider discussion of risks, benefits, and costs of various treatments. With drug therapy for BPH, patients must understand that the benefits continue only as long as the medication is taken.¹⁶

Drug therapy should be initiated with a single agent, usually with an α_1 -adrenergic antagonist, which is faster acting and more effective than 5 α -reductase inhibitors. In addition, α_1 -adrenergic antagonists are effective in reducing LUTS independent of prostate size, have no effect on serum levels of prostate-specific antigen (a tumor marker for prostate cancer), and are associated with less sexual dysfunction than 5 α -reductase inhibitors. A 5 α -reductase inhibitor is a good first choice agent in patients with a significantly enlarged

prostate, greater than 40 g, who cannot tolerate the cardiovascular adverse effects of α_1 -adrenergic antagonists. If a therapeutic dose regimen of a single drug fails, combination drug therapy with a 5 α -reductase inhibitor and an α -adrenergic antagonist could be attempted in patients with an enlarged prostate gland that is greater than 40 g,^{17,18} and an elevated serum prostate-specific antigen level (> 1.3 ng/mL).¹⁹ The rationale for such a combination is that using two drugs with different mechanisms of action can be pharmacologically beneficial. Combination regimens that have been clinically evaluated include terazosin plus finasteride,²⁰ and doxazosin plus finasteride.¹⁸ It should be noted that combination therapy is more expensive and has more adverse effects than monotherapy regimens. Alternatively, surgery is a choice. Finally, any severely symptomatic patient with BPH disease complications should undergo surgical correction.¹³

5 α -REDUCTASE INHIBITORS

As described earlier in the section on normal prostate physiology, two types of 5 α -reductase enzyme exist (see Table 82–1). Finasteride competitively inhibits type II 5 α -reductase, suppresses intraprostatic DHT by 80% to 90%, and decreases serum DHT levels by 70%. Dutasteride is a nonselective inhibitor of type I and II 5 α -reductase. It more quickly and completely suppresses intraprostatic DHT production and decreases serum DHT levels by 90%.²¹ However, it is not known if these pharmacodynamic actions of dutasteride result in clinical advantages over finasteride. These agents are indicated for management of moderate to severe BPH disease. In patients with severe disease, these agents generally must be used with urethral catheterization because of their slow onset (i.e., these agents take 6 months to maximally shrink an enlarged prostate gland).

Ideal patients for 5 α -reductase inhibitors are those with enlarged prostate glands of at least 50 g in size.^{21,22} In such patients, 5 α -reductase inhibitors may slow disease progression and decrease the risk of disease complications, thereby decreasing the ultimate need for surgical intervention.²³ When taken continuously for 4 years,

finasteride has been shown to decrease the risk of acute urinary retention and prostatectomy.²³ 5 α -Reductase inhibitors may also be preferred in patients with BPH who have uncontrolled arrhythmias, poorly controlled angina, patients taking multiple antihypertensive agents, or those unable to tolerate hypotensive adverse effects of second-generation α_1 -adrenergic antagonists.

5 α -Reductase inhibitors reduce prostate size by 25%, increase peak urinary flow rate by 1.6 to 2.0 mL/s, improve voiding symptoms in approximately 30% of treated patients, and produce very few serious adverse effects. Compared to α_1 -antagonists, 5 α -reductase inhibitors have several disadvantages. 5 α -Reductase inhibitors have a delayed onset of action, which is undesirable in patients with bothersome symptoms, and an adequate clinical trial is 6 to 12 months. In addition, the percentage of patients who experience objective improvement is less with 5 α -reductase inhibitors than with α_1 -adrenergic antagonists. Finally, 5 α -reductase inhibitors cause more sexual dysfunction than α -adrenergic antagonists. Therefore physicians consider 5 α -reductase inhibitors to be second-line agents for treatment of BPH.^{23–26}

CLINICAL CONTROVERSY

Dutasteride is a nonselective 5 α -reductase inhibitor that more quickly and effectively lowers intraprostatic DHT production and lowers plasma DHT levels than finasteride. Whether these hormonal changes result in clinical advantages remains to be determined.³⁷

Finasteride is well absorbed from the gastrointestinal tract (95%), and its absorption is unaffected by food. Peak serum concentrations are reached 1 to 2 hours after the dose. Finasteride is highly protein bound. The liver extensively metabolizes finasteride to inactive metabolites, which are largely excreted in stool. The plasma half-life is 4.7 to 7.1 hours, but its biologic half-life is probably longer, because decreased serum DHT levels persist for up to 2 weeks after finasteride dosing is stopped.²⁷

For BPH, finasteride is given in doses of 5 mg by mouth daily for at least 6 to 12 months. The dose can be taken with meals or on an empty stomach, and no dosage adjustment is needed in patients with renal dysfunction. Although no dosage reduction is recommended in patients with hepatic insufficiency, patients should be monitored carefully. Maximal reductions in prostate volume or symptom improvement may not be evident for 12 months, but noticeable changes from baseline should occur after 6 months of continuous treatment. No clinically relevant drug interactions have been reported with 5 α -reductase inhibitors.

Patients must continue to take 5 α -reductase inhibitors as long as they respond. Upon discontinuation of the drug, prostate size and voiding symptoms generally return to baseline.

5 α -Reductase inhibitors have few adverse effects. Ejaculation disorders (dry sex or delayed ejaculation) have been reported in 3% to 15% of treated patients. A possible result of decreased prostatic secretion, these disorders are reversible with drug discontinuation.

Erectile dysfunction has been reported in 3% to 5% of patients.¹⁶ It may be secondary to ejaculation disorders, or may be due to drug-induced inhibition of nitric oxide synthase (which is needed for producing nitric oxide, a vasodilatory substance) in cavernosal tissue.²⁸ The role of 5 α -reductase inhibitors in causing erectile dysfunction is not clear, as elderly men with BPH commonly develop erectile dysfunction as they age, or have concurrent medical illnesses or concomitant drug therapies that may predispose to the development of sexual dysfunction.²⁹

Other minor adverse effects include nausea, abdominal pain, asthenia, dizziness, flatulence, headache, rash, muscle weakness, and gynecomastia.

5 α -Reductase inhibitors are in FDA pregnancy category X, which means that they are contraindicated in pregnant females. Exposure of the fetus to finasteride may produce pseudohermaphroditic offspring with ambiguous genitalia, similar to those of patients with a rare genetic deficiency of type II 5 α -reductase. Because of this teratogenic effect, women who are pregnant or seeking to become pregnant should not handle 5 α -reductase inhibitor tablets and should not have contact with semen from men being treated with 5 α -reductase inhibitors. Women pharmacists of childbearing age should handle this product with rubber gloves if there is any chance that they are pregnant.

Normal doses of 5 α -reductase inhibitors reduce serum PSA levels by 50%. For this reason, PSA levels must be measured before treatment begins, and the patient should have a digital rectal examination. After 6 months of therapy, the patient should have a repeat PSA. If the level does not decline by 50% and the patient has been adherent to the 5 α -reductase inhibitor regimen, he should be evaluated for prostate cancer. Annually thereafter, the patient should have a PSA assay and digital rectal examination, and patients with any rise in PSA levels should be evaluated for prostate cancer.³⁰ To interpret a PSA level in a patient being treated with a 5 α -reductase inhibitor, it is generally recommended that the actual measured level be doubled to get an estimate of the true level.

CLINICAL CONTROVERSY

5 α -Reductase inhibitors have been shown to delay disease progression, which is linked to shrinkage of an enlarged prostate gland. This benefit of treatment remains to be demonstrated for α -adrenergic antagonists.³⁷

α -ADRENERGIC ANTAGONISTS

Three generations of α -adrenergic antagonists have been used to treat BPH through their relaxation of smooth muscle in the prostate and bladder neck. Because of their dose-limiting adverse effects on the heart (tachycardia and arrhythmias), first-generation agents such as phenoxybenzamine have been replaced by the second-generation postsynaptic α_1 -adrenergic antagonists and third-generation uroselective postsynaptic α_{1A} -adrenergic antagonists.³¹

The second- and third-generation α_1 -adrenergic antagonists are considered to be equally effective for BPH. These agents generally increase urinary flow rates by 2 to 3 mL/s in 60% to 70% of treated patients, and reduce postvoid residual urine volume. They have no effect on decreasing prostate volume. Terazosin and tamsulosin produce durable responses for 3 to 4 years, provided that the patient continues to take the drug.^{32,33} A preliminary study of alfuzosin has showed that α -adrenergic antagonists may lower the incidence of acute urinary retention.³⁴ Finally, α -adrenergic antagonists do not reduce PSA levels, preserving the utility of this prostate cancer marker in this high-risk population.³⁵

Second-generation agents include prazosin, terazosin, doxazosin, and alfuzosin. These differ in terms of duration of action and dosing schedule. Whereas prazosin requires dosing two to three times a day, terazosin, doxazosin, and alfuzosin offer more convenient once-daily dosing. Prazosin, terazosin, and doxazosin antagonize peripheral vascular α_1 -adrenergic receptors, in addition to those in the prostate, at the usual doses used to treat BPH. As a result, first-dose syncope, orthostatic hypotension, and dizziness are

TABLE 82-4. Dosing Schedule of α -Adrenergic Antagonists in Patients with BPH

| Drug | Half-Life (h) | Usual Daily Dosage | Time to Peak Effect on BPH Symptoms ^a |
|-----------------------|---------------|---------------------------------------|--|
| Prazosin (Minipress) | 2–3 | 2–10 mg in two to three divided doses | 2–4 weeks |
| Terazosin (Hytrin) | 12 | 1–10 mg as a single dose; max 20 mg | 2–4 weeks |
| Doxazosin (Cardura) | 19–22 | 1–4 mg as a single dose; max 8 mg | 2–4 weeks |
| Alfuzosin (UroXatral) | | 10 mg as a single dose | |
| Tamsulosin (Flomax) | 14–15 | 0.4–0.8 mg as a single dose | 1 day |

^aTime to peak effect on BPH symptoms is dependent on the titration period to full therapeutic doses.

This table is adapted with permission from Lee M, Sharifi R. Benign prostatic hyperplasia: Diagnosis and treatment guideline. *Ann Pharmacother* 1997;31:481–486.

characteristic adverse effects. To improve tolerance to these adverse effects, it is recommended that patients be started with a low dose of 1 mg daily, and slowly titrated up to a full therapeutic dose over several weeks. Additive blood pressure lowering effects commonly occur when these agents are used along with antihypertensive agents, which limits use of these agents in some patients. Because prazosin requires twice- to thrice-daily dosing and has significant cardiovascular adverse effects, it is not recommended in the current American Urological Association Guidelines for treatment of BPH.¹³ Finally, it should be noted that an α -adrenergic antagonist is not preferred as single-drug therapy in patients with BPH and hypertension. In one study of men with hypertension, doxazosin produced more congestive heart failure than other antihypertensives.^{36,37} Thus it is recommended that in patients with BPH and hypertension that appropriate and separate drug treatment be initiated for each medical condition.

Alfuzosin is considered to be functionally and clinically uroselective in that usual doses used to treat BPH are less likely than other second-generation agents to cause cardiovascular adverse effects in animal or human models.³⁶ This clinical observation has more often been seen with the once-daily, extended-release formulation of alfuzosin, which is the only commercially available formulation in the United States, as compared to the immediate-release formulation that is dosed three times a day that is available in Europe.^{37,38} It has been postulated that this may be due to higher concentrations of alfuzosin achieved in the prostate versus serum after usual doses,³⁹ decreased blood-brain barrier penetration of alfuzosin,¹⁶ and the absence of high peak serum levels with the extended-release formulation.⁴⁰ Extended-release alfuzosin dosing is FDA-approved for 10 mg daily, with no titration increase.^{41–43} This is convenient for physician prescribers and patients who are started on the medication.

Tamsulosin is the only third-generation α_{1A} -adrenergic antagonist available in the United States. It represents an advance over second-generation agents in that it is selective for prostatic α_{1A} -receptors, which comprise approximately 70% of the adrenergic receptors in the prostate gland.^{44,45} Blockade of these receptors results in smooth-muscle relaxation of the prostate and bladder neck without causing peripheral vascular smooth-muscle relaxation. Tamsulosin has low affinity for vascular α_{1B} -receptors, which explains why hypotension is not a common adverse effect and why the agent has not been studied as a therapy for hypertension.

Tamsulosin's selectivity for α_{1A} -receptors has multiple implications. Dose titration is minimal; therefore patients can begin therapy with the lowest effective maintenance dose, 0.4 mg orally once a day. Patients can be instructed to take the dose anytime during the day, unlike terazosin and doxazosin, which should be taken at bedtime. For best effect, tamsulosin should be taken on an empty stomach, as food decreases its bioavailability. The onset of peak action is quicker, in the range of 2 weeks, because only a minority of patients will

require a higher daily dose. No decreases in blood pressure or increases in heart rate have been reported in normotensive patients, subgroups of patients with well-controlled hypertension, or those with uncontrolled hypertension.^{46,47} Thus tamsulosin allows initiation of treatment with a therapeutic dose that is not limited by cardiovascular adverse effects, unlike terazosin and doxazosin.^{48–52} Finally, the addition of tamsulosin to selected antihypertensive regimens of patients does not result in potentiation of the hypotensive effect of furosemide, enalapril, nifedipine, and atenolol.⁵³ Therefore tamsulosin represents a good choice, particularly when patients cannot tolerate hypotension; have severe coronary artery disease, volume depletion, cardiac arrhythmias, severe orthostasis, or liver failure; are taking multiple antihypertensives; or when the titration would be too complicated for the patient or produce an unacceptable delay in onset for a particular patient.

A summary of the usual doses of α -adrenergic antagonists is included in Table 82-4.

When using the second-generation α_1 -adrenergic antagonists terazosin or doxazosin, slow titration up to a therapeutic maintenance dose is necessary to minimize orthostatic hypotension and first-dose syncope. Conservatively, dosage increases should be done in an orderly stepwise process, with dosage increases occurring at 2- to 7-day intervals, depending on the patient's response to the medication. A faster titration schedule can be used as long as the patient does not develop orthostatic hypotension or dizziness. Two sample titration schedules for terazosin are described here:

- Schedule 1: Slow titration
 - Days 1 to 3: 1 mg at bedtime
 - Days 4 to 14: 2 mg at bedtime
 - Weeks 2 to 6: 5 mg at bedtime
 - Weeks 7 and on: 10 mg at bedtime
- Schedule 2: Quicker titration
 - Days 1 to 3: 1 mg at bedtime
 - Days 4 to 14: 2 mg at bedtime
 - Weeks 2 to 3: 5 mg at bedtime
 - Weeks 4 and on: 10 mg at bedtime

Patients should continue taking the drug as long as they continue to respond to it. If BPH symptoms worsen, the patient should see his physician for a dosage increase or discuss an alternative form of treatment.

No dosage adjustments are recommended for α_1 -adrenergic antagonists in patients with renal failure. Because these drugs are hepatically catabolized, the lowest effective dose should be used in patients with hepatic dysfunction, and patients should be monitored carefully for adverse effects. No specific dosing guidelines are yet available in this patient population.⁵¹

Approximately 10% to 12% of patients discontinue second-generation α_1 -adrenergic antagonists because of adverse effects, especially those affecting the cardiovascular system (e.g., syncope, dizziness, and hypotension).⁵⁴

Patients who tolerate hypotension poorly should avoid second-generation α_1 -adrenergic antagonists. This includes patients with poorly controlled angina, serious cardiac arrhythmias, patients with reduced circulating volume, and patients on multiple antihypertensives.⁵² These patients are candidates for tamsulosin or finasteride, if drug therapy is deemed necessary. Whether extended-release alfuzosin is also a good choice remains to be elucidated in controlled comparison trials with tamsulosin.

Tiredness and asthenia, ejaculatory dysfunction, flu-like symptoms, and nasal congestion are the most common adverse effects of tamsulosin. These adverse effects are unavoidable, but by properly educating the patient, they should not lead to discontinuation of treatment.

Caution is needed when cimetidine or diltiazem is used with tamsulosin or other α -adrenergic antagonists, as a drug-drug interaction leads to decreased metabolism of the latter agents. In contrast, carbamazepine and phenytoin may increase hepatic catabolism of α -adrenergic antagonists.

Sildenafil, vardenafil, and tadalafil may produce systemic hypotension if used in large doses. Therefore package labeling for these drugs includes a warning to avoid α -adrenergic antagonists for 4 hours after taking a dose of one of these phosphodiesterase inhibitors.

CLINICAL CONTROVERSY

Among the α -adrenergic antagonists, tamsulosin and extended-release alfuzosin have been associated with the highest and lowest incidences of ejaculatory dysfunction, respectively. Although some clinicians claim that this difference should be considered when selecting one agent over another, this adverse effect is of variable clinical significance. Some patients may complain of decreased sexual satisfaction because of ejaculatory dysfunction, whereas other patients will not.

COMBINATION THERAPY

Combination therapy with a 5α -reductase inhibitor and an α_1 -adrenergic antagonist is ideal in patients with severe symptoms, who also have an enlarged prostate gland of at least 40 to 50 g and an increased PSA level.¹³ A regimen of finasteride and doxazosin for 5 years was shown to prevent symptom progression and decrease the risk of developing acute urinary retention, urinary tract infection, and the need for prostate surgery.⁵⁵ Although not proven by direct comparison trials, it is probable that any combination of 5α -reductase inhibitor and α_1 -adrenergic antagonist is similarly effective.¹³ The disadvantages of a combination regimen include increased cost to the patient and increased incidence of adverse drug effects.

SURGICAL INTERVENTION

 The gold standard for treatment of patients with complications of BPH is prostatectomy performed either transurethral or suprapubically.^{15,56} Surgical intervention is also used in patients who are not responsive to drug therapy, those who are noncompliant with

drug therapy, or those who prefer surgical intervention. Surgical removal of the prostate offers the highest rate of symptom improvement, but it also has the highest complication rate.

With transurethral resection of the prostate (TURP), an endoscopic resectoscope inserted through the urethra is used to remove the inside core of the prostate. This enlarges the urethral opening at the bladder neck. TURP is performed only in men with enlarged prostates that are less than 50 g so that the resection can be completed in less than 1 hour. Often performed as outpatient surgery, this procedure produces on average a peak urinary flow increase of 125% and improvement of voiding symptoms by almost 90% in approximately 90% of patients.⁶ A common complication of TURP is retrograde ejaculation, occurring in up to 75% of patients. Significant bleeding, urinary incontinence, and erectile dysfunction occur in smaller but significant numbers of patients (2% to 15%).^{57,58} Approximately 12% to 15% of patients require second surgeries within 8 years.⁵⁶

Men with larger prostates (>50 g) require an open surgical procedure (open prostatectomy), which can be performed retro- or suprapubically. This necessitates hospitalization for at least a few days, anesthesia, and a longer recuperation time. Adverse effects of open prostatectomy include bleeding, urinary and soft tissue infection, retrograde ejaculation in 77% of patients, erectile dysfunction in 16% to 33% of patients, and urinary incontinence in 2% of patients. The reoperation rate is 3% to 5% at 10 years.⁵⁶

Prostatectomy is ineffective for relieving irritative voiding symptoms of BPH because prostatectomy does not affect the detrusor muscle of the bladder.⁵⁹ These patients may respond to oral anticholinergic agents (e.g., oxybutynin or L-hyoscyamine), which improve bladder compliance and decrease detrusor muscle irritability, as discussed in Chap. 83.

A new trend in surgical treatment is use of less invasive or minimally invasive outpatient surgical procedures to remove excessive prostate tissue.⁶ These procedures use an energy source, (e.g., heat, cold, or laser) to eliminate excessive prostate tissue, characteristically are short (lasting minutes), have a lower potential to produce adverse effects, are less expensive than continuous drug therapy lasting years, and may be particularly useful in debilitated patients. One significant disadvantage of all minimally invasive surgical procedures is that many patients may require retreatment after an initial improvement in symptoms.⁶⁰ Of the procedures available, only transurethral incision of the prostate (TUIP) has been thoroughly evaluated. This procedure is ideal for patients with moderate or severe BPH symptoms who have an enlarged prostate gland less than 30 g in size. TUIP is as effective as TURP, but requires less operation time, causes less blood loss, and produces fewer adverse effects.^{61,62} TUIP involves making two to three incisions at the bladder neck to widen the opening. These incisions are made using an endoscopic resectoscope.

Other minimally invasive surgical procedures include visual laser ablation of the prostate (VLAP), transurethral electrovaporization of the prostate (TUVP), transurethral needle ablation of the prostate (TUNA), and transurethral microwave thermotherapy of the prostate (TUMT).^{8,63}

PHYTOTHERAPY

 Although phytotherapy is widely used in Europe for the management of BPH, the published data on herbal agents are largely inconclusive and conflicting. Studies often lack placebo controls, which are essential in assessing treatments for BPH because spontaneous regression of symptoms can occur. Furthermore, as these agents are

marketed under the Dietary Supplements Health and Education Act, their efficacy, safety, and quality are not regulated by the FDA. For these reasons, herbal products—including saw palmetto berry

(*Serenoa repens*),^{64–67} stinging nettle (*Urtica dioica*),⁶⁸ and African plum (*Pygeum africanum*)⁶⁹—are not recommended for BPH.¹³ An excellent review on phytotherapy for BPH has been published.⁷⁰

EVALUATION OF THERAPEUTIC OUTCOMES

The primary therapeutic outcome of BPH therapy is restoration of adequate urinary flow without adverse effects. As a disease in which therapy is directed at those symptoms the patient finds most bothersome, assessment of outcomes likewise depends on how the patient perceives the effectiveness and acceptability of therapy. Use of a validated, standardized instrument, such as the AUA Symptom Index, for assessing patient quality of life is important in this process.^{2,9,12,13}

In patients being treated with pharmacotherapy, objective measures of bladder emptying are also useful at an appropriate time after drug therapy begins (6 to 12 months for 5 α -reductase inhibitors, 3 to 4 weeks after the start of α_1 -adrenergic antagonists). These include the uroflowmeter and PVR urine volume, as described in the section on diagnostic evaluation section in this chapter.

Key laboratory tests to monitor on an ongoing basis are serum BUN and creatinine and urinalysis. Because this patient population is at high risk for prostate cancer, PSA should be measured and a digital rectal examination performed annually. For patients taking 5 α -reductase inhibitors, PSA must be compared with baseline and 6-month responses, as described in the section on 5 α -reductase inhibitor.

SUMMARY

A ubiquitous disease of aging men, symptomatic BPH requires medical attention to preserve patient quality of life and avoid complications, many of which can be life-threatening in this patient population. In men who have no or minor symptoms, watchful waiting is the therapeutic option of choice, as BPH remains stable or even regresses in about one-half of these men.

For those with moderate to severe symptoms but no complications, pharmacotherapy is indicated. An α_1 -adrenergic antagonist is the agent of first choice. Second-generation agents including terazosin, doxazosin, or alfuzosin are also useful. Terazosin and

TABLE 82–5. Comparison of 5 α -Reductase Inhibitors and α -Adrenergic Antagonists

| | 5 α -Reductase Inhibitors | α -Adrenergic Antagonists |
|-------------------------------------|---|---|
| Decreases prostate size | Yes | No |
| Peak onset | 3–6 months | 1–6 weeks |
| Efficacy | ++ (in patients with enlarged prostates) | ++ |
| Frequency of dosing | Once a day | 1–2 times a day, depending on the agent |
| Decreases prostate-specific antigen | Yes | No |
| Sexual dysfunction | ++ | + |
| Cardiovascular adverse effects | No | Yes |

doxazosin cause more cardiovascular adverse effects than extended-release alfuzosin and tamsulosin. Whether extended-release alfuzosin is as well tolerated as tamsulosin in patients at risk of hypotension or hypotension-related morbidity remains to be elucidated. 5 α -Reductase inhibitors are preferred drug treatment in patients with enlarged prostates, who are likely to poorly tolerate the hypotensive adverse effects of α_1 adrenergic antagonists (Table 82–5). However, 5 α -reductase inhibitors have a slow onset of action. For patients who fail monotherapy, combination drug therapy could be attempted and such regimens have been found to be most effective in patients with enlarged prostates greater than 40 g. Alternatively, surgery is an option.

In patients who have complications of BPH, surgery is required. Although it has more adverse complications than does pharmacotherapy or watchful waiting, transurethral resection of the prostate is considered the gold standard.

URINARY INCONTINENCE

Eric S. Rovner, Jean Wyman, Thomas Lackner, and David Guay

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 In evaluating urinary incontinence, drug-induced or drug-aggravated etiologies must be ruled out.
- 2 Accurate diagnosis and classification of urinary incontinence type is critical to the selection of appropriate pharmacotherapy.
- 3 Nonpharmacologic therapy is the cornerstone of management of urinary incontinence, should be the first therapy initiated, and should be continued even if drug therapy must be initiated.
- 4 Anticholinergic/antispasmodic agents are the therapies of choice for bladder overactivity (urge incontinence).
- 5 Duloxetine (when approved for treatment of urinary incontinence), α -adrenergic receptor agonists, and topical (vaginal) estrogens (alone or together) are the therapies of choice in urethral underactivity (stress incontinence).
- 6 Patient-specific treatment goals should be identified. They are not static and may change over time. Choice of therapy may also be influenced by characteristics such as patient age, comorbidities, concurrent medications, and ability to adhere to the prescribed regimen. If therapeutic goals are not achieved with a given agent at optimal dosage, consider adding a second agent or switching to an alternative single agent.

Urinary incontinence (UI) is defined as the complaint of involuntary leakage of urine.¹ It is frequently accompanied by other bothersome lower urinary tract symptoms such as urgency, increased daytime frequency, and nocturia. It is a common yet underdetected and underreported health problem that can significantly affect quality of life. Patients with UI may have depression as a result of the perceived lack of self-control, loss of independence, and lack of self-esteem, and they often curtail their activities for fear of an “accident.” It may also have serious medical and economic ramifications for untreated or undertreated patients, including perineal dermatitis, worsening of pressure ulcers, urinary tract infections, and falls.

This chapter highlights the epidemiology, etiology, pathophysiology, and treatment of stress, urge, mixed, and overflow UI in men and women.

EPIDEMIOLOGY

Determining the true prevalence of UI is difficult because of problems with definition, reporting bias, and other methodologic issues.² Epidemiologic studies have not historically used a standard definition of the condition or a standard methodology for data recording, with some studies including “postvoid dribbling,” while other studies specify “urinary leakage causing a social or hygienic problem.” The number of people suffering with UI is certainly great, and the impact of this condition is substantial, crossing all racial, ethnic, and geographic boundaries. Compared with continent controls, patients with UI have an overall poorer quality of life.³ Several studies have objectively shown that UI is associated with reduced levels of social and personal activities, increased psychological distress, and overall

decreased quality of life as measured by numerous indices.^{4,5} The condition can affect people of all age groups but the peak incidence of UI, at least in women, appears to occur around the age of menopause, with a slight decrease in the age group 55 to 60 years, and then a steadily increasing prevalence after age 65.

One of the earliest comprehensive epidemiologic studies on UI was conducted by Diokno and colleagues using a standardized survey questionnaire.⁶ The Medical, Epidemiologic, and Social Aspects of Aging survey found that the prevalence of UI in noninstitutionalized women 60 years of age and older was approximately 38%. Almost one-third of those surveyed noted urine loss at least once weekly and 16% noted UI daily. A recent publication from a National Institutes of Health working group conference estimated the median level of UI prevalence to be approximately 20% to 30% during young adult life, with a broad peak around middle age (30% to 40% prevalence) which increases in the elderly (30% to 50% prevalence).⁷

In the United States, chronic UI is one of the most common reasons cited for institutionalization of the elderly, and the condition is frequently encountered in the nursing home setting.⁸ Little is known about the basic differences in clinical and epidemiologic characteristics of incontinence across racial or ethnic groups.

Some studies report a higher incidence of UI overall in white populations^{9,10} as compared to African-Americans, but differences in access to health care as well as cultural attitudes and mores may contribute to these differences.

Consistent across all studies in unselected, noninstitutionalized populations, is the fact that UI is at least half as common in men as in women.^{11,12} Overall, the prevalence of UI in men has been recently estimated to be about 9%.¹³ Unlike in women, the prevalence of UI in men increases with age across most studies, with the highest prevalence recorded in the oldest patient cohorts.¹³

ETIOLOGY AND PATHOPHYSIOLOGY

ANATOMY

The lower urinary tract consists of the bladder, urethra, urinary or urethral sphincter, and the surrounding musculofascial structures including connective tissue, nerves, and blood vessels. The urinary bladder is a hollow organ composed of smooth muscle and connective tissue located deep in the bony pelvis in men and women. The urethra is a hollow tube that acts as a conduit for urine flow out of the bladder. The interior surface of both the bladder and urethra is lined by an epithelial cell layer termed *transitional epithelium*, which is in constant contact with urine. Previously considered inert and inactive, transitional epithelium may actually play an active role in the pathophysiology of many lower urinary tract disorders, including interstitial cystitis and UI. The urinary or urethral sphincter is a combination of smooth and striated muscle within and surrounding the most proximal portion of the urethra adjacent to the bladder in both men and women. This is a functional but not anatomic sphincter that includes a portion of the bladder neck or outlet as well as the proximal urethra.

URINARY CONTINENCE

To prevent incontinence during the bladder filling and storage phase of the micturition cycle, the urethra, or more accurately the urethral sphincter, must maintain adequate resistance to the flow of urine from the bladder at all times until voluntary voiding is initiated. Urethral resistance or closure is maintained to a large degree by the proximal (under involuntary control) and distal (under both voluntary and involuntary control) urinary sphincters, a combination of smooth and striated muscles within and external to the urethra. Variable contributions to urethral resistance may also come from the urethral mucosa, submucosal spongy tissue, and the overall length of the urethra. During bladder filling and storage, the bladder accommodates increasing volumes of urine flowing in from the upper urinary tract without a significant increase in bladder (intravesical) pressure. In addition, bladder or detrusor smooth muscle activity is normally suppressed during the filling phase by centrally mediated neural reflexes. Normal bladder emptying occurs with a decrease in urethral resistance concomitant with a volitional bladder contraction. The bladder contraction occurs in a coordinated fashion, resulting in a rise in intravesical pressure. The rise in intravesical pressure is ideally of adequate magnitude and duration to empty the bladder to completion. A concomitant decrease in urethral resistance and funneling of the bladder outlet results in opening of the functional urinary sphincters and urine flow into the urethra until the bladder is emptied completely.

The primary motor input to the detrusor muscle of the bladder is along the pelvic nerves emanating from spinal cord segments S₂ to S₄. Parasympathetic impulses travel to the bladder along the efferent fibers of the pelvic nerves. The impulses pass through ganglia situated in the bladder wall before reaching their target. Acetylcholine appears to be the primary neurotransmitter at the neuromuscular junction in the human lower urinary tract. Both volitional and involuntary contractions of the detrusor muscle are mediated by activation of postsynaptic muscarinic receptors by acetylcholine. Of the five known subtypes of muscarinic receptors, bladder smooth-muscle cholinergic receptors are mainly of the M₂ variety. However, M₃ receptors are responsible for both the emptying contraction of normal micturition, as well as involuntary bladder contractions that may result in UI.¹⁴ Thus most pharmacologic antimuscarinic therapy is primarily anti-M₃-based (see discussion below).

The bladder and urethra normally operate in unison during the bladder filling and storage phase, as well as the bladder emptying phase of the micturition cycle. The smooth and striated muscles of the bladder and urethra are organized during the micturition cycle by a number of reflexes coordinated at the pontine micturition center in the midbrain. Disturbances in the neural regulation of micturition at any level (brain, spinal cord, or pelvic nerves) often lead to characteristic changes in lower urinary tract function that may result in UI.

MECHANISMS OF URINARY INCONTINENCE

Simply stated, UI may occur only as a result of abnormalities of the urethra (including the bladder outlet and urinary sphincter) or the bladder, or from a combination of abnormalities of both structures.¹⁵ Abnormalities may result in either overfunction or underfunction of the bladder and/or urethra with the resulting development of UI. While this simple classification scheme excludes extremely rare causes of UI such as congenital ectopic ureters and urinary fistulas, it is useful in gaining a working understanding of the condition.

Urethral Underactivity (Stress Urinary Incontinence)

Some patients characteristically note UI during exertional activities such as exercise, running, lifting, coughing, and sneezing. This implies that the compromised urethral sphincter is no longer able to resist the flow of urine from the bladder during periods of physical activity. In essence, increases in intra-abdominal pressure during physical activity are transmitted to the bladder (an intra-abdominal organ), compressing it and forcing urine through the weakened sphincter.

This type of UI is known as *stress urinary incontinence* (SUI). Although the exact etiology of urethral underactivity and SUI in the woman is incompletely understood, clearly identifiable risk factors include pregnancy, childbirth, menopause, cognitive impairment, obesity, and age.^{16,17} The prevalence of SUI in women appears to peak during or after the onset of menopause. This implies that hormonal factors are important in maintaining continence.

In men, SUI is most commonly the result of prior lower urinary tract surgery or injury, with resulting compromise of the sphincter mechanism within and external to the urethra. Radical prostatectomy for treatment of adenocarcinoma of the prostate is probably the most common setting in which surgical manipulation leads to UI. Overall, SUI in the male is uncommon, and in the absence of prior prostate surgery, severe trauma, or neurologic illness, is extraordinarily rare. Transurethral resection of the prostate for benign prostatic hyperplasia (see Chap. 82) may also lead to SUI in men.

Bladder Overactivity (Urge Urinary Incontinence)

Bladder overactivity—including bladder filling and urinary storage characterized by involuntary bladder contractions—is termed *urge urinary incontinence* (UUI). Symptoms of bladder overactivity occur because the detrusor muscle is overactive and contracts inappropriately during the filling phase.

The symptoms caused by the overactive bladder are typically urinary frequency, urgency, and urge incontinence. Frequency is defined as emptying the bladder more often than eight times per day. Urgency is described as a sudden, strong desire to urinate. People suffering from bladder overactivity typically have to empty their bladders frequently, and when they experience a sensation of urgency, they may leak urine if they are unable to reach the toilet quickly or if the sensation of urgency is very strong. Many patients may also have associated nocturia (>2 micturitions per night) and/or nocturnal incontinence (enuresis).

The amount of urine lost may be large, as the bladder may empty completely. Sleep may be disturbed, as the need to void may be experienced during the night. Nocturia and enuresis are often particularly disruptive.

Most patients with overactive bladder and UUI have no identifiable underlying etiology. In fact, the most common cause of bladder overactivity and UUI is “idiopathic.” Clearly identifiable risk factors for UUI include normal aging, neurologic disease (including stroke, Parkinson’s disease, multiple sclerosis, and spinal cord injury), and bladder outlet obstruction (e.g., due to benign prostatic hyperplasia [BPH] or prostate cancer).

The mechanism for bladder overactivity must be either neurogenic or myogenic. The neurogenic hypothesis ascribes the overactive bladder and UUI to disease-related changes within the central or peripheral nervous system.¹⁸ The myogenic hypothesis states that overactive bladder and UUI result from changes within the smooth muscle of the bladder wall itself.¹⁹ Precipitating factors such as bladder outlet obstruction can cause a partial denervation of smooth muscle, leading to a state of decreased responsiveness to activation of intrinsic nerves, but supersensitivity to contractile agonists and direct electrical activation.²⁰ However, in practice, UUI is difficult to categorize as either neurogenic or myogenic in origin, as these etiologies often seem to be interconnected and complementary.

Urethral Overactivity and/or Bladder Underactivity (Overflow Incontinence)

Overflow incontinence, the result of urethral overactivity and bladder underactivity, is an important but uncommon type of UI in both men and women. Overflow incontinence results when the bladder is filled to capacity at all times but is unable to empty, causing urine to leak from a distended bladder past a normal outlet and sphincter.

In the setting of urethral overactivity, the resistance to the flow of urine during volitional voiding is increased, resulting in functional or anatomic obstruction and incomplete bladder emptying. Common causes of urethral overactivity in men include BPH and prostate cancer. In women, urethral overactivity is rare, but may result from cystocele formation, or surgical overcorrection (iatrogenic obstruction) following anti-SUI surgery. In both sexes, overflow UI may be associated with systemic neurologic dysfunction or diseases, such as spinal cord injury or multiple sclerosis.

Bladder underactivity may also result in overflow incontinence. Under certain circumstances, the detrusor muscle of the bladder may become progressively weakened and eventually lose the ability to voluntarily contract. In the absence of adequate contractility, the bladder is unable to empty completely, and large volumes of residual urine

are left after micturition. Both myogenic and neurogenic factors have been implicated in producing the impaired contractility seen in this condition. Clinically, overflow incontinence is most commonly seen in the setting of long-term chronic bladder outlet obstruction in the male such as that due to BPH or prostate cancer.

Mixed Incontinence and Other Types of Urinary Incontinence

Various types of UI may coexist in the same patient. The combination of bladder overactivity and urethral underactivity is termed *mixed incontinence*. This is often a difficult diagnosis to make because of the often-confusing array of presenting symptoms. Bladder overactivity may also coexist with impaired bladder contractility. This is most common in the elderly and is termed *detrusor hyperactivity with impaired contractility*.²¹

Functional incontinence is not caused by bladder- or urethra-specific factors. Rather, in patients with conditions such as dementia or cognitive or mobility deficits, the UI is linked to the primary disease process more than any extrinsic or intrinsic deficit of the lower urinary tract. An example of functional incontinence occurs in the postoperative orthopedic surgery patient. Following extensive orthopedic reconstructions such as total hip arthroplasty, patients are often immobile secondary to pain or traction. Therefore the patient may be unable to access toileting facilities in a reasonable period of time and may become incontinent as a result. The treatment of this type of UI may involve only placing a urinal or commode at the bedside that allows for simplified access to toileting.

Finally, many localized or systemic illnesses may also result in UI because of their effects on the lower urinary tract or the surrounding structures, including:

- Dementia/delirium
- Depression
- Urinary tract infection (cystitis)
- Postmenopausal atrophic urethritis or vaginitis
- Diabetes mellitus
- Neurologic disease (e.g., stroke, Parkinson’s disease, multiple sclerosis, or spinal cord injury)
- Pelvic malignancy
- Constipation
- Congenital malformations

◀ Many commonly used medications may also precipitate or aggravate existing voiding dysfunction and UI (Table 83–1).

TABLE 83–1. Medications Influencing Lower Urinary Tract Function

| Medication | Effect |
|--|---|
| Diuretics | Polyuria, frequency, urgency |
| α-Receptor antagonists | Urethral relaxation and stress urinary incontinence in women |
| α-Receptor agonists | Urethral constriction and urinary retention in men |
| Calcium channel blockers | Urinary retention |
| Narcotic analgesics | Urinary retention from impaired contractility |
| Sedative hypnotics | Functional incontinence caused by delirium, immobility |
| Antipsychotics | Anticholinergic effects and urinary retention |
| Anticholinergics | Urinary retention |
| Antidepressants, tricyclic | Anticholinergic effects, α-antagonist effects |
| Alcohol | Polyuria, frequency, urgency, sedation, delirium |
| Angiotensin-converting enzyme inhibitors (ACEIs) | Cough as a result of ACEIs may aggravate stress urinary incontinence by increasing intra-abdominal pressure |

CLINICAL PRESENTATION

CLINICAL PRESENTATION OF URINARY INCONTINENCE RELATED TO URETHRAL UNDERACTIVITY

GENERAL

The patient usually notes UI during activities like exercise, running, lifting, coughing, or sneezing. Much more common in females (seen only in males with lower urinary tract surgery or injury compromising the sphincter).

SYMPTOMS

Urine leakage with physical activity (volume is proportional to activity level). No UI with physical inactivity, especially when supine (no nocturia). May develop urgency and frequency as a compensatory mechanism (or as a separate component of bladder overactivity).

DIAGNOSTIC TESTS

Observation of urethral meatus while patient coughs or strains.

CLINICAL PRESENTATION OF URINARY INCONTINENCE RELATED TO BLADDER OVERACTIVITY

GENERAL

Can have bladder overactivity and UI without urgency if sensory input from the lower urinary tract is absent.

SYMPTOMS

Urinary frequency (>8 micturitions/day), urgency with or without urge incontinence; nocturia (≥ 2 micturitions/night) and enuresis may be present as well.

DIAGNOSTIC TESTS

Urodynamic studies are the gold standard for diagnosis. Also urinalysis and urine culture should be negative (rule out urinary tract infection as cause of frequency).

CLINICAL PRESENTATION OF URINARY INCONTINENCE RELATED TO URETHRAL OVERACTIVITY AND/OR BLADDER UNDERACTIVITY

GENERAL

Important but rare type of UI in both sexes. Urethral overactivity usually due to prostatic enlargement (males) or cystocele formation or surgical overcorrection following antiurethral underactivity (stress incontinence) surgery (females).

SYMPTOMS

Lower abdominal fullness, hesitancy, straining to void, decreased force of stream, interrupted stream, sense of incomplete bladder emptying. May have urinary frequency and urgency, too. Abdominal pain if acute urinary retention is also present.

SIGNS

Increased postvoid residual urine volume.

DIAGNOSTIC TESTS

Digital rectal exam or transrectal ultrasound to rule out prostatic enlargement. Renal function tests to rule out renal failure due to acute urinary retention.

2 UI may present in a number of ways, depending on the underlying pathophysiology. Generally, SUI is considered the most common type of UI and probably accounts for at least a portion of UI in more than half of all incontinent females. Some studies have found that mixed UI (SUI + UUI) represents the most common type of UI.⁶ However, the proportions of SUI versus UUI versus mixed UI vary considerably with age group and sex of patients studied, study methodology, and a variety of other factors. A complete medical history, including an assessment of symptoms and a physical examination, is essential in correctly classifying the type of incontinence and thereby assuring appropriate therapy.

URINE LEAKAGE

UI represents a spectrum of severity in terms of both volume of leakage and degree of bother to the patient. To carefully consider the level of patient discomfort when discussing urine leakage, the clinician must probe during the patient interview to accurately determine the precise nature of the problem.

The use of absorbent products such as panty liners, pads, or briefs is an obvious point to discuss, but the clinician must keep in mind that their use varies among patients. The number and type of pads may not relate to the amount or type of incontinence, as their use is a function of personal preference and hygiene. A high number of absorbent pads may be used every day by a patient with severe, high-volume UI, or alternatively, by a fastidiously hygienic patient with low-volume leakage who simply changes pads often to avoid a sense of wetness or odor. Nevertheless, a large number of pads that are described by the patient as “soaked” is indicative of high-volume urine loss.

Regardless of the volume of urine loss, the desire to seek evaluation and therapy for UI in all patients is almost always elective and contingent on the degree of bother to the individual patient. As with use of absorbent products, patients differ in the amount of urine loss they will tolerate before considering the condition bothersome enough to seek assistance.

SYMPTOMS

Under the best of circumstances, UI is difficult to categorize based on symptoms alone (Table 83–2).²² In a study of patients who appeared to have SUI based on symptoms and patient history, urodynamics showed that only 72% of patients had SUI as the sole cause of incontinence.²³

Patients with urethral underactivity or SUI characteristically complain of urinary leakage with physical activity. Volume of leakage is proportional to the level of activity. They will often leak urine during periods of exercise, coughing, sneezing, lifting, or even when rising from a seated to a standing position. Patients with pure SUI will not have leakage when physically inactive, especially when they are supine. Often they will have little or no UI at night, will not awaken to void during the night (nocturia), will not wet the bed, and often do not even wear absorbent products at bedtime. Urinary urgency and frequency may be associated with SUI, either as a separate component caused by bladder overactivity (mixed incontinence), or as a

TABLE 83–2. Differentiating Bladder Overactivity from Urethral Underactivity

| Symptoms | Bladder Overactivity | Urethral Underactivity |
|---|----------------------|------------------------|
| Urgency (strong, sudden desire to void) | Yes | Sometimes |
| Frequency with urgency | Yes | Rarely |
| Leaking during physical activity (e.g., coughing, sneezing, lifting) | No | Yes |
| Amount of urinary leakage with <i>each episode</i> of incontinence | Large if present | Usually small |
| Ability to reach the toilet in time following an urge to void | No or just barely | Yes |
| Nocturnal incontinence (presence of wet pads or undergarments in bed) | Yes | Rare |
| Nocturia (waking to pass urine at night) | Usually | Seldom |

Adapted from Rovner et al.²²

compensatory mechanism wherein the patient with SUI learns to toilet frequently to avoid large-volume urine loss during physical activity.

Typical symptoms of bladder overactivity include frequency, urgency, and urge incontinence. Nocturia and nocturnal incontinence are often present. Urine leakage is unpredictable and the volume loss may be large. Patients will often wear protection both day and night. Urinary frequency can be affected by a number of factors unrelated to bladder overactivity, including excessive fluid intake (polydipsia) and bladder hypersensitivity states such as interstitial cystitis and urinary tract infection, and these should be ruled out. In some patients, bladder overactivity may manifest as UI without awareness in the absence of a sense of urinary urgency or frequency. Urinary urgency, a sensation of impending micturition, requires intact sensory input from the lower urinary tract. In patients with spinal cord injury, sensory neuropathies, and other neurologic diseases, a diminished ability to perceive or process sensory input from the lower urinary tract may result in bladder overactivity and UI without urgency or urinary frequency. When the bladder contraction occurs without warning and sensation is absent, the condition is referred to as reflex incontinence.

Patients with overflow incontinence may present with lower abdominal fullness as well as considerable obstructive urinary symptoms, including hesitancy, straining to void, decreased force of urinary stream, interrupted stream, and a vague sense of incomplete bladder emptying. These patients may also have a significant component of urinary frequency and urgency. In patients with acute urinary retention and overflow incontinence, lower abdominal pain may also be present. Although these symptoms are not specific for overflow incontinence, they may warrant further investigation including an assessment of postvoid residual urine volume.

SIGNS

A presenting complaint of UI mandates a directed physical examination and a brief neurologic assessment. This should ideally include an abdominal examination to exclude a distended bladder, a neurologic assessment of the perineum and lower extremities, a pelvic exam in women (looking especially for evidence of prolapse or hormonal deficiency), and a genital and prostate examination in men.

SUI can usually be objectively demonstrated by having the patient cough or strain during the examination and observing the urethral meatus for a sudden spurt of urine. In women, SUI may be associated with varying degrees of vaginal prolapse including cystourethrocele (bladder and urethral prolapse), enterocele (small bowel prolapse),

rectocele (rectal prolapse), and uterine prolapse. These conditions may have important implications for therapy.

Perineal skin maceration, erythema, breakdown, and ulceration may be indicative of chronic, severe UI. Patients with chronic incontinence may also manifest fungal infections of the skin of the perineum and upper thighs.

In both sexes, digital rectal examination provides an opportunity to check ambient rectal tone, the integrity of the sacral reflex arc (e.g., anal wink), as well as assess the patient's ability to perform a voluntary pelvic floor muscle contraction (i.e., Kegel exercise), which may be an important factor in deciding on appropriate therapy. In men, a digital examination of the prostate assesses for the presence of prostate cancer, inflammation, and BPH.

A targeted neurologic examination includes an assessment of reflexes, rectal tone, and sensory or motor deficits in the lower extremities, which might be indicative of systemic or localized neurologic disease. As noted previously, neurologic diseases have the potential to affect bladder and sphincter function and thus may have significant implications in the incontinent patient.

PRIOR MEDICAL OR SURGICAL ILLNESS

UI may present in the setting of concurrent, seemingly unrelated illnesses. New-onset UI may be the initial manifestation of certain systemic illnesses such as diabetes mellitus, metastatic malignancies, multiple sclerosis, and other neurologic illnesses. Central nervous system disease, or injury above the level of the pons, generally results in symptoms of bladder overactivity and UUI. Spinal cord injury or disease may manifest as bladder overactivity and UUI or as overflow incontinence, depending on the spinal level and completeness of the injury or disease.

Medications may have wide-ranging effects on lower urinary tract function (see Table 83–1). A thorough inquiry into the use of new medications in the setting of recent-onset UI may show a relationship.

Acute UI manifest in the immediate postoperative setting may be secondary to a number of factors, including surgical manipulation and immobility, and to a number of medications, including analgesics. In the postoperative setting, acute urinary retention and overflow incontinence is commonly related to the administration of anesthetic agents and/or opioid analgesics in the perioperative period. These agents may have profound effects on bladder contractility that are completely reversible once the agents are metabolized and excreted.

Prior surgery may have effects on lower urinary tract function. UI following prostate surgery in men is very suggestive of injury to the

sphincter and resultant SUI. Pelvic surgery for benign and malignant conditions may result in denervation or injury to the lower urinary tract. This includes bowel surgery and gynecologic procedures. For example, new-onset total UI following gynecologic surgery for uterine fibroids suggests the possibility of intraoperative bladder injury and subsequent development of a postoperative vesicovaginal fistula. Radiation therapy to the pelvis for malignant disease (e.g., prostate cancer or cervical cancer) may result in injury to the bladder or urethra and subsequent UI.

In women, UI may be related to several gynecologic factors, including childbirth, hormonal status, and prior gynecologic surgery. Pregnancy and childbirth, particularly vaginal delivery, are associ-

ated with SUI and pelvic prolapse. Significant SUI in the nulliparous woman is rather uncommon. UI that becomes progressive at or around menopause suggests a hormonal component that may potentially be responsive to estrogen or hormone replacement therapy.

Finally, UI may present in the setting of other significant pelvic floor disorders, signs, and symptoms. Constipation, diarrhea, fecal incontinence, dyspareunia, sexual dysfunction, and pelvic pain may be related to UI. A history of gross hematuria in the setting of UI mandates further urologic investigation, including radiologic imaging of the upper urinary tract and cystoscopy. Acute dysuria with or without hematuria in the setting of UI suggests cystitis. A urinalysis and urine culture should be performed in these patients.

▶ TREATMENT: Urinary Incontinence

■ NONPHARMACOLOGIC TREATMENT

3 Nonpharmacologic treatment of UI constitutes the chief form of incontinence management at a primary care level. For patients in whom pharmacologic or surgical management is inappropriate or undesired, nondrug treatment is the only option. Examples of patients fulfilling these criteria include patients who are not medically fit for surgery or those who plan future pregnancies (as these may adversely affect long-term surgical outcomes); those with overflow incontinence whose condition is not amenable to surgery or drug therapy; those with comorbid conditions that place them at high risk for adverse effects from drug therapy; those who are delaying surgery or do not want to undergo surgery; and those with mild to moderate symptoms who do not want to take medication.

For additional information on nonpharmacologic interventions for UI, readers are referred to comprehensive literature reviews and consensus opinions of treatment guidelines on nonpharmacologic interventions by multidisciplinary experts.²⁴ Table 83-3 summarizes the basic nondrug approaches.

Behavioral interventions are the first line of treatment for SUI, UUI, and mixed UI. These include lifestyle modifications, scheduling regimens, and pelvic floor muscle rehabilitation. Because the key to the success with any type of behavioral intervention is the motivation of the patient or caregiver, these individuals must be active participants in developing a treatment plan. Regular follow-up is needed to help motivate patients and caregivers, provide reassurance and support, and to monitor treatment outcomes.

■ PHARMACOLOGIC TREATMENT

■ URGE URINARY INCONTINENCE

Pharmacotherapy is useful when UUI symptoms are not adequately controlled with nonpharmacologic therapies, particularly in patients with a low functional bladder capacity. In many cases, the combined use of pharmacotherapy with nonpharmacologic therapy produces a better response than either intervention alone.

4 Proven to be the most effective agents in suppressing premature detrusor contractions, enhancing bladder storage, and relieving UUI symptoms and complications, anticholinergic/antispasmodic drugs constitute the pharmacotherapy of first choice for UUI (Tables 83-4 and 83-5).²⁵⁻⁴⁴ Drugs with anticholinergic activity act by antagonizing muscarinic cholinergic receptors, through which efferent

parasympathetic nerve impulses evoke detrusor contraction. In addition, women with mixed UI or UUI plus urethritis or vaginitis may benefit from a topical or systemic estrogen (alone or in combination with an anticholinergic drug).

■ Immediate-Release Oxybutynin

Even though a substantial proportion of patients may discontinue oxybutynin immediate-release (IR) therapy because of its nonurinary antimuscarinic effects, oxybutynin IR remains the drug of first choice for UUI and the gold standard against which other drugs are compared. In addition to these antimuscarinic effects (e.g., dry mouth, constipation, vision impairment, confusion, cognitive dysfunction, and tachycardia), oxybutynin IR is associated with orthostatic hypotension secondary to α -adrenergic receptor blockade, as well as sedation and weight gain from histamine H₁-receptor blockade.^{26,31,45-49} Furthermore, adverse effects jeopardize medication adherence and can prevent dose escalation to that needed for optimal benefit.

Emerging evidence suggests that the high incidence of adverse effects, especially dry mouth, of oxybutynin IR, and to a lesser extent oxybutynin extended-release (XL) and oxybutynin transdermal system (TDS), may be largely due to the active metabolite, *N*-desethyloxybutynin (DEO). This metabolite is generated by extensive first-pass metabolism in the liver and upper gastrointestinal tract.⁵⁰ Since many of the adverse effects seen with oxybutynin are felt to be related to the primary hepatic metabolite DEO, the lower DEO plasma concentrations seen with oxybutynin TDS and oxybutynin XL (which are due to reduced first-pass metabolism) compared to those of oxybutynin IR may explain their lesser propensity to cause dry mouth and other anticholinergic adverse effects.

Another factor associated with the adverse effects of oxybutynin IR, especially in older patients, is the transient high peak serum oxybutynin plasma concentration and area under the plasma concentration-versus-time curve (AUC), which is twofold higher in elderly patients than in younger adults, after both single and multiple doses.⁵¹ Oxybutynin IR is best tolerated when the dose is gradually escalated from no more than 2.5 mg twice daily to start, to 2.5 mg three times daily after 1 month, then further increased in increments of 2.5 mg/day every 1 to 2 months until the desired response or the maximum recommended or tolerated dose is attained. The optimal response usually requires no more than 5 mg three times daily (see Table 83-4).^{26,52}

Adverse effects of oxybutynin IR can sometimes be managed by a dose reduction if this does not significantly compromise drug efficacy. Dry mouth can be relieved by the use of sugarless hard

TABLE 83–3. Nonpharmacologic Management of Urinary Incontinence

| Intervention | Description | Patient Characteristics |
|--|---|--|
| Lifestyle modifications | Self-management strategies targeted toward reducing or eliminating risk factors that cause or exacerbate urinary incontinence | Smoking cessation for patients with cough-induced stress incontinence; weight reduction for obese patients with stress incontinence; good bowel hygiene for patients with constipation; caffeine reduction, selected dietary and fluid modifications for patients with urge incontinence (e.g., eliminate aspartame, spicy foods, citrus fruits, carbonated beverages) |
| Scheduling regimens Timed voiding | Toileting on a fixed schedule whose interval does not change, typically every 2 hours during waking hours | Used for stress, urge, and mixed incontinence in patients with cognitive or physical impairments; also used in patients without impairments who have infrequent voiding patterns |
| Habit retraining | Scheduled toiletings with adjustments of voiding intervals (longer or shorter) based on patient's voiding pattern | Used for stress, urge, and mixed incontinence in institutionalized or homebound patients with cognitive or physical impairments; may also be used in patients who have diuretic-induced incontinence |
| Patterned urge response toileting (PURT) | A specialized type of habit training that involves the use of an electronic monitoring device to identify the timing of incontinent episodes | Used for stress, urge, and mixed incontinence in institutionalized and homebound elderly populations |
| Prompted voiding | Scheduled toiletings that require prompts to void from a caregiver, typically every 2 hours; patient assisted in toileting only if response is positive; used in conjunction with operant conditioning techniques for rewarding patients for maintaining continence and appropriate toileting | Used for stress, urge, and mixed incontinence in patients who are functionally able to use toilet or toilet substitute, able to feel urge sensation, and able to request toileting assistance appropriately; primarily used in institutional settings or in homebound patients with an available caregiver |
| Bladder training | Scheduled toiletings with progressive voiding intervals; includes teaching of urge control strategies using relaxation and distraction techniques, self-monitoring, and use of reinforcement techniques; sometimes combined with drug therapy | Used for stress, urge, and mixed incontinence in patients who are cognitively intact, able to toilet, and motivated to comply with training program |
| Pelvic floor muscle rehabilitation Pelvic floor muscle exercises (e.g., Kegel exercises) | Regular practice of pelvic floor muscle contractions; may involve use of pelvic floor muscle contraction for urge inhibition | Used for stress, urge, and mixed incontinence in patients who can correctly contract their pelvic floor muscles without use of accessory muscles; requires a cognitively intact and highly motivated patient |
| Vaginal weight training | Active retention of increasing vaginal weights; typically used in combination with pelvic floor muscle exercises at least twice a day | Women with stress incontinence who are cognitively intact, can correctly contract pelvic floor muscles, able to stand, and who have sufficient vaginal vault and introitus to retain cone and are highly motivated; contraindicated in patients with moderate to severe pelvic organ prolapse |
| Biofeedback | Use of electronic or mechanical instruments to display visual or auditory information about neuromuscular or bladder activity; used to teach correct pelvic floor muscle contraction and/or urge inhibition | Used for stress, urge, and mixed incontinence in patients who are able to understand analog or digital signals, who are motivated, and who have the capability to learn voluntary control through observation |
| Nonimplantable electrical stimulation | Application of electrical current to sacral and pudendal afferent fibers through vaginal, anal, or surface electrodes; used to inhibit bladder overactivity and to improve awareness, contractility, and efficiency of pelvic muscle contraction | Used for stress, urge, and mixed incontinence in patients who are highly motivated; contraindicated in patients with diminished sensory perception, moderate or severe pelvic organ prolapse; urinary retention, history of cardiac arrhythmia, or demand cardiac pacemaker |
| Extracorporeal magnetic innervation | Pulsed magnetic stimulation to pelvic floor musculature causing depolarization of motor neurons, thus inducing pelvic floor muscle contraction; stimulation is provided through a specially designed chair that contains a device for producing a pulsing magnetic field (e.g., Neotonus, Inc., Marietta, GA) | Initially tested in women with stress incontinence; contraindicated in patients with demand cardiac pacemakers, or with metallic joint replacements; may be useful treatment option when other approaches fail or are not feasible |
| Anti-incontinence devices Intravaginal support device (pessaries and bladder neck support prostheses) | Pessaries and other intravaginal devices designed to support the bladder neck, relieve minor pelvic organ prolapse, and change pressure transmission to the urethra (e.g., Coloplast AS, Humelbaek, Denmark) | Used for female stress incontinence; in postmenopausal women, estrogen replacement is typically prescribed to prevent ulceration and breakdown of vaginal tissue; requires good manual dexterity to manipulate device |

(continued)

TABLE 83–3. (Continued)

| Intervention | Description | Patient Characteristics |
|---|---|---|
| External occlusive device | Small, single-use device that covers the urethral meatus which is removed for voiding in women (e.g., FemAssist, Apple Medical, Marlboro, MA; CapSure, Bard Urological, Covington, GA); a penile clamp (e.g., Cunningham clamp) is available for men | Used for female and male stress incontinence; used in cognitively intact patients with good manual dexterity |
| Intraurethral occlusive device (urethral plug) | Small, single-use device that is worn in the urethra to provide mechanical obstruction to prevent urine leakage; removed for voiding (e.g., FemSoft Insert, Rochester Med. Corp., Stewartville, MN) | Used for female stress incontinence patients who are cognitively intact with good manual dexterity; contraindicated with primary urge incontinence, urinary tract infection, urethral stricture, and any anatomic or pathologic condition making catheter passage difficult |
| Complex valved catheter (investigational) | Intraurethral occlusive device that has a unidirectional valve that can be opened to permit voiding and resealed; may be left indwelling over a longer period of time than intraurethral occlusive devices, but requires a clinician to insert and remove; several devices are currently undergoing testing | Female stress incontinence and overflow incontinence |
| Supportive interventions | | |
| Toileting substitutes and other environmental modifications | Urinals, bedside commodes, elevated toilet seats | Used for patients with mobility impairments that make it difficult to reach a toilet in a timely fashion |
| Physical therapy | Gait and/or strength training | Used for frail elderly patients with mobility impairments that make it difficult to reach a toilet in a timely fashion |
| Absorbent products | Variety of reusable and disposable pads and pant systems; some products contain a polymer that absorbs urine and wicks it away from the body | Used for all types of incontinence |
| External collection devices (men only) | Condom catheter with leg bag | Used in men with urge, stress, and overflow incontinence and in those with functional impairments |
| Catheters | Disposable, intermittent catheters and indwelling urethral and suprapubic catheters | Used for overflow incontinence; also used in patients who are bed-bound or with significant mobility impairments and severe incontinence, those with terminal illness, and those with sacral pressure ulcers until healing occurs |

candy, gum, or a saliva substitute. Constipation can be minimized by increasing the intake of water, dietary fiber, physical activity such as walking, or laxative therapy. The need for multiple daily dosing of oxybutynin IR can further jeopardize adherence, especially in people who take multiple medications or those who are cognitively impaired.

Extended-Release Oral Oxybutynin

Because of problems noted with oxybutynin IR, oxybutynin extended-release (XL) was developed. It can be considered an alternative for the first-line therapy of UUI (see Table 83–5).

Oxybutynin XL (Ditropan XL) is an extended-release formulation of oxybutynin.⁵³ Its extended-release system consists of an osmotically active bilayer core (comprising a drug layer and a push layer containing osmotically active components) surrounded by a semipermeable membrane. Throughout the gastrointestinal tract, water permeates through the rate-controlling membrane into the tablet core, causing the drug to go into suspension and the push layer to expand, pushing the suspended drug out through an orifice.³¹ Following oral administration, oxybutynin XL is completely absorbed, and neither the rate nor extent of absorption are significantly affected by administration with food.

Unlike oxybutynin IR, oxybutynin XL delivers a controlled amount of oxybutynin chloride continuously throughout the gastrointestinal tract over a 24-hour time period, reducing first-pass metabolism by cytochrome P450 (CYP450) isoenzyme 3A4, which is

present in higher concentrations in the upper portion of the small intestine than the lower gastrointestinal tract.^{53,54} This results in relative bioavailabilities of oxybutynin and its active *N*-desethyloxybutynin metabolite of 153% and 69%, respectively, for oxybutynin XL compared with oxybutynin IR.⁵⁵ The greater ratio of parent drug to active metabolite after oxybutynin XL administration, and probably less importantly a lower peak plasma drug concentration, are believed to be the reasons for fewer dose- and concentration-dependent adverse effects and better patient tolerance with the XL preparation as compared to oxybutynin IR.⁵⁶ The elimination of oxybutynin XL is not known to be altered in patients with renal or hepatic impairment or in geriatric patients (up to 78 years of age).⁵³ The absence of an effect of advanced age on oxybutynin XL pharmacokinetics is unexpected since the clearance of oxybutynin IR is significantly lower in elderly individuals.

Controlled studies have demonstrated that oxybutynin XL is significantly more effective than placebo and equally effective as oxybutynin IR in terms of reducing the mean number of UI episodes, restoring continence, decreasing the number of micturitions per day, and increasing urine volume voided per micturition (see Table 83–5).^{30,31,45–47,57–59}

In short-term studies of up to 12 weeks' duration, oxybutynin XL was better tolerated than oxybutynin IR, with approximately 7% of patients discontinuing treatment because of adverse effects (as compared to approximately 27% in those taking oxybutynin IR).^{26,31,45,46,52,53} The rate and severity of adverse effects did not differ significantly between elderly persons (65 years of age and older) and younger adults

TABLE 83–4. Pharmacotherapeutic Options in Patients with Urinary Incontinence

| Type | Drug Class | Drug Therapy (Usual Dose) | Comments |
|---|---|---|---|
| Overactive bladder | Anticholinergic agents/antispasmodics | Oxybutynin IR (2.5–5 mg two, three or four times a day), oxybutynin XL (5–30 mg daily), oxybutynin TDS (3.9 mg/day) (apply 1 patch twice weekly), tolterodine IR (1–2 mg twice a day), tolterodine LA (2–4 mg daily), trospium chloride 20 mg twice a day, solifenacin 5–10 mg daily, darifenacin 7.5–15 mg daily | Anticholinergics are the first-line drug therapy (oxybutynin or tolterodine are preferred). |
| | Tricyclic antidepressants (TCAs) | Imipramine, doxepin, nortriptyline, or desipramine (25–100 mg at bedtime) | TCAs are generally reserved for patients with an additional indication (e.g., depression, neuralgia) |
| | Topical estrogen (only in women with urethritis or vaginitis) | Conjugated estrogen 0.5 g vaginal cream three times per week for up to 8 months. Repeat course if symptom recurrence. Or use estradiol vaginal insert/ring [2 mg (1 ring)] and replace after 90 days if needed. | Marginally effective. Few adverse effects with cream and vaginal insert |
| Dual serotonin-norepinephrine reuptake inhibitors | Duloxetine ^a | 40–80 mg/day (1 or 2 doses) | Once approved, will become first-line therapy. Most adverse events diminish with time so support patient during initial period of use |
| Stress | α -Adrenergic agonists | Pseudoephedrine (15–60 mg three times a day) with food, water, or milk | Pseudoephedrine is first-line therapy for women with no contraindication (notably hypertension) (second-line once duloxetine is approved) |
| | Estrogen | See estrogens (above). Works best if urethritis or vaginitis are present. | Phenylpropanolamine was the preferred agent until its removal from the U.S. market in 2000. Considered a somewhat less-effective alternative to pseudoephedrine. Combined pseudoephedrine and estrogen is somewhat more effective than pseudoephedrine alone in postmenopausal women. |
| | Imipramine | 25–100 mg at bedtime | Imipramine is an optional therapy when first-line therapy is inadequate. |
| Overflow (atonic bladder) | Cholinomimetics | Bethanechol (25–50 mg three or four times a day) on an empty stomach | Avoid use if patient has asthma or heart disease. Short-term use only. Never give IV or IM because of life-threatening cardiovascular and severe gastrointestinal reactions. |

IR, immediate-release; LA, long-acting; XL, extended-release, TDS, transdermal system.

^aInvestigational. Doses provided are those best supported by clinical trials to date.

with the XL preparation. A 12-week study demonstrated the superiority of oxybutynin XL over tolterodine IR in reducing the mean number of weekly incontinent episodes and micturitions.³⁹

In the OPERA trial, oxybutynin XL was comparable to tolterodine long-acting (LA) in decreasing the mean number of incontinence episodes, but was superior in reducing weekly micturition frequency and achieving total dryness.⁶⁰ In another study that pooled results of two open-label studies, tolterodine LA was associated with significantly greater patient-perceived improvement in bladder control and fewer withdrawals due to adverse effects than oxybutynin XL.

However, the treatments were similar in patients' or physicians' perception of benefit over baseline and proportions of withdrawals due to lack of efficacy. However, the lack of blinding may have introduced patient and observer bias.⁶¹

Oxybutynin XL, available only in a tablet formulation, is administered once daily, with or without food, and should not be crushed or chewed (see Table 83–4). Like oxybutynin IR, the dosage does not require adjustment in patients of advanced age, or in patients with renal or hepatic impairment. However, treatment should still be initiated at the smallest recommended dosage in the elderly (5 mg once daily).^{32,53}

TABLE 83–5. Efficacy of First-Choice Drugs for Bladder Overactivity in Placebo-Controlled Trials^a

| Drug | Decreased Incontinence Episodes | Restored Continence | Decreased Frequency of Micturitions | Increased Volume per Void |
|----------------|---------------------------------|---------------------|-------------------------------------|---------------------------|
| Oxybutynin IR | 24–52 | 16–67 | –2 to –63 | 9–24 |
| Oxybutynin XL | 47 | 37 | 1 | 13 |
| Oxybutynin TDS | 10–20 | 6–17 | 4–6 | 12–14 |
| Tolterodine | 16–33 | 9 | 4–19 | 11–20 |
| Tolterodine LA | 23 | NR | 6 | 14 |

^aAll values constitute mean or median drug effect (drug response minus placebo response in percent), predominantly using pooled data from multiple independent studies.

IR, immediate-release; LA, long-acting; NR, not reported; XL, extended-release; TDS, transdermal system.

The maximum benefit of oxybutynin XL may not be realized for up to 4 weeks after starting therapy or after dose escalation. No known clinically relevant drug-drug interactions with either oxybutynin XL or oxybutynin IR have been identified. However, other drugs with anticholinergic activity may increase overall anticholinergic effects (i.e., produce an additive or synergistic pharmacodynamic interaction), as would be expected.⁵³ Another potential pharmacodynamic interaction involves the mutual antagonism of anticholinergic agents and cholinergic stimulants such as the acetylcholinesterase inhibitors used to treat dementia.

Extended-Release Transdermal Oxybutynin

The oxybutynin transdermal system (Oxytrol), which delivers 3.9 mg per day, is applied twice weekly (every 3 or 4 days). Transdermal absorption of oxybutynin from this formulation bypasses first-pass hepatic and gut metabolism, resulting in similar oxybutynin but lower plasma *N*-desethyloxybutynin concentrations than after administration of an equivalent dose via the oral route.^{50,62} Similar findings have been noted for the active *R*-enantiomer of *N*-desethyloxybutynin.⁶³ No dosage adjustment of the TDS product for advancing age is necessary.⁴⁴

Oxybutynin TDS is superior to placebo in reducing incontinence episodes and number of micturitions and increasing the volume voided per micturition.^{43,44} It is also similar to oxybutynin IR in reducing the frequency of UUI episodes and improving patient-perceived urinary leakage.⁶⁴ Oxybutynin TDS and tolterodine LA are significantly superior to placebo and similar to each other in reducing the frequency of UUI episodes, increasing the volume voided per micturition, attaining complete continence, and improving quality of life.⁴³

The commonest adverse effects with the TDS formulation are pruritus (15%) and erythema (9%) at the application site. The events of dry mouth (11%), constipation (5%), dizziness (5%), and abnormal vision (<5%) occur less frequently with the TDS formulation than with the IR formulation, and similarly in frequency to those with oxybutynin XL and tolterodine IR/LA.^{39,40,42–44,47,60,64}

Immediate-Release Tolterodine

Tolterodine (Detrol) is a competitive muscarinic receptor antagonist that can be considered first-line therapy of UI in patients with symptoms of urinary frequency, urgency, or urge incontinence (see Tables 83–4 and 83–5).³³

Controlled studies demonstrated that tolterodine was significantly more effective than placebo and as effective as oxybutynin IR in decreasing the mean daily number of micturitions and increasing the mean volume voided per micturition (see Table 83–5).^{27,34–38,65,66} However, while three controlled trials showed significant decreases in the mean number of incontinence episodes per 24 hours as compared to placebo, most studies have not and the manufacturer's package insert does not claim a significant improvement in this parameter (see Table 83–5).^{28,34–38,66} The only controlled study of the ability of tolterodine to restore urinary continence reported an insignificant effect rate of 9% over placebo.³⁴

Extended-Release Tolterodine

In a controlled study of 1529 adult outpatients with urinary frequency and UUI, tolterodine LA, an extended-release formulation of tolterodine tartrate, significantly decreased the mean number of weekly incontinence episodes (23% effect rate over placebo and 7% effect rate over tolterodine IR). Patient withdrawal rates did not differ significantly between the two active treatments, but dry mouth was observed significantly less often in patients taking the LA formulation than among those patients receiving the IR formulation.⁴⁰

Tolterodine LA was significantly superior to placebo and similar in elderly and young patient populations in reducing the frequencies of incontinence episodes and micturitions, increasing the volume voided per micturition and ability to complete tasks before voiding, and enhancing the patient perception of benefit. Adverse effect types and frequencies were also similar in the two age groups.⁶⁷

A major consideration in using tolterodine is its pharmacokinetics, specifically its metabolism. The agent is predominantly eliminated by hepatic metabolism, and it exhibits genetic polymorphism.³³ The principal metabolic pathway in extensive metabolizers involves oxidation of the parent drug by the CYP450 isoenzyme 2D6 to the active 5-hydroxymethyl metabolite (DD01), followed by further oxidation and dealkylation.

In poor metabolizers who lack CYP450 isoenzyme 2D6 (approximately 7% of the U.S. population), the principal metabolic pathway involves CYP450 isoenzyme 3A4, with dealkylation of the amino group, oxidation to a dealkylated hydroxy metabolite, and further oxidation to a dealkylated acid metabolite that undergoes glucuronidation. Since tolterodine is principally metabolized by CYP450 isoenzyme 3A4 in this case, its elimination may be impaired by inhibitors of this isoenzyme (e.g., fluoxetine, sertraline, fluvoxamine, macrolide antibiotics, imidazoles, and grapefruit juice). For example fluoxetine, an inhibitor of CYP450 isoenzymes 2D6 and 3A4, decreases

the metabolism of tolterodine to DD01, resulting in a 4.8-fold increase in tolterodine AUC with a 52% decrease in the peak plasma concentration and a 20% decrease in the AUC of DD01.³³ Whether tolterodine significantly alters the pharmacokinetics of drugs metabolized by CYP450 isoenzyme 2D6 is unknown, so caution is advised with concurrent use of these agents.

Single-dose interaction studies have demonstrated that concurrent administration of tolterodine LA with antacid leads to a rapid release of drug (70% within 4 hours) and results in a 1.5-fold elevation in tolterodine peak plasma concentration compared with placebo. The clinical implications of this interaction and whether a similar interaction exists with gastric acid suppressants such as the histamine H₂-receptor antagonists and proton pump inhibitors are unclear. In the same study, the pharmacokinetics of oxybutynin XL were unaltered by antacid administration.⁶⁸

Although one of two phase I pharmacokinetic studies comparing healthy elderly volunteers (aged 64 to 80 years) with healthy volunteers younger than 40 years of age found no difference in pharmacokinetic parameters between the groups, the other study noted that the mean serum concentrations of tolterodine and DD01 were 20% and 50% greater in elderly volunteers than in young healthy volunteers, respectively. Despite possibly altered pharmacokinetics in elderly individuals, no differences in the incidence and severity of adverse effects between these age groups have been noted in clinical trials, and therefore no dosage adjustment is recommended on the basis of age alone.³³

Tolterodine elimination is diminished in patients with impaired hepatic function. Patients with hepatic cirrhosis who are extensive metabolizers exhibit a higher mean AUC of DD01, higher serum tolterodine and DD01 concentrations, and a longer terminal disposition half-life of tolterodine and DD01 than do healthy subjects who are extensive metabolizers. The tolterodine AUC was higher in cirrhotic patients who were poor metabolizers than in healthy poor metabolizers.³³ If the use of tolterodine cannot be avoided in patients with hepatic impairment or in those receiving inhibitors of CYP450 isoenzyme 3A4 (and possibly inhibitors of CYP450 isoenzyme 2D6), the initial dose should be reduced by 50% to tolterodine IR 1 mg twice daily or tolterodine LA 2 mg once daily (see Table 83–4).³³ No formal tolterodine dosage recommendation is possible based on available information for individuals who concurrently have hepatic impairment and are taking a CYP450 isoenzyme 3A4 inhibitor; intuitively, the initial dose should not exceed 1 mg twice daily (IR) or 2 mg once daily (LA).

The elimination of tolterodine has not been evaluated in patients with impaired renal function, and therefore the drug should be used more cautiously in such individuals (i.e., starting dose of the IR product of 1 mg twice daily with gradual dose escalation, if needed, to a maximum of 2 mg twice daily, or a starting dose of the LA formulation of 2 mg once daily with gradual dose escalation, if needed, to 4 mg once daily).³³

Tolterodine is better tolerated than oxybutynin IR, with about 8% of patients discontinuing treatment (compared with approximately 27% of individuals taking oxybutynin IR).^{26,28,34,35,37,45,69} The most common adverse effects of tolterodine are dry mouth, dyspepsia, headache, constipation, and dry eyes.³³

Tolterodine, available only as a tablet formulation, can be administered with or without food, and the LA product should not be crushed or chewed or taken less than 2 hours before or 4 hours after an antacid. The maximum benefit from tolterodine may not be realized for up to 8 weeks after starting therapy or dose escalation.

■ Trospium Chloride

Trospium chloride (Sanctura) is a quaternary ammonium anticholinergic approved in 2004 by the U.S. Food and Drug Administration (FDA) for the management of OAB. However, it has been available for many years in other countries. This agent has been comprehensively reviewed, and the data provided below come from that publication.⁷⁰

Preclinical studies have demonstrated that trospium chloride is an antimuscarinic agent in bladder and gastrointestinal tract tissues. It is poorly absorbed after oral administration (<10%), and food reduces bioavailability by 70% to 80%. It is principally cleared by the renal route (70%), with 80% of urinary excretion being accounted for by the parent compound. The mean half-life in the presence of normal renal function is 10 to 12 hours. Advancing age and mild to moderate hepatic impairment do not affect trospium chloride pharmacokinetics to a clinically significant degree. In contrast, renal impairment does significantly reduce drug clearance. When creatinine clearance is below 30 mL/min, AUC is increased by a mean of 4.5-fold, C_{max} by a mean of twofold, and half-life by a mean of two- to threefold. In this patient population, the daily dose should be reduced by 50%.

Nine English language efficacy/tolerability papers are available for trospium chloride in UUI. With the exception of the two trials described in the product information (one is published), trials have emphasized cystometric and not clinical endpoints. The paucity of clinical outcome data makes it difficult to evaluate this drug compared to other approved and investigational anticholinergics. Although statistically superior to placebo, the absolute differences in results between trospium chloride and placebo calls into question the clinical relevance of such differences. In the three trials with active controls, results with trospium chloride were statistically equivalent to those with oxybutynin IR and tolterodine IR. No comparative data with long-acting formulations of these two agents are available.

The expected anticholinergic adverse effects occur with trospium chloride as well. Of interest, the frequency of these events is increased in patients 75 years old and older compared to younger subjects. This is believed to be pharmacodynamic in nature (i.e., increased sensitivity) and not pharmacokinetic. There are no data at present to support the hypothesis that trospium chloride is less neurotoxic than non-quaternary-ammonium anticholinergics (based on the hypothesis of reduced transit across the blood-brain barrier of trospium chloride due to its positive electrical charge on the quaternary nitrogen). Available drug-drug interaction data are clearly inadequate.

The usual dosage regimen is 20 mg twice daily. The drug should be taken on an empty stomach. Dosage reduction (by 50% of the daily dose) is recommended when creatinine clearance is below 30 mL/min. In patients 75 years old and older, dose reduction to 20 mg once daily should be considered based upon tolerability. At this time, trospium chloride does not appear to be a significant advance over oxybutynin and tolterodine in managing UUI.

■ Anticholinergic Agents Under Development

Solifenacin succinate (Vesicare) was approved in late 2004 by FDA for the treatment of OAB with urge incontinence, urgency, and urinary frequency. This agent was comprehensively reviewed and the data provided below come principally from that publication.⁷¹

Preclinical studies have demonstrated that solifenacin is an antagonist at M₁, M₂, and M₃ muscarinic cholinergic receptors. Based on comparative *ex vivo* and animal studies with solifenacin and

oxybutynin, it was felt that solifenacin was a “uroselective” agent. The drug is well absorbed (mean absolute bioavailability = 88%) and food has no clinically relevant effect on absorption.^{72,73} It is principally eliminated via metabolism and renal excretion of metabolites, with renal excretion of parent compound being less than 10% of the dose. With a mean half-life of 50 to 60 hours, the drug can be dosed once daily.⁷⁴ Results of two placebo-controlled and two placebo- and active (tolterodine)-controlled clinical trials in UUI are available. Like oxybutynin and tolterodine, solifenacin significantly reduced the number of incontinence episodes, urge episodes and micturitions per day and increased the volume voided per micturition in a dose-dependent fashion compared to placebo. In the active-controlled trials, solifenacin was statistically superior to tolterodine in these effects. Surprisingly, the effect of tolterodine in these trials was no better than that of placebo. No comparative efficacy/tolerability data with oxybutynin are available. The effect sizes (solifenacin effect minus placebo effect) in these studies were similar to those noted earlier with oxybutynin and tolterodine. The recommended dose of solifenacin is 5 mg once daily. If well tolerated and the effectiveness is not optimal, the dose can be increased to 10 mg once daily. Solifenacin can be administered with or without food. For patients with severe renal impairment (creatinine clearance less than 30 mL/min) or moderate hepatic impairment (Child–Pugh class B), the daily dosage should not exceed 5 mg. If the patient has severe hepatic impairment (Child–Pugh class C), the drug should not be used. If the patient is receiving concurrent therapy with one or more potent CYP 3A4 inhibitors, the daily dose should not exceed 5 mg. In contrast to the preclinical studies, solifenacin behaves like a nonselective anticholinergic in humans, causing dry mouth, constipation, blurred vision, and other anticholinergic effects to a similar extent compared to tolterodine in the clinical trials and oxybutynin in the pharmacokinetic trials. At this time, solifenacin does not appear to be a significant advance over existing anticholinergics in managing UUI.

Darifenacin (Enblex) is another recently approved anticholinergic drug. This agent has also been comprehensively reviewed, and the data provided below come from that publication.⁷⁵

Preclinical studies have demonstrated that darifenacin is an antagonist at M₁, M₃, and M₅ muscarinic cholinergic receptors. As with solifenacin, darifenacin was also felt to be “uroselective” on the basis of preclinical data. The mean absolute bioavailabilities of the 7.5, 15, and 30 mg extended-release (ER) formulations are 15%, 19%, and 25%, respectively. Bioavailability is affected by formulation, CYP2D6 genotype, dose, and race. Bioavailability is enhanced using an ER formulation (70–110% higher than IR) in heterozygous extensive metabolizers (EM), poor metabolizers (2D6, 40–90% higher than homozygous EM), and Caucasian race (56% higher than Japanese). This agent is extensively metabolized, with urinary excretion of parent compound being less than 10%. The 2D6 and 3A4 isozymes of CYP450 are responsible for darifenacin metabolism. With a mean half-life of 3 to 5 hours (depending on 2D6 metabolizer status), an ER formulation is needed to allow once-daily dosing. Results of four placebo-controlled clinical trials (one published) in UUI are available. Once-daily darifenacin was significantly superior to placebo in reducing the numbers of micturitions, urinary urges, incontinence episodes, and urge severity and in increasing the volume voided per micturition. No comparative efficacy/tolerability data with other anticholinergics are available. The recommended daily dose of darifenacin is 7.5 to 15 mg once daily of an ER oral formulation. Again, as with solifenacin, darifenacin behaves like a nonselective anticholinergic in humans, causing dry mouth, constipation, and other well-known anticholinergic adverse effects. At this time, darifenacin does not

appear to be a significant advance over existing anticholinergics in managing UUI.

CLINICAL CONTROVERSY

Should anticholinergic pharmacotherapy be used to treat UUI in patients with mild or moderate dementia?

■ Other Anticholinergics and Antispasmodics

Other drugs for treating UUI are less effective, no safer, or have not been adequately studied (see Table 83–4);^{24,76} hence their use is not recommended. Tricyclic antidepressants are generally no more effective than oxybutynin IR and exhibit a high incidence of bothersome and potentially serious adverse effects (e.g., orthostatic hypotension, cardiac conduction abnormalities, dizziness, confusion, and they can be life-threatening in overdose). Therefore their use should be limited to those individuals who have one or more additional medical indications for these agents (e.g., depression or neuropathic pain); to patients with mixed UI (because of their effect of decreasing bladder contractility and increasing outlet resistance); and possibly to those with nocturnal incontinence associated with altered sleep patterns.^{24,76–79} Because of the lower incidence of adverse effects, desipramine and nortriptyline may be preferred over imipramine and doxepin. However, because of their lower anticholinergic activity, they may also not be as effective.

Propantheline, a quaternary ammonium anticholinergic and potential treatment, produces a high incidence of adverse effects and is only modestly effective for UUI.^{80–84} When used, propantheline appears to be best tolerated at a dose of no more than 15 mg three times daily plus 60 mg at bedtime.⁸⁰

Flavoxate, a tertiary amine that relaxes smooth muscle *in vitro*, is not recommended for treating UUI because four controlled trials have revealed that it is no more effective than placebo.²⁴

Dicyclomine hydrochloride, an anticholinergic agent that relaxes smooth muscle, produced minimal benefit as well as bothersome adverse effects in two small studies.^{85,86}

Hyoscyamine, an anticholinergic and antispasmodic drug related to atropine, has also been suggested for treating UUI, but data are insufficient to recommend its use.²⁴

In a systematic review and pooled analysis of 32 controlled trials of anticholinergic therapy for overactive bladder (January 2002 database), the above agents were found to be modestly effective clinically and urodynamically. While the clinical relevance of the small improvements in clinical and urodynamic parameters were questioned, the effects of these agents were still considered positive.⁸⁷

It is hoped that an improved understanding of the pathophysiology of UUI will lead to the development of safer and more effective pharmacotherapy.

CLINICAL CONTROVERSY

Which anticholinergic agent should be used as first-line pharmacotherapy of UUI (oxybutynin, tolterodine, trospium chloride, solifenacin, or darifenacin) and which formulation of oxybutynin (oral IR, oral XL, or topical) or tolterodine (oral IR, oral LA) is unclear. Financial considerations currently favor generic oxybutynin IR, and this is the initial choice of many clinicians.

■ Catheterization Combined with Medications

Patients with UUI and an elevated postvoid residual urine volume due to retention may require intermittent self-catheterization along with frequent voiding between catheterizations.

If intermittent catheterization is not possible, surgical placement of a suprapubic catheter may be necessary. The use of a chronic indwelling catheter should be avoided because of the increased occurrence of urinary tract infections and nephrolithiasis.

Regardless of catheterization status, patients may experience symptom relief with oxybutynin (IR, XL, or TDS formulations), tolterodine (IR or LA formulations), trospium chloride, or solifenacin or darifenacin, as these relax the detrusor muscle and enhance bladder storage. Patients with UUI and symptoms of retention may also benefit from an α -adrenergic receptor antagonist that relaxes the internal bladder sphincter (e.g., prazosin, terazosin, doxazosin, tamsulosin, and alfuzosin). Although theoretically of benefit, bethanecol, a cholinergic agonist, has not been demonstrated effective in improving bladder emptying in well-done trials. In addition, it causes numerous bothersome (e.g., muscle and abdominal cramping and diarrhea) and potentially life-threatening adverse effects, and should not be used in patients with asthma or heart disease.²⁴

■ URETHRAL UNDERACTIVITY

5 Urethral underactivity, or SUI, may be aggravated by agents with α -adrenergic receptor blocking activity, including prazosin, terazosin, doxazosin, tamsulosin, alfuzosin, methyl dopa, clonidine, guanfacine, guanadrel, and labetalol. The goal of therapy is to improve the urethral closure mechanism by either stimulating α -adrenergic receptors in the smooth muscle of the bladder neck and proximal urethra, enhancing the supportive structures underlying the urethral epithelium, or enhance the positive effects of serotonin and norepinephrine in the afferent and efferent pathways of the micturition reflex. There is no role for medications in the management of SUI after radical prostatectomy.⁸⁸

■ Estrogens

Local and systemic estrogens have been considered the mainstays of pharmacologic management of SUI since the 1940s. Estrogens are believed to work via several mechanisms, including enhancement of the proliferation of urethral epithelium, local circulation, and numbers and/or sensitivity of urogenital α -adrenergic receptors.⁸⁹ However, a recent trial has questioned whether estrogens exert a stimulatory effect on vaginal collagen production, at least over the short term.⁹⁰

Open trials support the use of a variety of estrogens in the management of SUI: transdermal estradiol, conjugated estrogen vaginal cream, Estrin, oral-conjugated estrogen, oral quinestradol, oral estradiol, intramuscular estrogens, estriol vaginal suppositories, and oral estradiol.⁹¹ Variable effects of estrogen treatment on urodynamic parameters, such as maximum urethral closure pressure, functional urethral length, and pressure transmission ratio, have been noted in these studies.

Unfortunately, results of four placebo-controlled comparative trials have not been as favorable, finding no significant clinical or urodynamic effects for oral estrogen as compared with placebo (see Table 83–4).^{92–95} In fact, observational studies have documented that

estrogen use is associated with an increased risk of UI compared to that in nonusers.^{96–99} Systemic estrogen therapy is associated with numerous adverse effects, including mastodynia, uterine bleeding, nausea, thromboembolism, cardiac and cerebrovascular ischemic events, and enhancement of the risk of certain cancers.⁷⁶ If estrogens are to be used in the treatment of SUI, only topical products should be administered. Estrogen use is best justified when SUI exists together with urethritis or vaginitis due to estrogen deficiency.

■ α -Adrenergic Receptor Agonists

Numerous open trials have supported the use of a variety of α -adrenergic receptor agonists in SUI, including ephedrine, norfenefrine, phenylpropranolamine, and midodrine.⁸⁶ Phenylpropranolamine was withdrawn from the U.S. market in late 2000 because of a risk of stroke in women using the agent.¹⁰⁰ Some patients may have leftover supplies of this agent or may obtain it from international sources. If so, those with the contraindications listed below—especially coronary artery disease and/or cardiac arrhythmias—should be warned against self-treatment with this or other α -adrenergic receptor agonists.

Placebo-controlled comparative trials with phenylpropranolamine, norfenefrine, and norephedrine support the modest efficacy of these agents in mild or moderate SUI.⁹¹ These agents have been found to variably affect maximum urethral closure pressure and functional urethral length.

Adverse effects include hypertension, headache, dry mouth, nausea, insomnia, and restlessness.⁷⁶ Contraindications to the use of these agents include the presence of hypertension, tachyarrhythmias, coronary artery disease, myocardial infarction, cor pulmonale, hyperthyroidism, renal failure, and narrow-angle glaucoma.

Usual doses are ephedrine 25 to 50 mg four times daily (25 mg twice daily in elders) and pseudoephedrine 60 mg three times daily (15 to 30 mg three times daily in elders; see Table 83–4).

Several studies have evaluated whether the clinical and urodynamic effects of a combination of estrogen and an α -adrenergic receptor agonist exceed those of the individual therapies in SUI.^{101–105} In general, combination therapy has resulted in somewhat superior clinical and urodynamic responses compared with monotherapy, including severity of complaints, amount of urine lost per episode, number of daily voluntary micturitions, number of leakage episodes per day, patient preference, pad use, maximum urethral closure pressure, functional urethral length, and pressure transmission ratio.

■ Duloxetine

Duloxetine, a dual inhibitor of serotonin and norepinephrine reuptake, was approved in 2004 for the treatment of depression and painful diabetic neuropathy (Cymbalta).¹⁰⁶ Its use in SUI (which was in early 2005 awaiting FDA approval under the trade name Yentreve) is based on studies in rats and cats which demonstrated that central serotonergic and noradrenergic regions are involved in ascending and descending control of urethral smooth muscle and the external urethral sphincter. These mechanisms facilitate the bladder-to-sympathetic reflex pathway, increasing urethral and external urethral sphincter muscle tone during the storage phase. Data documenting this control mechanism in humans are currently very limited. The mean half-life, clearance, and volume of distribution of duloxetine in healthy volunteers are 10 to 12 hours, 114 to 119 L/h, and 1787 to 1943 L,

respectively. The drug is extensively metabolized to inactive metabolites (via oxidation at the 4, 5, and/or 6 positions in the naphthyl ring followed by further oxidation or via methylation) with elimination in the urine as conjugated metabolites. CYP450 isoenzymes 2D6 and 1A2 are involved in the ring oxidations. This was demonstrated in studies involving the interaction of duloxetine with the 2D6 substrate desipramine (wherein desipramine's maximum concentration, AUC, and half-life were increased 1.7-, 2.9-, and 1.9-fold, respectively; and clearance fell by 66% during concurrent therapy) and the 2D6 inhibitor paroxetine (wherein duloxetine's maximum concentration, AUC, and half-life increased 1.6-, 1.6-, and 1.3-fold, respectively; and clearance fell 37% during concurrent therapy). Fluvoxamine, a 1A2 inhibitor, increased duloxetine's maximum concentration, AUC, and half-life by over 5-fold, 2.5-fold, and 3-fold, respectively. Thus clinicians will have to be careful when duloxetine is to be used concurrently with 2D6 and 1A2 substrates or inhibitors. The effect of advancing age on duloxetine pharmacokinetics is not clinically significant. Moderate hepatic dysfunction (Child–Pugh class B) significantly affects duloxetine disposition, increasing mean AUC and half-life 5-fold and 3-fold, respectively, and reducing clearance 85% compared with controls. Mild renal impairment does not affect drug disposition, and no data are available for moderate renal impairment. In hemodialysis patients, mean maximum concentration and AUC are each increased 100% while metabolite concentrations are increased up to 900%.

Results of six large clinical trials with duloxetine in SUI have been published. All were double-blind, randomized, placebo-controlled, and parallel group in design. Compared with placebo, duloxetine therapy produced significant reductions in incontinent episode frequency and number of micturitions per day, improvement in Incontinence Quality of Life questionnaire scores and patient self-assessment, and increase in mean micturition interval. Results were independent of baseline UI severity (based on incontinent episode frequency). Significant intergroup differences were seen by week 4. However, cure rates were generally not improved by duloxetine. When evaluating the absolute differences between treatments, the actual benefit of duloxetine was generally quite modest.

Although duloxetine is an encouraging development in the pharmacologic management of SUI, its adverse event profile may make adherence problematic. In the SUI trials, treatment-emergent adverse events occurred in 68% to 93% of duloxetine and 50% to 72% of placebo recipients. Premature study withdrawal rates (due to adverse events) were 12% to 33% for duloxetine and 2% to 8% for placebo. The frequencies of individual events in duloxetine recipients were as follows: nausea, 9% to 46%; headache, 7% to 27%; insomnia, 13% to 14%; constipation, 4% to 27%; dry mouth, 4% to 22%; dizziness, 8% to 16%; fatigue, 10% to 18%; somnolence, 8% to 13%; vomiting, 6% to 13%; and diarrhea 4% to 6%. Of additional interest, the drug may be associated with small increases in blood pressure (like venlafaxine, another dual reuptake inhibitor) and withdrawal symptoms (sleep disturbances).

Despite these negatives, duloxetine would be the first drug approved by the FDA for treating SUI. Based on studies conducted to date, a dosage regimen of 40 to 80 mg/day (in 1 or 2 doses) appears reasonable.

■ OVERFLOW INCONTINENCE

Overflow incontinence secondary to benign or malignant prostatic hyperplasia may be amenable to pharmacotherapy. For management of malignant prostatic disease, the reader is referred to Chap. 128. The pharmacotherapy of BPH is described in Chap. 82.

CURRENT CONTROVERSY

The optimal approach to the pharmacotherapy of SUI, is unclear. Although not supported by evidence-based medicine, many clinicians will initiate a trial of topical estrogen initially, followed by addition of an α -adrenergic receptor agonist in estrogen nonresponders unless contraindicated. Once duloxetine is approved, it will probably be the drug of choice in SUI, providing that it is tolerated.

■ SURGICAL TREATMENT

Only rarely does surgery play a role in the initial management of UI.¹⁰⁹ In the absence of secondary complications from UI (e.g., skin breakdown or infection), the decision to surgically treat symptomatic UI should be based on the premise that the degree of bother or lifestyle compromise to the patient is great enough to warrant an elective operation, and that nonoperative therapy is either undesired or has been ineffective.

Successful application of surgery depends most on defining the underlying abnormalities responsible for UI (bladder vs. urethra, underactivity vs. overactivity). Once the underlying factors are clear, other considerations come into play: renal function, sexual function, severity of the leakage, history of prior abdominal or pelvic surgery, the presence of concurrent abdominal or pelvic pathology requiring surgical correction, and finally the patient's suitability for, and willingness to accept the risks of, surgery.

When patients with uncomplicated SUI become dissatisfied with the initial management approaches of pelvic floor exercises, medications, and/or behavioral modification,¹⁰⁹ surgical treatment assumes the primary role.

Surgical correction of female SUI (urethral underactivity) is directed toward either: (1) repositioning the urethra and/or creating a backboard of support, or otherwise stabilizing the urethra and bladder neck in a well-supported retropubic (intra-abdominal) position that is receptive to changes in intra-abdominal pressure; or (2) creating coaptation and/or compression or otherwise augmenting the urethral resistance provided by the intrinsic sphincteric unit, with (i.e., sling) or without (i.e., periurethral collagen and other injectables) urethral and bladder neck support.

In men, SUI may be treated surgically with collagen or the artificial urinary sphincter. The vast majority of collagen injections in men are performed in a retrograde fashion under direct vision through a cystoscope. However, a transabdominal, transvesical, suprapubic antegrade approach has also been used.¹¹⁰ The artificial urinary sphincter is generally considered to be the gold standard for the treatment of male SUI. Placement of this manually operated silicone device has been associated with very high long-term success and satisfaction rates.¹¹¹

Most patients with UUI are managed nonsurgically with a combination of behavioral modification, pelvic floor exercises, and pharmacologic therapy. Only rarely is surgery applied to the problem of UUI.¹⁰¹ When employed, surgery may involve bladder denervation, implantation of a sacral nerve stimulator, or augmentation (enlargement) cystoplasty.

Currently there are no effective surgical treatments for bladder underactivity. After an appropriate evaluation is performed for reversible causes, the most effective management for this condition is intermittent self-catheterization performed by the patient or a caregiver

three or four times per day. Alternative methods of management that are less satisfactory are indwelling urethral or suprapubic catheters and urinary diversion.

Urethral overactivity is most commonly caused by anatomic obstruction. Anatomic obstruction in men is most often caused by benign prostatic enlargement, which is discussed in Chap. 82.

Rarely, bladder outlet obstruction may be caused by a functional obstruction at the level of the bladder neck. Hypertrophy of the smooth muscle fibers at the level of the bladder neck in men and women may result in obstruction to the flow of urine. In those patients who fail pharmacologic therapy with α -adrenergic receptor antagonists, endoscopic incision using the cystoscope is highly effective in treating this very uncommon condition.

EVALUATION OF THERAPEUTIC OUTCOMES

6 In the long-term management of UI, the patient-specific clinical signs and symptoms of most distress (“bother”) to the individual need to be monitored. Use of a daily diary may be very useful in this regard. Some of the short-form instruments used in incontinence research for measuring symptom impact and condition-specific quality-of-life can be used in clinical monitoring. In addition, quantitating the use of ancillary supplies such as pads may be useful. The goal of therapy is to minimize those signs and symptoms of most bother to the patient, as well as the use of pads and other ancillary supplies or devices. Total elimination of UI signs and symptoms may not be possible, and patients and practitioners need to mutually establish realistic goals of therapy. As the therapies for UI frequently have nuisance adverse effects, such as anticholinergic effects like xerostomia, xerophthalmia, and constipation, that may compromise regimen adherence, the presence and severity of adverse effects need to be carefully elicited at each visit to the health care practitioner. Emergence of adverse effects may necessitate drug dosage adjustment or use of alternative strategies (e.g., chewing sugarless gum, sucking on hard sugarless candy, or the use of saliva substitutes in xerostomia) or even drug discontinuation.

ABBREVIATIONS

AUC: area under the plasma or serum concentration-versus-time curve
 BPH: benign prostatic hyperplasia
 CYP450: cytochrome P450
 DD01: 5-hydroxymethyl metabolite of tolterodine
 DEO: N-desethyloxybutynin
 IEF: incontinence episode frequency
 IR: immediate-release
 LA: long-acting
 SUI: stress urinary incontinence
 TDS: transdermal system
 UI: urinary incontinence
 UUI: urge urinary incontinence
 XL: extended-release

FUNCTION AND EVALUATION OF THE IMMUNE SYSTEM

Philip D. Hall and Mary S. Hayney

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 After activation, dendritic cells express higher concentrations of MHC class II molecules B7-1, B7-2, and CD40 and, ICAM-1 and LFA-3 molecules than other antigen-presenting cells. They also produce more interleukin 12 (IL-12). This may explain why in vitro dendritic cells are the most efficient antigen-presenting cells.
- 2 A T-lymphocyte expresses hundreds of T-cell receptors (TCRs). All the TCRs expressed on the surface of an individual T-lymphocyte have the same antigen specificity.
- 3 A B-lymphocyte can simultaneously express membrane immunoglobulin as IgM (monomeric) or IgD with the same variable region (i.e., antigen-binding site). The B-lymphocyte then can secrete different isotypes [e.g., IgM (pentamer), IgA, IgG, or IgE] with the same variable region as the membrane immunoglobulin.
- 4 A serum protein electrophoresis determines the total concentration of circulating immunoglobulins (i.e., IgG, IgA, IgM, IgD, and IgE). If one wishes to determine the concentration of the individual isotypes, one needs to order isotype quantification. The vast majority of clinical laboratories quantitate only IgG, IgM, and IgA because they are the most prevalent isotypes in the bloodstream. In patients with allergic disorders, quantification of IgE may be useful. Depending on the clinical laboratory, results may be measured in International Units per milliliter or milligrams per deciliter for IgE.

The immune system encompasses a wide range of components, including mechanical immunodefenses, soluble mediators, and cellular and humoral immune responses. Cells involved in the immune response, from granulocytes to antigen-presenting cells to lymphocytes, develop from a common pluripotent stem cell. Please refer to Chap. 98 for a review of normal hematopoiesis. The human immune system evolved to protect the body against infectious pathogens and cancer. To accomplish this task, the immune system exhibits specificity, memory, mobility, and replicability. *Specificity* indicates that the immune system can distinguish between non-cross-reacting antigens. *Memory* ensures a quicker and more vigorous response to subsequent pathogenic invasion. *Mobility* of the elements of the immune system enables local reactions to provide systemic protection. *Replication* of the cellular components of the immune system amplifies the immune response. In addition, the immune response normally distinguishes “self” from “non-self” to prevent damage to the host. This discrimination between “self” and “nonself” is done by the adaptive or specific arm of the immune response. The immune system includes two functional divisions: *innate* (nonspecific) and *adaptive* (specific)¹ (Table 84–1). Despite this simple separation, these divisions interact heavily.²

The innate arm provides the first line of defense against pathogens. One of the most frequently overlooked methods of host

defense is the body’s ability to provide a physical and chemical defense against invading pathogens. The skin, the largest organ of the body, has the primary role of providing a physical defense. Alterations in the skin, such as burns or abrasions, allow an easy portal of entry for pathogens. The gastrointestinal tract also plays an important role in providing a physical defense against pathogenic invasion. The low pH of the stomach (pH 1–2) kills many organisms. The rapid turnover of intestinal cells also limits systemic infection because cells, including infected cells, are sloughed frequently. Drugs such as cell-cycle-specific antineoplastics that disrupt the sloughing process leave the patient at an increased risk of infection. Likewise, the respiratory tract has its forms of physical defense. The mucus coating the epithelial cells serves in part to prevent microorganisms from adhering to cell surfaces, and the cilia lining the epithelium of the lungs help to repel inhaled organisms. The combination of cilia, mucus, and reactive coughing provides a natural barrier to invasion via the respiratory tract. Other examples of mechanical or nonspecific defenses include normal urine flow, lysozymes in tears and saliva, and the normal flora in the throat, the lower gastrointestinal tract, and the genitourinary tract. It is these physical and chemical defenses that often form the first line of defense against infectious pathogens. It is well known that conditions or devices that allow microorganisms to transgress these normal barriers predispose patients to infections. As

TABLE 84–1. Functional Divisions of the Immune System

| | Innate | Adaptive |
|-------------------|--|------------------------------|
| Exterior defenses | Skin, mucus, cilia, normal flora, saliva, low pH of the stomach, skin, and genitourinary tract | None |
| Specificity | Limited and fixed | Extensive |
| Memory | None | Yes |
| Time to response | Hours | Days |
| Soluble factors | Lysozymes, complement, C-reactive protein, interferons, mannose binding lectin | Antibodies, cytokines |
| Cells | Neutrophils, monocytes, macrophages, NK cells, eosinophils | B-lymphocytes, T-lymphocytes |

NK, natural killer.

such, patients with a substantial loss of the skin from a burn or those requiring mechanical ventilation, bladder catheterization, or central venous access are at increased risk of infection.

THE IMMUNE RESPONSE

When an infectious pathogen eludes the exterior defenses of the body, an immune response involving both leukocytes and soluble mediators then attacks the pathogen.

INNATE RESPONSE

Innate immunity is present from birth and uses a preexisting but limited repertoire of receptors to recognize pathogens and destroy them. The innate leukocytes include monocytes, macrophages, neutrophils, basophils, mast cells, and eosinophils. All except basophils act as phagocytes, while mast cells and basophils secrete inflammatory mediators when stimulated. The phagocytes recognize, internalize, and destroy invading pathogens. These cells use either opsonin-dependent phagocytosis or opsonin-independent phagocytosis. For opsonin-dependent phagocytosis, antibody (e.g., IgG), complement (e.g., C3b), or lectin (e.g., C-reactive protein) coats the infectious pathogens in a process termed *opsonization*; then the antibody, complement, or lectin binds to the receptors on the innate leukocyte (Fig. 84–1), thereby activating the phagocytic process. For opsonin-independent phagocytosis, innate leukocytes utilize pattern-recognition receptors. Pattern-recognition receptors focus on highly conserved structures present on a large group of microorganisms and essential for survival of the microorganisms or pathogenicity. These receptors include the macrophage mannose receptor, the macrophage scavenger receptor, and members of the toll-like receptor family. Pattern-recognition receptors on phagocytes directly recognize ligands (e.g., lipoteichoic acid from gram-positive organisms, lipopolysaccharide from gram-negative organisms, or mannoses) on the surfaces of infectious pathogens (see Fig. 84–1). The macrophage mannose receptor recognizes a variety of gram-positive bacteria, gram-negative bacteria, and fungi based on their overexpression of mannoses. The macrophage scavenger receptor recognizes

FIGURE 84–1. Phagocytosis of bacteria by macrophages, dendritic cells, and neutrophils. Macrophages, dendritic cells, and neutrophils recognize bacteria that are opsonized and coated with antibody or complement (C3b). On the surfaces of the macrophages, dendritic cells, and neutrophils reside receptors for antibody (Fc receptor) and complement (CR1, CR3, CR4). In addition, these cells may recognize the bacteria by pattern-recognition receptors on the surfaces of the macrophages, dendritic cells, and neutrophils. Pattern-recognition receptors include the toll-like receptors, scavenger receptors, and mannose receptors.

the lipopolysaccharide from bacteria and double-stranded RNA from RNA viruses. The major function of these receptors is phagocytosis of the pathogen. Other pattern-recognition receptors that mediate phagocytosis include MARCO and DEC205. Toll-like receptors are another family of pattern-recognition receptors on the cell surface of innate leukocytes. To date, 10 toll-like receptors have been identified in humans. They recognize a broad spectrum of antigens ranging from lipopolysaccharide and flagellin on bacteria to zymosan on yeast to double-stranded RNA from RNA viruses. Binding of the ligand to the toll-like receptors results in the secretion of chemokines, inflammatory cytokines, and antimicrobial peptides, as well as the increased expression of costimulatory proteins (e.g., B7) and the major histocompatibility complex (MHC) proteins. This leads to the recruitment and activation of antigen-specific lymphocytes.^{2–4}

The granulocytes include neutrophils, eosinophils, and basophils. The cytoplasmic granules of these cells often contain inflammatory mediators or digestive enzymes. Neutrophils are polymorphonuclear cells, often denoted as PMNs for this reason, that serve as the primary human defense against invasive bacteria and comprise the majority of leukocytes in the bloodstream. Neutrophils migrate from the bloodstream into infected or inflamed tissue in response to chemotactic factors such as IL-8 and C3a and C5a, breakdown products of complement. This migration of neutrophils to sites of infection is termed *chemotaxis*, whereupon they recognize, adhere to, and phagocytose pathogens. Neutrophils can only recognize pathogens opsonized or coated with complement or IgG (antibody) via the complement and antibody receptors located on the surface of the neutrophil. They also can recognize pathogens via toll-like receptors. Once bound, the neutrophil then releases its granular contents into lysosome and generates the release of oxidative metabolites, thereby killing engulfed pathogens.⁵

Eosinophils are also granulocytic cells involved in innate immunity. They exhibit motility and migrate from the blood into the tissues. They play a less significant role in combating bacterial infections, but eosinophils play a major role against nonphagocytizable multicellular pathogens such as parasites. After activation via a high-affinity receptor for IgE (i.e., Fc ϵ), granule exocytosis releases the granule contents (e.g., major basic protein, reactive oxygen metabolites) into the microenvironment to lyse the parasite. Besides Fc ϵ receptors, eosinophils express lower levels of complement receptor 3 and Fc γ for IgG than neutrophils. Because of their ability to bind IgE, eosinophils contribute to the pathogenesis of allergic disorders (i.e., allergic asthma).⁶

Macrophages and monocytes are mononuclear cells capable of phagocytosis. Tissue macrophages arise from the migration of monocytes from the bloodstream into the tissues. Macrophages differ from monocytes by possessing an increased number of Fc and complement receptors. Macrophages are found within specific tissues such as the liver, spleen, gastrointestinal tract, lymph nodes, brain, and others. These specific types of macrophages are often called *histiocytes* or referred to by a specialized name depending on the site where they are found (Kupffer cells in the liver, osteoclasts in the bone, microglial cells in the central nervous system, etc.). The term *reticuloendothelial system* (RES) was used commonly to refer to macrophages found in reticular connective tissue, but the preferred term is now the *mononuclear phagocyte system*.⁷

Despite the first description of Langerhans cells, a type of dendritic cell found in the skin, in 1868, our understanding of the biologic function of dendritic cells did not develop until the past decade. Before encountering a pathogen, most dendritic cells are in an immature/resting state with limited ability to activate T-lymphocytes; however, they express numerous receptors (e.g., Fc receptors of IgG

and IgE, macrophage mannose receptor, toll-like receptors) to capture antigen. After taking up antigen, they become activated, which leads to a dramatic increase in their expression of MHC class II, B7, CD40, and adhesion molecules. Dendritic cells then begin to migrate through the tissues toward lymphoid organs (e.g., spleen, lymph nodes) to present antigen to T-lymphocytes to initiate the activation process.⁸

❖ In addition to phagocytosing pathogens, macrophages and dendritic cells act as antigen-presenting cells (APCs) to stimulate the adaptive (specific) system. Macrophages and dendritic cells internalize the organism, digest it into small peptide fragments, and then combine these antigenic fragments together with MHC proteins. Once the APC has formed the antigen-MHC complex, the APC places the complex on its surface. This surface complex then can be recognized by the T-cell receptor on the surface of a T-lymphocyte. Recognition of the antigen-MHC complex by the T-cell receptor is the first step in the activation of the T-lymphocyte (Fig. 84–2). Other cells, B-lymphocytes and mast cells, can act as APCs^{7–9} (Fig. 84–3).

Mast cells and basophils act primarily by releasing inflammatory mediators. Mast cells are tissue cells predominately associated with IgE-mediated inflammation. They are especially abundant in the skin, lungs, and nasal mucosa. Granules within the mast cells contain large amounts of preformed mediators that include histamine, heparin, serotonin, etc. Mast cells can phagocytize, destroy, and present bacterial antigens to T-lymphocytes.¹⁰ Basophils are similar to mast cells because they contain granules filled with histamine, but they typically are found circulating in the blood and are not found in connective tissue. Like mast cells, basophils also express high-affinity IgE Fc receptors (Fc ϵ). IgE-mediated anaphylaxis (type I hypersensitivity; see Chap. 86) is caused by the stimulation of mast cells and/or basophil degranulation and the release of preformed mediators after allergen binds to IgE bound to the Fc ϵ receptor on the surface of mast cells or basophils.¹¹

Soluble mediators of innate immunity include the complement system, mannose-binding lectin, and C-reactive protein (CRP).¹ The complement system consists of more than 30 proteins in the plasma and on cell surfaces that play a key role in immune defense. The four major functions of the complement system include (1) the ability to lyse certain microorganisms and cells, (2) the ability to stimulate the chemotaxis of phagocytic cells, (3) the ability to coat or opsonize foreign pathogens, which allows phagocytosis of the pathogen by leukocytes expressing complement receptors, and (4) the clearance of immune complexes. Complement factors (C3a, C5a) act as chemotactic factors for phagocytic cells.¹² Two different pathways stimulate the complement cascade. In the *classic pathway*, antibody binds to its target antigen and activates the first component of complement (C1), thereby initiating the complement cascade. The *alternative complement pathway* relies on the inability of microorganisms to clear spontaneously produced C3b, the active form of third complement protein, from their surfaces. Patients with hereditary deficiencies of complement have recurrent bacterial infections or immune-complex disease. Both mannose-binding lectin and C-reactive protein are acute-phase reactants produced by the liver during the early stages of an infection that bind to infectious pathogens and then activate the lectin or minor pathway of the complement system. Mannose-binding lectin binds to mannose-rich glycoconjugates on microorganisms, whereas C-reactive protein binds to phosphorylcholine on bacterial surfaces.^{1,12}

Chemokines play an essential role in linking the innate and adaptive immune responses by orchestrating leukocyte trafficking. The chemokine system consists of a group of small polypeptides and their receptors. Chemokines possess four conserved cysteines. Based on

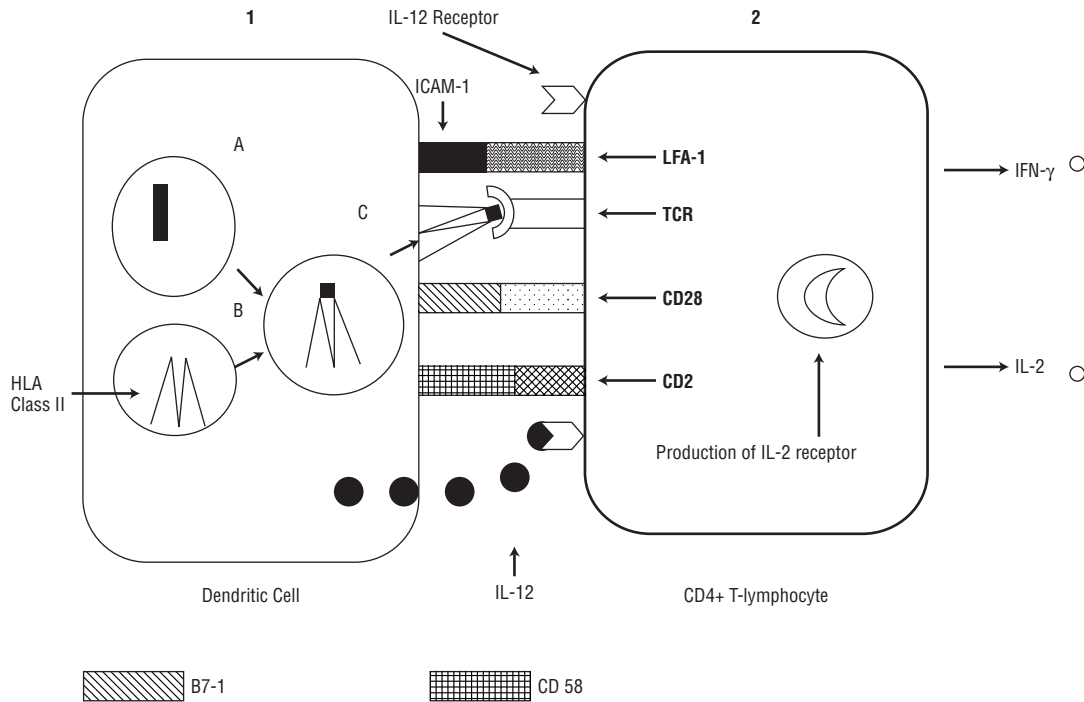

FIGURE 84–2. Induction of TH₁ response. The antigen-presenting cell, in this case a dendritic cell, engulfs the pathogen by any of numerous cell surface receptors (see Fig. 84–1). (1) After phagocytosis of the bacteria by the dendritic cell (A), the pathogen is digested into small peptides and becomes associated with MHC class II within the endosome (B). Finally, the MHC class II plus peptide is expressed on the surface of the dendritic cell (C). The activated dendritic cell also secretes IL-12. (2) The naïve CD4⁺ T-lymphocyte activation requires the T-cell receptor (TCR) to recognize the antigenic peptide in association with MHC class II as well as the B7-1 (CD80) binding to CD28. The binding of CD2–CD58 and LFA-1 (CD11a/CD18) allows the adherence between the T-lymphocyte and dendritic cell. Upon activation, the TH₁ CD4⁺ T-lymphocyte secretes IL-2 and γ-interferon and increases the production and the expression of the IL-2 receptor.

the positions of the cysteines, almost all chemokines fall into one of two categories: (1) the CC group, in which the conserved cysteines are contiguous, or (2) the CXC subgroup, in which the cysteines are separated by some other amino acid (X). As with all ligand-receptor interactions, a cell can only respond to a chemokine if it possesses a receptor that recognizes it. Chemokine receptors are unique in that they traverse the membrane seven times. CC receptors (CCR) and CXC receptors (CXCR) bind CC ligands (CCL) and CXC ligands (CXCL), respectively (Table 84–2).

Binding of infectious pathogens to pattern-recognition receptors stimulates the release of macrophage inflammatory protein (MIP) 1α, MIP-1β, MIP-3α, and IP-10 from macrophages and dendritic cells

embedded in the tissues. These chemokines attract more immature dendritic cells to the site of inflammation/infection. Immature dendritic cells constitutively express CCR1, CCR5, and CCR6. The interaction between pattern-recognition receptors on the dendritic cell and the infectious pathogen causes the activation and maturation of the dendritic cell. After activation, dendritic cells downregulate the expression of CCR1, CCR5, and CCR6 and upregulate the expression of CCR7. This switch in chemokine-receptor expression results in the antigen-loaded dendritic cell leaving the tissue and migrating toward the lymph nodes.¹³

ADAPTIVE RESPONSE

To amplify the immune response, activation of the adaptive immune system is required. The adaptive immune response differs from the innate immune response in two critical areas: specificity and memory. T- and B-lymphocytes comprise the cells of the adaptive response. These cells have surface receptors specific for the invading organism. In a manner that uses genetic rearrangement of their DNA, it is estimated that lymphocytes have the ability to recognize over 10¹⁵ different types of antigens. Generally, the body will employ both the innate and adaptive immune responses to kill foreign pathogens.¹

The adaptive immune response can be divided into two major arms: humoral and cellular-mediated. The B-lymphocytes and plasma cells, activated B-lymphocytes that secrete antibody, comprise the humoral arm of the adaptive immune response. The humoral response is so denoted because it was found that the factors that provided the

TABLE 84–2. Common Chemokines

| Receptor | Cell Expression | Ligand |
|----------|-----------------------------------|-------------------------------|
| CCR1 | Immature DC | MIP-1α, MIP-1β, MCP-2, RANTES |
| CCR3 | Eosinophils, basophils | Eotaxin-1, -2, -3, MCP-4 |

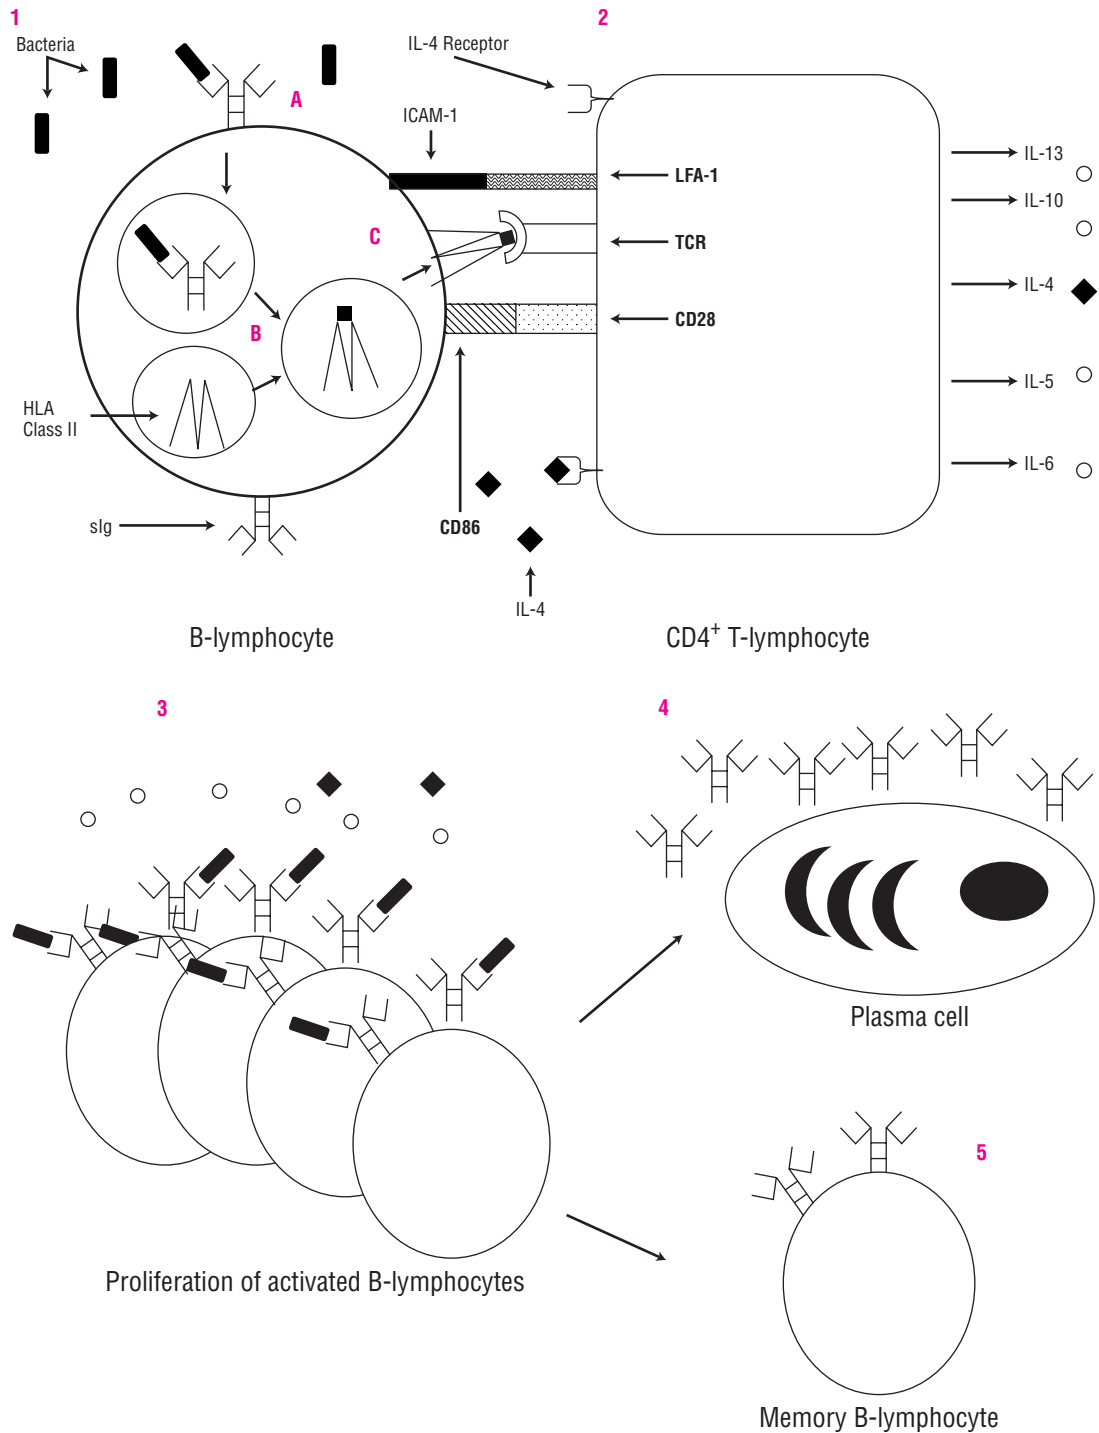

FIGURE 84-3. Induction of a TH₂ response. (1A) A B-lymphocyte recognizes an invading bacteria via its surface immunoglobulin (slg) (B). (1B) The bound bacteria is then phagocytosed into an endosome, where the bacteria is broken down into small peptide fragments (B). (1C) The small peptide fragments are then placed within MHC class II molecules and transported to the surface of the B-lymphocyte for antigen presentation to a CD4⁺ T-lymphocyte (C). (2) CD4⁺ T-lymphocyte recognition requires antigen recognition within the MHC class II peptide groove by the T-lymphocyte receptor (TCR) and a secondary signal from B7 from the antigen presenting cell, in this case a B-lymphocyte, binding to CD28 on the T-lymphocyte. When both signals are delivered to the CD4⁺ T-lymphocyte, it becomes activated. In the TH₂ environment (see text), the naïve CD4⁺ T-lymphocyte develops into a TH₂ subtype and secretes IL-4, IL-5, IL-6, IL-10, and IL-13 that promote a TH₂ response. (3) In the presence of these cytokines plus antigen binding to the its slg, the B-lymphocyte becomes activated. The activated B-lymphocyte becomes a plasma cell (4) that produces and secretes immunoglobulin or becomes a memory B-lymphocyte (5). The minority of B-lymphocytes become memory B-lymphocytes.

immune protection could be found in the blood humor or serum. The cell-mediated arm is mediated by T-lymphocytes. The immune protection provided by these cells could not be transferred by serum alone. Rather, it is essential to actually have T-lymphocytes present, thus the term *cell-mediated immunity*. T-lymphocytes are specially tailored to defend against infections that are intracellular, such as virally infected cells, whereas B-lymphocytes secrete antibodies that can neutralize pathogens prior to their entry into host cells.

2 T-lymphocytes do not recognize intact antigen. T-lymphocytes recognize processed antigen in association with the MHC. APCs (e.g., macrophages and dendritic cells) phagocytize the pathogen and then break down the pathogen and express peptide fragments of the processed antigen in association with the MHC on their surface. T-lymphocytes express a specific antigen receptor, the TCR. The TCR is comprised of two chains, with each chain having a variable and a constant region. The variation in the amino acid sequence within the variable domain of the TCR gives the cell its unique antigen specificity. Linked to the TCR is a complex of single chains known as the *CD3 complex*.^{1,9}

Naïve T-lymphocytes, cells that have not been exposed previously to an antigen specific for their TCR, require two signals for activation. The first signal for activation involves the T-lymphocyte recognizing both the processed antigen and the MHC-molecule complex. The second signal involves the interaction of the B7-1 (CD80) or B7-2 (CD86) molecule on the APC with the CD28 molecule on the surface of the T-lymphocyte (see Figs. 84-2 and 84-3). Without the second signal, the T-lymphocyte becomes anergic or inactive. Memory T-lymphocytes are less dependent on the second signal than are naïve T-lymphocytes. CD28 is expressed on both resting and activated T-lymphocytes, whereas CTLA-4, a second ligand for B7 on T-lymphocytes, is expressed only on activated T-lymphocytes. CTLA-4 binding B7 transduces a negative signal so that it plays a role in downregulating a T-lymphocyte response.¹⁴ After the two activation signals, a message is sent through the TCR to the CD3 complex into the cell. Then a calcium influx occurs with subsequent activation of the T-lymphocyte. Activated CD4⁺ T-lymphocytes release various soluble factors (e.g., IL-2) to stimulate T-lymphocytes and other cells of the immune system (see Fig. 84-2) and to express high-affinity IL-2 receptor. Autocrine stimulation by IL-2 leads to the proliferation of the activated T-lymphocyte.

Cell surface markers or functional activity delineate T-lymphocyte populations. All T-lymphocytes express the CD3 protein. Typically, T-lymphocytes are further divided into helper cells (CD4⁺), suppressor cells (CD8⁺), and cytotoxic cells (CD8⁺). Each of the subclasses appears to play a distinct role in the cell-mediated immune response. Naïve T-lymphocytes express CD45RA, a high-molecular-weight isoform of CD45, while memory T-lymphocytes express CD45RO, a lower-molecular-weight isoform of CD45.¹⁵ The primary role of CD4⁺ cells is to stimulate other cells in the immune response. Functionally, CD4⁺ cells can be divided into TH₁ and TH₂. This functional system was first described in mice. TH₁ cells secrete IL-2 and γ -interferon and stimulate CD8⁺ cytotoxic cells, while TH₂ cells secrete IL-4, IL-5, and IL-10 and stimulate B-lymphocyte production of antibody.¹⁶ Multiple factors determine whether a naïve CD4⁺ T-lymphocyte develops into a TH₁ or a TH₂ cell. The cytokine microenvironment plays an important role in this development. IL-12 secreted by the APCs promotes TH₁, whereas IL-4 promotes TH₂ development. Other factors that promote TH₁ development include B7-1 (CD80), high affinity of the TCR for the antigen, γ -interferon, and α -interferon. Factors that promote TH₂ development include B7-2 (CD86), low affinity of the TCR for the antigen, IL-10, and IL-1.¹⁷

CD8⁺ T-lymphocytes recognize antigen in association with MHC class I. CD8⁺ cytotoxic cells are instrumental in killing cells

recognized as foreign, such as those which have become infected by a virus. These cells also play an important beneficial role in the eradication of tumor cells but also are responsible for rejection of transplanted organs.⁹ Classically, a second type of CD8⁺ T-lymphocyte was a suppressor cell. It is clear that some T-lymphocytes help to suppress the immune responses, but whether this subset is CD8⁺ is debatable. Emerging evidence is leading away from CD8⁺ T-lymphocytes toward CD4⁺ and CD25⁺ T-lymphocytes in maintaining self-tolerance. The preferred term for these suppressive T-lymphocytes is *regulatory T-lymphocytes*.¹⁸

To fully activate the CD8⁺ cytotoxic T-lymphocyte requires CD4⁺ T-lymphocyte activation, namely, the TH₁ subset, and its subsequent secretion of IL-2 (Fig. 84-4A). This model of CD8⁺ cytotoxic T-lymphocyte activation requires the close proximity of two rare- antigen-specific T-lymphocytes. In addition, some CD8⁺ cytotoxic T-lymphocyte responses can occur in the absence of CD4⁺ T-lymphocytes. New data suggest that CD4⁺ T-lymphocytes can activate/prime APCs through CD40. This interaction primes the APC (e.g., dendritic cell) to fully activate CD8⁺ cytotoxic T-lymphocytes¹⁹ (see Fig. 84-4B). It is important to remember that the classification of CD4⁺ lymphocytes as T-helper lymphocytes and CD8⁺ lymphocytes as T-cytotoxic lymphocytes is not an absolute. Some CD8⁺ T-lymphocytes secrete cytokines similar to a T-helper lymphocyte, and some CD4⁺ T-lymphocytes can act as cytotoxic cells.

Unlike neutrophils and macrophages, cytotoxic T-lymphocytes are unable to ingest their targets. They destroy target cells by two different mechanisms: the *perforin system* and the *Fas ligand pathway*. After recognition by the cytotoxic T-lymphocyte, cytoplasmic granules containing perforins and granzymes are oriented rapidly toward the target cell, and the contents of the granules are released into the intracellular space. Like the membrane-attack complex formed after complement activation, perforins form a pore in the target cell membrane. Besides a direct cytotoxic effect on the target cell, the pores produced by perforins allow the granzymes to penetrate into the target cell to induce apoptosis. The second mechanism of cytotoxicity involves the binding of Fas ligand on the cytotoxic T-lymphocyte to the Fas receptor on the target cell. The Fas ligand is predominately expressed on CD8⁺ cytotoxic T-lymphocytes and natural killer (NK) cells, and its expression increases after activation. After killing by either mechanism, the cytotoxic T-lymphocyte detaches from the target cell and attacks other targets.²⁰

B-lymphocytes recognize antigen via its antibody or immunoglobulin located on the surface of the B-lymphocyte (see Fig. 84-3). The antibody on the surface can recognize an intact pathogen, such as bacteria, and present antigen to T-lymphocytes (i.e., acting as APC). However, the major function of B-lymphocytes is to produce antibody to bind to the invading pathogen, a process that first entails activation of the lymphocyte. The activation of B-lymphocytes also requires two steps: (1) recognition of antigen by the surface immunoglobulin and (2) the presence of B-lymphocyte growth factors (IL-4, IL-5, and IL-6) secreted by activated CD4⁺ T-lymphocytes. Once activated, the B-lymphocyte becomes a plasma cell, a differentiated cell capable of producing and secreting antibody. A fraction of activated B-lymphocytes does not differentiate into plasma cells but rather forms a pool of memory cells. The memory cells will respond to subsequent encounters with the pathogen, generating a quicker and more vigorous response to the pathogen. Some B-lymphocytes can become activated without help from T-lymphocytes, but these responses generally are weak and do not invoke memory.^{1,9}

3 When binding of a specific antigen to the surface immunoglobulin receptor of B-lymphocytes occurs, the B-lymphocyte matures into a plasma cell and produces large quantities of antibodies that have the ability to bind to the inciting antigen. The secreted

FIGURE 84-4. In the classic model of CD8⁺ T-lymphocyte activation (A), the CD4⁺ and CD8⁺ T-lymphocytes recognize antigen on the same dendritic cell. In the presence of IL-2 from the activated CD4⁺ T-lymphocyte and the recognition of antigen in association with MHC class I, the CD8⁺ T-lymphocyte becomes activated. In the new model (B), activated CD4⁺ T-lymphocytes activate dendritic cells via CD40 ligand binding to CD40. The activated dendritic cell then migrates through the tissues to present antigen to CD8⁺ T-lymphocytes. If recognition via the TCR on the CD8⁺ T-lymphocyte occurs, the dendritic cell can fully activate the CD8⁺ T-lymphocyte without the presence of CD4⁺ T-lymphocytes.

antibodies may be of five different isotypes. On primary exposure to the pathogen, the plasma cell will secrete IgM, but eventually there is a switch to predominately IgG during the first exposure. On second exposure, the memory B-lymphocytes will predominately produce IgG. Isotype switching from IgM to IgG, IgA, or IgE is controlled by T-lymphocytes.

An antibody or immunoglobulin is a glycoprotein consisting of two different chains, heavy and light (Fig. 84-5). The basic structure of every immunoglobulin consists of four peptide chains: two identical

FIGURE 84-5. Schematic structure of the immunoglobulin G (IgG) molecule. An IgG molecule consists of two heavy (H) and two light (L) chains covalently linked by disulfide bonds. Each chain is comprised of variable (V) and constant (C) regions. A light chain consists of one variable (VL) and one constant (CL) region. Heavy chains consist of one variable (VH) and three or four constant (CH) regions, depending on the isotype. The variable regions (VL and VH) comprise the antigen-binding region of the IgG molecule, or fragment antigen binding (Fab). The constant regions provide the structure to the IgG molecule as well as binding the first component of complement (CH2) and binding to Fc receptors via the Fc portion of the molecule (CH3).

heavy chains and two identical light chains held together by disulfide bonds. The basic structure of the antibody is a Y-shaped figure. Each arm of the Y is formed by the linkage of the end of the light chain to its heavy-chain partner. These arms contain the portions described as the *fragments of antigen binding (Fab fragment)*. The stem of the Y contains the heavy chains that comprise the *fragment crystallizable (Fc fragment)* portion of the antibody. It is within the Fc portion that complement is activated once the antibody has bound its target. Likewise, it is the Fc portion of the antibody that is recognized by Fc receptors on the surface of phagocytes (see Fig. 84-1). The amino acid composition of the same isotype is homogeneous except in the variable regions of the light (VL) and heavy chains (VH). The variation in amino acid composition of the variable region gives the antibody its unique specificity (see Fig. 84-5)

IgG, the most prevalent of the antibody classes, comprises approximately 80% of serum antibody. IgG is usually the second isotype of antibody to be produced in an initial humoral immune response. IgG is the only isotype of antibody that can cross the placenta. Therefore, early maternal humoral protection of neonates is primarily due to maternal IgG that crossed the placenta in utero.

Four different subclasses of IgG have been described: IgG₁, IgG₂, IgG₃, and IgG₄. These subclasses differ slightly in their constant amino acid sequences. IgG₁ constitutes the majority (60%) of the subclasses. It appears that different subclasses recognize different types of antigen. IgG₁ and IgG₃ are principally responsible for recognition of protein antigens. Whereas IgG₂ and IgG₄ commonly bind to carbohydrate antigens. Another difference in the subclasses is the ability to activate complement, with IgG₃ and IgG₁ being the most efficient but IgG₄ unable to do so.

IgG can be found on the surfaces of B-lymphocytes as a monomeric Y-shaped structure. In contrast, IgM is a pentamer in which five of the monomers are joined together by a joining chain (*J-chain*). IgM is the first class of antibody to be produced on initial exposure to an antigen. Because the pentameric form of IgM has no Fc portions exposed, phagocytic cells cannot bind pathogens opsonized

by IgM. However, IgM is an excellent activator of the complement cascade by the classic pathway.

IgA is found primarily in the fluid secretions of the body—tears, saliva, and nasal fluids—as well as in the gastrointestinal, genitourinary, and respiratory tracts. IgA functions by preventing pathogens from adhering to and infecting the epithelial cells at these sites. IgA is also secreted in a nursing mother's breast milk, as are IgG and IgM in lower concentrations. In bodily secretions, IgA is in a dimeric form in which a J-chain and a secretory chain hold two monomers together. The dimeric form is resistant to proteolysis in mucosal secretions.

IgD is the least understood isotype. IgD is found on the surface of B-lymphocytes at different stages of maturation and may be involved in the differentiation of these cells. The main function of circulating IgD has not yet been determined.

IgE is the least common of the serum antibody isotypes. Most of the IgE in the body is bound to the IgE Fc receptors on mast cells. When the IgE on the surface of mast cells binds antigen, it causes the release of various inflammatory substances (e.g., histamine) from the mast cell. The overall effect is the stimulation of inflammation. Asthma and hay fever are a few examples of allergic reactions primarily due to antigen binding to IgE.²¹

NK cells, often referred to as *large granular lymphocytes*, are defined functionally by their ability to lyse target cells without prior sensitization and without restriction by MHC. Resting NK cells express the intermediate-affinity IL-2 receptor CD122. Upon exposure to IL-2, NK cells exhibit greater cytotoxic activity against a wide variety of tumors. NK cells recognize target cells by two mechanisms. First, NK cells express an IgG Fc receptor, CD16, that allows recognition of IgG-coated cells. Second, NK cells express killer-activating and killer-inhibiting receptors. The killer-activating receptors recognize multiple targets on normal cells; however, the binding of MHC class I to the killer-inhibitor receptor blocks release of perforins and granzymes. Therefore, cells (e.g., tumor cells, virally infected cells) that downregulate MHC class I expression are susceptible to NK cell cytotoxicity. NK cells play important roles in surveillance against tumors and virally infected host cells, as well as in the regulation of hematopoiesis.^{1,22}

MAJOR HISTOCOMPATIBILITY COMPLEX (MHC)

The MHC, a cluster of genes found on chromosome 6 in humans, is also known as the *human leukocyte antigen (HLA) complex*. The genes from this complex encode for molecules that play a pivotal role in immune recognition and response. The MHC complex is divided into three different classes: I, II, and III. The molecules encoded by class I HLA genes include HLA-A, HLA-B, and HLA-C antigens. These molecules can be found on all nucleated cells within the body, as well as on platelets. Class I antigens are not found on mature red blood cells. Molecules encoded by class II HLA genes include HLA-DP, HLA-DQ, and HLA-DR. The expression of these molecules is more restricted and can be found primarily on APCs such as macrophages, dendritic cells, B-lymphocytes, etc. The class III HLA antigens encode for soluble factors, complement, and tumor necrosis factors.²³

In order for a CD4⁺ T-lymphocyte to become activated, CD4⁺ T-lymphocyte must recognize the antigenic peptide in association with MHC class II (see Figs. 84–2 and 84–3). CD8⁺ T-lymphocytes recognize antigenic peptide in association with class I molecules. Class I molecules generally contain endogenous peptides from within the cell, such as those derived from viruses, whereas class II molecules contain exogenous peptides from antigen that has been phagocytized

and digested, such as bacterial peptides (see Fig. 84–2). For it to destroy a virally infected cell, a CD8⁺ cytotoxic T-lymphocyte requires two steps. First, its TCR must recognize the antigenic fragment, such as a viral protein, in association with MHC class I. The second step involves the costimulatory step of B7-CD28 binding. Because any cell can become infected, it is advantageous that the CD8⁺ cytotoxic T-lymphocyte recognizes the MHC class I molecule that is expressed on all cells except red blood cells. The ability of the MHC class I to present endogenous peptides allows the CD8⁺ cytotoxic T-lymphocytes to constantly screen cells for infections.^{23,24} Dendritic cells demonstrate the unique capacity to direct exogenous antigens toward MHC class I molecules, a process termed *cross-presentation*.²⁵

CYTOKINES

Cytokines, soluble factors released or secreted by cells, affect the activity of other cells or the secreting cell itself. Research has shown that many cytokines have a broad spectrum of effects depending on their concentration, the presence of other factors, and the target cell. Cytokines orchestrate the complex homeostasis of cells and tissues by acting in both an autocrine and a paracrine fashion. For example, activated CD4⁺ T-lymphocytes secrete IL-2 that activates itself as well as activating CD8⁺ T-lymphocytes and NK cells. Cytokines also can be membrane-bound (e.g., IL-1 α) and require direct cell-to-cell contact. In vivo, cytokines do not act alone but in combination with other cytokines. For example, activated CD4⁺ T-lymphocytes secrete both IL-2 and interferon- γ , which are synergistic in activating NK cells. As shown in Table 84–3, cytokines are broadly classified as regulatory or hematopoietic growth factors.^{9,26–30} This classification does not describe all their activities. Granulocyte-macrophage colony-stimulating factor (GM-CSF) released by activated T-lymphocytes acts as a hematopoietic growth factor but also activates granulocytes and macrophages to phagocytize foreign pathogens.

The division of the immune system into the two functional groups does not imply that the divisions do not interact. In order to generate a vigorous immune response, both soluble mediators (e.g., complement, antibody, and cytokines) and cells (e.g., neutrophils, macrophages, T-lymphocytes, and B-lymphocytes) are needed. Generally, the innate system will respond first. Dendritic cells, macrophages, and neutrophils in the tissues will recognize the opsonized pathogen (see Fig. 84–1). In order to amplify the immune response, the APCs will present antigen to CD4⁺ T-lymphocytes (see Figs. 84–2 and 84–3). The activated CD4⁺ T-lymphocytes then will secrete cytokines to activate B-lymphocytes, CD8⁺ T-lymphocytes, NK cells, macrophages, and neutrophils. The next section of this chapter discusses evaluation of the immune system.

EVALUATION OF COMPONENTS OF THE IMMUNE SYSTEM

Assessment of a patient's immune function requires consideration of multiple components, including mechanical defenses, cell phenotypes and cell numbers, and soluble components. Recent developments in biotechnology made possible extraordinary progress in the characterization of immune function. Despite the technological advances, careful patient evaluations are required to assess the structure and function of the immune system accurately. Specific methods for assessment of patient immune status are discussed below.

TABLE 84–3. Cytokines

| Cytokines | Sources | Principal Effects |
|-------------------------------------|---|--|
| Regulatory | | |
| IL-1 | Macrophages, fibroblasts, endothelial cells | Activation of T- and B-lymphocytes, hematopoietic growth factor, and induction of inflammatory events |
| IL-2 | CD4 ⁺ T-lymphocytes (TH ₁ subset) | Activation of T- and B-lymphocytes and NK cells |
| IL-4 | CD4 ⁺ T-lymphocytes (TH ₂ subset), mast cells, basophils, eosinophils | B- and T-lymphocytic growth factor, activation of macrophages, promotes IgE production, proliferation of bone marrow precursors |
| IL-5 | CD4 ⁺ T-lymphocytes (TH ₂ subset), mast cells | Activation of B-lymphocytes and eosinophils, promotes IgE production |
| IL-6 | CD4 ⁺ T-lymphocytes (TH ₂ subset), macrophages, mast cells, fibroblasts | T- and B-lymphocytic growth factor, hematopoietic growth factor, augments inflammation |
| IL-8 | T-lymphocytes, monocytes, endothelial cells, fibroblasts | Neutrophil, basophil, and T-lymphocyte chemotaxis |
| IL-10 | T- and B-lymphocytes, macrophages | Cytokine synthesis inhibitory factor, growth of mast cells |
| IL-12 | Macrophages, neutrophils, dendritic cells | Induce TH ₁ cells, ↑ NK cell activity, ↑ generation of cytotoxic T-lymphocytes |
| IL-13 | Activated T-lymphocytes | Proliferation of B-lymphocytes, suppression of proinflammatory cytokines, directs IgE isotype switching |
| IL-14 | T-lymphocytes | Induces B-lymphocyte proliferation, inhibits secretion of Igs |
| IL-15 | Macrophages, fibroblasts, dendritic cells, epithelial cells | T-lymphocyte proliferation and activation of NK cells |
| IL-16 | CD8 ⁺ T-lymphocytes, epithelial cells | Chemoattractant for CD4 ⁺ T-lymphocytes and eosinophils; stimulation of secondary cytokine secretion from and proliferation of CD4 ⁺ T-lymphocytes |
| IL-18 | Macrophages | Induces γ -interferon production |
| TNF- α | Macrophages, NK cells, T-lymphocytes, B-lymphocytes, mast cells | Activation of neutrophils, endothelial cells, lymphocytes, and liver cells to produce acute-phase proteins |
| TNF- β | T-lymphocytes | Tumoricidal |
| IFN- α | Monocytes, other cells | Antiviral, activation of NK cells and macrophages, upregulation MHC class I |
| IFN- γ | T-lymphocytes, NK cells | Activation of macrophages, NK cells, upregulation of MHC classes I and II |
| Hematopoietic Growth Factors | | |
| IL-3 | T-lymphocytes, macrophages | Maturation and differentiation of hematopoietic and mast cells |
| IL-7 | Bone marrow stromal cells | Lymphopoietin |
| IL-9 | T-lymphocytes | Maturation and proliferation of T-lymphocytes and mast cells |
| IL-11 | Bone marrow stromal cells | Maturation of B-lymphocytes and megakaryocytes |
| G-CSF | Macrophages, endothelial cells, fibroblasts | Maturation and activation of neutrophils |
| GM-CSF | T-lymphocytes, macrophages, endothelial cells, fibroblasts | Maturation and activation of granulocytes dendritic cells, monocytes-macrophages, and eosinophils |
| M-CSF | Macrophages, endothelial cells, fibroblasts | Maturation and activation of monocytes-macrophages |
| Erythropoietin | Kidney, liver | Maturation of red blood cells |
| Stem cell factor | Bone marrow stromal cells, hepatocytes | Activation of mast cells, early-acting growth factor for myeloid and lymphoid precursors |
| c-MPL ligand (thrombopoietin) | Bone marrow stromal cells, liver, kidney | Lineage-specific growth factor for megakaryocytes (platelets) |
| FLT3 ligand | Bone marrow stromal cells | Early-acting growth factor |

MECHANICAL AND NONSPECIFIC IMMUNODEFENSES

As discussed earlier, the mechanical aspects of host defense are extremely important in protection from infection; therefore, assessment of mechanical defenses is critical. Much of the assessment of mechanical immunodefense is accomplished by recognition of situations

where such defense is compromised. Careful patient examination usually reveals the extent of compromise, and laboratory tests generally are not necessary for evaluation of this component. To assess the extent of compromise in mechanical immunodefenses, the clinician should examine the patient carefully and identify the specific types of risks present. Specific examples of altered mechanical defenses are listed in Table 84–4.

TABLE 84–4. Examples of Alteration in Mechanical Immunodefenses That Result in Impaired Immune Status

| |
|--|
| Reduced gastric pH |
| Achlorhydria |
| Use of histamine-2 blockers and proton pump inhibitors |
| Patients with acquired immunodeficiency syndrome (AIDS) |
| Break in skin barrier |
| Burns |
| Surgical incision |
| Penetrating trauma |
| Vascular access devices |
| Impaired mucociliary function of the lungs |
| Smoking |
| Impaired esophageal or epiglottal function |
| Endotracheal intubation |
| Stroke |
| Recumbent position |
| Altered urine flow |
| Urinary stones |
| Anatomic deformities obstructing flow |
| Bladder catheter |
| Anatomic alterations of the heart resulting in turbulent blood flow and endocarditis |

CELLULAR ASPECTS OF IMMUNE FUNCTION

A major aspect of the assessment of immune function relates to the cells of the immune system. Assessment of cells in the clinical setting includes determination of cell type, cell number, and/or function. Generally, determination of the cell types and quantification of the cell numbers are performed first because of the ease of obtaining these results and the common correlation with the clinical situation.

QUANTIFICATION

To quickly screen cell numbers, a white blood cell (WBC) count with differential is performed. Normal cell counts are shown in Table 84–5.³¹ This simple test often steers the differential diagnosis. In interpreting a WBC count with differential, several factors must be considered. A normal cell count does not mean that a leukocyte disorder does not exist. For example, in chronic granulomatous disease, a child has a normal neutrophil count, but the neutrophils are unable to

TABLE 84–5. Leukocytes in Adults

| Cell | Absolute Count (Range) ^a | Percent (Range) |
|-------------------|-------------------------------------|-------------------------|
| White blood cells | 7.5 (4.5–11.0) | 100 |
| Neutrophils | 4.5 (2.3–7.7) | 60 (50–70) |
| Eosinophils | 0.2 (0.0–0.45) | 3 (0–5) |
| Basophils | 0.04 (0.0–0.2) | 1 (0–2) |
| Monocytes | 0.3 (0.0–0.8) | 4 (0–10) |
| Lymphocytes | 2.1 (1.6–2.4) | 32 (28–39) |
| T-lymphocytes | 1.4 (1.1–1.7) | 72 (67–76) ^b |
| CD4 ⁺ | 0.8 (0.7–1.1) | 42 (38–46) ^b |
| CD8 ⁺ | 0.7 (0.5–0.9) | 35 (31–40) ^b |
| B-lymphocytes | 0.3 (0.2–0.4) | 13 (11–16) ^b |
| NK cells | 0.3 (0.2–0.4) | 14 (10–19) ^b |
| CD4:CD8 ratio | 1.2 (1.0–1.5) | |

^aTimes 10³ cells/mm³.^bPercentage of lymphocyte subpopulations expressed as percentage of total lymphocyte population.

destroy the bacteria. Second, a differential is reported as a percentage of the WBC count; therefore, one must assess the absolute number as well as the percentage of WBC subtypes. For example, a patient admitted to the hospital with pneumonia has an elevated WBC count (15.0×10^3 cells/mm³) that is predominately neutrophils (segs + bands $\times 100 = 80\%$). The percentage of lymphocytes appears low at 15%, but the absolute number of lymphocytes is actually normal, 2250 cells/mm³. A third factor to consider is that the majority of lymphocytes are in secondary lymphoid organs (e.g., lymph nodes, spleen), and changes in peripheral blood lymphocytes do not always mirror changes in the secondary lymphoid organs. Additionally, the majority of granulocytes, macrophages, and mast cells are in the tissues, not the bloodstream.

Generally, the numbers of granulocytes (neutrophils, basophils, eosinophils) and monocytes are assessed by a WBC count with differential. It has long been recognized that the lower the absolute neutrophil count, the greater is the risk of infection. Drugs (e.g., chemotherapy) and diseases (e.g., collagen-vascular disorders) may lower the neutrophil count and make the patient more susceptible to infections. Patients with a neutrophil count below 1500 cells/mm³ are considered to have neutropenia. Functional analysis of these cell types is done rarely in routine clinical practice. Patients with functional deficits in these cell types generally are referred to tertiary medical centers for evaluation and treatment.

A routine WBC count with differential can determine the total lymphocyte count. Total lymphocyte count has been used as a measure of nutritional status because this changes rapidly with nutrient loss or repletion. This is a relatively gross measure of a patient's immune status, although it has been correlated with patient outcome and risk of infection.

Lymphocyte populations with different functions or in various stages of activation can be enumerated based on their cell surface markers. These cell surface markers are known as *clusters of differentiation* (CDs). The CD is usually a protein or glycoprotein on the surface of the cell. CD followed by a number designates the marker. Hundreds of monoclonal antibodies have been designed to recognize these cell surface markers. Monoclonal antibodies can be coupled with a fluorescent marker. The labeled monoclonal antibodies are incubated with the lymphocytes. Antibodies will recognize and bind to the cells expressing the CD of interest. The cells are then counted with flow cytometry. For flow cytometry, the cell suspension is put under pressure such that the cells flow past a laser in a stream of single cells. The laser will excite the fluorescently-labeled antibodies bound to the lymphocytes. A light detector is able to count the labeled cell as the fluorescent tag emits light and determines the size of the cell based on its light scatter. These evaluations are valuable for assessment of patients with immune-deficiency states such as AIDS or leukemias and for patients who have received organ transplants. Quantification of CD3⁺ and CD4⁺ cells is used to monitor muromonab immunosuppression and in the clinical management of patients with human immunodeficiency virus (HIV) infection, respectively. Some of the more common CD antigens and their respective cellular distribution are listed in Table 84–6.³² Flow cytometry can be used for leukocyte phenotyping, tumor cell phenotyping, and some types of DNA analysis.

FUNCTIONAL EVALUATION OF IMMUNE RESPONSE

In Vivo

The most common in vivo assay of lymphocyte function is the delayed hypersensitivity skin test. This test specifically evaluates the presence

TABLE 84–6. Cluster of Differentiation (CD) Guide: Characterization of Human Leukocyte Antigens

| CD | Predominant Cellular Distribution |
|------|---|
| CD3 | All T-lymphocytes |
| CD4 | Helper T-lymphocytes either TH ₁ or TH ₂ |
| CD5 | T-lymphocytes, B-lymphocyte subset |
| CD8 | Cytotoxic/suppressor T-lymphocytes |
| CD14 | Monocytes, macrophages |
| CD20 | B-lymphocytes |
| CD25 | Activated T-lymphocytes, B-lymphocytes IL-2-receptor alpha chain (Tac) |
| CD33 | Committed myeloid progenitor cells |
| CD34 | Hematopoietic progenitor cells that include the stem cell |
| CD56 | NK cells |
| CD83 | Dendritic cells |

NK, natural killer.

of delayed-type hypersensitivity or memory T-lymphocytes. By injecting a small amount of test material, antigen to which the patient has been exposed previously, into the patient's skin, a visual assessment can be made of the patient's ability to react to the antigen.

When an antigen to which a normal patient has been exposed previously is injected into the skin, the area of the injection becomes infiltrated with lymphocytes within a few hours. In the next stage, additional lymphocytes and phagocytes (e.g., macrophages, neutrophils) infiltrate. The maximal intensity of the inflammatory reaction occurs by 24 to 72 hours. This reaction is often referred to as *type IV hypersensitivity* (i.e., cell-mediated; see Chap. 86). In type I hypersensitivity, a positive skin reaction is evident usually within 15 minutes and always within 24 hours. Type I hypersensitivity involves the release of histamine from basophils and mast cells when antigen binds to the IgE on the surfaces of these cells.

A delayed-type hypersensitivity reaction is a test of cell-mediated immunity. The most common method is to administer intradermally a panel of recall antigens. Commonly used antigens include *Candida albicans*, mumps, *Trichophyton*, tetanus toxoid, and purified protein derivative of tuberculin (PPD).³³ Measurements in millimeters of induration at the site of injection should be taken 48 to 72 hours after placement of the antigens. A reaction is considered positive if the diameter of induration is 2 mm or greater. The degree of sensitivity correlates with the area of induration.³² Reaction to even a single antigen indicates a functioning cell-mediated immunity. The majority of immunocompetent individuals will show a positive reaction to at least one of these antigens. Possible reasons for not mounting a response to these antigens include congenital T-lymphocyte deficiency, cancer, HIV infection, or immunosuppressive drug therapy.³³ Sometimes, no response is mounted because the individual being tested has not been exposed previously to a particular test antigen, although this is rare.

The accepted indications for delayed hypersensitivity skin testing include evaluation of immune disorders or chronic diseases that cause cellular immune dysfunction (e.g., uremia, cancer, AIDS, etc), exposure to infectious pathogens (e.g., *Mycobacterium tuberculosis*), evaluation of nutritional status (because malnutrition can result in cell-mediated immune deficiency), and in some cases, assessment of immune senescence.

In vivo assessment of B-lymphocyte function involves immunizing the patient with a protein (e.g., tetanus toxoid) and a polysaccharide (e.g., pneumococcal polysaccharide vaccine) antigen to elicit and

measure antibody responses after immunization. After two to three weeks, the patient's serum is tested for antibodies specific for the immunized antigen. This test measures B-lymphocyte responsiveness to the inoculated antigens but is reserved for patients who are suspected to have impaired B-lymphocyte function.³²

In Vitro

There are a number of specific lymphocyte functional assays that are used in the research setting. A few assays are performed at specialized clinical laboratories. One of these tests is the lymphocyte proliferation assay. In this assay, lymphocytes are obtained from a patient's peripheral blood and cultured in vitro. The cells are exposed to non-specific mitogens such as pokeweed mitogen, phytohemagglutinin, or concanavalin A. Then the cells are incubated in growth media containing tritium-labeled [³H]thymidine, a nucleotide used in the synthesis of DNA. Normally, in the presence of the mitogens, lymphocytes will be stimulated to proliferate. Proliferating lymphocytes will incorporate [³H]thymidine as they replicate DNA. The level of radioactivity of the cells can be measured on a β -scintillation counter and is proportional to the degree of proliferation. The patient sample would be compared with samples from normal, healthy controls. Patients with immune deficiencies (AIDS, cancer, etc.) have fewer active or less active lymphocytes, as detected by this test.

A modification of the lymphocyte proliferation assay is used in allogeneic hematopoietic stem cell transplantation to evaluate how closely a donor and host are "matched" in order to predict a patient's risk for developing graft-versus-host disease. A mixed-lymphocyte culture (MLC) can be used to assess the potential of the donor cells to attack the host cells (see Chap. 134). In this test, donor cells and host cells are incubated in vitro. The host lymphocytes are irradiated prior to the incubation so that they cannot proliferate. In vitro, [³H]thymidine is provided to the cells, and uptake is measured. The degree of uptake correlates with the level of proliferation of donor lymphocytes. If the cells are well matched, proliferation is minimal. If the cells are mismatched, proliferation will be noted, with the level of proliferation predictive of the risk of graft-versus-host disease. With the introduction of DNA-based molecular typing of HLA antigens, the clinical utility of the MLC appears less important. However, the MLC may play a role in selecting not completely histocompatible donors.³⁴

In addition to the test just described, a number of other tests have been devised to evaluate the function of CD8⁺ T-lymphocytes, NK cells, and monocytes/macrophages. Although these evaluations are not performed commonly, they may be helpful in some specific diseases. A thorough discussion of these tests is available.³⁵

HUMORAL ASPECTS OF HUMORAL FUNCTION

The humoral components of the immune system (e.g., immunoglobulins, complement, and cytokines) are often assessed. Assays of humoral components may be either quantitative to determine the absolute concentration of the factor or qualitative to determine the function of the component.

IMMUNOGLOBULINS

The most common evaluation of immunoglobulins is the estimation of total immunoglobulin. This is approximated by subtracting the albumin concentration from the total protein concentration in serum. This difference gives a gross estimation of the total immunoglobulin concentration. Actual determination of the total immunoglobulin

TABLE 84–7. Potential Indications for Measurement of Antigen-specific Antibody

concentration is done by serum protein electrophoresis (SPEP). Five separate zones are detected by this method: albumin, α_1 -globulin, α_2 -globulin, β -globulin, and γ -globulin.

4 The γ -globulin fraction contains the five isotypes of immunoglobulin (i.e., IgG, IgA, IgM, IgE, and IgD). A normal total immunoglobulin or γ -globulin concentration ranges from 0.8 to 1.6 g/dL. This test is used to determine if patients have hypogammaglobulinemia (i.e., primary and secondary immunodeficiencies), a monoclonal peak (e.g., multiple myeloma, Waldenstrom's macroglobulinemia), or a polyclonal hypergammaglobulinemia (e.g., chronic inflammatory conditions such as systemic lupus erythematosus or chronic active hepatitis). Total immunoglobulin or γ -globulin concentrations cannot be used to measure antigen-specific antibodies or specific isotypes, although other evaluations can.

In a patient suspected of having humoral immune deficiency or B-lymphocyte failure (i.e., primary and secondary immunodeficiency), specific immunoglobulin isotypes in the plasma should be measured.

There are many indications for the measurement of antigen-specific antibody. Some common indications are listed in Table 84–7. Methods to perform these measurements include enzyme-linked

immunosorbent assay (ELISA), radioimmunoassay (RIA), and radioallergosorbent test (RAST) (Fig. 84–6). The most common reason to measure antigen-specific antibody is to determine whether or not a patient has been exposed to an infectious agent. Generally, IgM antibodies directed against the pathogen indicate an active or recent infection, whereas IgG antibodies directed against the pathogen indicate prior exposure. Initially, plasma cells produce IgM in response to an infection, but subsequently, memory B-lymphocytes produce IgG. Therefore, IgM antibodies will be present during an active infection and shortly after recovery from the infection, but IgG concentrations will go up in a second exposure. Other uses of antigen-specific antibody include determining if a patient has had exposure and is likely to be protected from infection (e.g., hepatitis A virus) or to determine adequate response to vaccination (e.g. hepatitis B vaccine).

Antigen-specific IgE is commonly measured in patients with allergies. Because the presence of antigen-specific IgE is related to clinical allergy, measurement of these antibodies can be helpful in diagnosing allergies and determining offending substances. A standard method for determination of allergen-specific IgE is the RAST. The basic technique involves adding the antigen of interest, which is bound to beads or disks, to the patient's serum. After precipitation and several washings, the antibody bound to the bead or disk is isolated. Finally, a radiolabeled antibody that binds to IgE is added. After further washings, the radiolabeled antibody bound to IgE, which is bound to the antigen on the bead or disk, is counted on a gamma counter.

Antigen skin testing is the preferred method to determine the presence of allergen-specific IgE. When it is produced, IgE binds to high-affinity IgE Fc receptors on basophils or mast cells. Contact of an allergen with the specific IgE on the basophil or mast cell surface causes activation of these cells and the release of inflammatory mediators (e.g., histamine). When this occurs systemically, it can cause anaphylaxis. When it occurs in a confined area such as the skin, erythema and induration are observed within a few minutes of allergen injection. This is the principle used for detection of penicillin allergy, as well as for environmental or food allergies. A positive skin reaction (5 mm or greater of induration) within 15 to 20 minutes is indicative of the presence of allergen-specific IgE.

IgG SUBCLASSES

There are four subclasses of IgG: IgG₁, IgG₂, IgG₃, and IgG₄, that make up 65%, 20%, 10%, and 5% of total plasma IgG, respectively. Concentrations of the subclasses are often measured in patients with primary and secondary immunodeficiencies. IgG₂ and IgG₄ deficiencies are associated with chronic infections. IgG₄ deficiencies are also associated with autoimmune disorders.

FIGURE 84–6. Enzyme-linked immunosorbent assay (ELISA). ELISA is a commonly used method to measure concentrations of a wide variety of substances. To measure the concentration of antibodies to a particular antigen, the antigen is coated onto a solid phase, such as a microtiter plate, beads, etc. If the purpose of the assay is to measure the concentration of antigen in solution, an antibody to the antigen is coated on the solid phase. The biologic fluid, often sera, is added to the wells. An enzyme-labeled antihuman antibody is added next. Finally, the chromogenic substrate for the enzyme is added. The intensity of the color as measured spectrophotometrically is proportional to the concentration of the antibody in the biologic fluid.

COMPLEMENT SYSTEM

The complement system consists of a group of over 30 different proteins involved in lysing and opsonizing invading pathogens, as well as serving as chemotactic factors. Numbers following the letter C (e.g., C1, C2) name the various proteins of the complement system. A test for the global assessment of the complement system is the CH₅₀, the total hemolytic complement test. This test is based on the premise that complement is needed for a rabbit anti-sheep antibody to lyse sheep red blood cells. The source of the complement is the patient's serum. Each laboratory standardizes the test, so normal ranges vary, but a standard curve is developed by adding titrated amounts of sera and measuring the amount of hemolysis. The hemolysis is determined with a spectrophotometer to measure the amount of hemoglobin released. The patient's serum is then tested, and the amount of serum that is needed to lyse 50% of the red blood cells is reported as the CH₅₀. This test does not provide an indication of the function of any specific complement component but is used as a screening test for any complement system defects. If a defect is found, individual complement proteins then can be evaluated by functional or immunochemical methods. Assessment of the complement system is important in patients suspected of having humoral immune deficiencies (i.e., recurrent infections).³²

Several disease states can alter complement concentrations. Complement concentrations frequently are found to be lower than normal during states of acute inflammation. Low complement concentrations often are associated with systemic lupus erythematosus, rheumatoid arthritis, collagen-vascular disorders, poststreptococcal glomerulonephritis, and subacute bacterial endocarditis. These states of apparent low complement concentrations generally are due to high rates of complement utilization that cannot be compensated for by increased complement synthesis.¹²

The liver is the primary source of several components of the complement system (i.e., C2, C3, C4, and factors B and D); therefore, in severe liver failure, a global decrease in complement factors occurs. Inherited complement deficiencies have been described in patients with systemic lupus erythematosus, autoimmune diseases, recurrent gonococcal and meningococcal infections, membranoproliferative glomerulonephritis, and hereditary angioedema.¹²

CYTOKINES

Cytokines are an important means of communication among cells of the immune system and other organ systems. Multiple cytokines with overlapping and redundant functions have been identified. Methods to detect and measure cytokines in biologic samples have been developed. For nearly all the currently identified cytokines, commercial kits are available to measure endogenous and exogenously administered cytokines. The most common and preferable methods to measure cytokines are ELISAs and RIAs. ELISAs and RIAs are easy to run and measure immunoactivity but not biologic activity (see Fig. 84–6). Bioassays measure biologic activity but are cumbersome and extremely variable. Using ELISA, we are able to measure only how much cytokine was produced by the cells in the culture. An ELISPOT is an enzyme-linked assay for detecting and enumerating cytokine-producing leukocytes.³⁶ In contrast to conventional ELISA, ELISPOT allows the user to detect absolute numbers and frequencies of cytokine-secreting leukocytes.

We are still at the very early stages of interpreting the clinical relevance of endogenous cytokine concentrations. Not only is the immune system affected by cytokines such as IL-1, IL-6, and tumor necrosis factor α (TNF- α), but other systems (skeletal, endocrine, central nervous system) are also affected. Therefore, measurement of

cytokine concentrations may be important in the evaluation of other systems as well as the immune system.

Administering cytokines in clinical practice may change not only the concentration of that particular cytokine but also the resulting concentration of other cytokines. For example, systemic administration of GM-CSF to patients increases concentrations not only of GM-CSF but also of TNF- α , IL-6, IL-8, macrophage colony-stimulating factor, and erythropoietin.^{37,38} Secondary endogenous cytokine release should be taken into account when considering the therapeutic effects of these agents and when monitoring cytokine concentrations.

In the future, tissue concentrations as well as blood concentrations may be measured. For example, while most centers currently measure cyclosporine concentrations to estimate the potential for immunosuppressive effects, it may be advantageous to monitor IL-2 concentrations. One of the primary actions of cyclosporine is the inhibition of IL-2 production. Furthermore, perhaps it would be beneficial to measure tissue concentrations of IL-2 in the transplanted organ to get a better estimate of the extent of immunologic suppression.

SOLUBLE CYTOKINE RECEPTORS AND RECEPTOR ANTAGONISTS

The inflammatory response is highly regulated. The activity of cytokines, their receptors, and their antagonists is in a delicate balance. Although cytokine receptors typically are thought of as being found on the target cell, soluble cytokine receptors can modulate the activity of a cytokine in at least two ways: (1) acting as anti-inflammatory agents by binding the cytokine with high affinity but without biologic activity³⁹ and (2) augmenting cytokine activity by prolonging the cytokine's plasma half-life and even maintaining agonist activity on cells that do not inherently respond to the cytokine.⁴⁰ Finally, antagonists to cytokine receptors have been identified.

TNF- α plays a central role in the inflammatory response by both increasing the expression of adhesion molecules in the tissues and stimulating production of proinflammatory cytokines (e.g., IL-2, IL-8), prostaglandins, and nitric oxide. Soluble tumor necrosis factor receptors (sTNFRs) act primarily as inhibitors of TNF by preventing TNF from binding to the membrane-bound TNFRs or by causing the cells to shed the receptor from the surface of the cell so that it can no longer serve as a signaling molecule.⁴¹ Monoclonal antibodies against both TNF (e.g., infliximab and adalimumab) and sTNFRs (e.g., etanercept) have been shown to modulate the activity of TNF and are used clinically for the treatment of autoimmune diseases.

The best-characterized receptor-binding antagonist is the IL-1 receptor antagonist (IL-1RA). IL-1RA blocks the binding of IL-1 to its receptor by competing for the same binding site, but IL-1RA does not possess agonist activity.⁴² A recombinant IL-1RA, anakinra, is used clinically for the treatment of severe rheumatoid arthritis.⁴³

Our developing understanding of soluble receptors and receptor antagonists allows us to better mimic natural mechanisms for minimizing the toxicity of exogenously administered cytokines (e.g., IL-1, IL-2, TNF- α , etc.), as well as for immunomodulating of various diseases (e.g., solid organ transplant rejection, collagen-vascular disorders, sepsis, etc).

MODULATION OF THE IMMUNE RESPONSE

IMMUNOSUPPRESSION

Glucocorticoids, cytotoxic drugs, and antibody preparations have been employed in the control of transplant rejection and to modulate the inflammatory process in autoimmune diseases. As our

understanding of the pathogenesis of transplant immunology and autoimmune diseases has improved, more directed therapy at the underlying pathogenesis has been developed.

Since the 1980s, two mainstays in the transplant armamentarium have been: (1) a polyclonal antibody preparation, equine antithymocyte globulin, and (2) a murine monoclonal antibody, muromonab CD3. Clinically, these products lead to destruction of host T-lymphocytes. Since both products are animal proteins, patients can develop a humoral response to the products [e.g., serum sickness to the equine antithymocyte product or a human antimurine antibody (HAMA) response to muromonab CD3]. To overcome the immune response to foreign proteins, several humanized monoclonal antibodies were developed and are now being used clinically. Humanized monoclonal antibodies consist of the murine hypervariable regions incorporated into a human IgG molecule.⁴⁴

A second concern with equine antithymocyte globulin and muromonab CD3 is that they are directed against all T-lymphocytes. By eliminating all T-lymphocytes, the patient's risk of developing a cytomegalovirus infection and/or posttransplant lymphoproliferative disease increases. The alpha chain of the IL-2 receptor is an ideal target for a humanized monoclonal antibody because it is selectively expressed on activated T-lymphocytes. Chimeric and humanized monoclonal antibodies directed against the alpha chain of the IL-2 receptor offer the advantages of selective immunosuppression and decreased adverse effects. Basiliximab and daclizumab in combination with other maintenance immunosuppressants are highly effective for the prevention of acute rejection in patients with renal transplants (see Chap. 87).⁴⁵ Their use is also being investigated in other types of transplants, for reversal of acute rejection episodes, and for the treatment of autoimmune diseases.

IMMUNOPOTENTIATION

In an attempt to restore normal immune system function or to activate the immune system, immunopotentiators often are used. The best example of immunopotentiation of the immune system is the practice of immunizations. Active immunization with a vaccine or toxoid induces the host's immune system to confer protection against a pathogen (e.g., hepatitis A, hepatitis B, diphtheria toxoid, etc.). This process requires the uptake of the immunogenic epitope by APCs, followed by presentation to CD4⁺ T-lymphocytes, and the subsequent development of either a cellular or humoral immune response.

In contrast to active immunization, passive immunity entails the administration of human immunoglobulin to provide short-term protection to individuals who will be or have been exposed to a pathogen. Intravenous immunoglobulin (IVIG) consists of more than 90% polyclonal IgG that is prepared from donated plasma. In patients with primary or secondary immunodeficiencies, IVIG restores circulating IgG concentrations, thus decreasing the incidence of infections in these patients. In addition to restoring IgG concentrations, IVIG potentially can immunomodulate the immune response. For example, in immune thrombocytopenic purpura (ITP), an autoantibody directed against the platelets leads to the destruction of platelets by antibody-dependent cellular cytotoxicity (ADCC). IVIG saturates the Fc receptors on phagocytic cells, thereby preventing the engulfment of autoantibody-opsonized platelets. IVIG also can contain anti-idiotypic antibodies to immunomodulate an immune response. Anti-idiotypic antibodies are directed against the idiotype or hypervariable region of a native antibody. After administration of IVIG, the anti-idiotypes bind to the hypervariable region of the autoantibody and prevent the autoantibody from opsonizing circulating platelets. In addition, the

anti-idiotypes directed against the autoantibody can bind to the surface immunoglobulin on the B-lymphocyte, producing the autoantibody that leads to destruction of the B-lymphocyte.⁴⁶

There is an inverse relationship between the absolute neutrophil count (ANC) and the risk of infection. As the ANC falls, the risk of infection increases, with a dramatic rise in the incidence of infections when the ANC falls below 500 cells/mm³. Filgrastim (and pegfilgrastim) and sargramostim are myeloid growth factors that accelerate neutrophil recovery after chemotherapy. Filgrastim (and pegfilgrastim) and sargramostim administered after myelosuppressive chemotherapy reduce the severity and duration of neutropenia compared with placebo. In addition to accelerating neutrophil recovery, these myeloid growth factors also enhance the activity (e.g., phagocytosis, superoxide production) of mature neutrophils. Currently, both filgrastim (and pegfilgrastim) and sargramostim are being investigated as adjuncts to antibiotics in patients with bacterial and/or fungal diseases and as immunotherapy in patients with sepsis. Sargramostim or GM-CSF, plays a critical role in the maturation and proliferation of dendritic cells. Because of the essential role of dendritic cells in antigen presentation, sargramostim is also being investigated as an adjunct to vaccines.^{47,48}

CONCLUSION

Our understanding of the immune system has increased dramatically over the last decade. An immune response encompasses dynamic events involving both immunologic cells (e.g., phagocytes, lymphocytes) and soluble mediators (e.g., complement, cytokines, antibodies). A better understanding of the normal immune response allows us to investigate the pathophysiology of diseases in which the immune response is inappropriate. All clinicians need a basic understanding of the immune system and a familiarity with parameters to monitor immune system function in order to refine the development of immunologic treatments for diseases ranging from diabetes mellitus to collagen-vascular disorders to cancer.

SYSTEMIC LUPUS ERYTHEMATOSUS AND OTHER COLLAGEN-VASCULAR DISEASES

Jeffrey C. Delafuente and Kimberly A. Cappuzzo

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Systemic lupus erythematosus (SLE) is a disease predominantly in women.
- 2 The hallmark of SLE is the development of autoantibodies to cellular nuclear components, resulting in chronic inflammatory autoimmune disease. Symptoms and organ involvement depend on the nature of the autoantibodies.
- 3 SLE has a large spectrum of symptoms and organ system involvement, making therapy highly patient-specific. In addition, the signs and symptoms will fluctuate over time.
- 4 The large spectrum of symptoms and organ system involvement makes pharmacotherapy difficult because therapy must be individualized based on each patient's disease activity.
- 5 There is a paucity of quality evidence for the treatment of SLE except for lupus nephritis.
- 6 Almost all classes of medications, including anti-inflammatory and immunosuppressive agents, have been reported to cause vasculitis in most major organ systems.

The collagen-vascular diseases are a heterogeneous group of diseases that can involve the musculoskeletal system, integument, and blood vessels. Each collagen-vascular disease has its own set of diagnostic criteria, although diagnosis can be difficult because of overlapping and nonspecific clinical presentations. The etiology of the various collagen-vascular diseases is often unknown, although the immune system usually is involved in mediation of disease. Therefore, pharmacotherapy usually includes anti-inflammatory agents with or without immunosuppressive drugs.

Although the prevalence of other collagen-vascular diseases may be greater than that of SLE (e.g., polymyalgia rheumatica), SLE is discussed most extensively in this chapter because it is a major collagen-vascular disease with numerous clinical manifestations, its pharmacotherapy can be complex, and a plethora of data is available on the therapy of SLE. Since all the diseases discussed in this chapter have an immune-mediated pathogenesis, the therapeutic principles of SLE can be applied to other autoimmune collagen-vascular diseases. The collagen-vascular diseases discussed include systemic sclerosis, polymyositis/dermatomyositis, polymyalgia rheumatica, and drug-induced vasculitis; these were chosen because they are seen in general practice.

SYSTEMIC LUPUS ERYTHEMATOSUS

SLE is a fluctuating multisystem disease with a diversity of clinical presentations. Abnormal immunologic function and formation of antibodies against “self” antigens underlie the pathogenesis of SLE.

The term *lupus erythemateux* was first used in 1851 by Cazenave, a Frenchman who described an illness in a patient with manifestations occurring in the skin. It is not surprising that SLE was first recognized

as a skin disorder because cutaneous manifestations constitute one of the most common clinical features of the disease. Further descriptions by Kaposi in 1872 and Osler in 1895 led to the concept of a multisystem disease as it became recognized that patients developed complications in other organ systems.^{1,2}

The hallmark of SLE is the development of autoantibodies to cellular nuclear components that leads to a chronic inflammatory autoimmune disease. Recognition of SLE as an autoimmune disease of multisystemic nature led the American College of Rheumatology (ACR) to develop criteria for identifying lupus patients (Table 85–1). These criteria were developed in 1971, revised in 1982, and modified slightly in 1997. The criteria do not include all the clinical manifestations of the disease and are used primarily for distinguishing SLE from other collagen-vascular diseases.³ If 4 or more of the 11 criteria are documented at any time in a patient's medical history, the diagnosis of SLE can be made with about 95% specificity and 85% sensitivity.⁴ Although these criteria may be helpful, diagnosis requires additional serologic, immunopathologic, and clinical evaluations.

EPIDEMIOLOGY

- 1 The incidence of SLE in the United States is estimated to be 5.6 to 7.3 per 100,000 persons per year, with a prevalence of between 124 and 130 cases per 100,000 persons.^{5–7} International studies report similar ranges.^{8,9} The disease occurs predominantly in women, with a reported female-to-male ratio approaching 10:1. Those afflicted with SLE are usually diagnosed between the ages of 15 and 45.^{9,10} SLE is reported to be less prevalent in whites than in other ethnic groups, including blacks, Hispanics, Native Americans, and Asians.^{8–11} Although the most typical SLE patient is a young

TABLE 85–1. Revised Criteria for Classification of Systemic Lupus Erythematosus^a

| Criterion | Definition |
|----------------------|--|
| Malar rash | Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds |
| Discoid rash | Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions |
| Photosensitivity | Skin rash as a result of unusual reaction to sunlight, by patient history or physician observations |
| Oral ulcers | Oral or nasopharyngeal ulceration, usually painless, observed by a physician |
| Arthritis | Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion |
| Serositis | Pleuritis—convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion or Pericarditis—documented by ECG or rub or evidence of pericardial effusion |
| Renal disorder | Persistent proteinuria greater than 0.5 g/day or greater than 3+ if quantitation not performed or Cellular casts—may be red cell, hemoglobin, granular, tubular, or mixed |
| Neurologic disorder | Seizures—in the absence of offending drugs or known metabolic derangements, e.g., uremia, ketoacidosis, or electrolyte imbalance or Psychosis—in the absence of offending drugs or known metabolic derangements, e.g., uremia, ketoacidosis, or electrolyte imbalance |
| Hematologic disorder | Hemolytic anemia—with reticulocytosis or Leukopenia—fewer than 4000/mm ³ total on two or more occasions or Lymphopenia—fewer than 1500/mm ³ on two or more occasions or Thrombocytopenia—fewer than 100,000/mm ³ in the absence of offending drugs |
| Immunologic disorder | Anti-DNA; antibody to native DNA in abnormal titer or Anti-Sm; presence of antibody to Sm nuclear antigen or Positive finding of antiphospholipid antibodies based on (1) an abnormal serum level of IgG or IgM anticardiolipin antibodies, (2) a positive test result for lupus anticoagulant using a standard method, or (3) a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by <i>Treponema pallidum</i> immobilization or fluorescent treponemal antibody absorption test. |
| Antinuclear | An abnormal titer of antinuclear antibody by immunofluorescence or an antibody equivalent assay at any point in time in the absence of drugs known to be associated with “drug-induced lupus” syndrome |

^aThe proposed classification is based on 11 criteria. For the purpose of identifying patients in clinical studies, a person shall be said to have systemic lupus erythematosus if any 4 or more of the 11 criteria are present, serially or simultaneously, during any interval of observation.
From Tan EM, Cohen AS, Fries JF, et al. The 1982 revised criteria for the classification of systemic lupus erythematosus. *Arthritis Rheum* 1982;25:1274; and Hochberg MC. Updating the American College of Rheumatology Revised Criteria for the Classification of Systemic Lupus Erythematosus, *Arthritis Rheum* 1997;40:1725, with permission.

adult woman, the disease can occur in people of any age or race and either gender.

ETIOLOGY

The etiology of abnormal autoantibody production and development of SLE is still unknown. Genetic, environmental, and hormonal factors all may play a role in loss of “self” tolerance and expression of disease. A popular theory is that autoimmune disease such as SLE develops in genetically susceptible individuals after exposure to a triggering agent, possibly something in the environment.^{10,12,13}

Genetic analysis shows that at least four susceptibility genes are required for the expression of lupus in humans.¹³ Familial and twin studies indicate a genetic predisposition for the development of SLE. First-degree relatives of SLE patients are approximately 20 times more likely to develop SLE than the general population; more than 5% of cases are familial. The concordance rate among identical twins ranges from 24% to 58% compared with 3% to 10% for nonidentical twins.¹⁴ Multiple genes contribute to SLE susceptibility, and at least 100 genes have been linked to SLE in humans. Evidence indicates that

major histocompatibility complex (MHC) genes, particularly several human leukocyte antigen (HLA) genes, may be important in lupus. However, non-MHC genes, such as immunoglobulin receptor genes and mannose-binding protein genes, also may contribute to disease susceptibility.^{13,14} Environmental agents that may have a role in induction or activation of SLE include sunlight (i.e., ultraviolet light), drugs, chemicals such as hydrazine (found in tobacco) and aromatic amines (found in hair dyes), diet, environmental estrogens, and infection with viruses or bacteria.¹³ A number of viruses have been implicated as causative agents in genetically susceptible people, but much of the evidence is circumstantial.¹⁵ Additionally, androgen may inhibit and estrogen enhance the expression of autoimmunity, and elevated circulating prolactin levels have been associated with lupus in males and females.^{12,13}

PATHOPHYSIOLOGY

➤ SLE represents a clinical syndrome rather than a discrete disease with a unique pathogenesis.¹⁶ SLE has a large spectrum of

symptoms and organ system involvement. A major event in the development of SLE is excessive and abnormal autoantibody production and the formation of immune complexes. Patients may develop autoantibodies against multiple nuclear, cytoplasmic, and surface components of multiple types of cells in various organ systems in addition to soluble markers such as immunoglobulin G (IgG) and coagulation factors; this fact underlines the multiple organ system involvement of the disease.¹³

Excessive autoantibody production results from hyperactive B-lymphocytes. Multiple mechanisms likely lead to B-cell hyperactivity, including loss of immune “self” tolerance and high antigenic load consisting of environmental and self antigens presented to B cells by other B cells or specific antigen presenting cells (APCs), a shift of T-helper 1 (Th₁) cells to Th₂ cells that further enhance B-cell antibody production, and defective B-cell suppression. Impairment in other immune regulatory processes involving T-lymphocytes (suppressor T cells), cytokines (e.g., interleukins, interferon- γ , tumor necrosis factor α , transforming growth factor β), and natural killer cells also may be involved.^{13,17}

Many autoantibodies are directed against nuclear constituents of the cell and are called collectively *antinuclear antibodies*. Several antinuclear antibodies are important because their presence or absence may aid in the diagnostic and clinical evaluation of patients with SLE. The SLE patient usually has more than one antigen-specific antinuclear antibody in his or her serum and tissues.¹⁸ These are antibodies against such nuclear constituents as double-stranded, or native, DNA (dsDNA); single-stranded, or denatured, DNA (ssDNA); and RNA. Four RNA-associated antigens frequently occurring in SLE are the Smith (Sm) antigen, the small nuclear ribonucleoprotein (snRNP), the Ro (SS-A) antigen, and the La (SS-B) antigen.^{19,20} Histone, a basic component of chromatin and nucleosomes, is another important

nuclear component against which antinuclear antibodies are formed in lupus patients. Antibodies to Ro, La, Sm, or RNP antigens plus antibodies to dsDNA will detect most patients with SLE.¹⁹ Antibodies also may be directed against the phospholipid moiety of the prothrombin activator complex (lupus anticoagulant) and against cardiolipin. The lupus anticoagulant and anticardiolipin antibodies constitute the two main types in a group of autoantibodies called *antiphospholipid antibodies*.

These autoantibodies often are present many years before the diagnosis of SLE.²¹ The appearance of these autoantibodies follows a predictable pattern, with accumulation of specific autoantibodies before the onset of clinical illness. For instance, antinuclear, anti-La, anti-Ro, and antiphospholipid antibodies often precede the onset of SLE by many years, whereas anti-Sm and anti-snRNP antibodies appear only months before diagnosis, usually when clinical symptoms begin to manifest.

Immune dysregulation leading to B-cell hyperactivity and subsequent production of pathogenic autoantibodies, coupled with defective clearance of apoptotic cells, followed by immune-complex formation, complement activation, and defective clearance of immune complexes all lead to inflammatory reactions that ultimately result in tissue injury and damage. An overview of the pathogenesis¹³ of SLE is illustrated in Fig. 85–1.

CLINICAL PRESENTATION

3 As mentioned previously, SLE is a multisystem disease. Below are many of the signs and symptoms and incidences in patients with SLE.^{22–24} Although certain of these may be more common than others, each patient presents differently, and the course of the disease is highly unpredictable. Furthermore, SLE is not static, and

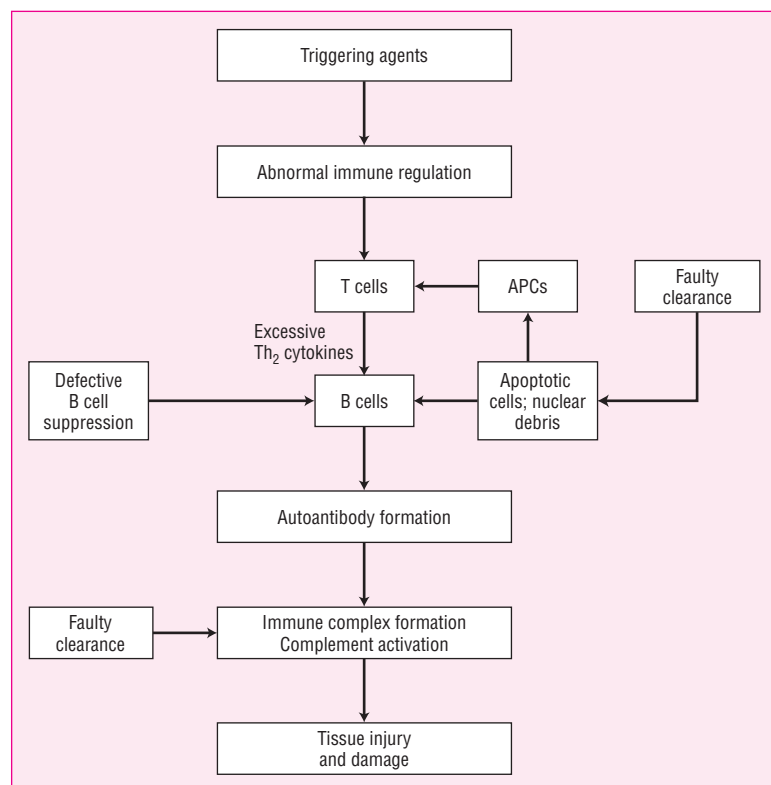

FIGURE 85–1. Pathogenesis of systemic lupus erythematosus. Environmental factors, such as infectious organisms, drugs, and chemicals, serve as triggering agents in genetically and hormonally susceptible individuals to induce a state of immune dysregulation. These abnormal immune responses lead to hyperactive T-helper-2 lymphocyte and B-lymphocyte function. Suppressor T-lymphocyte function, cytokine production, faulty clearance mechanisms, and other immune regulatory mechanisms also are abnormal and fail to downregulate autoantibody formation from hyperactive B-lymphocytes. The autoantibodies formed from this immune dysregulation become pathogenic, form immune complexes, and activate complement that leads to damage of host tissue.

most patients have fluctuations or flare-ups during the course of the disease.

CLINICAL PRESENTATION OF SLE

| Sign/Symptom | Incidence (%) |
|-------------------------------|---------------|
| Musculoskeletal: | |
| Arthritis and arthralgia | 53–95 |
| Constitutional | |
| Fatigue | 81 |
| Fever | 41–86 |
| Weight loss | 31–71 |
| Mucocutaneous | 55–85 |
| Butterfly rash | 10–61 |
| Photosensitivity | 11–45 |
| Raynaud's phenomenon | 10–44 |
| Discoid lesions | 9–29 |
| Central nervous system | 13–59 |
| Psychosis | 5–37 |
| Seizures | 6–26 |
| Pulmonary | |
| Pleuritis | 31–57 |
| Pleural effusion | 12–40 |
| Cardiovascular | |
| Pericarditis | 2–45 |
| Myocarditis | 3–40 |
| Heart murmur | 1–44 |
| Hypertension | 23–46 |
| Renal | 13–65 |
| Gastrointestinal | |
| Nausea | 7–53 |
| Abdominal pain | 8–34 |
| Bowel hemorrhage (vasculitis) | 1–6 |
| Hematologic | |
| Anemia | 30–78 |
| Leukopenia | 35–66 |
| Thrombocytopenia | 7–30 |
| Lymphadenopathy | 10–59 |

Nonspecific signs and symptoms such as fatigue, fever, anorexia, and weight loss are seen frequently in patients with active disease. Musculoskeletal involvement (e.g., arthralgia, myalgia, and arthritis) is very common in SLE,^{22,24,25} with arthritis and arthralgia frequently the chief complaint on initial presentation of the disease.²⁴ All major and minor joints may be affected, and the pattern of arthritis is often recurrent and of short duration, presenting mainly as joint stiffness, pain, and sometimes inflammation.²⁶ Objective evidence of musculoskeletal disease often is missing, although a few patients may present with deforming arthritis or subcutaneous nodules.

Manifestations in the skin are nearly as common as those involving the musculoskeletal system.^{2,22,24} The most well known of these is the butterfly rash, which occurs over the bridge of the nose and the malar eminences. The classic butterfly rash is seen in approximately one-half of patients and often is observed after sun exposure. In fact, photosensitivity is common to many SLE patients who present with cutaneous manifestations. Skin lesions characteristic of discoid lupus occur in 10% to 20% of patients with SLE and may occur without other clinical or serologic evidence of lupus.^{22,23,27} Some individuals are said to develop *subacute cutaneous lupus erythematosus*, the nature of whose lesions falls between discoid (one type of *chronic*

cutaneous lupus erythematosus) and the butterfly rash (an example of *acute cutaneous lupus erythematosus*).²⁷ Other cutaneous manifestations include vasculitis (which may be ulcerative), livedo reticularis, periungual erythema, Raynaud's phenomenon, and alopecia.^{2,24}

Another common source of symptomatology in SLE is the pulmonary system, with manifestations such as pleurisy, coughing, and dyspnea. Pleurisy may present as pleuritic pain, a pleural rub, or a pleural effusion that usually is exudative in nature. Lupus pneumonitis may present acutely with fever, dyspnea, tachypnea, cough, rales, and patchy infiltrates or chronically with interstitial fibrosis. Lupus pneumonitis is an uncommon manifestation of SLE and can be difficult to distinguish from infectious pneumonia, which is more common in SLE patients and should be the primary consideration when evaluating new pulmonary infiltrates.²⁸ Pulmonary hypertension associated with SLE is more common than previously thought, which is likely due to the fact that asymptomatic increases in pulmonary artery pressures are more common than symptomatic increases. Patients with SLE-associated pulmonary hypertension have a poor prognosis. Pulmonary embolism also should be ruled out in any SLE patient presenting with pleuritic chest pain and dyspnea.

Cardiac manifestations of SLE often present as pericarditis, myocarditis, electrocardiographic (ECG) changes, or valvular heart disease, including the classic cardiac lesion of Libman-Sacks endocarditis (nonbacterial verrucous endocarditis).²⁸ Coronary artery disease (CAD) is being seen in SLE with increasing frequency as the life expectancy of SLE patients increases.²⁹ It is thought that the development of heart disease in these patients is multifactorial. Traditional CAD risk factors are common in patients with SLE.

Corticosteroid therapy and underlying renal disease are also believed to be contributing factors in the development of these cardiac risk factors.²⁸ Although hypertension, obesity, and hyperlipidemia are common in SLE patients, these traditional risk factors do not account for the strikingly high cardiovascular event rate found in some recent studies.^{30,31} Other SLE-related risk factors highlight the importance of autoimmunity and inflammation in the pathogenesis of accelerated atherosclerotic cardiovascular disease.^{31,32} Additionally, two recent studies found that long-term corticosteroid therapy was not associated with a significantly increased risk of accelerated atherosclerosis.^{33,34} In fact, one of the studies³³ found that patients with higher mean daily doses of prednisone and more frequent use of other common therapies for SLE exhibited less plaque formation. The implication is that more aggressive control of disease activity actually may help to prevent CAD.^{32,33}

CLINICAL CONTROVERSY

Some research suggests that long-term corticosteroid therapy is responsible for the increased incidence of coronary heart disease, whereas other data suggest that it has no effect on atherosclerosis.

Neuropsychiatric manifestations of SLE may present in a diversity of ways, including psychosis, depression, anxiety, seizure, stroke, peripheral neuropathy, cognitive impairment, and others.³⁵ Cognitive dysfunction is seen in 12% to 87% of patients with SLE. Depression and anxiety are common among SLE patients, but it is unclear if they are direct manifestations of central nervous system (CNS) involvement or secondary to the distress of living with a chronic illness.³⁶

Symptoms associated with gastrointestinal manifestations often are nonspecific for lupus and include dyspepsia, abdominal pain, nausea, and difficulty swallowing. Mesenteric vasculitis and venous occlusion owing to thrombosis may be problematic if not diagnosed

TABLE 85–2. Antinuclear Antibody Test: Patterns, Antigens, and Specificities

| Pattern | Antigen | Disease |
|------------------------|-----------------------------|---------------------------------|
| Peripheral Speckled | dsDNA | SLE |
| | Acidic nuclear protein | Rheumatoid arthritis |
| | Ribonucleoprotein | SLE |
| | Extractable nuclear antigen | Scleroderma |
| Homogeneous | dsDNA, ssDNA | Mixed connective tissue disease |
| | Histones | Rheumatoid arthritis |
| | Nucleolar RNA | SLE, drug-induced lupus |
| Nucleolar | Nucleolar RNA | Progressive systemic sclerosis |

ds = double-stranded; ss = single-stranded.

and treated promptly. Hepatitis and pancreatitis also may be present and may be secondary to drugs used to treat SLE or the disease itself.³⁷

HEMATOLOGIC MANIFESTATIONS

Anemia is found in many patients with SLE. It is usually an anemia of chronic inflammation, with a mild normochromic, normocytic smear and low serum iron concentration but adequate iron stores. Some patients may develop a hemolytic anemia with a positive Coombs' test.³⁸ Leukopenia, usually mild, is present in approximately half of SLE patients. Both granulocytes and lymphocytes may be affected, but there is usually a larger decrease in lymphocytes.^{2,24} Thrombocytopenia may occur in SLE, often during disease exacerbation, but is usually mild and does not increase bleeding tendency.³⁸ Another significant finding associated with SLE is the presence of antiphospholipid antibodies such as the lupus anticoagulant (LA) and anticardiolipin antibodies. Although the LA is directed against the prothrombin activator complex and implies potential bleeding complications, this is not the case. In fact, the presence of LA, anticardiolipin, or other antiphospholipid antibodies may be associated with thrombosis, neurologic disease, thrombocytopenia, and fetal loss.^{25,39} Thrombotic events occur in more than 10% of patients with SLE.³⁹ Not all patients with antiphospholipid syndrome have lupus. If a patient has no concomitant autoimmune disease, the syndrome is *primary*. If a patient has accompanying SLE, the syndrome is *secondary*.^{40,41}

LUPUS NEPHRITIS

Clinical evidence of renal involvement, such as a rising serum creatinine or proteinuria level, generally is associated with a poorer outcome compared with patients without renal involvement. Progression to end-stage renal disease is a major cause of morbidity and mortality in SLE. However, the extent and course of renal disease are quite variable, and many lupus nephritis patients do very well. The World Health Organization (WHO) has classified lupus nephritis on the basis of histologic characteristics observed following renal biopsy. This system, revised in 1995, identifies lupus nephritis as normal (class I), mesangial (classes IIA and IIB), focal proliferative (class IIIA–C), diffuse proliferative (class IVA–D), diffuse membranous (class VA and VB),

or advanced sclerosing (class VI) glomerulonephritis.⁴² Many patients progress from one form of nephritis to another during the course of the disease. Predictors of poorer outcome in proliferative lupus nephritis include African-American race, increased serum creatinine level, poor initial response to immunosuppressive drugs, hypertension, and persistent nephrotic syndrome.⁴³

DIAGNOSIS

As mentioned earlier, the diagnostic criteria listed in Table 85–1 should not be the primary means for diagnosing SLE, although many of the criteria may be valuable in the diagnostic process. Epidemiologic characteristics, clinical signs and symptoms, and common laboratory abnormalities all are used in the diagnosis of SLE.

Once the disease is suspected, serologic tests may be helpful in making the diagnosis. A serologic test used extensively to aid in the diagnosis of SLE is the fluorescent antinuclear antibody (ANA) test. Nearly all SLE patients are ANA-positive, but other diseases also can be associated with a positive test (Table 85–2); however, in other diseases, many of the positive ANA tests are of a lower titer. The pattern of immunofluorescence of the ANA test also may be of diagnostic value (see Table 85–2), with a peripheral (also called *rim*) pattern being specific for SLE. Detecting antibodies to specific nuclear constituents also may be useful diagnostically. Antibodies to native DNA (dsDNA) and to Sm antigen are quite specific for and are considered diagnostic of SLE.^{13,19,44,45}

PROGNOSIS

In earlier years, SLE was associated with a poor prognosis. For example, the classic report of patients diagnosed between 1949 and 1953 showed a 5-year survival rate of less than 50%.⁴⁶ Today, as a result of improved treatment and improved diagnostic techniques that allow earlier diagnosis, the 5-year survival exceeds 96%, and 20-year survival rates approach 70%.^{47,48} The natural course of SLE has changed dramatically since the 1970s not only because of improved therapies but also because of improvement in ability to manage patients with kidney disease (e.g., dialysis), infection, and CAD.^{8,43,48,49} However, CAD and infection are still among the leading causes of death among SLE patients.⁸

► TREATMENT: Systemic Lupus Erythematosus

Desired treatment outcomes for the patient with SLE are twofold: (1) management of symptoms and induction of remission during times of disease flare and (2) maintenance of remission for as long as possible between disease flares. An approach to the management of the

patient with SLE is outlined in Fig. 85–2. Because of the variability in clinical presentation of disease, treatment will vary accordingly and should be highly individualized. Optimal care of the patient with SLE will offer education and support services in addition to

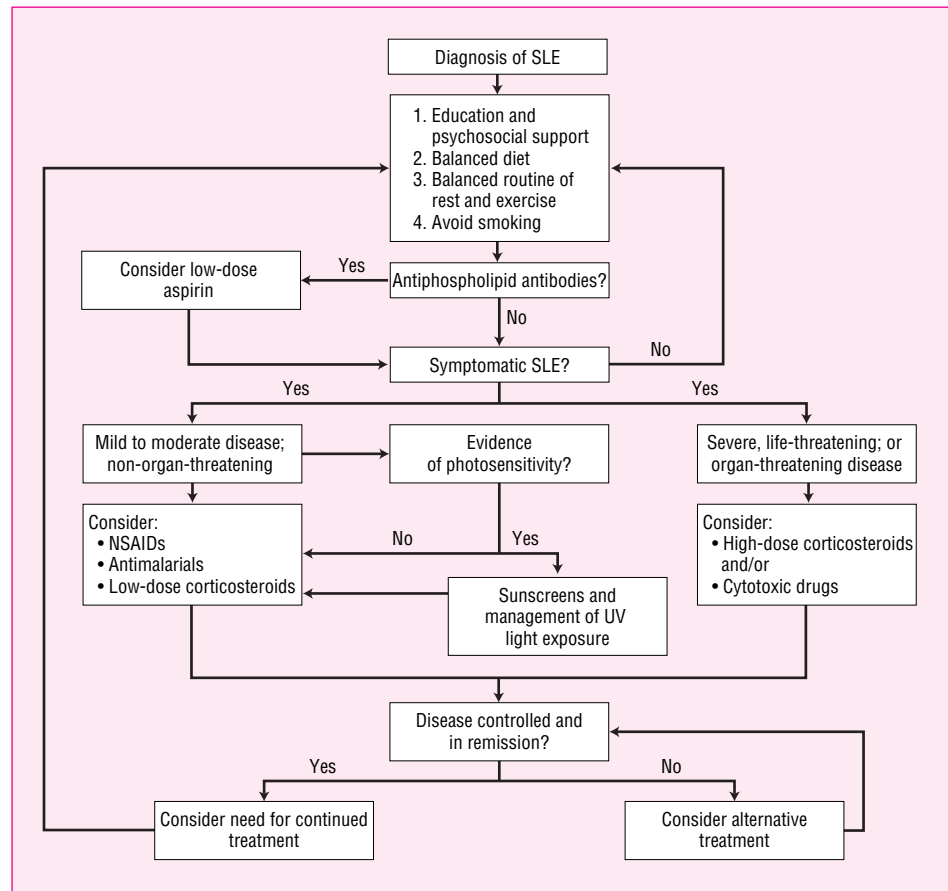

FIGURE 85–2. General approach to the management of SLE.

the nonpharmacologic and pharmacologic treatments discussed below. Numerous lupus organizations exist throughout the world and can be located by contacting the Lupus Foundation of America⁵⁰ (www.lupus.org), the Arthritis Foundation⁵¹ (www.arthritis.org), and Lupus Canada⁵² (www.lupuscanada.org).

■ NONPHARMACOLOGIC THERAPY

Several nonpharmacologic measures can be employed to manage symptoms and help maintain remission. Fatigue is a common symptom in patients with lupus.⁴⁷ A balanced routine of rest and exercise, while avoiding overexertion, is essential in managing fatigue.⁵³ Avoidance of smoking may be particularly important because hydrazines in tobacco smoke may be an environmental trigger of lupus and likely contribute to accelerated CAD.¹³ Smoking also has been associated with increased disease activity in SLE patients.⁵⁴ No specific dietary measures are known to clearly affect the clinical course of lupus. However, fish-oil derivatives might prevent miscarriages in pregnant women with antiphospholipid antibodies,⁵³ but alfalfa sprouts should be avoided because they contain the amino acid L-canavanine, which has been linked to the development of lupus-like symptoms in numerous case reports.¹³ Many patients with SLE will need to limit exposure to sunlight and use sunscreens to block the possible exacerbating effects of ultraviolet light.⁵⁵ The amount of sunlight exposure limitation should be individualized.

■ PHARMACOLOGIC THERAPY

5 Drug therapy for SLE is often designed to suppress the immune response and inflammation. Except for lupus nephritis, large controlled clinical trials comparing treatment options for SLE are needed. Table 85–3 lists common agents and doses used to control SLE. In general, the choice of drug therapy depends on the extent and severity of disease. Table 85–4 describes selected monitoring parameters and adverse events for many of the drugs used to treat collagen-vascular diseases.

■ NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

As discussed earlier, signs and symptoms such as fever, arthritis, and serositis are among the most common in patients with active disease. Therefore, in many patients with mild disease, initial treatment with a nonsteroidal anti-inflammatory drug (NSAID) is a logical choice. The choice of NSAIDs in SLE is empirical. The dose used should be adequate to provide anti-inflammatory effects, although low-dose aspirin may be useful in the management of patients with antiphospholipid syndrome.³⁹

Nonselective cyclooxygenase NSAIDs significantly increase the risk of gastric irritation and peptic ulceration. Coprescribing with a gastroprotective agent such as a proton pump inhibitor may be beneficial.⁴¹ Patients with SLE taking NSAIDs may experience

TABLE 85-3. Drug Treatment of Systemic Lupus Erythematosus

| Drug Class | Drug and Dose | Indication |
|----------------|---|--|
| NSAID | Various agents Anti-inflammatory dose | Mild disease: fever, arthritis, skin rash, serositis |
| Antimalarial | Hydroxychloroquine, 200–400 mg PO daily Chloroquine, 250–500 mg PO daily | Mild disease: arthritis, skin rash, serositis |
| Corticosteroid | Prednisone, 1–2 mg/kg/d PO (or equivalent) <1 mg/kg/d (or equivalent) | Initial control of severe disease Control of mild disease or maintenance after disease suppression with higher doses |
| Cytotoxic | Methylprednisolone, 500–1000 mg IV daily × 3–6 d Cyclophosphamide, 0.5–1.0 g/m ² IV monthly for 6 months; then, every 3 months for 2 years or for 1 year after remission Azathioprine, 1–3 mg/kg PO daily Cyclophosphamide, 1–3 mg/kg PO daily Mycophenolate mofetil, 1–3 g PO daily | Life-threatening disease Most commonly used in severe lupus nephritis; may be necessary for other severe disease manifestations |

TABLE 85-4. Monitoring Adverse Effects of Drugs Commonly Used in SLE

| Drug | Toxicities to Monitor | Baseline Evaluation | Monitoring | |
|-----------------------|--|--|--|--|
| | | | System Review | Laboratory |
| Salicylates, NSAIDs | Gastrointestinal bleeding, hepatic toxicity, renal toxicity, hypertension | CBC, creatinine, urinalysis, AST, ALT | Dark/black stool, dyspepsia, nausea/vomiting, abdominal pain, shortness of breath, edema | CBC yearly, creatinine yearly |
| Corticosteroids | Hypertension, hyperglycemia, hyperlipidemia, hypokalemia, osteoporosis, avascular necrosis, cataract, weight gain, infections, fluid retention | Blood pressure, bone densitometry, glucose, potassium, cholesterol, triglycerides (HDL, LDL) | Polyuria, polydipsia, edema, shortness of breath, blood pressure, visual changes, bone pain | Urinary dipstick for glucose every 3–6 months, total cholesterol yearly, bone densitometry yearly to assess osteoporosis |
| Hydroxychloroquine | Macular damage | None unless patient is over 40 years of age or has previous eye disease | Visual changes | Funduscopy and visual fields every 6–12 months |
| Azathioprine | Myelosuppression, hepatotoxicity, lymphoproliferative disorders | CBC, platelet count, creatinine, AST or ALT | Symptoms of myelosuppression | CBC and platelet count every 1–2 weeks with changes in dose (every 1–3 months thereafter), AST yearly, Pap test at regular intervals |
| Cyclophosphamide | Myelosuppression, myeloproliferative disorders, malignancy, immunosuppression, hemorrhagic cystitis, secondary infertility | CBC and differential and platelet count, urinalysis | Symptoms of myelosuppression, hematuria, infertility | CBC and urinalysis monthly, urine cytology and Pap test yearly for life |
| Mycophenolate mofetil | Myelosuppression, hepatotoxicity, lymphoproliferative disorders, malignancy | CBC, hepatic function tests, renal function tests | Symptoms of myelosuppression, diarrhea, nausea/vomiting, dyspepsia, abdominal pain, dark/black stool or blood in stool | CBC weekly during first month, twice monthly during the second and third months, then monthly through the first year |

NSAIDs = nonsteroidal anti-inflammatory drugs; CBC = complete blood count; AST = aspartate transaminase; ALT = alanine transaminase; HDL = high density lipoprotein; LDL = low density lipoprotein.

Modified from American College of Rheumatology Ad Hoc Committee on Systemic Lupus Erythematosus Guidelines. Guidelines for referral and management of systemic lupus erythematosus in adults. *Arthritis Rheum* 1999; 42:1790 (with permission). Other refs. 25, 110, and 111.

a decline in renal function because of drug effects and not the underlying disease. NSAIDs can decrease renal blood flow and glomerular filtration rates. This may be particularly important for patients with nephritis. Awareness of this effect is important because declining renal function may be attributed mistakenly to progression of lupus nephritis. Patients with SLE have a higher incidence of hepatotoxicity than other patients taking traditional NSAIDs. There also exist reports of an association between aseptic meningitis in SLE patients and the use of NSAIDs.^{4,25,55}

■ ANTIMALARIAL DRUGS

Antimalarial agents such as chloroquine and hydroxychloroquine have been used successfully in the management of discoid lupus and SLE. A few controlled trials provide evidence for the role of antimalarial therapy in controlling disease exacerbations and as steroid-sparing agents.^{56–58} In general, the manifestations of SLE that can be managed with antimalarials are cutaneous manifestations, arthralgia, pleuritis, mild pericardial inflammation, fatigue, and leukopenia.^{25,41} Because these drugs are not effective immediately, they are best used in long-term management. Response to chloroquine occurs within 1 to 3 months, while the maximal effect of hydroxychloroquine may not occur for 3 to 6 months.²⁵ Hydroxychloroquine is probably safer than chloroquine and is considered the antimalarial of first choice.

The mechanism of action of the antimalarial drugs is uncertain. It has been proposed that antimalarials interfere with T-lymphocyte activation.²⁵ Other effects of antimalarials that may benefit patients with SLE include inhibition of cytokines, decreased sensitivity to ultraviolet light, anti-inflammatory activity, antiplatelet effects, and antihyperlipidemic activity.^{25,32}

Dosage and duration of therapy depend on patient response, tolerance of side effects, and development of retinal toxicity, which is a potentially irreversible adverse reaction associated with long-term therapy, especially with chloroquine. Current recommended doses of antimalarials in SLE are hydroxychloroquine 200–400 mg/day and chloroquine 250–500 mg/day. After 1 or 2 years of treatment, gradual tapering of dosage can be attempted. Some patients may require only one or two tablets per week to suppress cutaneous manifestations.^{25,59}

Side effects of these drugs include CNS effects (e.g., headache, nervousness, insomnia, and others), rashes, dermatitis, pigmentary changes of the skin and hair, gastrointestinal disturbance (e.g., nausea), and reversible ocular toxicities such as cycloplegia and corneal deposits. Potentially serious retinal toxicity is uncommon when the currently recommended doses are used and is least common with hydroxychloroquine.⁶⁰ However, because of the possibility of permanent damage associated with the retinopathy, an ophthalmologic evaluation should be done at baseline and every 3 months when chloroquine is used and every 6 to 12 months when hydroxychloroquine is used. If retinal abnormalities are noted, antimalarial therapy should be discontinued or the dose reduced.²⁵

■ CORTICOSTEROIDS

Corticosteroid therapy is commonplace in therapeutic regimens for SLE. Although evidence for improved survival with corticosteroid therapy is inadequate, these agents are known to be effective for suppressing the clinical expression of disease and are considered by many to be a major factor in the improved prognosis in recent years. Although most controlled trials of corticosteroid therapy have been conducted in patients with severe lupus nephritis, evidence suggests that corticosteroids are also effective in the management of severe cases of

CNS disease, pneumonitis, polyserositis, vasculitis, thrombocytopenia, and other clinical manifestations.²⁵

A patient with the diagnosis of SLE does not automatically require corticosteroid therapy. Mild disease with such manifestations as fever, arthralgia, pleuritis, or skin manifestations may respond adequately to NSAIDs or antimalarials, but patients with clinical manifestations that are more serious or unresponsive to other drugs may require corticosteroids. Some patients with lupus dermatitis may benefit from topical or intralesional administration of corticosteroids.²⁵

The goal of treatment when using corticosteroids in SLE is to suppress and maintain suppression of active disease with the lowest dose possible. In patients with mild disease, low-dose therapy (prednisone 10–20 mg/day) is adequate,^{41,45} but in patients with more severe disease (severe hemolytic anemia or cardiac involvement), higher doses, such as prednisone 1–2 mg/kg daily, may be required. Once adequate suppression of disease is achieved, the dose should be tapered to the minimum amount required for continued disease suppression. When analyzing the need to treat with corticosteroids, the clinician should consider other conditions that may increase the risk of corticosteroid therapy, such as infection, hypertension, atherosclerotic disease, diabetes, obesity, osteoporosis, and psychiatric disease.^{4,25,41}

Steroid pulse therapy is the administration of short-term, high-dose intravenous corticosteroids with the goal of inducing remission in SLE patients with serious, life-threatening disease, such as severe active nephritis, CNS involvement, or hemolytic disease. A standard pulse regimen consists of intravenous methylprednisolone 500–1000 mg for 3 to 6 consecutive days. Pulse therapy usually is followed by high-dose prednisone (1–1.5 mg/kg per day) therapy that is tapered rapidly to low-dose maintenance therapy.²⁵ Potential advantages of pulse therapy over high-dose oral steroids include a quicker response and avoidance of side effects associated with the longer duration of therapy required with oral steroids. Although generally well tolerated, methylprednisolone pulse therapy may result in significant adverse effects, including infection, gastrointestinal disturbances, rapid increases in blood pressure, arrhythmias, seizures, and sudden death. Furthermore, there are insufficient data from controlled clinical trials to clearly define the role of pulse steroids in the management of SLE. Thus pulse therapy represents an alternative mode of treatment for patients with life-threatening disease or disease unresponsive to other pharmacotherapy.

■ CYTOTOXIC DRUGS

A considerable amount of literature exists describing the use of cytotoxic and immunosuppressive drugs in SLE, although few of these are reports of controlled clinical trials. Included in this category are the alkylating agent cyclophosphamide and the antimetabolite azathioprine. These agents, usually used in combination with corticosteroids, have been the mainstays of immunosuppressive therapy. Although both are known to suppress and stabilize extrarenal disease activity, much of the evaluation of these agents has focused on lupus nephritis, a major factor associated with morbidity and mortality in SLE.

Evidence supporting the use of cyclophosphamide in lupus nephritis has been collected over the last several decades. Controlled clinical trials have shown that cyclophosphamide improved the long-term outcomes in lupus nephritis.^{41,61,62} Based on controlled trials, combination prednisone and cyclophosphamide has become standard treatment for focal and diffuse proliferative lupus nephritis (WHO class III/IV) and is superior to prednisone alone.¹⁶ There are no studies examining cyclophosphamide in earlier stages of nephritis (WHO class II/III), and therefore, corticosteroids remain the treatment of

choice for these less severe forms of nephritis.⁶¹ A meta-analysis of clinical trials revealed that pulse intravenous cyclophosphamide plus prednisone was more effective at increasing patient survival and renal function than prednisone only.⁶³ Cyclophosphamide plus corticosteroids preserves renal function and decreases the risk of developing end-stage renal failure requiring dialysis and renal transplantation.¹⁶ Intermittent pulse administration of intravenous cyclophosphamide is preferred over daily oral therapies because of reduced adverse effects. However, pulse cyclophosphamide plus prednisone is not always effective. Other cytotoxic combinations have been examined, but none has been found to be significantly better than any other at reducing the risk of death or renal failure.¹⁶

When used in combination with corticosteroids, cyclophosphamide is dosed at 1–3 mg/kg for oral therapy and 0.5–1.0 g/m² of body surface area for intravenous therapy. The most common route of cyclophosphamide administration is intravenous, although there is little evidence that this is better than oral administration.^{61,62} Likewise, there is no evidence to suggest the optimal duration of treatment. Based on empirical experience, cyclophosphamide generally is dosed monthly for 6 months and then every 3 months for a period of either 2 years or for 1 year after the nephritis is in remission.^{43,61,64} Of course, cyclophosphamide therapy is not without risk. Serious toxic effects include suppression of hematopoiesis, opportunistic infections, bladder complications (e.g., hemorrhagic cystitis and cancer), sterility, and teratogenesis. White blood cell counts must be monitored during cyclophosphamide therapy, and if the nadir is less than 1500/mm³, the dose must be adjusted to keep the white cell count above 1500/mm³. Nausea and vomiting associated with cyclophosphamide can be controlled with oral ondansetron plus dexamethasone.⁶¹

Azathioprine can be used as a “steroid-sparing” agent, allowing for the reduction of corticosteroid doses.^{41,45} Azathioprine has not been studied as extensively as cyclophosphamide for lupus nephritis. Additionally, azathioprine is only slightly more effective than prednisone alone.⁴³ Azathioprine may find usefulness in treating early-onset and less severe nephritis.^{41,43} Long-term maintenance azathioprine therapy also may be beneficial in preventing renal flares after successful induction with cyclophosphamide.⁶² Azathioprine is given orally in doses of 1 to 3 mg/kg per day, often in combination with corticosteroids for severe disease.²⁵ Azathioprine generally is less toxic than cyclophosphamide, but adverse reactions may be serious and include suppression of hematopoiesis, opportunistic infections including herpes zoster, cancer, hepatotoxicity, and ovarian failure.

Cyclophosphamide often is administered intravenously in intermittent pulse doses to minimize toxicity. To decrease the risk of bladder toxicity, patients should be well hydrated with oral or intravenous fluids, and urinary output should be monitored. Mesna may

be used to prevent hemorrhagic cystitis. Mesna is administered as a bolus of 25 mg/kg 30 minutes before cyclophosphamide therapy and 3, 6, and 9 hours after therapy.⁴⁴

Cyclophosphamide may be of benefit to some patients with other serious, refractory manifestations of lupus, including neurologic manifestations.⁶⁵ Reports of the use of other cytotoxic drugs for lupus in recent years include methotrexate,²⁵ mycophenolate mofetil,^{7,25,41,62} mechlorethamine (nitrogen mustard), chlorambucil, and cyclosporine.^{7,25,41,62}

Mycophenolate mofetil is a new immunosuppressive agent now rapidly establishing its role in the treatment of severe renal and nonrenal lupus refractory to conventional cytotoxic agents.^{41,62} Mycophenolate mofetil showed equal efficacy at 12 months in a randomized, controlled trial comparing mycophenolate mofetil with sequential oral cyclophosphamide followed by azathioprine in proliferative lupus nephritis.^{62,66} However, the extended follow-up for 36 months demonstrated higher renal relapse rates in the mycophenolate mofetil–treated group.^{62,67} Additionally, in an ongoing randomized, controlled trial, mycophenolate mofetil maintenance therapy thus far has proven to be more effective in preventing renal flares than quarterly intravenous pulse cyclophosphamide or daily azathioprine with fewer adverse events.^{62,68}

Cytotoxic therapy is useful in combination with corticosteroids, allowing for lower steroid doses and improved efficacy compared with steroids alone. However, cytotoxic therapy must be monitored closely for adverse effects, and maximum response may take 6 months or longer in some patients. No data from controlled trials are available to support the combination of two or more cytotoxic agents; however, this approach has been used in patients refractory to standard therapies.^{16,61}

ALTERNATIVE AND EXPERIMENTAL TREATMENTS

As the pathogenesis of SLE continues to be elucidated, new and promising treatments are being developed. Several alternative treatments reportedly successful in managing various manifestations of SLE^{53,69–73} are listed in Table 85–5. However, many of these are reports of uncontrolled trials. Furthermore, in addition to reports of success, the literature contains reports of unsuccessful or controversial treatments for many of these therapies (e.g., plasmapheresis or immune globulin for lupus nephritis). A number of newer agents are being examined and include various biologic therapies that interfere with immune response, ablative chemotherapy with stem cell transplantation, and combination chemotherapy.^{16,55,74,75}

TABLE 85–5. Alternative and Experimental Treatments for SLE

| Treatment | Symptom | Reference |
|---|---|-----------|
| Cyclosporine | Nephritis | 69 |
| | Multiple symptoms—anemia, leukopenia, thrombocytopenia, nephritis | 53 |
| Dehydroepiandrosterone (DHEA) | Multiple symptoms | 70 |

| | Nephritis | 72 |
| Anti-CD20 monoclonal antibody (Rituximab) | Multiple symptoms | 73 |
| Thalidomide | Cutaneous lesions | 75 |
| Cladribine | Nephritis | 75 |

SPECIAL POPULATIONS

PREGNANCY AND SLE

Pregnancy in SLE patients has been associated with exacerbation of disease during pregnancy, exacerbation during the early postpartum period, a greater incidence of spontaneous abortion, and a greater chance of developing preeclampsia or pregnancy-induced hypertension (particularly in patients with nephritis).

Lupus flares during pregnancy are associated with prematurity. Whether there is an increased risk for lupus flares during pregnancy versus those who are not pregnant is controversial, but exacerbation of lupus during pregnancy seems to be less likely if the disease is in remission at conception.^{7,76,77} Disease exacerbations can be managed aggressively with corticosteroids, if needed, with little concern about harm to the fetus.⁷⁶ The decision to use other classes of drug therapy to control disease exacerbation should be highly individualized, although hydroxychloroquine has been shown to be safe during pregnancy.^{64,78,79} In fact, it may be safer to continue hydroxychloroquine during pregnancy than to discontinue it.^{41,76} The decision to use cytotoxic drugs during pregnancy should be made with extreme caution because of potential harmful effects (e.g., teratogenesis, fetal loss) to the fetus.⁸⁰ Azathioprine may be the safest of the cytotoxic drugs if needed during pregnancy.^{64,76}

Antiphospholipid antibodies may be associated with a greater likelihood of spontaneous abortion.^{7,41} Corticosteroids, intravenous immunoglobulin, aspirin, and heparin, alone and in various combinations, have been used to try to improve fetal outcome.⁴⁵ Fetal survival increases with all these therapies, and none has been shown to be superior.²⁵ The optimal treatment regimen for pregnant patients with antiphospholipid antibodies is yet to be determined, although it has been recommended that women with antiphospholipid antibodies and no prior fetal losses should receive low-dose daily aspirin. High-risk women with a history of recurrent fetal loss should be treated with low-dose subcutaneous heparin with or without aspirin.^{25,76} Low-molecular-weight heparin may be an effective alternative to low-dose heparin in the treatment of antiphospholipid syndrome-related pregnancy loss.^{7,25,76}

Although there is an increased chance of a high-risk pregnancy in women with SLE, appropriate planning and disease management will result in a high likelihood of a successful pregnancy and a healthy child.

ANTIPHOSPHOLIPID SYNDROME AND THROMBOSIS

As mentioned earlier, the presence of antiphospholipid antibodies may result in several clinical manifestations, including thrombosis. There is no agreement on prophylaxis of patients with antiphospholipid antibodies without a history of thromboembolism.³⁹ In such patients, low-dose aspirin (100–325 mg/day) may be used prophylactically, although efficacy has not been established.³⁹ Patients with an acute thrombotic event should receive standard treatment with anticoagulants (e.g., heparin). Follow-up treatment with warfarin to prevent recurrence may require an international normalized ratio (INR) of 3 or greater in patients with antiphospholipid syndrome.^{7,45} However, currently, there is no consensus on the intensity of anticoagulation or duration of secondary prophylaxis, but since recurrence is common, patients usually are treated with oral anticoagulants indefinitely.⁴⁵

CLINICAL CONTROVERSY

The optimal dose of aspirin and the intensity of anticoagulation therapy have not been well established, and clinicians will use various strategies for prevention of thrombosis in the presence of antiphospholipid antibodies.

DRUG-INDUCED LUPUS

One of the earliest descriptions of a drug-induced SLE-like syndrome was reported in 1945 and was associated with the use of sulfadiazine.⁸¹ Today, procainamide and hydralazine are associated most commonly with drug-induced lupus (DIL), although numerous other drugs have been implicated^{41,81–83} (Table 85–6). A consensus on diagnostic criteria for DIL does not exist. To meet criteria for DIL, a patient should have exposure to a suspected drug, no prior history of idiopathic SLE prior to the use of the drug, development of ANAs (usually antihistone antibodies) and at least one clinical feature of SLE, and rapid improvement of symptoms with a gradual decline in ANAs following drug discontinuation.^{81,82,84} The epidemiologic characteristics of DIL are different from those of idiopathic SLE. In general, patients with procainamide- or hydralazine-induced lupus develop the disease much later in life compared with idiopathic SLE probably because the majority of people who use these drugs are older. There is also an absence of female predominance when compared with idiopathic SLE.⁸⁵

Patients of the slow acetylator phenotype may have a greater risk for developing DIL, particularly with procainamide and hydralazine.^{13,81,85} Procainamide-induced lupus can present as early as 1 month or even after years of therapy. Hydralazine-induced lupus is related to dose and appears in patients receiving 100 mg/day or more.^{81,85}

Musculoskeletal symptoms are the most common clinical manifestations, whereas renal manifestations and CNS involvement are rare. Other common features of DIL include fever, fatigue, pericarditis, pleurisy, and weight loss.⁸⁴ Although the classic malar rash is

TABLE 85–6. Medications Implicated in Drug-Induced Lupus

| | | |
|------------------------------------|----------------------|---------------------|
| Acebutolol | Interleukin 2 | Pindolol |
| Amiodarone | Isoniazid | Primidone |
| Anti-TNF therapies | Labetalol | Procainamide |
| Atenolol | Lisinopril | Propranolol |
| Captopril | Lithium | Propylthiouracil |
| Carbamazepine | Mephenytoin | Quinidine |
| Chlorpromazine^a | Methimazole | Reserpine |
| Ciprofloxacin | Methyldopa | Simvastatin |
| Clobazam | Metoprolol | Streptomycin |
| Clonidine | Minocycline | Sulfasalazine |
| Clozapine | Nifedipine | Tetracycline |
| Diltiazem | Oral contraceptives | Thiazide diuretics |
| Ethosuximide | Para-aminosalicylate | Ticlopidine |
| Gold salts | Penicillamine | Timolol |
| Griseofulvin | Penicillin | Tocainide |
| Hydralazine | Phenytoin | Valproate |
| Hydroxyurea | Phenylbutazone | Verapamil |
| Interferon (α , γ) | Phenelzine | Zafirlukast |

^aDrugs in boldface represent those with best evidence of association.

Adapted from refs. 81–83.

rare in DIL, skin manifestations are seen in 25% to 53% of patients with DIL.^{81,84} A positive ANA test is found in nearly all (~90%) hydralazine-induced cases and in 50% to 90% of procainamide-induced disease. The immunofluorescence pattern usually is homogeneous, and antibodies are primarily against ssDNA and not dsDNA as in idiopathic SLE. Antihistone antibodies are specific for DIL but might be found in only 20% of patients with idiopathic SLE.⁸¹

If signs and symptoms of SLE appear in a patient and are thought to be drug-related, the drug should be discontinued. If the lupus is drug-induced, the clinical manifestations should disappear in days to weeks, although it may take up to 1 year or longer for symptoms and serologic abnormalities to resolve completely.⁴¹ A NSAID might be useful in treating musculoskeletal manifestations. Other, more aggressive drug therapy should not be necessary unless manifestations are deemed more serious.

PHARMACOECONOMIC CONSIDERATIONS

Treating patients with SLE is costly, requiring frequent visits to physician offices for monitoring therapy and treating adverse reactions from therapy and hospitalization for disease exacerbation and adverse drug effects. Therefore, it is particularly important in the management of a potentially debilitating chronic disease such as SLE to achieve desired treatment outcomes in an optimal manner to minimize the impact on use of health care resources. Costs of treating patients with SLE are similar in the United States, Canada, and the United Kingdom.⁸⁶ In one study, the average total annual costs in 1997 were approximately \$3800 per patient with SLE, with medication costing approximately \$880 per patient.⁸⁶

Lupus patients with poor physical or poor psychological functioning have been shown to incur higher direct medical costs, whereas patients with the poorest psychological functioning and those with the most severe pain incur higher indirect costs (costs associated with loss of productivity such as days of work missed).⁸⁷ Higher direct, indirect, and total costs also have been associated with higher education level, greater disease activity, and lower physical functioning in another study.⁸⁷ Specific treatment strategies that incorporate therapies to improve physical and psychological functioning, as well as reduce disease activity and end-organ damage, might reduce use of health care resources.

One study targeting a cohort of patients with severe lupus nephritis found that compared with prednisone alone, combined treatment with intravenous cyclophosphamide and prednisone resulted in slightly higher costs early in therapy (0–4 years) but substantial savings later (5–10 years) as a result of less need for dialysis and transplantation and increased productivity of patients.⁸⁸ Another study examined antiemetic therapy in patients with lupus nephritis receiving pulse cyclophosphamide and found that a regimen of combined oral ondansetron plus dexamethasone was completely effective in preventing emesis and was less expensive than a conventional intravenous regimen in patients who had previously failed conventional antiemetic therapy.⁸⁹

As the field of pharmacoeconomics grows, and as clinicians and researchers attempt to define the optimal management of patients in our cost-conscious environment, additional examination of the economics of treating patients with lupus will be needed.

SYSTEMIC SCLEROSIS

CLINICAL MANIFESTATIONS

Systemic sclerosis is characterized by alteration of the microvasculature and by massive deposition of collagen. This disease can present as a spectrum of differing manifestations depending on affected areas and the extent of disease. Sclerosis of the skin is a hallmark for this disease. There can be a proximal diffuse (truncal) sclerosis,

with skin tightness and marked skin thickening involving most of the body. There also can be internal organ involvement, such as the gastrointestinal tract, lung, kidney, or heart, which can result in death. *Scleroderma* refers to patients with only skin involvement. Disease that affects only the fingers and toes is referred to as *sclerodactyly*.

CLINICAL PRESENTATION OF SYSTEMIC SCLEROSIS

GENERAL

- Sclerosis of the skin

SYMPTOMS

- Raynaud's phenomenon
- Dyspepsia
- Constipation
- Diarrhea
- Steatorrhea
- Esophageal dysmotility

Most patients with systemic sclerosis have Raynaud's phenomenon, where the digits turn white, followed by a bluish color, which is then followed by reddening in response to an appropriate stimulus. Usually the precipitating event is cold temperature or emotion. The pallor is due to vasospasm, the bluish color is from ischemia, and the reddish color is caused by a reactive hyperemia. Raynaud's phenomenon is a common manifestation of other syndromes, and most patients with Raynaud's phenomenon do not have systemic sclerosis. Approximately 50% to 80% of patients with systemic sclerosis have gastrointestinal symptoms, and 75% to 90% of patients have esophageal dysmotility.^{90,91}

Survival rates are highly variable depending on the extent of disease presentation, organ involvement, and other factors. In general, the 5-year survival rate is greater than 60%, which diminishes to approximately 50% at 10 years.^{92,93}

ETIOLOGY AND PREVALENCE

The cause of systemic sclerosis is unknown. Ninety-five percent of patients have identifiable autoantibodies. There are two major subsets of the disease, limited cutaneous and diffuse systemic sclerosis. Patients with limited cutaneous involvement often have the CREST syndrome (*calcinosis*, *Raynaud's*, *esophageal dysmotility*, *sclerodactyly*, and *telangiectasias*), whereas patients with diffuse systemic sclerosis have a more aggressive disease with renal, cardiac, or pulmonary involvement. The prevalence of the disease is estimated to be between 138 and 286 cases per 1 million population.⁹³ The wide range may be due to differences in diagnostic criteria, regional variation, or sample sizes used to estimate the prevalence.

► TREATMENT: Systemic Sclerosis

Treatment often is empirical because there are no well-controlled trials evaluating and comparing various forms of therapy. Available data are difficult to interpret because of the heterogeneity of the disease and spontaneous remissions that can occur. There is also a lack of objective measures to assess changes in clinical status. D-Penicillamine is used most often for skin involvement. When started within the first 2 years of the disease, this drug does seem to improve the skin manifestations and prolong survival.⁹⁴ The initial dose of D-penicillamine is 250 mg/day, with gradual increases in dose every 2 to 3 months to an optimal dose of 750–1000 mg/day. Response occurs over many months, and the drug is not always effective. The high incidence of severe adverse events and the increased dropout rates for D-penicillamine limit its usefulness. Anti-inflammatory agents and corticosteroids have not been effective in systemic sclerosis.

Angiotensin-converting enzyme (ACE) inhibitors have improved survival dramatically in patients with renal involvement and improve outcomes in patients with disease-associated pulmonary hypertension or myocardial involvement.^{95,96} Patients with sclerosis of the kidneys develop hypertension, leading to a renal crisis. In these patients, plasma renin activity and angiotensin concentrations can be more than twice normal. Renal involvement should be anticipated

in all systemic sclerosis patients who develop hypertension. Patients with systemic sclerosis and hypertension should be treated and maintained with an ACE inhibitor regardless of renal involvement. ACE inhibitors have allowed some dialysis-dependent systemic sclerosis patients to discontinue dialysis.⁹⁵ Treatment of Raynaud's phenomenon requires patient education and sometimes drug therapy. Patients must maintain their peripheral extremity and core body temperatures. Wearing appropriate clothing in cold environments is essential. Reaching into a freezer with unprotected hands should be avoided. Drugs that can cause peripheral vasoconstriction, such as pseudoephedrine and β -blockers, should be avoided in patients with Raynaud's or systemic sclerosis. Smoking causes cutaneous vasoconstriction and should be eliminated, including passive smoke. When preventive measures are not sufficient, calcium channel blocking agents have become the agents of choice for Raynaud's phenomenon. Nifedipine (10–20 mg three or four times per day) decreases the frequency and duration of attacks. Diltiazem (60 mg three or four times per day) also can be used. The sustained-release formulations of these agents may enhance patient compliance. Although there are limited data, other agents that may be beneficial for Raynaud's are selective serotonin reuptake inhibitors and angiotensin II receptor antagonists.⁹¹

POLYMYOSITIS AND DERMATOMYOSITIS

CLINICAL MANIFESTATIONS

Polymyositis (PM) and dermatomyositis (DM) are chronic inflammatory diseases of skeletal muscle and skin of unknown etiology. DM is distinguished from PM by a typical rash, which is red, scaly, and plaquelike over the knuckles, wrists, elbows, and knees. A blue-purple discoloration on the upper eyelids with edema also can occur in dermatomyositis.

There is an increase in serum creatine kinase concentration and electromyography abnormalities. Other serum enzymes, such as the alanine transaminase, aspartate transaminase, and lactate dehydrogenase, also may be increased.⁹⁷ Muscle biopsies show a necrotizing inflammatory process. The skin lesions of dermatomyositis show an immune-complex-mediated necrosis of the microvasculature. PM

appears to be related to cytotoxic T-cell activity, and up to 20% of patients with inflammatory myopathies have ANAs and cytoplasmic antibodies.

CLINICAL PRESENTATION OF POLYMYOSITIS AND DERMATOMYOSITIS

GENERAL

- Inflammation of skeletal muscle and skin

SYMPTOMS

- Muscle weakness in shoulder and hip girdles and trunk
- Insidious onset
- Arthritis, Raynaud's phenomenon, and other symptoms of connective tissue diseases

► TREATMENT: Polymyositis and Dermatomyositis

Large controlled trials of drug therapy have not been conducted. The goal of therapy is to increase muscle strength so as to improve function in activities of daily living (e.g., bathing, dressing, feeding, and toileting). Treatment consists of physical therapy during periods of remission and rest during periods of disease activity. Prednisone is the first line of drug therapy for PM and DM. There is no consensus as to the optimal dose of prednisone to use. Most clinicians use prednisone at a starting dose of 60–100 mg/day or approximately 1 mg/kg per day as a single morning dose.^{97–99} Higher prednisone doses of 1.5 mg/kg per day can be used if needed.¹⁰⁰ The initial dose of prednisone is continued for 1 to 2 months or until maximum benefit is achieved or a remission is induced. The full effect of prednisone may not be evident for several months. Approximately 85% of patients treated with prednisone will have normal muscle strength after 4 months of treatment. The prednisone dose is tapered when muscle strength improves

and serum creatine kinase concentrations decrease. If the prednisone is working and there are no serious side effects, the drug is tapered slowly. Again, there is no consensus on how to accomplish this. One expert advocates using prednisone for 3 to 4 weeks and then tapering the dose over 10 weeks to an every-other-day regimen.⁹⁷ The dose that maintains a good clinical response can be used as maintenance. Tapering too quickly can cause an exacerbation of disease activity. Monitoring serum creatine kinase concentrations is useful because they tend to increase several weeks before clinical symptoms become apparent. Some clinicians will treat patients with daily prednisone for 1 or more years, whereas others may use every-other-day therapy for many years.

One complication from corticosteroid use is the development of a myopathy. Based on symptoms, it is difficult to know if increased muscle weakness is due to the corticosteroid or to worsening disease

status. Lowering the prednisone dose may be useful. If patients get better on a lower dose of prednisone, then most likely the muscle weakness was due to the drug. It may take 2 to 8 weeks for this to become evident clinically. Use of serum creatine kinase concentration also may be helpful because this does not increase with steroid myopathy. It is possible that a steroid myopathy and worsening disease can coexist.

Although most patients with PM or DM improve with prednisone, some will not, and some will develop corticosteroid resistance. In these patients, azathioprine has been used at a dose of 2–3 mg/kg

per day in divided doses, with a maintenance dose of 0.5 mg/kg per day.⁹⁹ Clinical response may take 3 to 6 months. Another alternative is methotrexate at a dose of 5–20 mg once weekly.⁹⁹ In patients resistant to these therapies, cyclophosphamide, cyclosporine, or chlorambucil can be tried. Intravenous γ -globulin at a dose of 2 g/kg per month for 3 months may be effective in patients with refractory disease.¹⁰⁰ There are no large series of data available on clinical outcomes in patients on alternative therapies for PM or DM. These alternative therapies also may be beneficial in patients who cannot take corticosteroids because of serious adverse effects.

POLYMYALGIA RHEUMATICA AND GIANT CELL ARTERITIS

CLINICAL MANIFESTATIONS

Polymyalgia rheumatica (PMR) and giant cell arteritis are closely related diseases, and some experts consider them to be different phases of the same disease.^{101,102}

Giant cell arteritis is a vasculitis of large and medium-sized vessels. The most frequent symptom is headache, with pain usually in the temporal or occipital areas, and signs of systemic inflammation also usually are present.^{101,103} Giant cell arteritis was referred to previously as “temporal arteritis” or “granulomatous arteritis.” Both PMR and giant cell arteritis occur in people over 50 years of age, and the incidence increases with age, peaking between 70 and 80 years.¹⁰¹ Some patients go from exhibiting no symptoms to overt clinical manifestations overnight, whereas others have a gradual onset of symptoms over a number of weeks. The etiology is unknown.

CLINICAL PRESENTATION OF PMR AND GIANT CELL ARTERITIS

GENERAL

- Aching and morning stiffness of neck, shoulder, and pelvic girdle musculature and torso.

SYMPTOMS

- Pain and morning stiffness lasting 1–6 hours
- Fatigue, malaise, weight loss usually present
- Anorexia
- Headache in giant cell arteritis

SIGNS

- Low-grade fever

LABORATORY TESTS

- ESR is generally >40 mm/h and often >100 mm/h

► TREATMENT: Polymyalgia Rheumatica and Giant Cell Arteritis

The treatment of choice for PMR is prednisone at a dose of 10–20 mg/day, and giant cell arteritis requires doses of 40–60 mg/day. Pulse therapy with intravenous methylprednisolone, 1000 mg/day for 3 days, may be used in patients experiencing visual loss.^{101,102} Corticosteroid therapy is so effective that if improvement does not occur within a week, another diagnosis should be considered. The erythrocyte sedimentation rate (ESR) should decrease by 2 weeks and be normal after 4 weeks of therapy. The prednisone should be tapered beginning several weeks following control of symptoms. The rate of tapering is based on clinical response. A taper of 2.5 mg/day at 2- to 4-week intervals to 5–10 mg/day followed by a slower tapering of 1 mg/day at monthly intervals has been suggested.^{104,105} The lowest dose of prednisone that controls symptoms should be used for maintenance, which is usually between 7 and 15 mg/day. Maintaining the

ESR and C-reactive protein concentration in the normal range is a good monitoring approach. For elderly patients, the normal ESR may be slightly higher than that usually given as a reference value by the clinical laboratory. PMR is a self-limited disease, and patients usually continue maintenance therapy for 2 to 5 years. Patients may experience a relapse when the prednisone is discontinued and may require prednisone therapy for up to 15 years.¹⁰⁶ Every-other-day prednisone has not been as successful as daily therapy. Since these are diseases of the elderly, it is particularly important to use calcium and vitamin D supplements to prevent corticosteroid-induced osteoporosis. Prophylactic bisphosphonate therapy also should be considered. Unlike most other autoimmune diseases, other forms of immunosuppressive therapy are not as effective as corticosteroids in PMR and giant cell arteritis.¹⁰²

DRUG-INDUCED VASCULITIS

CLINICAL MANIFESTATIONS

6 Drugs are common causes of vasculitis, often occurring in the skin, but other organ involvement can occur. The pathogenesis of inflammation of small and medium-sized blood vessel walls caused by drugs is poorly understood.¹⁰⁷ Even drugs used to treat inflammatory and immune-mediated disease, such as NSAIDs, sulfasalazine, and etanercept, can cause vasculitis.

CLINICAL PRESENTATION OF DRUG-INDUCED VASCULITIS

GENERAL

- Signs and symptoms depend on organ involvement

SYMPTOMS

- Rash
- Glomerulonephritis

- Hepatitis
- Fatigue
- Myalgias
- Arthralgias

SIGNS

- Fever

Symptoms can occur within hours of drug administration or after more than 15 years of using a drug.¹⁰⁸ Most classes of medications have been reported to cause vasculitis. There are no specific diagnostic tests for drug-induced vasculitis. Antineutrophil cytoplasmic autoantibodies have been identified in many cases of drug-induced vasculitis.^{107,108} Eosinophilia, leukocytosis, and elevated ESR also may occur.

▶ TREATMENT: Drug-Induced Vasculitis

The first step in therapy of drug-induced vasculitis is to discontinue the suspected inducing agent. This may be all that is necessary to abate symptoms in mild cases. For more serious cases, corticosteroids may be used, and where life-threatening organ involvement occurs,

immunosuppressive therapy with agents such as cyclophosphamide may be used.¹⁰⁸ Following therapy, symptoms resolve within a few weeks to a few months.

EVALUATION OF THERAPEUTIC OUTCOMES

The diversity of clinical features and disease severity associated with the collagen-vascular diseases leads to a number of possible clinical outcomes with a broad range of desired therapeutic outcomes. Achieving desired therapeutic outcomes for most of the collagen-vascular diseases is highly variable. Currently, it is not possible to predict which patients will have a satisfactory therapeutic response and which will have unrelenting progressive disease. These diseases often have fluctuating courses, necessitating frequent changes in drug therapy and drug doses.

Evaluation of drug therapy of several of the collagen-vascular diseases often only requires monitoring for resolution of symptoms such as rash or muscle pain. However, patients with life-threatening disease receiving aggressive pharmacotherapy may require intensive monitoring and evaluation of therapy. For example, the patient receiving cytotoxic drug therapy for severe lupus nephritis requires close monitoring of laboratory indices of renal function, as well as monitoring of symptomatology and laboratory indices for possible bone marrow suppression, infection, cystitis, or other undesired therapeutic outcomes.

Evaluation of therapeutic outcomes also should include an awareness of the possibility of drug therapy mimicking signs and symptoms of disease, such as the lupus patient receiving NSAID

therapy and presenting with renal insufficiency or the patient with PM receiving prednisone and presenting with an exacerbation of muscle weakness.

As patients live longer, as is the case with SLE, outcome measures other than mortality will be needed to assess the effect of treatment. Clinicians and researchers working with lupus patients have developed and continue to refine some of these alternative outcome measures. Three important domains for assessing lupus patients include disease activity, accumulated damage, and quality of life.¹⁰⁹ Several instruments useful for assessing patients with SLE are listed in Table 85–7. Increased use of these and similar instruments for assessment of treatment outcomes in patients with SLE can be expected.

CONCLUSION

SLE is a disease that affects multiple organ systems and consists of abnormal immunologic function and the development of autoantibodies. The disease is quite variable in clinical presentation and progression. The cause of lupus is unknown, although several factors (e.g., genetics, environment, and hormones) may predispose an individual to the development of the disease. Although SLE was once thought to be rapidly fatal, today nearly 90% of patients survive 10 years.

Drug therapy is nonspecific and is aimed at suppressing the inflammation and abnormal immune response associated with active disease. Clinical trials with various agents often have been inadequate and contradictory, and the therapeutic management of lupus is not optimal. Nevertheless, drug therapy of recent years probably has contributed significantly to the improved survival of these patients. As the understanding of SLE progresses and advances in biotechnology occur, we can expect to see the development of more specific and optimal treatment and further improvement in survival.

Each of the collagen-vascular diseases has its own recommended form of therapy. For most of these diseases, there are few well-controlled clinical trials evaluating pharmacotherapy. Treatment of most of these diseases requires anti-inflammatory or immunosuppressive drugs. Monitoring therapeutic outcomes is essential because drugs and drug doses may need to be modified frequently.

ABBREVIATIONS

- ACE: angiotensin-converting enzyme
- ACR: American College of Rheumatology
- ANA: antinuclear antibodies

TABLE 85–7. Instruments Used for Assessing Outcome Measures in Patients with SLE

| Outcome Domain | Instrument |
|--------------------|--|
| Disease activity | Systemic Lupus Activity Measure (SLAM)/Revised SLAM (SLAM-R) Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) British Isles Lupus Activity Group (BILAG) |
| Accumulated damage | Systemic Lupus International Collaborating Clinics/American College of Rheumatology (SLICC/ACR) damage index |
| Quality of life | Health Assessment Questionnaire (HAQ) functional ability index Medical Outcome Survey short form (MOS SF-20) and (MOS SF-36) |

From ref. 109.

APCs: antigen-presenting cells
 CAD: coronary artery disease
 DIL: drug-induced lupus
 DM: dermatomyositis
 DNA: deoxyribonucleic acid
 dsDNA: double-stranded DNA
 ECG: electrocardiograph
 ESR: erythrocyte sedimentation rate
 HLA: human leukocyte antigen
 INR: international normalized ratio
 LA: lupus anticoagulant
 MHC: major histocompatibility complex
 NSAID: nonsteroidal anti-inflammatory drug
 PM: polymyositis
 PMR: polymyalgia rheumatica
 RNP: ribonucleoprotein
 SLE: systemic lupus erythematosus
 ssDNA: single-stranded DNA
 RNA: ribonucleic acid
 Th: T-helper cell
 WHO: World Health Organization

ALLERGIC AND PSEUDOALLERGIC DRUG REACTIONS

Joseph T. DiPiro and Dennis R. Ownby

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Allergic reactions are responsible for 6% to 10% of adverse reactions to medications. Although some reactions are relatively well defined, the majority are due to mechanisms that are either unknown or poorly understood.
 - 2 The following criteria suggest that a drug reaction may be immunologically mediated: (a) The reaction occurs in a small percentage of patients receiving the drug, (b) the observed reaction does not resemble the drug's pharmacologic effect, (c) the type of manifestation is similar to that seen with other allergic reactions (anaphylaxis, urticaria, serum sickness), (d) there is a lag time between first exposure of the drug and reaction, (e) the reaction is reproduced even by minute doses of the drug, (f) the reaction is reproduced by agents with similar chemical structures, (g) eosinophilia is present, and (h) the reaction resolves after the drug has been discontinued. Exceptions to each of these criteria are observed commonly.
 - 3 Factors that influence the likelihood of allergic drug reactions are the dose of the allergen, the route of exposure, and the sensitivity of the individual as determined by age, genetics, or environmental factors. For many drugs, the severity of a reaction is determined by the dose and duration of exposure.
 - 4 Anaphylaxis is an acute, life-threatening allergic reaction involving multiple organ systems that generally begins within 30 minutes but almost always within 2 hours after exposure to the inciting allergen. Anaphylaxis requires prompt treatment to restore respiratory and cardiovascular function. Epinephrine is administered as primary treatment to counteract bronchoconstriction and vasodilatation. Intravenous fluids should be administered to restore intravascular volume.
 - 5 Patients with a history of a reaction to penicillin are advised not to receive cephalosporins if they can be avoided. Patients who have negative penicillin skin tests or experienced only mild cutaneous reactions, such as maculopapular rashes, have a low risk of serious reactions to cephalosporins.
 - 6 Less than 1% of patients receiving nonionic radiocontrast agents experience some type of adverse reaction. Of the variety of reactions reported, approximately 90% are allergic-like, mostly urticarial, with severe reactions occurring as infrequently as 0.02%.
 - 7 Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) can produce two general types of reactions, urticaria/angioedema and rhinosinusitis/asthma, in susceptible patients. Approximately 20% of asthmatics are sensitive to aspirin and other NSAIDs.
 - 8 Adverse reactions to trimethoprim-sulfamethoxazole have been observed to occur much more frequently in AIDS patients compared with those without AIDS (50% to 80% of AIDS patients compared with 10% in other immunocompromised patients).
 - 9 The basic principles of management of allergic reactions to drugs or biologic agents include (a) discontinuation of the medication or agent when possible, (b) treatment of the adverse clinical signs and symptoms, and (c) substitution, if necessary, of another agent.
 - 10 One of the most helpful tests to evaluate risk of penicillin allergy is the skin test. Skin testing can demonstrate the presence of penicillin-specific IgE and predict a relatively high risk of immediate hypersensitivity reactions. Skin testing does not predict the risk of delayed or most dermatologic reactions.
- The true frequency of allergic drug reactions is difficult to determine because many reactions may not be reported, and others may be difficult to distinguish from nonallergic adverse events. Dermatologic reactions represent the most frequently recognized and reported form of allergic drug reaction.³

TABLE 86–1. Classification of Allergic Drug Reactions

| Type | Descriptor | Characteristics | Typical Onset | Drug Causes |
|------|-----------------------------|--|------------------|--|
| I | Anaphylactic (IgE mediated) | Allergen binds to IgE on basophils or mast cells resulting in release of inflammatory mediators | Within 30 min | Penicillin immediate reaction Blood products Polypeptide hormones Vaccines Dextran |
| II | Cytotoxic | Cell destruction occurs because of cell-associated antigen that initiates cytolysis by antigen-specific antibody (IgG or IgM). Most often involves blood elements. | Typically 5–12 h | Penicillin, quinidine, phenylbutazone, thiouracils, sulfonamides, methyl dopa |
| III | Immune complex | Antigen–antibody complexes form and deposit on blood vessel walls and activate complement. Result is a serum-sickness-like syndrome. | 3–8 h | May be caused by penicillins, sulfonamides, radiocontrast agents, hydantoins |
| IV | Cell mediated (delayed) | Antigens cause activation of lymphocytes, which release inflammatory mediators. | 24–48 h | Tuberculin reaction |

MECHANISMS OF ALLERGIC DRUG REACTIONS

Drugs can cause allergic reactions by a variety of immunologic mechanisms. Although some reactions are relatively well defined, the majority are due to mechanisms that are either unknown or poorly understood.⁴

2 The following criteria suggest that a drug reaction may be immunologically mediated⁵: (1) The reaction occurs in a small percentage of patients receiving the drug, (2) the observed reaction does not resemble the drug’s pharmacologic effect, (3) the manifestations are similar to those seen with other allergic reactions (e.g., anaphylaxis, urticaria, serum sickness), (4) there is a lag time between first exposure of the drug and reaction unless the recipient has been sensitized by prior exposure to the drug, which can lead to immediate reactions, (5) the reaction is reproduced even by minute doses of the drug, (6) the reaction may be reproduced by agents with similar chemical structures, (7) peripheral blood eosinophilia is present, and (8) the reaction resolves after the drug has been discontinued. Exceptions to each of these criteria are observed commonly.

Many allergic reactions can be classified into one of four immunopathologic categories: types I, II, III, and IV^{6,7}(Table 86–1 and Fig. 86–1). Some drug reactions suspected of being mediated immunologically are considered possibly allergic. Examples include drug-associated skin eruptions, drug fever, drug-induced hepatitis, and interstitial nephritis. Other drug reactions can be classified as *pseudoallergic* or *idiosyncratic*. Examples include anaphylactoid (anaphylaxis-like) reactions to radiocontrast media, sulfite sensitivity, and reactions to local anesthetics.

EFFECTORS OF ALLERGIC DRUG REACTIONS

Allergic drug reactions can involve most of the major components of the immune system, including the cellular elements, immunoglobulins, complement, and cytokines. Most immunoglobulin isotypes have been implicated in immunologically mediated drug reactions.

Immunoglobulin E (IgE) bound to basophils or mast cells mediates immediate (anaphylactic-type) reactions. IgG or IgM antibodies also may be involved in allergic reactions, resulting in destruction of cells and tissues.

CELLULAR ELEMENTS

A variety of cells may be involved in immunologic drug reactions. Basophils, mast cells, eosinophils, and lymphocytes are involved most

FIGURE 86–1. Types of hypersensitivity reactions.

frequently. Platelets and vascular endothelial cells are also important because they also can release a number of inflammatory mediators. Most cells of the body, including nerve cells, can become involved directly or indirectly in allergic drug reactions.⁸

MEDIATORS OF ALLERGIC REACTIONS

The release of a number of preformed, pharmacologically active chemical mediators (e.g., histamine, serotonin, eosinophil chemotactic factor, neutrophil chemotactic factor, and bradykinin-generating factor, also known as *basophil kalikrein of anaphylaxis*) is triggered by antigen cross-linking IgE molecules on the surface of circulating basophils and tissue mast cells. Newly generated mediators include platelet-activating factor and arachidonic acid metabolites (e.g., prostaglandins, thromboxanes, and leukotrienes). Each of these mediators is discussed in the following sections.

Histamine is a low-molecular-weight amine compound formed by decarboxylation of histidine and is stored in basophil and mast cell granules.⁹ The release of histamine from these cells is triggered by antigen cross-linking IgE bound to specific receptors on the surface membranes of mast cells and basophils. The tissue effects of histamine are evident within 1 to 2 minutes, but it is rapidly metabolized within 10 to 15 minutes. The major effects of histamine on target tissues include increased capillary permeability, contraction of bronchial and vascular smooth muscle, and hypersecretion of mucus glands.

Serotonin is also a low-molecular-weight amine stored in and released from platelets and mast cells with effects similar to histamine. It may cause vasoconstriction or vasodilatation in some animal species but has no clear role in human anaphylaxis. Eosinophil chemotactic factors are a group of preformed cellular tetrapeptides and dodecapeptides released by stimulated mast cells. They attract eosinophils to inflammatory sites and participate in phagocytosis. Neutrophil chemotactic factor is a high-molecular-weight protein that enhances neutrophil migration to areas of mast cell activation. Bradykinin-generating factor is a series of proteases that activate Hageman factor, resulting in the production of kinins, including bradykinin, which is more potent than histamine on a molar basis in causing vascular permeability and contraction of smooth muscle.

Platelet-activating factor (PAF) is a glyceride-derived substance that is released by mast cells, alveolar macrophages, neutrophils, platelets, and other cells but not by basophils. It has potent bronchoconstrictor effects and also causes platelet aggregation and lysis. It attracts neutrophils and causes their activation. Also, PAF enhances vascular permeability and can cause pain, pruritus, and erythema.

The leukotrienes (LTs) are metabolites of arachidonic acid produced through the 5-lipoxygenase pathway that have potent effects on bronchial and vascular smooth muscle. Three important leukotrienes, LTC₄, LTD₄, and LTE₄, are produced by basophils or mast cells. These three substances are also referred to as *cystinyl leukotrienes* and in older literature as *slow-reacting substances of anaphylaxis*. The LTs have more potent and longer-lasting bronchoconstrictor effects than histamine and also can increase vascular permeability and cause arteriolar vasoconstriction followed by vasodilatation. Their effects are slower in onset but longer lasting than those of histamine. Another product, LTB₄, is a potent chemoattractant, particularly for neutrophils. It is also produced by neutrophils, macrophages, and monocytes.

Prostaglandins (PGs) and thromboxanes are metabolites of arachidonic acid produced through the cyclooxygenase pathway. Some PGs have vasoconstrictive and/or bronchodilatory properties, whereas others are vasodilatory (e.g., PGD₂) and/or bronchoconstrictive

(e.g., PGF_{2α}). PGD₂ is the major prostaglandin product of mast cells. It is a potent inhibitor of platelet aggregation. Thromboxanes cause platelet aggregation and are important regulators of coagulation.

The complement system consists of approximately 30 plasma proteins and is involved in hypersensitivity through a variety of immunologic responses, including enhancement of phagocytosis (opsonization of target cells), cell lysis, and generation of anaphylatoxins (C3a, C4a, and C5a), which can cause non-IgE-mediated activation of mast cells and release of inflammatory mediators.

CLASSIFICATION OF IMMUNOPATHOLOGIC DRUG REACTIONS

Immunologic mechanisms have been identified for some drug reactions. Many can be classified into one of four immunopathologic reactions, as described below. In general, small-molecular-weight molecules (<10,000 MW) are not immunogenic. Most drugs are less than 1000 MW. To become immunogenic, these small compounds must first combine with carrier proteins in plasma or tissue. The combination of the drug bound to a carrier protein can be recognized as foreign, leading to an immune response. The more likely that large amounts of the drug become chemically bound to a protein, the greater is the risk that it will produce an allergic reaction. Penicillin G (356 MW) is an example of a drug that binds covalently to serum proteins through amide or disulfide linkages. For drugs such as the sulfonamides, the parent compound first must be converted to a metabolite before it can combine with the macromolecule. The species that combines with the carrier macromolecule is referred to as a *hapten* or an *incomplete antigen*.¹⁰ Some macromolecular drugs such as insulin are referred to as *complete antigens* because they are large enough to initiate an immune response without binding to another protein.

TYPE I

Type I reactions require the presence of IgE specific for the drug or the portion of the drug that becomes a hapten. IgE specific for the drug allergen is produced on initial exposure to the drug, and then it binds to basophils and mast cells through high-affinity receptors. On repeat exposure to the drug, two or more IgE molecules on the basophil or mast cell surface may bind to one multivalent antigen molecule (referred to as *cross-linking*; see Fig. 86-1), initiating an activation of the cell. Activation causes the extracellular release of granules with preformed inflammatory mediators, including histamine, serotonin, heparin, proteases (tryptase in the mast cell), bradykinin-generating factor, eosinophil chemotactic factors, and neutrophil chemotactic factor, as well as generation of newly formed mediators, as previously discussed, such as LTs, prostaglandins, thromboxanes, and PAF, among others.

Generation of a type I reaction can be evident as an immediate hypersensitivity reaction, or anaphylaxis. Immediate reactions may be limited to single organs, typically in the nasal mucosa (rhinitis), respiratory tract (acute asthma), skin, or gastrointestinal tract, or can involve multiple organs simultaneously, termed *anaphylaxis*.

TYPE II

Type II immunopathologic reactions involve destruction of host cells (usually blood cells) through cytotoxic antibodies by one of two mechanisms (see Fig. 86-1). First, the drug binds to the cell as a hapten (e.g., the platelet or red blood cell). Antibodies (IgG or IgM) specific for the

bound drug or to a component of the cell surface that has been altered by the drug then bind, initiating a cytolytic reaction. The cell destruction may be mediated by complement or by phagocytic cells that have Fc receptors on their surfaces. Activation of complement near the cell surface can result in loss of cell membrane integrity and cell death. Alternatively, neutrophils, monocytes, or macrophages may bind to an antibody-coated cell through IgG Fc receptors on their cell surfaces, and this binding results in phagocytosis of the target cell. The process of enhancement of phagocytosis by antibody binding to cell surfaces or other particles is referred to as *opsonization*. In addition, cell-bound IgG may direct the nonphagocytic action of T cells or natural killer cells, which results in cell destruction by a process called *antibody-dependent cellular cytotoxicity*. This process can proceed in a nonspecific fashion as T cells bind to the target cell through IgG Fc receptors on the T-cell surface. Contact is necessary between the target and effector cells.

Cells commonly affected by these types of reactions include erythrocytes, leukocytes, and platelets, resulting in hemolytic anemia, agranulocytosis, or thrombocytopenia, respectively. This process may be initiated by drugs such as penicillin, quinidine, quinine, phenacetin, cephalosporins, and sulfonamides.

Another type of reaction that may affect the formed elements in blood is the “innocent bystander” reaction. With this type of reaction, antigen-antibody complexes formed in blood adhere nonspecifically to cells. Complement is then activated, resulting in cell lysis.

TYPE III

Type III immunologic reactions are caused by antigen-antibody complexes that are formed in blood. The complexes form with drug allergen and antibody in varying ratios and may deposit in tissues, resulting in local or disseminated inflammatory reactions. Antigen-antibody complex formation can result in platelet aggregation, complement activation, or macrophage activation. Chemotactic substances such as C4a are also produced, and they cause the influx of neutrophils and result in the release of a number of toxic substances from the neutrophil (e.g., proteinases, collagenases, kinin-generating enzymes, and reactive oxygen and nitrogen substances), which can cause local tissue destruction.

Platelet aggregation may occur as a result of immune-complex formation, resulting in the formation of microthrombi and the release of vasoactive mediators. Also, insoluble complexes may be phagocytized by macrophages and activate these cells.

The formation of antigen-antibody complexes can lead to clinical syndromes such as the Arthus reaction. In this model, a high level of preformed specific IgG antibody combines with antigen to produce a localized edematous, erythematous reaction within 5 to 8 hours. The reaction involves local formation of insoluble antigen-antibody complexes, complement activation with release of C3a and C5a collectively referred to as *anaphylatoxins*, mast cell degranulation, and influx of polymorphonuclear cells.

TYPE IV

Type IV reactions are delayed hypersensitivity reactions that typically are demonstrated as dermatologic reactions and are mediated by T cells (CD4⁺ or CD8⁺).¹¹ Type IV reactions require memory T cells specific for the antigen in question. On exposure to the antigen, T cells become activated and produce an inflammatory response. Although these reactions may be associated with adverse effects (e.g., contact dermatitis, maculopapular exanthemas, bullous exanthemas, eczema, or pustular exanthemas), they also may be useful for diagnostic pur-

poses. Examples of the latter include the purified protein derivative (PPD) antigen from *Mycobacterium tuberculosis* used in the tuberculin skin test and other recall skin test antigens, such as mumps. After intradermal injection, these antigens produce a local reaction (erythema and induration) within 48 to 72 hours. Delayed contact hypersensitivity also can be caused by a wide variety of chemicals and drugs.

OTHER ALLERGIC REACTIONS

The precise mechanisms of many drug reactions are not known, although the reactions are believed to be immune mediated. Perhaps most common are the delayed dermatologic reactions that occur with a variety of drugs (especially penicillins and sulfonamides).¹¹ These reactions may be evident as macropapular, morbilliform, or erythematous rashes; exfoliative dermatitis; photosensitivity reactions; or eczema. These reactions also may be manifest as pruritus, urticaria, and angioedema.

Other serious dermatologic syndromes may be the result of immunologic reactions. Erythema multiforme is an acute syndrome characterized by a variety of skin lesions. The skin lesions typically start as a maculopapular eruption that may progress to irregular lesions with central clearing (target lesions) mostly on the extremities. The rash may be accompanied by bullous lesions that break down into erosions involving more of the body, especially mucous membranes. This more extensive disease usually associated with fever and extensive purpura is called *erythema multiforme major* or *Stevens-Johnson syndrome* (SJS). Some have termed these types of reactions *febrile mucocutaneous syndromes*. If the skin lesions progress to sloughing of large portions of the skin, resembling third-degree burns, the term *toxic epidermal necrolysis* (TEN) is applied. Mortality from TEN can be as high as 30%. Drugs commonly associated with these syndromes include the penicillins, sulfonamides, and anti-convulsants such as phenytoin and phenobarbital, as well as a number of other agents. Drug-induced fever also may involve immunologic mechanisms. Other general types of reactions believed to be immune mediated in some cases include hepatic drug reactions (cholestatic or hepatocellular) and pulmonary reactions, e.g., interstitial pneumonitis, which has been associated with nitrofurantoin.

ANAPHYLACTOID REACTIONS

Various drugs and other substances can produce anaphylactoid (anaphylaxis-like) reactions that are similar to anaphylaxis in clinical signs and symptoms. The substances causing these reactions can produce the direct release of inflammatory mediators from cells by a pharmacologic or physical effect rather than through cell-bound IgE. These reactions are sometimes referred to as *pseudoallergic*, but not all pseudoallergic reactions are anaphylactoid. Drugs that can produce anaphylactoid reactions include vancomycin, opiates, iodinated radiocontrast agents, amphotericin, and D-tubocurarine. The “red man syndrome” is a common example of an anaphylactoid reaction from vancomycin. If vancomycin is infused too rapidly, it can cause the direct release of histamine and other mediators from cutaneous mast cells. This produces a typical clinical picture of itching, flushing, and hives first around the neck and face and then progressing to the chest and other parts of the body usually beginning shortly after the infusion has begun. Most patients who have had “red man syndrome” will tolerate vancomycin if the rate of infusion is slowed. A number of other agents (including aspirin) may produce anaphylactoid reactions by altering the metabolism of inflammatory mediators such as PGs or kinins.

CLINICAL MANIFESTATIONS OF ALLERGIC AND ALLERGIC-LIKE REACTIONS

ANAPHYLAXIS

4 Anaphylaxis is an acute, life-threatening allergic reaction involving multiple organ systems.¹² Approximately 1500 deaths occur annually in the United States from anaphylaxis.¹³ From 1.2% to 15% of the U.S. population may be at risk of anaphylactic reactions.¹⁴ Although many drugs may cause anaphylaxis (or anaphylactoid) reactions, those reported most commonly are aspirin and other NSAIDs, penicillins, and insulins.¹⁵ The manifestations of anaphylaxis may include signs and symptoms referable to the skin, gastrointestinal tract, respiratory tract, and cardiovascular system or any combination of these systems. Common dermatologic manifestations include urticaria, angioedema, and pruritus.¹⁵ Urticaria is a dermatologic reaction noted by elevated, erythematous patches that are pruritic. Gastrointestinal manifestations include nausea, abdominal pain, vomiting, and diarrhea. With respiratory tract involvement, the patient may experience stridor, dyspnea, or wheezing. The major cardiovascular manifestations include hypotension, tachycardia, and arrhythmias.

Anaphylactic reactions generally begin within 30 minutes but almost always within 2 hours of exposure to the inciting allergen. The risk of fatal anaphylaxis is greatest within the first few hours. After apparent recovery, anaphylaxis may recur 6 to 8 hours after antigen exposure. Because of the possibility of these “late phase” reactions, patients should be observed for at least 12 hours after an anaphylactic reaction. Fatal anaphylaxis most often results from asphyxia due to airway obstruction either at the larynx or within the lungs. Cardiovascular collapse may occur as a result of asphyxia in some cases, whereas in others cases cardiovascular collapse may be the dominant manifestation from the release of mediators within the heart muscles and coronary blood vessels.

SERUM SICKNESS

Serum sickness is a clinical syndrome resulting from the effects of soluble circulating immune complexes that form under conditions of antigen excess. The reaction commonly results from the use of antisera containing foreign (donor) antigens such as equine serum in the form of antitoxins or antivenins. The onset of serum sickness usually occurs 7 to 14 days after antigen administration. The onset may be more rapid with reexposure to the same agent in an individual with prior serum sickness. Fever, malaise, and lymphadenopathy are the most common clinical manifestations. Arthralgias, urticaria, and morbilliform skin eruption also may be present. Although often associated with administration of heterologous antisera, serum sickness also may be caused by drugs, including sulfonamides, hydantoins, penicillins, minocycline, and cephalosporins (especially cefaclor). In addition, immune-complex-mediated systemic lupus erythematosus-like syndrome has been attributed to reactions from drugs such as hydralazine, procainamide, isoniazid, and phenytoin.

DRUG FEVER

Fever may occur in response to an inflammatory process or develop as a manifestation of a drug reaction. Drug fever occurs in as many as 10% of hospital inpatients.¹⁶ A large number of drugs have been reported to cause fever, including methyldopa, procainamide, phenytoin, barbiturates, quinidine, and a variety of antibiotics. These drugs may affect the central nervous system directly to alter temperature regulation or stimulate the release of endogenous pyrogens (e.g.,

interleukin 1 and tumor necrosis factor) from white blood cells. Drugs also may cause fever as a result of their pharmacologic effects on tissues, e.g., fever resulting from massive tumor cell destruction caused by chemotherapy. However, the mechanism of drug fever remains unknown for agents such as amphotericin B and radiographic contrast agents.

The temperature pattern of drug-induced fever is quite variable and therefore of little help in the diagnosis. It may be low grade and continuous or spiking and intermittent. A temporal relationship between drug administration and occurrence of fever has been noted for some medications. Generally, withdrawal of the causative agent results in prompt defervescence as soon as the drug is eliminated completely. Fever usually recurs on readministration of the causative agent.

DRUG-INDUCED AUTOIMMUNITY

Autoimmune diseases have been associated with drugs and may involve a variety of tissues and organs. A commonly recognized drug-related autoimmune disorder is systemic lupus erythematosus (SLE) induced by procainamide, hydralazine, or isoniazid. Other drugs associated with SLE include methyldopa, β -adrenergic blockers, penicillamine, quinidine, interferon- γ , and sulfasalazine.¹⁷ Exposure of susceptible persons to these agents appears to alter normal body proteins, RNA, or DNA in such a way as to make these components antigenic, leading to the formation of autoreactive antibodies and cells. The most common clinical manifestations include arthralgias, myalgias, and polyarthritis. Facial rash, ulcers, and alopecia occur less frequently. Renal or pulmonary involvement also may occur. These reactions typically develop several months after beginning the drug and generally resolve soon after it is discontinued.¹⁸

Other syndromes believed to involve autoimmune mechanisms include drug-induced hemolytic anemia owing to methyldopa, renal interstitial nephritis produced by methicillin, and hepatitis caused by phenytoin and halothane. Interstitial nephritis is characterized by fever, rash, and eosinophilia associated with proteinuria and hematuria. Hepatic damage due to drugs generally is manifested as either hepatocellular necrosis or cholestatic hepatitis. Drug-induced hepatitis has been associated with phenothiazines, sulfonamides, halothane, phenytoin, and isoniazid (see Chap. 38). Hepatocellular destruction is evidenced by elevations in serum transaminases. Hepatomegaly and jaundice sometimes may be evident. Cholestasis may be manifested by jaundice and elevations in serum alkaline phosphatase and sometimes by rash, fever, and eosinophilia.

VASCULITIS

Vasculitis is a clinicopathologic process characterized by inflammation and necrosis of blood vessels walls. The vasculitic process may be limited to the skin or may involve multiple organs, including the liver or kidney, joints, or central nervous system. Characteristically, cutaneous vasculitis is manifested by purpuric lesions that vary in size and number. Vasculitis also may be manifested as papules, nodules, ulcerations, or vesiculobullous lesions, generally occurring on the lower extremities, but the upper extremities, including the hands, also may be involved. Drugs associated with vasculitis include allopurinol, β -lactam antibiotics, sulfonamides, thiazide diuretics, and phenytoin.

DERMATOLOGIC REACTIONS

A wide variety of dermatologic drug reactions has been reported to have an immunologic basis (see Chap. 94).^{4,19} As noted previously,

TABLE 86–2. Top 10 Drugs or Agents Reported to Cause Skin Reactions

| | Reactions per 1000 Recipients |
|-------------------------------|-------------------------------|
| Amoxicillin | 51.4 |
| Trimethoprim-sulfamethoxazole | 33.8 |
| Ampicillin | 33.2 |
| Iopodate | 27.8 |
| Blood | 21.6 |
| Cephalosporins | 21.1 |
| Erythromycin | 20.4 |
| Dihydralazine hydrochloride | 19.1 |
| Penicillin G | 18.5 |
| Cyanocobalamin | 17.9 |

Adapted from Ref. 19.

cutaneous reactions are the most common manifestations of allergic drug reactions. Although most dermatologic reactions are mild and resolve promptly after discontinuing the drug, some may progress to serious or even life-threatening reactions (e.g., toxic epidermal necrolysis or Stevens-Johnson syndrome). Stevens-Johnson syndrome is a serious dermatologic reaction characterized by blistering of the mucous membranes (mouth, eyes, vagina) with patchy rashes that can cover most of the body. Patients also may experience fever, headache, and cough. Toxic epidermal necrolysis is a syndrome similar to Stevens-Johnson syndrome characterized by blistering of skin and mucous membranes in response to administration of a drug. Large areas of skin may peel off.

Cutaneous adverse reactions were reported to occur in 2.7% of hospitalized patients.²⁰ Serious dermatologic drug reactions are estimated to occur in 1.9 cases per 1 million people per year and can have a mortality rate as high as 40%.^{21,22} Table 86–2 lists drugs and agents associated most commonly with cutaneous reactions.²³ Antimicrobials are implicated most frequently with reaction rates ranging from 1% to 8%. In a report of almost 6000 children, about 12% developed rashes with cefaclor compared with 7.4% with penicillins and 8.5% with sulfonamides.²⁴

RESPIRATORY REACTIONS

Drugs also may produce upper or lower respiratory tract reactions, including rhinitis and asthma. Respiratory tract manifestations may result from direct injury to the airways or may occur as a component of a systemic reaction (e.g., anaphylaxis). Asthma may be induced by aspirin and other NSAIDs or by sulfites used as preservatives in foods and medications. Other pulmonary drug reactions believed to be immunologic include acute infiltrative and chronic fibrotic pulmonary reactions. The latter is often caused by antineoplastic agents such as bleomycin. For a more detailed discussion of drug-induced pulmonary disease, see Chap. 29.

HEMATOLOGIC REACTIONS

Most formed elements and soluble components of the hematopoietic system may be affected by immunologic drug reactions. Eosinophilia is a common manifestation of drug hypersensitivity and may be the only presenting sign. Hemolytic anemia may result from hypersensitivity to drugs. Other hematologic reactions include thrombocytopenia, granulocytopenia, and agranulocytosis. For a detailed discussion of hematologic drug reactions, see Chap. 102.

FACTORS RELATED TO THE OCCURRENCE OR SEVERITY OF ALLERGIC DRUG REACTIONS

3 Among the factors that influence the likelihood of allergic drug reactions are the dose of the drug, how the drug is metabolized and the degree to which the drug and metabolites bind to human proteins, the route of exposure, and the sensitivity of the individual as determined by age, genetics, and environmental factors. For many drugs, the severity of a reaction is determined by the dose and the duration of exposure. A relatively larger dose or longer duration of treatment encourages development of drug sensitivity. The route of administration also influences drug sensitivity. The topical route of drug administration appears to be the most likely to sensitize and predispose to drug reactions. The oral route is the safest, and the parenteral route is the most hazardous for administration of drugs in sensitive individuals. There are relatively few reported cases of immediate hyper sensitivity-associated deaths with oral β -lactam antimicrobials. Although intravenous administration is more likely to result in severe immediate reactions in a sensitized individual, it may be the least likely route for initially inducing sensitivity. One possible explanation is that intravenous administration results in systemic drug exposure for the shortest period of time.

Individual host factors are also important in determining drug sensitivity. There may be a genetic predisposition for some types of allergic reactions. Slow acetylators of procainamide and hydralazine are at increased risk for SLE.

Drug allergies appear to develop with equal frequency in atopic and nonatopic individuals.⁴ In addition, patients with a history of drug allergy appear to be at increased risk of adverse reactions to other pharmacologic agents. Age seems to be related to the risk of allergic reactions because they occur less frequently in children. This may be related to immaturity of the immune system or decreased exposure. The presence of some concurrent diseases predisposes to drug reactions. Examples include the morbilliform rash that occurs after ampicillin administration to patients with infectious mononucleosis and the reactions that occur with trimethoprim-sulfamethoxazole in AIDS patients.

DRUGS COMMONLY CAUSING ALLERGIC OR ALLERGIC-LIKE DRUG REACTIONS

β -LACTAM ANTIMICROBIALS

Allergic reactions to penicillin occur in 0.7% to 8% of treatment courses but was as high as 15% in one retrospective report of hospitalized patients treated with penicillin.^{25,26} While most patients reporting penicillin allergy do not have allergy, a reported history is associated with a higher likelihood of positive skin test reactivity.²⁷ Only 10% to 20% of patients reporting penicillin allergy are found to be allergic by skin testing.²⁷

The most common reactions to penicillin include urticaria, pruritus, and angioedema. All four of the major types of hypersensitivity reactions have been reported with penicillin, as well as some reactions that do not fit into these categories. A wide variety of idiopathic reactions occurs, e.g., maculopapular eruptions, eosinophilia, Stevens-Johnson syndrome, and exfoliative dermatitis. Cutaneous reactions can occur in up to 4.4% of treatment courses of penicillin²⁸ and in up to 8% with aminopenicillins.²⁹ The incidence of ampicillin rash is 69% to 100% in patients with Epstein-Barr virus infection, cytomegalovirus infection, or acute lymphocytic leukemia.³⁰

FIGURE 86-2. Formation of a benzyl penicilloyl hapten–protein complex.

Some aspects of the mechanism of penicillin immunogenicity have been determined. Because benzylpenicillin is a relatively small molecule (MW 356), it must combine with macromolecules (presumably proteins) to elicit an immune response. Penicillin may bind covalently to the lysine residues of proteins such as albumin through an amide linkage involving the β -lactam ring (Fig. 86-2). This is the penicilloyl-protein conjugate and is referred to as the *major antigenic determinant*. In addition, a number of other penicillin metabolites may bind covalently to proteins. These are referred to as *minor antigenic determinants*. The terms *major* and *minor* refer to the relative proportions of these conjugates that are formed and not to the clinical severity of the reactions generated. Immediate hypersensitivity reactions may be mediated by IgE for both minor and major determinants. In fact, the minor antigenic determinants are more likely to cause life-threatening anaphylactic reactions.

Patients who are allergic to penicillins also may be sensitive to other β -lactams.³¹ The exact incidence of cross-reactivity between cephalosporins and penicillins is not known, although it is believed to be low. Patients who report penicillin allergy and are penicillin-skin-test-positive have an eightfold greater risk of allergic reaction to cephalosporins compared with patients not reporting penicillin allergy. In contrast, patients with reported penicillin allergy and negative skin test are at no greater risk.³²

5 Most allergists would not administer cephalosporins to patients who had a history of hives or other immediate hypersensitivity reactions from penicillin, although some studies have suggested that there is little risk of an allergic response to a cephalosporin even in a person with a positive skin test to penicillin.^{33–35} One post-marketing surveillance report states that there was no increase in allergic reactions to second- and third-generation cephalosporins in patients with histories of penicillin allergy.³⁶ Results of skin testing with cephalosporins are not reliable because the mechanism of cephalosporin sensitivity has not been clearly defined. A study from France has suggested that skin tests are predictive of hypersensitivity to a number of β -lactam antibiotics, but this study only performed oral challenges on skin-test-negative children.³⁵ At present, patients with positive penicillin skin tests are advised not to receive cephalosporins if they can be avoided. Patients who have negative penicillin skin tests

or experienced only mild cutaneous reactions, such as maculopapular rashes, may receive cephalosporins with caution.

Other β -lactam derivatives (e.g., monobactams and carbapenems) have been studied for potential cross-reactivity with penicillins. In vitro and in vivo studies have demonstrated that aztreonam only weakly cross-reacts with penicillin and that it may be administered safely to most patients who are penicillin-allergic.³⁷ In contrast, there is considerable cross-reactivity between imipenem (a carbapenem) and penicillin. Therefore, imipenem (and other carbapenems) should not be administered to patients who have positive penicillin skin tests.

RADIOCONTRAST MEDIA

6 Radiocontrast agents frequently cause allergic-like reactions because these agents are used commonly in medical practice and are administered as large, rapidly infused intravenous boluses. Fewer than 1% of patients receiving nonionic radiocontrast agents experience some type of adverse reaction.³⁸ Of the variety of reactions reported, approximately 90% are allergic-like, mostly urticarial, and severe reactions occur as infrequently as 0.02%. In addition, radiocontrast agents may cause dose-dependent toxic reactions that can produce cardiovascular effects, arrhythmias, changes in renal blood flow, diuresis, or proteinuria.^{39,40} The older, high-osmolar agents that are now used less commonly have a greater frequency of reactions compared with the newer, low-osmolar agents.

The mechanism of reactions to radiocontrast agents is not clearly understood. Histamine release and mast cell triggering have been documented in severe immediate reactions, suggesting an IgE-mediated mechanism.⁴¹ The older, high-osmolar radiocontrast agents can activate mast cells and basophils directly (IgE-independent mechanism), resulting in the release of inflammatory mediators.⁴² The low-osmolar contrast agents appear to result in fewer anaphylactoid reactions. The adverse reaction rate for ionic iodinated contrast media was as high as 6% to 8%.³⁸ The relative risk of having a reaction to a lower-osmolarity, nonionic agent is estimated to be at least five times lower than with the ionic agents.⁴³

Patients at risk of reactions to radiocontrast agents are difficult to identify. History is helpful because a patient who has experienced

previous reactions is more likely to experience subsequent reactions. The risk of allergic reactions to radiocontrast media is greater in women and in patients with a history of atopy or asthma.^{43,44} Despite a common misconception, a seafood allergy does not predispose to radiocontrast media reactions. Neither skin tests nor oral tests are useful for predicting reactions to these agents. Some regimens have been recommended to prevent reactions in patients who have experienced them previously. One pretreatment regimen includes the administration of prednisone 50 mg orally 13, 7, and 1 hours before the procedure; diphenhydramine 50 mg orally or intramuscularly 1 hour before the procedure; and ephedrine 25 mg orally 1 hour before.⁴⁵ The ephedrine should be omitted if the patient has angina, arrhythmia, or hypertension. Guidelines have been published for treatment of acute reactions to contrast media and may include adrenergic agents such as epinephrine, fluid replacement, diphenhydramine, H₂-receptor antagonist, and systemic corticosteroids.⁴⁰

INSULIN

Insulin is capable of producing allergic reactions through a variety of immunologic mechanisms. A protein molecule, insulin is a complete antigen. Allergic reactions have been reported with beef, pork, and recombinant human insulin, although the frequency of reactions with human insulin appears low. Reactions to insulin may involve the insulin molecule itself or other substances that have been added to insulin (e.g., protamine). Most patients have anti-insulin IgG antibodies after a few months of therapy.

Insulin reactions may be limited to the site of injection, or they may produce systemic reactions. Local reactions present most often as a wheal and flare at the injection site and may occur immediately after injection or up to 8 to 12 hours later. Generally, these reactions are mild, do not require treatment, and resolve with continued insulin administration. If a patient does not tolerate the local reaction well, antihistamines may be given or a different insulin source (or product of higher purity) may be substituted. Rarely, systemic reactions to insulin (e.g., urticaria or anaphylaxis) occur. IgE-mediated reactions to insulin allergy appear to be declining with greater use of human insulins.⁴⁶ Skin testing with various products can aid in selecting the type of insulin least likely to cause a systemic reaction. Human insulin appears to be least allergenic but occasionally may cause reactions. In some patients, insulin desensitization may be indicated.

ASPIRIN AND NSAIDS

7 Aspirin and other NSAIDs can produce two general types of reactions, urticaria/angioedema or rhinosinusitis/asthma, in susceptible patients.⁴⁷ Approximately 20% of asthmatics are sensitive to aspirin and other NSAIDs.^{48,49}

The rhinosinusitis/asthma syndrome typically develops in middle-aged patients who are nonatopic and have no history of aspirin intolerance. Generally, it progresses from rhinitis to sinusitis with nasal polyps and steroid-dependent asthma. It is uncommon in children and young adults. However, children with asthma may be aspirin-sensitive. Aspirin-sensitive asthma appears to be an inherited disorder characterized by overexpression of LTC₄ synthase in airways.⁵⁰ In aspirin-sensitive asthmatics, administration of aspirin and NSAIDs may provoke severe and sometimes fatal asthmatic attacks. Ketorolac can cause severe, life-threatening bronchospasm in aspirin-sensitive asthmatics.⁵¹ The mechanism of aspirin sensitivity is not completely understood. One suspected mechanism of aspirin and NSAID sensitivity is cyclooxygenase-1 blockade, which may

facilitate production of alternative arachidonic acid metabolites (e.g., LTs). This is supported by the observation that there is a correlation between the degree of cyclooxygenase-1 blockade and the risk of a reaction; thus agents such as acetaminophen, which minimally block cyclooxygenase-1, rarely cause reactions. Additional support is found in the clinical observation that leukotriene-modifying drugs can reduce the severity of aspirin-induced reactions.⁴⁹ It is possible that aspirin and NSAIDs may stimulate mast cells directly to release inflammatory mediators. Also, subjects with aspirin-induced asthma have a marked increase in airway responsiveness to LTs.⁵² There does not appear to be cross-reactivity with the cyclooxygenase-2-selective inhibitors celecoxib and rofecoxib.^{53–55}

In patients with asthma or those suspected of being sensitive to aspirin, an oral challenge can be performed. This should be performed with great caution in a hospital setting with resuscitation equipment at hand. For patients known to be aspirin-sensitive, the major preventive measure is avoidance. Other agents reported to be cross-reactive with aspirin include tartrazine dye, indomethacin, and phenylbutazone.

NSAIDs also have been associated with pulmonary infiltrates and eosinophilia (PIE) syndrome. This syndrome is associated with fever, cough, dyspnea, infiltrates on chest roentgenogram, and a peripheral eosinophilia that develop 2 to 6 weeks after initiating treatment. PIE syndrome occurs more frequently for naproxen compared with other NSAIDs and is noted to resolve rapidly after discontinuation of the offending agent.⁵⁶

SULFONAMIDES

Sulfonamide drugs, including antimicrobials, diuretics, oral hypoglycemics, and carbonic anhydrase inhibitors, are a common cause of allergic reactions. Allergic reactions were recognized in 4.8% of 20,226 patients who received a sulfonamide antibiotic and in 2.0% of patients who received a nonantibiotic sulfonamide.⁵⁷ Although immediate IgE-mediated reactions such as anaphylaxis can occur, sulfonamides typically cause delayed cutaneous reactions, often beginning with fever and then followed by a rash (e.g., morbilliform eruptions, erythema multiforme, or less frequently, Stevens-Johnson syndrome/toxic epidermal necrolysis).² Other reactions to sulfonamides may include mucocutaneous, gastrointestinal, hepatic, renal, or hematologic complications, which may be fatal. Immune-mediated sulfonamide reactions involve the production of reactive metabolites (hydroxylamines).⁵⁸ Patients with the slow acetylator phenotype may be at increased risk of these reactions.³

While allergic reactions to sulfonamides can occur with a wide variety of chemical entities, there appears to be a low level of cross-reactivity between sulfonamide antibiotics and nonantibiotics (about 10%). The occurrence of allergic reactions after receipt of nonantibiotic sulfonamides may reflect a predisposition to allergic reactions rather than cross-reactivity with sulfonamide antibiotics.⁵⁷

8 Trimethoprim-sulfamethoxazole is used frequently for preventive or active treatment of *Pneumocystis carinii* pneumonia in patients with the AIDS. Adverse reactions to trimethoprim-sulfamethoxazole have been observed to occur much more frequently in these patients compared with those without AIDS. Adverse effects to trimethoprim-sulfamethoxazole occur in 50% to 80% of AIDS patients compared with 10% of other immunocompromised patients.⁵⁹ Trimethoprim-sulfamethoxazole was associated with an adverse-event rate of 26.3 per 100 person-years and hypersensitivity events at 22 per 100 person-years. Adverse-event rate was related to lower CD4⁺ cell count. When the CD4⁺ cell count was less than 100/mm³, the adverse drug event rate was 31 per 100 person-years.⁶⁰

PHARMACEUTICAL EXCIPIENTS AND ADDITIVES

Pharmaceutical products contain a number of “inert” additives (e.g., dyes, fillers, buffers, and stabilizers) in addition to the therapeutic ingredients. These additives are not always inert and may cause adverse effects, including allergic reactions.

The azo dye tartrazine (FD&C Yellow No. 5) is associated with anaphylactoid reactions, acute bronchospasm, urticaria, rhinitis, and contact dermatitis.^{61,62} Although the immunologic mechanisms are unclear, approximately 10% of aspirin-sensitive asthmatics are also intolerant to tartrazine,^{63,64} suggesting a role for tartrazine as a cyclooxygenase inhibitor. As little as 0.85 mcg or as much as 25 mg tartrazine has provoked positive responses.⁶³

Sulfites (including sulfur dioxide, sodium sulfite, sodium and potassium bisulfite, and sodium and potassium metabisulfite) are used commonly as antioxidants in pharmaceutical products and some foods. Over 250 cases of adverse reactions associated with ingestion of sulfites (usually in foods) have been reported to the Food and Drug Administration (FDA),⁶⁵ including wheezing, dyspnea, chest tightness, urticaria, angioedema, flushing, weakness, nausea, anaphylaxis, and death.

IgE-mediated and nonimmunologic sulfite hypersensitivity has been demonstrated in children with a history of chronic asthma. Adverse reactions to sulfite-preserved injectables, such as gentamicin, metoclopramide, lidocaine, and doxycycline, have been reported. In contrast to reactions caused by foods, these reactions do not occur more frequently in steroid-dependent asthmatics and do not always coincide with a positive oral sulfite challenge.^{65,66} Blunted bronchodilation may be observed in asthmatics following inhalation of sulfite-containing nebulizer solutions. Although many nebulizer solutions contain sulfites, metered-dose inhalers do not. Many aqueous epinephrine products also contain sulfites. The FDA labeling states that in emergency situations when sulfite-free preparations are not available, sulfite-containing epinephrine should not be withheld from a sulfite-intolerant individual because small subcutaneous doses of sulfites usually are well tolerated. However, an increased risk of anaphylaxis exists after subcutaneous injection in rare patients with a positive oral challenge to 5 to 10 mg sulfite.

Parabens (including methyl-, ethyl-, propyl-, and butylparaben) are used widely in pharmaceutical products as a biocidal agent. The majority of allergic reactions to parabens are observed after topical exposure.⁶⁷ Delayed hypersensitivity contact dermatitis occurs more often in individuals with preexisting dermatitis.⁶³ Immediate hypersensitivity after parenteral administration is rare. Although these

agents are chemically related to benzoic acid and *p*-aminobenzoic acid, the evidence for cross-sensitivity is lacking.⁶³

CANCER CHEMOTHERAPY AGENTS

Chemotherapy agents are implicated in hypersensitivity reactions in 5% to 15% of patients who receive them.⁶⁸ Up to 65% of patients receiving L-asparaginase experience immediate hypersensitivity reactions such as urticaria and anaphylaxis.⁶⁹

The combination regimen of paclitaxel (or docetaxel) and carboplatin frequently is responsible for producing hypersensitivity reactions. Each agent precipitates a distinct reaction, allowing for differentiation between causative factors. Hypersensitivity reactions have been observed with paclitaxel and docetaxel as frequently as 34% of patients.^{2,70,71} The reaction, typically occurring shortly after initiation of the first dose, is due to Cremophor EL, the polyoxyethylated castor oil vehicle for paclitaxel. Severe reactions are characterized by dyspnea, bronchospasm, urticaria, and hypotension. Minor reactions include flushing and rashes. In patients receiving a 3-hour infusion, the incidence of severe reactions is reduced to 1.3%, and the incidence of minor reactions is 42%.⁷² To reduce the risk of hypersensitivity reaction, patients are routinely premedicated with corticosteroids and H₁- and H₂-receptor antagonists. Carboplatin hypersensitivity develops after six or more courses of carboplatin or its parent compound, cisplatin.⁷³ Reactions typically develop shortly after completing the infusion or up to 3 days after therapy.⁷⁴ Symptoms of severe reaction include tachycardia, dyspnea, facial swelling, rigors, and hypotension. Mild reactions include itching, erythema, and facial flushing. Desensitization with carboplatin usually is not successful owing to previous prolonged exposure. Skin testing is useful because a negative test has a high predictive value for nonreactivity.⁷⁵

ANTICONVULSANTS

Many anticonvulsant drugs produce a variety of hypersensitivity reactions and pseudoallergic reactions. Drugs such as phenytoin, phenobarbital, carbamazepine, and lamotrigine can cause a “anticonvulsant hypersensitivity syndrome” characterized by fever, rash, lymphadenopathy, and internal organ involvement. Eosinophilia is frequently present. The onset is usually several weeks into therapy.^{2,76} In some cases, morbilliform rash develops in exfoliative dermatitis. Concomitant use of valproate significantly increases the risk of hypersensitivity owing to reduced lamotrigine metabolism, leading to a prolonged elimination half-life.⁷⁷

► TREATMENT: Allergic Reactions

9 The basic principles for management of allergic reactions to drugs or biologic agents include (1) discontinuation of the medication or agent when possible, (2) treatment of the adverse clinical signs and symptoms, and (3) substitution, if necessary, of another agent.¹

Identification of patients at high risk for allergic drug reactions requires a careful history and, where appropriate, performance of specific tests to evaluate sensitivity.⁷⁸ One of the most helpful tests to evaluate risk is the allergen skin test. For some drugs, skin testing can demonstrate the presence of drug-specific IgE and predict a relatively high risk of immediate hypersensitivity reactions. Note that skin testing does not predict the risk of delayed or most dermatologic reactions.

A higher proportion of patients report an “allergic reaction” to penicillin than actually experience a reaction. However, patients with a history of penicillin allergy are recognized to have a four- to sixfold greater risk of subsequent reactions.²⁵ In addition, a negative history of penicillin allergy does not eliminate the risk of immediate reactions because many serious and even fatal allergic reactions to β -lactam antibiotics occur in patients who have no history of penicillin allergy.²⁵

10 Skin testing can reduce the uncertainty of penicillin sensitivity and should be performed in all patients who have a history of penicillin allergy and require treatment with these agents. Penicillin skin testing in advance of need for penicillin treatment in patients with a history of penicillin allergy does not appear to induce sensitization.⁷⁹ Testing for the major penicillin determinant is accomplished with

TABLE 86–3. Procedure for Performing Penicillin Skin Testing

| A. Percutaneous (prick) skin testing | |
|--|---------|
| Materials | Volume |
| Pre-Pen 6 × 10 ⁶ M | 1 drop |
| Penicillin G 10,000 U/mL | 1 drop |
| β-Lactam drug 3 mg/mL | 1 drop |
| 0.03% albumin-saline control | 1 drop |
| Histamine control (1 mg/mL) | 1 drop |
| 1. Place a drop of each test material on the volar surface of the forearm. 2. Prick the skin with a sharp needle inserted through the drop at a 45° angle gently tenting the skin in an upward motion. 3. Interpret skin responses after 15 minutes. 4. A wheal at least 2 × 2 mm with erythema is considered positive. 5. If the prick test is nonreactive, proceed to the intradermal test. 6. If the histamine control is nonreactive, the test is considered uninterpretable. | |
| B. Intradermal skin testing | |
| Materials | Volume |
| Pre-Pen 6 × 10 ⁶ M | 0.02 mL |
| Penicillin G 10,000 U/mL | 0.02 mL |
| β-Lactam drug 3 mg/mL | 0.02 mL |
| 0.03% albumin-saline control | 0.02 mL |
| Histamine control (0.1 mg/mL) | 0.02 mL |
| 1. Inject 0.02–0.03 mL of each test material intradermally (amount sufficient to produce a small bleb). 2. Interpret skin responses after 15 minutes. 3. A wheal at least 6 × 6 mm with erythema and at least 3 mm greater than the negative control is considered positive. 4. If the histamine control is nonreactive, the test is considered uninterpretable. | |
| Antihistamines may blunt the response and cause false-negative reactions. | |

From Sullivan TJ. *Current Therapy in Allergy*. St Louis, Mosby, 1985:57–61.

penicilloyl-polylysine (PPL; Pre-Pen). If this agent is used alone, patients reacting only to minor determinants will be missed. At present, there is no commercially available product that can be used to test for most of the minor determinants. Benzylpenicillin (at a concentration of 10,000 units/mL) has been used; however, some reactive patients still will be missed. Penicillin skin testing can facilitate the safe use of penicillin in 90% of patients with a history of penicillin allergy.⁸⁰ Even in patients who report a history of penicillin allergy, if they are skin-test-negative, penicillin treatment does not appear to cause re-sensitization.⁸¹ The procedure for performing penicillin skin testing is presented in Table 86–3.

The National Institute of Allergy and Infectious Diseases reported a collaborative trial to test the predictive value of skin testing with major and minor penicillin derivatives.⁸² The frequency of IgE-mediated reactions to penicillin was 1.2% and 0% in patients with a positive and negative history of penicillin allergy, respectively, in subjects who were skin-test-negative. Of skin-test-positive patients who received penicillin, 22% experienced immediate or accelerated penicillin allergy. Of skin test-positive patients, 84% had dermal reactions to skin testing with the major determinant (benzylpenicilloyl-octalysine), whereas 16% reacted only to an experimental minor determinant mixture of benzylpenicillin, benzylpenicilloate, and benzylpenicilloyl-*N*-propylamine.

Immediate hypersensitivity reactions to penicillin are rare after a properly performed negative skin test when both major and minor determinants are used. Dermatologic reactions occur in 1% of skin-test-negative patients.²⁵ A negative penicillin skin test indicates

that the risk of life-threatening reactions is extremely low with administration of penicillin or other β-lactams. Occasionally, patients may experience systemic reactions after skin testing. Also, certain types of patients (e.g., those with dermatographism or taking antihistamines) may be unsuitable for skin testing because a false-positive or false-negative test may result. Penicillin is the only drug for which the predictive value of skin testing has been well established. The value of skin testing for evaluating the risk of adverse reactions to other drugs is largely unknown, but these tests are recommended in selected patients with histories of immediate reactions to nonpenicillin antibiotics.⁸¹

ANAPHYLAXIS

Anaphylaxis requires prompt treatment to minimize the risk of serious morbidity or death. On presentation, attention should be given first to stopping the likely offending agent, if possible, and restoring respiratory and cardiovascular function. A protocol for the treatment of anaphylaxis is presented in Table 86–4. Epinephrine is administered as primary treatment to counteract bronchoconstriction and vasodilatation. Epinephrine should be administered intramuscularly in the lateral aspect of the thigh.⁸³ If blood pressure is not restored by epinephrine, crystalloids should be administered intravenously to restore intravascular volume. Typically, 1 L of 0.9% sodium chloride or lactated Ringer's solution will be administered over 10 to 15 minutes. This may be repeated if the patient is still believed to be volume-depleted. Intravenous fluids should be given early in the course in an attempt to prevent shock. A maintenance intravenous fluid then will be initiated. An immediate priority is establishment and maintenance of an airway. This should be achieved by the use of endotracheal intubation if necessary. When a patient with anaphylaxis is hypotensive, vasopressors also will be needed in addition to crystalloids. Norepinephrine is the vasoconstrictor agent of choice for treatment of anaphylactic shock, although dopamine also may be useful.

A number of other agents may be required for the treatment of anaphylactic reactions. Corticosteroids (hydrocortisone sodium succinate intravenously) are recommended to reduce the risk of late-phase reactions. Aminophylline may be used as adjunctive therapy for bronchospasm. Histamine (H₁) receptor blockers (such as diphenhydramine) may be administered to reduce some of the symptoms associated with anaphylaxis; however, these agents are not effective as primary therapy.

DESENSITIZATION

For some patients allergic to penicillin, no reasonable alternatives exist, and penicillin therapy may be necessary for treatment of severe, life-threatening infection. In this situation, penicillin desensitization should be considered. Desensitization can reduce the risk of anaphylaxis but does not influence the likelihood of other types of reactions such as exfoliative dermatitis or Stevens-Johnson syndrome.

Penicillin desensitization should be performed in a hospital setting where resuscitation equipment is readily available by a physician experienced in the risks and management of severe allergic reactions. The potential risks and benefits should be discussed with the patient. Prior to initiating the protocol, the patient should be stabilized and fluid, pulmonary, and cardiovascular function optimized. The use of

TABLE 86-4. Treatment of Anaphylaxis

1. Place patient in recumbent position and elevate extremities.
2. Monitor vital signs often (or continuously if possible).
3. Apply tourniquet proximal to site of antigen injection; remove every 10–15 min.
4. Administer epinephrine 1:1000 into nonoccluded site: 0.3–0.5 mL subcutaneously or intramuscularly in adults and 0.01 mL/kg subcutaneously or intramuscularly in children.
5. Administer aqueous epinephrine 1:1000 into site of antigen injection; 0.15–0.25 mL subcutaneously in adults and 0.005 mL/kg subcutaneously in children.
6. Establish and maintain airway with oropharyngeal airway device, endotracheal intubation, transtracheal catheterization, or cricothyrotomy.
7. Administer oxygen at 6–10 L/min.
8. Institute rapid fluid replacement with 0.9% sodium chloride, lactated Ringer's, or colloid solution (e.g., 5% albumin or 4% hetastarch).
9. For hypotension in adults, administer norepinephrine, 32 mcg/min (use 8 mg in 500 mL dextrose 5%) with the rate adjusted to maintain low-normal blood pressure. Alternatively, administer dopamine at 2–10 mcg/kg/min intravenously.
10. If refractory hypotension is present, administer cimetidine 300 mg or ranitidine 50 mg, intravenously over 3–5 min.
11. If bronchospasm is present, administer aminophylline 6 mg/kg intravenously over 20 min.
12. Administer hydrocortisone sodium succinate 100 mg intravenously (push) and 100 mg intravenously in saline every 2–4 h to block the late-phase reaction.
13. Administer diphenhydramine 1–2 mg/kg intravenously (up to 50 mg) over 3 min to block histamine-1 receptors.
14. For adults taking a β -adrenergic blocker, administer atropine (0.5 mg intravenously) every 5 min until heart rate is greater than 60 beats/min, or isoproterenol 2–20 mcg/min intravenously titrated to heart rate of 60 beats/min, or glucagon 0.5 mg/kg intravenously (push) followed by 0.07 mg/kg/h continuously intravenously.

From Weiss ME, Adkinson NF, *Clin Allergy* 1988;18:515–540.

premedicants (antihistamines or corticosteroids) is controversial because these agents may mask the early signs of acute reactions and do not reliably reduce the severity of acute reactions. About one-third of patients who have undergone desensitization experience mild, transient allergic reaction either during the desensitization procedure or during penicillin therapy.²⁵ Patients who can take oral medication should undergo desensitization with oral penicillin. Protocols for oral and intravenous penicillin desensitization are presented in Tables 86–5 and 86–6. It is important that once the desensitization protocol is begun it not be interrupted except for severe reactions. Antihistamines

or epinephrine may be administered to treat reactions. In addition, if the patient completes the desensitization regimen and then undergoes penicillin treatment, a lapse between doses of as little as 24 hours can allow for reemergence of sensitivity.

Desensitization of trimethoprim-sulfamethoxazole can be achieved within 2 days in most AIDS patients.^{2,84} This can be accompanied by use of the following schedule of doses (milligrams of sulfamethoxazole-trimethoprim): day 1: 9 A.M., 4 and 0.8 mg; 11 A.M., 8 and 1.6 mg; 1 P.M., 20 and 4 mg; 5 P.M., 40 and 8 mg; day 2: 9 A.M., 80 and 16 mg; 3 P.M., 160 and 32 mg; 9 P.M., 200 and 40 mg; day 3: 9 A.M.,

From Ref. 78.

400 and 80 mg, and 400 and 80 mg daily thereafter. Other investigators have described a 6-hour graded challenge in HIV-infected patients.⁸⁵

Skin tests often become negative during and shortly after desensitization. The mechanism by which desensitization is protective is

unclear. It does not seem to be that penicillin-specific IgE is neutralized or that IgG as “blocking antibody” is produced. One possible explanation is that basophils and mast cells attain some degree of tolerance on exposure to the antigen.

ABBREVIATIONS

IgE: immunoglobulin E

LT: leukotriene

PAF: platelet activating factor

PG: prostaglandin

PIE: pulmonary infiltrates and eosinophilia

SLE: systemic lupus erythematosus

SOLID-ORGAN TRANSPLANTATION

Heather J. Johnson and Kristine S. Schonder

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 T cells are the primary component of the immune system responsible for acute allograft rejection. The activity of T cells in acute rejection is mediated, to a large degree, by interleukin 2 (IL-2).
- 2 Immunosuppressive protocols use a multidrug approach to target various levels of the immune cascade to prevent allograft rejection.
- 3 The goals of immunosuppression are to decrease the incidence of acute and chronic rejection while minimizing adverse events associated with immunosuppressive medications.
- 4 Calcineurin inhibitors (CIs), such as cyclosporine and tacrolimus, block T-cell activity by inhibiting the production of IL-2. They are associated with significant adverse effects, namely, nephrotoxicity and neurotoxicity.
- 5 CI-induced nephrotoxicity often manifests clinically in the same manner as acute or chronic rejection. A biopsy is the definitive diagnostic tool.
- 6 Glucocorticoids inhibit the initial steps in allograft rejection. They also aid in reversing the clinical symptoms associated with rejection.
- 7 Antiproliferative agents such as azathioprine and mycophenolate mofetil inhibit T-cell proliferation by altering purine synthesis to prevent acute rejection. Bone marrow suppression is the most significant adverse effect associated with these agents.
- 8 Sirolimus exerts its activity by inhibiting T-cell response to IL-2. The adverse effects associated with sirolimus include thrombocytopenia, anemia, and hyperlipidemia.
- 9 Antibody preparations target specific receptors on the surface of T cells. The effect on T cells and adverse effects depend on the receptor targets.
- 10 Long-term allograft and patient survival is limited by chronic rejection, cardiovascular disease, and long-term immunosuppressive complications, such as malignancy.

Solid-organ transplantation provides a lifesaving treatment for patients with end-stage cardiac, kidney, liver, lung, and intestinal disease. In 2003, 25,463 transplants were performed. Of these, the most common were kidney (8667 cadaveric donors, 6468 living donors), liver (5348 cadaveric donors, 322 living donors), and heart (2056).¹ Despite the demand for transplantation, the number of cadaveric donors has remained relatively stable during the past decade. In 2004, almost 87,000 persons in the United States were waiting for transplantation (kidney > 60,000; liver > 17,000; heart > 3200). Median waiting time for a cadaveric kidney is over 3 years. For liver transplantation the median time to transplant is over 2 years, whereas for heart transplantation it is approximately 6 months. For both heart and liver transplantation, clinical status is an important factor affecting waiting times, with the sickest patients receiving priority for available organs.

In order to increase the number of organs available for transplantation, several strategies have been employed. The use of living donors for renal transplantation represents almost half of all kidney transplants. Between 1998 and 2001, the number of living liver transplants increased over 700%. Efforts to expand the cadaveric donor pool include relaxation of age restrictions, development of better preservation solutions, use of “marginal” and non-heart beating donors, and the use of split livers. Procurement of donor hearts with longer ischemic times, those with borderline left ventricular function, and even those with mild coronary artery disease amenable to bypass grafting

have all been considered in an effort to increase the supply.² The use of heart donors older than 45 years of age is associated with a higher risk for 1-year mortality, but this must be viewed in the context of the higher risk of death with longer time on the waiting list if only younger donors are used.¹

Despite all these efforts, patients continue to die awaiting transplant. In 2001, over 6000 people died on transplant waiting lists. While renal dialysis may be used for an extended period of time to partially replace the function of the kidneys, such options are not readily available for all liver and heart transplant candidates. Hepatocyte transplantation and artificial liver support are areas of research as alternatives or bridges to liver transplantation.³ Left-ventricular assist devices (LVADs) are now used commonly as a bridge to transplantation for many heart transplant candidates.

Patient and graft survival rates following transplantation have improved significantly over the past 30 years as a result of advances in pharmacotherapy, surgical techniques, organ preservation, and the postoperative management of patients. (Table 87–1). In this chapter the epidemiology of endstage kidney, liver and heart disease is presented, the pathophysiology of organ rejection is reviewed, the pharmacotherapeutic options for the generation of individualized immunosuppressive regimens are critiqued and the unique complications of these regimens along with the therapeutic challenges they present are discussed.

TABLE 87–1. Organ-Specific Waiting Times for Transplant and Patient and Graft Survival Rates

| Organ | Median Waiting Time (days) | Patient Survival (%) | | Graft Survival (%) | |
|-----------------|----------------------------|----------------------|---------|--------------------|---------|
| | | 1 Year | 5 Years | 1 Year | 5 Years |
| Kidney | 1,144 ^a | | | | |
| Living donor | | 97.5 | 90.1 | 94.3 | 78.6 |
| Cadaveric donor | | 94.2 | 80.7 | 88.7 | 65.7 |
| Liver | 412 | | | | |
| Living donor | | 86.9 | 84.2 | 79.3 | 78.1 |
| Cadaveric donor | | 86.3 | 72.1 | 80.6 | 64.1 |
| Heart | 141 | 85.6 | 72 | 85.3 | 70.6 |

^aBased on data from 1999; inadequate follow-up for 2002 data. From ref. 1.

EPIDEMIOLOGY AND ETIOLOGY

KIDNEY

The number of people diagnosed with end-stage kidney disease (ESKD) in 2002 exceeded 400,000. There were over 100,000 new cases of ESKD in 2002. The primary therapeutic options for these individuals are hemodialysis, peritoneal dialysis, and/or renal transplantation. Renal transplantation is the preferred long-term therapeutic option for most patients with ESKD because it provides patients with the greatest potential improvement in overall quality of life. Dialysis catheter–related infections, update peritoneal dialysis–associated peritonitis, and scheduled dialysis treatments are avoided, and dietary restrictions are fewer. While the analysis of quality of life is complex, patients generally report improved quality of life following transplantation as compared with patients on maintenance dialysis.⁴

The most commonly reported causes of ESKD, diabetes mellitus, hypertension, and glomerulonephritis account for about 80% of all kidney transplants (see Chap. 44).⁵ Patients with medical conditions such as unstable cardiac disease or recently diagnosed malignancy, for whom the risk of surgery or chronic immunosuppression would be greater than the risks associated with chronic dialysis, are excluded from consideration for transplantation.

LIVER

Noncholestatic cirrhosis (hepatitis C, alcoholic cirrhosis, hepatitis B, cryptogenic cirrhosis, and autoimmune hepatitis) accounts for approximately 60% of liver transplant recipients (see Chap. 37).¹ Other indications for liver transplantation include primary biliary cirrhosis, primary sclerosing cholangitis, acute hepatic failure, primary liver cancer, and inborn errors of metabolism such as α_1 -antitrypsin deficiency, Wilson's disease, tyrosinemia, types I, III, and IV glycogen storage disease, type I hyperoxaluria, and hemophilia A and B. Pediatric liver transplantation has been performed primarily for biliary atresia and inborn errors of metabolism. Timing of the transplant is critical for correction of the metabolic disease in order to prevent irreversible damage to the end organ (e.g., central nervous system in ornithine transcarbamylase deficiency) or to prevent hepatocellular carcinoma (e.g., tyrosinemia). In an effort to better allocate the available livers, a system based on the MELD (Model for End-stage Liver Disease) score has been adapted by the United Network for Organ Sharing (UNOS). This score, based on serum creatinine concentration, total serum bilirubin concentration, international normalization ratio (INR), and etiology of cirrhosis, is useful in predicting mortality.

There are few absolute contraindications to liver transplantation. Patients should have a reasonable life expectancy after transplantation. While hepatitis B and C can recur in the transplanted liver, these are not absolute contraindications to liver transplantation.^{3,6} However, retransplant for hepatitis B or C is highly controversial.

HEART

Heart failure affects an estimated 4.9 million Americans, and approximately 400,000 new case are diagnosed each year (see Chap. 14).⁷ Cardiac transplant candidates typically are patients with end-stage heart failure who have New York Heart Association (NYHA) class III or IV symptoms despite maximal medical management and have an expected 1-year mortality risk of 25% or greater without a transplant.⁸ Idiopathic cardiomyopathy and ischemic heart disease account for heart failure in almost 90% heart transplant recipients.¹ Other less common etiologies include valvular disease (4%), retransplantation for graft atherosclerosis or dysfunction (2%), and congenital heart disease (1.5%).

Absolute contraindications to orthotopic cardiac transplantation include the presence of an active infection (except in the case of an infected ventricular assist device, which is an indication for urgent transplantation) or the presence of other diseases (i.e., malignancy) that may limit survival and/or rehabilitation and severe, irreversible pulmonary hypertension.

SURGICAL PROCEDURES

Kidney transplantation is generally performed by placing the allograft retroperitoneally in the right iliac fossa. The renal artery and vein are anastomosed to the external iliac artery and vein, respectively, and the donor ureter is connected directly to the bladder. If the donor kidney has not undergone prolonged ischemia, the production of urine immediately follows revascularization. For the most part, native kidneys are not removed.⁹

The transplanted liver, in contrast to kidney, is placed orthotopically; the recipient's own liver must be removed. Liver transplant occurs in several phases: removal of recipient liver, donor graft revascularization, and biliary reconstruction. During the anhepatic phase, the patient is placed on venovenous bypass to preserve venous return from the kidney and lower extremities. Size may be a limiting factor in liver transplantation. Donor and recipient are usually matched for size ($\pm 20\%$) to prevent splinting of the diaphragm and pulmonary complications that would result from transplantation of an excessively large liver.¹⁰

Heart transplantation is usually an orthotopic procedure. Leaving most of the atria and septum of the recipient, the patient is placed on cardiopulmonary bypass. The donor heart is implanted by anastomosis of the left atrium to the residual left atrial wall and joining the right atrial wall and septum. The main pulmonary artery is connected to the ascending aorta.¹¹

PHYSIOLOGIC CONSEQUENCES OF TRANSPLANTATION

Transplantation is truly lifesaving for heart and liver transplant recipients, whereas renal transplantation is associated with improved quality of life and survival when compared with dialysis.¹² Most heart transplant patients return to NYHA functional class I following transplantation. In fact, 89.9% of patients consider themselves to have no limitations on activity at 1-year follow-up; however, not all have returned to work.¹³ The specific physiologic consequences of kidney, liver, and heart transplantation are discussed below.

KIDNEY TRANSPLANTATION

The glomerular filtration rate (GFR) of a successfully transplanted kidney may be near normal almost immediately after transplantation. In some patients, however, the concentration of standard biochemical indicators of renal function, such as serum creatinine and blood urea nitrogen (BUN), may remain elevated for several days. Standard formulas used to predict drug dosing rely on a stable serum creatinine and may be inaccurate immediately following transplantation (see Chap. 41).

Although the allograft is able to remove uremic toxins from the body, it may take several weeks for other physiologic complications of chronic renal failure, such as anemia, calcium and phosphate imbalance, and altered lipid profiles, to resolve. The renal production of erythropoietin and 1-hydroxylation of vitamin D may return toward normal early in the postoperative period. Because the onset of physiologic effects may be delayed, continuation of pretransplant calcitriol, calcium supplementation, and/or phosphate binders may be warranted in some patients.

Primary nonfunction of a renal allograft or delayed graft function (DGF) is characterized by the need for dialysis in the first 7 postoperative days or the failure of the serum creatinine to fall below 4 mg/dL or by 30% of the pretransplant value. The incidence of DGF in primary cadaveric renal transplantation ranges from 8% to 50% and results in a slower return of the kidney's excretory, metabolic, and synthetic functions. DGF is associated with prolonged hospital stays, higher costs, difficult management of immunosuppressive therapy, slower patient rehabilitation, and poor graft survival. Urinary complications such as ureteral obstruction, thrombosis, or leak or vascular complications, including arterial or venous stenosis or thrombosis, also may result in early graft dysfunction.

The primary cause of DGF is acute tubular necrosis (ATN). The incidence of ATN increases when kidneys are harvested from donors following cardiac arrest, from donors who are hypotensive or on vasopressors, or from older donors. Prolonged periods of ischemia can increase the risk of ATN. The management of patients with ATN may be difficult (see Chap. 42). Cyclosporine and tacrolimus may be implicated in the prolongation of ATN, but a clear cause-and-effect relationship has not been established.

Persistently elevated serum creatinine and BUN levels confirm the perioperative management of renal transplant recipients.

Among the differential diagnoses are acute rejection, ATN, and/or cyclosporine or tacrolimus toxicity (see Chap. 46). These processes are not mutually exclusive. Definitive diagnosis is made by renal biopsy. In the presence of an elevated serum creatinine level, clinicians may reduce the dose of cyclosporine or tacrolimus to minimize the potential for drug nephrotoxicity and hasten the recovery from ATN. This practice may result in subtherapeutic immunosuppressant concentrations and hasten the occurrence of acute rejection. DGF predisposes patients to acute rejection. Induction therapy (e.g., using antibody preparations) and delaying the initiation of cyclosporine or tacrolimus administration may be useful in this setting.

LIVER TRANSPLANTATION

The physiologic consequences of liver transplantation are complex, involving changes in both metabolic and synthetic function. Postoperatively, the liver transplant recipient likely will have many fluid, electrolyte, and nutritional abnormalities. Biliary tract dysfunction may alter the absorption of fats and fat-soluble drugs.¹⁴ The poor absorption of the lipid-soluble drug cyclosporine improves after successful liver transplantation and reestablishment of bile flow. Vitamin E deficiency and its neurologic complications in liver failure patients are reversed after successful liver transplantation in pediatric patients. In stable adult liver transplant patients, the concentrations of retinol and tocopherol are similar to those seen in normal healthy subjects, indicating recovery of transplanted liver production and excretion of bile salts needed for fat-soluble vitamin absorption. The effects of liver metabolism on drug disposition and elimination are summarized in Table 87-2.

Failure of the newly transplanted liver occurs in 10% to 15% of cases and can result from several different mechanisms. Early graft failure can result from preexisting disease in the donor, and even coagulation defects have been acquired through donor organs. The technical complexity of the operation can produce flaws in revascularization that also lead to graft nonfunction. Surgical complications occur in about 25% of cases and result in a doubling of the hospital expense for the patient.¹⁵ Portal vein thrombosis, hepatic artery thrombosis, and bile duct leaks are all technical problems that have been encountered. Ischemic injury to the donor liver through preservation is difficult to predict and can produce early graft dysfunction. Perioperative immune events rarely lead to the classic picture of hyperacute rejection in liver transplantation, but graft failure in the first 2 postoperative weeks still may indicate antibody-mediated graft destruction.

HEART TRANSPLANTATION

The orthotopically transplanted heart is denervated and no longer responds to physiologic stimuli in a normal manner. Patients, for example, do not experience classic angina. In situations requiring an increased heart rate (e.g., exercise or hypotension), the denervated heart is unable to acutely increase heart rate but instead relies on increasing the stroke volume. Later in the course of exercise or hypotension, heart rate increases in response to circulating catecholamines. While the maximum exercise capacity of heart transplant recipients is below normal, most patients are able to resume normal lifestyles and reasonably vigorous activity levels. Partial reinnervation may occur over time, thereby facilitating more normal physiologic (e.g., presence of classic angina) and pharmacologic responses and better exercise capacity.¹⁶

In the acute postoperative phase (0–6 weeks), responses present in the normal heart are interrupted or blunted. In the acutely

TABLE 87–2. Changes in Drug Disposition and Elimination Following Liver Transplantation

| | Result | Comment |
|-------------------------------|---|---|
| Serum Proteins | | |
| ↓ Albumin | ↑ Free fraction of drugs usually bound to albumin | Diazepam, salicylic acid binding greater in liver transplant than chronic liver disease due to endogenous binding inhibitors (up to 45 days posttransplant) |
| ↑ Alpha-acid glycoprotein | Lower free fraction of drugs-lidocaine | |
| Metabolism/Elimination | | |
| Microsomes | | |
| | ↑ CYP2E1 activity | Increased drug metabolism (induction) |
| | ↔ CYP2D6 | Unaffected |
| | ↓ P450 enzymes activity | Decreased drug elimination (inhibition) |
| Oxidation | Stable | |
| Conjugation | Normalizes after transplant | Renal elimination of metabolites limited |
| Biliary dysfunction | ↓ Absorption of lipophilic compounds | |
| | ↑ CSA metabolites in blood | |
| Renal elimination | Elimination of gentamicin, vancomycin, cephalosporins less than predicted by serum creatinine | |

CYP = cytochrome P450 liver enzyme system.

From ref. 14.

denervated heart, changes in cardiac output (heart rate × stroke volume) largely depend on heart rate changes engendered by circulating catecholamines. The donor sinus node function may be impaired by preservation injury, direct surgical trauma at excision, the presence of long-acting antiarrhythmics (e.g., amiodarone) taken prior to transplant by the recipient, and a lack of “conditioning” responsiveness to catecholamines.¹⁶ Therefore, the transplanted heart generally requires chronotropic support with either milrinone or pacing in the early posttransplant period to maintain a heart rate of 90 to 110 beats per minute and satisfactory hemodynamics (i.e., blood pressure, urine output, and tissue perfusion). Approximately 10% to 20% of transplant patients will have persistent chronotropic incompetence requiring either cardiac pacing or pharmacologic manipulation of the heart with theophylline or terbutaline after hospital discharge; however, few patients who receive a pacemaker use it permanently. Anatomic variables may further compromise optimal hemodynamic function and complicate hemodynamic assessment of the patient.

Right ventricular function frequently is impaired, presumably as a result of preservation injury and elevated pulmonary vascular resistance. A “restrictive” hemodynamic pattern may be present initially, but it usually improves over the 6 weeks following transplantation. Donor-recipient size mismatch may contribute to early posttransplantation hemodynamic abnormalities characterized by higher right and left ventricular end-diastolic pressures. Supraventricular arrhythmias in the early posttransplant period usually are transient and may result from overvigorous use of catecholamines or milrinone; later, they should raise suspicion for acute rejection.

Myocardial depression frequently occurs and generally requires inotropic support with agents such as dobutamine, milrinone, and epinephrine. On occasion, intra- or postoperative administration of vasodilators, including nitric oxide, and inotropic agents may be necessary to treat right-sided failure in the transplant patient; milrinone and isoproterenol are the preferred inodilators in this setting.

Persistent abnormalities of diastolic function are noted in the transplanted heart such that intracardiac pressures increase in an exaggerated fashion with response to exercise and/or volume infusion.¹⁶ These abnormalities of diastolic function are due, at least in part, to

denervation but also to acute rejection or to the scarring secondary to previously treated rejection episodes, hypertension, or cardiac allograft vasculopathy.

Hypertension often occurs following surgery secondary to the elevated catecholamine levels and systemic vascular resistance associated with end-stage heart failure on a healthy heart. Systolic blood pressure is maintained at 110 to 120 mm Hg to enhance cardiac function. Initial treatment may include nitroprusside or nitroglycerin; hydralazine and amlodipine are used later.

The pharmacologic implications of the physiologic consequences of the transplanted heart are summarized in Table 87–3.²

PATHOPHYSIOLOGY OF REJECTION

GENERAL CONCEPTS

Allograft rejection depends on activation of alloreactive T cells and antigen-presenting cells (APCs) such as B-lymphocytes, macrophages, and dendritic cells. Acute allograft rejection is caused primarily by the infiltration of T cells into the allograft, which triggers inflammatory and cytotoxic effects on the graft. Complex interactions between the allograft and cellular cytokines, cell-to-cell interactions, CD4+ and CD8+ T cells, and B cells ultimately lead to chronic rejection and graft loss if adequate immunosuppression is not maintained.¹⁷

The sequence of events that underlies graft rejection is recognition of the donor’s histocompatibility differences by the recipient’s immune system, recruitment of activated lymphocytes, initiation of immune effector mechanisms, and finally graft destruction.

Class I and II antigens of the major histocompatibility complex (MHC) are important for histocompatibility in transplantation.¹⁷ Class I antigens are present on virtually all nucleated cells in the body, whereas the class II antigens are located primarily on B-lymphocytes, APCs, and vascular endothelium.¹⁷ T helper (TH) cells, specialized to direct the immune system, can only recognize foreign antigen in the presence of MHC type II. Cytotoxic T cells, specialized to destroy, can only recognize antigen in the presence of MHC type I antigens.

TABLE 87-3. Effect of Denervation on Cardiac Pharmacology

| Drug | Effect | Mechanism | Comment |
|------------------------------|---|--|--|
| Digitalis | Normal inotropic effect Minimal effect on AV node | Direct myocardial effect Denervation | |
| Atropine | No effect on AV node | Denervation | |
| Adrenaline/ noradrenaline | Increased contractility Increased chronotropy | Denervation Hypersensitivity | Increased cardiac output mediated by increased heart rate |
| Isoproterenol | Normal increase in contractility; normal increase in chronotropy | No neuronal uptake | |
| Quinidine | No vagolytic effect | Denervation | |
| Verapamil | AV block | Direct effect | |
| Nifedipine | No reflex tachycardia | Denervation | |
| Hydralazine | No reflex tachycardia | Denervation | |
| β -Blocker | Increased antagonist effect | Denervation | Impair HR response, use sparingly Life-threatening asystole (>0.5 min) may occur if used to treat supraventricular arrhythmia or stress testing |
| Adenosine | Negative chronotropic effect | Hypersensitivity Effect on sinus node of denervated heart | |
| Acetylcholine | Negative chronotropic effect | Hypersensitivity Effect on sinus node of denervated heart | |

AV = atriovenous node.
From ref. 2.

Lymphocytes are the only cells in the body that can recognize specific antigens and are central to allograft rejection.

T-cell activation is caused by interactions between T-cell receptors, the MHC, cellular adhesion molecules, and costimulatory molecules. Among the series of events is calcineurin activation, which ultimately promotes interleukin 2 (IL-2) proliferation. After initial T-cell activation, the process of clonal expansion and immunologic progression is mediated by cytokines. IL-2 is released from T cells and activates T-lymphocytes locally and in other regions of the

body. Undifferentiated T-helper cells can be induced to develop along two lines: TH₁ cells secrete IL-2, interferon- γ , and IL-12 and favor cytotoxicity, while TH₂ cells secrete IL-4, -5, -10, and 13, which stimulate B-cell and immunoglobulin development. A predominance of TH₂ cells has been associated with tolerance (the ability of the body to recognize the transplanted allograft as “self”) in some experimental models. The complex nature of these cytokine interactions makes it very difficult to design drugs with exclusive actions (see Fig. 87-1). Allograft inflammation results from these processes

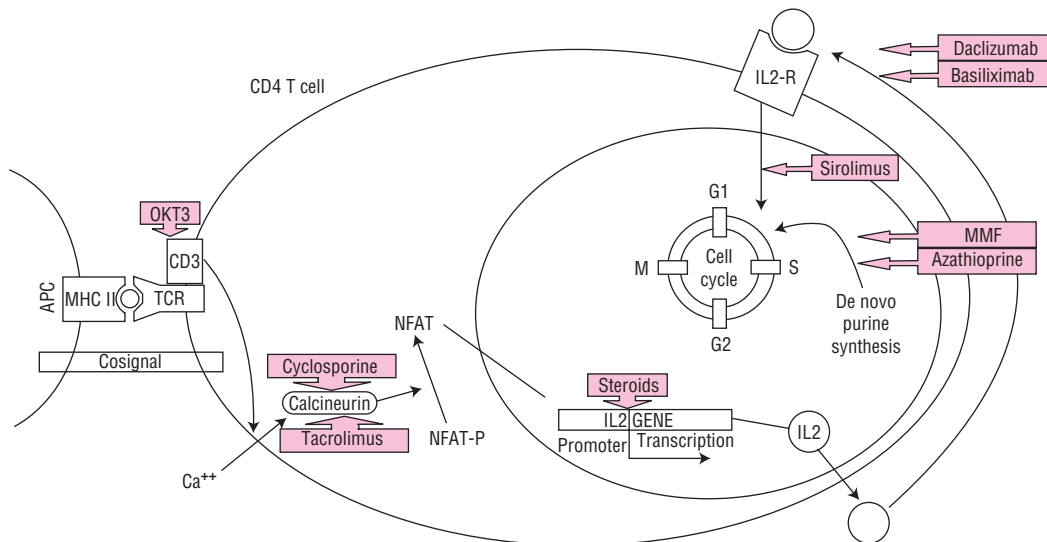

FIGURE 87-1. Stages of CD4 T-cell activation and cytokine production with identification of the sites of action of different immunosuppressive agents. Antigen-major histocompatibility complex (MHC) II molecule complexes are responsible for initiating the activation of CD4 T cells. These MHC-peptide complexes are recognized by the T-cell recognition complex (TCR). A costimulatory signal initiates signal transduction with activation of second messengers, one of which is calcineurin. Calcineurin removes phosphates from the nuclear factors (NFAT-P) allowing them to enter the nucleus. These nuclear factors specifically bind to an interleukin-2 (IL-2) promoter gene facilitating IL-2 gene transcription. Interaction of IL-2 with the IL-2 receptor (IL-2R) on the cell membrane surface induces cell proliferation and production of cytokines specific to the T cell. APC = antigen-producing cells; MMF = mycophenolate mofetil. (With permission from ref. 17.)

acting through specific (T-cell interactions with APCs) and nonspecific immunologic mechanisms (natural killer cell chemotaxis, release of vasoactive substances). Rejection of the transplanted tissue can take place at any time following surgery and is classified clinically as hyperacute rejection, acute cellular rejection, humoral rejection or chronic rejection.

Efforts are made to allocate well-matched (HLA-A, -B, -DR) kidneys to improve overall rejection and survival rates. However, the benefit of having no recipient donor mismatches may be negated by excessive cold ischemia time (>36 hours) and donor age older than 60 years. Because of greater organ availability and more restricted cold ischemia times for livers and hearts, HLA tissue matching is not performed routinely before transplantation. However, if the potential recipient is reactive against a panel of random donor antigens (i.e., patient has a positive panel reactive antibody [PRA] > 10% to 20%), then a negative T-cell crossmatch is required prior to transplantation. Transplanted organs must be matched for ABO blood group compatibility with the recipient. ABO mismatching will result in hyperacute rejection. Liver transplantation may be carried out in emergency situations across ABO blood groups, but survival is lower than for ABO compatible liver transplants.

HYPERACUTE REJECTION

Hyperacute rejection may occur when preformed donor-specific antibodies are present in the recipient at the time of the transplant and may be evident within minutes of the transplant procedure. Hyperacute rejection can be induced by immunoglobulin G (IgG) antibodies that bind to antigens on the vascular endothelium, such as class I MHC, ABO, and vascular endothelial cell antigens. Tissue damage can be mediated through antibody-dependent, cell-mediated cytotoxicity or through activation of the complement cascade. The ischemic damage to the microvasculature rapidly produces tissue necrosis.

Hyperacute rejection has become uncommon in kidney and heart transplants because transplant donors are matched for ABO blood groups and crossmatch testing is done to determine the presence of donor-specific lymphocytotoxic antibodies. A positive crossmatch presents a serious risk for graft failure even if hyperacute rejection does not occur. A negative lymphocytotoxicity crossmatch does not entirely rule out the possibility of hyperacute rejection because non-MHC antigens on the vascular endothelium can serve as targets of donor-specific antibodies.

Hyperacute rejection rarely occurs in patients receiving a liver transplant. The liver's special status for transplantation is not fully understood, but the local release of cytokines may alter the immunologic reaction taking place in the liver. Early graft dysfunction is treated with supportive care and retransplantation if possible.

ACUTE CELLULAR REJECTION

Acute rejection is most common in the first few months following transplantation but can occur at any time during the life of the allograft. Acute rejection generally is reversible, especially if treated. While most cases of acute rejection can be treated effectively, none of the currently available therapies prevents or changes the course of chronic rejection.

Cellular rejection is mediated by alloreactive T-lymphocytes that appear in the circulation and infiltrate the allograft through the vascular endothelium. After the graft is infiltrated by lymphocytes, the cytotoxic cells can specifically kill allograft targets, whereas the local release of lymphokines will attract and stimulate macrophages to

produce tissue damage through a delayed hypersensitivity-like mechanism. These immunologic and inflammatory events lead to the nonspecific signs and symptoms of acute rejection: pain and tenderness, fever, and lethargy.

KIDNEY

Acute rejection which may affect 20% of patients during the first 6 months following transplantation is evidenced by an abrupt rise in serum creatinine concentration of $\geq 30\%$. A specific histologic diagnosis can be obtained via biopsy of the allograft and often is used to guide therapy for rejection. A biopsy specimen with a diffuse infiltrate of lymphocytes is consistent with acute cellular rejection. After the diagnosis of rejection has been confirmed, the potential risks and benefits of specific antirejection therapies must be evaluated. Hypertension often worsens during an episode of rejection. Patients may experience edema and weight gain as a result of sodium and fluid retention. Symptomatic azotemia also may develop in severe cases. Appropriate adjustments in pharmacotherapy are warranted in the face of diminished renal function.

LIVER

The liver appears to be less immunogenic and more likely to promote immunologic tolerance than the other vascularized organs. An immunologic explanation for graft dysfunction becomes more probable as time passes in a patient with an initially functioning liver graft. Initial episodes of acute cellular rejection often occur between 6 days and 6 weeks post-transplantation but also can occur earlier or later. The clinical signs of acute cellular rejection include leukocytosis and a change in the color or quantity of bile. An increased serum bilirubin concentration and increases in hepatic enzymes are the most common biochemical parameters monitored and are sensitive markers of rejection. The liver biopsy is used as definitive evidence of the diagnosis of rejection, but response to antirejection medication also has been used in differentiating rejection from other causes of hepatic dysfunction in a liver transplant patient. Other reasons for graft dysfunction include defects in bile duct reconstruction, opportunistic infections, and toxicity from parenteral nutrition, sepsis, or drug-induced hepatotoxicity.

HEART

Acute rejection is a major determinant of survival following cardiac transplantation and accounts for approximately 17% of all deaths.¹⁸ The incidence of rejection is substantially higher during the early months following transplantation, with 90% of all rejections occurring within the first 6 months. Because the incidence of acute rejection is highest during this time period, surveillance endomyocardial biopsies are performed at regularly scheduled intervals following transplantation. A typical schedule would be to perform weekly biopsies for the first postoperative month, biweekly biopsies for the next 2 months, monthly biopsies for the next 4 to 6 months, and bimonthly biopsies for the next 7 to 12 months. Biopsy frequency subsequently decreases to every 3 to 12 months. In addition, the severity of rejection tends to be greater when it occurs early in the postoperative period. Although a minority of patients (37%) remain rejection-free, most will experience at least one episode of rejection during the first year. Rejection of the cardiac allograft is not necessarily accompanied by overt clinical signs or symptoms. Nonspecific findings may include low-grade fever, malaise, and mild reduction in exercise capacity, whereas heart failure or atrial arrhythmias may reflect more severe rejection. The

“gold standard” for detection of rejection is histologic confirmation using endomyocardial specimens obtained by transvenous biopsy of the right ventricle. Cardiac function is assessed by either echocardiography or measurement of right-sided heart and pulmonary wedge pressures and cardiac output by pulmonary artery catheterization at the time of each biopsy. The majority of rejection episodes are characterized histologically by lymphocytic infiltrates with or without myocyte degeneration. The treatment of rejection is based on a number of factors, including type, histologic grade, clinical symptoms, hemodynamic changes, noninvasive findings, and duration of time post-transplantation. Mild degrees of acute cellular rejection usually are not treated unless the patient is symptomatic, whereas the presence of moderate to severe rejection with or without necrosis mandates treatment.¹⁹

HUMORAL REJECTION

Humoral rejection, sometimes referred to as *vascular rejection*, is an antibody-mediated process directed against HLA antigens present on the donor vascular endothelium. It can be characterized by capillary deposition of immunoglobulins (IgG), complement, and fibrinogen on immunofluorescence staining. Circulating immune complexes often precede humoral rejection. This form of rejection is less common than cellular rejection and generally occurs in the first 3 months after transplantation. It is associated with an increased fatality rate and appears to be more common when antilymphocyte antibodies are used for rejection prophylaxis. An increased risk of humoral rejection has been linked to females, recipients with elevated PRA, cytomegalovirus seropositivity, a positive crossmatch, and prior sensitization to OKT3.²⁰ Strategies to reverse humoral rejection include plasmapheresis, often in combination with intravenous immunoglobulin (IVIG), high-dose intravenous glucocorticoids, antithymocyte globulin, cyclophosphamide, rituximab, and mycophenolate mofetil.

CHRONIC REJECTION

Chronic rejection is a major cause of late graft loss and is one of the most important problems that remains to be resolved. While chronic rejection simply may be a slow and indolent form of acute cellular rejection, the involvement of the humoral immune system and antibodies against the vascular endothelium appear to play a role. Persistent perivascular and interstitial inflammation is a common finding in kidney, liver, and heart transplantation. Owing to the complex interaction of multiple drugs and diseases over time, it is difficult to delineate the true nature of chronic rejection. For example, cytomegalovirus is associated with the development of chronic rejection in both liver and heart transplant recipients. Unlike acute rejection, chronic rejection is not reversible.

► TREATMENT: Solid-Organ Rejection

■ DESIRED OUTCOME

2 Transplant immunosuppression must be balanced in terms of graft and patient survival (the prevention of rejection versus the risk of adverse effects associated with therapy, including life-threatening infection or malignancy). A multidrug approach is rational from the immunomechanistic viewpoint because the agents

KIDNEY

Advances in the management of acute rejection, has increased the duration of functioning grafts from living and cadaveric donors by more than 70%.²¹ Chronic rejection remains the most common cause of graft loss in the late post-transplant period (>1 year). Although acute rejection is a strong predictor of chronic rejection, it is unclear why the reduction in the incidence of acute rejection associated with the widespread adoption of cyclosporine and tacrolimus has not had an impact on the incidence of chronic rejection. The current tendency to decrease doses of cyclosporine and tacrolimus in the face of “good” graft function without dynamic measurement of immunologic factors may lead to subclinical rejection. Hypertension, proteinuria, and a progressive decline in renal function represent the classic triad of chronic rejection. Manifestations of chronic rejection generally depend on the degree of renal insufficiency and hypoalbuminemia. Classic symptoms of uremia occur as end-stage kidney disease develops.

LIVER

Chronic rejection of the liver is characterized by an obliterative arteriopathy and the loss of bile ducts, which has been referred to as the *vanishing bile duct syndrome*. These patients experience an asymptomatic rise in the canalicular liver enzymes (alkaline phosphatase and γ -glutamyl transpeptidase) and become jaundiced. These changes are considered the result of immunologic and ischemic injury and can be seen in patients who have not responded adequately to therapy for acute rejection.

HEART

Chronic rejection is the leading cause of graft failure and death in heart transplant recipients.²² It manifests as a vasculopathy that is characterized by accelerated intimal thickening or development of atherosclerotic plaques, similar to those seen in the general population with coronary artery disease (CAD). Endothelial injury is the first step in the process, which can be caused by both cell-mediated and humoral responses to the transplanted allograft. Vasculopathy can affect both the arterial and venous vessels but is restricted to the transplanted allograft and rarely affects the recipient’s native vessels. Lipid abnormalities, immunosuppressants, and cytomegalovirus have been linked to the development of vasculopathy. Routine surveillance with coronary angiography, intravascular ultrasound, or other procedures can aid in the diagnosis of vasculopathy. HMG-CoA reductase inhibitors and angiotensin-converting enzyme inhibitors (ACEIs) have been used to decrease the incidence of vasculopathy.²² Percutaneous transluminal coronary angioplasty (PTCA) and coronary artery bypass grafting (CABG) have been used in severe cases of vasculopathy; these procedures, however, are limited by significantly increased mortality compared with the general population.²²

may have overlapping and potentially synergistic mechanisms. Furthermore, multidrug immunosuppression may allow the use of lower doses of individual agents associated with different side-effect profiles to minimize the severity of expected adverse effects.

The goals of immunosuppression vary depending on the time interval since transplantation. Immediately following surgery, the primary goal of therapy is to prevent hyperacute and acute rejection. The high doses of immunosuppressants required to achieve this goal may

result in serious complications (e.g., nephrotoxicity, infection, thrombocytopenia, and drug-induced diabetes) if maintained long term. Rapid dosage reductions may minimize these effects.

GENERAL APPROACH TO TREATMENT

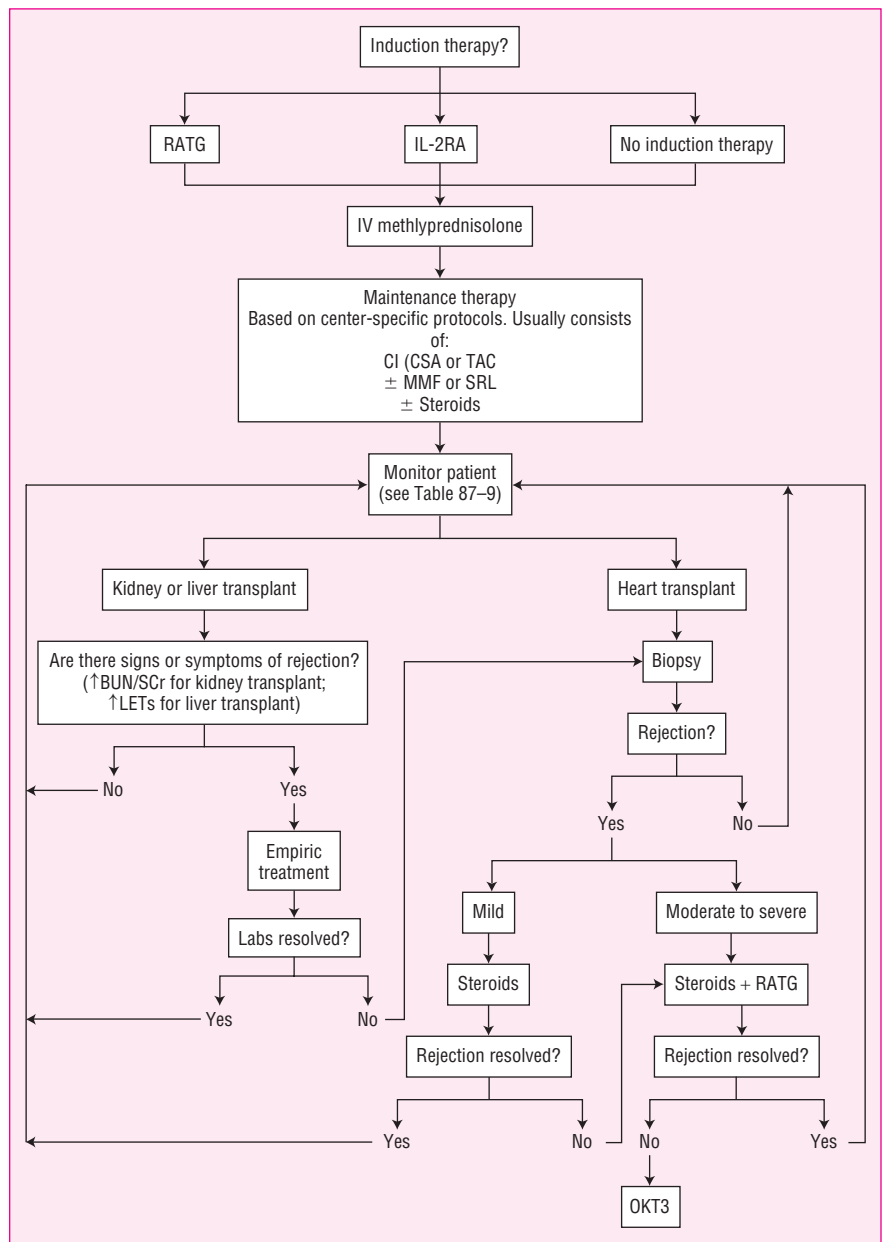

INDUCTION THERAPY

Induction therapy involves the use of a high level of immunosuppression at the time of transplantation with or without the immediate introduction of cyclosporine or tacrolimus (see Fig. 87–2). While induction historically consisted of the use of polyclonal or monoclonal antibodies in addition to triple therapy of azathioprine, high-dose corticosteroids, and a calcineurin inhibitor (e.g., cyclosporine

or tacrolimus) at the time of transplantation, the term is used more recently to define two perioperative immunosuppressive strategies: (1) the provision of a highly intense level of immunosuppression, either universally or on the basis of patient-specific risk factors such as age and race, or (2) the use of antibody therapy to provide enough immunosuppression to delay the administration of the nephrotoxic calcineurin inhibitors cyclosporine and tacrolimus. The rationale for delayed calcineurin inhibitor administration varies slightly depending on the type of transplant. In renal transplantation, the newly transplanted kidney is susceptible to nephrotoxic injury, whereas in liver and heart transplantation, the idea is to protect patients with preexisting renal insufficiency from further insults during the perioperative period. Additionally, cyclosporine and tacrolimus dosage adjustment to maintain target concentrations may be difficult in the perioperative period.

FIGURE 87–2. Center-specific protocols may use RATG, an IL2RA, or no induction therapy. In any situation, patients receive IV methylprednisolone prior to, during, or immediately following the transplant operation. The patient will then begin the maintenance immunosuppressive regimen. The center-specific protocol will specify which calcineurin inhibitor (cyclosporine or tacrolimus) is used in combination with mycophenolate mofetil or sirolimus with or without steroids. Patients are then monitored for signs and symptoms of rejection. If rejection is suspected, a biopsy can be done for definitive diagnosis or the patient may be empirically treated for rejection. Empiric treatment generally involves administration of high-dose corticosteroids. If signs and symptoms of rejection are resolved with empiric therapy, the patient will continue to be monitored according to the center-specific protocol. If rejection is confirmed by biopsy, treatment may be based on the severity of rejection. High-dose corticosteroids are most frequently used for mild to moderate rejection. RATG can be used for moderate to severe rejections or steroid-resistant rejections. Severe rejection episodes that are not resolved with steroids or RATG are treated with OKT3.

RATG = rabbit antithymocyte immunoglobulin; IL2RA = interleukin-2 receptor antagonist; CI = calcineurin inhibitor; CSA = cyclosporine; TAC = tacrolimus; MMF = mycophenolate mofetil; SRL = sirolimus; BUN = blood urea nitrogen; SCr = serum creatinine; LFTs = liver function tests; OKT3 = muromonab CD3.

CLINICAL CONTROVERSY

Some clinicians use induction therapy with IL2RAs or RATG for all transplant recipients. Others reserve induction therapy for patients who are at a higher risk for rejections, such as those who have a high PRA, had previous transplants or multiple pregnancies, or are of non-Caucasian race.

■ ACUTE REJECTION

The primary goal of acute rejection therapy is to minimize the intensity of the immune response and prevent irreversible injury to the allograft. The available options may include (1) increasing the doses of current immunosuppressive drugs such as cyclosporine or tacrolimus, (2) “pulse” steroids with subsequent dose taper, (3) addition of an additional immunosuppressant indefinitely, or (4) short-term treatment with antirejection therapy such as OKT3 or antithymocyte globulin. The treatment of acute rejection varies among transplant centers and by type of allograft, but most always begins with “pulse” steroid therapy for several days (oral or intravenous). Recent data in renal transplantation indicate, however, that African-Americans do not respond as well to glucocorticoids as non-African-Americans. Other therapies, such as antithymocyte globulin, thus may be preferable for this patient population.²³

If biopsy results are available, these findings also may guide therapy in favor of other approaches such as antilymphocyte preparations. Cytolytic agents generally are reserved for steroid-resistant rejection, signs of hemodynamic compromise (heart), or more severe rejections. For the treatment of acute allograft rejection, antithymocyte globulin is better tolerated than and preferred over OKT3. Other innovative forms of therapy for persistent or intractable rejection have been investigated, including mycophenolate mofetil, tacrolimus, low-dose methotrexate, sirolimus, total lymphoid irradiation, and photopheresis (e.g., immune-modulating therapy, which involves apheresis with isolation of peripheral blood leukocytes, treatment of the leukocytes *ex vivo* with 8-methoxypsoralen and ultraviolet light, and subsequent reinfusion into the patient).^{24,25}

The dosages of other immunosuppressant drugs often are decreased while administering corticosteroids, OKT3, or antithymocyte globulin therapy. Prophylactic agents such as valganciclovir, nystatin, trimethoprim-sulfamethoxazole, H₂-receptor antagonists or proton-pump inhibitors, and/or antacids may be used to minimize adverse effects associated with intensive immunosuppression.

■ MAINTENANCE THERAPY

3 The goal of maintenance immunosuppression is to prevent acute and chronic rejection while minimizing drug-related toxicity. In the long-term management of the transplant patient, the doses of immunosuppressants are reduced gradually (over 6 to 12 months) in an effort to minimize adverse effects. Many institutions may withdraw specific immunosuppressives completely in select patients to reduce long-term toxicity as well as cost. It is important to recognize that while the goals of transplant immunosuppression are universal, protocols for immunosuppressive therapy vary widely among institutions.

Maintenance therapy can involve numerous combinations of the various available immunosuppressive agents. Transplant organ and

type (cadaveric versus living-related), the degree of HLA mismatch, time post-transplant, post-transplant complications (including the number of acute rejections), previous immunosuppressive adverse reactions, compliance, and financial considerations are among the patient-specific factors considered in individualizing maintenance immunosuppression. Calcineurin inhibitors (CIs) generally are a central component in most maintenance regimens, although CI-free immunosuppression remains the “Holy Grail” of transplant immunology. Transplant patients may receive mono-, dual-, or triple-drug therapy during the maintenance phase. As patients progress through the posttransplant course, the risk of acute rejection decreases; accordingly, maintenance immunosuppression is tapered, and in some cases, certain agents may be discontinued.

The changes seen with chronic rejection are not reversible with current immunosuppressive therapies. Some strategies for managing chronic rejection include increasing immunosuppression or changing immunosuppression to prevent further progression of chronic rejection. However, often this strategy provides little clinical benefit. Ideally, immunosuppression should be optimized to prevent acute rejection episodes to minimize the occurrence of chronic rejection.

■ CALCINEURIN INHIBITORS (CIs)

■ CYCLOSPORINE (CSA)

4 The introduction of CSA has improved the outcomes of transplantation significantly. Patient and graft survival rates have improved secondary to a lower incidence of acute rejection episodes and severe infectious complications.²⁶ Despite these improvements in survival, concerns regarding its long-term use include late rejection episodes, frequency of hypertension, drug cost, and quality of kidney function.

■ Pharmacology/Mechanism of Action

CSA inhibits T-cell proliferation by inhibiting the production of IL-2 and other cytokines by T cells (see Fig. 87-1). CSA binds to cyclophilin, a cytoplasmic immunophilin. The CSA-cyclophilin complex inhibits the action of calcineurin, an enzyme that activates the nuclear factor of activated T cells (NF-AT), which is, in turn, responsible for the transcription of several key cytokines necessary for T-cell activity, including IL-2. IL-2 is a potent growth factor for T cells, responsible for activation and clonal expansion.

■ Pharmacokinetics

CSA is highly lipophilic and depends on bile for intestinal absorption. Following oral administration, the absorption of CSA is incomplete and erratic, especially in liver recipients with T-tube diversion of bile. CSA is associated with clinically significant interpatient and inpatient variability in pharmacokinetic parameters owing to unpredictable bioavailability, which averages 30% (range 3% to 60%). Bowel function and bile flow play a major role in intestinal absorption. Because of the significant variability in absorption, peak concentrations are reached within 2 to 6 hours of oral administration. CSA is distributed widely into tissues and body fluids, resulting in a large and variable volume of distribution. The mean terminal half-life with normal liver function is 19 hours.

TABLE 87-4. Summary of Immunosuppressant Adverse Effects

| Adverse Effects | AZA | MMF | Steroids | CSA | TAC | SIR | IL2RA | ATG | OKT3 | Management |
|--------------------------------|------------------------|--|----------|-----|-----|-----|--------------------------------------|-----|------|---|
| Adrenal suppression | | | + | | | | | | | Taper doses slowly; administer every other day; patient identification card |
| Cataracts/glaucoma | | | + | | | | | | | Annual eye examinations or as indicated |
| Hypertension | | | ++ | ++ | ++ | | | | | Monitor blood pressure; sodium restriction and antihypertensive medications as needed |
| Tremor | | | | ++ | ++ | | | | | Adjust dose as needed |
| Gastrointestinal abnormalities | ++ Nausea, vomiting | ++ Diarrhea, nausea, abdominal pain | + | + | ++ | | Diarrhea, nausea, vomiting, anorexia | | | AZA: administer after meals; MMF: decrease or divide dose, administer with food; TAC/PRED: administer with food; ulcer prophylaxis |
| Respiratory abnormalities | | | | | | | | | + | TAC: pleural effusion, dyspnea OKT3: pulmonary edema |
| Nephrotoxicity | | | | ++ | ++ | + | | | | Monitor serum creatinine/BUN; adjust dose and discontinue as needed |
| Headache | | | | + | ++ | | | | | Check drug concentration; adjust dose |
| Hepatotoxicity | + | | | + | ++ | | | | | Monitor liver enzymes; AZA-associated toxicity is reversible and usually occurs within the first 6 months of therapy; adjust dose and discontinue as needed |
| Hyperlipidemia | | | ++ | ++ | + | ++ | | | | Dietary counseling; pharmacotherapy as needed |
| Glucose alterations | | | ++ | + | ++ | | | | | Monitor glucose; adjust doses of hypoglycemics or immunosuppressants |
| Osteoporosis/aseptic necrosis | | | + / ++ | | | | | | | Annual bone examinations; weight bearing exercise |
| Personality changes | | | ++ | | | | | | | Patient and family education |
| Weight gain | | | ++ | | | | | | | Patient education; exercise |
| Acne | | | + | + | | | | | | Dose reduction; increased hygiene; topical agents (e.g. retinoic acid) |
| Gingival hyperplasia | | | | ++ | | | | | | Patient education; appropriate dental hygiene; consider TAC |
| Hirsutism | | | | ++ | | | | | | Patient education; consider TAC |
| Pruritis | | | | | ++ | | | | | Treatment when appropriate |
| Thrombocytopenia | ++ | + | | | + | ++ | | | | Monitor platelets |
| Leukocytosis | | | ++ | | ++ | | | | | Monitor WBCs |
| Leukopenia | ++ | ++ | | + | | ++ | | | | Monitor WBCs; dose-dependent and reversible with AZA/MMF |
| Hyperkalemia | | | | + | ++ | | | | | Monitor serum electrolytes |
| Hypokalemia | | | | | | | + | | | |
| Hypomagnesemia | | | | + | ++ | | | | | Monitor serum magnesium |

++ indicates >10% risk; + indicates <10% risk.

AZA = azathioprine; MMF = mycophenolate mofetil; CSA = cyclosporine; TAC = tacrolimus; SIR = sirolimus; IL2RA = interleukin 2 receptor antagonist; ATG = antithymocyte globulin; OKT3 = muromonab CD3; PRED = prednisone; BUN = blood urea nitrogen; WBC = white blood cells.

To overcome the pharmacokinetic problems of CSA, a microemulsion formulation was developed. Both forms are available commercially in the United States, referred to as “cyclosporine, USP” and “cyclosporine, USP [MODIFIED].” The two formulations are not bioequivalent and should not be used interchangeably. The microemulsion formulation is self-emulsifying and forms a microemulsion spontaneously with aqueous fluids in the gastrointestinal tract, making it less dependent on bile for absorption. The result is a significantly greater rate and extent of absorption and decreased intraindividual variability in pharmacokinetic parameters. Bioavailability is enhanced owing to better dispersion and absorption and does not require bile excretion. The relative bioavailability of the microemulsion formulation is 60%. Peak concentrations generally are reached within 1.5 to 2 hours after oral administration. The terminal half-life is 8.4 hours.

Following oral absorption, 90% to 97% of CSA is bound to lipoproteins in the blood. CSA is metabolized by the cytochrome P450 3A4 (CYP 3A4) system in both the gut and the liver, which accounts for both its poor bioavailability and numerous drug interactions. Children have a shorter half-life as a result of an increased rate of metabolism.

■ Efficacy

The introduction of CSA significantly improved the outcomes of transplantation. Since its approval and widespread use, patient and graft survival rates have improved secondary to a lower incidence of acute rejection episodes and severe infectious complications. In heart transplant recipients, for example, 1-year survival rates increased from 56% to 85%, and 5-year survival rates increased from 31% to 75%.²⁷ The efficacy of CSA is well established in all types of solid-organ transplants. Currently, CSA is approved for use in kidney, liver, and heart transplantation.

When compared with the standard formulation, the microemulsion formulation has demonstrated equivalent or superior efficacy in kidney, liver, and heart transplant recipients. Other areas of research include CSA as monotherapy and as rescue therapy for patients who are unable to tolerate tacrolimus.

The efficacy of CSA monotherapy has been described.²⁸ The avoidance of long-term steroids is the primary advantage of CSA monotherapy, whereas the primary disadvantage is the higher incidence of rejection. As a result, CSA is used rarely as monotherapy.

Patients who are unable to tolerate tacrolimus owing to side effects can be switched to CSA as rescue therapy. CSA rescue therapy was studied in a group of kidney and liver transplant recipients who were unable to tolerate tacrolimus. The initial dose of CSA was based on organ function, tacrolimus levels, and the reason for tacrolimus intolerance and generally began 24 hours after tacrolimus was discontinued. Symptoms improved or resolved in more than 70% of patients within 3 months of conversion to CSA. However, 27% of patients who were switched to CSA experienced an episode of acute rejection.²⁹ Jain and colleagues³⁰ reported similar results with a 39% rejection rate but noted that many patients were able to be converted back to tacrolimus without recurrence of the original complication.

■ Adverse Effects

The adverse effects of CSA and other immunosuppressants are summarized in Table 87–4. The magnitude of adverse effects is often related to the dose and duration of exposure to CSA. Neurotoxicity

typically manifests as tremors, headache, and peripheral neuropathy but can be as severe as seizures. Nephrotoxicity is displayed as increased serum creatinine concentration, decreased glomerular filtration rate, and hyperkalemia. Hypertension can be uncontrollable and may warrant drug discontinuation in some cases. Often, additional drug therapy is required to manage the adverse effects of CSA. Cosmetic changes such as hirsutism and gingival hyperplasia often are managed by converting from CSA to tacrolimus or by proper hygiene in patients who cannot be switched to tacrolimus.

■ Drug-Drug and Drug-Food Interactions

Drug interactions occur frequently with CSA since it extensively metabolized by CYP 3A4 in both the gut and the liver. CSA is also a substrate for *p*-glycoprotein, which contributes to its drug interactions.^{31,32} Inhibition of CYP 3A4 by drugs such as diltiazem or ketoconazole can increase drug concentrations significantly, whereas induction by drugs such as phenytoin or rifampin can decrease drug concentrations significantly. Some centers take advantage of these interactions by routinely using CSA-sparing agents to reduce the dosage and cost of therapy while maintaining the same therapeutic concentrations.³³

While most drug interactions with CSA result from the effects of the CYP 3A4 on CSA, it is important to remember that CSA is also an inhibitor of CYP 3A4 (Table 87–5). The inhibitory effects of CSA on CYP 3A4 can be seen with weaker substrates, such as the HMG-CoA reductase inhibitors. Concomitant administration of CSA with HMG-CoA reductase inhibitors results in an increase in the HMG-CoA reductase inhibitor levels, which increases the risk of HMG-CoA reductase inhibitor adverse effects, most notably myopathy.³⁵ Myopathy associated with this reaction usually is reversible with discontinuation of the HMG-CoA reductase inhibitor.

Consistency in administration of CSA with regard to meals and food intake is important to minimize alterations in CSA absorption and pharmacokinetics. High-fat meals can enhance both plasma clearance and the volume of distribution by more than 60%.³⁶ Grapefruit juice increases CSA concentrations significantly. Furanocoumarins found in grapefruit juice, such as quercetin, naringin, and bergamottin, are potent inhibitors of CYP 3A4. The area under the concentration-time curve (*AUC*) and *C*_{max} of CSA have been reported to be increased by more than 55%, and CSA peak concentration levels were 35% higher when CSA was taken with grapefruit juice.³⁷ Commonly administered drugs which are known to result in clinically significant alterations of CSA levels are listed in Table 87–6.

■ Dosing and Administration

Initiation of oral CSA therapy generally begins with a dose of 8–18 mg/kg per day divided into two doses administered every 12 hours. Higher CSA doses are used more commonly in two-drug regimens, whereas lower doses are part of triple-drug regimens. Some immunosuppressive strategies use lower doses of CSA (e.g., 1 to 3 mg/kg per day) until day 3 or 4 to decrease potential nephrotoxicity in the immediate postoperative period. Since the risk for acute rejection decreases with time, oral CSA doses are reduced and may be as low as 3 to 5 mg/kg per day or less during maintenance therapy. If oral administration is not possible, CSA may be administered intravenously at one-third the oral dosage, usually 2 to 5 mg/kg per day.

CSA is excreted in the bile and is nephrotoxic; therefore, dosage adjustments should be made when hepatic dysfunction is present.

TABLE 87–5. (Continued)

| CYP1A <i>Inhibitors</i> | CYP2C <i>Inhibitors</i> | CYP2D6 <i>Inhibitors</i> | CYP3A <i>Inhibitors</i> | |

Liver transplant recipients with T-tube diversion of bile require increased doses because of decreased absorption. Children require higher doses of CSA to maintain therapeutic drug concentrations, up to 14 to 18 mg/kg per day.

CSA blood concentrations are measured routinely in an attempt to optimize therapy. Radioimmunoassay (RIA) and fluorescence polarization immunoassay are the most commonly used methods; how-

ever, high-performance liquid chromatography (HPLC) is recognized as the reference procedure.³⁸ It is important to determine which assay methodology the laboratory is using because target ranges vary between nonspecific (which quantitates parent plus metabolite concentration, such as RIA) and specific (which quantitates parent CSA, such as HPLC using mass spectrometry) assays. The therapeutic range for whole-blood RIA is 375 to 400 ng/mL versus 100 to 300 ng/mL

TABLE 87–6. Effect of Concomitant Drug Administration on Cyclosporine, Tacrolimus and Sirolimus^a

^aThis is not a complete list of all drug interactions.

^bMedications known to inhibit the cytochrome P450 3A4 enzyme system can increase levels of cyclosporine, tacrolimus, and sirolimus.

^cMedications known to induce the cytochrome P450 3A4 enzyme system can decrease levels of cyclosporine, tacrolimus, and sirolimus.

From refs. 31,32,33, and 34.

for HPLC. In serum or plasma, the therapeutic range for RIA or HPLC is 150 to 250 ng/mL and 75 to 150 ng/mL, respectively.

The most common and practical method of CSA monitoring is the measurement of trough blood concentrations. CSA trough concentrations are measured frequently (daily or three times per week) following initiation of the drug and during the stabilization period after transplantation. However, studies have revealed lack of predictive value of trough concentrations and rejection.³⁹ Alternative strategies have been proposed to better correlate CSA levels with rejection. Proposed strategies include pharmacokinetic profiling to determine the area under the concentration curve and peak concentration, which are suggested to correlate with graft function.⁴⁰ *AUC* monitoring can be problematic because of the need for sequential CSA levels throughout the dosing interval. Limited sampling techniques using two to five blood samples within the first 4 hours after an oral dose have been used. *AUC* levels >440 mcg/L per hour have been shown to correlate with rejection.⁴⁰ Peak concentrations measured 2 hours after an oral dose (C_2) have been shown to have a better predictive value in terms of rejection compared with trough concentrations.³⁹ Some transplant centers have adopted this strategy to manage CSA levels because of the convenience of a single blood sample. The suggested therapeutic range for C_2 CSA levels is 1.5 to 2 mcg/mL for the first few months after transplant and 0.8 mcg/mL after 6 to 12 months.^{40,41}

■ TACROLIMUS (TAC)

TAC is a macrolide antibiotic with immunosuppressive activity via inhibition of calcineurin. It was thought originally that TAC may decrease the risk of chronic allograft rejection, but experience has demonstrated that this is not the case. However, it should be noted that up to this point, TAC traditionally has been used in high-risk patients. Today, TAC is used more commonly than CSA by most transplant centers in all transplant patients, regardless of risk category.

■ Pharmacology/Mechanism of Action

TAC inhibits T-cell activity by inhibiting the production of IL-2 and other cytokines by T cells (See Fig. 87–1). TAC binds to a cytoplasmic immunophilin called *FK-binding protein-12* (FKBP12). Like CSA, the TAC-FKBP12 complex inhibits calcineurin, ultimately inhibiting NF-AT and the transcription of cytokines necessary for T-cell activity, most notably IL-2.

■ Pharmacokinetics

TAC is a highly lipophilic compound; however, it does not rely on bile for absorption. Following oral administration, the bioavailability of TAC ranges from 5% to 67%, with a mean of 29%.⁴² FKBP12 is found in high concentrations in red blood cells, which causes extensive binding of TAC to erythrocytes. TAC is also metabolized primarily by CYP 3A4, although other cytochrome P450 enzymes have been reported.⁴² The elimination half-life of TAC is 8.7 hours. Increased metabolism in children results in a shorter half-life.

■ Efficacy

Currently, TAC is approved for use in kidney and liver transplants. However, it has been studied extensively and is used widely in all types of solid-organ transplants. Studies comparing CSA with TAC

as primary immunosuppression demonstrate equal efficacy of the two agents in kidney, liver, and heart transplants.

The potency and effectiveness of TAC have prompted studies to investigate withdrawal of corticosteroids or other concomitant immunosuppressants. A large randomized, controlled trial compared triple-drug therapy, consisting of TAC, corticosteroids, and mycophenolate mofetil, with early withdrawal of corticosteroids or mycophenolate in kidney transplant recipients. The results demonstrated equal efficacy in the three arms with no difference in acute rejection rates after 6 months of therapy.⁴³ Furthermore, TAC has demonstrated equal efficacy to CSA, each in combination with azathioprine, with regard to corticosteroid withdrawal.⁴⁴

■ Adverse Effects

The adverse effects associated with TAC include neurologic toxicity, nephrotoxicity, and electrolyte disturbances such as hyperkalemia and hypomagnesemia⁴² (see Table 87–4). The incidence of post-transplant diabetes is approximately 8% to 10% but is often reversible when doses of TAC and/or steroids are reduced.⁴⁵ As observed with CSA, most adverse effects related to TAC improve with dosage reduction or discontinuation.

In comparison with CSA, TAC may be associated with increased occurrence of neurologic complications, including tremor, paresthesias, headache, and insomnia. On the contrary, TAC is associated with less hypercholesterolemia and hypertension.^{45–47} The occurrence of nephrotoxicity appears to be similar to CSA. TAC also has been reported to cause alopecia, which is usually self-limiting and reversible.

■ Drug-Drug and Drug-Food Interactions

Because of their common metabolic pathways, CSA and TAC share the same drug interaction profile (see Table 87–6). CYP 3A4 inhibitors increase TAC concentrations, whereas CYP 3A4 inducers decrease blood levels. One distinct drug interaction with TAC that differs from CSA is an interaction with antacids. In vitro data suggest that drugs that increase the pH of the gastrointestinal tract, such as magnesium-, aluminum- or calcium-containing antacids, sodium bicarbonate, and magnesium oxide, can cause a pH-mediated degradation of TAC or physical adsorption to TAC in the gastrointestinal tract.^{48,49} Such compounds should be separated from TAC administration by at least 2 hours to prevent the physical interaction.

Reversible myopathy has been reported with concomitant administration of TAC with HMG-CoA reductase inhibitors.⁵⁰ TAC is also an inhibitor of CYP 3A4 but much weaker than CSA.⁵¹ The number of reported cases of myopathy with HMG-CoA reductase inhibitors in patients treated with TAC is fewer than with CSA. Nonetheless, patients should be monitored for clinical signs of myopathy when receiving HMG-CoA reductase inhibitors in combination with TAC.

It is also important to maintain consistency with administration of TAC with regard to meals and food intake to minimize alterations in TAC absorption and pharmacokinetics. One study in healthy volunteers indicates that the C_{max} , *AUC*, and t_{max} of TAC were significantly higher when administered after a 10-hour fast compared with either a high-fat or low-fat/high-carbohydrate meal. Administration of TAC with food decreased C_{max} by 77% for the high-fat meal and 64.7% for the low-fat meal. *AUC* also was decreased by 33.5% and 26.1%, respectively, and t_{max} was increased 4.72- and 2.34-fold, respectively. The authors concluded that food reduces both the rate and extent of TAC absorption and that a high-fat meal may further delay gastric

emptying, further reducing TAC concentrations.⁵² As with CSA, grapefruit juice also significantly increases TAC concentrations.

■ Dosing and Administration

Initial intravenous TAC doses range from 0.05 to 0.1 mg/kg per day and are administered by continuous infusion. Oral doses range from 0.1 to 0.3 mg/kg per day given in two divided doses every 12 hours. TAC doses are then adjusted according to trough blood levels, clinical response, and adverse effects. A review of the role of TAC in renal transplantation suggests that target 12-hour whole-blood trough concentrations are 15 to 20 ng/mL (0 to 1 month after transplantation), 10 to 15 ng/mL (1 to 3 months after transplantation), and 5 to 12 ng/mL (>3 months after transplantation).⁴⁴ Because TAC is highly bound to red blood cells, plasma levels are much lower than whole blood concentrations. Therapeutic plasma levels of TAC range from 0.5 to 2 ng/mL. Pediatric transplant patients clear the drug more rapidly and require doses two- to fourfold higher than adults on a milligram per kilogram basis to maintain equivalent therapeutic concentrations. A modified release formulation of TAC that will allow for once-daily administration is currently in phase III clinical trials.

■ CALCINEURIN INHIBITOR NEPHROTOXICITY

◀ One of the most common side effects observed in all transplant recipients receiving maintenance CSA or TAC therapy is nephrotoxicity. Two types of toxicity can occur. Acute nephrotoxicity frequently is seen early and is dose-dependent and reversible, but chronic nephropathy is more common. Clinical manifestations of CI nephrotoxicity include elevated serum creatinine and blood urea nitrogen levels, hyperkalemia, hyperuricemia, mild proteinuria, and a decreased fractional excretion of sodium. CI nephrotoxicity is recognized as the leading cause of renal dysfunction following nonrenal solid-organ transplant. One study looked at more than 69,000 liver, heart, lung, and intestinal transplant recipients and found a combined incidence of 16.5% of newly diagnosed chronic renal failure after a mean follow-up of 46 months. A total of 28.9% of these patients with chronic renal failure went on to develop ESRD, requiring dialysis or kidney transplant. Patients with no history of CI use had a lower relative risk of developing nephropathy compared with those who did receive CI. Furthermore, CSA was associated with a higher risk of developing nephropathy compared with TAC (RR 1.25, $p < 0.001$).⁵³

The predominant mechanism for CI nephrotoxicity is renal vasoconstriction, primarily of the afferent arteriole, resulting in increased

renal vascular resistance, decreased renal blood flow by up to 40%, reduced glomerular filtration rate by up to 30%, and increased proximal tubular sodium reabsorption with a reduction in urinary sodium and potassium excretion. A number of other mechanisms have been implicated, including changes in the renin-angiotensin-aldosterone system, prostaglandin synthesis, nitrous oxide production, sympathetic nervous system activation, and calcium handling.⁵⁴

Measures to reduce CI nephrotoxicity include delaying administration immediately postoperatively in patients at high risk for nephrotoxicity (using alternative induction protocols including an IL-2 receptor antagonist or antilymphocyte globulin), monitoring CI trough blood levels and reducing the CI dosage if the vasoconstrictive effects are problematic, and avoiding other nephrotoxins (e.g., aminoglycosides, amphotericin B, and NSAIDs) when possible. When using these agents, drug concentrations of CI and those of the other drugs, if available, should be monitored closely. In addition, the concomitant administration of drugs known to elevate CI levels requires intentional dosage reductions to avoid unnecessary renal and other toxicity³¹ (see Table 87–6). Currently, no proven therapies consistently prevent or reverse the nephrotoxic effects of CSA; however, a number of agents have been studied, including prostaglandin analogues, pentoxifylline, and fish oils.⁵⁵

In kidney transplants, it is often difficult to differentiate CI nephrotoxicity from renal allograft rejection. Because the clinical features of acute renal allograft rejection and CI nephrotoxicity may overlap considerably, a renal biopsy continues to be the diagnostic “gold standard” (Table 87–7). However, differentiating between chronic renal allograft rejection and CI nephrotoxicity may be more difficult because, in addition to clinical signs and symptoms, biopsy findings also may be similar.

CLINICAL CONTROVERSY

Although CIs are the mainstay of immunosuppressive protocols, some clinicians attempt to use CI-sparing protocols to avoid the significant adverse effects associated with CIs. Others will delay the initiation of CIs to avoid the dose-related adverse effects associated with early use of CIs post-transplantation.

■ GLUCOCORTICOIDS

◀ Corticosteroids have been used since the beginning of the modern transplantation era. Despite their many adverse events, they

TABLE 87–7. Differential Diagnosis of Acute Rejection and CSA or TAC Nephrotoxicity

| | Acute Rejection | CSA or TAC Nephrotoxicity |
|-----------------------|---|---|
| History | Often <4 weeks postoperatively | Often >6 weeks postoperatively |
| Clinical presentation | Fever Hypertension Weight gain Graft swelling/tenderness Decreased daily urine volume | Afebrile Hypertension Graft nontender Good urine output |
| Laboratory Biopsy | Rapid rise in serum Cr (0.3 mg/dL/day) Normal CSA or TAC concentration Interstitial lymphocytic infiltrates | Gradual rise in serum Cr (>0.15 mg/dL/day) Elevated CSA or TAC concentration Interstitial fibrosis, tubular atrophy, glomerular thrombosis, arterial inflammation |

CSA = cyclosporine; TAC = tacrolimus; Cr = creatinine.

continue to be a cornerstone of immunosuppression regimens in many transplant centers. The most commonly used corticosteroids in transplantation are methylprednisolone and prednisone.

■ PHARMACOLOGY/MECHANISM OF ACTION

Corticosteroids block cytokine activation by binding to glucocorticoid response elements, thereby inhibiting IL-1, -2, -3, and -6, γ -interferon, and tumor necrosis factor α (TNF- α) synthesis (See Fig. 87–1). Additionally, steroids interfere with cell migration, recognition, and cytotoxic effector mechanisms.⁵⁶

■ PHARMACOKINETICS

Prednisone is converted to active prednisolone in the body and has multiple effects on the immune system. Prednisone is very well absorbed from the gastrointestinal (GI) tract and has a long biologic half-life, so it can be dosed once daily.

■ EFFICACY

Animal models of transplantation in the 1950's and 1960's used steroids empirically in combination with azathioprine.⁵⁷ Steroids subsequently became a part of the immunosuppressive regimens used in the first human transplants⁵⁸ and continue to be used in immunosuppressive protocols today. The efficacy of steroids is irrefutable based on the decades of clinical experience. Systematic studies comparing steroid-free immunosuppressive agent combinations with conventional therapy are difficult to perform due to the hundreds of potential combinations that now exist. However, recent studies of steroid-free immunosuppressive agent combinations with newer, more specific immunosuppressants suggests that steroids may in the future have less of a role in maintenance immunosuppression.^{43,44}

■ ADVERSE EFFECTS

Adverse effects of prednisone that occur in more than 10% of patients include increased appetite, insomnia, indigestion (bitter taste), and mood changes. Side effects that occur less commonly but which are seen with high doses or prolonged therapy include cataracts, hyperglycemia, hirsutism, bruising, acne, sodium and water retention, hypertension, bone growth suppression, and ulcerative esophagitis (see Table 87–4).

■ DRUG-DRUG AND DRUG-FOOD INTERACTIONS

Barbiturates, phenytoin, and rifampin induce hepatic metabolism of prednisone and thus decrease the effectiveness of prednisone. Prednisone decreases the effectiveness of vaccines and toxoids.⁵⁶

■ DOSING AND ADMINISTRATION

An intravenous corticosteroid, commonly high-dose methylprednisolone, is given during the perioperative period. The dose of methylprednisolone is tapered rapidly and discontinued within days and oral prednisone is initiated. Prednisone doses are tapered progressively over time depending on the type of additional immunosuppression

and organ function. As doses are tapered, it is preferable to administer steroids every other day and between 7 and 8 A.M. to mimic the body's diurnal release of cortisol. Although conversion to alternate-day regimens or complete withdrawal of prednisone in patients with stable posttransplant courses has been used with success in some transplant centers, steroids often are continued for the entire life of the functional graft. Long-term steroid use and its associated deleterious effects are well recognized and particularly troublesome in transplant patients (see Table 87–4).

The first-line therapy for the treatment of acute graft rejection is high-dose intravenous methylprednisolone (250 to 1000 mg) daily for 3 days or oral prednisone (200 mg). Doses of oral prednisone are then tapered over 5 days to 20 mg/day. Prednisone should be taken with food to minimize GI upset. The dose of prednisone varies with the transplant center's protocol but usually is highest immediately following transplant and during treatment for acute rejection. It is becoming frequent practice to taper prednisone with the goal of discontinuation over a period of months. Corticosteroids never should be discontinued abruptly; tapering should be gradual because of suppression of the hypothalamic-pituitary-adrenal axis. Corticosteroids slow the growth rates in children, prompting clinicians to use alternate-day dosing or to withhold steroids until rejection occurs.

Because of the many detrimental effects associated with chronic steroid therapy, dose minimization has been the goal of therapy. The availability of CSA, TAC, and mycophenolate mofetil has permitted complete withdrawal of corticosteroids in some patients. Steroid withdrawal protocols use either a rapid taper of steroids within days of the transplant or a slower taper, whereby patients are weaned gradually from steroids over months to years after transplant. Factors to consider when evaluating studies of these alternative strategies in transplant patients include patient selection criteria, timing and rapidity of withdrawal, and duration of follow-up.

■ ANTIPROLIFERATIVE AGENTS

■ MYCOPHENOLATE MOFETIL (MMF)

➤ Mycophenolic acid (MPA) was first isolated from the *Penicillium glaucum* mold. It was first studied as an antibiotic but later was found to have immunosuppressive properties. Mycophenolate mofetil (MMF) the morpholinoethyl ester of MPA appears to be a specific immunosuppressant for lymphocytes, resulting in fewer adverse effects than azathioprine, making it the preferred agent over azathioprine.

■ Pharmacology/Mechanism of Action

MMF is rapidly and completely converted to MPA by first-pass metabolism. MPA exerts its immunosuppressive effect through non-competitive binding to inosine monophosphate dehydrogenase (IMPDH). IMPDH is the key enzyme responsible for guanosine nucleotide synthesis via the de novo pathway. Inhibition of IMPDH results in decreased nucleotide synthesis and diminished DNA polymerase activity, ultimately reducing lymphocyte proliferation.⁵⁹ The actions of MPA are more specific for T and B cells, which use only the de novo pathway for nucleotide synthesis (see Fig. 87–1). Other cells within the body have a salvage pathway by which they can synthesize nucleotides, making them less susceptible to the actions of MPA and thereby reducing, but not eliminating, the potential for the hematologic adverse effects seen with azathioprine, which affects both the de novo and salvage pathways. In addition to the decreasing

lymphocyte proliferation, MPA also may downregulate activation of lymphocytes.⁶⁰

■ Pharmacokinetics

Following oral administration, bioavailability of MMF is 94%, and peak concentrations of MPA are reached within 1 hour. A total of 97% of MPA is bound to albumin in the blood. MPA is eliminated by the kidney and also undergoes glucuronidation in the liver to an inactive glucuronide metabolite (MPAG) that is excreted in the bile and urine. Enterohepatic cycling of MPAG can undergo deconjugation, thereby recirculating MPA into the bloodstream. The half-life of MPA is 18 hours.

■ Efficacy

Currently, MMF is approved for use in kidney, liver, and heart transplants. A recent analysis of 5599 patients in the Joint International Society for Heart and Lung Transplantation (ISHLT) and UNOS Thoracic Registry showed a statistically significant survival advantage for MMF compared with azathioprine (1 year, 96% versus 93%; 3 years, 91% versus 86%).⁶¹ Efficacy has been demonstrated in combination with both CSA and TAC.

MMF also has demonstrated efficacy in the treatment of acute rejection. Kidney transplant recipients converted to MMF after the first acute rejection episode had fewer subsequent rejections compared with those who continued with azathioprine after rejection treatment. The change in therapy was associated with no increase in adverse effects or malignancies and a trend toward better graft function and survival.⁶²

Monotherapy with MMF can decrease the risk of nephrotoxicity associated with CIs. Clinical trials have evaluated the benefits of CI withdrawal from MMF-based immunosuppression in stable kidney and liver transplants. Withdrawal of CIs resulted in improved renal function and lower blood pressure, lipid, and uric acid levels. These benefits, however, were offset by an unacceptable increase in organ rejection in all the studies.^{63–65} Monotherapy with MMF generally is not used in clinical practice.

■ Adverse Effects

Unlike CSA and TAC, MMF is not associated with nephrotoxicity, neurotoxicity, or hypertension. GI side effects such as nausea, vomiting, diarrhea, and abdominal pain, however, occur more frequently in MMF-treated patients compared with those receiving azathioprine or placebo⁶⁶ (see Table 87–4). In addition, GI symptoms occur with similar frequency during intravenous and oral therapy. Clinically, however, dose reduction, dividing the total daily dose into three, administration with food, and upward titration from lower doses during initial therapy may alleviate some of these GI symptoms. MMF also has hematologic effects resulting in leukopenia and anemia, particularly with higher doses. Tissue-invasive cytomegalovirus (CMV) also was more common in MMF-treated patients,⁶⁶ although this may be related to differences in the use of CMV prophylaxis within the studies. Malignancy and post-transplant lymphoproliferative disease (PTLD) are of significant concern with greater amounts of immunosuppression. Longer follow-up of patients receiving MMF is required to characterize the lifelong risk of malignancy. Because peripheral intravenous MMF administration is associated with local edema and inflammation, central venous administration may be the preferred route.

■ Drug-Drug and Drug-Food Interactions

Food delays the absorption and decreases MPA C_{max} by 25% but has no effect on MPA AUC . As a result, prescribing information indicates that MMF should be taken on an empty stomach; however, MMF is often given with food in clinical practice to minimize GI adverse effects. Administration with aluminum- and magnesium-containing antacids or cholestyramine, significantly decreases the AUC of MPA and should be avoided.⁵⁹ It has been suggested that administration of iron may produce similar results, but this has not been tested.

Acyclovir, commonly used in renal transplant recipients for the treatment and prevention of viral infections, competes with MPAG for renal tubular secretion. $AUCs$ of both entities are increased with concomitant acyclovir and MMF administration.⁵⁹ Single-dose intravenous ganciclovir in combination with MMF produced no change in the disposition of ganciclovir, MPA, or MPAG.⁶⁷ Although no pharmacokinetic interaction in a single-dose study was demonstrated, there is potential for additive pharmacodynamic effects such as bone marrow suppression.

Decreased MPA trough concentrations have been reported when MMF is administered with CSA compared with those achieved when MMF is given with TAC or sirolimus. This interaction is most likely due to CSA interference with the enterohepatic recycling of MPAG, which results in decreased MPA concentrations.⁶⁸ To achieve equivalent MPA and MPAG concentrations, it is necessary to administer MMF 3 g/day with CSA compared with MMF 2 g/day with TAC.

■ Dosing and Administration

MMF is currently available in both oral and intravenous formulations. Although intravenous administration of equal doses closely mimics oral administration, the two cannot be considered bioequivalent.⁶⁹ Unlike other immunosuppressive agents, there is no compelling indication that MMF should be dosed in adult patients on a milligram per kilogram basis given the weak correlation between MPA AUC and body weight.⁵⁹ The dose of MMF for optimizing immunosuppression and minimizing adverse effects is 2 g/day administered in two divided doses given every 12 hours. The dose of MMF in heart transplantation is 3 g/day in two divided doses to achieve the necessary higher levels of immunosuppression. Pediatric doses of MMF are approximately 40 mg/kg per day in two doses. The total daily dose may be separated into three or four dosing intervals if patients are unable to tolerate the GI side effects.

With regard to therapeutic drug monitoring, plasma appears to be the most appropriate medium for measuring MPA. Better outcomes are associated with MPA AUC levels of greater than 42.8 mcg/mL per hour (by HPLC)⁷⁰ although a reference range of 30 to 60 mcg/mL per hour has been proposed.⁷¹ However, the correlation between MPA AUC levels and adverse effects is low. Further studies are required to determine the best modality to monitor MPA levels (AUC versus trough concentrations), the acceptable targets for each, and the appropriate strategy to monitor MPA levels.^{70,71}

■ MYCOPHENOLATE SODIUM

Mycophenolate sodium is an enteric-coated formulation of the sodium salt of mycophenolic acid designed to reduce the GI side effects of MMF. This formulation allows for mycophenolic acid to be released directly in the small intestine for absorption rather than in the stomach. Because mycophenolic acid is the activated form of MMF, the actions

are identical between the two. Likewise, the adverse effects are similar between the two, including the incidence of GI toxicity, despite the enteric coating. Clinical trials have demonstrated similar efficacy between MMF and mycophenolate sodium in kidney transplants both immediately following transplantation⁷² and in patients who were switched from MMF to mycophenolate sodium.⁷³ Mycophenolate sodium 1.44 g/day is therapeutically equivalent to MMF 2 g/day.⁷⁴

■ AZATHIOPRINE

Azathioprine, a prodrug for 6-mercaptopurine, has been used as an immunosuppressant in combination with glucocorticoids since the earliest days of the modern transplant era. It is associated with substantial toxicities, however, and its use has dramatically declined with the availability of newer, less toxic immunosuppressants.

■ Pharmacology/Mechanism of Action

Azathioprine is an inactive compound that is converted rapidly to 6-mercaptopurine (6-MP) in the blood and is subsequently metabolized by three different enzymes. Xanthine oxidase (XO), found in the liver and GI tract, converts 6-MP to the inactive final end product, 6-thiouric acid. Thiopurine methyltransferase (TPMT), found in hematopoietic tissues and red blood cells, methylates 6-MP to an inactive product, 6-methylmercaptopurine. Finally, hypoxanthine-guanine phosphoribosyltransferase (HGPRT) is the first step responsible for converting 6-MP to 6-thioguanine nucleotides (TGNs), the active metabolites, which are incorporated into nucleic acids, ultimately disrupting both the salvage and de novo pathways of DNA, RNA, and protein synthesis. This process is toxic to the cell and renders the cell unable to proliferate (see Fig. 87–1). TGNs eventually are catabolized by XO and TPMT to inactive products.

■ Pharmacokinetics

Oral bioavailability of azathioprine is approximately 40%. Metabolism of 6-MP is primarily by xanthine oxidase to inactive metabolites, which are excreted by the kidneys. The half-life of azathioprine, the parent compound, is very short, approximately 12 minutes. The half-life of 6-MP is longer, ranging from 0.7 to 3 hours. However, it is the activity of the TGNs that determines the pharmacodynamic half-life of the drug. The half-life of TGNs has been estimated to be 9 days once therapy has been stopped.⁷⁵

■ Adverse Effects

Dose-limiting adverse effects of azathioprine are often hematologic (see Table 87–4). Leukopenia, anemia, and thrombocytopenia can occur within the first few weeks of therapy and can be managed by dose reduction or discontinuation of azathioprine. Other common adverse effects include nausea and vomiting, which can be minimized by taking azathioprine with food. Alopecia, hepatotoxicity and pancreatitis are less common adverse effects of azathioprine; they generally are reversible on dose reduction or discontinuation.²⁶

■ Drug-Drug and Drug-Food Interactions

Allopurinol inhibits xanthine oxidase and can increase the bioavailability of azathioprine and 6-MP concentrations by as much as fourfold. The metabolic pathways shift to favor production of TGNs which

ultimately results in increased bone marrow suppression and pancytopenia. Doses of azathioprine should be reduced by 50% to 75% when allopurinol is added. Additional clinically significant drug interactions include other bone marrow-suppressing agents such as ganciclovir, sulfamethoxazole-trimethoprim, and sirolimus and other drugs that irritate the GI tract.

■ Dosing and Administration

Initial doses of azathioprine are 3 to 5 mg/kg per day intravenously or orally. Individualization to maintain the white blood cell count between 3500 and 6000 cells/mm may be accomplished in some with doses as low as 0.25 mg/kg per day.³ Patients often are instructed to take azathioprine in the evening when initiating or titrating therapy to allow for dose adjustments based on morning determinations of their white blood cell count.

■ SIROLIMUS (SRL)

8 Sirolimus (SRL), also known as rapamycin, is another immunosuppressive macrolide antibiotic that is structurally similar to TAC. It represents the first in the newest class of immunosuppressants, with a unique mechanism of action. The potential of SRL to decrease the incidence of chronic rejection remains to be seen.

■ PHARMACOLOGY/MECHANISM OF ACTION

The mechanism of action of SRL is distinct from CSA or TAC. SRL binds to FKBP12, but the resulting complex does not inhibit the activity of calcineurin. Whereas CSA and TAC inhibit cytokine production, SRL appears to inhibit the response to these cytokines. The SRL-FKBP12 complex binds to the mammalian target of rapamycin (mTOR) (see Fig. 1). IL-2 stimulates mTOR to activate kinases that ultimately advance the cell cycle from G₁ to the S phase. Thus the SRL-FKBP12 complex inhibits T-cell proliferation by inhibiting the cellular response to IL-2 and progression of the cell cycle.⁷⁶

■ PHARMACOKINETICS

SRL is a lipophilic compound. Bioavailability after oral administration is low, only 15%, with peak concentrations being reached within 1 to 2 hours.⁷⁶ SRL has a high volume of distribution, readily distributing into most tissues of the body. SRL binds extensively to erythrocytes because of the high FKBP12 concentration found in red blood cells (RBCs). Metabolism occurs primarily by CYP 3A4 both in the gut and in the liver. The half-life is reported to be 60 hours but can range up to 110 hours in patients with liver dysfunction.⁷⁷

■ EFFICACY

Currently, SRL is only approved for the prevention of rejection in kidney transplants in combination with corticosteroids and CSA or after withdrawal of CSA in patients with low to moderate immunologic risk.

Two concurrent clinical trials evaluated the use of SRL in kidney transplants. All patients in both studies received CSA and steroids and were randomly assigned to one of three groups. The U.S. trial compared patients randomly assigned to receive SRL in a fixed dose of a 6-mg loading dose followed by 2 mg daily (I), a fixed dose of a

15-mg loading dose followed by 5 mg daily (II), or azathioprine (III). The global trial used the same SRL administration arms (I and II) but compared patients with placebo (III). The results of both studies showed similar patient and graft survival in all groups at 12 months but lower rates of acute rejection in the SRL arms compared with azathioprine and placebo.^{78,79}

Studies evaluating early CSA withdrawal in SRL-based immunosuppressive protocols enrolled patients 3 months after transplant who were receiving SRL, which was adjusted based on trough blood concentrations, who did not have a recent or severe rejection episode and adequate renal function. Patients were randomly assigned to continue triple-drug therapy with SRL (adjusted to trough concentrations of greater than 5 ng/mL), CSA, and steroids or to double-drug therapy with SRL (adjusted to trough concentrations of 20 to 30 ng/mL) and steroids. The results showed a low risk of acute rejection following CSA discontinuation (5.6%) and no difference in graft survival. Long-term follow-up (2 years) showed improved renal function and blood pressure without an increase in acute rejection or graft loss in patients who discontinued CSA.⁸⁰

Currently, since the safety and efficacy of SRL has not been established in liver or lung transplants, it is recommended that its use be avoided in these populations immediately following transplant. In contrast, limited data on the use of SRL in heart transplantation indicate benefit in reversing acute rejection in patients who do not respond to antilymphocyte therapy.⁸¹ Furthermore, SRL may slow the progression of vasculopathy, which may have an impact on chronic rejection and long-term patient survival after heart transplantation.⁸²

Use of SRL and TAC concomitantly was avoided in early studies because it was thought that the two would compete for FKBP12 receptor binding sites. However, clinical experience has demonstrated that this is not the case, and literature now substantiates the efficacy of SRL in combination with TAC.^{83,84} SRL has also demonstrated efficacy in combination with MMF in kidney transplants to avoid the use of CIs and decrease the risk of nephrotoxicity.^{85,86}

ADVERSE EFFECTS

Myelosuppression associated with SRL appears to be dose-related. Thrombocytopenia is usually seen within the first 2 weeks of SRL therapy but generally improves with continued treatment. Leukopenia and anemia caused by SRL typically are transient.⁸⁷ SRL levels greater than 15 ng/mL have been correlated with thrombocytopenia and leukopenia.⁸⁸ Hypercholesterolemia and hypertriglyceridemia are quite common in patients receiving SRL. It is postulated that the mechanism of this adverse effect is related to an overproduction of lipoproteins or inhibition of lipoprotein lipase. Peak cholesterol and triglyceride levels are often seen within 3 months of starting SRL but usually decrease after 1 year of therapy and can be managed by reducing the dose, discontinuing SRL, or by starting therapy with a HMG-CoA reductase inhibitor or fibric acid derivative. One recent study suggests that the dyslipidemia associated with SRL is not a major risk factor for early cardiovascular complications following kidney transplant.⁸⁹ Reports of delayed wound healing and wound dehiscence could be due to inhibition of smooth muscle proliferation and intimal thickening.⁹⁰ Mouth ulcers also have been reported with SRL, more commonly with the oral solution. The cause may be a direct effect of the drug or secondary to activation of herpes simplex virus.⁹¹ Interstitial pneumonitis has been described in kidney, liver, and heart-lung transplant recipients that is reversible after discontinuing SRL.⁷⁷ Other adverse effects reported with SRL include increased liver enzymes, hypertension, rash, acne, diarrhea, and arthralgia (see Table 87-4).

DRUG-DRUG AND DRUG-FOOD INTERACTIONS

CYP 3A4 is the major metabolic pathway for SRL; thus the drug interactions mediated by induction or inhibition of the CYP 3A4 enzyme system are similar to those seen with CSA and TAC (see Table 87-6). Administration of the microemulsion formulation of CSA with SRL significantly increases the *AUC* and trough SRL levels. The same is not seen with the standard formulation of CSA. Conversely, CSA concentrations and *AUC* are also increased by SRL. The mechanism is proposed to be competitive binding to CYP 3A4 and *p*-glycoprotein.⁷⁷ It is recommended that patients separate the dose of SRL and CSA by 4 hours to minimize the interaction.⁹² Concomitant administration of TAC does not affect SRL levels.⁹³

As with CSA and TAC, grapefruit juice produces increases in SRL levels. Administration of SRL with a high-fat meal was associated with a delayed rate of absorption, decreased C_{max} , and increased *AUC*, indicating an increase drug exposure, whereas the half-life remained unchanged.⁹⁴ The clinical significance of this is unknown.

DOSING AND ADMINISTRATION

A fixed SRL dosing regimen is approved for concomitant use with CSA that includes a loading dose of 6- or 15-mg followed by 2 or 5 mg daily, respectively. Therapeutic monitoring of SRL is advocated using whole blood concentrations measured by HPLC, which is specific for the parent compound to a target level of 10 to 15 ng/mL when used in combination with a CI or, 15 to 25 ng/mL, when used in regimens that include CSA withdrawal. When RIA is used, which measures the parent compound and metabolites, reference ranges of 15 to 20 ng/mL and 20 to 30 ng/mL should be used, respectively.

CLINICAL CONTROVERSY

Routine therapeutic drug monitoring of SRL therapy is not recommended in patients who are receiving triple-drug therapy with CSA and steroids. However, many clinicians now feel that SRL drug levels should be monitored in all patients, although there is no accepted therapeutic range.

POLYCLONAL ANTIBODIES (ANTITHYMOCYTE GLOBULINS)

There are currently two antithymocyte globulins available in the United States: ATG (ATGAM[®]), an equine polyclonal antibody, and RATG (Thymoglobulin[®]), a rabbit polyclonal antibody. The rabbit preparation is less immunogenic and may have other advantages over the equine preparation. Both ATG and RATG are currently approved only for the treatment of rejection; however, the drugs are used often as induction therapy to prevent acute rejection.

PHARMACOLOGY/MECHANISM OF ACTION

Because of their polyclonal antibody nature, both ATG and RATG exert their immunosuppressive effect by binding to a wide array of lymphocyte receptors, including CD2, CD3, CD4, CD8, CD25, and CD45, among others. Binding of ATG or RATG to the various

receptors results in complement-mediated lysis and subsequent lymphocyte depletion. T cells are the major lymphocytic target for the compounds; however, other blood cell components are also affected, including B cells and other leukocytes (see Fig. 87–1). Damaged T cells are removed subsequently by the spleen, liver, and lungs.

■ PHARMACOKINETICS

ATG is poorly distributed into lymphoid tissue and binds primarily to circulating lymphocytes, granulocytes, and platelets. The terminal half-life of ATG is 5.7 days. RATG has a volume of distribution of 0.12 L/kg. The terminal half-life in renal transplant recipients is significantly longer than ATG at 30 days.⁹⁵ Peak plasma concentrations are reached after 5 to 7 days of ATG or RATG infusions. Antiequine antibodies can form in up to 78% of patients receiving ATG therapy. Similarly, antirabbit antibodies can form in up to 68% of patients receiving RATG therapy. The effects of preformed antibodies on the efficacy and safety of these preparations has not been studied adequately.

■ EFFICACY

ATG and RATG are used most commonly for the treatment of acute allograft rejection or as induction therapy to prevent acute rejection. ATG is currently approved for both indications in kidney transplants. RATG, however, is approved only for the treatment of acute allograft rejection in kidney transplants. However, both drugs have been studied extensively for both indications.

The efficacy of ATG and RATG induction therapy has been described in liver and heart transplant recipients. Use of RATG as part of quadruple therapy in liver transplant is associated with similar rates of patient and graft survival and acute rejection compared with dual therapy; however, a significant increase in the number of CMV infections was noted. The clinical usefulness of quadruple therapy is questionable in light of the increased cost.⁹⁶ Quadruple-drug therapy results in similar rates of patient and graft survival and malignancy in heart transplants, but a significantly lower rate of acute rejection and infection episodes is seen at 1 year compared with triple-drug therapy.⁹⁷

■ ADVERSE EFFECTS

Most adverse effects reported with ATG and RATG are related to the lack of specificity for T cells owing to their polyclonal nature. Dose-limiting myelosuppression, including leukopenia, anemia, and thrombocytopenia, occurs frequently. Other adverse effects include anaphylaxis, hypotension, hypertension, tachycardia, dyspnea, urticaria, and rash (see Table 87–4). Serum sickness is seen more frequently with ATG than RATG. Nephrotoxicity has been reported but is rare in the absence of serum sickness. Infusion-related febrile reactions are most common with the first few doses and can be managed by premedicating the patient with acetaminophen, diphenhydramine, and steroids. Finally, as with any immunosuppressive agent, ATG and RATG are associated with an increased risk of infections, particularly viral infections, and malignancy.

■ DRUG-DRUG AND DRUG-FOOD INTERACTIONS

Administration of ATG or RATG can interfere with the immune response to live vaccines, such as varicella vaccine. Immune globu-

lins, including ATG and RATG, should not be administered within 2 months of receiving a live vaccine.

■ DOSING AND ADMINISTRATION

ATG doses range from 10 to 30 mg/kg per day as a single dose for 7 to 14 days. RATG is a more potent compound and is administered at doses of 1 to 1.5 mg/kg per day as a single dose for 7 to 14 days for rejection or for 5 to 10 days for induction of immunosuppression. It is recommended that both ATG and RATG be administered centrally or through a high-flow vein with an in-line 0.22-micron filter over at least 4 hours to minimize phlebitis and thrombosis. However, literature supports peripheral administration of both agents.^{98,99}

■ MONOCLONAL ANTIBODIES

■ INTERLEUKIN 2 RECEPTOR ANTAGONISTS (IL2RA)

There are currently two available interleukin 2 receptor antagonists, basiliximab, a chimeric monoclonal antibody (25% murine), and daclizumab, a humanized monoclonal antibody (90% human, 10% murine). Daclizumab contains a greater proportion of human sequences, making it theoretically less immunogenic. The percentage of murine component determines the antibody's affinity for the epitope. Therefore, the chimeric antibody basiliximab has a higher affinity than daclizumab.¹⁰⁰

■ Pharmacology/Mechanism of Action

Both basiliximab and daclizumab exert their immunosuppressive effect by specifically binding to the alpha chain (CD25) on the surface of activated T-lymphocytes (see Fig. 87–1). Binding of either basiliximab or daclizumab to the IL-2 receptor prevents IL-2-mediated activation and proliferation of T cells, a critical step in clonal expansion of T cells and the development of allograft rejection. Saturation of the IL-2 receptor occurs rapidly and confers immunosuppressive effect immediately.¹⁰⁰

■ Pharmacokinetics

Most of the pharmacokinetic data available for both basiliximab and daclizumab are in renal transplant patients. Caution must be used when extrapolating these data to non-renal-transplant recipients. Daclizumab has a small volume of distribution, approximately 5.3 L. The system clearance is highly variable and depends on body weight. The terminal half-life of daclizumab is about 20 days in renal transplant patients compared with 3 to 4 days in bone marrow transplant recipients. Specific data on the pharmacokinetics of daclizumab in liver transplant patients are lacking, but the half-life appears to be significantly lower compared with renal transplant recipients. It has been suggested that the increased elimination rate seen in liver transplant recipients may be due to significant intraoperative blood losses as well as loss via ascites. Therapeutic concentrations are 5 to 10 mg/L. Adjustments are not required on the basis of weight, race, gender, or degree of proteinuria.

Basiliximab has a slightly higher volume of distribution, 8 L, and a shorter half-life, approximately 7 days. Additionally, the half-life of basiliximab appears to be lower in liver transplant recipients. Increased blood loss did not account for this difference in

elimination, but losses via ascites accounted for about 20% of basiliximab elimination. It has been recommended that patients with volumes of ascites greater than 10 L receive an additional dose of basiliximab on postoperative day 8.¹⁰¹ While drug elimination is enhanced in liver transplants, receptor suppression with the two-dose regimen seems to be long lasting.¹⁰² Both basiliximab and daclizumab saturate CD25 *in vivo* at serum concentrations of 0.2 and 1 mg/L or greater, respectively.¹⁰³

■ Efficacy

Induction therapy with IL-2 receptor antagonists has been studied extensively in kidney, liver, and heart transplants.^{102–107} A meta-analysis of daclizumab and basiliximab in renal transplantation evaluated the result of eight randomized, controlled trials involving more than 1800 patients. IL-2 receptor antagonists reduced the risk of rejection significantly (odds ratio 0.51) in CSA-based regimens at 6 months. No increases in graft loss, infectious complications, malignancy, or death were noted.¹⁰⁴ Review of the daclizumab trials continued to show less biopsy-proven rejection at 1 year, 28% versus 43% ($p < 0.0001$) in the daclizumab (both double- and triple-therapy combined) and standard-therapy arms, respectively. No graft or patient survival advantage was found for daclizumab-treated patients, but the studies were not powered to detect this difference.¹⁰³

A large multicenter, randomized trial of 381 liver transplant recipients compared basiliximab with CSA and steroids alone. The results showed a decrease in acute rejection in the basiliximab group regardless of hepatitis C virus (HCV) status, although only the HCV-negative cohort was statistically significant.¹⁰² Other investigators have reported higher rates of HCV recurrence in patients receiving daclizumab (54% versus 15%).¹⁰³ The most effective IL-2 receptor antagonist regimens remain to be defined, particularly for those with HCV.

In heart transplantation, induction with daclizumab produced favorable results with a lower incidence of acute rejection: 18% in the daclizumab-treated patients compared with 63% in the group receiving CSA, MMF, and prednisone with no induction therapy ($P = 0.04$). The time to occurrence of the first rejection episode also was significantly longer in the daclizumab-treated patients.¹⁰⁶ There were no adverse reactions to daclizumab and no significant differences between the groups in the incidence of infection or cancer during follow-up. Data for basiliximab in heart transplant recipients are lacking.

IL-2 receptor antagonists offer a reasonable addition to CI- or steroid-sparing protocols. In renal transplant recipients, 40% to 50% of patients receiving daclizumab with no initial CI required the eventual addition of CSA.¹⁰³ Alternative protocols using low-dose CSA in conjunction with daclizumab, MMF, and steroids showed similar results to matched controls¹⁰⁷ and lower rejection rates compared with OKT3 induction.¹⁰⁰ Basiliximab has been used in combination with low-dose TAC in patients with early evidence of DGF. Similar rates of rejection and steroid-resistant rejection were seen in patients who received basiliximab (20 mg at the time of diagnosis of DGF and again 5 days later) in conjunction with lower TAC doses compared with patients without DGF who received standard TAC doses and no IL2RA induction.¹⁰⁰

■ Adverse Effects

Few adverse effects have been reported with basiliximab and daclizumab (see Table 87–4). In clinical trials, these drugs were asso-

ciated with no increased risk of infectious complications or malignancy when compared with standard immunosuppression. In contrast to polyclonal antibody preparations and OKT3, basiliximab and daclizumab have not been associated with infusion-related reactions. However, since the marketing of basiliximab, an increased number of hypersensitivity reactions have been reported. Of note, only one patient developed anti-idiotypic antibodies to the murine portion during clinical trials.¹⁰⁰ The manufacturer of basiliximab reported an increase in mortality in a placebo-controlled trial, which was associated with an increase in severe infections.

■ Drug-Drug and Drug-Food Interactions

Reports of increased CSA and TAC levels in patients receiving concomitant basiliximab have recently been published.^{109,110} Both authors hypothesized a potential interaction with the cytochrome P450. No drug interactions have been reported with daclizumab.

■ Dosing and Administration

Basiliximab is administered as two 20-mg intravenous doses: intraoperatively and again on postoperative day 4. Basiliximab is compatible with both 0.9% sodium chloride and 5% dextrose and can be administered either centrally or peripherally over 20 to 30 minutes in a solution of 50 mL. This regimen results in saturation of the IL-2 receptor for 30 to 45 days. The daclizumab approved dosing regimen for renal transplantation is 1 mg/kg every 2 weeks from the time of transplant for a total of five doses. Daclizumab should be diluted in 50 mL sterile 0.9% sodium chloride and administered peripherally or centrally over 15 minutes. This regimen saturates the IL-2 receptors for approximately 90 to 120 days after renal transplantation.^{56,100}

Alternative dosing regimens have been proposed for daclizumab in combination with TAC, MMF, and steroids: 1 mg/kg every 2 weeks for five doses or, daclizumab 2 mg/kg every 2 weeks for two doses. At 6 months, the probability of kidney or pancreas allograft rejection and patient survival was similar in the daclizumab groups. This is an important finding because the two-dose regimen may have considerable implications for posthospital administration.¹⁰⁸ Eckhoff and colleagues¹¹¹ compared liver transplant recipients at risk for renal dysfunction who received daclizumab 2 mg/kg on day 0 followed by daclizumab 1 mg/kg on day 5 with a group who received conventional immunosuppression without daclizumab. There were fewer rejection episodes in the daclizumab group, and graft and patient survival were similar.¹¹¹

■ MUROMONAB-CD3 (OKT3)

■ Pharmacology/Mechanism of Action

Muromonab-CD3 (OKT3) is a murine monoclonal antibody to the CD3 receptor on mature human T cells (see Fig. 87–1). Minutes following the administration of OKT3, T-cell concentrations decrease dramatically, as measured by CD3 levels. Cells reappear after a few days but bear no CD3 receptors. After cessation of OKT3 therapy, T-cell function normalizes in a week.¹¹²

■ Pharmacokinetics

OKT3 has a volume of distribution of 6.5 L and half-life of about 18 hours. Concentrations above 0.9 mcg/mL are considered

therapeutic. OKT3 concentrations of 800 ng/mL or greater in combination with a CD3+ T cell counts of <25 cells/mL is also a reasonable therapeutic target. If CD3 levels begin to rise, this may signify the presence of antimurine antibodies antagonizing OKT3. Administration of MMF has been suggested to reduce the formation of antimurine antibodies during OKT3 administration. While T-cell depletion is achieved within minutes of administration, resolution of rejection takes 3 to 4 days.

■ Efficacy

OKT3 generally is reserved for steroid-resistant rejection, but it also has been used as induction therapy. Induction with the conventional OKT3 dose (5 mg/day for 7 to 14 days) effectively prevents rejection in renal transplant recipients. OKT3 can be used safely and successfully as rejection therapy in patients who have undergone previous OKT3 induction.¹¹² Specifically, these studies confirm that the presence of low anti-OKT3 antibody titers ($\leq 1:100$) does not preclude successful retreatment with OKT3 for rejection.

A sequential induction protocol using OKT3 is more cost-effective than conventional therapy in renal transplantation.¹¹³ Furthermore, low-dose administration of OKT3 in this setting additionally may enhance cost-effectiveness. The exact role of OKT3 in induction therapy needs to be further defined (i.e., high- versus low-risk patients and conventional versus reduced dosing).

In addition to maintenance therapy, a number of heart transplant centers use either monoclonal or polyclonal induction agents including the IL2RAs (e.g., basiliximab or daclizumab), OKT3, or the antithymocyte globulins (e.g., ATG or RATG) for short periods of time immediately after transplantation in high-risk patients (e.g., high PRA, retransplants) or to spare the kidney from exposure to the nephrotoxicity of CSA or TAC.¹¹² To date, pooled data series show no clearcut survival advantages with induction therapy, although it appears that a higher percentage of patients may be weaned from prednisone, thereby reducing the incidence of steroid-associated complications.¹¹² Controversy exists as to whether prophylactic therapy with these cytolytic agents confers any added benefit other than delaying the onset of the first rejection episode.¹¹² In addition, this combination therapy is very expensive, inconvenient to administer, possibly alters the incidence and character of infectious complications, and may result in a higher incidence of malignancy.

■ Adverse Effects

OKT3 administration is associated with significant first-dose adverse reactions. The cytokine-release syndrome related to OKT3, including fever, chills, rigors, pruritus, and alterations in blood pressure, may occur with the first several doses. Methylprednisolone, acetaminophen, diphenhydramine, indomethacin, and pentoxifylline may be used as premedications. Other adverse effects include capillary leak syndrome and pulmonary edema, which may be particularly associated with OKT3 use in fluid overloaded patients (see Table 87-4). It is recommended that patients be within 3% of their dry weight and have chest x-rays evaluated prior to administration. Aseptic meningitis is another potential complication of OKT3 therapy. If encephalitic symptoms develop, OKT3 should be discontinued and appropriate care initiated. Other adverse effects include encephalopathy, nephrotoxicity, infection, and posttransplant lymphoproliferative disorder.⁵⁶

■ Drug-Drug and Drug-Food Interactions

No drug or food interactions have been reported with OKT3.

■ Dosing and Administration

OKT3 should be filtered with a 0.2- to 0.22-micron filter and then administered as intravenous push over 1 minute. The dose of OKT3 usually is 5 mg/day for 5 to 14 days. Induction with 2.5 mg also has been used effectively.¹¹² Vital signs should be assessed frequently during the first few doses, and it is advisable to have a physician present for the first dose. A high proportion of patients treated with OKT3 form antibodies to one of the components of OKT3 and may not be able to receive or adequately respond to retreatment.¹¹²

■ INVESTIGATIONAL AGENTS

■ ALEMTUZUMAB

Alemtuzumab is a humanized monoclonal antibody directed at cells that express the CD52 surface antigen which is found on both T- and B-lymphocytes, as well as macrophages, monocytes, and natural killer (NK) cells. When alemtuzumab binds to the CD52 surface antigen, antibody-dependent lysis occurs, which removes T cells from the blood, bone marrow, and organs, resulting in T-cell depletion.

The adverse effects of alemtuzumab include infusion-related reactions, hematologic effects, and infections. Infusion-related reactions include rigors, hypotension, fever, shortness of breath, bronchospasms, and chills. The potential for developing these reactions can be reduced by administering premedications, including steroids, diphenhydramine, and acetaminophen or by administering smaller doses and escalating the dose gradually. Hematologic effects include pancytopenia, neutropenia, thrombocytopenia, and lymphopenia. Dose modifications are recommended based on the degree of thrombocytopenia.

Several dosing regimens have been proposed for alemtuzumab in solid-organ transplantation. For induction therapy, the most commonly reported doses in the literature are 0.3 mg/kg per dose, as a single or multiple dose regimen 20 mg times two doses given on days 0 and 1, 30 mg given on day 0 or 30 mg times two once on day 0 and once again between day 1-5.¹¹³⁻¹¹⁷ The latter dosing scheme is currently recommended for use in most patient situations.¹¹⁷ Early experience indicates that monotherapy with CSA, TAC, or SRL may be used following alemtuzumab induction.¹¹⁴⁻¹¹⁸

CLINICAL CONTROVERSY

New immunosuppressive protocols are being used to promote tolerance in transplant recipients to avoid long-term use of immunosuppressants. These protocols typically use high doses of RATG or alemtuzumab before transplantation and low-dose immunosuppression after transplantation with gradual weaning.

■ EVEROLIMUS

Everolimus, also known as SDZ-RAD or RAD, is a rapamycin derivative (RAD) with similar immunosuppressive activity as SRL. Everolimus binds to FKBP12 and inhibits mTOR and the cellular response to IL-2, ultimately preventing progression of the cell cycle. It

is a lipophilic compound that readily distributes into RBCs, as well as into tissues. The half-life of everolimus is shorter than SRL at 16 to 19 hours, lending itself to twice-daily dosing as compared with once-daily dosing with SRL.¹¹⁹

Adverse effects of everolimus are similar to SRL. Thrombocytopenia and leukopenia are common within the first 2 months of therapy. Both total cholesterol and triglyceride levels also increase with everolimus use and generally peak within the first month of therapy.¹²⁰ Increases in cholesterol values appear to plateau after 2 to 3 months of therapy, most likely as the result of the initiation of antihyperlipidemic agents. The hematologic and cholesterol adverse effects have been reported to occur when RAD concentrations are within the accepted therapeutic range of 7–15 ng/mL.¹²¹ Significant increases in serum creatinine were noted in phase III studies using everolimus with full-dose CSA. This is believed to be caused by CSA. Improved renal function has been noted in trials investigating reduced-dose CSA, which are ongoing.¹²²

Phase III clinical trials currently are evaluating doses of 0.75 mg twice daily and 1.5 mg twice daily in combination with CSA and steroids. Favorable preliminary results in kidney and heart transplant recipients are suggested by the decrease allograft loss and death.¹²³

LEFLUNOMIDE

Leflunomide is a prodrug the active metabolite of which inhibits *de novo* pyrimidine synthesis and tyrosine kinase activity in T- and

B-lymphocytes. It is currently approved for use in rheumatoid arthritis. Bioavailability is 80% after oral administration. Leflunomide is metabolized in the liver to the active metabolite A77,1726. Biliary recirculation of A77,1726 contributes to the long half-life of 15 to 18 days. Adverse effects noted with leflunomide in solid-organ transplantation studies include skin rash, anemia, and elevated liver enzymes.

Studies of leflunomide in kidney and liver transplant recipients utilized a loading dose of 200 mg daily for 7 days, followed by a maintenance dose of 40 to 60 mg daily. The target concentration appears to be 50 to 80 mcg/mL, which also allows for lower doses of steroids and CIs.¹²⁴ A small open-label pilot study reported potential benefit with leflunomide in reversing chronic renal allograft dysfunction.¹²⁵

FTY-720

FTY-720 is a novel immunosuppressant that alters lymphocyte migration via alteration of adhesion molecules. The resulting effect is a transient sequestration of T cells into lymphoid organs away from the allograft. Preliminary data from clinical trials indicate that FTY-720 is effective in reducing CSA doses in renal transplant recipients. FTY-720 has shown promise in preventing and reversing chronic rejection in animal models.¹²⁶ Early experience in clinical trials indicated that FTY-720 is associated with bradycardia compared with other immunosuppressants, namely, MMF,¹²⁷ but the effects are reported to be transient and usually occur following the first dose.¹²⁸ Phase III human trials in kidney transplantation are currently underway.

EVALUATION OF THERAPEUTIC OUTCOMES

The success of transplantation can be measured in terms of length of graft and patient survival or quality of life. Several donor and recipient factors have been identified that have an impact on graft and patient survival (Table 87–8). Estimated half-lives for kidneys are 26.9 years for HLA-identical grafts and 12.2 and 10.8 years, respectively, for grafts from a sibling or parent who are 1-haplotype matches. The estimated half-life for HLA-matched grafts was 17.3 and 7.8 years for mismatched kidneys.²¹ The overall median survival time for heart transplant recipients is 9.8 years, and for patients surviving the first year after transplantation, the median survival is 12 years.¹ The highest rate of mortality occurs within the first year

after liver transplantation owing to the risks of surgery and early postoperative complications but progressively decline after the first year. A typical post-transplantation laboratory monitoring plan is depicted in Table 87–9.

IMMUNOSUPPRESSION-RELATED COMPLICATIONS

Comorbidities such as cardiovascular disease and malignancy, recurrent disease, drug toxicities (namely nephrotoxicity), and chronic rejection are the primary causes of mortality in patients beyond year five after transplantation.¹ Special considerations for therapy in transplant patients are discussed below and are summarized in Table 87–10.

TABLE 87–8. Factors Affecting Allograft and Patient Survival

| | Kidney | Liver | Heart |
|-------------------|--|--|---|
| Donor factors | HLA matching Age Serum creatinine Cardiac instability Prolonged ischemia time History of hypertension | Size mismatch Age (youngest, oldest) | Size mismatch Age Ischemia time |
| Recipient factors | Age <15, >50 years Retransplantation African race PRA Multiparous women Drug compliance | Age Retransplantation African race ICU pretransplant ABO blood type Drug compliance | Age <5, >60 years ICU pretransplant Mechanical ventilation LVAD IABP Drug compliance |

HLA = human leukocyte antigens; PRA = panel of reactive antibodies; LVAD = left ventricular assist device; IABP = intraaortic balloon pump.

TABLE 87–9. Laboratory Monitoring After Transplantation and Example of Frequency Parameters

| | 1–2 weeks | 1 month | 2–4 months | 4–12 months | >12 months |
|---------------------------|-----------|--------------------|-----------------|------------------|------------------|
| SCr/BUN | Daily | 1–2 times per week | Every 1–2 weeks | Monthly | Every 1–2 months |

| Liver function tests | | | | | |
| Kidney or heart recipient | Once | Once | Monthly | Every 1–3 months | Every 1–3 months |
| Liver recipient | Daily | 1–3 times per week | Every 1–2 weeks | Monthly | Every 1–2 months |
| Immunosuppressant level | Daily | 1–2 times per week | Every 1–2 weeks | Monthly | Every 1–2 months |
| Complete blood count | Daily | 1–2 times per week | Every 1–2 weeks | Monthly | Every 1–2 months |
| Lipid panel | Once | Every 3 months | Every 3 months | Every 3 months | Every 3 months |
| HbA1c | Once | Every 3 months | Every 3 months | Every 3 months | Every 3 months |

Chemistries include sodium, potassium, chloride, CO₂ content, magnesium, calcium, phosphorus and blood glucose.

Liver function tests include total bilirubin, aspartate transaminase (AST), alanine transaminase (ALT), gamma glutamyl transpeptidase (GGTP), alkaline phosphatase.

Complete blood count includes white blood cells (WBC), red blood cells (RBC), platelets and/or differential.

Lipid panel includes total cholesterol, low-density lipoprotein (LDL), high-density lipoprotein (HDL), triglyceride and/or very low-density lipoprotein (VLDL).

SCr = serum creatinine; BUN = blood urea nitrogen; HbA1c = hemoglobin A1c.

CARDIOVASCULAR DISEASE

Cardiovascular disease is a leading cause of morbidity and mortality in transplant patients.¹²⁹ Preexisting cardiovascular disease, which is common in end-stage organ failure, is not reversed with transplantation. Additionally, hypertension, hyperlipidemia, and diabetes are common complications in transplant recipients and are independent risk factors that contribute significantly to cardiovascular disease. Chronic rejection has been linked to hypertension and hyperlipidemia.^{130,131}

HYPERTENSION

Corticosteroids, CSA, TAC, and impaired kidney graft function may cause post-transplant hypertension. The primary mechanism of CI-associated hypertension in heart transplant recipients may be related to the CI-induced stimulation of intact renal sympathetic nerves and the absence of reflex cardiac inhibition of the sympathetic nervous system, but a number of other mechanisms, including decreased prostacyclin and nitric oxide production, also have been proposed.^{54,132,133} In addition to the propensity to cause peripheral vasoconstriction, CIs promote sodium retention, resulting in extracellular fluid volume expansion. TAC appears to have less potential to induce hypertension following transplantation than CSA.¹³⁴ Most classes of antihypertensive medications effectively reduce blood pressure in transplant patients (see Chap. 13).¹³⁵

Calcium channel blockers traditionally have been the first-line agents to treat hypertension after transplantation.¹³⁶ In addition to their ability to control blood pressure, calcium channel blockers may ameliorate the nephrotoxic effects of CSA, improve renal hemodynamics, decrease the incidence of delayed graft function and development of allograft atherosclerosis, and provide some immunosuppression. Calcium channel blockers, however, also may contribute to gingival hyperplasia that is often associated with CSA-based immunosuppression.¹³⁰ CYP 3A4 interactions with CSA and TAC are of concern with this class of medications, particularly with diltiazem, verapamil, and nifedipine, and CSA or TAC concentrations must be monitored to ensure proper dosage adjustments.

ACEIs and angiotensin II receptor blockers (ARBs) traditionally have been avoided in kidney transplant recipients because of the potential for hyperkalemia and decreased glomerular filtration rate. ACEIs and ARBs are now considered to be an equivalent alternative to calcium channel blockers for the treatment of hypertension in all transplant recipients. When ACEIs or ARBs are used in patients after transplantation, serum creatinine and potassium levels should be mon-

itored closely. If the increase in serum creatinine is greater than 30% within 1–2 weeks after initiating ACEIs or ARBs, the drug should be discontinued and other measures used to control blood pressure (see Chap. 46).

CLINICAL CONTROVERSY

Many clinicians avoid using ACEIs in kidney transplant recipients because of the potential to decrease the glomerular filtration rate by promoting efferent arteriole vasodilation in the presence of CI-induced afferent arteriole vasoconstriction. Emerging evidence suggests that this situation does not occur. ACEIs should be avoided in recipients with renal artery stenosis or discontinued in recipients who have an acute significant elevation in serum creatinine after ACEI initiation.

Multiple antihypertensive agents usually are necessary to achieve the goal blood pressure in transplant recipients. Therefore, the addition of β -blockers, diuretics, or centrally acting antihypertensives usually is necessary. β -blockers generally are considered to be second-line therapy in solid-organ transplant recipients, because of the potential to worsen metabolic disturbances caused by immunosuppressants, such as hyperkalemia and dyslipidemia. CI-induced hypertension is often salt-sensitive, making it very responsive to diuretics. Central-acting agents (e.g., clonidine) are used often as adjunctive therapy in transplant recipients who are not able to achieve blood pressure control with calcium channel blockers or ACEIs.

HYPERLIPIDEMIA

Hyperlipidemia may be exacerbated by corticosteroids, CIs, diuretics, and β -blockers.¹³⁷ Corticosteroids promote insulin resistance and a decrease in lipoprotein lipase activity, as well as excessive triglyceride production. The mechanism of CI-induced hyperlipidemia is not well understood. CIs may decrease the activity of the low-density lipoprotein (LDL) receptor or lipoprotein lipase, altering LDL catabolism.¹³¹ TAC appears to have less potential to induce hyperlipidemia than CSA.^{44,45,138} Post-transplant hyperlipidemia is characterized by elevated LDL, very-low-density lipoprotein (VLDL), triglyceride apolipoprotein B, and lipoprotein(a) levels.¹³¹ It is controversial whether the management of hyperlipidemia in transplant recipients should be more aggressive than current guidelines for the general population established by the National Cholesterol Education Program (NCEP).¹³⁹ Aggressive lipid lowering may not only

TABLE 87–10. Special Pharmacotherapy Considerations in Transplant Recipients

| Problem | Pharmacotherapy | Special Considerations |
|---|---|---|
| Infection | | |
| Perioperative prophylaxis | | Donor culture results Penicillin allergy: vancomycin |
| <i>Pneumocystis carinii</i> pneumonia prophylaxis | Bowel decontamination TMP/SMX 400/80 qd or tiw Pentamidine 300 mg inhaled q mo OR Dapsone 50–100 mg po qd | Sulfa allergy |
| Fungal Prophylaxis Treatment | Nystatin, clotrimazole Fluconazole, itraconazole, ketoconazole Amphotericin B | Inhibit P450 3A4; monitor CSA and TAC levels; decrease doses Consider liposomal products; decrease or stop CSA or TAC to minimize nephrotoxicity Remember to adjust doses of renally eliminated drugs, e.g., acyclovir, ganciclovir, TMP-SMX May be exacerbated by CSA or TAC or ACEIs, acidosis or RI; fludrocortisone acetate 0.1 mg PO qd–bid for refractory hyperkalemia |
| Hyperkalemia | Restrict dietary intake; dialysis | |
| Hyperglycemia | | |
| Diabetes pretransplant | Insulin Oral hypoglycemics | Glucocorticoids, TAC, and CSA also increase hypoglycemic requirements Insulin requirements will increase with improving renal function |
| Post-transplant diabetes | Metformin Insulin Oral hypoglycemics | Avoid in those with RI Risk factors: Obesity, family history, African-American race, cadaveric kidney, TAC > CSA May resolve/improve as immunosuppressive doses decrease |
| Ulcer Prophylaxis | H ₂ -receptor antagonists Sucralfate | Adjust dose in those with RI Decreased TAC absorption If RI: Caution aluminum content No RI: Caution hypophosphatemia |
| Hyperlipidemia | Proton pump inhibitors Diet HMG-CoA reductase inhibitors (“statins”) Gemfibrozil | CSA > TAC; consider switch to TAC; discontinue or hold SRL CSA/TAC may increase “statin” levels; start at lowest dose Monitor for muscle cramps, CPK levels and LFTs Adjust dose in those with RI Caution with concomitant “statin” |
| Hypertension | Calcium channel blockers ACE inhibitors; angiotensin II receptor antagonists | Diltiazem, verapamil inhibit CSA/TAC metabolism Dihydropyridines may potentiate CSA-gingival hyperplasia May exacerbate hyperkalemia Monitor K ⁺ , S _{Cr} to assess for renal allograft vascular disease; may be useful in post-transplant erythrocytosis (HCT > 55%) |
| Osteoporosis | Oral calcium supplementation (1000–1500 mg/day) Oral vitamin D Calcifediol (1000 IU/day) Calcitriol (0.5 mcg/day) Hormone-replacement therapy Calcitonin or oral bisphosphonates | If daily intake <1000 mg elemental calcium Documented deficiency If kidney functioning If kidney not functioning Postmenopausal women without contraindications Documented loss in bone mineral density > 3% Data lacking for bisphosphonates in patients with RI |
| Malignancy | | |
| Prevention | Minimize immunosuppressant doses; avoid sun exposure (sun block, hats, clothing); routine self-examinations (skin, lymph nodes); yearly gynecologic/prostate exams | AZA particularly associated with skin cancers CSA/TAC may be associated with lymphoproliferative disorders (lymphomas) |
| Treatment | Discontinue or minimize immunosuppressants Surgical, radiologic, or anti-neoplastic therapy | Do not abruptly withdraw corticosteroids |

TMP-SMX = trimethoprim-sulfamethoxazole; CSA = cyclosporine; TAC = tacrolimus; ACEI = ACE inhibitor; RI = renal insufficiency; CMV = cytomegalovirus; SRL = sirolimus; CPK = creatinine phosphokinase enzymes; LFTs = liver function tests; K⁺ = potassium; S_{Cr} = serum creatinine; HCT = hematocrit.

arrest the progress or prevent the complications of atherosclerosis but also may promote graft survival in the kidney and heart transplant population. With the use of lipid-lowering agents, potential interactions with immunosuppressive regimens must be considered.

Dietary intervention, although safe, may be relatively ineffective for the treatment of hyperlipidemia in the transplant population. Along with dietary modification, dose reduction or withdrawal of CSA and/or steroids may assist in minimizing hyperlipidemia. For most patients, the combination of dietary intervention and an HMG-CoA reductase inhibitor should be considered the treatment of choice. HMG-CoA reductase inhibitors are highly effective in the treatment of hyperlipidemia, especially increased LDL, in transplant patients. HMG-CoA reductase inhibitors as a class have been shown to have immunomodulatory effects on MHC expression and T-cell activation and have been shown to reduce cardiac allograft rejection.^{131,140}

HMG-CoA reductase inhibitors should be used with caution in transplant recipients because of several reports of rhabdomyolysis when these agents are combined with CIs.^{35,50,140} Safety measures, including the use of low HMG-CoA reductase inhibitor doses and avoiding inappropriately high CSA or TAC concentrations. The concurrent use of medications known to increase the risk of myopathy (such as gemfibrozil) should be avoided.¹³¹ Patients should be informed of the signs and symptoms of rhabdomyolysis. Baseline and follow-up creatine phosphokinase (CPK) measurements (every 6 months) have been used to identify patients who develop subclinical rhabdomyolysis when cholesterol-lowering therapy is used. Pravastatin may be preferred as a result of its lower interactive potential with CIs because it is not metabolized by CYP 3A4. The potential for hepatotoxicity from HMG-CoA reductase inhibitors warrants close monitoring of liver function in all transplant recipients.¹³⁷

Bile acid-binding resins may be used to lower cholesterol in transplant patients, but adequate doses are difficult to achieve without the development of GI adverse effects. Because the absorption of CSA is dependent on the presence of bile in the GI tract, patients should be instructed to separate dosing of bile acid-binding resins and CSA by at least 2 hours. Bile acid-binding resins also should be separated from other immunosuppressants by at least 2 hours to avoid physical adsorption in the GI tract. For transplant patients who have hypertriglyceridemia refractory to dietary intervention, fish oil and fibric acid derivatives are well-tolerated, effective alternatives (see Chap. 21). Fibric acid derivatives are most effective in lowering serum triglyceride concentrations.

POST-TRANSPLANT DIABETES MELLITUS (PTDM)

Corticosteroids and CIs can impair glucose control in previously diabetic patients, as well as cause new-onset post-transplant diabetes mellitus (PTDM) in 4% to 20% of patients. Corticosteroids induce insulin resistance and impair peripheral glucose uptake, whereas CIs appear to inhibit insulin production.¹⁴² TAC seems to be more diabetogenic than CSA, although recent studies have failed to show a statistical difference.⁴⁴ Other possible risk factors that have been identified for PTDM include ethnicity (African-American or Hispanic), age (>40 years), pretransplant diabetes status, family history, and weight.¹⁴³

Patients with PTDM should be referred for nutritional counseling and advised on the merits of weight loss (if appropriate). There are, however, some special considerations in transplant patients. Up to 40% of patients with PTDM will require insulin therapy.¹⁴² In diabetic patients who can be managed with an oral hypoglycemic agent, glipizide, which is metabolized extensively by the liver, may be preferred over renally eliminated agents such as glyburide. Metformin should

be used with extreme caution because of the risk of accumulation and lactic acidosis in those with moderate renal impairment. Regardless of therapy, frequent blood glucose monitoring is imperative in the early postoperative phase both to improve glucose control and to identify those with PTDM. Changes in renal function secondary to CI nephrotoxicity or delayed graft function or acute rejection in kidney transplant recipients affects the elimination of many hypoglycemic agents, including insulin, and may result in hyper- or hypoglycemia. Patients and clinicians also should be aware that dose changes of immunosuppressant drugs also affect glycemic control. Tapering of immunosuppressive medications may result in reduced insulin requirements, whereas steroid pulses for the treatment of rejection may result in increased insulin requirements.

INFECTION

Both the severity and incidence of infections and deaths due to infections have decreased dramatically since the introduction of CSA and the use of lower steroid dosages. Nonetheless, infection and rejection remain the most frequently encountered complications associated with immunosuppression in the first year after transplantation.¹⁴⁴ The risk of infection is related directly to the overall level of immunosuppression and is greatest during the first 3 postoperative months, as well as following treatment of acute rejection episodes.¹⁴⁵ Infectious complications following transplantation generally are classified according to the causative organism, site of infection, and time of appearance following surgery. Bacterial infections occur most frequently within the first month after transplantation and generally affect the urinary tract, wound, or vascular access sites. Viral infections are caused most commonly by herpes simplex (early transplant), herpes zoster (late post-transplant), or cytomegalovirus (CMV). Chapter 120 discusses the treatment of infection in the immunocompromised host. Special considerations of therapy in transplant patients for CMV, herpes, and *Pneumocystis carinii* infections are described in the following paragraphs.

Cytomegalovirus (CMV) is the most important viral pathogen affecting transplant patients; 50% to 60% of patients have been infected with the virus. Following transplantation, patients may develop symptomatic primary or secondary CMV infections. A previously CMV-seronegative patient who receives an organ or blood product from a CMV-seropositive donor is considered to have primary CMV infection. A secondary infection is characterized by reactivation of the latent virus or reinfection in a previously seropositive patient. Patients with primary infections generally are more symptomatic than patients with secondary infections.

The incidence and severity of CMV infections in transplant recipients are related to the intensity of immunosuppression required to prevent graft rejection. Patients treated on multiple occasions with high-dose steroids or patients receiving OKT3 or antilymphocyte preparations¹⁴⁶ and patients with poor HLA matching, cadaveric allografts, and CMV-positive donor serology have more severe CMV disease. Transplant centers use different strategies for managing CMV, which often are based on the risk of CMV infection. Prophylactic strategies use oral or intravenous antiviral or immunoglobulin preparations to prevent the reactivation or emergence of CMV. Prophylaxis is used most often in high-risk patients (i.e., donor-recipient CMV-serology mismatch or use of antilymphocyte preparations). Some centers routinely screen transplant recipients for CMV via blood tests (i.e., pp65 antigenemia, polymerase chain reaction [PCR]) and use preemptive therapy in patients who have a positive test. Treatment is given to all patients who have evidence of active CMV infection. Ganciclovir and valganciclovir have been used prophylactically and

preemptively in transplant patients. Other treatment strategies include intravenous immunoglobulins (IVIGs) and CMV hyperimmune immunoglobulin (CMVIG). Ganciclovir and CMVIG are the mainstays for treatment of CMV infection. CMV has been linked to chronic rejection and cardiac allograft vasculopathy.

CLINICAL CONTROVERSY

Some clinicians will use CMV prophylaxis for all patients receiving transplants. Others will reserve prophylaxis for only those patients who are at a higher risk for CMV infection, such as those with donor-recipient CMV serology mismatch or recipients who have received induction therapy or rejection treatment with antithymocyte globulin. A third strategy is to preemptively treat patients who have laboratory evidence of CMV infection.

Herpes simplex virus (HSV) infections in transplant patients are most commonly the result of reactivation of a previous infection. Symptomatic HSV infection usually presents as labial or oral lesions in the first 1 to 3 months after transplantation, but patients also may present with reactivation of varicella-zoster as “shingles.” Prophylactic therapy with low-dose oral acyclovir delays the development of HSV infections in patients following transplantation.

The incidence of *Pneumocystis carinii* pneumonia (PCP) within the first year after transplantation is reported to be 3% to 5%.¹⁴⁷ Low-dose trimethoprim-sulfamethoxazole (TMP-SMX 400 mg/80 mg three times weekly) is effective in the prevention of PCP infections. Alternative agents include aerosolized pentamidine (300 mg every month), dapsone, and atovaquone. The duration of PCP prophylaxis is unclear. The risk of infection caused by *P. carinii* is likely to decrease as immunosuppression is reduced; therefore, prophylaxis in patients requiring treatment for acute rejection may be appropriate.

MALIGNANCY

Advances in immunosuppression have decreased the incidence of acute rejection and increased patient survival, thus increasing the patient's lifetime exposure to immunosuppression. While the precise mechanism is unclear, post-transplant malignancy seems to be related to the overall level of immunosuppression, as evidenced by a difference in the rates of malignancy associated with quadruple versus triple versus dual immunosuppressant regimens. The risk of malignancy in transplant recipients is increased three- to fourfold over the general population. While the risk of lung, breast, colon, and prostate cancers does not appear to be increased, a number of cancers that are uncommon in the general population often occur with a higher prevalence in transplant recipients: post-transplant lymphomas and lymphoproliferative disorders (PTLD), Kaposi's sarcoma, renal carcinoma, in situ carcinomas of the uterine cervix, hepatobiliary tumors, and anogenital carcinomas. Skin cancers are the most common tumors, accounting for 38% of all malignancies. Factors that may predispose transplant recipients to skin cancers include copious sun exposure and therapy with azathioprine, possibly due to azathioprine's metabolite, nitroimidazole, which causes significant photosensitivity.¹⁴⁸ Azathioprine therapy is associated with a 2:1 predominance of squamous over basal cell carcinomas, whereas basal cell carcinoma occurs more frequently in the general population. Azathioprine-induced cutaneous squamous cell carcinoma is also associated with more metastatic disease and accounts for 6% of all deaths in comparison with less than 1% with CSA. Patients must be encouraged to use effective techniques to reduce sun exposure.¹⁴⁸

PTLD encompasses a broad spectrum of disorders ranging from benign polyclonal hyperplasias to malignant monoclonal lymphomas. Factors that predispose patients to PTLT include Epstein-Barr virus seronegativity at transplant and intense immunosuppression, particularly with OKT3 and antithymocyte globulin. Non-renal-transplant recipients are more likely to develop PTLT secondary to the heavy immunosuppression used to reverse rejection. Administration of ganciclovir or acyclovir preemptively during antilymphocyte therapy may decrease the risk of eventual PTLT. Treatment of life-threatening PTLT generally includes severe reduction or cessation of immunosuppression. Other options include systemic chemotherapy or rituximab.¹⁴⁹

Post-transplant malignancies appear an average of 5 years after transplantation and increase with the length of follow-up. As many as 72% of patients surviving greater than 20 years may be affected. Malignancy accounts for 11.8% of deaths after cardiac transplantation and is the single most common cause of death in the sixth to the tenth posttransplant years.¹⁴⁷

CONCLUSION

Transplantation is a lifesaving therapy for several types of end-organ failure. Advances in the understanding of transplant immunology have produced an unprecedented number of choices in terms of immunosuppression. The increasing number of effective immunosuppressive medications and therapies offer clinicians diverse ways to prevent allograft rejection in a patient-specific manner. However, the vast array and efficacy of currently available immunosuppressive agents make it increasingly difficult to evaluate their long-term efficacy. Clinicians must be keenly aware of the adverse effects of immunosuppressive medications and their treatment in order to optimize the care of the transplanted patient.

ABBREVIATIONS

6-MP: 6-mercaptopurine
 ACE: angiotensin-converting enzyme
 ARB: angiotensin II receptor blocker
 ATG: antithymocyte globulin
 ATN: acute tubular necrosis
 AUC: area under the concentration curve
 AZA: azathioprine
 BUN: blood urea nitrogen
 CABG: coronary artery bypass grafting
 CAD: coronary artery disease
 CI: calcineurin inhibitor
 C_{max}: peak concentration
 CMV: cytomegalovirus
 CPK: creatinine phosphokinase
 CSA: cyclosporine
 CYP: cytochrome P450 liver enzyme system
 DGF: delayed graft function
 ESRD: end-stage renal disease
 FKBP: FK-binding protein
 GI: gastrointestinal
 HCT: hematocrit
 HLA: human leukocyte antigen
 HPLC: high-performance liquid chromatography
 HSV: herpes simplex virus
 IABP: intraaortic balloon pump

IgG: immunoglobulin G
 IL-2: interleukin 2
 IL2RA: interleukin 2 receptor antagonist
 IMPDH: inosine monophosphate dehydrogenase
 ISHLT: International Society of Heart and Lung Transplantation
 LDL: low-density lipoprotein
 LVAD: left ventricular assist device
 MELD: model for end-stage liver disease
 MHC: major histocompatibility complex
 MMF: mycophenolate mofetil
 MPA: mycophenolic acid
 MPAG: mycophenolic acid glucuronide
 mTOR: mammalian target of rapamycin
 NFAT: nuclear factor of activated T cells
 NYHA: New York Heart Association
 OKT3: muromonab-CD3
 PCP: *Pneumocystis carinii* pneumonia
 PRA: panel of reactive antibodies
 PTCA: percutaneous transluminal coronary angioplasty
 PTDM: posttransplant diabetes mellitus
 PTLD: posttransplant lymphoproliferative disorder
 RBC: red blood cell
 RIA: radioimmunoassay
 SIR: sirolimus
 TAC: tacrolimus
 TGN: 6-thioguanine nucleotides
 t_{\max} : time to peak concentration
 TMP-SMX: trimethoprim-sulfamethoxazole
 TNF: tumor necrosis factor
 TPMT: thiopurine methyltransferase
 UNOS: United Network for Organ Sharing
 VLDL: very-low-density lipoprotein
 WBC: white blood cells
 XO: xanthine oxidase

OSTEOPOROSIS AND OSTEOMALACIA

Mary Beth O'Connell and Terry L. Seaton

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Women and men over age 50 should be assessed for factors that increase the risk of developing osteoporosis and related fractures. Patients with premature or severe osteoporosis should be evaluated for secondary causes of bone loss.
- 2 Bone density testing can establish the degree of bone health, predict fracture risk, and influence prevention and treatment decisions. Portable equipment can be used as a preliminary screening method in the community to determine the need for further testing.
- 3 All people, regardless of age, should incorporate a healthy lifestyle beginning at birth that emphasizes regular exercise, nutritious diet, and tobacco avoidance to prevent and treat osteoporosis.
- 4 To ensure adequate calcium intake, most Americans will need supplementation with 500 mg of elemental calcium once or twice daily. Most elderly patients require vitamin D supplementation of 400 to 1000 units/day, from sources such as beverages, multivitamins, and combination calcium and vitamin D products.
- 5 Bisphosphonates are the cornerstone for osteoporosis treatment. They are the drugs of choice because they prevent both nonvertebral (especially hip) and vertebral fractures.
- 6 Raloxifene is an alternative treatment option to prevent vertebral fractures, particularly in women who cannot tolerate or will not take bisphosphonates. It may also be useful for women who have a history of breast cancer or a significant risk for developing breast cancer (investigational).
- 7 Although estrogens increase bone mineral density and decrease fractures, they are no longer recommended for osteoporosis prevention because of toxicity concerns. When used to treat menopausal symptoms, they will have a positive bone effect.
- 8 Male osteoporosis is often secondary to specific diseases and drugs and responds well to bisphosphonate therapy and lifestyle changes including diet.
- 9 Patients chronically taking glucocorticoids need to be identified and started on bisphosphonate therapy to prevent osteoporosis-related fractures.
- 10 Osteomalacia, although less common than osteoporosis, can be insidious and coexist with osteoporosis. A serum 25-hydroxyvitamin D concentration should be obtained in anyone with decreased oral vitamin D intake, limited or no sun exposure, or unexplained muscle weakness or pain.

Despite being an essentially preventable condition, osteoporosis remains a disturbingly common health problem. As such, the U.S. president declared 2002–2011 to be the “Decade of the Bone and Joint,” and the U.S. Surgeon General in 2004 released a report, “Bone Health and Osteoporosis.” This report has activities for patients and health professionals to use in promoting bone health and preventing complications of osteoporosis (www.hhs.gov/surgeongeneral/library/bonehealth/). Decreased bone mass, quality, and strength contribute to increased osteoporosis and fracture risk. Osteoporosis-related fractures commonly cause pain, kyphosis, disability, and death. Because a perfect bone formation therapy remains elusive, clinicians must actively promote a bone-healthy lifestyle beginning at birth in all people to prevent bone loss. Osteomalacia, or deficient bone mineralization, is less common but also leads to skeletal muscle weakness, fractures, and other complications. This chapter reviews bone physiology, pathophysiol-

ogy, and assessment, and offers nonpharmacologic and pharmacologic prevention and treatment strategies for these skeletal diseases.

OSTEOPOROSIS

EPIDEMIOLOGY

The exact prevalence is unknown, but experts estimate that nearly half of Americans aged 50 years or older, or approximately 44 million people, have low bone mass. This number is expected to rise to over 60 million people during the next 15 years. The incidence varies widely among subpopulations and depends on many risk factors, the skeletal site measured, and the radiologic technology used. In the late 1990s, based on peripheral bone mineral density (BMD) measurements, 40% of postmenopausal women had osteopenia and 7% had osteoporosis.¹

When World Health Organization BMD classifications are applied to central BMD (femoral neck) data from the third National Health and Nutrition Examination Survey (NHANES III, conducted from 1988 to 1994), the respective osteopenia and osteoporosis prevalences among American subgroups are as follows:²

- Non-Hispanic white women: 52% and 20%
- Mexican-American women: 49% and 10%
- Non-Hispanic black women: 35% and 5%
- Men of all races: 47% and 6%, using the mean young male BMD
- Men of all races: 33% and 4%, using the mean young female BMD

Osteoporosis increases with age. Osteoporosis prevalences are even higher for nursing home residents.

Hundreds of thousands of fractures occur each year in the United States. The lifetime risk of a white woman experiencing a fracture is approximately 50%.³ Fracture risk increases with age and lower BMD.

ETIOLOGY AND RISK FACTORS

Many modifiable and nonmodifiable factors are associated with an increased risk of developing osteoporosis and related bone fractures (Table 88–1).^{3–8} The magnitude and significance of these risk factors varies by gender, ethnicity, age, and the duration of risk factor presence. After accounting for confounders, the four strongest factors that predict fracture risk are low BMD, prior fragility fracture, age, and family history of osteoporosis.⁷ The largest trial, the Study of Osteoporotic Fractures, revealed that women with five or more risk factors were at increased risk of hip fracture compared to women with two or fewer risk factors.⁹ While the existence of multiple risk factors incurs greater fracture risk, the absence of risk factors does not necessarily eliminate fracture risk.

PHYSIOLOGY

BONE FUNCTION AND COMPOSITION

The skeleton provides structural support, protects vital organs and the hematopoietic system, and maintains homeostasis of calcium and other ions. The two types of bone, trabecular (cancellous) and cortical (compact) bone, occur in varying amounts at different anatomic sites:

- Distal radius: 75% cortical and 25% trabecular
- Lumbar spine: 34% cortical and 66% trabecular
- Femoral neck: 75% cortical and 25% trabecular
- Trochanter: 50% cortical and 50% trabecular.¹⁰

Trabecular bone is a meshwork of struts giving it a large surface area that is in close contact with the bone marrow cavity for bone turnover and metabolic activity. Cortical bone is formed in layers and is highly calcified (about 80% to 90%). Because of these different structures and environments, trabecular bone is more metabolically active and cortical bone is more structurally strong and protective.

Bone comprises minerals (50% to 70%), an organic matrix (20% to 40%), water (5% to 10%), and lipids (<3%).¹⁰ The predominant mineral is hydroxyapatite [$3\text{Ca}_3(\text{PO}_4)_2(\text{OH})_2$]. Bone contains 99% of the body's calcium and 85% of its phosphorus. The organic matrix is primarily protein; 90% type I collagen and 10% to 15% noncollagenous proteins (proteoglycans, glycosylated proteins [e.g., osteonectin], and γ -carboxylated proteins [e.g., osteocalcin]); and cells (osteoclasts, osteoblasts, and osteocytes). The mineral provides strength and rigidity while the proteins provide elasticity and flexibility.

Bone Remodeling and Its Control

The skeleton undergoes constant remodeling throughout life. Peak bone mass is achieved by age 20 to 30 years, long after maximum bone length has been achieved. Men achieve higher peak bone mass than women. For 5 to 10 years after menopause, women have accelerated bone loss, up to 3% per year. Age-related bone loss, about 0.5% per year, begins 10 to 15 years after menopause in women and in men at about age 55 years.¹⁰

Bone is a dynamic tissue. The majority of the skeleton is replaced approximately every 7 to 10 years. Remodeling repairs microfractures, prepares bone for weight bearing, and provides access to mineral stores. Teams of osteoclasts and osteoblasts, termed *basic multicellular units* (BMUs), perform this remodeling process. Steps in remodeling are resorption, reversal, formation, and quiescence (Fig. 88–1). This process begins with activation of osteoclasts, causing bone resorption. Osteoclasts attach to bone by an integrin, $\alpha\text{V}\beta3$, and create a leakproof seal. The osteoclast's ruffled border secretes acid and proteases, such as H^+ and cathepsin K, to dissolve bone. Osteoclasts create tunnels in cortical bone and pits (Howship lacunae) in trabecular bone. By-products of collagen degradation include hydroxyproline, and *N*-terminal and *C*-terminal collagen peptides, which can also serve as biomarkers of resorption. When excavation is complete, reversal begins by osteoclasts undergoing apoptosis or moving to a new section. Resorption takes 3 to 4 weeks. Formation begins with osteoblasts making osteoid that is mineralized over the ensuing 3 to 4 months. Osteoblasts then either line the bone (lining cells) or become part of the bone as osteocytes. Quiescence follows mineralization.

Numerous agents control mesenchymal stem cell derivation and differentiation of osteoblasts (Fig. 88–2).^{10,11} Adipocytes can be converted to osteoblasts under the control of Runx2 and peroxisome proliferator-activated receptor- γ 2 (PPAR γ 2). Osteoclasts are derived from the myeloid/monocyte cell line with derivation and differentiation also under the control of numerous agents, some of which are expressed from osteoblasts.^{10,12}

A complex array and timing of cytokines and hormones control osteoblasts and osteoclasts during bone remodeling (see Fig. 88–2).¹⁰ Intensive investigation continues to define the complete process. Although the triggers to begin remodeling are not completely understood, osteocytes may act as mechanosensors, reacting to bone strain and sensing fatigue and damage. Osteocytes communicate with lining cells via a homing signal, which is thought to summon osteoclast precursors to initiate resorption. Osteoblasts regulate osteoclastic activity by secreting colony-stimulating factors (macrophage colony-stimulating factor [M-CSF]; CSF-1) to promote differentiation of osteoclast precursors, receptor activator of nuclear factor κB ligand (RANKL) to promote osteoclast differentiation and maturation, and osteoprotegerin (OPG) to compete with RANKL and prevent osteoclastic differentiation. Regulation of osteoblast secretion of CSF-1, RANKL, and OPG is complex, involving parathyroid hormone (PTH), 1α -25-dihydroxyvitamin D, leptin, estrogen, and other agents. Transforming growth factor- β (TGF- β), platelet-derived growth factor (PDGF), insulin-like growth factor-1 (IGF-1), PTH, growth hormone, and other factors promote bone formation.

Bone mineral density peaks between the ages of 20 and 30 in men and women. Peak bone mass and rate of bone loss is controlled partly by genetics. Polymorphisms of collagen type I, vitamin D receptor, estrogen receptor, and other genes are being investigated as contributors to this variance. Under normal conditions in adults, resorption equals formation for no net loss or gain of bone mass. Aging, menopause, and certain diseases and drugs can create an imbalance between formation and resorption and result in bone loss.

TABLE 88–1. Risk Factors Affecting Bone Health

| | |
|---|--|
| Factors associated with clinical bone fractures | Prior fragility fracture Low bone mineral density Advanced age Family history of osteoporosis or fragility fracture |
| Factors associated with low bone mass | Gender (female) Ethnicity (Caucasian or Asian) Lifestyle (sedentary) Immobility Low body weight (<125 pounds) Low calcium intake (anytime in life; lactose intolerance) Smoking (tobacco) Weight loss (>10% of weight at age 25) Alcohol (excessive intake) Malnutrition (eating disorders) Low sun exposure Nulliparity <i>Medical problems</i> Rheumatoid arthritis Hyperthyroidism Hyperparathyroidism Cushing's syndrome Gastrointestinal disorders (gastrectomy, malabsorption syndromes, inflammatory bowel disease, sprue) Genetic bone disorders Cancers (multiple myeloma, lymphoma, leukemia) Diabetes (type 1) Pernicious anemia Human immunodeficiency virus infection Transplantation Cystic fibrosis Hypophosphatasia Scoliosis Severe liver disease (especially primary biliary cirrhosis) Sex hormone deficiency (hypogonadism, menopause [natural, premature, oophorectomy], female athlete triad) Amyloidosis Ankylosing spondylitis Chronic obstructive pulmonary disease <i>Medications (usually long-term)</i> Glucocorticoids (systemic exposure >3 months) Anticonvulsants (phenytoin, phenobarbital) Heparin Parenteral nutrition Thyroid supplements Aluminum Medroxyprogesterone (acetate contraceptive implant) Lithium Immunosuppressants Diuretics (loop) Cancer chemotherapy Gonadotropin-releasing hormone agonists |

Serum Calcium and Phosphate Regulation and Vitamin D Metabolism

Vitamin D and PTH maintain calcium homeostasis (Fig. 88–3).^{10,13,14} The sun (ultraviolet B, 290 to 315 nm) converts 7-dehydrocholesterol in the skin to vitamin D₃. Sunscreens inhibit vitamin D skin production. In northern climates, during the winter months the angle of the sun limits the ability to create vitamin D. Significant seasonal variations lead to fluctuations in 25(OH) vitamin D concentrations. Nadirs occur in February and March and peaks occur in August.^{15,16} Although a few foods naturally contain vitamin D₃ (e.g., cholecalciferol from fish oils) or vitamin D₂ (e.g., ergocalciferol from plants), most dietary intake is from foods fortified with vitamin D (Table 88–2). Because both vitamin D₃ and D₂ work similarly in the body, they are referred to here as vitamin D. Vitamin D undergoes hepatic conversion to 25(OH) vitamin D (calcidiol) via D-25-hydroxylase (cytochrome P450 27A1). PTH stimulates renal conversion of 25-hydroxyvitamin D to the active form, 1 α -25-dihydroxyvitamin D (calcitriol), via 25(OH)D-1 α -hydroxylase (cytochrome P450 27B1).

Decreased serum calcium concentrations lead to increased serum PTH concentrations, which lead to elevated calcitriol concentrations (see Fig. 88–3). Calcitriol promotes intestinal calcium absorption, and calcitriol and PTH work together to release calcium from bone to restore homeostasis. Polymorphisms with the intestinal vitamin D receptor (*BsmI*, *ApaI*, *TaqI*, and *FokI*) have been inconsistently

FIGURE 88–3. Effects of vitamin D and parathyroid hormone on calcium balance. See text for details. PTH, parathyroid hormone, Ca, calcium, Pi, phosphorus.

associated with low bone density.¹⁷ Vitamin D receptors are found in many tissues, such as bone, intestine, brain, heart, stomach, pancreas, lymphocytes, skin, and gonads.¹⁴

Serum phosphorus is less tightly regulated than serum calcium. Excess ingested phosphorus is absorbed and adjusted by the kidney.

TABLE 88–2. Dietary Sources of Calcium and Vitamin D^a

| Food | Serving Size | Calcium Content (mg) | Vitamin D Content (units) |
|-------------------------|-----------------|----------------------|---------------------------|
| Milk | 1 cup | 300 | 100 |
| Powdered nonfat milk | 1 teaspoon | 50 | |
| Ice cream | 1 cup | 200 | |
| Yogurt, fortified | 1 cup | 240–415 | 60 |
| American cheese | 1 oz | 150 | |
| Cheddar cheese | 1 oz | 211 | |
| Cottage cheese | 1/2 cup | 100 | |
| Swiss cheese | 1 oz | 250 | |
| Parmesan cheese | 1 tablespoonful | 70 | |
| Cheese pizza | 1 slice | 150 | |
| Macaroni and cheese | 1 cup | 360 | |
| Slim Fast | 11 oz | 400 | 140 |
| Orange juice, fortified | 1 cup | 350 | 100 |
| Soymilk, fortified | 1 cup | 80–300 | 100 |
| Bread, fortified | 1 slice | 100 | |
| Cereals, fortified | 1 cup | 100–250 | 60 |
| Sardines with bones | 3 oz | 370 | 230 |
| Salmon with bones | 3 oz | 170–210 | 310 |
| Catfish | 3 oz | | 570 |
| Halibut | 3 oz | | 680 |
| Tuna | 4 oz | | 260 |
| Almonds | 1 oz | 80 | |
| Bok choy | 1/2 cup | 125 | |
| Broccoli | 1 cup | 130–160 | |
| Collards | 1/2 cup | 180 | |
| Cornbread | 1 slice | 85 | |
| Egg, medium | 1 | 55 | 25 |
| Figs, dried | 5 medium | 125 | |
| Kale | 1/2 cup | 95 | |
| Orange | 1 | 52 | |
| Soybeans | 1 cup | 130 | |
| Spinach | 1/2 cup | 110 | |
| Tofu | 4 oz | 140 | |
| Turnip greens | 1/2 cup | 125 | |

^aTo calculate calcium content, multiply percentage on package by 1000. To calculate vitamin D content, multiply percentage on package by 400.

PTH also controls the kidney “set point” and decreases renal phosphorus reabsorption.

PATHOPHYSIOLOGY OF OSTEOPOROSIS

Osteoporosis is “characterized by low bone mass and microarchitectural deterioration of bone tissue leading to enhanced bone fragility and a consequent increase in fracture risk.”³ Bone loss results when resorption exceeds formation. The World Health Organization classifies bone mass based on T-score (number of standard deviations from the mean compared to bone mass of average young women). Normal bone mass is defined as a T-score greater than -1 , osteopenia as a T-score of -1 to -2.5 , and osteoporosis as a T-score of less than -2.5 .^{3,7} In addition to low BMD, high bone turnover, poor bone strength, and impaired bone architecture result in the bone’s increased susceptibility to fracture. Severe osteoporosis is defined as a history of a fragility fracture plus a T-score < -2.5 . Women with osteopenia have a 1.8-fold increase in fracture rate, and women with osteoporosis have a fourfold increase in fracture rate, compared to women with normal BMD.¹

Clinically, osteoporosis is categorized as postmenopausal, age-related, or secondary. Postmenopausal osteoporosis affects primarily trabecular bone in the decade following menopause, with fractures occurring predominantly at vertebral and distal forearm sites. Within a few years after peak BMD is attained, usually in the mid- to late-30s, bone loss slowly begins. The cumulative effect over time can translate into age-related osteoporosis that affects both cortical and trabecular bone and leads to vertebral, hip, and wrist fractures. Secondary osteoporosis is caused by either diseases or medications and afflicts both bone types. Secondary causes can be found in 11% to 31% of women and 30% to 54% of men.⁴

POSTMENOPAUSAL

The rate of bone loss commonly accelerates at menopause due to a decline in trophic sex hormone production, especially when a bone-healthy lifestyle is not practiced. In older studies, approximately 10% to 25% of bone loss was documented in the decade after menopause. Bone loss then slows to 8% to 12% per decade, a rate that was similar to that of older men.¹⁸ This accelerated loss has not been demonstrated in most of the placebo groups who were taking calcium and vitamin D supplements in recently conducted randomized controlled trials.

Estrogen deficiency increases bone resorption more than formation. This process appears to depend on tumor necrosis factor (TNF), interleukin-1 (IL-1), interleukin-11, interleukin-6, MCSF, and prostaglandin E₂, which stimulate osteoclastic activity through the OPG/RANK/RANKL system (see Fig. 88–2). Reduced TGF- β , associated with estrogen loss, enhances osteoclast action through decreased apoptosis. Osteocytes also may play a role. Normally, with more weight bearing, osteocytes trigger increased BMD. With menopause, osteocyte apoptosis blunts this response. With the resetting of the mechanostat set point at menopause, increased loading is required to maintain bone. After menopause, some estrogen is still synthesized by aromatization in adipose tissue.

AGE-RELATED

Bone resorption increases with age, but changes in bone formation are not observed consistently. Increased osteocyte apoptosis may decrease responses to mechanical strain and hinder bone repair. Cortical porosity from years of remodeling and decreased trabecular connectivity, particularly of horizontal struts, promotes microarchitectural deterioration of bone that is not always reflected in BMD. Aging also increases fracture risk in other ways that are independent of BMD.

Comorbid conditions, cognitive impairment, medications, and deconditioning can increase falls. Some falls lead to fractures, usually of the hip.

Inadequate calcium, vitamin D, and nutritional intake also contribute to bone loss and fractures. Vitamin D insufficiency results from poor sun exposure, decreased cutaneous production, insufficient dietary intake, and decreased absorption. Calcium and vitamin D insufficiency promotes secondary hyperparathyroidism and associated bone loss (see Fig. 88–3).

MEN

For many reasons, men experience fewer osteoporosis-related fractures than women.¹⁹ Men comprise only approximately 20% of all persons with osteoporosis. This is likely attributable to men attaining a 20% to 40% higher peak BMD than women and losing BMD at a slower rate after the peak. Men’s bones also have a mechanical advantage because the larger bone diameter makes them more fracture-resistant. Finally, men have a shorter life expectancy and experience fewer falls than women. Male osteoporosis remains an underrecognized problem. Although fewer men than women have osteoporosis, men still suffer up to 30% of all hip fractures and are more likely than women to die within 1 year after fracture.²⁰

Hypogonadism, secondary to age-related decreased testosterone and increased sex hormone-binding globulin (SHBG), endocrine dysfunction, or androgen ablation, can also cause bone loss. Estrogen, synthesized from testosterone by the enzyme aromatase, appears more important than testosterone in men for bone maintenance, with greater bone density seen in men with higher estradiol concentrations. Secondary causes often contribute to male osteoporosis. Other factors are listed in Table 88–1.

SECONDARY CAUSES

Numerous diseases and drugs can decrease bone mass (see Table 88–1). Secondary causes are suspected when osteoporosis occurs in premenopausal women, men younger than age 70, those with no risk factors, multiple low trauma fractures (especially at a young age), a Z-score less than -2.0 (see section below on quantification of BMD), or bone loss despite adequate drug treatment and calcium supplementation.⁴ Patients suspected of having secondary causes should undergo careful evaluation that includes a comprehensive physical exam and laboratory assessment. Both the osteoporosis and contributing disorders should be treated.

DRUG-INDUCED

Unfortunately, several medications (see Table 88–1) can cause bone loss by a variety of mechanisms. Examples include systemic glucocorticoids (see section on glucocorticoid-induced osteoporosis, below),^{21,22} thyroid hormone replacement, some antiepileptic drugs, and heparin use. Thyroid dose adjustment is needed to keep the thyroid-stimulating hormone (TSH) in the upper half of the normal range to minimize bone loss. Some anticonvulsants, like phenobarbital and phenytoin, hasten vitamin D metabolism and the resultant effects can lead to osteomalacia (see section later in the chapter on osteomalacia).²³ Those at higher risk include people who take multiple anticonvulsants, are institutionalized, or have multiple comorbidities. Heparin therapy, in excess of 15,000 to 30,000 units daily for greater than 3 to 6 months, is associated with bone loss and vertebral fractures. Low-molecular-weight heparins such as enoxaparin may pose less risk of bone loss. A black-box warning has been added to the product labeling of medroxyprogesterone acetate injectable contraceptive warning that it significantly decreases bone loss that increases

TABLE 88–3. Clinical Presentation of Osteoporosis**General**

Many patients are unaware they have osteoporosis and only present after fracture.

Fractures can occur after bending, lifting, or falling, or independent of any activity.

Symptoms

Pain

Immobility

Bruising

Depression and lower self-esteem can result from pain and physical changes.

Signs

Shortened stature, kyphosis, or lordosis

Vertebra, hip, or forearm fracture

Laboratory tests

25(OH) vitamin D

Other tests to identify secondary causes (e.g., thyroid-stimulating hormone, parathyroid hormone, complete blood count)

Other diagnostic tests

Central or peripheral bone density measurement

with longer durations of therapy. Thus, this contraceptive product should be used only when other medications prove inadequate.

CLINICAL PRESENTATION

Osteopenia and asymptomatic osteoporosis are generally diagnosed only by bone density measurement. Osteoporosis is frequently diagnosed after a fragility fracture or after a work-up of pain or curvature in the spine (Table 88–3). Although fractures can occur after any minimal activity, such as bending, lifting, or twisting, the shearing force from a fall is the greatest contributor to fracture, especially nonvertebral fracture. Multiple vertebral fractures, even clinically unrecognizable ones, may lead to dorsal kyphosis and exaggerated cervical lordosis, frequently referred to as *dowager* or *widow's hump*. Subsequent chest wall changes can lead to pulmonary and cardiovascular complications. Collapsed vertebrae rarely lead to spinal cord compression. Recurrent fractures are common. Nonvertebral fractures are almost always evident because of severe pain at the fracture site, inability to bear weight, and obvious deformity. Depression and lower self-esteem can result from pain, physical changes, and dependence on others for activities of daily living.

FRACTURE OUTCOMES

Fractures can be devastating. While acute fracture pain usually resolves within 2 to 3 months, chronic fracture pain can occur, and is manifested as a deep, dull, nagging pain near the fracture site. Up to 50% of hip fracture patients do not regain their prefracture function by up to 1 year following hip fracture.^{3,8} About 25% of women will spend some time in a nursing home after a hip fracture. Between 10% and 20% of hip fracture patients die within 1 year following the fracture. In the late 1990s, 51% of women and 96% of men were not screened for osteoporosis nor did they receive treatment after a fracture.²⁴

PATIENT ASSESSMENT

Patient assessment should begin with identifying risk factors for osteoporosis and fractures (see Table 88–1). Important points include age, history of nontraumatic adult fractures, family history of osteoporosis or fragility fractures, comorbid medical and mental illnesses, lifestyle habits (diet, physical activity, smoking, and alcohol use), menstrual history, fall risk, prior and current medications (especially

glucocorticoid use), and calcium and vitamin D supplements. Lateral spine radiographs to detect vertebral fractures are reasonable in patients with acute or chronic severe back pain. For patients in whom a diagnosis of osteoporosis is made, secondary causes (see Table 88–1) should be sought if the degree of bone loss is severe or unexplained.⁴ Surveys and questionnaires are used in research and for screening and sometimes for prediction and treatment evaluation. For patients with established osteoporosis, the validated Mini Osteoporosis Quality of Life tool, which takes 2 to 3 minutes to administer, can evaluate the impact of osteoporosis on daily physical and emotional functioning.²⁵ A risk factor checklist can be developed to help direct care plans for lifestyle changes to prevent and treat osteoporosis.

QUANTIFICATION OF BONE MINERAL DENSITY

▶ BMD remains a very strong predictor of fracture risk.^{3,7,8,10} The gold standard method of bone density assessment is to measure central skeletal BMD (hip and spine) by dual-energy x-ray absorptiometry (DXA). DXA uses minimal radiation and has the greatest precision (reproducibility on repeat examinations). Quantitative computed tomography measures trabecular and cortical bone separately, but is not ideal for routine use because it is expensive, not widely available, and uses more radiation. Measurements at peripheral sites (forearm, heel, and phalanges) with ultrasound or DXA are currently just used for screening purposes and to determine the need for further testing. Portable units are easy to transport.

Variability exists with BMD measurements. A T-score is the number of standard deviations an individual's BMD is away from the mean BMD for normative reference databases for young women or men. The Z-score compares bone mass to a group matched for age, sex, weight, and race. Different central and peripheral T-scores can be measured. The lowest T-score is used for decision making. Differences also depend on the technology used, thus only the same machine's T-scores can be compared. Most machines use a different normal reference population to calculate the T- and Z-scores. Consensus does not exist regarding what peripheral T-score should be used as a threshold for obtaining a central DXA measurement, but -1 or -1.6 has been suggested. T-score adjustments need to be made for children and thin adults.

Medicare patients are eligible for BMD testing.³ In the United States, the Centers for Medicare & Medicaid Services regulations provide reimbursement to providers every 2 years for BMD measurement for patients with estrogen-deficiency or clinical risk for osteoporosis, those with vertebral abnormalities or primary hyperparathyroidism, and those on long-term glucocorticoid therapy (>7.5 mg prednisone/day for >3 months) or FDA-approved osteoporosis therapy. Knowledge of low BMD can encourage prevention and lead to positive lifestyle changes.

BIOCHEMICAL AND BIOPSY EVALUATION

A complete blood count, chemistry panel (with calcium corrected for albumin), erythrocyte sedimentation rate, PTH concentration, and 24-hour urine for calcium and creatinine are occasionally ordered to determine secondary causes.⁴ Measurement of 25(OH) vitamin D is becoming more common. Measurement of TSH, free T₄ (thyroxine) and free T₃ (triiodothyronine) can be used to rule out hyperthyroidism from endogenous disease or thyroid replacements.

In the past, biochemical markers have been considered as research tools only.^{7,10} Now that increased bone turnover independently predicts fracture risk and more automated and precise assays exist, these tests may become more common for drug selection and monitoring.¹⁰ Response to drug therapy can be measured more quickly than bone density measurements, 1 to 3 months vs. 6 to 12 months,

respectively.^{4,10} A decrease of bone resorption tests of at least 20% is considered a positive response. Until assay variability is further improved, these tests should not be used for diagnosis. Commonly used markers of bone resorption include urine and serum C-terminal or N-terminal telopeptides and urine deoxypyridinoline, and of bone

formation include bone-specific alkaline phosphatase and osteocalcin. When possible, these tests should be performed at similar times due to circadian rhythms.

Bone biopsy is rarely useful for osteoporosis, but can be used to identify other conditions such as osteomalacia.

► PREVENTION AND TREATMENT: Osteoporosis

■ DESIRED OUTCOMES

The goal from birth to around 20 to 30 years of age is to achieve the highest peak bone mass as possible. Beyond this age, the goals are to maintain BMD and minimize age-related and postmenopausal bone loss. In women and men with osteopenia, prevention of osteoporosis is the goal. For a variety of reasons, osteoporosis prevention is not always possible. For those at significant risk of developing an osteoporosis-related fracture, the aims are to increase bone mineral density, prevent further bone loss, and to prevent falls and fractures and their associated sequelae. For those who experience an osteoporosis-related fracture, the goals are to achieve adequate pain control, maximize rehabilitation

to restore independence and quality of life, and prevent subsequent fractures or death.

■ GENERAL APPROACH TO TREATMENT

A bone-healthy lifestyle beginning at birth is advocated for all people throughout life. Calcium and vitamin D supplements are used for everyone when diet is insufficient. Treatment of osteopenia remains controversial (see clinical controversy below). Prescription medications, with bisphosphonates being the drugs of choice, are used for treating patients with a T-score of -2.5 or lower. Figure 88–4

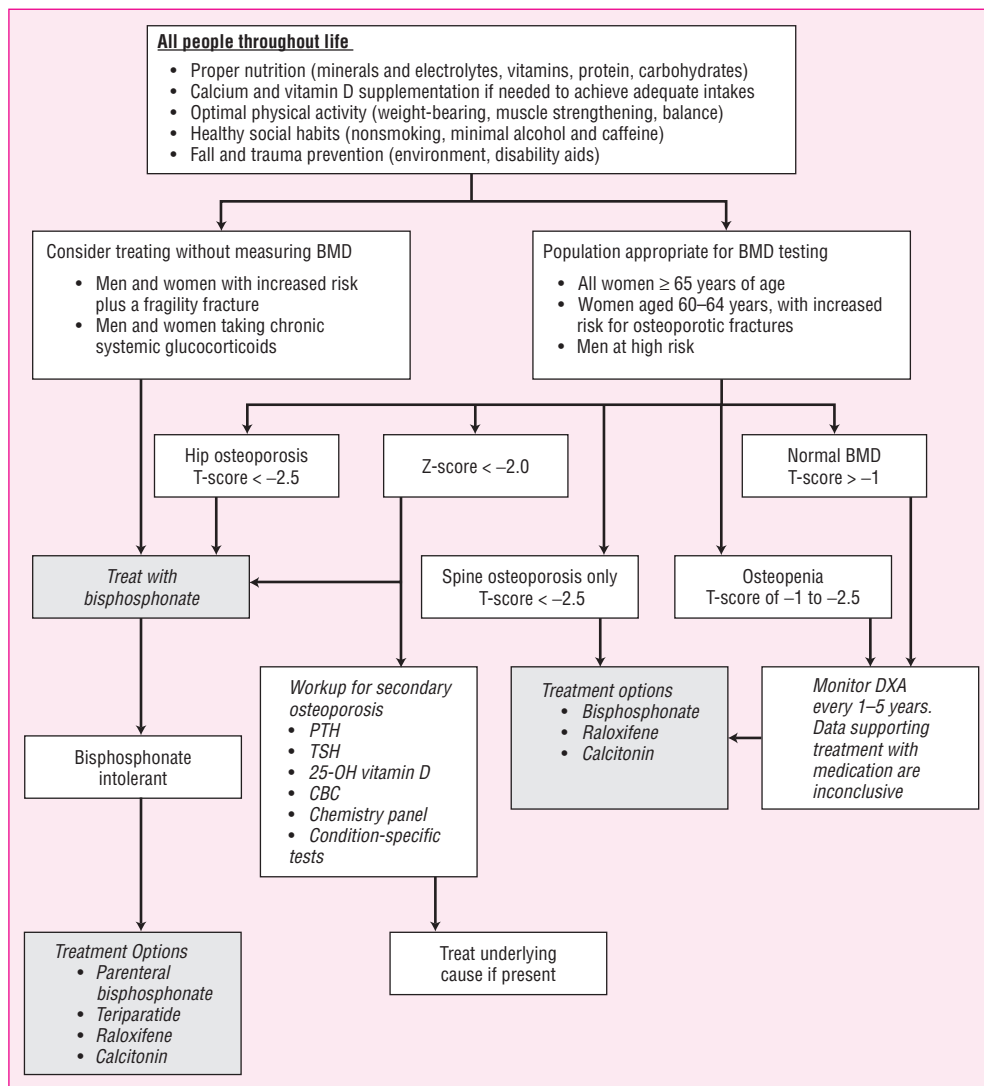

FIGURE 88–4. Bone health therapeutic algorithm. BMD, bone mineral density; CBC, complete blood count; DXA, dual-energy x-ray absorptiometry; PTH, parathyroid hormone; TSH, thyroid-stimulating hormone.

provides an osteoporosis management algorithm that incorporates both nonpharmacologic and pharmacologic approaches.

CLINICAL CONTROVERSY

Not all clinicians believe that women and men with osteopenia, especially premenopausal women, should receive osteoporosis prevention beyond instituting bone-healthy lifestyle and calcium and vitamin D supplementation. Although some statistically significant findings exist, the absolute clinical value of treatment is very small. Women with osteopenia have a 1.8-fold greater risk for developing a fracture than women with normal BMD, but the absolute risk difference is very low (0.86 fractures/100 person-years with normal BMD vs. 1.55 fractures/100 person-years with osteopenia).¹ The FOSIT study investigators report reduced fracture risk in 1 year with alendronate in patients with either osteopenia or osteoporosis, but in a trial that was only designed to assess BMD change.¹³⁰ Furthermore, the patients with osteopenia were not analyzed separately. Reanalysis of the Multiple Outcomes of Raloxifene Evaluation (MORE) trial⁷² found that postmenopausal women with osteopenia had a 75% reduction in new clinical vertebral fractures compared with the placebo group (16 vs. 4 new fractures, respectively).¹³¹ Because long-term data on treating osteopenia in younger premenopausal, perimenopausal, or postmenopausal women or men with osteoporosis prescription medications are not known, the benefit-risk profile for early or lifelong use is also not known. Until clinical data are sufficiently collected, an adequate guideline cannot be established and a pharmacoeconomic analysis cannot be conducted.

NONPHARMACOLOGIC PREVENTION AND TREATMENT

DIET CHANGES

3 For all individuals, a well-balanced diet with adequate calcium and vitamin D is essential for healthy bones (see Table 88–2). Dairy products account for most dietary calcium intake. Americans, especially seniors and those with lactose intolerance, ingest insufficient dietary calcium. Serum calcium does not reflect dietary intake because calcium homeostasis is tightly controlled. A practical approach is to count calcium contributions from certain key foods: milk, yogurt, cheese, ice cream, cottage cheese, and fortified orange juice or soy products. Most vitamin D comes from sun-induced skin conversion, except in northern climates or people with minimal to no sun exposure. Besides fatty fish, few unfortified foods contain substantial amounts of vitamin D (see Table 88–2). In the United States, milk and orange juice are fortified with 400 units/quart of vitamin D; however, quantities are quite variable and the process is not well regulated. If adequate intakes²⁶ (Table 88–4) cannot be achieved with food, calcium and vitamin D supplements are needed (Table 88–5).

Many observational studies have found an association between high caffeine intake and decreased BMD. This finding, however, could be a surrogate marker for decreased calcium-containing beverage and food intake.²⁷ Although 2 to 5 cups of caffeine produce small increases in calcium excretion (about 4 to 5 mg calcium per cup of coffee), the effect can be offset with adequate calcium intake.

Phosphorus is part of bone hydroxyapatite [$3\text{Ca}_3(\text{PO}_4)_2(\text{OH})_2$]. Normally the body has sufficient phosphorus and bone resorption is not required. Insufficient intake (e.g., carbonated beverages replacing milk) or increased phosphorous-bound calcium complexes (e.g.,

TABLE 88–4. Daily Calcium and Vitamin D Requirements

| | Adequate Calcium Intake (mg) | Adequate Vitamin D Intake (units) |
|-------------------|------------------------------|-----------------------------------|
| Infant | | |
| Birth to 6 months | 210 | 200 |
| 6 months–1 year | 270 | 200 |
| Children | | |

| ≥71 years | 1200 | 600 |

Adapted from Institute of Medicine Dietary Reference Intakes.²⁶

calcium ingested with food) can produce hypophosphatemia and a corresponding rise in PTH.²⁸ A growing concern now exists for approximately 10% to 15% of seniors who are hypophosphatemic, and also during teriparatide administration, when the need for phosphorus is large. Drinking some milk or orange juice, eating some meals without supplemental calcium, or occasionally using a calcium phosphate supplement may help. Phosphorus supplementation is not routinely recommended.

Magnesium is found in bone and is required for enzymatic reactions. Fruits and vegetables contain magnesium and may be important for healthy bone.²⁹ No data currently exist to support supplementation.

Vitamin A can increase production and action of osteoclasts and impair osteoblasts. Excessive vitamin A intake (≥ 1.5 to 2 mg/day) from foods or supplements has been associated with decreased BMD and increased fracture risk in women³⁰ and men.³¹ Patients should be educated to avoid consuming excessive amounts of vitamin A.

Vitamin C positively influences collagen production, and increases osteoblast formation and osteoclast formation and survival. Some, but not all, observational studies showed that vitamin C supplementation (1000 mg or more) was associated with higher BMD than that of nonusers.³² Again, it is premature to suggest routine supplementation.

Vitamin K is required for γ -carboxylation of osteocalcin before incorporation into bone matrix.³³ Low-vitamin-K diets are associated with high amounts of uncarboxylated osteocalcin, lower BMD, and higher hip fracture rates. Early research suggests added vitamin K, especially when combined with other antiresorptive agents, has a positive effect on bone health. Currently, however, supplements are not recommended. Although warfarin decreases clotting factor production by antagonizing vitamin K, it alone probably does not cause bone loss.

Protein intake can increase IGF-1, low-protein diets can increase PTH, and high-protein diets can increase urinary calcium excretion.³⁴ Many observational studies reported higher BMD with higher protein intakes; however, most observational studies also found low protein intake to be associated with a lower fracture rate.³⁵ Moderate protein intake is recommended.

SOCIAL HABIT CHANGES

3 Smoking cessation and minimal alcohol use should be advocated. Smoking causes bone loss and increases hip fracture risk by several mechanisms. Smoking is associated with early menopause,

TABLE 88–5. Calcium and Vitamin D Product Selection^a

| Product ^b | Calcium (mg) | Vitamin D (units) |
|--|------------------|-------------------|
| <i>Calcium carbonate (40%)</i> | | |
| Trade and generic products | 200–600 | |
| Generic suspension | 500/5 mL | |

^aOnly calcium products with 500–600 mg per tablet or with an alternative dosage form (i.e., chewable, liquid, or dissolvable tablet) are listed.

^bMany products beginning to add magnesium, boron, zinc, copper, and manganese, and adding “Plus” or “Ultra” to name.

^cAlso contains vitamin K.

^dTablet for solution.

^eAlso contains magnesium, zinc, copper, boron, and manganese.

^fAlso contains phosphorus and magnesium.

decreased body weight, enhanced estrogen metabolism, increased PTH concentrations, and decreased vitamin D concentrations. Excessive alcohol use has been associated with low BMD and subsequent fracture in some, but not all, studies. The effects are greater with chronic heavy drinking early in life. Malnutrition associated with alcoholism could also play a role. Alcohol use also may increase the risk of falls.

EXERCISE

3 Bones adapt to handle the workload to which they are subjected. Long-term exercise (likely many years) during youth increases peak BMD. Physical activity, especially aerobics, weight

bearing, and resistance exercise and walking, preserves BMD in postmenopausal women.³⁶ Continued activity appears necessary to maintain benefit. Exercise also enhances calcium and estrogen therapy.³⁷ In addition to the positive bone effects, physical activity likely reduces fracture risk by reducing falls (from improved balance, posture, flexibility, range of motion, muscle strength, and endurance). Physical activity, as tolerated, should be encouraged for all patients with osteoporosis. Before starting an exercise program for an elderly patient or one with severe osteoporosis, a medical examination is recommended. Referral to a physical therapist may be helpful.

Excessive exercise in a premenstrual woman, however, can lead to amenorrhea and estrogen deficiency with consequent bone loss and increased fracture risk.³⁸

■ FALL PREVENTION

Exercises to improve muscle strength, gait, balance, and flexibility should be employed whenever possible. Tai chi also reduces fall risk.³⁹ The need for ambulation-assistive devices (canes and walkers) and assistance with transferring from various positions or for toileting should be assessed. Vision should be assessed and corrected when necessary. The living environment should be evaluated and modified to minimize falls. Loose rugs and extension cords should be eliminated, grab bars mounted in the bathroom, handrails installed on stairs, nonskid tape placed in bathtubs, and adequate lighting ensured. Although the use of hip protectors decreases fractures from falls, most patients do not like to wear them.

Medications should be reviewed and those that may cause falls should be eliminated when possible. Examples include psychotropics, sedative-hypnotics, antidepressants, antihypertensives, and diuretics. Sedative-hypnotic use should be limited or discontinued. When benzodiazepines must be used, shorter-acting ones are recommended, but are still not risk-free. Other drugs altering balance and lowering blood pressure and blood glucose changes should be carefully monitored. Patients should be warned about medications that contribute to orthostasis and should be warned about abrupt postural changes.

■ PHARMACOLOGIC PREVENTION AND TREATMENT

Nonpharmacologic interventions alone are not always sufficient to prevent osteoporosis-related fractures, and drug therapy is often necessary. Table 88–6 describes the important aspects of the commonly prescribed medications for osteoporosis. The choice of pharmacotherapy depends on many individual patient-specific characteristics and preferences. Regardless of the medication selected, all patients should receive adequate calcium and vitamin D intake. In order to optimally reduce fracture risk, all people should also implement lifestyle modifications that reduce fall risk.

The two FDA-approved indications for osteoporosis medications—prevention and treatment—were created before enhanced understanding of the disease. The “prevention” of osteoporosis indication applies to drugs that demonstrate maintenance of BMD above the osteoporosis threshold (T-score >-2.5) compared to placebo over a 3-year period in patients with low bone mass (T-score <-1.0). Although commonly misinterpreted by clinicians, this indication does not infer a fracture risk reduction, the primary therapeutic end point. The “treatment” indication, however, is based on a drug’s ability to demonstrate fracture risk reduction, either at the vertebral or nonvertebral sites, compared to placebo.

■ TREATMENT GUIDELINES

No single, widely accepted treatment guideline exists for osteoporosis. Several organizations have suggested various treatment approaches, most of which are based more on consensus opinion than evidence-based medical data.

The updated 2003 National Osteoporosis Foundation (NOF) guidelines, created in collaboration with nine specialty physician professional organizations, encourage a healthy lifestyle, including adequate calcium and vitamin D, exercise, and tobacco avoidance.³ The NOF favors BMD testing in all women 65 years and older as well as younger postmenopausal white women with at least one risk factor. Their recommendations for testing all postmenopausal women with a

fragility fracture and the initiation of therapy for those with osteopenia (T-score <-2.0 without risk factors and <-1.5 with one or more risk factors) are not data-based. They currently consider all approved medications as appropriate pharmacotherapy. A specific monitoring approach is not articulated. No recommendations exist for men. Unfortunately, the guidelines often lack sufficient detail and supporting clinical evidence and rationale.

For postmenopausal women, the 2002 U.S. Preventive Services Task Force addressed screening and only recommends routine screening beginning at age 65, with earlier screening suggested at age 60 for women who are at increased risk.⁴⁰ A companion document provides discussion of the specific evidence.⁴¹

The 2002 Canadian osteoporosis guidelines for women and men were developed using an evidence-based process.⁷ This comprehensive document cites levels of supporting evidence and grades its recommendations. They identify four key risk factors for osteoporosis: low BMD, prior fragility fracture, age, and positive family history of osteoporosis. The guidelines also advocate treating patients with a clinical diagnosis of osteoporosis (BMD <-2.5 , but history of atraumatic fracture).

The 2002 North American Menopause Society’s position statement on the management of postmenopausal osteoporosis reviews pertinent literature pertaining to the pathophysiology, identification, and treatment of osteoporosis.⁸

■ ANTIRESORPTIVE THERAPY

■ Calcium

4 Hypocalcemia can result from inadequate dietary intake, decreased fractional calcium absorption (as seen with increasing age), or enhanced calcium excretion. To restore calcium homeostasis after hypocalcemia, PTH concentrations rise, and vitamin D metabolism increases to enhance intestinal calcium absorption (see Fig. 88–3), renal calcium reabsorption, and bone resorption. Fracture risk is greatest with low calcium intake and low fractional calcium absorption.⁴²

■ *Clinical Effectiveness.* Although a few studies have found calcium to decrease fractures,⁴³ most well-conducted studies do not.^{44,45} When fracture prevention was documented, concomitant vitamin D therapy was usually given. Over 150 studies have evaluated calcium’s effect on BMD, with almost all trials and observational studies showing higher calcium intake in children and adults produced greater increases or maintenance of BMD compared to BMD losses with placebo.⁴⁶ During the first 5 years following menopause, calcium is less effective, when estrogen deficiency is the predominant cause of accelerated bone loss. Calcium’s effects are augmented when combined with exercise or antiresorptive drugs.⁴³ Thus adequate calcium intake (see Table 88–4) is considered standard for osteoporosis prevention and treatment for all people.

Nonbone benefits of high calcium intake include reduced colorectal cancer risk and decreased blood pressure.⁴³

■ *Administration.* Most children and adults do not ingest sufficient dietary calcium and require supplements (see Tables 88–5 and 88–6). Individuals with certain characteristics or conditions—such as lactose intolerance; nondairy vegetarian diet; malnutrition; low-fat diets; and glucocorticoid, antiresorptive, or parathyroid therapy—also require evaluation for calcium supplementation. To ensure adequate calcium absorption, 25(OH) vitamin D concentrations should be maintained in the normal range.⁴⁷

TABLE 88–6. Medications Used to Prevent and Treat Osteoporosis

| Drug | Dosage | Pharmacokinetics | Adverse Effects | Drug Interactions |
|---|--|---|--|---|
| Calcium | 200–1500 mg/day; see Tables 88–3 and 88–5; divided doses | Absorption: predominantly active transport with some passive diffusion; fractional absorption 10–60%; fecal elimination for the unabsorbed and renal elimination for the absorbed calcium | Constipation, gas, upset stomach, rare kidney stones | <ul style="list-style-type: none"> Absorption is decreased with proton pump inhibitors Decreases absorption of iron, tetracycline, quinolones, alendronate, risedronate, etidronate, phenytoin, and fluoride when given concomitantly May antagonize verapamil May induce hypercalcemia with thiazide diuretics Fiber laxatives, oxalates, phytates, and sulfates decrease calcium absorption if given concomitantly |
| Vitamin D ₂ or D ₃ | 200–1000 units/day; if malabsorption or on multiple anticonvulsants, may require higher doses (~4000 units/day or more); for vitamin D deficiency, 50,000 units once weekly or once monthly can be used; monitor serum calcium | Hepatic and renal metabolism to active compound 1,25 (OH) vitamin D; active and inactive metabolites | Hypercalcemia, (weakness, headache, somnolence, nausea, cardiac rhythm disturbance); hypercalciuria | <ul style="list-style-type: none"> Phenytoin, barbiturates, carbamazepine, rifampin increase vitamin D metabolism Cholestyramine, colestipol, orlistat, or mineral oil decrease vitamin D absorption May induce hypercalcemia with thiazide diuretics in hypoparathyroid patients |
| <i>Bisphosphonates</i> | | | | |
| Alendronate (Fosamax) | 5 mg daily (prevention); 10 mg daily; 70-mg tablet or 75-mL single-use oral dose weekly (treatment) | Poorly absorbed <1%, decreasing to zero with food or beverage intake; long half-lives (2–10 years); renal elimination (of absorbed) and fecal elimination (of unabsorbed) | Nausea; GI irritation, perforation, ulceration, and/or bleeding | <ul style="list-style-type: none"> Do not coadminister with any other medication, including calcium |
| Risedronate (Actonel) | 5 mg daily, 35 mg weekly | | | |
| Ibandronate (Boniva) | 2.5 mg daily, ^a 100–150 mg monthly, ^b 3 mg IV every 3 months ^c | | | |
| <i>Selective estrogen receptor modulators</i> | | | | |
| Raloxifene (Evista) | 60 mg daily | Hepatic metabolism | Hot flushes, leg cramps, venous thromboembolism | None |
| Calcitonin (Miacalcin) | 200 units daily, intranasally (alternating nares every other day) | 3% nasal availability; renal elimination | Rhinitis, epistaxis | None |
| Teriparatide (Forteo) | 20 mcg subcutaneously daily for up to 2 years | 95% bioavailability; T _{max} : ~30 minutes; half-life ~60 minutes; hepatic metabolism | Pain at injection site, dizziness, leg cramps | None |
| Testosterone (used in men) | | Hepatic metabolism; highly protein bound to SHBG | Weight gain, acne, hirsutism, dyslipidemia, hepatotoxicity, gynecomastia, priapism, prostate disorders, testicular atrophy, sleep apnea, aggressive behavior, erythrocytosis, skin reaction to patches, drug absorption by sex partner | <ul style="list-style-type: none"> Potential of oral anticoagulants Can increase or decrease glucose, necessitating monitoring of antidiabetic medications at start of therapy |
| Androderm | 2.5–5 mg daily | | | |
| Testoderm TTS | 5-mg patch/day | | | |
| Androgel | 5 mg/day | | | |
| Testim gel | 5 mg/day | | | |
| Injectable products | 10–400 mg IM every 2–4 weeks | | | |
| Pellets | 150–450 mg/implant every 3–6 months | | | |

T_{max}, time to maximum concentration; SHBG, sex hormone-binding globulin; IV, intravenous; IM, intramuscular; FDA, Food and Drug Administration.

^cFiled for FDA review, December 2004.

Calcium carbonate is the salt of choice because it contains the highest amount of elemental calcium and is the least expensive (see Table 88–5). The fraction of calcium absorbed is dose-limited, so maximum single doses of 600 mg or less of elemental calcium are recommended. Calcium carbonate tablets should be taken with meals to enhance absorption. Calcium citrate absorption is acid-independent and need not be administered with meals. Although tricalcium phosphate contains 39% calcium, nonabsorbable calcium-phosphorus complexes may limit overall calcium absorption compared to other products. This product may be required for up to 10% of seniors with hypophosphatemia that cannot be resolved with increased dietary intake.²⁸ Disintegration and dissolution rates vary significantly between products and lots. Products with good disintegration and dissolution rates and lead contents of less than 1 mcg/day should be recommended.

Calcium's most common adverse reaction, constipation, can be treated with increased water intake, dietary fiber (given separately from calcium), and exercise. Calcium carbonate can create gas, causing stomach upset, or absorb acid and relieve stomach upset. Food sources may be better tolerated. In some cases, the dosage may need to be lowered and reinstated slowly over time.

■ Diuretics

Thiazide diuretics increase urinary calcium resorption. A 10-year retrospective study of 83,728 women demonstrated fewer fractures among patients currently taking thiazides.⁴⁸ A prospective trial demonstrated maintenance of BMD at the spine and hip over a 3-year period with low-dose hydrochlorothiazide, with a greater effect seen in women.⁴⁹ Prescribing thiazide diuretics solely for osteoporosis is not recommended, but is a reasonable choice for the patient with osteoporosis who requires a diuretic.

■ Vitamin D and Its Metabolites

4 Vitamin D is responsible for maintaining calcium homeostasis. Low calcium concentrations lead to hyperparathyroidism and bone resorption. Vitamin D insufficiency (11 to 20 ng/mL) and deficiency (<10 ng/mL) [25(OH) vitamin D measurement, 10 ng/mL = 25 mcg/L] is becoming more commonly recognized in all age groups,^{50–52} especially malnourished individuals, northerners, women wearing veiled dresses, African-Americans, seniors, and long-term care residents. Low vitamin D concentrations result from insufficient intake, decreased sun exposure, decreased skin production, decreased liver and renal metabolism, and winter residence in northern climates.

■ **Clinical Effectiveness.** Product and dose influence outcomes. Observational data suggested daily vitamin D intakes of 12.5 mcg or greater are associated with decreased hip fracture.⁴⁵ A meta-analysis of eight studies evaluating vertebral fractures found vitamin D to be protective, with a relative risk of 0.63 (95% confidence interval [CI] 0.45 to 0.88).⁵³ Seven of the eight studies evaluated calcitriol. The relative risk for nonvertebral fractures was 0.78 (95% CI 0.55 to 1.09) for the one standard vitamin D study and 0.87 (95% CI 0.29 to 2.59) for hydroxylated vitamin D studies. Combined calcium and vitamin D (700 to 800 units/day) supplementation reduced nonvertebral fractures in elderly community dwellers and nursing home residents.⁴³ Higher doses of vitamin D are associated with improved BMD. Vitamin D 400 units with calcium 500 mg twice daily increased spine and

hip BMD in seniors with vitamin D deficiency.⁵⁴ Vitamin D's effect on maintaining muscle function⁵⁵ and decreasing pain are also important in the prevention and treatment of osteoporosis and falls. Because vitamin D receptors are found in intestine, brain, heart, stomach, pancreas, lymphocytes, skin, and gonads, vitamin D is being explored for effects on hypertension and certain cancers.¹⁴

Orally administered vitamin D₃, in a dosage of 100,000 units once every 4 months for 5 years, reduced the risk of fracture by 22% to 33% in a population of men and women.⁵⁶

Doxercalciferol (1 α -hydroxyvitamin D₂) is under investigation for osteoporosis treatment.

■ **Administration.** Although the Institute of Medicine adequate intakes (see Table 88–4) are usually recommended,²⁶ many experts feel that adult daily vitamin D intake should be 800 to 1000 units.

Given the relatively low cost and safety of vitamin D, no patient should have hypovitaminosis D. Sunlight exposure of 5% of skin equates to 435 units and whole-body exposure to sunlight to cause slight pinkness of the skin equates to 10,000 to 25,000 units of vitamin D.^{10,13} Within 20 minutes for whites and 60 to 120 minutes for blacks, the skin reaches maximum production for that day.¹³ In addition to milk, more foods—such as orange juice, soymilk, and cereals—are being fortified with vitamin D (see Table 88–2). Multivitamins, cod liver oil, combination calcium and vitamin D supplements, and single source products contain vitamin D (see Tables 88–5 and 88–6). Daily intake of more than one multivitamin or large doses of cod liver oil are no longer advocated to reduce the risk of hypervitaminosis A.

In patients with vitamin D deficiency, oral vitamin D 50,000 units daily for 10 days³⁷ or once weekly for 8 weeks, or 50,000 to 500,000 units intramuscularly¹⁰ is recommended. Serum calcium and 25(OH) vitamin D should be monitored periodically. Once replete, daily intakes of 600 to 1000 units are usually required. In the community or nursing home, vitamin D 100,000 units once per quarter is reasonable.⁵⁶ In patients with vitamin D malabsorption (e.g., gluten-sensitive celiac sprue), 25(OH) vitamin D (calcidiol) administration is needed. In patients with severe hepatic or renal disease, calcitriol therapy may be required. This drug requires careful titration and serum calcium and creatinine monitoring because of its hypercalcemic potential and the limited calciuric ability of the dysfunctional kidney.

When monitoring therapy, 25(OH) vitamin D concentrations, reflective of stores, should be used instead of 1,25(OH) vitamin D. Pharmacokinetics and season need to be taken into account. Since the half-life of vitamin D is about 1 month, minimally 1 to 4 months of therapy are required before the new steady state is achieved.¹³

CLINICAL CONTROVERSY

Although the Institute of Medicine recommends 400 units daily if under 71 years old and 600 units daily if 71 years or older,²⁶ many prescribers recommend higher doses since Institute of Medicine–recommended doses do not prevent hyperparathyroidism in everyone, which requires attaining 25(OH) vitamin D concentrations of 30 to 40 ng/mL.¹³ The relationship between intake and 25(OH) vitamin D concentration is curvilinear. Vitamin D 400 units produced average 25(OH) vitamin D concentrations of 18 ng/mL.¹³² Vitamin D 1000 units per day for more than 3 months produced 25(OH) vitamin D concentrations of at least 30 ng/mL in 35% of subjects (range among all patients, 16 to 40 ng/mL), and 4000 units of vitamin D daily produced these concentrations in 88% of subjects (range, 28 to 50 ng/mL). Vitamin D

800 units per day with calcium increased 25(OH) vitamin D concentrations by 22 ng/mL, decreased parathyroid hormone concentrations, and increased bone density in seniors with vitamin D deficiency,⁵⁴ whereas 400 units a day did not. Furthermore, fracture prevention with vitamin D was seen with 1,25(OH)₂ vitamin D products or standard vitamin D of 800 units or greater.^{43,45,53}

■ Bisphosphonates

◀⁵ Bisphosphonates mimic endogenous pyrophosphate. By binding to hydroxyapatite in bone, they decrease resorption by inhibiting osteoclast adherence to bone surfaces. The estimated terminal half-lives of bisphosphonates reflect the slow rates of bone turnover (many years). Etidronate may also inhibit bone mineralization that could lead to osteomalacia. Alendronate, risedronate, and ibandronate are currently FDA-approved for the prevention and treatment of postmenopausal osteoporosis. Risedronate and alendronate are indicated in glucocorticoid-induced osteoporosis, and alendronate is approved for osteoporosis in men.

■ **Clinical Effectiveness.** Bisphosphonates reduce the risk of fracture by 45% to 55% at all skeletal sites: vertebral, nonvertebral, and hip. Of the antiresorptive agents, bisphosphonates consistently provide the greatest BMD increases and fracture risk reductions at all skeletal sites. The effect demonstrated in large clinical studies is dose-dependent. The respective BMD increases range from 5% to 8% at the lumbar spine and 2% to 4% at the femoral neck. BMD increases are greatest in the first year of therapy, continue for at least 2 to 3 years, and then plateau for the duration of therapy. After discontinuation, the increased BMD is sustained for at least 1 year and remains higher than that of nonusers. BMD increases are seen in all subsets of patients (women, men, and seniors) but are not as pronounced in patients taking glucocorticoids. Although combination therapy with bisphosphonates plus either estrogen therapy (ET) or raloxifene produces greater BMD increases than either agent alone, alendronate appears to blunt the effects of teriparatide.^{58,59}

Alendronate is the most widely studied agent. Data generated from 10 years of therapy support its long-term benefit.⁶⁰ The Fracture Intervention Trial studied two populations of patients with low bone mass. First, alendronate demonstrated a robust and early (1 year) fracture risk reduction in a group with severe osteoporosis and pre-existing fractures at study entry.⁶¹ This was the first trial specifically showing a reduction in hip fractures. A second study arm evaluated the effects in patients with either osteopenia or osteoporosis, but without prevalent fractures. Although alendronate significantly reduced fracture risk in those with osteoporosis (T-score < -2.5), it did not reduce the risk of fractures in patients with osteopenia (T-score between -1.0 and -2.5) over a 3-year period.

The second bisphosphonate approved, risedronate, has also demonstrated significant fracture risk reduction in several North American and multinational studies.^{62,63} A pre-planned analysis revealed that risedronate reduced the risk of vertebral fractures by approximately 63% within the first year of therapy. Risedronate also reduced the risk of hip fractures.⁶⁴

Because ibandronate is the newest approved agent in the class, fewer published studies exist to support its beneficial effects on fracture rates. One 3-year pivotal efficacy trial, the BONE trial, demonstrated a 52% relative reduction (4.7% with daily doses, 4.9% with intermittent doses, and 9.6% with placebo) in new vertebral fractures in postmenopausal women.⁶⁵ The MOBILE trial evaluated once-

monthly ibandronate, but results had not been published when this chapter was finalized.

Oral etidronate, the first bisphosphonate to demonstrate a benefit, is rarely used because up to 33% of patients develop osteomalacia. Etidronate is administered intermittently as quarterly cycles of 400 mg daily for 2 weeks followed by calcium and vitamin D for 11 weeks. It increases vertebral BMD and decreases vertebral fracture risk, but not nonvertebral fracture risk.⁶⁶ When given with ET for 4 years, additive vertebral and hip BMD effects were seen without osteomalacia.

Some patients cannot tolerate oral bisphosphonates. Zoledronic acid is not FDA-approved for osteoporosis treatment, but is sometimes administered intravenously once yearly in patients for whom bisphosphonates are indicated. It improved BMD similarly to oral bisphosphonates,⁶⁷ but the impact on fracture rates is under investigation. Quarterly administration of intravenous pamidronate⁶⁸ or ibandronate⁶⁹ also improves BMD.

■ **Administration.** Even under optimal conditions, all bisphosphonates are poorly absorbed (bioavailability = 1% to 5%). Bisphosphonates must be administered carefully to optimize the clinical benefit and minimize the risk of adverse GI effects. Each oral tablet should be taken with at least 4 ounces of plain tap water (not coffee, juice, mineral water, or milk) at least 30 minutes before consuming any food or any other supplement or medication. The weekly oral solution needs to be taken with only 2 ounces of water. The patient should remain upright (either sitting or standing) for at least 30 minutes after bisphosphonate administration. When calcium and vitamin D dietary consumption are insufficient, supplementation is needed to ensure the beneficial effects of bisphosphonates.

Most patients prefer once-weekly bisphosphonate administration (see Table 88–6). This dosing schedule lowers GI tract drug exposure. Because the turnover rate of the cells lining the GI tract is about 5 days, any cells damaged during drug exposure are theoretically replaced before the next week's dose is taken. Once-weekly alendronate administration achieved similar BMD results, had similar GI adverse effects, and did not impair mineralization, compared with daily doses of 10 mg.⁷⁰

The most common bisphosphonate adverse effects are nausea, abdominal pain, and dyspepsia. They occur in 10% to 20% of women taking alendronate 10 mg daily, a rate that is similar to placebo in clinical trials. GI event rates are not significantly higher in bisphosphonate users who take nonsteroidal anti-inflammatory drugs. Increased perforations, ulcerations, and bleeding have been seen in the oldest women in studies, but the frequencies were not significantly different from events for similarly aged women in the placebo group. Perforations, ulcerations, and bleeding can also result when administration directions are not followed or when bisphosphonates are prescribed for patients with contraindications. Patients should be encouraged to discuss GI complaints with a health care provider. Risedronate, a pyridinyl bisphosphonate, may have fewer GI effects than alendronate, an amino bisphosphonate, but long-term comparisons are not available.

■ Selective Estrogen Receptor Modulators

◀⁶ Raloxifene, the first selective estrogen receptor modulator (SERM) approved for prevention and treatment of postmenopausal osteoporosis, is an estrogen agonist in bone tissue but an antagonist in the breast and uterus. Although tamoxifen, a SERM that is approved for breast cancer prevention, also inhibits bone loss, it is an agonist in the uterus and thus can cause endometrial cancer.⁷¹ Investigational SERMs include arzoxifene, bazedoxifene, lasofoxifene, and ospemifene.

■ **Clinical Effectiveness.** Raloxifene increases spine and hip BMD by 2% to 3%, a response less than that seen with bisphosphonates or estrogen therapy.⁷¹ From the Multiple Outcomes of Raloxifene Evaluation (MORE) 4-year trial, raloxifene reduced vertebral fractures by 68% within the first year,⁷² with prevention persisting throughout the study duration (4-year relative risk, 0.64; 95% CI 0.53 to 0.76).⁷³ Although fracture prevention was associated with increased BMD, this surrogate outcome only accounted for 4% of the fracture prevention.⁷⁴ Raloxifene improved bone quality by increasing heterogeneous bone mineralization.⁷⁵ Nonvertebral fractures were not prevented by raloxifene.⁷³

Raloxifene combined with alendronate⁷⁶ produced greater BMD effects than raloxifene alone, but not greater than alendronate alone. The impact on fracture outcomes, however, is not yet known. Contrary to bisphosphonate discontinuation—in which the achieved BMD is maintained or decreased much more slowly than among those in the placebo group—raloxifene discontinuation results in BMD decreasing immediately at a rate similar to that of placebo.⁷⁷

Like tamoxifen, raloxifene is associated with decreased breast cancer risk. In the MORE trial, raloxifene users developed an estrogen-dependent first breast cancer 70% less often than those in the placebo group, but differences were not statistically significant with regard to estrogen-negative breast cancers.⁷⁸ Greater prevention was seen in women with pretreatment estrogen concentrations greater than 10 pmol/L. Raloxifene is not approved yet for breast cancer prevention or treatment. In the Study of Tamoxifen and Raloxifene trial, these SERMs are being compared for breast cancer prevention in high-risk women.

Despite seemingly positive lipid effects (decreased total and LDL cholesterol, neutral effect on HDL cholesterol, but slightly increased triglycerides) with SERMs, beneficial cardiovascular effects have not yet been clinically demonstrated. Coronary and cerebrovascular outcomes as well as safety end points were similar to placebo in the 4-year MORE trial, even within the first year.⁷⁹

For women with severe osteoporosis, particularly when hip fracture risk reduction is desired, a bisphosphonate is likely a better choice than a SERM.

■ **Administration.** Overall, raloxifene therapy is well tolerated, but hot flashes occasionally cause women to discontinue therapy (see Table 88–6). Raloxifene use is associated with a threefold increased risk of venous thromboembolism,⁷³ similar to the increased risk seen in women taking estrogens. Raloxifene is contraindicated for those with active thromboembolic disease. Therapy should be stopped if a patient anticipates a significant period (several hours or more) of immobility. Raloxifene does not induce endometrial bleeding.

■ Calcitonin

Calcitonin is released from the thyroid gland when serum calcium is elevated. Salmon calcitonin is used clinically because it is more potent and longer lasting than the mammalian form. Pharmacologic doses decrease bone resorption. Calcitonin is indicated for osteoporosis treatment for women at least 5 years past menopause. Although the agent is also used in men, it is not approved for this indication. Because calcitonin reduces fracture risk to a lesser extent than other osteoporosis medications, calcitonin is reserved for second-line treatment.

■ **Clinical Effectiveness.** The largest calcitonin study, the PROOF study, randomized 1255 osteoporotic women, most with prevalent vertebral fractures, to intranasal calcitonin or placebo for up to

5 years.⁸⁰ The 200-unit daily regimen increased spine BMD and reduced new vertebral fractures by 36%. A dose-response relationship did not exist and the dropout rate was 59%. Calcitonin does not consistently affect hip BMD and does not decrease hip fracture risk.

Calcitonin may provide pain relief to some patients with acute vertebral fractures, but this effect is minimal. Calcitonin should not be used in place of other more effective and much less expensive analgesics.^{81,82}

■ **Administration.** The intranasal dose of calcitonin is sprayed in alternating nares every other day (see Table 88–6). Other than minor nasal adverse effects, calcitonin is well tolerated. Subcutaneous administration at 100 units daily is available but rarely used.

■ Estrogen and Hormonal Therapy

◀ Estrogen receptors exist on osteoblasts, osteoclasts, macrophage cells, intestinal cells, and many other tissues. Estrogens decrease osteoclast recruitment and activity, inhibit PTH peripherally, increase calcitriol concentrations and intestinal calcium absorption, and decrease renal calcium excretion. They also decrease cytokine concentrations and decrease the activity of the OPG/RANK/RANKL pathway, inhibiting bone resorption. Response to estrogen deficiency and replacement may be related to estrogen receptors and polymorphisms.

■ **Clinical Effectiveness.** Hormonal therapy (HT) was shown to statistically decrease vertebral, hip, and all fractures by 34%, 34%, and 24%, respectively; however, this effect became insignificant when analyzed as a secondary finding in the Women's Health Initiative.⁸³ The estrogen-alone arm of the Women's Health Initiative (WHI) trial also found decreased hip fractures in estrogen therapy (ET) users.⁸⁴ Meta-analyses using various study inclusion criteria also found ET/HT to decrease vertebral and nonvertebral fractures by 33% to 40% and 13% to 27%, respectively.^{85,86}

BMD effects from ET or HT are less than for bisphosphonates or teriparatide, but greater than for raloxifene, tibolone, and phytoestrogens. Pooled results from prevention studies showed that ET and HT increased lumbar spine BMD by 4.9% and 7.0%, femoral neck BMD by 2.3% and 4.1%, and forearm BMD by 3% and 4.5% in the first and second years, respectively.⁸⁶ Both younger and older postmenopausal women achieve increased BMD with ET and HT. Oral and transdermal estrogens at equivalent doses and continuous or cyclic HT regimens have similar BMD effects. ET implants and intrauterine impregnated devices and creams have shown positive bone effects. Effect on BMD is dose-dependent, with benefit seen with doses as low as 0.025 mg transdermal estradiol, 0.3 mg conjugated equine estrogen,⁸⁷ and 0.3 mg esterified estrogen. Most BMD gains were seen within the first few years of treatment, with slight increases or a plateau thereafter. Longer duration of use is associated with greater BMD effects. Women who continuously used ET or HT since menopause or those with long-term use beginning in their senior years had the highest BMD.⁴¹ ET and HT is not protective for all women; thus women who have or are receiving ET or HT should be monitored for effectiveness. BMD effects are increased when ET or HT is combined with bisphosphonates¹⁰ and parathyroid hormone.⁸⁸ Progestins added to ET resulted in no change or a slight increase in BMD. When ET or HT was discontinued, bone loss was accelerated for a short period, compared with placebo, in most⁷⁷ but not all studies.

The bone benefits of ET and HT documented in observational and clinical trials are not greater than the negative effects. Contrary to observational studies, ET and HT do not prevent primary or secondary

cardiovascular disease, and may even increase events within the first years of use.^{83,85} For every 10,000 woman-years of HT, 5 hip fractures and 6 colorectal cancers were prevented, while 7 coronary heart disease events, 8 strokes, 8 breast cancer cases, and 8 pulmonary emboli were caused.⁸³ The net balance for HT prevention in the WHI trial would be an additional 19 negative events per 10,000 woman-years, which is not considered acceptable by most. Of note, mortality was not changed with HT. None of the subgroups of patients at high risk for osteoporotic fractures had a positive overall effect from HT.⁸⁹ Increased strokes were the reason for the ET WHI arm to be stopped early.⁸⁴ For every 10,000 woman-years of ET, the net balance between benefit and risk was 2 additional negative events, which was not significant. Like the HT arm, ET did not change overall mortality. Reasons why the WHI trial refutes the large volume of supportive literature may be due to selection biases such as higher socioeconomic status, greater literacy, better access to health care, more preventive health behaviors, earlier detection of conditions with better survival rates, and less baseline cardiovascular disease and mortality of women who chose to use ET or HT.

Thus ET and HT are not advocated for prevention of osteoporosis and fractures since other better and safer medications exist.^{90,83} Even though the WHI trial only assessed one ET and HT dose, most clinicians are extrapolating the results to all estrogen replacement therapies until data exist to document the contrary. The lowest effective dose of ET and HT should still be used for preventing and controlling menopausal symptoms, with use discontinued with symptom abatement.

■ **Administration.** The risks and benefits of beginning or continuing ET and HT must be discussed with all women. Numerous contraindications to ET and HT exist and must be identified before initiation. For women with an intact uterus, a progestin (e.g., medroxyprogesterone 2.5 to 5 mg daily or the equivalent) should also be used to decrease the risk of endometrial cancer. The lowest estrogen dose to maintain BMD is advocated (see menopause chapter for other ET product doses, specific use, and adverse effects information). Vaginal administration from creams or rings results in significant systemic absorption, but concentrations are much lower than normal oral dosing of ET products, and thus effects on BMD are minimal.

■ Tibolone

Tibolone, a synthetic steroid, and its metabolites are weak estrogen-, progesterone-, and androgen-receptor agonists. They relieve hot flashes and increase BMD, but have no effect on the endometrium. In younger and older postmenopausal women, tibolone increased spine and hip BMD after 1 to 10 years of 1.25 or 2.5 mg daily.⁹¹ Effects on fractures and cardiovascular disease are still unknown. Adverse effects are less than with estrogen/progestin regimens. Currently used in Europe, tibolone is not yet FDA-approved for use in the United States.

■ Phytoestrogens

The isoflavonoids (soy proteins) and lignans (flaxseed) are the most common forms of phytoestrogens. Isoflavones are metabolized to genistein and daidzein, ligands for both estrogen α and β receptors, with a greater affinity for β receptors.⁹² Bone effects may be related to bone estrogen receptor agonist activity or potentially direct or indirect effects on osteoblasts and osteoclasts. A red clover-derived supplement decreased lumbar spine but not hip bone loss in a large, placebo-controlled clinical trial.⁹³ No fracture outcome data are available. Bone density results are difficult to analyze due to different phy-

toestrogen products, quantities, and preparations; differing age and race of the study samples; small samples; and suboptimal study design. Overall, isoflavone pharmaceuticals or food studies using larger doses have reported decreased bone resorption markers and small increases in bone density; however, inconsistencies and negative results have been reported as well.^{92,94} Thus these products can be used for preventive bone-sparing effects, but are probably not sufficient alone for treatment.

Although ipriflavone, a synthetic isoflavone available in health food stores, is partially metabolized to daidzein, it is void of estrogenic activity outside of bone. Increased to no change in BMD were measured in 2-year or shorter studies.^{92,95} A 4-year study with 474 postmenopausal women showed no effect of ipriflavone 200 mg three times daily on vertebral fractures or BMD.⁹⁶ Subclinical lymphocytopenia developed in 13% of the sample, with 19% of these women's lymphocyte counts not returning to normal after 2 years off therapy. Therefore ipriflavone's use, especially long-term use, should be discouraged.

■ Testosterone and Anabolic Steroids

Decreased testosterone concentrations are seen with certain gonadal diseases, eating disorders, glucocorticoid therapy, oophorectomy, and menopause, and in aging men with hypogonadism. In a few studies, women receiving methyltestosterone 1.25 or 2.5 mg oral daily or testosterone implants 50 mg every 3 months had increased BMD.⁹⁷ Testosterone, in various salt forms, was associated with increased BMD in some studies when given to hypogonadal men and senior men with normal hormone levels or mild hormonal deficiency.¹⁹ Transdermal gel, oral, intramuscular, and pellet testosterone products are available. Testosterone products are generally prescribed only by specialist physicians. Anabolic steroids (nandrolone decanoate) have shown minimal to no effect on BMD, but do increase muscle strength.

The virilizing and estrogenic adverse effects of these products are listed in Table 88-6.^{97,98} Patients using these products should be evaluated within 1 to 2 months of onset and then every 3 to 6 months thereafter.

■ BONE-FORMATION THERAPY

■ Teriparatide (Parathyroid Hormone)

Teriparatide contains the first 34 amino acids in human parathyroid hormone and represents a novel approach to osteoporosis treatment. Although hyperparathyroidism leads to bone loss (see Fig. 88-3), therapeutic doses (for shorter periods of time) conversely improve BMD and reduce fracture risk. Parathyroid hormone is currently the only approved osteoporosis medication that works by stimulating bone formation. Because of adverse effects and cost concerns, teriparatide is reserved for treating those at high risk of osteoporosis-related fracture who cannot or will not take or have failed bisphosphonate therapy.

Recombinant human parathyroid hormone (1-84) and once-weekly PTH administration are being evaluated.

■ **Clinical Effectiveness.** Teriparatide works equally well in women and men with osteoporosis. Teriparatide has reduced the risk of new vertebral fractures by 65% compared with placebo (actual fracture incidence 5% vs. 14%, respectively) in postmenopausal women with osteoporosis and pre-existing fractures.⁹⁹ New nonvertebral fracture risk was reduced by 53% (3% fractures with teriparatide vs. 6% fractures with placebo) with the 20-mcg/day dosage. Teriparatide can

increase lumbar spine BMD by 9% to 13% and femoral neck BMD by 2.8%. In men with osteoporosis, teriparatide increased BMD, but its impact on fracture rate remains undetermined.¹⁰⁰ In a small study, when parathyroid hormone 25 mcg/day was added to established HT, spine BMD increased by 13.4% and total hip BMD increased by 4.4%, and resulted in a corresponding 75% to 100% reduction of vertebral fractures.⁸⁸ Teriparatide should not be used in combination with alendronate because the bisphosphonate may blunt the teriparatide's beneficial effects.^{58,59}

■ **Administration.** Teriparatide is contraindicated in patients with Paget's disease of the bone, unexplained elevations in alkaline phosphatase, or a history of previous skeletal radiation therapy (a black-box warning from the manufacturer). Osteosarcoma was seen in a small number of rats, but the incidence in humans is unknown but of potential concern.

Teriparatide is commercially available as a prefilled 3-mL pen-type delivery device that administers subcutaneous injections in the thigh or abdominal area (see Table 88–6). The initial dose should be administered with the patient either sitting or lying down in case orthostatic hypotension occurs. Health care providers should re-educate patients about syringe use with each refill, and the patient or caregiver should also re-read the user's manual each month. The pen should be refrigerated and can be used for up to 28 days following the initial injection. Teriparatide is also the most expensive of the approved osteoporosis therapies.

■ Strontium

Strontium stimulates bone formation and decreases bone resorption. In a preliminary study of postmenopausal women with severe osteoporosis, strontium ranelate 1 g twice daily or 2 g once daily reduced new vertebral fractures by 41%, and increased lumbar spine BMD by 14% and femoral neck BMD by 8% compared with placebo.¹⁰¹ Nonvertebral fracture rates were similar. Diarrhea was more common in the strontium group. Small decreases in serum calcium and PTH, small increases in serum phosphate, and transient increases in creatine kinase were measured.

■ HMG-CoA Reductase Inhibitors (Statins)

In the search for agents to increase bone formation through bone morphogenetic proteins, 3-hydroxymethyl-4-glutaryl CoA reductase inhibitors (statins) were discovered to increase bone density in animal models. Interest in the potential skeletal benefits of statins was heightened by the discovery that bisphosphonates may also affect cholesterol biosynthesis, but at a different step than statins. Although observational studies have linked statin use with decreased fracture risk, a large case-control study did not demonstrate reduction in fracture risk for statin-treated patients. A meta-analysis casts doubt on a protective effect of statins (odds ratio for hip fracture, 0.87; 95% CI 0.48 to 1.58).¹⁰²

■ Growth Hormones and Factors

Growth hormone (GH) and IGF-1 play important roles in bone turnover and remodeling, with multiple effects on other tissues. Their serum concentrations decline with age and frequently are decreased in osteoporosis. Growth hormone injections have been found to increase or cause no change in BMD in patients with osteoporosis and normal GH concentrations, and patients with GH deficiency.¹⁰³ Short-

term studies showed a negative effect, while the longer-term studies showed a positive effect that continued to increase for 1 to 2 years after discontinuation of GH therapy.^{103,104} Growth hormone-releasing hormone and other GH secretagogues, some of which are oral, are undergoing extensive research.^{103,105} Recombinant IGF-1 injections, with or without IGF-3 binding protein, increased both bone formation and resorption.¹⁰⁶

Adverse effects reported for GH and for IGF-1 include skin irritations, alterations in glucose utilization, joint stiffness, and peripheral edema.

■ Fluoride

Although fluoride increases osteoblastic activity and bone formation through intracellular signaling pathways involving tyrosine phosphatases and mitogen-activated protein kinases, it remains an unapproved therapy despite 30 years of clinical study. Early studies, in fact, demonstrated an increased risk of cortical bone fractures. Although men and women given fluoride monophosphate and women given lower-dose, slow-release sodium fluoride had fewer vertebral fractures, these findings were not validated in two other studies. A meta-analysis also determined that fluoride lacked antifracture efficacy.¹⁰⁷ Fluoride is currently not recommended for use.

■ Investigational Agents

In addition to the above drugs, new classes of medications are beginning to show promise.¹⁰⁸ Osteoprotegerin (OPG), a competitive inhibitor of RANKL, blocks osteoclastic differentiation and has decreased bone resorption biomarkers (phase I and II). As it is a large protein, administration is via injection. Agents to enhance endogenous OPG, decrease RANKL production, or block RANKL binding to RANK are being developed. Agents to block osteoclast attachment ($\alpha V \beta 3$ integrin receptor antagonists, in preclinical testing), inhibit bone matrix degradation (cathepsin K inhibitors, in phase I studies), and nitrosylated nonsteroidal anti-inflammatory drugs, in phase II studies), or change osteoclast cell structure (Src inhibitors, in preclinical studies) have been initially effective.

■ VERTEBROPLASTY AND KYPHOPLASTY

The percutaneous injection of polymethylmethacrylate (PMMA) bone cement into a compressed vertebral fracture confers significant pain relief for many patients. Under local anesthetic, with computed tomography scanning or fluoroscopic guidance, PMMA is injected under slight pressure during vertebroplasty. The procedure stabilizes the damaged vertebrae and reduces pain in 70% to 92% of patients. Pain scores usually improve by approximately 50% at 1 month following the treatment.¹⁰⁹

Kyphoplasty is a newer procedure that requires drilling into the vertebral body and inflating a balloon to re-expand the fracture. The process is followed by the injection of about 7 mL of the PMMA cement. The patient remains in a supine position for 1 to 2 hours to allow the cement to cure. Because this curing process creates an exothermic reaction, surrounding tissue is slightly damaged. It remains unclear whether this is an unwanted side effect or in fact the mechanism by which pain is relieved. Cement leakage into the spinal column can result in complicating nerve damage.¹¹⁰

■ SPECIAL POPULATIONS

■ WOMEN WITH AMENORRHEA

Adolescents and women with primary or secondary amenorrhea, due to diet,¹¹¹ excessive exercise,³⁸ or hypothalamus-pituitary-ovarian axis disorders,¹¹² have lower BMD than other age-equivalent individuals.

Although predominantly attributed to hypoestrogenemia, diet has a significant impact, since BMD is lower in those with amenorrhea from anorexia than in those whose conditions result from excessive exercise. Anorexia's effect is greatest if it occurs before peak bone mass achievement. After 6 months of amenorrhea, a bone density test should be performed and then repeated yearly while amenorrheic. BMD measurements may be inaccurate in small-boned people and children, requiring the use of Z-scores, especially before peak bone mass achievement, or corrections for age and sexual maturity. For those with amenorrhea or anorexia, higher calcium intakes of 1200 to 1500 mg and adequate vitamin D are recommended.

In anorexia, the primary therapy is normal diet, weight gain, and return of normal menses. Of note, BMD improves but never returns to the level of age-matched controls.

The American Academy of Pediatrics recommends low-dose estrogen supplementation for amenorrhea if age is greater than 16 until normal menses returns.³⁸ Most studies do not find that oral contraceptives improve BMD.^{38,111} Bisphosphonates are not approved for children. Hormone therapy and bisphosphonates may be used in adults. Recombinant IGF-I and dehydroepiandrosterone are being explored as possible for treatments for women with osteoporosis.

■ MEN

8 Some men with osteoporosis possess clearly identifiable risk factors. In others, further investigation for secondary causes is warranted (see above patient assessment section). Men 70 years and older should have DXA tests to screen for osteoporosis. DXA standards state T-scores should be compared with a white male normative reference database, regardless of ethnicity. BMD determination should also be considered for men with a low-trauma fracture, prevalent vertebral deformity, glucocorticoid use, hypogonadism, alcoholism, or poor overall health. Measurement of serum free or total testosterone can also determine if hypogonadism is contributing to bone loss.

Management of male osteoporosis is similar to that of women except that neither estrogens nor SERMs are used. Lifestyle modifications (see above) are important interventions in men. Bisphosphonates are the drugs of first choice. Although alendronate is FDA-approved for men and reduces the risk of vertebral fractures, other available bisphosphonates are also clinically used.¹¹³ Osteoporosis due to secondary causes should include treatment of the underlying cause plus a bisphosphonate. Bisphosphonates also appear to have beneficial BMD effects in men receiving androgen deprivation therapy for prostate cancer.¹¹³

For the man with symptomatic hypogonadism (decreased libido, energy loss, and erectile dysfunction), a normal prostate examination, and a normal serum prostate-specific antigen, testosterone can be considered as adjunctive therapy. Testosterone patches (2.5–5 mg daily), intramuscular injections (10 to 400 mg every 2 to 4 weeks), 1% topical gel, pellet implants (150–450 mg every 3–6 months), and a buccal formulation are available (see Table 88–6). Testosterone replacement increases bone density in men. The benefits of therapy need to be

weighed against a higher risk of prostate cancer and benign prostatic hyperplasia. Adverse effects are listed in Table 88–6.

■ SENIORS

Even though therapies exist, many seniors are not evaluated or treated for osteoporosis, including those who have had a fracture.¹¹⁴ In these patients, fall prevention plus BMD optimization is necessary to optimally reduce fracture risk. Functional status impairment is also an important contributor to fractures in seniors.¹¹⁵

Adequate calcium and vitamin D intake (see Table 88–4) should be assured. For seniors with severe osteoporosis, a 25(OH) vitamin D concentration should be used to guide vitamin D supplementation. Centenarians have a particularly high rate of hypovitaminosis D.¹¹⁶ Smoking cessation and exercise begun late in life still have positive bone effects.

For most seniors, bisphosphonates are the preferred agents. Esophageal dysfunction should be clinically ruled out, and the patient's ability to adhere to the complex administration process must be assured before beginning therapy. Once-weekly dosing is usually preferred. Although bisphosphonates are not recommended in patients with renal insufficiency (creatinine clearance <35 mL/min), some clinicians are using lower-dose (alendronate 35 mg once weekly) therapy. Because many seniors do not have medication coverage, cost issues need to be addressed.

Raloxifene, nasal calcitonin, or parenteral teriparatide are treatment options for seniors who will not or cannot take an oral bisphosphonate. Hormone therapy is no longer advocated because of the WHI trial results. Current ET or HT use still confers a bone benefit, but benefits from past hormone use are lost after discontinuation. Seniors have a greater incidence of ET and HT adverse effects (especially breast tenderness). Most seniors should be tapered off ET and HT if they are still using either one. When used, lower ET/HT doses (0.3 mg conjugated equine estrogen or equivalent) should be prescribed. Clinical guidelines for the diagnosis and management of osteoporosis in the long-term setting have been created.^{117,118} Patients and family may help decide if pharmacotherapy for bone health is wanted.

■ TRANSPLANT RECIPIENTS

Underlying diseases that necessitate solid organ or bone marrow transplantation can cause bone loss prior to surgery. After the transplant, bone loss may accelerate during the first 6 months. Decreased physical activity and glucocorticoid use are major contributors to this phenomenon (see below).¹¹⁹ After transplantation, fractures are greater and Z- and T-scores are lower in transplant recipients. During the early posttransplant period, resorption decreases and formation increases, but later after transplantation, both formation and resorption increase. Additional causes for bone loss include other medications (loop diuretics, aluminum-containing phosphate binders, and heparin), hyperparathyroidism, hypogonadism, hypovitaminosis D, decreased calcium intake or absorption, hepatic congestion, prerenal azotemia, and cystic fibrosis. Animal, but not human, research showed cyclosporine and tacrolimus decreased BMD.

Before transplant, BMD should be measured and vitamin D and gonadal status assessed. Bone-healthy lifestyle changes and therapy should be instituted as needed (see Fig. 88–4) and hypogonadism corrected before and after transplant. Intermittent pamidronate has decreased bone loss in most transplant recipients.¹¹⁹ Use of bisphosphonates in children and when creatinine clearance is less than 30 mL/min is being explored. Glucocorticoid doses should be

reduced as quickly as possible. Estrogen enhances hepatic metabolism of cyclosporine. Ovulation and testosterone production may increase after transplantation and hormone supplementation may no longer be needed. Calcitriol may be needed instead of vitamin D, depending on the severity of renal or liver dysfunction. A multidisciplinary clinic may be best suited to identify and ensure appropriate therapy for transplant recipients.¹²⁰

■ HIV/AIDS

Although the connection between the human immunodeficiency virus (HIV), its therapy, and osteoporosis is still being studied, current data suggest that both the virus and its medical treatments can decrease BMD. The effects are greater if other osteoporosis risk factors exist.¹²¹ Potential mechanisms include direct and indirect effect on osteoblasts and osteoclasts such as HIV invasion of cells and changes in cytokines and hormone concentrations, inhibition of 1α hydroxylase metabolism of 25(OH) vitamin D, lipodystrophy, and lactic acidosis. Other medications to treat HIV complications such as foscarnet, trimethoprim-sulfamethoxazole, and certain antibiotics can cause hypocalcemia. BMD measurements are only warranted if additional risk factors, long-term HIV, or long-term HIV medication use are present. Screening recommendations do not yet exist. Standard treatment, usually consisting of a bisphosphonate plus calcium and vitamin D supplementation, should be used once osteoporosis is diagnosed, although no specific population data yet exist.

■ ARTHRITIS

In most studies, patients with rheumatoid arthritis have lower BMD and more fractures than do age-matched controls.¹²² Common disease pathways, including proinflammatory cytokines and the OPG/RANK/RANKL system, may be responsible along with increased glucocorticoid use, hypogonadism, decreased activity, and increased fall risk. Patients taking glucocorticoids should be managed with calcium and vitamin D supplementation plus a bisphosphonate. Otherwise, standard osteoporosis prevention and treatment interventions are recommended.

■ CYSTIC FIBROSIS

Osteoporosis and fractures may develop in patients with cystic fibrosis from vitamin D deficiency, glucocorticoid use, calcium malabsorption, hypogonadism, inactivity, increased cytokines, and lung transplantation.¹²³ Bone density monitoring is done for patients at high risk, including those with malnutrition and glucocorticoid use. BMD testing corrections for children need to be made.

Prevention and treatment efforts usually include adequate calcium and vitamin D intake, adherence to pancreatic enzymes, correction of hypogonadism, exercise, potential use of GH in children whose height is below the tenth percentile, and when possible, reductions in glucocorticoid use. Calcitriol may be needed to overcome vitamin D malabsorption problems, but needs to be monitored for hypercalcemia. Bisphosphonates are generally not recommended for children.

■ GASTROINTESTINAL DISEASE

Recently, comprehensive reviews have been written on the lower BMD and higher fracture rates seen with inflammatory bowel

disease,¹²⁴ celiac disease,¹²⁴ postgastrectomy,¹²⁴ and liver disease.¹²⁵ Mechanisms include malabsorption, glucocorticoid use, increased inflammatory cytokines, and decreased metabolism. In patients with these diseases, and especially with other osteoporosis risk factors, bone density and secondary cause evaluations may be warranted. Prevention and treatment options currently reflect those for children, postmenopausal women, and men, and when applicable, for glucocorticoid use.

■ DIABETES

Patients with type 1 and type 2 diabetes have increased fracture rates in some studies.¹²⁶ Increased fall risk may contribute to this increased fracture risk. Standard assessment and prevention and treatment regimens are employed. In many studies, ET and HT have beneficial effects on glucose homeostasis and overall positive lipid effects, except for the increased triglycerides, which might be problematic.¹²⁷ Testosterone may cause hypoglycemia. Although one study with alendronate documented decreased insulin requirements, further data are needed.¹²⁶

■ PHARMACOECONOMIC CONSIDERATIONS

Annual direct costs for osteoporotic fractures were estimated to be \$17 billion (in 2001 dollars).^{3,128} A hip fracture costs about \$40,000 (in 2001 dollars). Health care costs for women aged 45 and older indicate that osteoporosis accounts for 6.9% of direct medical expenditures, with one-half of these expenses borne by Medicare. Direct costs in the year following hip fracture range from \$16,000 to \$36,000. Indirect costs of hip fracture, including lost quality of life, add at least \$20,000 per fracture. Appreciation of these costs and availability of preventive therapies have established osteoporosis as a significant public health priority.

The estimated cost for each quality-adjusted life year (QALY) for treating women with T-scores below -2 is \$51 to \$8,447, varying by age, with the lowest cost for the oldest women.¹²⁸ This analysis assumed a drug treatment cost of \$300/year and a hip fracture cost of \$30,000. The National Osteoporosis Foundation estimated that for women with average fracture risks, age-specific costs of osteoporosis prevention or treatment per QALY were \$13,794 for a 50-year-old, \$6,884 for a 60-year-old, \$2,924 for a 70-year-old, and \$949 for a 80-year-old. These estimates conservatively assume a 33% fracture risk reduction and annual treatment costs of \$500. The adjusted cost values are lower for women at greater risk. To put these pharmacoeconomic figures into perspective, the average cost per QALY saved approximates \$2,800 for Papanicolaou smears done every 3 years after age 65, \$34,000 for lovastatin for men 45 to 54 with total cholesterol equal to 300 mg/dL or higher, \$32,000 for hypertension treatment for those 40 and older with diastolic blood pressures of 95 to 104 mm Hg; and \$62,000 for annual mammography for women 40 to 49 years of age.¹²⁹ Based on this economic analysis, the National Osteoporosis Foundation indicated that treatment could be appropriate for postmenopausal women with T-scores less than -2 and in those with T-scores below -1.5 who also have increased risk.

Key pharmacoeconomic issues are the human and economic burden from an expanding elderly population, development of new, more effective, but potentially more expensive medications, enhanced screening and identification of patients at risk, and targeting of high-risk populations.

EVALUATION OF THERAPEUTIC OUTCOMES

Patients receiving pharmacotherapy for low bone mass should be examined at least annually. Because the primary therapeutic outcome is fracture prevention, patients should be asked about possible fracture symptoms (primarily bone pain or disability) at each visit. Routine bone x-ray films are not warranted. Patients should be questioned about medication adherence and tolerability at each visit. Collecting a detailed history, according to the pertinent review of systems, should identify commonly occurring or potentially serious side effects unique to each medication.

Two approaches of monitoring BMD exist in clinical practice. Some clinicians choose to measure BMD every 1 to 2 years following the commencement of therapy. They argue that this tactic identifies patients with medication nonadherence or secondary osteoporosis. Others advocate no subsequent BMD measurement because of expense and lack of correlation to fracture risk reduction. The optimal strategy has not yet been determined.

GLUCOCORTICOID-INDUCED OSTEOPOROSIS

9 The drug class most commonly associated with drug-induced osteoporosis is glucocorticoids.²² Oral daily doses greater than 7.5 mg of prednisone or equivalent generally constitute significant risk. Inhaled daily doses greater than 800 to 1200 mcg for beclomethasone, 800 to 1000 mcg for budesonide, 750 mcg for fluticasone, and 1000 mcg for flunisolide¹³³ are generally required for significant bone loss. Bone loss and fractures rarely occur with lower inhaled doses.²¹

PATHOPHYSIOLOGY

Glucocorticoids decrease muscle strength and bone formation and increase bone resorption.¹³⁴ Glucocorticoids decrease calcium ab-

sorption, increase renal calcium excretion, and result in secondary hyperparathyroidism. Glucocorticoid effects on vitamin D are variable. Differentiation, replication, and life span of osteoblasts are reduced, as is osteoid synthesis. Osteoblasts change in their sensitivity to prostaglandins, PTH, cytokines, growth factors, and calcitriol. Changes at the pituitary and gonadal level decrease synthesis of estrogen and testosterone. Myopathy can decrease mobility and lead to further bone loss. Although bone loss is continuous throughout steroid therapy, the greatest loss is experienced during the first 6 to 12 months of therapy. Trabecular bone (ribs, vertebrae, and pelvis) is affected more than cortical bone. Women, men, and children are susceptible. Although low BMD found in steroid users is a good predictor of fracture risk, patients with osteopenia and even normal BMD still develop fractures because of impaired bone quality, which is difficult to measure. For each 1 standard deviation decrease in T-score prior to therapy, the relative risk of fracture is 1.85.¹³⁵ Similarly, the relative risk is 1.62 for each 10-mg prednisone dosage equivalent. Compared to nonusers, the overall relative risk of fracture is 5.67 and the risk is present whether or not osteoporosis (T-score < -2.5) exists.

DIAGNOSIS

Patients taking long-term glucocorticoids represent a challenging group in which to diagnose osteoporosis. Because bone quality is compromised, at any level of BMD, some clinicians choose to treat without BMD testing. However, guidelines for the management of glucocorticoid-induced osteoporosis recommend measuring BMD at the beginning of chronic therapy, defined as ≥ 5 mg prednisone or equivalent daily for 3 months, and follow-up monitoring with a DXA in up to 6–12 months, and measurement of BMD in those on chronic therapy whose baseline values were not measured.^{133,136}

► PREVENTION AND TREATMENT: Glucocorticoid-Induced Osteoporosis

Although the best means of preventing glucocorticoid-induced osteoporosis and related fracture would be discontinuing glucocorticoids, this is not always clinically feasible. Using the lowest possible dose for the shortest duration minimizes glucocorticoid exposure. The bone effects of alternate-day therapy and pulse (intermittent) therapy are not completely known, but some data suggest that these regimens also have negative bone effects.

All patients receiving chronic or recurrent glucocorticoid therapy should adopt bone-healthy lifestyle changes (see above) and ingest adequate amounts of calcium and vitamin D.¹³⁷ According to the American College of Rheumatology guidelines, calcium intakes should be higher: 800 mg for children between 1 and 5 years, 1200 mg

for children between 6 and 10 years, and 1500 mg for other patients.¹³³ All children should receive 400 units and adults 800 units vitamin D per day.

Bisphosphonates are the best therapeutic choice for patients with glucocorticoid-induced osteoporosis. Bisphosphonates generally produce greater BMD increases than do other agents used to treat osteoporosis. They increase spine (4.3%) and femoral neck (2.1%) BMD, but to a lesser extent than in bisphosphonate users who do not take glucocorticoids.¹³⁸ They also likely reduce the risk of vertebral fractures by approximately 50%.¹³⁹

Data using calcitonin for glucocorticoid-induced osteoporosis do not support its routine use.¹⁴⁰

OSTEOMALACIA

10 Osteomalacia results from defective osteoid mineralization. Defective mineralization in the infant or child produces rickets. In the adult, the syndrome is called osteomalacia.

EPIDEMIOLOGY

The incidence of osteomalacia is not known precisely, but is lower in the United States because foods are supplemented with vitamin D. However, hypovitaminosis D in the United States is still identified

in young, old, and new immigrants.^{50–52,141} Osteomalacia is more prevalent in countries with little sun exposure, minimal dietary supplementation, malnutrition, or traditional clothing covering most of the skin. Dark-skinned individuals synthesize less vitamin D cutaneously and can be at risk for hypovitaminosis D.¹⁴

PATHOPHYSIOLOGY

Mechanisms leading to osteomalacia include low serum calcium or phosphorus, chronic acidosis, hypophosphatemia, liver or renal disease, and drug-induced mineralization defects.^{10,23,142,143} The

most common cause is vitamin D deficiency secondary to inadequate intake, decreased sun exposure, malabsorption, or decreased metabolism. Renal disease is associated with decreased 25(OH) vitamin D 1 α -hydroxylase, with consequently decreased calcitriol and poor calcium absorption. In vitamin D–dependent rickets type I, a genetic defect exists in 25(OH) vitamin D 1 α -hydroxylase. Vitamin D–dependent rickets type II results from defects in the vitamin D receptor or its activity. In vitamin D–resistant rickets, renal phosphate reabsorption is defective, and 25(OH) vitamin D 1 α -hydroxylase activity is inadequate. A genetic defect in the *PHEX* gene may allow inappropriate activity of an undefined inhibitor of phosphate reabsorption that also lowers serum calcitriol concentrations. Pancreatitis, chronic hepatobiliary disease, Crohn’s disease, gastrectomy, and celiac sprue are also risk factors for vitamin D deficiency.

Other chronic disorders cause osteomalacia.^{10,142,143} Phosphate depletion from low dietary intake, phosphate-binding antacids, and oncogenic osteomalacia (potentially phosphaturic effect) can cause osteomalacia. Hypophosphatasia is an inborn error of metabolism in which deficient activity of alkaline phosphatase causes impaired mineralization of bone matrix. Acidosis from renal dysfunction, distal renal tubular acidosis, hypergammaglobulinemic states (e.g., multiple myeloma), and drugs (e.g., chemotherapy) compromises bone mineralization. Renal tubular disorders secondary to Fanconi’s syndrome, hereditary diseases (e.g., Wilson’s disease, a defect in copper metabolism), acquired disease (e.g., myeloma), and toxins (e.g., lead) cause osteomalacia to varying degrees. Chronic wastage of phosphorus and/or calcium limits mineralization, which may be further compromised by acidosis and secondary hyperparathyroidism.

DRUG-INDUCED OSTEOMALACIA

Drugs induce osteomalacia through various mechanisms.²³ Phenytoin, primidone, phenobarbital, carbamazepine, rifampin, and some hypnotic medications may cause osteomalacia, potentially through

hepatic microsomal cytochrome P450 induction and increased vitamin D metabolism. Anticonvulsant-associated osteomalacia usually occurs only in patients living in an institution or those receiving multiple anticonvulsant drugs. Cholestyramine may decrease vitamin D absorption. Long-term hyperalimentation may also result in osteomalacia. Defective mineralization can result from continuous or intermittent etidronate treatment or sodium fluoride. Aluminum accumulation in patients with severe renal impairment or in patients undergoing hemodialysis may lead to osteomalacia, potentially through insoluble complexes with phosphates and inhibition of mineral deposition.

CLINICAL PRESENTATION

Adult osteomalacia often has an insidious presentation.^{10,142,143} The underlying disorder may be more apparent than skeletal defects (e.g., diarrhea in sprue). Diffuse skeletal pain, bony tenderness, and proximal muscle weakness may occur. Pain on movement and muscle weakness may result in a characteristic waddling gait. Hypophosphatemia and secondary hyperparathyroidism may contribute to these symptoms. Tetany can result from sufficiently depressed serum ionized calcium. Skeletal deformities (infrequent in adults) include leg bowing, pigeon chest, scoliosis, kyphosis, and shortening of the spine.

Findings on x-ray films depend on the cause and age of the patient.¹⁴³ Radiographic changes include changes in the growth plate bone areas, bone erosion, osteopenia, and pseudofractures (Looser’s zones).

Various etiologies produce differing biochemical pictures.¹⁴³ Determination of serum content of calcium (albumin corrected), phosphorus, alkaline phosphatase, urea nitrogen, creatinine, PTH, 25(OH) vitamin D, and calcitriol, as well as urinary calcium, creatinine, and phosphorus, can help in determining the cause, deciding on treatment, and monitoring efficacy of therapy. Definitive diagnosis is by bone biopsy.

► PREVENTION AND TREATMENT: Osteomalacia

Treatment of osteomalacia depends on the underlying cause.^{10,142,143} Management may be difficult and may require a renal, bone, or endocrine specialist.

Treatment of osteomalacia from vitamin D deficiency is vitamin D therapy, with dose depending on severity. Supplements of 800 to 4000 units/day or 50,000 units weekly for 8 weeks may be necessary. For sprue, a gluten-free diet is necessary. With intestinal malabsorption, high oral doses (50,000 to 100,000 units/day) or daily intramuscular injections of 10,000 units of vitamin D may be initially required. With disordered vitamin D metabolism caused by anticonvulsants or rifampin, supplemental vitamin D (4000 units/day) can be effective. Sun exposure can also be useful. Serum calcium and 25(OH) vitamin D monitoring is necessary with high vitamin D doses.

Renal disease with deficient 1,25(OH) vitamin D synthesis can be treated with calcitriol, with careful monitoring of serum calcium and creatinine. This compound has a 6-hour half-life and a rapid onset of action. Patients with renal dysfunction should decrease oral

phosphate ingestion, use a phosphate binder, and avoid aluminum-containing antacids.

Vitamin D–dependent rickets type I can be treated with calcitriol (0.25 to 1 mcg/day) to achieve physiologic levels. Vitamin D–dependent rickets type II can be treated with high vitamin D doses or calcitriol if necessary. Often, maintenance of serum calcitriol above the physiologic level is required, with doses of calcitriol up to 30 to 60 mcg/day.

For vitamin D–resistant rickets, patients can be treated with calcitriol and phosphate supplements. For oncogenic osteomalacia, tumor resection is best. Otherwise, pharmacologic doses of calcitriol (1.5 to 3 mcg/day) and phosphate supplementation may help.

For osteomalacia with renal tubular acidosis, acidosis is corrected with oral bicarbonate. For osteomalacia from Fanconi’s syndrome, treatment depends on the underlying disorder, but often includes phosphate supplements and vitamin D analogues.

No established treatment exists for hypophosphatasia. Intramedullary rods can help prevent fractures. Bone marrow transplant is being considered.

CONCLUSIONS

Osteoporosis can be prevented or minimized through a healthy diet and an active lifestyle throughout life. Postmenopausal estrogen de-

fiency, aging, and various diseases and medications can lead to osteoporosis. Although teriparatide can increase bone formation, only short-term therapy is used. Thus prevention is the key. Prevention of osteoporosis includes adequate calcium and vitamin D intake,

exercise, smoking cessation, and minimal alcohol use. For osteopenia, preventive therapy with bisphosphonates or raloxifene is sometimes used, even though convincing data continue to be lacking. For osteoporosis treatment, bisphosphonates are the mainstay of therapy. Raloxifene, calcitonin, and teriparatide are alternative therapies in those who will not or cannot take an oral bisphosphonate. Fall prevention and pain control after fracture are important.

Osteomalacia is a disease of decreased bone mineralization with multiple etiologies, involving calcium, phosphorus, or vitamin D homeostasis. Vitamin D insufficiency and deficiency are becoming common again. Adequate intake of vitamin D is essential for everyone. Eliminating or treating any underlying causes of osteomalacia is the first step. In most cases, pharmacologic doses of vitamin D or treatment with calcitriol are also required.

ABBREVIATIONS

BMD: bone mineral density
 BMU: basic multicellular unit
 CSF-1: colony-stimulating factor-1
 DXA: dual-energy x-ray absorptiometry
 ET: estrogen therapy
 GH: growth hormone
 HIV: human immunodeficiency virus
 HMG-CoA reductase: 3-hydroxymethyl-4-glutaryl CoA reductase
 HT: hormonal therapy (estrogen plus progestin)
 IGF-1: insulin-like growth factor-1
 IL-1, IL-6, IL-11: interleukins-1, -6, and -11
 MCSF: macrophage colony-stimulating factor
 MORE: Multiple Outcomes of Raloxifene Evaluation trial
 NOF: National Osteoporosis Foundation
 OPG: osteoprotegerin
 PDGF: platelet-derived growth factor
 PMMA: polymethylmethacrylate
 PPAR γ 2: peroxisome proliferator-activated receptor- γ 2
 PTH: parathyroid hormone
 QALY: quality-adjusted life year
 RANK: receptor activator of nuclear factor κ B
 RANKL: receptor activator of nuclear factor κ B ligand
 SERM: selective estrogen receptor modulator
 TGF- β : transforming growth factor- β
 TNF: tumor necrosis factor
 TSH: thyroid-stimulating hormone
 WHI: Women's Health Initiative trial

RHEUMATOID ARTHRITIS

Arthur A. Schuna

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Rheumatoid arthritis is a systemic disease characterized by symmetrical inflammation of joints, yet may involve other organ systems.
- 2 Control of inflammation is the key to slowing or preventing disease progression as well as managing symptoms.
- 3 Drug therapy should be only part of a comprehensive program for patient management, which would also include physical therapy, exercise, and rest. Assistive devices and orthopedic surgery may be necessary in some patients.
- 4 Disease-modifying antirheumatic drugs (DMARDs) or biological agents should be started within 3 months of the diagnosis of rheumatoid arthritis.
- 5 When DMARDs used singly are ineffective or not adequately effective, combination therapy with two or more DMARDs or a DMARD plus biological agents may be used to induce a response.
- 6 Nonsteroidal anti-inflammatory drugs (NSAIDs) and/or corticosteroids should be considered adjunctive therapy early in the course of treatment and as needed if symptoms are not adequately controlled with DMARDs.
- 7 Patients require careful monitoring for toxicity and therapeutic benefit for the duration of treatment.

Rheumatoid arthritis is the most common systemic inflammatory disease, and is characterized by symmetrical joint involvement. Extra-articular involvement including rheumatoid nodules, vasculitis, eye inflammation, neurologic dysfunction, cardiopulmonary disease, lymphadenopathy, and splenomegaly are manifestations of the disease. Although the usual disease course is chronic, some patients will enter a remission spontaneously.

EPIDEMIOLOGY

Rheumatoid arthritis is estimated to have a prevalence of 1% to 2% and does not have any racial predilections. It can occur at any age, with increasing prevalence up to the seventh decade of life. The disease is three times more common in women. In people aged 15 to 45 years, women predominate by a ratio of 6:1; the sex ratio is approximately equal among patients in the first decade of life and in those more than 60 years old.

Epidemiologic data suggest that a genetic predisposition and exposure to unknown environmental factors may be necessary for expression of the disease. The major histocompatibility complex (MHC) molecules, located on T lymphocytes, appear to have an important role in most patients with rheumatoid arthritis. These molecules can be characterized using human lymphocyte antigen (HLA) typing. A majority of patients with rheumatoid arthritis have HLA-DR4, HLA-DR1, or both antigens found in the MHC region. Patients with HLA-DR4 antigen are 3.5 times more likely to develop rheumatoid arthritis than those who have other HLA-DR antigens.¹ Although the MHC region is important, it is not the sole determinant, because patients can have the disease without these HLA types. Rheumatoid arthritis is six times more common among dizygotic twins and nontwin children of

parents with rheumatoid factor–positive erosive rheumatoid arthritis when compared with children whose parents do not have the disease. If one of a pair of monozygotic twins is affected, the other twin has a 30 times greater risk of developing the disease.^{2,3}

PATHOPHYSIOLOGY

1 Chronic inflammation of the synovial tissue lining the joint capsule results in the proliferation of this tissue. The inflamed, proliferating synovium characteristic of rheumatoid arthritis is called *pannus* (Fig. 89–1). This pannus invades the cartilage and eventually the bone surface, producing erosions of bone and cartilage and leading to destruction of the joint. The factors that initiate the inflammatory process are unknown.

The immune system is a complex network of checks and balances designed to discriminate self from nonself (foreign) tissues. It helps rid the body of infectious agents, tumor cells, and products associated with the breakdown of cells. In rheumatoid arthritis this system no longer can differentiate self from nonself tissues and attacks the synovial tissue and other connective tissues.

The immune system has both humoral and cell-mediated functions (Fig. 89–2). The humoral component is necessary for the formation of antibodies. These antibodies are produced by plasma cells. Most patients with rheumatoid arthritis form antibodies called *rheumatoid factors*. Rheumatoid factors have not been identified as pathogenic, nor does the quantity of these circulating antibodies always correlate with disease activity. Seropositive patients tend to have a more aggressive course of their illness than do seronegative patients. Immunoglobulins can activate the complement system. The complement system amplifies the immune response by encouraging

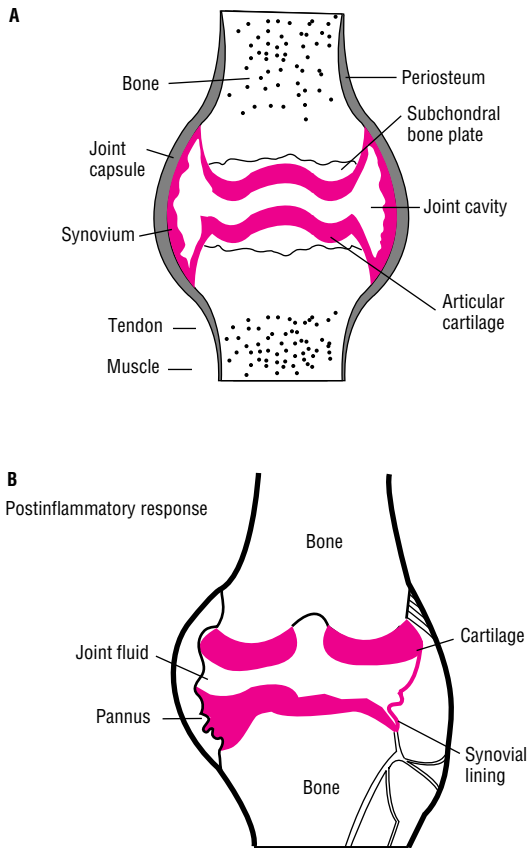

FIGURE 89-1. A. Schematic diagram of a normal diarthrodial joint. B. Schematic diagram of a knee joint with active rheumatoid arthritis showing pannus invading and destroying the cartilage and bone. (Adapted from the Arthritis Foundation Allied Health Professions Teaching Slide Collection, Copyright ©1980, with permission.)

chemotaxis, phagocytosis, and the release of lymphokines by mononuclear cells, which are then presented to T lymphocytes. The processed antigen is recognized by MHC proteins on the lymphocyte, which activates it to stimulate the production of T and B cells. The proinflammatory cytokines tumor necrosis factor (TNF), interleukin-1 (IL-1), and interleukin-6 (IL-6) are key substances in the initiation and continuance of rheumatoid inflammation. Lymphocytes may be either B cells (derived from bone marrow) or T cells (derived from thymus tissue). T cells may be either T-helper (which promote inflammation) or T-suppressor cells (which attenuate the inflammatory response). Activated T cells produce cytotoxins, which are directly toxic to tissues, and cytokines, which stimulate further activation of inflammatory processes and attract cells to areas of inflammation. Macrophages are stimulated to release prostaglandins and cytotoxins. Activated B cells produce plasma cells, which form antibodies. These antibodies in combination with complement result in the accumulation of polymorphonuclear leukocytes (PMNs). These PMNs release cytotoxins, oxygen free radicals, and hydroxyl radicals that promote cellular damage to synovium and bone. Patients with rheumatoid arthritis appear to have an excessive amount of T-helper cell activity in synovial tissues.

Vasoactive substances also play a role in the inflammatory process. Histamine, kinins, and prostaglandins are released at the site of inflammation. These substances increase both blood flow to the site of inflammation and the permeability of blood vessels. These substances cause the edema, warmth, erythema, and pain associated with joint inflammation and make it easier for granulocytes to pass from blood vessels to the site of inflammation.

The end results of the chronic inflammatory changes are variable. Loss of cartilage may result in a loss of the joint space. The formation of chronic granulation or scar tissue can lead to loss of joint motion or bony fusion (called *ankylosis*). Laxity of tendon structures can result in a loss of support to the affected joint, leading to instability or subluxation. Tendon contractures also may occur, leading to chronic deformity.^{1,3-6}

FIGURE 89-2. Pathogenesis of the inflammatory response. Phase 1: Antigen-presenting cell phagocytizes antigen. Phase 2: Antigen is presented to a T lymphocyte. The T lymphocyte attaches to antigen at the MHC portion of cell wall, causing activation. Phase 3: An activated T cell stimulates T- and B-lymphocyte production, promoting inflammation. Phase 4: Activated T cells and macrophages release factors that promote tissue destruction, increase blood flow, and result in cellular invasion of synovial tissue and joint fluid. Ag, antigen; PMN, polymorphonuclear leukocyte.

CLINICAL PRESENTATION OF RHEUMATOID ARTHRITIS

SYMPTOMS

Joint pain and stiffness of more than 6 weeks' duration. May also experience fatigue, weakness, low-grade fever, and loss of appetite. Muscle pain and afternoon fatigue may also be present. Joint deformity is generally seen late in the disease.

SIGNS

Tenderness with warmth and swelling over affected joints usually involving hands and feet. Distribution of joint involvement is frequently symmetrical. Rheumatoid nodules may also be present.

LABORATORY TESTS

Rheumatoid factor detectable in 60% to 70%. Elevated erythrocyte sedimentation rate and C-reactive protein are markers for inflammation. Normocytic normochromic anemia is common, as is thrombocytosis.

OTHER DIAGNOSTIC TESTS

Joint fluid aspiration may show increased white blood cell counts without infection, and crystals. Joint radiographs may show periarticular osteoporosis, joint space narrowing, or erosions.

CLINICAL PRESENTATION

The symptoms of rheumatoid arthritis usually develop insidiously over the course of several weeks to months. Prodromal symptoms include fatigue, weakness, low-grade fever, loss of appetite, and joint pain. Stiffness and muscle aches (myalgias) may precede the development of joint swelling (synovitis). Fatigue may be more of a problem

in the afternoon. During disease flares, the onset of fatigue begins earlier in the day and subsides as disease activity lessens. Most commonly, joint involvement tends to be symmetrical; however, early in the disease some patients present with an asymmetrical pattern involving one or a few joints that eventually develops into the more classic presentation. About 20% of patients develop an abrupt onset of their illness with fevers, polyarthritis, and constitutional symptoms (e.g., depression, anxiety, fatigue, anorexia, and weight loss).^{2,3} No single test or physical finding can be used to make the diagnosis of rheumatoid arthritis.

JOINT INVOLVEMENT

The joints affected most frequently by rheumatoid arthritis are the small joints of the hands, wrists, and feet (Fig. 89–3). In addition, elbows, shoulders, hips, knees, and ankles may be involved. Patients usually experience joint stiffness that typically is worse in the morning. The duration of stiffness tends to be correlated directly with disease activity, usually exceeds 30 minutes, and may persist all day. Chronic inflammation with lack of an adequate exercise program results in loss of range of motion, atrophy of muscles, weakness, and deformity.

On examination, the swelling of the joints may be visible or may be apparent only by palpation. The swelling feels soft and spongy because it is caused by proliferation of soft tissues or fluid accumulation within the joint capsule. The swollen joint may appear erythematous and feel warmer than nearby skin surfaces, especially early in the course of the disease. In contrast, the swelling associated with osteoarthritis usually is bony (caused by osteophytes) and infrequently is associated with signs of inflammation.

Involvement of the hands and wrists is common in rheumatoid arthritis. Hand involvement is manifested by pain, swelling, tenderness, and grip weakness during the acute phase, and by subluxation, instability, deformity, and muscle atrophy in the chronic phase of the disease. Functional difficulties with clasp, grasp, and pinch alter both strength and fine motor movement.

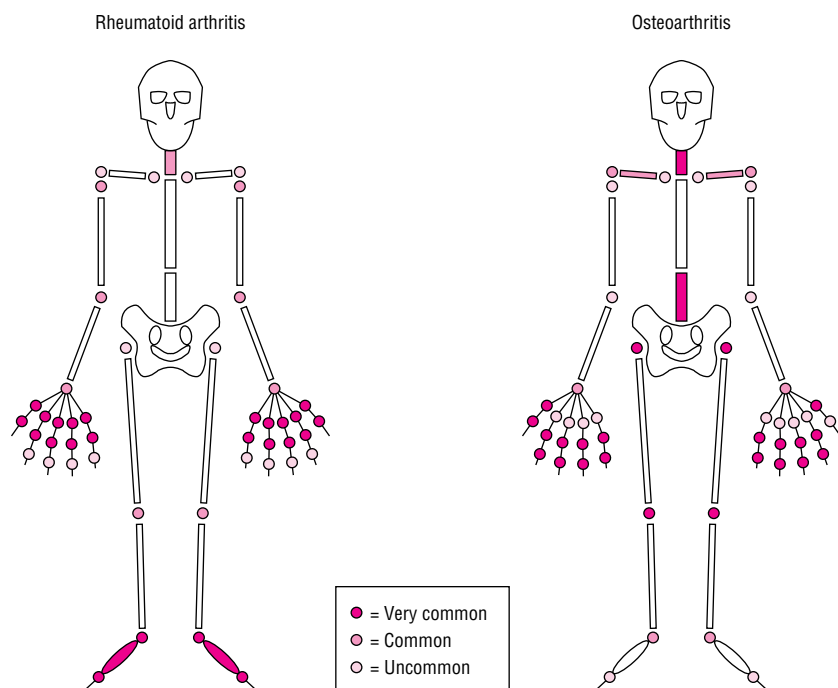

FIGURE 89-3. Patterns of joint involvement in rheumatoid arthritis and osteoarthritis.

Deformity of the hand may be seen with chronic inflammation. These changes may alter the mechanics of hand function, reducing grip strength and making it difficult to perform usual daily activities.

Swelling at the elbow is most evident at the radiohumeral joint. Shoulder pain may result from involvement of the joint itself or from tendon inflammation (tendinitis) or inflammation of the bursa (bursitis) near the deltoid muscle.

The knee also can be involved, with loss of cartilage, instability, and joint pain. Synovitis of the knee may cause the formation of a cyst behind the knee called a popliteal or Baker's cyst. These cysts may become painful as they get tense, or they may rupture, producing a clinical picture similar to thrombophlebitis secondary to the release of inflammatory components into the area of the calf muscle. Chronic joint pain leads to muscle atrophy, which can result in a laxity of the ligamentous structures that support the knee, causing instability. Maintenance of an adequate range of motion of the knee is essential to normal gait.

Foot and ankle involvement in rheumatoid arthritis is common. The metatarsophalangeal joints are involved commonly in rheumatoid arthritis, making walking difficult. Subluxation of the metatarsal heads leads to "cock-up" or hammer-toe deformities. Subluxation also may cause a flexion deformity at the proximal interphalangeal joint of the toe, leading to pressure necrosis of the skin over the joint secondary to irritation caused by shoes. Hallux valgus (lateral deviation of the digit) and bunion or callus formation may occur at the great toe. A widening of the foot occurs commonly with long-standing disease.

Involvement of the spine usually occurs in the cervical vertebrae; lumbar vertebral involvement is rare. Involvement of the first and second cervical vertebrae can lead to instability of this joint. Patients with this problem are at a greater risk for spinal cord compression, although this complication is rare.

The temporomandibular joint (jaw) can be affected, resulting in malocclusion and difficulty in chewing food. Inflammation of cartilage in the chest can lead to chest wall pain. Hip pain may occur as a result of destructive changes in the hip joint, soft-tissue inflammation (e.g., bursitis), or referred pain from nerve entrapment at the lumbar vertebrae.

EXTRA-ARTICULAR INVOLVEMENT

RHEUMATOID NODULES

Rheumatoid nodules occur in 20% of patients with rheumatoid arthritis. These nodules are seen most commonly on the extensor surfaces of the elbows, forearms, and hands, but also may be seen on the feet and at other pressure points. They also may develop in the lung or pleural lining of the lung, and rarely in the meninges. Rheumatoid nodules usually are asymptomatic and do not require any special intervention. Nodules are observed more commonly in patients with erosive disease.⁷

VASCULITIS

Vasculitis usually is seen in patients with long-standing rheumatoid arthritis. Vasculitis may result in a wide variety of clinical presentations. Invasion of blood vessel walls by inflammatory cells results in an obliteration of the vessel, producing infarction of tissue distal to the area of involvement. Most commonly, small-vessel vasculitis produces infarcts near the ends of the fingers or toes, especially around the nail beds. These infarcts are usually of little consequence.

Vasculitis also may cause the breakdown of skin, especially in the lower extremities, producing ulcers that may be indistinguishable in appearance from stasis ulcers. However, these ulcers do not heal

with the usual modes of treatment used for stasis ulcers. Involvement of larger vessels with vasculitis can result in life-threatening complications. Infarction of vessels supplying blood to nerves can cause irreversible motor deficits. Involvement of vessels supplying other organ systems can lead to visceral involvement and a polyarteritis nodosa-like illness. Aggressive treatment of the inflammatory process is necessary in these patients. Fortunately, the more serious vasculitic picture is seen rarely.

PULMONARY COMPLICATIONS

Rheumatoid arthritis may involve the pleura of the lung, which is often asymptomatic, although pleural effusions may result. Pulmonary fibrosis also may develop as a result of rheumatoid involvement; smoking appears to increase the risk of this complication. Rheumatoid nodules may develop in lung tissue and appear similar to neoplasms on chest x-ray films. Interstitial pneumonitis and arteritis are rare, potentially life-threatening complications of rheumatoid arthritis.

OCULAR MANIFESTATIONS

Ocular manifestations include keratoconjunctivitis sicca and inflammation of the sclera, episclera, and cornea. Atrophy of the lacrimal duct may result in a decrease in tear formation, causing dry and itchy eyes, termed *keratoconjunctivitis sicca*. When this is observed in association with rheumatoid arthritis, it is referred to as Sjögren's syndrome. Artificial tears may be used to relieve symptoms. Inflammation of the superficial layers of the sclera (episcleritis) is generally self-limiting. Involvement of deeper tissues (scleritis) usually results in a more serious, painful, and chronic inflammation. Rheumatoid nodules may develop on the sclera.

CARDIAC INVOLVEMENT

The heart is sometimes affected by rheumatoid arthritis. Rheumatoid arthritis is associated with an increased risk of cardiovascular mortality. This risk appears to be higher in those with more active inflammation and is reduced with treatment, particularly with methotrexate.^{8,9} Pericarditis may occur, resulting in the accumulation of fluid. Although many patients show evidence of previous pericarditis at autopsy, the development of clinically evident pericarditis with tamponade is a rare complication. Cardiac conduction abnormalities and aortic valve incompetence, caused by aortic root dilatation, may occur. Myocarditis is a rare complication of rheumatoid arthritis.

FELTY'S SYNDROME

Rheumatoid arthritis in association with splenomegaly and neutropenia is known as Felty's syndrome. Thrombocytopenia also may be a manifestation of the syndrome. Patients with Felty's syndrome and severe leukopenia are more susceptible to infection. The decrease in granulocytes appears to be mediated by the immune system because splenectomy does not result in improvement of the patient.⁷

OTHER COMPLICATIONS

Lymphadenopathy may occur in patients with rheumatoid arthritis, particularly in nodes proximal to more actively involved joints. Renal involvement is rare but can be associated with treatment, including nonsteroidal anti-inflammatory drugs (NSAIDs), gold salts, and penicillamine. Amyloidosis is a rare complication of long-standing rheumatoid arthritis. It appears to be more common in Europe than in the United States.

LABORATORY FINDINGS

Hematologic tests often reveal a mild to moderate anemia with normocytic, normochromic indices. The hematocrit may fall as low as 30%. The anemia is usually inversely related to inflammatory disease activity and is referred to as an *anemia of chronic disease*. This type of anemia does not respond to iron therapy and can present a diagnostic dilemma because NSAIDs may induce gastritis and chronic blood loss, leading to iron-deficiency anemia. Laboratory tests useful in differentiating these anemias include stool guaiac (or other stool tests for occult blood), serum iron:iron-binding capacity ratio (decreased in iron deficiency), and mean corpuscular volume (more likely to be decreased in iron deficiency). Other causes of anemia also must be considered in the differential diagnosis (see anemias, Chap. 99).

Thrombocytosis is another common hematologic finding with active rheumatoid arthritis. Platelet counts rise and fall in direct correlation with disease activity in many patients. Thrombocytopenia may result from toxicity of gold salts, penicillamine, or immunosuppressive therapy. Thrombocytopenia also may be observed in Felty's syndrome or vasculitis.

Although leukopenia is associated with Felty's syndrome, it also may result from toxicity of gold, sulfasalazine, penicillamine, immunosuppressive drugs, and biologic agents. Leukocytosis is seen commonly as a result of corticosteroid treatment.

The erythrocyte sedimentation rate is usually elevated in patients with rheumatoid arthritis and other inflammatory diseases. This test is very nonspecific, and although the erythrocyte sedimentation rate usually falls as patients respond to therapy, there is a large variability among patients in response to treatment. C-reactive protein is another nonspecific marker for inflammatory arthritis when it is elevated. This protein is produced by the liver in response to certain cytokines.

Rheumatoid factor is present in 60% to 70% of patients with rheumatoid arthritis. The usual laboratory test for rheumatoid factor is an antibody specific for IgM rheumatoid factor. Patients with rheumatoid arthritis and a negative test for rheumatoid factor may have IgG or IgA rheumatoid factors, but tests for these are not routinely available. Rheumatoid factor tests may be reported positive at a specific serum dilution. Serum is diluted to a standard series of dilutions; the greatest dilution that yields a positive test result will be reported (e.g., rheumatoid factor positive at 1:640). Some laboratories quantify rheumatoid factor rather than using titers. Higher dilutional titers or serum concentrations of rheumatoid factors usually indicate a more severe disease, but like the erythrocyte sedimentation rate, the large interpatient variability makes this test unreliable as a means of assessing patient progress. Rheumatoid factor may be positive in patients without rheumatoid arthritis (Table 89–1).

Antinuclear antibodies are detected in 25% of patients with rheumatoid arthritis. These antibodies usually have a diffuse pattern of immunofluorescence. Tests for antibodies to double-stranded DNA (usually positive in systemic lupus erythematosus) are negative. Serum complement is usually normal, although complement concentrations of joint fluid often are depressed from consumption secondary

to the inflammatory process. In patients with vasculitis, serum complement concentrations may be low.

Synovial fluid usually is turbid because of the large number of leukocytes in inflammatory fluid. White cell counts of 5000 to 50,000/mm³ are not uncommon in inflamed joints. The fluid is usually less viscous than that in normal joints or in fluid associated with osteoarthritis. Glucose concentrations of joint fluid are normal or low compared with those in serum drawn at the same time as synovial aspirates. The decrease is not as profound as the decrease associated with joint infection or systemic lupus erythematosus.

Radiologic manifestations of rheumatoid arthritis include soft-tissue swelling and osteoporosis near the joint (periarticular osteoporosis). Erosions tend to occur later in the course of the disease and usually are seen first in the metacarpophalangeal and proximal interphalangeal joints of the hands and the metatarsophalangeal joints of the feet. Periodic joint radiographs are a useful way of evaluating disease progression.

SERONEGATIVE INFLAMMATORY ARTHRITIS

Although rheumatoid arthritis may have a negative rheumatoid factor titer, a number of other systemic inflammatory arthritic conditions exist, including psoriatic arthritis, ankylosing spondylitis, and arthritis associated with inflammatory bowel disease. These conditions often tend to be less aggressive than those typically seen with rheumatoid arthritis. Detailed discussion about these conditions is beyond the scope of this chapter, but further information may be found elsewhere.³ Management principles are similar to those for rheumatoid arthritis.

▶ TREATMENT: Rheumatoid Arthritis

■ DESIRED OUTCOME

2 The primary objective is to improve or maintain functional status, thereby improving quality of life. Treatment of rheumatoid

arthritis is a multifaceted approach that includes pharmacologic and nonpharmacologic therapies. Recent emphasis has been placed on aggressive treatment early in the disease course. The ultimate goal is to achieve complete disease remission, although this goal is seldom achieved. Additional goals of treatment include controlling disease

activity and joint pain, maintaining the ability to function in daily activities or work, improving the quality of life, and slowing destructive joint changes.

NONPHARMACOLOGIC THERAPY

3 Rest, occupational therapy, physical therapy, use of assistive devices, weight reduction, and surgery are the most useful types of nonpharmacologic therapy used in patients with rheumatoid arthritis. Rest is an essential component of a nonpharmacologic treatment plan. It relieves stress on inflamed joints and prevents further joint destruction. Rest also aids in alleviation of pain. Too much rest and immobility, however, may lead to decreased range of motion, and ultimately muscle atrophy and contractures.

Occupational and physical therapy can provide the patient with skills and exercises necessary to increase or maintain mobility. These disciplines also may provide patients with supportive and adaptive devices such as canes, walkers, and splints.

Other nonpharmacologic therapeutic options include weight loss and surgery. Weight reduction helps to alleviate stress on inflamed joints. This should be instituted and monitored with close supervision of a health care professional. Tenosynovectomy, tendon repair, and joint replacements are surgical options for patients with rheumatoid arthritis. Such management usually is reserved for patients with severe disease.^{10,11}

PHARMACOLOGIC THERAPY

4 A disease-modifying antirheumatic drug (DMARD) should be started within the first 3 months of onset of symptoms of rheumatoid arthritis¹⁰ (Fig. 89–4). Early introduction of DMARDs results in a more favorable outcome.^{12–17} NSAIDs and/or corticosteroids may be used for symptomatic relief if needed. They provide relatively rapid improvement in symptoms compared with DMARDs, which may take weeks to months before benefit is seen; however, NSAIDs

have no impact on disease progression, and corticosteroid use carries a long-term risk of complications that makes them less desirable.¹⁷

Early treatment with DMARDs can reduce mortality. Patients with rheumatoid arthritis have increased mortality compared to people without the disease. In one trial, methotrexate reduced risk of mortality.⁸ Early treatment with DMARDs in patients followed for up to 10 years had mortality rates similar to patients without the disease.¹⁸

DMARDs—including biologic agents—should be used in all patients except those with limited disease or those with class IV disease, in whom little reversibility of disease is expected. Commonly used DMARDs include methotrexate, hydroxychloroquine, sulfasalazine, and leflunomide. The biologic agents that have also been demonstrated to have disease-modifying activity include the anti-TNF drugs (etanercept, infliximab, and adalimumab) and the interleukin-1-receptor antagonist, anakinra. Less frequently used are azathioprine, d-penicillamine, gold (including auranofin), minocycline, cyclosporine, and cyclophosphamide. This is due to either less efficacy, high toxicity, or both. The order in which the first-line agents are used is not clearly defined, though methotrexate is often chosen in more severe cases due to long-term data suggesting superior outcomes than those with other DMARDs, and lower cost than biologic agents. Leflunomide appears to have similar long-term efficacy as that of methotrexate.¹⁹

The biologic agents have proven effective for patients who fail treatment with other DMARDs. Infliximab should be given in combination with methotrexate to prevent development of antibodies that may reduce drug efficacy or induce allergic reactions.

5 Combination therapy with two or more DMARDs may be effective when single-DMARD treatment is unsuccessful.^{17,20–26} The combinations of cyclosporine plus methotrexate and methotrexate plus sulfasalazine and hydroxychloroquine have been shown to be particularly effective.²⁵

Corticosteroids can be used in various ways. They are valuable in controlling symptoms before the onset of action of DMARDs. A burst of corticosteroids can be used in acute flares. Continuous low doses may be adjuncts when DMARDs do not provide adequate disease control. Corticosteroids may be injected into joints and soft tissues to control local inflammation. Steroids seldom should be used as monotherapy. There are data to suggest they have disease-modifying activity;^{27,28} however, it is preferable to avoid chronic use when possible to avoid long-term complications. NSAIDs and DMARDs have steroid-sparing properties that permit reductions of steroid doses.

For monitoring parameters and dosing guidelines for DMARDs and NSAIDs used in rheumatoid arthritis, see Tables 89–2 and 89–3.

CLINICAL CONTROVERSY

For patients with rheumatoid arthritis, the order of DMARD or biological agent choice is not clearly defined. In addition, some advocate trials of combination DMARD therapy before courses of biological agents are tried.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

6 NSAIDs should seldom be used as monotherapy for rheumatoid arthritis. NSAIDs possess both analgesic and anti-inflammatory properties and reduce stiffness associated with rheumatoid arthritis. NSAIDs mainly inhibit prostaglandin synthesis, which is only a small

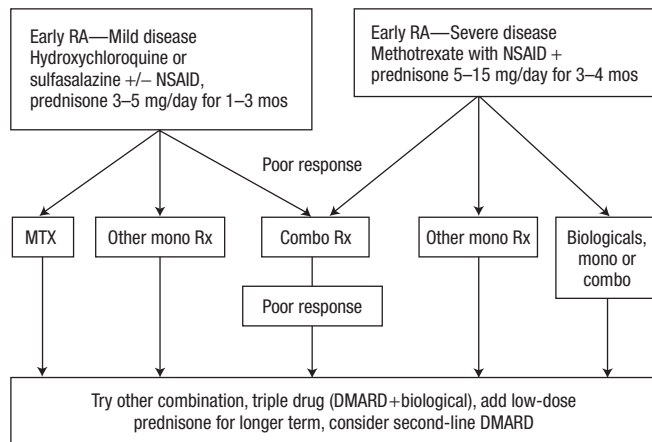

FIGURE 89–4. Algorithm for treatment of rheumatoid arthritis. RA, rheumatoid arthritis; NSAID, nonsteroidal anti-inflammatory drugs; Rx, therapy; DMARD, disease-modifying antirheumatic drug.

TABLE 89–2. Usual Doses and Monitoring Parameters for Antirheumatic Drugs

| Drug | Usual Dose | Initial Monitoring Tests | Maintenance Monitoring Tests |
|--------------------|---|---|--|
| NSAIDs | See Table 90–4 in the osteoarthritis chapter | S _{Cr} or BUN, CBC every 2–4 weeks after starting therapy for 1–2 months; <i>salicylates</i> : serum salicylate levels if therapeutic dose and no response | Same as initial plus stool guaiac every 6–12 months |
| Methotrexate | Oral or IM: 7.5–15 mg per week | Baseline: AST, ALT, ALK-P, albumin, total bilirubin, hepatitis B and C studies, CBC with platelets, S _{Cr} | CBC with platelets, AST, albumin every 1–2 months |
| Leflunomide | Oral: 100 mg daily for 3 days, then 10–20 mg daily | Baseline: ALT | ALT monthly initially, and then periodically when stable |
| Hydroxychloroquine | Oral: 200–300 mg twice daily; after 1–2 months may increase to 200 mg once or twice daily | Baseline: color fundus photography and automated central perimetric analysis | Ophthalmoscopy every 9–12 months and Amsler grid at home every 2 weeks |
| Sulfasalazine | Oral: 500 mg twice daily, then increase to 1 g twice daily max | Baseline: CBC with platelets, then every week for 1 month | Same as initial every 1–2 months |
| Etanercept | 25 mg SC twice weekly or 50 mg every 7 days | None | None |
| Infliximab | 3 mg/kg IV at 0, 2, and 6 weeks, then every 8 weeks | None | None |
| Adalimumab | 40 mg SC every 2 weeks | None | None |
| Anakinra | 100 mg SC daily | None | None |
| Auranofin | Oral: 3 mg once or twice daily | Baseline: UA, CBC with platelets | Same as initial every 1–2 months |
| Gold thiomalate | IM: 10-mg test dose, then weekly dosing 25–50 mg; after response may increase dosing interval | Baseline and until stable: UA, CBC with platelets preinjection | Same as initial every other dose |
| Azathioprine | Oral: 50–150 mg daily | CBC with platelets, AST every 2 weeks for 1–2 months | Same as initial every 1–2 months |
| D-Penicillamine | Oral: 125–250 mg daily, may increase by 125–250 mg every 1–2 months; max 750 mg/day | Baseline: UA, CBC with platelets, then every week for 1 month | Same as initial every 1–2 months, but every 2 weeks if dose changes |
| Cyclophosphamide | Oral: 1–2 mg/kg per day | UA, CBC with platelets every week for 1 month | Same tests as initial but every 2–4 weeks |
| Cyclosporine | Oral: 2.5 mg/kg per day | S _{Cr} , blood pressure every month | Same as initial |
| Corticosteroids | Oral, IV, IM, IA, and soft-tissue injections: variable | Glucose; blood pressure every 3–6 months | Same as initial |

ALK-P, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; CBC, complete blood cell count; IA, intra-articular; IM, intramuscular; IV, intravenous; SC, subcutaneously; S_{Cr}, serum creatinine; UA, urinalysis.

portion of the inflammatory cascade (see Fig. 89–2). Cyclooxygenase-2–specific NSAIDs have a better gastrointestinal safety profile and similar therapeutic efficacy as conventional NSAIDs.^{29,30} For discussion of the mechanism of action, adverse effects, and drug interactions, see osteoarthritis, Chap. 90. Dosing information for NSAIDs is provided in Table 90–4.

■ METHOTREXATE

Methotrexate is now considered the DMARD of choice by many rheumatologists for treating rheumatoid arthritis. In psoriatic arthritis it not only treats the joint symptoms, but also improves the skin disease for most patients. Methotrexate is contraindicated in pregnant and nursing women. It is also contraindicated in patients with chronic liver disease, immunodeficiency, pleural or peritoneal effusions, leukopenia, thrombocytopenia, pre-existing blood disorders, and a creatinine clearance of less than 40 mL/min.

Absorption of methotrexate is variable and averages about 70% of an oral dose. Methotrexate is 35% to 50% bound to albumin; it may

be displaced by highly protein-bound drugs such as NSAIDs, but the clinical importance of this interaction is not known. Methotrexate is extensively metabolized intracellularly to polyglutamated derivatives. It is excreted by the kidney, 80% unchanged, by glomerular filtration and active transport. Some methotrexate may be reabsorbed, but this transport process may be saturated even with low doses, resulting in increased renal clearance.

Methotrexate inhibits cytokine production, inhibits purine biosynthesis, and may stimulate release of adenosine, all of which may lead to its anti-inflammatory properties. The drug has a fairly rapid onset of action; results may be seen as early as 2 to 3 weeks after starting therapy. Some 45% to 67% of patients remain on methotrexate therapy in studies ranging from 5 to 7 years.^{31,32} Methotrexate may be given intramuscularly, subcutaneously, or orally. Doses greater than 15 mg per week generally are given parenterally because of decreased oral bioavailability of larger doses.

The toxicities of methotrexate therapy are mainly gastrointestinal, hematologic, pulmonary, and hepatic. Stomatitis occurs in 3% to 10% of patients and may be painful or painless. Diarrhea, nausea, and vomiting may occur in up to 10% of patients. The most common

TABLE 89–3. Clinical Monitoring of Drug Therapy in Rheumatoid Arthritis

| Drug | Toxicities Requiring Monitoring | Symptoms to Inquire About ^a |
|----------------------------------|--|--|
| NSAIDs and salicylates | GI ulceration and bleeding, renal damage | Blood in stool, black stool, dyspepsia, nausea/vomiting, weakness, dizziness, abdominal pain, edema, weight gain, shortness of breath |
| Corticosteroids | Hypertension, hyperglycemia, osteoporosis ^b | Blood pressure if available, polyuria, polydipsia, edema, shortness of breath, visual changes, weight gain, headaches, broken bones or bone pain |
| Azathioprine | Myelosuppression, hepatotoxicity, lymphoproliferative disorders | Symptoms of myelosuppression (extreme fatigue, easy bleeding or bruising, infection), jaundice |
| Gold (intramuscular or oral) | Myelosuppression, proteinuria, rash, stomatitis | Symptoms of myelosuppression, edema, rash, oral ulcers, diarrhea |
| Hydroxychloroquine | Macular damage, rash, diarrhea | Visual changes including a decrease in night or peripheral vision, rash, diarrhea |
| Methotrexate | Myelosuppression, hepatic fibrosis, cirrhosis, pulmonary infiltrates or fibrosis, stomatitis, rash | Symptoms of myelosuppression, shortness of breath, nausea/vomiting, lymph node swelling, coughing, mouth sores, diarrhea, jaundice |
| Leflunomide | Hepatitis, GI distress, alopecia | Nausea/vomiting, gastritis, diarrhea, hair loss, jaundice |
| Penicillamine | Myelosuppression, proteinuria, stomatitis, rash, dysgeusia | Symptoms of myelosuppression, edema, rash, diarrhea, altered taste perception, oral ulcers |
| Sulfasalazine | Myelosuppression, rash | Symptoms of myelosuppression, photosensitivity, rash, nausea/vomiting |
| Etanercept, adalimumab, anakinra | Local injection-site reactions, infection | Symptoms of infection |
| Infliximab | Immune reactions, infection | Postinfusion reactions, symptoms of infection |

^aAltered immune function increases infection, which should be considered, particularly in patients taking azathioprine, methotrexate, corticosteroids, or other drugs that may produce myelosuppression.

^bOsteoporosis is not likely to manifest early in treatment, but all patients should be taking appropriate steps to prevent bone loss.

NSAID, nonsteroidal anti-inflammatory drug.

TABLE 89–4. Dosage Regimens and Durations of Antiplatelet Effect for Nonsteroidal Anti-Inflammatory Drugs

| Drug | Recommended Total Daily Anti-Inflammatory Dosage | | Dosing Schedule | Approximate Duration of Antiplatelet Effect |
|---------------------------|--|-------------------------|--|---|
| | Adult | Children | | |
| Aspirin | 2.6–5.2 g | 60–100 mg/kg | Four times daily | 14 days |
| Celecoxib | 200–400 mg | – | Once or twice daily | None |
| Diclofenac | 150–200 mg | – | Three to four times daily Extended release: twice daily | 5–10 h |
| Diflunisal | 0.5–1.5 g | – | Twice daily | 2–7 days |
| Etodolac | 0.2–1.2 g (max. 20 mg/kg) | – | Three to four times daily | 36 h |
| Fenoprofen | 0.9–3.0 g | – | Four times daily | 15–24 h |
| Flurbiprofen | 200–300 mg | – | Two to four times daily | 24–48 h |
| Ibuprofen | 1.2–3.2 g | 20–40 mg/kg | Three to four times daily | 5–10 h |
| Indomethacin | 50–200 mg | 2–4 mg/kg (max. 200 mg) | Two to four times daily Extended release: once daily | 24–48 h |
| Ketoprofen | 150–300 mg | – | Three to four times daily Extended release: once daily | 5–10 h |
| Meclofenamate | 200–400 mg | – | Three to four times daily | 24–48 h |
| Meloxicam | 7.5–15 mg | – | Once daily | Uncertain |
| Nabumetone | 1–2 g | – | Once or twice daily | 4–7 days |
| Naproxen | 0.5–1.0 g | 10 mg/kg | Twice daily Extended release: once daily | 4 days |
| Naproxen sodium | 0.55–1.1 g | – | Twice daily | 4 days |
| Nonacetylated salicylates | 1.2–4.8 g | – | Two to six times daily | None |
| Oxaprozin | 0.6–1.8 g (max. 26 mg/kg) | – | One to three times daily | 8–10 days |
| Piroxicam | 10–20 mg | – | Once daily | 7–20 days |
| Sulindac | 300–400 mg | – | Twice daily | 4 days |
| Tolmetin | 0.6–1.8 g | 15–30 mg/kg | Three to four times daily | 8–16 h |
| Valdecoxib | 10 mg | – | Once daily | None |

hematologic toxicity is thrombocytopenia in 1% to 3% of patients. Leukopenia also may occur, but in a smaller number of patients. Although pulmonary fibrosis and pneumonitis can be severe adverse effects, they are rare.

Elevated liver enzymes may occur in up to 15% of patients; cirrhosis is rare. Liver function tests, aspartate aminotransferase (AST) or alanine aminotransferase (ALT), should be performed periodically. Methotrexate should be discontinued if these test values show sustained results greater than twice the upper limits of normal. Serum albumin levels also should be checked periodically, as signs of liver toxicity in some patients may not have liver inflammation manifested by AST or ALT elevation. Liver biopsy is now recommended before beginning methotrexate therapy only for patients with a history of excessive alcohol use, ongoing hepatitis B or C infection, or recurring elevation of AST. Biopsies during methotrexate therapy are recommended only for patients who develop consistently abnormal liver function tests.¹⁰

Since the drug is teratogenic, patients should use contraception to avoid pregnancy and discontinue the drug if conception is planned.

Because it is a folic acid antagonist, methotrexate can induce a folic acid deficiency. This deficiency is thought to be partly responsible for methotrexate toxicity, and supplementation with folic acid has been shown to alleviate some adverse effects. Addition of folic acid to a methotrexate regimen for rheumatoid arthritis does not compromise drug efficacy.^{10,33,34}

■ LEFLUNOMIDE

Leflunomide is a DMARD that inhibits pyrimidine synthesis, leading to a decrease in lymphocyte proliferation and modulation of inflammation. It is given as a loading dose of 100 mg daily for 3 days, followed by a maintenance dose of 20 mg daily. Lower doses may be used if patients have gastrointestinal intolerance, complain of hair loss, or have other signs of dose-related toxicity. The loading dose allows the patient to achieve a therapeutic response, usually within the first month. The long elimination half-life of the drug (14 to 16 days) would require the patient to take the drug for months to achieve steady state without a loading dose.

Leflunomide has efficacy similar to that of methotrexate for treating rheumatoid arthritis. The drug may cause liver toxicity and is contraindicated in patients with pre-existing liver disease. Patients taking the drug should have ALT monitored monthly initially, and periodically thereafter as long as they continue treatment.

The drug is teratogenic, and appropriate contraceptive measures are recommended to avoid pregnancy for all sexually active male and female patients taking leflunomide. If conception is desired, leflunomide must be discontinued. Because leflunomide undergoes enterohepatic circulation, the drug takes many months to drop to a plasma concentration considered safe during pregnancy (<0.02 mcg/mL). Cholestyramine may be used to rapidly clear the drug from plasma. Unlike many DMARDs, leflunomide bone marrow toxicity is reported so rarely that blood cell monitoring is not necessary.^{19,35,36}

■ HYDROXYCHLOROQUINE

The pharmacokinetics of hydroxychloroquine are poorly understood. It is well absorbed orally and widely distributed to body tissues. Hydroxychloroquine is partially metabolized in the liver and is excreted by the kidney. The onset of action of hydroxychloroquine may

be delayed up to 6 weeks, but the drug is considered a therapeutic failure only when 6 months of therapy without a response has elapsed.

The main advantage of hydroxychloroquine is the lack of myelosuppressive, hepatic, and renal toxicities that may be seen with other DMARDs, which simplifies monitoring. Short-term toxicities of hydroxychloroquine include gastrointestinal effects such as nausea, vomiting, and diarrhea, which can be managed by taking doses with food. Ocular toxicity includes accommodation defects, benign corneal deposits, blurred vision, scotomata (small areas of decreased or absent vision in the visual field), and night blindness. Although the risk of true retinopathy with hydroxychloroquine approaches zero, pre-retinopathy may occur in 2.7% of patients. All patients must understand the importance of adhering to hydroxychloroquine monitoring guidelines as delineated in Table 89–2. Any visual change must be reported immediately. Dermatologic toxicities include rash, alopecia, and increased skin pigmentation; neurologic adverse effects such as headache, vertigo, and insomnia usually are mild.^{26,37,38}

■ SULFASALAZINE

Sulfasalazine, a prodrug, is cleaved by bacteria in the colon into sulfapyridine and 5-aminosalicylic acid. It is believed that the sulfapyridine moiety is responsible for the agent's antirheumatic properties, although the exact mechanism of action is not known. Once the colonic bacteria have cleaved sulfasalazine, sulfapyridine and 5-aminosalicylic acid are absorbed rapidly from the gastrointestinal tract. Sulfapyridine distributes rapidly throughout the body, but higher concentrations are found in certain tissues such as serous fluid, liver, and intestines. Both sulfasalazine and its metabolites are excreted in the urine. Antirheumatic effects should be seen within 2 months.

Use of sulfasalazine is often limited by its adverse effects. Gastrointestinal adverse effects such as nausea, vomiting, diarrhea, and anorexia are the most common. These can be minimized by initiating therapy with low doses and titrating gradually to higher doses, dividing the dose more evenly throughout the day, or using enteric-coated preparations. Rash, urticaria, and serum sickness–like reactions can be managed with antihistamines, and if indicated, corticosteroids. If a hypersensitivity reaction occurs, therapy should be stopped immediately and another DMARD substituted. Sulfasalazine has been associated with leukopenia, alopecia, stomatitis, and elevated hepatic enzymes. It also may cause the patient's urine and skin to turn a yellow-orange color which is of no clinical consequence; however, patients should be educated about this to avoid premature discontinuance.

Sulfasalazine's absorption can be decreased when antibiotics are used that destroy the colonic bacteria. Sulfasalazine also binds iron supplements in the gastrointestinal tract that can lead to a decreased absorption of sulfasalazine. The administration of these two agents should be separated temporally to avoid this interaction. Sulfasalazine can potentiate warfarin's effects by displacing it from protein-binding sites. Close monitoring of the patient's International Normalized Ratio is indicated.^{39,40}

■ OTHER DMARDS

Gold salts, azathioprine, d-penicillamine, cyclosporine, cyclophosphamide, and minocycline have all been used to treat rheumatoid

arthritis. Although these drugs can be effective and they may be of value in certain clinical settings, they are used less frequently today due to toxicity, lack of long-term benefit, or both. See Tables 89–2 and 89–3 for dosing and toxicity information.

■ BIOLOGIC AGENTS

Biologic agents are genetically engineered protein molecules that block proinflammatory cytokines. These drugs may be effective when other DMARDs fail to achieve adequate responses, but they are considerably more expensive to use. They have no toxicity that requires laboratory monitoring, but have a small increased risk for infection. There is an increased incidence of tuberculosis in patients treated with these agents. Tuberculin skin testing is recommended before treatment with these drugs.^{41–44} Patients with a history of significant tuberculosis exposure or recurrent infection may not be good candidates for these drugs. Those who develop infections while on biologic agents should at least temporarily discontinue them until the infection is cured. Additionally, congestive heart failure is a relative contraindication for infliximab and etanercept. Increased cardiac mortality has been seen in patients treated with infliximab, and etanercept-associated heart failure exacerbations have been documented.^{45,46} TNF inhibitors may predispose patients to increased cancer risk, as TNF plays a role in ridding the body of cancer cells. The reported incidence of malignancy is similar to that of patients with rheumatoid arthritis who are not on these drugs; however, long-term surveillance studies are lacking.^{47,48}

■ Etanercept

Etanercept is a fusion protein consisting of two p75 soluble TNF receptors linked to an Fc fragment of human IgG₁. The drug binds to TNF, making it biologically inactive and preventing it from interacting with the cell-surface TNF receptors and thereby activating cells.

The drug is given by subcutaneous injection, 25 mg twice weekly or 50 mg once weekly, usually through self-injections or administration by a caregiver. Aside from local injection-site reactions, adverse effects are rare. There have been case reports of pancytopenia and neurologic demyelinating syndromes like multiple sclerosis that have prompted Food and Drug Administration (FDA) warnings, but the incidence of these complications is not known at this time. The infection and congestive heart failure precautions are discussed above. No laboratory monitoring is required.

Most clinical trials have used etanercept in patients who failed DMARDs. Response was seen in 60% to 75% of patients. The drug also has been shown to be useful in juvenile rheumatoid arthritis and psoriatic arthritis, for which it is approved by the FDA, and ankylosing spondylitis and other inflammatory arthropathies, for which it is not approved. It has been shown in clinical trials to slow erosive disease progression to a greater degree than oral methotrexate therapy in patients with inadequate response to methotrexate monotherapy.^{49–54}

■ Infliximab

Infliximab is a chimeric antibody combining portions of mouse and human IgG₁. An anti-TNF antibody was created by exposing mice to human TNF. The binding portion of that antibody was fused to a

human constant-region IgG₁ to reduce the antigenicity of the foreign protein. This antibody, when injected in humans, binds to TNF and prevents its interaction with TNF receptors on inflammatory cells.

Infliximab is given by intravenous infusion at a dose of 3 mg/kg at 0, 2, and 6 weeks, and then every 8 weeks. To prevent the formation of antibodies to this foreign protein, methotrexate should be given orally in doses typically used to treat rheumatoid arthritis for as long as the patient continues on infliximab. The clinical significance of these antibodies in rheumatoid arthritis has not been demonstrated, but in Crohn's disease they are associated with infusion reactions and reduce the duration of response.⁵⁵ Infusion reactions may occur in any patient treated with the drug. Loss of response may be seen in patients with rheumatoid arthritis who have initial good response, which requires increased doses or shorter intervals between doses to maintain response.

The drug may increase risk of infection as noted above. An acute infusion reaction with symptoms including fever, chills, pruritus, and rash may occur within 1 to 2 hours after giving the drug. Autoantibodies and lupus-like syndrome also have been reported. In clinical trials, the combination of methotrexate plus infliximab halted progression of joint damage in patients and was superior to methotrexate monotherapy.^{53,56–58}

■ Adalimumab

Adalimumab is a human IgG₁ antibody to TNF. Since it has no foreign protein components, it is less antigenic than infliximab. The drug is provided as a premixed syringe containing 40 mg, which is administered by subcutaneous injection every 14 days. It has similar response rates to those seen with the other TNF inhibitors. Local injection-site reactions were the most common adverse reactions noted in clinical trials. It has the same precautions regarding tuberculosis and other infections as the other biologics. To date, congestive heart failure exacerbations have not been reported.^{59,60}

■ Anakinra

Anakinra is an interleukin-1-receptor antagonist (IL-1ra) which is a naturally occurring anti-inflammatory. By binding to IL-1 receptors on target cells, it prevents the interaction between IL-1 and the cell.

IL-1 is very important in the pathogenesis of rheumatoid arthritis. It stimulates release of chemotactic factors and adhesion molecules, and these promote migration of inflammatory leukocytes to tissues. It also causes release of factors known to dilate blood vessels and direct cytotoxins that produce connective tissue damage.

In a double-blind, placebo-controlled trial, anakinra 150 mg given by daily subcutaneous injection had a response rate of 43% compared with 27% for placebo-treated patients. Less radiographic progression of joint damage was noted in those receiving anakinra. Injection-site reactions were the most common adverse effect noted. Infection risk and precautions are similar to those for the TNF inhibitors.^{61–64}

■ CORTICOSTEROIDS

Corticosteroids are used in rheumatoid arthritis for their anti-inflammatory and immunosuppressive properties. They interfere with antigen presentation to T lymphocytes, inhibit prostaglandin and

leukotriene synthesis, and inhibit neutrophil and monocyte superoxide radical generation. Corticosteroids also impair cell migration and cause redistribution of monocytes, lymphocytes, and neutrophils, thus blunting the inflammatory and autoimmune responses.

Oral corticosteroids are absorbed rapidly and completely from the gastrointestinal tract. They are metabolized and inactivated primarily by the liver and excreted in the urine. The elimination half-life of most corticosteroids is sufficiently long that once-daily dosing is possible.

Oral corticosteroids can be used in several ways. They can be used in bridging therapy, continuous low-dose therapy, and short-term high-dose bursts to control flares. Oral steroids (e.g., prednisone and methylprednisolone) can be used to control pain and synovitis while DMARDs are taking effect. This is termed *bridging therapy* and is often used in patients with debilitating symptoms when DMARD therapy is initiated. Patients with difficult-to-control disease may be placed on low-dose, long-term corticosteroid therapy to control their symptoms. Prednisone doses below 7.5 mg daily are well tolerated, but are not devoid of the long-term adverse effects associated with corticosteroids. The lowest dose of corticosteroid that controls symptoms should be used to reduce adverse effects. Alternate-day dosing of low-dose oral corticosteroids usually is ineffective in rheumatoid arthritis; symptoms usually flare on days without medication. High-dose corticosteroid bursts often are used to suppress disease flares. High doses are sustained for several days until symptoms are controlled, followed by a taper to the lowest effective dose.

Corticosteroids also may be delivered by injection. The intramuscular route is preferable in patients with compliance problems, since a depot effect is achieved. Depot forms of corticosteroids include triamcinolone acetonide, triamcinolone hexacetonide, and methylprednisolone acetate. This provides the patient with 2 to 8 weeks of symptomatic control. The depot effect provides a physiologic taper, avoiding withdrawal reaction associated with hypothalamic-pituitary axis suppression. It should be noted that the onset of effect via this route may be delayed by several days. Intravenous corticosteroids may be used to provide the patient with large amounts of drug during a steroid burst to control severe symptoms. Intra-articular injections of depot forms of corticosteroids can be useful in treating synovitis and pain when a small number of joints are affected. The onset and duration of symptomatic relief are similar to those of intramuscular injection. The intra-articular route often is preferred because it is associated with the fewest number of systemic adverse effects. If efficacious, intra-articular injections may be repeated every 3 months. No one joint should be injected more than two to three times per year because of the risk of accelerated joint destruction and atrophy of tendons. Soft tissues such as tendons and bursae also may be injected. This may help control the pain and inflammation associated

with these structures. The onset and duration of symptomatic relief are similar to those of intramuscular and intra-articular injections.

The major limitation to the long-term use of corticosteroids is adverse effects. They include hypothalamic-pituitary-adrenal suppression, Cushing's syndrome, osteoporosis, myopathies, glaucoma, cataracts, gastritis, hypertension, hirsutism, electrolyte imbalances, glucose intolerance, skin atrophy, and increased susceptibility to infections. To minimize these effects, use the lowest effective corticosteroid dose and limit the duration of use. Patients on long-term therapy should be given calcium and vitamin D (and estrogen supplements for postmenopausal women) to minimize bone loss. Alendronate has been shown to be effective in preventing the bone loss and might be considered prophylactically for patients when long-term corticosteroid use is anticipated, particularly for patients at high risk (e.g., postmenopausal females and the elderly).^{65,66} There is no evidence that corticosteroids alone increase the risk of gastrointestinal ulcerations, even though they have been implicated often. Therefore gastrointestinal protective measures usually are not indicated.⁶⁷

CLINICAL CONTROVERSY

Even the best therapy currently available does not completely eliminate all signs and symptoms of rheumatoid arthritis for most patients. Clinicians struggle with determining how much treatment is enough. Also, some patients show evidence of disease progression despite apparent control of clinical symptoms. How can these patients be identified and the treatment course changed before progression occurs?

PHARMACOECONOMIC CONSIDERATIONS

The total cost of treating a patient with rheumatoid arthritis is estimated to be between \$5000 and \$7300 annually (1991 dollars). Of this, drugs account for roughly 10% of the total, excluding monitoring costs. These costs are approximately three times the cost of medical care for patients of similar age and gender without rheumatoid arthritis. However, if biologic agents are used, the cost of this drug therapy alone may be as much as \$12,000. The costs must be balanced against the high cost of disability to earning potential in these patients. Men with rheumatoid arthritis have average annual wages that are 50% lower than those of men of similar age without rheumatoid arthritis. In women with the disease, average annual wages are only 25% of those without. The costs of disability make treatment worth the price if disability can be prevented or delayed, and patients can continue to function as productive members of society.⁶⁸

EVALUATION OF THERAPEUTIC OUTCOMES

The evaluation of therapeutic outcomes is based primarily on improvements of clinical signs and symptoms of rheumatoid arthritis. Clinical signs of improvement include a reduction in joint swelling, decreased warmth over actively involved joints, and decreased tenderness to joint palpation. Improvement in rheumatoid arthritis symptoms includes reduction in perceived joint pain and morning stiffness, longer time to onset of afternoon fatigue, and improvement in ability to perform activities of daily living. Improvement of activities of daily living may be assessed objectively using a health assessment questionnaire. Joint radiographs may be of some benefit in assessing the progression of the disease and should

show little or no evidence of disease progression if treatment is effective.

⚠ Laboratory monitoring is of little value in monitoring individual patient response to therapy. Monitoring of toxicity of drugs is shown in Tables 89-2 and 89-3. Routine monitoring of patients is essential to the safe use of these drugs. In addition, patients should be questioned about symptoms of the adverse effects outlined in the drug section of this chapter.

CONCLUSION

Rheumatoid arthritis is the most common inflammatory arthritis, affecting approximately 1% of the population. The disease is

characterized by symmetrical swelling and stiffness of the involved joints. The stiffness is usually more prominent in the morning. Extra-articular features of rheumatoid arthritis include rheumatoid nodules, vasculitis, and ocular, cardiac, and pulmonary complications. The course of the disease is highly variable. Treatment is aimed at relieving pain and inflammation and maintaining and preserving joint function. Nondrug therapy, including exercise and adequate rest periods, should also be used early in the course of treatment. Early use of a DMARD or biologic agent has been shown to result in better patient outcomes. Methotrexate, sulfasalazine, and hydroxychloroquine are often considered for initial therapy. Biologic agents have also been shown to be effective in these patients, but may be considered second-line agents due to cost considerations and lack of long-term outcome documentation. Combination DMARDs or biologicals may be considered in those who fail adequate trials of single-agent therapy. Corticosteroids and NSAIDs may be useful adjuncts for treatment, but because of adverse effects and limited impact on long-term outcomes, they should not be considered as sole treatment for most patients.

ABBREVIATIONS

ALT: alanine aminotransferase
 AST: aspartate aminotransferase
 DMARD: disease-modifying antirheumatic drug
 HLA: human lymphocyte antigen
 IL-1, IL-6: interleukins-1, and -6
 IL-1ra: interleukin-1-receptor antagonist
 MHC: major histocompatibility complex
 NSAID: nonsteroidal anti-inflammatory drugs
 PMN: polymorphonuclear leukocyte
 TNF: tumor necrosis factor

OSTEOARTHRITIS

Karen E. Hansen and Mary Elizabeth Elliott

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The most common form of arthritis is osteoarthritis (OA). It affects individuals in the middle to later years of life, with women more commonly affected than men after age 45 years.
- 2 OA is primarily a disease of cartilage that reflects a failure of the chondrocyte to maintain proper balance between cartilage formation and destruction.
- 3 The most common symptom associated with OA is pain, which leads to decreased function and motion, and pain relief is the primary objective of medication therapy.
- 4 Patients have bony proliferation of affected joints that should be differentiated from the swelling of rheumatoid or inflammatory arthritis. OA is not a systemic disease such as rheumatoid arthritis. The joint distribution often involves the knees, hips, and hands, although other joints also can be affected.
- 5 Nonpharmacologic therapy is the foundation of the pharmaceutical care plan and should be initiated before, or simultaneously with, initiation of pharmacologic therapy.
- 6 Based upon efficacy, safety, and cost considerations, scheduled acetaminophen, up to 4 g/day, should be tried initially for pain relief in OA.
- 7 Failure with acetaminophen warrants a trial with a nonsteroidal anti-inflammatory drug (NSAID).
- 8 NSAIDs are associated with GI, renal, liver, or central nervous system toxicity. Appropriate monitoring with complete blood count, serum creatinine, and hepatic transaminase levels is valuable in detecting potential toxicity. Cyclooxygenase-2 (COX-2)-specific inhibitors carry a lower risk of GI bleeding or platelet inhibition, and may be appropriate in selected patients.
- 9 Prevention of NSAID-induced GI toxicity includes the use of nonacetylated salicylates, COX-2 inhibitors, or use of protective agents with NSAIDs. Misoprostol reduces both gastric and duodenal ulcers, while histamine (H₂)-receptor antagonists are effective in preventing duodenal ulcers but not gastric ulcers. Proton pump inhibitors may have comparable effects to misoprostol and are also recommended for reducing GI toxicity.
- 10 Glucosamine, alone or with chondroitin sulfate, warrants further study for its potential to relieve OA symptoms and possibly slow disease progression.

Osteoarthritis (OA) is the most common joint disease, affecting nearly 50% of those over 65 years of age and almost all individuals over age 75.¹⁻⁴ OA ranks second only to cardiovascular disease in causing chronic disability, making this condition of substantial importance to public health. Appreciation of the human and economic costs of this disease has prompted exciting advances concerning etiology and treatment.

OA affects primarily the weight-bearing joints of the axial and peripheral skeleton, causing pain, limitation of motion, deformity, progressive disability, and decreased quality of life.¹⁻⁵ Other names for OA include *degenerative joint disease* and *hypertrophic arthritis*, but these terms have shortcomings. OA implies lack of inflammation and excess materials in the joint, degenerative joint disease suggests a wearing out of the joint, and hypertrophic arthritis describes the overgrowth of bone and cartilage that is only one aspect of OA. Thus the term “osteoarthritis” best reflects the degenerative changes that occur in the metabolically active cartilage and bone within a joint.

OA is characterized by increased destruction of cartilage and subsequent proliferation of adjacent bone. The regenerated articular

surfaces do not possess the same qualities and architecture as the original joint, and this change in structure leads to pain, decreased or altered motion, crepitus, and possibly local inflammation.² The pain of OA typically worsens with use and improves with rest. Morning stiffness lasting less than 1 hour and “gelling” of the joints after inactivity are also common. The inflammation associated with OA is usually mild or localized, in contrast to that of rheumatoid arthritis or other inflammatory diseases affecting the joints.

The major goals of OA therapy are to educate the patient, alleviate pain and other symptoms, and improve function.^{1,6-8} Nonpharmacologic therapy is the foundation of OA management and includes patient education, strengthening and range-of-motion exercises, and use of assistive devices, joint protection, and weight loss as necessary.⁸⁻¹¹ Pharmacologic therapy begins with nonopioid analgesics such as acetaminophen, followed by nonsteroidal anti-inflammatory drugs (NSAIDs), inhibitors specific for the cyclooxygenase-2 (COX-2) enzyme when indicated, and topical analgesic creams containing capsaicin or methylsalicylate.^{1,6-8} Intra-articular glucocorticoid or hyaluronic acid injections and opioid analgesics play an important

role in management of pain related to OA, with use of the latter in those unresponsive to other therapies. New therapeutic approaches are being developed based on recent information about chondrocyte metabolism and the control of proteases that contribute to cartilage destruction.

EPIDEMIOLOGY

1 OA is the most prevalent of the rheumatic diseases, and is responsible for enormous disability and loss of productivity.¹⁻⁴ Prevalence increases with age, and radiographic data show that OA at some skeletal site occurs in the majority of people over 65 years of age, and in nearly everyone over 75 years of age. Despite intense epidemiologic study, the exact prevalence of OA is unknown, owing to the uncertainties and variations of diagnostic definition and reporting mechanisms. Another confounder is that many patients with radiographically apparent OA do not have symptoms that lead them to medical care.

PREVALENCE BY AGE, SEX, AND RACE

Based on prevalence data from the National Centers for Health Statistics, an estimated 15.8 million adults, or 12% of those between 25 and 74 years of age, have signs and symptoms of OA.⁴ The prevalence of OA increases with age. In those under age 45, about one-fifth have OA of the hands, while for those aged 75 to 79 years, 85% have OA of the hands. OA of the knee occurs in less than 0.1% of those aged 25 to 34 years, but in 10% to 20% of those aged 65 to 74 years.

OA severity also increases with age.¹⁻⁴ For those between 65 and 74 years of age, 33% have moderate to severe knee OA, and 50% have moderate to severe hip OA. The National Arthritis Data Workgroup, using National Health and Nutrition Examination Survey and other data, has projected that by the year 2020, 18.2% of Americans (59.4 million people) will be affected by OA. In the United States, women are more often affected by OA; older women are twice as likely as men to have OA of the knee and hands.^{2,4} Women are also more likely to have inflammatory OA of the proximal and distal interphalangeal joints of the hands, giving rise to the formation of Bouchard's and Heberden's nodes, respectively. Knee OA appears to be twice as prevalent in black as opposed to white women. Chinese, East Indian, and Native American people have lower incidences of hip OA than do Caucasians.

INCIDENCE

The overall incidence of hip or knee OA is approximately 200 per 100,000 person-years. The incidence of hip OA is greater in women than in men, whereas the rate for knee OA is similar between genders. In men, rates of knee and hip OA increase with age, but in women rates remain stable. Based on these population data, one-half million symptomatic cases of idiopathic OA are estimated to occur annually in the U.S. white population.

ETIOLOGY

OBESITY

Increased body weight is strongly associated with hip, knee, and hand OA.^{3,12,13} Obesity often precedes OA and contributes to its development, rather than occurring as a result of inactivity from joint pain. In

a three-decade Framingham Study, the highest quintile of body mass was associated with a higher relative risk of knee OA (relative risk of 1.5 to 1.9 for men and 2.1 to 3.2 for women). Another study of 1,108 men in their twenties also showed that high body mass index was associated with later development of knee OA.¹³ The risk of developing OA increases by about 10% with each additional kilogram of weight, and in obese persons without OA, weight loss of even 5 kg decreases the risk of future knee OA by one-half. In addition to being a risk factor for OA, obesity is also a predictor for eventual prosthetic joint replacement.

OCCUPATION, SPORTS, AND TRAUMA

Those participating in activities involving repetitive motion or injury are at increased risk for developing OA.¹⁴ Workers exposed to repetitive stress of the hands or lower limbs are at higher risk for OA of the stressed joints. Lower-extremity OA in some professional sports is also increased, likely secondary to repetitive motion, trauma to the joint, loss of ligament integrity, or damage to the meniscus. Risk for OA depends on the type and intensity of physical activity. The Framingham Study showed that heavy physical activity increases knee OA risk, especially in the obese, whereas moderate or light activity does not.¹⁵ Interestingly, long-distance runners are not at higher risk of developing OA. Age at injury does matter, because older individuals who damage ligaments tend to develop OA more rapidly than young people with a similar injury.

Finally, there are interesting inverse associations between quadriceps strength and knee OA and disability. Quadriceps weakness, once thought to result from disuse atrophy in OA patients, may precede and even contribute to the development of OA, possibly through decreased knee stability.¹⁶

GENETIC FACTORS

Heredity plays a role in osteoarthritis.^{3,17} Heberden's nodes are 10 times more prevalent in women than in men, with a twofold higher risk if the woman's mother had them. Genetic links also have been shown with OA of the first metatarsophalangeal joint and with generalized OA. Premature development of OA is associated with a defect in type II procollagen. The discovery of a genetic link between the cartilage matrix and OA may shed light on disease development, and has the potential to aid in screening and treatment strategies in certain groups of patients.

OSTEOPOROSIS

An inverse correlation between OA and osteoporosis has been demonstrated, and both men and women with OA have increased bone mineral density at numerous skeletal sites.^{2,18} This relationship may derive from the influence of body weight on both diseases, because heavy individuals have higher bone density as well as increased risk of OA. Despite their lower risk of osteoporosis, individuals with OA are not protected against fracture. OA patients tend to be less posturally stable and more likely to fall, so despite the higher bone density, their fracture rates are similar to those of patients without OA.

PATHOPHYSIOLOGY

2 OA falls into two major etiologic classes. *Primary (idiopathic) OA*, the most common type, has no identifiable cause. Subclasses of primary OA are *localized OA*, involving one or two sites, and

TABLE 90–1. Classification of Osteoarthritis

| Primary (Idiopathic) | Secondary |
|----------------------|---|
| Localized | Trauma—acute/chronic |
| Generalized | Underlying joint disorder |
| | Local (fracture/infection) |

| | Avascular necrosis |
| | Bone dysplasia |

Data from Felson et al³ and Mankin et al.²⁰

generalized OA, affecting three or more sites. *Erosive osteoarthritis* is used to describe the presence of erosion and marked proliferation in the proximal and distal interphalangeal joints of the hands. *Secondary OA* is that associated with a known cause such as rheumatoid or another inflammatory arthritis, trauma, metabolic or endocrine disorders, and congenital factors (Table 90–1).^{2,19–21}

To aid uniform reporting of rheumatic diseases, a classification scheme and criteria for OA of the hip, knee, and hand were devised by the American College of Rheumatology (ACR). Criteria include the presence of pain, bony changes on examination, a normal erythrocyte sedimentation rate, and characteristic radiographs.^{1,2,22} For hip OA, a patient must have hip pain plus two of the following: an erythrocyte sedimentation rate of less than 20 mm/h, radiographic femoral or acetabular osteophytes, or radiographic joint space narrowing. For knee OA, a patient must have knee pain and radiographic osteophytes plus one of the following: age greater than 50 years, morning stiffness of 30 minutes' or less duration, or crepitus on motion.

Improved understanding of articular cartilage physiology has transcended the wear-and-tear theory of OA. Some changes in the

OA joint may reflect compensatory processes to maintain function in the face of ongoing joint destruction. As such, the pathogenesis of OA involves not only biomechanical forces, but also inflammatory, biochemical, and immunologic factors.^{19–21,23–26} To understand the pathophysiology of OA, familiarity with the normal joint is essential. To this end, a review of the biochemistry and function of normal cartilage and of the diarthrodial joint is provided.

NORMAL CARTILAGE

FUNCTION

In the diarthrodial joint (Fig. 90–1), cartilage provides a low-friction surface covering the concave and convex ends of the bone. Cartilage has viscoelastic properties that provide lubrication with motion, shock absorbercy during rapid movements, and load support. The major functions of cartilage are to (1) enable movement within the required range of motion, (2) distribute loading across joint tissues, thereby preventing damage, and (3) stabilize the joint during use. Cartilage is avascular, aneural, and alymphatic, with a calcified base over a thin layer of cortical bone, the subchondral plate. It is easily compressed, losing up to 40% of its original height when a load is applied. Compression increases the area of contact and disperses force more evenly to underlying bone, tendons, ligaments, and muscles.

STRUCTURE AND BIOCHEMICAL COMPOSITION OF CARTILAGE

Articular cartilage is a hydrated (75% to 80% water), complex extracellular matrix (ECM) with a small number of chondrocytes (<5%). The remaining 20% to 25% of matrix contains three types of molecules: collagens, large aggregates of proteoglycans, and noncollagenous proteins. Orientation of collagen fibers is critical: superficial fibers are parallel to the surface, reducing friction and allowing forces to be dissipated; basal layer collagen fibers are perpendicular to the surface to anchor cartilage to the calcified zone or subchondral bony end plate.

Cartilage undergoes continual biochemical and structural remodeling controlled by chondrocytes, which synthesize collagen and proteoglycans, and also play a role in their degradation. Because adult articular cartilage is avascular, chondrocytes are nourished by synovial fluid. With the cyclic movement and loading of joints, nutrients flow into the cartilage, whereas immobilization reduces nutrient supply.

Recent research has highlighted the role of peptides and proteins regulating chondrocyte function and cartilage metabolism.^{19–21,23–26}

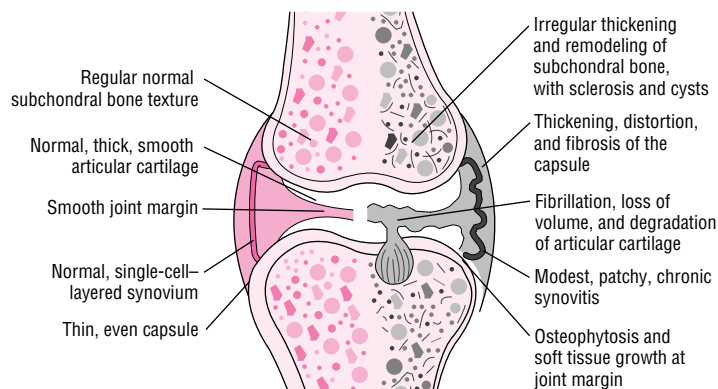

FIGURE 90–1. Characteristics of osteoarthritis in the diarthrodial joint.

Insulin-like growth factor, epidermal growth factor, fibroblast growth factor, and other agents enhance chondrocyte proliferation and proteoglycan synthesis. By contrast, interleukin-1 and tumor necrosis factor- α promote chondrocyte secretion of matrix metalloproteinases (MMPs), including collagenase (MMP-1) and stromelysin (MMP-2). These proteinases in turn degrade matrix proteins. Interleukin-1 and tumor necrosis factor- α also suppress proteoglycan and collagen synthesis in the ECM. Biomechanical factors, including load and strain, also affect chondrocyte function, and joint loading increases proteoglycan synthesis. The following sections will review the components of the joint matrix, and the pathologic changes in this matrix leading to OA.

Collagen

Five types of collagen (II, IX, X, XI, and VI) are located in cartilage. Type II collagen accounts for 90% to 95% of the total collagen in articular cartilage.^{19–21,23–26} Type VI appears to attach chondrocytes to the matrix. Type IX collagen, a proteoglycan, may link matrix molecules together. The cross-linked network of type II collagen fibrils with other ECM proteins provides tensile strength and maintains cartilage volume and shape.

Proteoglycans

The cartilage matrix is comprised of large proteoglycan (PG) aggregates within a collagen network. PGs combine with long hyaluronate molecules in hydrophilic and anionic aggregates that maintain the high water content of cartilage. PGs within the collagen network, coupled with the high water content, endow cartilage with the viscoelastic properties required for resiliency and load bearing. Under pressure, PGs release water and enhance solute flux and chondrocyte nutrition; with removal of pressure, the matrix regains water.

The structure of the PG molecule renders it vulnerable to degradation by MMPs, since cleavage of only one or two peptide bonds can destroy its function.^{23–26} As a result, PG turns over more rapidly than collagen. When protease degradation of PGs is induced experimentally, cartilage maintains its shape but loses elasticity.

With degradation of the ECM, collagen and PG fragments are released into the synovial fluid, eventually reaching the blood and urine. Identification and quantitation of these fragments could potentially aid in diagnosis or monitoring of disease, and also may provide insights into metabolic changes in OA.

OSTEOARTHRITIC CARTILAGE

BIOCHEMICAL CHANGES

Numerous compositional differences have been noted between cartilage in OA and normal individuals (Table 90–2).^{19–21,23–26} Early in OA, cartilage water content increases, possibly as a result of a

TABLE 90–2. Changes in Osteoarthritic Cartilage

| |
|--|
| Increase in water content |
| Increase in chondroitin sulfate-4:chondroitin sulfate-6 ratio |
| Increase in proteases, especially neutral metalloproteinases |
| Decrease in glycosaminoglycans—chondroitin sulfate and keratan sulfate |
| Decrease in proteoglycan aggregation |
| Decrease in proteoglycan monomer size |
| Minimal change in collagen content |

Data from Kraus,¹⁹ Mankin et al,²⁰ Lajeunesse et al,²¹ and Mansell et al.²⁶

damaged collagen network that is unable to constrain PGs, which subsequently gain water. As osteoarthritis progresses, cartilage PG content decreases, possibly through the action of MMPs. Increased collagen synthesis and altered distribution and diameter of the fibers are seen, but collagen content does not appear to change until severe disease is present.

Earlier theories suggested that cartilage was passively eroded in OA, but in fact, there is increased metabolic activity, suggesting a reparative response to damage.^{19–21,23–26} Despite the increased matrix synthesis by chondrocytes, there is a net loss of PG, as degradation proceeds faster than synthesis.

Intense research efforts are directed toward understanding the roles of MMPs and other collagen-degrading enzymes. MMPs are zinc-containing proteinases falling into five related subgroups. MMPs are normally held in check by tissue inhibitors of metalloproteinases (TIMPs), but there are also substances produced by chondrocytes that activate MMPs.^{23–26} Imbalance between activators and inhibitors of MMPs in synovial fluid or local tissues can lead to proteolysis of the ECM, promoting osteoarthritic changes. Recent work showed that cartilage from osteoarthritic human joints exhibited increased collagen-degrading activity colocalized with increased levels of MMP mRNA.²⁴

The subchondral bone adjacent to articular cartilage also undergoes pathologic changes that may precede, coincide with, or follow damage to the articular cartilage. Nevertheless, this damage to subchondral bone is required and appears to permit continued damage to articular cartilage, leading to progression to OA.²⁵ This subchondral bone demonstrates increased bone turnover, with both increased osteoclast and osteoblast activity. There is an associated release of vasoactive peptides and matrix metalloproteinases, neovascularization, and subsequent increased permeability of the adjacent cartilage.^{25,26} This sequence of events leads to continued cartilage degradation, and eventually substantial loss of cartilage, leading to a painful, deformed joint.

In summary, the slow progressive changes in OA consist of an increase in water content, loss of PG, and reduction of PG aggregates of cartilage. The cartilage is subsequently unable to repair itself. Alterations in metabolism of subchondral bone adjacent to articular cartilage appear necessary for continued cartilage destruction. Eventually, progressive loss of articular cartilage and increasing subchondral sclerosis lead to an abnormal and painful joint.

PATHOLOGIC CHANGES

Pathologic changes in bone and cartilage accompany the biochemical changes just described. These changes are noted in both weight-bearing and non-weight-bearing joints, and in both primary and secondary OA. A summary of the biochemical changes in cartilage in OA follows.^{19,20}

1. Initial thickening of articular cartilage as ECM is damaged and water content increases
2. Proliferation of chondrocytes and an increase in ECM anabolic and catabolic activity secondary to tissue damage or alterations in ECM structure
3. Decline in response of chondrocytes to stabilize or restore tissue, resulting in progressive cartilage loss
4. Increased turnover of adjacent subchondral bone, leading to release of vasoactive peptides and enzymes, causing cartilage degradation, neovascularization, and increased leakiness of adjacent cartilage, likely contributing to subsequent loss of articular cartilage

5. Fibrillation or splitting of the noncalcified cartilage, likely related to the biochemical changes described earlier; loss of cartilage exposes the underlying subchondral bone and may lead to microfractures

As cartilage is destroyed and the adjacent subchondral bone undergoes pathologic changes, cartilage is eroded completely, leaving denuded subchondral bone to become dense, smooth, and glistening (eburnation). A more brittle, stiffer bone results, with decreased weight-bearing ability and development of sclerosis and microfractures.^{19,20} Microfractures lead to callus and osteoid production. New bone formations at the joint margins distant from cartilage destruction are referred to as *osteophytes*, and may be an attempt to stabilize the joint.

The joint capsule and synovium also show pathologic changes in OA. Inflammation, noted clinically as synovitis, may result from release of inflammatory mediators from chondrocytes, such as prostaglandins.^{19–21,23–26} Inflammation is localized to the affected

joint, in contrast to that seen in rheumatoid or other inflammatory arthritides.

The pain of OA is not related to the destruction of cartilage, but arises from the activation of nociceptive nerve endings within the joint by mechanical and chemical irritants.²⁷ OA pain may result from distention of the synovial capsule by increased joint fluid, microfracture, periosteal irritation, or damage to ligaments, synovium, or the meniscus.^{2,27}

CLINICAL PRESENTATION

- 3** Key aspects of the clinical presentation of OA are provided in Table 90–3.^{2,28} Presentation of OA depends on duration and severity of disease, and the number of joints affected.

If several joints are involved or if systemic symptoms are present, another form of arthritis or connective tissue disease should be considered. Pain caused by bursitis, tendinitis, or muscular pain

TABLE 90–3. Presentation of Osteoarthritis

| | |
|--|---|
| Age Usually elderly | Hips Groin pain during weight-bearing activities Stiffness, especially after inactivity Limited joint motion |
| Gender Age <45 more common in men Age >45 more common in women | Spine L3 and L4 involvement is most common in the lumbar spine Signs and symptoms of nerve root compression Radicular pain Paresthesias Loss of reflexes Muscle weakness associated with the affected nerve root |
| Symptoms Pain Deep, aching character Pain on motion Pain with motion early in disease Pain with rest late in disease Stiffness in affected joints Resolves with motion, recurs with rest (“gelling” phenomenon) Usually <30 minutes’ duration Often related to weather Limited joint motion May result in limitations activities of daily living Instability of weight-bearing joints | Feet Typically involves the first metatarsophalangeal joint Other sites, less commonly involved Shoulder, elbow, acromioclavicular, sternoclavicular, and temporomandibular joints |
| Signs, history, and physical examination Monarticular or oligoarticular; asymmetrical involvement | Observation on joint examination Bony proliferation or occasional synovitis Local tenderness Crepitus Muscle atrophy Limited motion with passive/active movement Deformity |
| Hands Distal interphalangeal joints Heberden’s nodes (osteophytes or bony enlargements) Proximal interphalangeal joints Bouchard’s nodes (osteophytes) First carpometacarpal joint Osteophytes give characteristic square appearance of the hand (shelf sign) | Radiologic evaluation Early mild OA Radiographic changes often absent Progression of OA Joint space narrowing Subchondral bone sclerosis Marginal osteophytes |
| Knees Patellofemoral compartment involvement Pain related to climbing stairs Medial compartment involvement Genu varum (bowlegged deformity) Lateral compartment involvement Genu valgum (knock-knee deformity) Transient joint effusions Typically noninflammatory synovial fluid (WBC <2000/mm ³) | Late OA Abnormal alignment of joints Effusions Characteristics of synovial fluid High viscosity Mild leukocytosis (<2000 WBC/mm ³) Laboratory values No specific test Erythrocyte sedimentation rate and hematologic and chemistry survey are normal |

may complicate the clinical presentation and requires an accurate diagnosis.

PHYSICAL EXAMINATION

4 Examination of the affected joints reveals tenderness, crepitus, and joint enlargement.^{2,7,19,22} Crepitus is a crackling or grating sound heard with joint movement that is caused by irregularity of joint surfaces. Joint enlargement is related to bony proliferation or to thickening of the synovium and joint capsule. Joint deformity may be present in the later stages of OA as a result of subluxation, collapse of subchondral bone, formation of bone cysts, or bony overgrowth. The presence of a warm, red, tender joint may indicate the presence of an inflammatory arthritis such as gout.

HANDS

Hand OA is associated with pain in specific joints and often with development of bony enlargements (osteophytes). These usually develop slowly and painlessly, appear on lateral and medial aspects of the joint, and are about 10 times more common in women than in men.^{2,22} Occasionally, these nodes become red, warm, swollen, and painful, usually as a result of trauma or use.

KNEES

The knee is commonly affected in OA. It is important to localize the symptoms because the joint has three separate articulations. Knee OA is associated with pain, tenderness, crepitus, and limited range of motion. Limited joint motion occurs from loss of articular surfaces, muscle spasm, capsular contracture, or mechanical blockage secondary to osteophytes (bony enlargements). Weakness or instability (the joint “gives way”) is frequently noted by patients with knee OA. Such joint instability may lead to decreased activity and muscle atrophy.

HIPS

Hip OA is common in the elderly, with a characteristic presentation as shown in Table 90-3. However, pain located on the lateral hip typically represents trochanteric bursitis, while pain in the buttock region may indicate lumbar spine OA or iliopsoas bursitis.

► TREATMENT: Osteoarthritis

■ DESIRED OUTCOME AND GOALS OF TREATMENT

Management of the patient with OA begins with a diagnosis based on a careful history, physical examination, radiographic findings, and an assessment of the extent of joint involvement. Treatment should be tailored to each individual. Goals are (1) to educate the patient, caregivers, and relatives; (2) to relieve pain and stiffness; (3) to maintain or improve joint mobility; (4) to limit functional impairment; and (5) to maintain or improve quality of life.^{1,6–8}

■ GENERAL APPROACH TO TREATMENT

Treatment for each OA patient depends on the distribution and severity of joint involvement, comorbid disease states, concomitant medications, and allergies (Fig. 90-2). Management for all individuals with

SPINE

Degenerative changes involving the spine may occur in the intervertebral disks, vertebral bodies, or posterior apophyseal articulations. Aside from pain and limitation of motion, nerve root compression is a potential complication of arthritis (see Table 90-3).

LABORATORY FINDINGS

No specific laboratory abnormalities occur in *primary* OA.² If secondary OA is suspected, specific laboratory tests can help identify the cause.

RADIOLOGIC EVALUATION

Radiologic evaluation is an absolute necessity in the diagnosis of OA (see Table 90-3). Bone erosions and unequivocal radiographic osteopenia are uncommon except in erosive or secondary OA. Finally, many patients who do not have clinical OA and do not have pain may nonetheless exhibit radiologic changes typical of OA.²⁸

Newer techniques—computed tomography, magnetic resonance imaging, and ultrasound—have been used, but are not suitable for routine use in diagnosing OA.^{2,19,20,28}

DIAGNOSIS

The diagnosis of OA is easily made by history, physical examination, and characteristic radiographic findings.^{2,6,22,28} The major diagnostic goals are (1) to discriminate between primary and secondary OA, and (2) to clarify the joints involved, severity of joint involvement, and response to prior therapies, providing a basis for a treatment plan.

PROGNOSIS

The prognosis for patients with primary OA is variable and depends on the joint involved. If a weight-bearing joint or the spine is involved, considerable morbidity and disability are possible. In the case of secondary OA, the prognosis depends on the underlying cause. Treatment of OA may relieve pain or prevent further progression, but does not reverse pre-existing damage to the articular cartilage.

OA should begin with patient education, and physical and/or occupational therapy, and weight loss or assistive devices if appropriate.

The primary objective of medication is to alleviate pain.^{1,6–8} Scheduled acetaminophen, up to 4 g/day, should be tried initially. If this is ineffective, NSAIDs are prescribed, with specific COX-2 inhibitors preferable for some patients. Application of capsaicin or methyl salicylate topical creams over specific joints can sometimes be helpful adjuncts for pain control. Many patients have turned to glucosamine or chondroitin, and evidence is accumulating that these agents may have benefit in OA.^{29–30} Joint aspiration followed by glucocorticoid or hyaluronate injection can relieve pain, and is offered concomitantly with oral analgesics or after their lack of efficacy, depending on the practitioner’s style. Narcotic analgesics are a final medication to prescribe if other therapies are unsuccessful. When symptoms are intractable or there is significant loss of function, joint replacement may be appropriate if the patient is a surgical candidate.

Finally, for patients interested in clinical trials, investigational strategies with oral doxycycline, matrix metalloproteinase inhibitors,

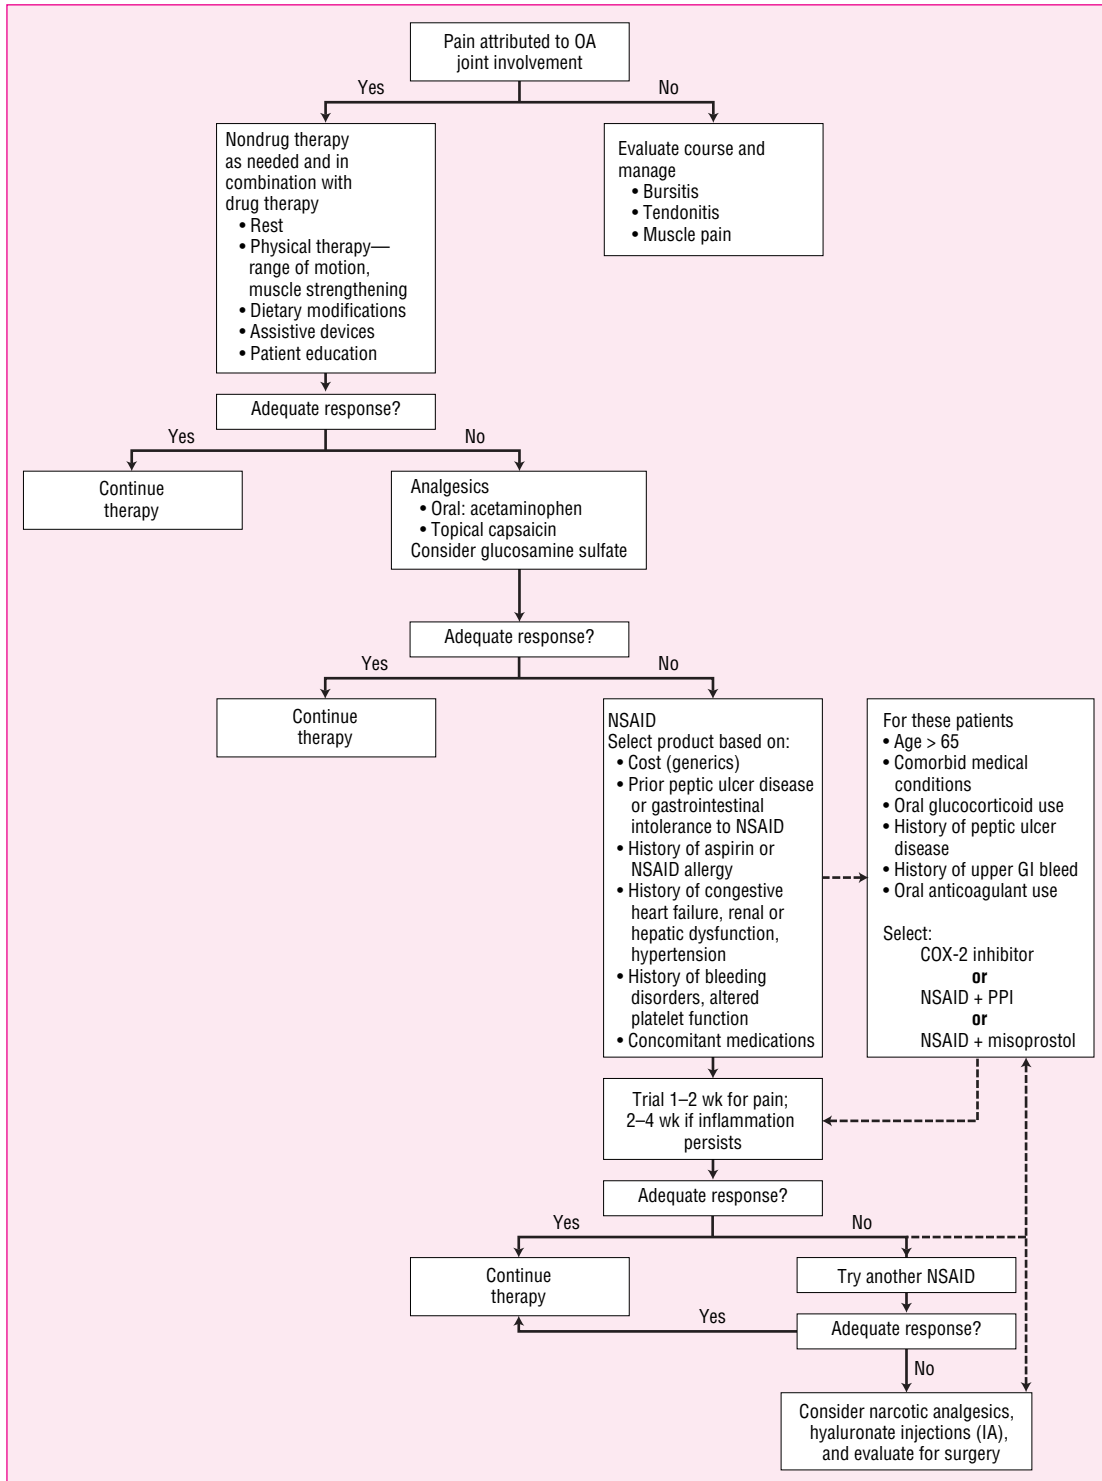

FIGURE 90-2. Treatment for osteoarthritis.

intramuscular injection of pentosan polysulfate and polysulfated glycosaminoglycans, or cartilage transplants may be considered.

NONPHARMACOLOGIC THERAPY

5 The first step in OA treatment is patient education about the disease process, the extent of OA, the prognosis, and treatment

options. Education is paramount, in that OA is often seen as a “wear and tear” disease, an inevitable consequence of aging for which nothing helps. Even worse, patients may resort to the use of alternative but unproven medications or quackery. Patients should be warned about these and encouraged to access information from local or national units of the Arthritis Foundation or at <http://www.arthritis.org>. The Arthritis Foundation provides literature about OA and OA medications, as well as information about local clinics and agencies offering physical and economic assistance. The Arthritis

Foundation also sponsors support groups and public education programs.

The benefits of patient education have been highlighted in a variety of programs, including those using monthly telephone contact between trained volunteers and individuals with OA.¹ Volunteers speak with patients about symptoms, function, drugs, and clinic visits, resulting in improved pain and functional status at low cost. Likewise, OA patients participating in the program report decreases in joint pain and OA-related clinic visits, and improved physical activity and quality of life.¹

■ DIET

Excess weight increases the biomechanical load on weight-bearing joints,^{3,12,13} and is the single best predictor of need for eventual joint replacement. Weight loss is associated with decreased symptoms and disability, but controlled studies are needed to confirm benefits. Even 5 pounds of weight loss can decrease the biomechanical force on a weight-bearing joint. Although dietary intervention for overweight OA patients is reasonable, weight loss usually requires a motivated patient and a structured weight-loss program.

■ PHYSICAL AND OCCUPATIONAL THERAPY

Physical therapy—with heat or cold treatments and an exercise program—helps to maintain and restore joint range of motion and reduce pain and muscle spasms. Warm baths or warm water soaks may decrease pain and stiffness. Heating pads should be used with caution, especially in the elderly, and patients should be warned not to fall asleep on the heat source or to lie on it for more than brief periods to minimize the risk of burns.

Exercise programs and quadriceps strengthening can improve physical functioning and can decrease disability, pain, and analgesic use by OA patients.^{1,9–11,31,32} The American Geriatrics Society has developed guidelines for exercise in OA patients.¹¹ Isometric exercise is preferred over isotonic exercises because the latter can aggravate the affected joint. Exercises should be taught and then observed before the patient exercises at home. Exercises should be performed three to four times daily. If severe pain develops with exercise, the patient should be instructed to decrease the number of repetitions.

The decision about whether to encourage walking should be made on an individual basis. With weak or deconditioned muscles, the load is transmitted excessively to the joints, so weight-bearing activities can exacerbate symptoms. However, avoidance of activity by those with hip or knee OA leads to further deconditioning or weight gain. A program of patient education, muscle stretching and strengthening, and supervised walking can improve physical function and decrease pain in patients with knee OA.^{1,9–11,31,32}

Referral to the physical and/or occupational therapist is especially helpful for patients with functional disabilities. The therapist can assess muscle strength and joint stability, and recommend exercises and methods of protecting the affected joint from excessive forces. The therapist can also provide assistive and orthotic devices, such as canes, walkers, braces, heel cups, splints, or insoles for use during exercise or daily activities.

■ SURGERY

Surgery can be recommended for OA patients with functional disability and/or severe pain that is unresponsive to conservative therapy.^{33–35} Indications for total hip replacement were developed by

a National Institutes of Health consensus development conference,³³ and indications for total knee replacement were summarized based on three consensus groups of orthopedic surgeons.³⁴ Indeed, for patients with advanced disease, a partial or total arthroplasty can relieve pain and improve motion, with especially good outcomes after hip or knee arthroplasty.

Other surgical options are also worth discussing with the patient. Arthrodesis (joint fusion) can reduce pain but will restrict motion, and may be appropriate for smaller joints with intractable pain. For patients with mild knee OA, an osteotomy may correct the misalignment of genu varum or genu valgum. Although knee arthroscopy or lavage have been recommended for short-term relief of pain, a recent study showed these two procedures to be equivalent to sham surgery.³⁵ Experimental but potentially restorative approaches involve soft tissue grafts, penetration of subchondral bone, cell transplantation, and use of growth factors or artificial matrices.³⁶ Cartilage-restoration approaches are investigational, and results regarding pain control and joint function have been mixed.

■ PHARMACOLOGIC THERAPY

Drug therapy in OA is targeted at relief of pain. OA is seen commonly in older individuals who have other medical conditions, and OA treatment is often long-term. As such, a conservative approach to drug treatment, focusing on the needs of the individual patient, is warranted (see Fig. 90–2). For mild or moderate pain, topical analgesics or acetaminophen can be used. If these measures fail, or if there is inflammation, NSAIDs may be useful. Even when drug therapy is initiated, appropriate nondrug therapies should be continued and reinforced as the cornerstone of OA management and because they may provide as much relief as drug therapy.

■ ANALGESICS

6 The ACR recommends acetaminophen as first-line drug therapy for pain management in OA, due to its relative safety, efficacy, and lower cost compared to NSAIDs.^{1,37} Pain relief with acetaminophen can be similar to that obtained with aspirin, naproxen, ibuprofen, and other NSAIDs, although some patients will respond better to NSAIDs.^{1,37}

Although acetaminophen is one of the safest analgesics, its use still carries some risks, particularly hepatotoxicity with overdose or in individuals at risk of liver disease.^{1,38}

In addition to guidelines from the American College of Rheumatology, recommendations for various aspects of OA management have been published by The European League Against Rheumatism, and a review of the evidence and suggestions for OA management have been formulated by rheumatology faculty in the Medical Research Council (UK) Environmental Epidemiology Unit.^{1,6,7} These guidelines stress the importance of acetaminophen as first-line drug therapy for OA.

7 The ACR recommends NSAID use for pain management in OA patients in whom acetaminophen is ineffective. NSAIDs have analgesic properties at lower doses and anti-inflammatory effects at higher doses. The various NSAIDs all display comparable analgesic and anti-inflammatory efficacy and are similarly beneficial in OA (Table 90–4).³⁹ Although some studies have shown comparable efficacy for acetaminophen and NSAIDs, others have reported that patients experienced better pain control with NSAIDs than with acetaminophen, and that OA patients preferred NSAIDs to acetaminophen.^{37,39,40}

TABLE 90-4. Medications Commonly Used in the Treatment of Osteoarthritis

| Medication | Dosage and Frequency | Maximum Dosage (mg/day) |
|--|--|--------------------------------|
| Oral analgesics | | |
| Acetaminophen | 325–650 mg every 4–6 hours or 1 g 3–4 times/day | 4000 |
| Tramadol | 50–100 mg every 4–6 hours | 400 |
| Topical analgesics | | |
| Capsaicin 0.025% or 0.075% | Apply to affected joint 3–4 times per day | — |
| Nutritional supplements | | |
| Glucosamine sulfate | 500 mg 3 times/day or 1500 mg once daily | 1500 |
| Nonsteroidal anti-inflammatory drugs (NSAIDs) | | |
| <i>Carboxylic acids</i> | | |
| <i>Acetylated salicylates</i> | | |
| Aspirin, plain, buffered, or enteric-coated | 325–650 mg every 4–6 hours for pain; anti-inflammatory doses start at 3600 mg/day in divided doses | 3600 ^a |
| <i>Nonacetylated salicylates</i> | | |
| Salsalate | 500–1000 mg 2–3 times a day | 3000 ^a |
| Diflunisal | 500–1000 mg 2 times a day | 1500 |
| Choline salicylate ^b | 500–1000 mg 2–3 times a day | 3000 ^a |
| Choline magnesium salicylate | 500–1000 mg 2–3 times a day | 3000 ^a |
| <i>Acetic acids</i> | | |
| <i>Etodolac</i> | | |
| Etodolac | 800–1200 mg/day in divided doses | 1200 |
| <i>Diclofenac</i> | | |
| Diclofenac | 100–150 mg/day in divided doses | 200 |
| <i>Indomethacin</i> | | |
| Indomethacin | 25 mg 2–3 times a day; 75 mg SR once daily | 200; 150 |
| <i>Ketorolac^c</i> | | |
| Ketorolac ^c | 10 mg every 4–6 hours | 40 |
| <i>Nabumetone^d</i> | | |
| Nabumetone ^d | 500–1000 mg 1–2 times a day | 2000 |
| <i>Propionic acids</i> | | |
| <i>Fenoprofen</i> | | |
| Fenoprofen | 300–600 mg 3–4 times a day | 3200 |
| <i>Flurbiprofen</i> | | |
| Flurbiprofen | 200–300 mg/day in 2–4 divided doses | 300 |
| <i>Ibuprofen</i> | | |
| Ibuprofen | 1200–3200 mg/day in 3–4 divided doses | 3200 |
| <i>Ketoprofen</i> | | |
| Ketoprofen | 150–300 mg/day in 3–4 divided doses | 300 |
| <i>Naproxen</i> | | |
| Naproxen | 250–500 mg twice a day | 1500 |
| <i>Naproxen sodium</i> | | |
| Naproxen sodium | 275–550 mg twice a day | 1375 |
| <i>Oxaprozin</i> | | |
| Oxaprozin | 600–1200 mg daily | 1800 |
| <i>Fenamates</i> | | |
| <i>Meclofenamate</i> | | |
| Meclofenamate | 200–400 mg/day in 3–4 divided doses | 400 |
| <i>Mefenamic acid^e</i> | | |
| Mefenamic acid ^e | 250 mg every 6 hours | 1000 |
| <i>Oxicams</i> | | |
| <i>Piroxicam</i> | | |
| Piroxicam | 10–20 mg daily | 20 |
| <i>Meloxicam</i> | | |
| Meloxicam | 7.5 mg daily | 15 |
| <i>Coxibs^f</i> | | |
| <i>Celecoxib</i> | | |
| Celecoxib | 100 mg twice daily or 200 mg daily | 200 (400 for RA) |
| <i>Valdecoxib</i> | | |
| Valdecoxib | 10 mg daily | 10 (40 for dysmenorrheic pain) |

^aMonitor serum salicylate levels over 3–3.6 g/day.

^bOnly available as a liquid; 870 mg salicylate/5 mL.

^cNot approved for treatment of OA for more than 5 days.

^dNonorganic acid but metabolite is an acetic acid.

^eNot approved for treatment of OA.

^fSee note at end of text regarding cardiovascular problems with coxibs.

RA, rheumatoid arthritis; SR, sustained-release.

8 The most common adverse effects of NSAIDs involve the gastrointestinal tract. Minor complaints (nausea, dyspepsia, anorexia, and abdominal pain) are common (up to 60% of patients). Serious GI complications associated with NSAIDs including perforations, gastric outlet obstruction, and GI bleeding, occur in 1.5% to 4% of patients per year.

NSAIDs may cause renal dysfunction, characterized by increased serum creatinine and blood urea nitrogen, hyperkalemia, elevated blood pressure, peripheral edema, and weight gain. Hypersensitivity reactions may also occur in response to NSAIDs.

Alternative drug treatments include topical agents such as capsaicin and methyl salicylate, injections with glucocorticoids,

and other oral agents (narcotic analgesics and chondroitin sulfate/glucosamine).^{29,30,41}

■ ACETAMINOPHEN

■ Pharmacology and Mechanism of Action

Acetaminophen is thought to work within the central nervous system to inhibit the synthesis of prostaglandins, agents that enhance pain sensations. Acetaminophen prevents prostaglandin synthesis by blocking the action of central cyclooxygenase. Acetaminophen is well

absorbed after oral administration (bioavailability is 60% to 98%), achieves peak concentrations within 1 to 2 hours, is inactivated in the liver by conjugation with sulfate or glucuronide, and its metabolites are renally excreted.

■ Efficacy

Comparable relief of mild to moderate OA pain has been demonstrated for acetaminophen at 2.6 to 4 g/day, aspirin 650 mg four times daily, ibuprofen at 1200 or 2400 mg daily, and naproxen 750 mg/day, as well as other NSAIDs.¹

■ Adverse Effects

Although acetaminophen is one of the safest analgesics, its use carries some risks, primarily hepatotoxicity, and possibly renal toxicity with long-term use.^{1,38,42} Serious and potentially fatal hepatotoxicity with overdose is well documented. It should be used with caution in patients with liver disease or those who chronically abuse alcohol. The FDA has recommended that chronic alcohol users (three or more drinks daily) should be warned regarding an increased risk of liver damage or GI bleeding with acetaminophen. Other individuals do not appear to be at increased risk of GI bleeding.

The National Kidney Foundation strongly discourages the use of over-the-counter combination analgesic products (e.g., acetaminophen and NSAIDs) because this is associated with an increased prevalence of renal failure.³⁸ Finally, patients should be warned about potential toxicity if they inadvertently ingest more than the recommended dose when using both nonprescription and prescription products containing acetaminophen.

■ Drug-Drug Interactions and Drug-Food Interactions

Drug interactions with acetaminophen can occur; for example, isoniazid can increase the risk of hepatotoxicity. Chronic ingestion of maximal doses of acetaminophen may intensify the anticoagulant effect in patients taking warfarin, so that such individuals may require closer monitoring. Food decreases the maximum serum concentration of acetaminophen by approximately one-half.

■ Dosing and Administration

When used for chronic OA, acetaminophen should be administered in a scheduled manner. It may be taken with or without food. The dose of acetaminophen is 325 to 650 mg taken up to four times daily, or to a maximum dose of 4 g daily.

■ NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

■ Pharmacology and Mechanism of Action

Blockade of prostaglandin synthesis through inhibition of cyclooxygenase (both COX-1 and COX-2 enzymes) is believed to be the principal mechanism by which NSAIDs relieve pain and inflammation^{43–46} (Fig. 90–3). Given the similar efficacy of nonspecific NSAIDs and COX-2 inhibitors, toxicity and cost play major roles in determining the medication chosen for a given patient. To understand the differences between nonspecific NSAIDs and COX inhibitors, the next section will review the COX-2 paradigm.^{44–50}

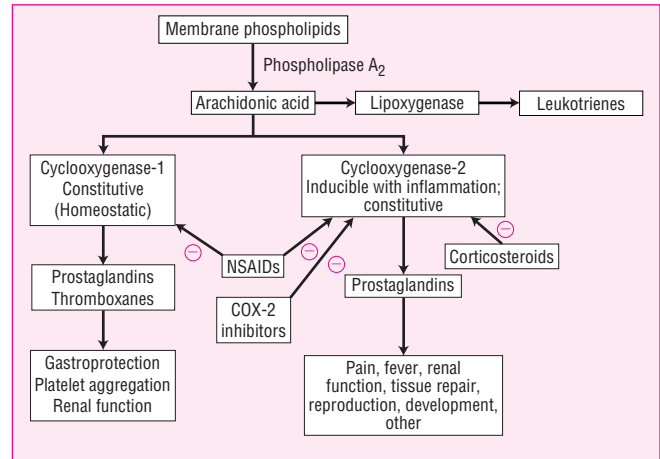

FIGURE 90–3. Pathway of synthesis for prostaglandins and leukotrienes. COX-1 and COX-2 are cyclooxygenase 1 and 2 enzymes.

■ The COX-2 Paradigm

Table 90–5 depicts basic facts about cyclooxygenase enzymes and their inhibition.^{43–50} The COX-1 enzyme is involved in “housekeeping” or routine physiologic functions such as generation of gastroprotective prostaglandins to promote gastric blood flow and bicarbonate generation. COX-1 is expressed constitutively in gastric mucosa, vascular endothelial cells, platelets, and renal collecting tubules, so that COX-1–generated prostaglandins also participate in hemostasis and renal blood flow.

In contrast, the COX-2 enzyme is not normally expressed in most body tissues, but is rapidly induced by inflammatory mediators, local injury, and cytokines including interleukins, interferon, and tumor necrosis factor (see Fig. 90–3 and Table 90–5). COX-1 blockade (which occurs with nonspecific NSAIDs) is potentially undesirable and may lead to GI ulcers and increased bleeding risk due to inhibition of platelet aggregation. Specific COX-2 inhibition is considered desirable for the potential lack of such toxicities while exerting anti-inflammatory and analgesic effects.

Nonspecific NSAIDs and COX-2 inhibitors exhibit mechanistic differences. The former penetrate the enzyme active site for both COX-1 and COX-2 and block entry of the enzyme’s usual substrate, arachidonic acid. By contrast, COX-2 inhibitors are much more potent at inhibiting COX-2; they tightly interact in a time-dependent manner with a side pocket within the active site of COX-2. This high-affinity binding to COX-2 provides excellent COX-2 inhibition with virtually no effect on COX-1.

Although the COX-2 paradigm has merit, several issues and observations regarding COX enzymes and NSAIDs require further scrutiny and could carry implications for COX-2 inhibitor safety.^{44–55} These observations and issues include the following:

1. Gastroprotection by COX-1 and gastropathy via COX-1 blockade may not be as simple as originally thought. Knockout mice lacking COX-1 do not develop spontaneous gastropathy, but they do develop ulcers when given nonspecific NSAIDs.
2. COX-2 activity in the gastric mucosa may be helpful in some situations. COX-2 is induced with gastric injury and is seen at the rim of ulcers in humans, and COX-2 inhibitors retard ulcer healing in humans and animals and angiogenesis in experimental systems.^{47,53,54}

TABLE 90–5. Characteristics of Cyclooxygenase-1 (COX-1) and Cyclooxygenase-2 (COX-2) Enzymes

| | COX-1 Enzyme | COX-2 Enzyme |
|----------------------------------|---|---|
| Location in genome | Chromosome 9 | Chromosome 1 |
| Molecular weight (kDa) | 69,054 | 69,093 |
| Cellular location | Integral membrane protein in ER and nuclear envelope | Integral membrane protein in ER and nuclear envelope |
| Tissue location | Gastric mucosa, intestine, kidney, platelets, endothelial cells, other | Macrophages, fibroblasts, chondrocytes, epithelial cells, endothelial cells, synoviocytes, CNS, bone, kidney, reproductive tract, other |
| Control of expression | Constitutive | Rapidly inducible: inflammation, IL-1, TNF TGF- β mitogens, lipopolysaccharides |
| Effect of glucocorticoids | Unaffected | Constitutive in some tissues |
| Enzymologic function | Arachidonic acid \rightarrow PGG ₂ \rightarrow PGH ₂ . (PGH ₂ \rightarrow final products [PGs, PGI ₂ , TX] depends on tissue) | Inhibited (transcriptional level) Arachidonic acid \rightarrow PGG ₂ \rightarrow PGH ₂ PGH ₂ \rightarrow final products (PGs, PGI ₂) depends on tissue |
| Biologic function | Gastrointestinal mucosal integrity, platelet aggregation; renal function; other | Inflammation, development, renal function, reproduction, bone metabolism, other |
| Kinetics of inhibition by NSAIDs | Immediate, competitive inhibition (strong for COX-1 inhibitors, weak for COX-2 inhibitors) ^a | COX-2 inhibitors: noncompetitive (irreversible?), time-dependent COX-1 inhibitors: competitive, immediate |

^aAspirin inhibition is irreversible.

CNS, central nervous system; ER, endoplasmic reticulum; IL-1, interleukin-1; kDa, kilodalton;

NSAID, nonsteroidal anti-inflammatory drug; PG, prostaglandin; PGG₂, prostaglandin G₂;

PGH₂, prostaglandin H₂; PGI₂, prostaglandin I₂; TNF, tumor necrosis factor; TGF- β , transforming growth factor- β ; TX, thromboxane.

Data from Hawkey,⁴⁴ Golden et al,⁴⁵ Garavito et al,⁴⁶ Jones et al,⁴⁷ Wolfe et al,⁴⁸ Lichtenstein et al,⁴⁹ and Crofford et al.⁵⁰

- COX-2 activity is beneficial in renal function. COX-2 has some constitutive expression in the kidney, and its intrarenal distribution and its upregulation in salt depletion suggest that it helps regulate renal hemodynamics in some situations.
- A COX-2 inhibitor's analgesic mechanism may not be as simple as sometimes thought, because COX-2 inhibitors reduce pain, even in noninflammatory conditions.
- There may be a tendency to overprescribe COX-2 inhibitors, especially in patients who are frail, if the potential toxicities of these agents are unappreciated.
- Since aspirin blocks the COX-1 enzyme, the GI safety advantage of COX-2-specific inhibitors is blunted by the concomitant use of aspirin, even at low doses.⁵⁵

CLINICAL CONTROVERSY

Controversy has arisen regarding whether or not COX-2 inhibitors may increase cardiovascular risk in some patients.^{51,52} Concern has arisen about the possible prothrombotic potential of the available COX-2 inhibitors. Patients taking rofecoxib had more thrombotic events than did patients taking naproxen in the Vioxx Gastrointestinal Outcomes Research Study (VIGOR), which led to an FDA labeling change for rofecoxib regarding cardiovascular risk. However, since naproxen may possess antiplatelet effects, and some subjects normally taking low-dose aspirin were asked to stop aspirin to participate in the study, it is unclear whether thrombotic events resulted from rofecoxib toxicity, antiplatelet effects of naproxen, discontinuation of aspirin, or a combination of these factors. Patients given rofecoxib also had higher rates

of hypertension and congestive heart failure. (See Note at end of chapter.)

Despite these complexities, COX-2-specific inhibitors relieve pain in many OA patients with a lower risk of GI adverse events than nonspecific NSAIDs. COX-2 inhibitors, members of the “coxib” class newly created by the World Health Organization,⁴⁹ have become extremely widely used over a short period of time. These agents continue to be studied intensely not only for their efficacy and toxicity profile in rheumatic disease, but also for exciting potential applications such as the prevention of Alzheimer's disease and colorectal cancer.

Pharmacokinetics

The various NSAIDs exhibit several pharmacokinetic similarities, including high oral availability, high protein binding, and absorption as active drugs (except for sulindac and nabumetone, which require hepatic conversion for activity). The most important difference in NSAIDs is a serum half-life ranging from 1 hour for tolmetin to 50 hours for piroxicam, impacting the frequency of dosing and potentially, compliance with therapy.⁴³ Elimination of NSAIDs largely depends on hepatic inactivation, with a small fraction of active drug being renally excreted. NSAIDs penetrate joint fluid, reaching about 60% of blood levels.⁴³

Efficacy

Prescription-strength NSAIDs are often prescribed for OA patients after treatment with acetaminophen proves ineffective, or for patients with inflammatory OA. All NSAIDs and aspirin have similar analgesic

and anti-inflammatory effects.^{39,43,56} Analgesic effects begin within hours, whereas anti-inflammatory benefits may require 2 to 3 weeks of continuous therapy.

A systematic review of studies of NSAIDs for OA found no evidence to support a definitive ranking of NSAID efficacy.⁵⁶ However, individual patient response does differ among NSAIDs. The prescriber often relies on personal experience in choosing an NSAID. To assess efficacy in the individual patient, a trial that is adequate in time (2 to 3 weeks) and dose is needed. If the first trial fails, another NSAID in the same or another chemical class can be tried until an effective agent is found. Thus if a trial with one NSAID fails, the clinician should try a different NSAID (see Table 90-4).^{39,43,56} Patients must understand this approach, appreciate the necessity of adherence to medication therapy throughout the trial, and actively participate in assessment of drug efficacy. Combining two NSAIDs increases adverse effects without providing additional benefit.

COX-2 inhibitors demonstrate similar analgesic benefits when compared to traditional NSAIDs.⁵⁷ For example, 748 subjects randomized to rofecoxib (12.5 or 25 mg daily) or diclofenac (50 mg three times daily) showed similar improvements in pain, stiffness, physical function, and other measures of efficacy.⁵⁸ In a 12-week trial of 1003 subjects with knee OA, celecoxib at 100 or 200 mg twice daily was more effective than placebo and comparable to naproxen 500 mg twice daily for relief of pain, stiffness, and limitation of physical function.⁵⁹

Valdecoxib, a more recently marketed coxib, has been studied in 14 clinical studies involving more than 4000 patients, for OA, rheumatoid arthritis, or pain associated with dysmenorrhea or surgery. Valdecoxib 10 mg once daily was as effective as naproxen 500 mg twice daily for pain relief from knee OA and for hip OA.⁶⁰

■ Adverse Effects

■ **Gastrointestinal Effects of NSAIDs.** The most common adverse effects of NSAIDs involve the GI tract, contributing to many treatment failures.⁴⁸ Minor complaints—nausea, dyspepsia, anorexia, abdominal pain, flatulence, and diarrhea—affect 10% to 60% of patients. To minimize these symptoms, NSAIDs should be taken with food or milk, except for enteric-coated products, which should *not* be taken with milk or antacids.

All NSAIDs have the potential to cause GI bleeding.⁴⁸ Unionized NSAIDs enter gastric mucosal cells, release hydrogen ions, and are concentrated (“ion trapped”) within cells, with cell death or damage. Gastric mucosal injury can also result from NSAID inhibition of gastroprotective prostaglandins.

The most common sites of GI injury are the gastric and duodenal mucosae.⁴⁸ The incidence of gastric ulcers with NSAID use is approximately 11% to 13%, and that for duodenal ulcers is 7% to 10%. Serious GI complications associated with NSAIDs, including perforations, gastric outlet obstruction, and GI bleeding, occur in 1.5% to 4% of patients per year. NSAIDs are so widely used that these small percentages translate into substantial morbidity and mortality.^{1,48} Moreover, the risk increases to 9% per year for patients with the risk factors of advanced age, history of peptic ulcer or GI bleeding, or cardiovascular disease. Consequently, about 16,500 deaths are associated annually with NSAID use in rheumatoid arthritis or OA patients.

Notably, there is a poor correlation between GI ulceration and GI symptoms, with 50% of dyspeptic patients having a normal-appearing mucosa, and 40% of asymptomatic persons having endoscopically evident erosive gastritis. Approximately 80% of those who develop serious GI complications have no preceding dyspepsia.⁶¹ The ACR

has thus recommended a complete blood count yearly to detect a silent bleeding ulcer by means of an asymptomatic decline in hematocrit.⁶² Fecal occult blood is an unreliable predictor of complications.

8 H₂-receptor antagonists prevent NSAID-induced *duodenal* ulcers, and at high dose may prevent *gastric* ulcers.¹ Misoprostol protects against both gastric and duodenal NSAID-induced ulcers, and more importantly, their associated complications.¹ Unfortunately, misoprostol frequently causes diarrhea and abdominal cramps. Because of its abortifacient properties, misoprostol is contraindicated in pregnancy and in women of childbearing age who are not maintaining adequate contraception. It must be dispensed in its original container, which carries a warning for these individuals. Misoprostol is also available in a combination product with diclofenac, which bears the same restrictions as misoprostol alone.

Other agents have been evaluated in attempts to prevent NSAID-induced gastropathy. Among 935 NSAID users with baseline gastric or duodenal erosions, omeprazole and misoprostol were similarly effective in the treatment of ulcers and their symptoms, but omeprazole maintenance therapy conferred a lower rate of relapse.⁶³ Thus several medications are available for the treatment or prevention of ulcers in high-risk patients.

■ **Gastrointestinal Effects of COX-2 Inhibitors.** For treatment of OA patients at high risk for GI complications of NSAIDs, the ACR recommends either a COX-2 inhibitor or an NSAID in combination with either a proton pump inhibitor or misoprostol. Studies of both rofecoxib and celecoxib, using endoscopy to assess appearance of gastric ulcers, demonstrated little or no increase in ulcers with these agents. Among 1149 patients with RA randomized to receive placebo, celecoxib (100, 200, or 400 mg twice daily), or naproxen (500 mg twice daily), the incidence of endoscopically-determined gastroduodenal ulcers after 12 weeks was significantly higher with naproxen (26%) than celecoxib at any dose (4% to 8%) or placebo (4%).⁶⁴ Similarly, in comparing rofecoxib (25 or 50 mg daily), ibuprofen (800 mg three times daily), or placebo, fewer endoscopic ulcers were detected in subjects taking rofecoxib than ibuprofen, while results were similar for rofecoxib and placebo.⁶⁵

The incidence of endoscopically observed gastroduodenal ulcers in RA patients taking valdecoxib 20 mg daily (6%) and valdecoxib 40 mg daily (4%) was reduced compared to that in patients receiving diclofenac 75 mg sustained-release twice daily (16%; $p < 0.001$). Valdecoxib 20 mg daily was also associated with significantly improved GI tolerability ($p = 0.035$) compared with diclofenac.⁶⁶ Four safety studies and two reviews of clinical trials indicated decreased rates of gastroduodenal ulceration with valdecoxib versus ibuprofen, naproxen, and diclofenac ($p < 0.001$ to < 0.05).⁶⁷

To study effects on clinically important GI complications with celecoxib, the CLASS study used celecoxib (400 mg twice daily, or twice the highest FDA-approved dose) compared to diclofenac and ibuprofen at standard dose. Celecoxib use was reported to be associated with a reduced incidence for the combined end point of symptomatic ulcers and ulcer complications (perforations, gastric outlet obstruction, or bleeding).⁵⁵ Some subjects also used aspirin for cardioprotection, but there is concern that GI safety of COX-2 inhibitors is blunted with use of concomitant aspirin (even 30 mg of aspirin can suppress gastric prostaglandin production).⁴³ For patients taking aspirin and celecoxib, ulcer complications were higher than with celecoxib only, but lower than with traditional NSAIDs.

Concerns have been raised by the FDA and others with regard to the CLASS study design and whether the published results, based on 6 months, clearly reflect the overall GI safety profile, as these patients were actually followed for a longer time period.^{68,69} The

FDA concluded that although there were trends favoring celecoxib, this drug did not show clear statistical superiority over nonspecific NSAIDs for clinically significant upper GI events.

To further assess whether COX-2 inhibitors cause fewer serious GI events (perforations, bleeding, and gastric outlet obstruction), a meta-analysis of eight double-blind studies was performed. These studies used rofecoxib and either ibuprofen, diclofenac, nabumetone, or placebo.⁷⁰ The risk of serious adverse GI events was lowest for placebo, intermediate for rofecoxib, and highest with NSAID therapy. The VIGOR study, a large study included in this meta-analysis, randomized 8076 rheumatoid arthritis patients to receive rofecoxib 50 mg daily or naproxen 500 mg twice daily; use of concomitant aspirin was prohibited. Subjects randomized to rofecoxib experienced a 50% lower risk of serious GI events.⁷¹ FDA-approved labeling for rofecoxib states that the VIGOR study showed a significant reduction in the risk of development of peptic ulcer bleeding (symptomatic ulcers, upper GI perforation, obstruction, major or minor upper GI bleeding), including complicated peptic ulcer bleeding in patients taking rofecoxib compared to naproxen.

Aside from consideration of the relatively uncommon but serious GI adverse effects described above, fewer overall GI complaints from patients are found for COX-2 inhibitors compared to nonspecific NSAIDs.^{55,59,65,70} Moreover, celecoxib use was associated with decreased outpatient physician claims for upper GI symptoms compared with other prescription nonspecific NSAIDs.⁷² Finally, celecoxib was comparable to a combination of diclofenac and misoprostol in reducing the risk of recurrent GI bleeding in patients who had a prior GI bleed.⁷³

In summary, there is evidence that COX-2 inhibitors pose a decreased risk of GI toxicity compared to nonspecific NSAIDs, an especially important consideration when treating those at risk for clinically significant GI adverse effects. Rofecoxib decreases the extent of clinically significant GI complications. Celecoxib likely decreases these events, although the proof is less rigorous and still debated. For valdecoxib, its effect on clinically significant GI events awaits further study.

9 ■ Other Toxicities Associated with NSAIDs. NSAIDs may cause kidney diseases, including acute renal insufficiency, tubulointerstitial nephropathy, hyperkalemia, and renal papillary necrosis.⁷⁴ Clinical features of these NSAID-induced renal syndromes include increased serum creatinine and blood urea nitrogen, hyperkalemia, elevated blood pressure, peripheral edema, and weight gain. Mechanisms of NSAID injury include direct toxicity, and inhibition of local prostaglandins that promote vasodilation of renal blood vessels and preserve renal blood flow. Patients at high risk have conditions associated with decreased renal blood flow, including chronic renal insufficiency, congestive heart failure, severe hepatic disease, nephrotic syndrome, advanced age, or diuretic therapy (Fig. 90-4).⁷⁴ Close monitoring is advisable for high-risk patients taking an NSAID, with monitoring of serum creatinine at baseline and within 3 to 7 days of drug initiation. For those with impaired renal function, the National Kidney Foundation recommends acetaminophen as the drug of choice.³⁸

COX-2 inhibitors also have potential for renal toxicity; COX-2 activity has been demonstrated in a variety of sites in the kidney and is upregulated in salt-depleted states^{74,75} (see Fig. 90-4). Importantly, COX-2 inhibitors decrease urinary prostaglandins and cause sodium and potassium retention, as do nonspecific NSAIDs. Postmarketing surveillance of coxibs has confirmed the risk of renal dysfunction. Therefore coxibs should be prescribed with the same caution as NSAIDs in patients at increased risk for renal dysfunction.

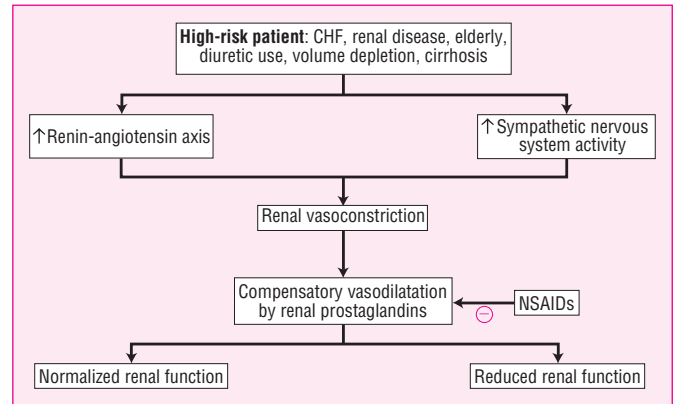

FIGURE 90-4. Mechanisms implicated in NSAID-induced renal injury.

Recent evidence has indicated the potential for cardiovascular risk with coxibs, particularly rofecoxib.^{51,52}

Coxibs and NSAIDs uncommonly cause drug-induced hepatitis; the two NSAIDs most frequently implicated are diclofenac and sulindac. Patient monitoring should include periodic liver enzymes (aspartate aminotransferase and alanine aminotransferase), with cessation of therapy if these values exceed two to three times the normal range.

Other toxic effects of NSAIDs include hypersensitivity reactions, rash, and central nervous system complaints of drowsiness, dizziness, headaches, depression, confusion, and tinnitus.⁴³ Although NSAIDs are generally avoided in patients with asthma who are aspirin-intolerant, studies indicate that celecoxib and rofecoxib are well tolerated in aspirin-sensitive asthma, providing a viable option for these patients.⁷⁶⁻⁷⁸ Celecoxib and valdecoxib are sulfonamides and are thus contraindicated for those with sulfa allergies.

All nonspecific NSAIDs inhibit COX-1–dependent thromboxane production in platelets and thus increase bleeding risk. Importantly, aspirin inhibition is irreversible, and bleeding time requires 5 to 7 days to normalize after cessation of therapy, as new platelets enter the circulation. Other nonspecific NSAIDs inhibit thromboxane formation reversibly, with normalization of platelet function 1 to 3 days after the drug is stopped. The nonacetylated salicylate products and nabumetone, which have partial COX-2 selectivity, may be preferable to nonspecific NSAIDs.⁴³ COX-2 inhibitors do not block thromboxane synthesis and pose even less bleeding risk. Among subjects treated with supratherapeutic doses of celecoxib (600 mg twice daily) and regular doses of naproxen (500 mg twice daily), a substantial decrease in platelet aggregation and thromboxane production occurred with naproxen but not with celecoxib. However, because warfarin and celecoxib are metabolized by the cytochrome P450 (CYP450) isoenzyme CYP2C9, and since postmarketing interactions between warfarin and both celecoxib and rofecoxib have been noted, patients receiving warfarin and COX-2 inhibitors should be followed closely.

In a study of healthy adults, valdecoxib (40 mg twice a day), did not affect platelet function, whereas naproxen 500 mg twice a day or diclofenac 75 mg twice a day significantly reduced the platelet aggregation response. In elderly subjects (65 to 85 years), valdecoxib (40 mg twice daily) had no platelet effects (platelet aggregation, bleeding time, and serum thromboxane B₂ levels), whereas ibuprofen (800 mg three times a day) significantly decreased platelet aggregation, significantly increased bleeding time, and significantly decreased thromboxane B₂ levels.⁷⁹

Finally, NSAIDs should be used cautiously during pregnancy because of the risk to the fetus posed by the bleeding problems. In late

pregnancy, all NSAIDs should be avoided because they may enhance premature closure of the ductus arteriosus. Ibuprofen and naproxen are rated as pregnancy category B by the FDA, with use prohibited in the last trimester, while celecoxib, rofecoxib, valdecoxib, and etodolac fall into pregnancy category C. Several NSAIDs have no rating for use in pregnancy and are best avoided until data are available regarding safety; these include indomethacin and sulindac.

■ Drug-Drug and Drug-Food Interactions

Important drug interactions with NSAIDs can be pharmacokinetic or pharmacodynamic in origin and have been reviewed.^{43,80} The most potentially serious interactions include the use of NSAIDs with lithium, warfarin, oral hypoglycemics, high-dose methotrexate, antihypertensives, angiotensin-converting enzyme inhibitors, β -blockers, and diuretics. Anticipation and careful monitoring often can prevent serious events when these drugs are used together.

Celecoxib metabolism is primarily via cytochrome P450 2C9.⁸⁰ In clinical studies, increased celecoxib levels were seen with fluconazole administration. Cytochrome P450 inducers such as rifampin, carbamazepine, and phenytoin have the potential to reduce celecoxib levels. However, no clinically significant interactions have been documented with celecoxib and methotrexate, glyburide, ketoconazole, phenytoin, or tolbutamide. Because celecoxib inhibits CYP450 2D6, it has the potential to increase concentrations of a variety of agents, including antidepressants. Celecoxib increases lithium levels, as do other NSAIDs, thus caution is needed when using coxibs or NSAIDs with lithium.

Rofecoxib is metabolized in the liver, primarily by cytosolic enzymes, with little renal excretion of unchanged drug. Rofecoxib at 75 mg daily modestly increased methotrexate concentrations, and at 50 mg daily modestly elevated the International Normalized Ratios (INRs) of warfarin patients. Additionally, rifampin can decrease rofecoxib concentrations. Clinically significant interactions were not observed when rofecoxib was administered with cimetidine, digoxin, oral contraceptives, or ketoconazole. Rofecoxib inhibits CYP450 1A2 and may increase serum theophylline area under the curve.

Valdecoxib undergoes metabolism in hepatic microsomes (primarily by CYP450 3A4 and CYP450 2C9) and by other pathways, including glucuronidation. Inhibitors of CYP450 3A4 and CYP450 2C9 such as fluconazole and ketoconazole may increase valdecoxib plasma levels. Valdecoxib moderately inhibits CYP450 2C19 and weakly inhibits CYP450 3A4 and CYP450 2C9. Valdecoxib modestly increases concentrations of *R* and *S* warfarin, slightly increases INR, and increases INR variability. Valdecoxib increases lithium plasma concentrations by an unknown mechanism. Coxibs may decrease the antihypertensive effects of angiotensin-converting enzyme inhibitors and may interfere with the natriuretic effect of diuretics by affecting renal prostaglandin production.^{74,80}

■ Dosing and Administration

Administration of NSAIDs must be tailored to the individual patient with OA. For the OA patient who has failed an adequate trial of acetaminophen, trial with an NSAID is warranted. Selection of an NSAID depends on the prescriber's experience, medication cost, patient preference, allergies, toxicities, and adherence issues. Individual patient response differs among NSAIDs (see Table 90-4), so if an inadequate response is obtained with one NSAID, another NSAID may yet provide benefit.^{1,39,43}

■ TOPICAL THERAPIES

Topical products can be used alone or in combination with oral analgesics or NSAIDs. Capsaicin, isolated from hot peppers, releases and ultimately depletes substance P from afferent nociceptive nerve fibers. Substance P has been implicated in the transmission of pain in arthritis, and capsaicin cream has been shown in four controlled studies to provide pain relief in OA when applied over affected joints.^{1,41}

To be effective, capsaicin must be used regularly, and it may take up to 2 weeks to work. It is well tolerated, except that some patients experience a temporary burning sensation at the site of application. Patients should be warned not to get the cream in their eyes or mouth and to wash their hands after application. Although use is recommended four times a day, a twice-daily application may enhance long-term adherence and still provide adequate pain relief.⁴¹

■ GLUCOSAMINE AND CHONDROITIN

◀ Interest in chondroitin and glucosamine was spurred initially by anecdotal reports of benefit in animals and humans, and by the fact that these substances stimulate proteoglycan synthesis from articular cartilage in vitro and have an excellent safety profile. Enthusiasm for these agents continues.^{81–85}

A total of 17 double-blind, placebo-controlled trials have subsequently shown that chondroitin and glucosamine are superior to placebo in alleviating pain from knee or hip OA. In one study, chondroitin sulfate showed similar analgesic benefits to diclofenac.⁸²

A recent meta-analysis of glucosamine and chondroitin indicated that both agents had efficacy in reducing pain and improving mobility, and that glucosamine reduced joint space narrowing.⁸³ Use of glucosamine or chondroitin sulfate was associated with slower loss of cartilage than placebo, in knees affected by OA.^{29,84} Further support for the structural benefits of these compounds comes from a follow-up survey 5 years after completion of a 3-year study comparing glucosamine and placebo. In this survey, rates of lower limb joint replacement were twofold higher in subjects given placebo, compared with subjects given glucosamine. In addition, subjects treated with glucosamine had lower rates of pain, joint space narrowing, and limitations of physical function.⁸⁵ If the positive findings with these compounds are confirmed by an ongoing study sponsored by the National Institutes of Health, this would represent an important advance in the treatment of OA.

Because glucosamine and chondroitin are marketed in the United States as dietary supplements, neither the products nor their purity is adequately regulated by the FDA. Some reliable products include Cosamin DS, Condrosulf, and Dona.^{29,86}

■ CORTICOSTEROIDS

Intra-articular glucocorticoid injections can provide excellent pain relief, particularly when a joint effusion is present.^{1,87} Aspiration of the effusion and injection of glucocorticoid are carried out aseptically, and examination of the aspirate to exclude crystalline arthritis or infection is recommended. After injection, the patient should minimize activity and stress on the joint for several days. The risk of infection is estimated at 1 in 50,000 joint injections.

A recent randomized, placebo-controlled, double-blind study showed that intra-articular triamcinolone 40 mg every 3 months was superior to placebo in alleviating knee pain and stiffness due to OA

during a 2-year trial.⁸⁷ The potential risk of cartilage destruction with steroid injections was not substantiated, as the rate of cartilage loss was similar in both groups. The therapy is generally limited to three or four injections per year because of the potential systemic effects of steroids, and because the need for more frequent injections indicates little response to the therapy.

Systemic corticosteroid therapy is not recommended in OA, given the lack of proven benefit and the well-known adverse effects with long-term use.

■ HYALURONATE INJECTIONS

Agents containing hyaluronic acid (HA) (sodium hyaluronate) are available for intra-articular injection for treatment of knee OA.^{88–90} High-molecular-weight HA is an important constituent of normal cartilage, with viscoelastic properties providing lubrication with motion and shock absorbency during rapid movements. Endogenous HA also may have anti-inflammatory effects. Because the concentration and molecular size of synovial HA decrease in OA, administration of exogenous HA products has been studied, with the theory that this could reconstitute synovial fluid and reduce symptoms. Injections temporarily and modestly increase viscosity. Although HA injections were reported to decrease pain, many studies were short term and poorly controlled, and placebo injections also reduced OA pain dramatically.

HA products are injected once weekly for either 3 or 5 weeks. Injections are well tolerated, although acute joint swelling and local skin reactions, including rash, ecchymoses, and pruritus have been reported.

HA injections may be beneficial for patients unresponsive to other therapies. These agents are expensive because the treatment includes both drug costs and administration costs. As a result, HA injections are often used after less expensive therapies have demonstrated lack of efficacy.

■ DISEASE-MODIFYING DRUGS

Disease-modifying drugs are targeted not at pain relief but at preventing, retarding, or reversing damage to articular cartilage.⁹¹ Most products have been tested in animal models, and limited human data are available.

Thus far, OA is a disease whose symptoms can be alleviated, but whose progress is impossible to stop. Because of this, clinicians were very interested to learn that both chondroitin and glucosamine show disease-modifying potential in patients with OA (see above information on these agents).

Another approach is that of pharmacologic agents that could mimic TIMPs and thus potentially decrease cartilage destruction. Some studies have explored the use of tetracycline or doxycycline, which appear to inhibit the degradative MMPs.^{19,92} Preliminary data indicate that doxycycline delays loss of articular cartilage in humans when compared with placebo.⁹³ Other studies using heparinoid products that contain glycosaminoglycans, sodium pentosan polysulfate, and calcium pentosan polysulfate show promise in preliminary work limited largely to animal models and *in vitro* studies.⁹⁴ There is also recent interest in the potential of cyclooxygenase-inhibiting nitric oxide-donor compounds to relieve OA while sparing GI adverse effects.⁹⁵ Thus ongoing research with several agents may identify new treatment options to delay OA progression, thereby improving outcomes for people with OA.

■ NARCOTIC ANALGESICS

Low-dose narcotic analgesics may be very useful in patients who experience no relief with acetaminophen, NSAIDs, intra-articular injections, or topical therapy. These agents are particularly useful in patients who cannot take NSAIDs due to renal failure, or for patients in whom all other treatment options have failed and who are at high surgical risk, precluding joint arthroplasty. Low-dose narcotics are the initial intervention, usually given in combination with acetaminophen.

Sustained-release compounds usually offer better pain control throughout the day, and are used when simple narcotics are ineffective. A recent randomized double-blind placebo-controlled study showed that extended-release oxycodone (40 to 50 mg twice daily) was superior to placebo in reducing pain and improving both function and quality of life.⁹⁶

If pain is intolerable and limits activities of daily living, and the patient has sufficiently good cardiopulmonary health to undergo a major surgery, joint replacement may be preferable to continued reliance on narcotics.

■ PHARMACOECONOMIC CONSIDERATIONS

Economic considerations in the treatment of OA are of considerable import, since the disease is extremely common, ranking second in causes of disability in the United States.^{97–99}

One of the largest costs associated with OA is hospitalization for joint replacement or treatment of NSAID-related complications, particularly serious GI adverse events. To provide perspective on patient care costs for GI complications of NSAIDs, a 1997 report on more than 10,000 OA patients followed in a managed-care setting showed that the mean annual cost of care per patient was \$543, with hospital costs accounting for 46%, medications 32%, and ambulatory care 22%.¹⁰⁰ Consequently, intense focus has emerged on the cost:benefit ratio of medications to prevent ulcer complications, and the use of coxibs, which cause fewer ulcer complications.

For example, analysis of the cost effectiveness of misoprostol was reported, based on data from a study of RA patients taking NSAIDs.^{55,97} Misoprostol was shown to be cost-effective if reserved for high-risk patients. The cost of avoiding one serious GI complication would be \$94,766 if all NSAID patients were given misoprostol, but only \$4,101 if misoprostol were limited to high-risk patients. A problem with misoprostol, however, is its low tolerability because it often causes diarrhea. Cost-effectiveness of a different strategy, that of using COX-2-specific inhibitors rather than NSAIDs, is still being debated.^{101–103}

Pharmacoeconomic considerations for OA involve the selection of therapy for the initial treatment of patients with OA. Use of the nonprescription analgesic acetaminophen as initial therapy has greatly reduced medication costs in comparison with the use of NSAIDs, many of which are by prescription only. NSAID costs range from \$20 to \$100 per month, depending on the medication, daily dose, and regimen selected. Since NSAIDs as a class are therapeutically equivalent, use of less expensive NSAIDs, such as nonprescription ibuprofen or naproxen, may minimize the cost of medicine to the patient. More expensive NSAIDs can be prescribed if neither of these offers benefit after a 2-week trial at sufficient doses.

Although use of nonprescription medications can be viewed as a reduction in the cost of prescription medications, cost shifting to “out of pocket” expense greatly affects patients on fixed incomes. Many

elderly patients, who are most likely to need OA drugs, have little or no prescription reimbursement. Careful attention to affordability of medication should be given for all patients receiving drug therapy for OA.

CLINICAL CONTROVERSY

COX-2 inhibitors are recommended by ACR guidelines for those at high risk of adverse GI events, and controversy has arisen regarding cost-effectiveness of this recommendation. For patients without risk factors, 500 patients would need treatment with a COX-2 inhibitor, costing \$400,000, to avoid one serious GI complication from a nonspecific NSAID. For high-risk individuals, the number needed to treat would be 40, costing \$30,000.¹⁰¹ Another study indicated

that, without regard to risk factors, it would be cost-effective to provide rofecoxib or celecoxib for those over age 76 and 81, respectively.¹⁰² Another report examined the cost-utility of COX-2 inhibitors in a model system including RA and OA patients, and found costs of \$275,809 per quality-adjusted life year gained when using coxibs in average-risk patients. If costs as low as \$150,000 per quality-adjusted life year were to be obtained, it would be necessary to restrict coxib use to the 4.2% of patients at highest risk.¹⁰³ These findings are being debated, based on the many assumptions that had been made in the model. Debates about cost effectiveness are likely to continue. However, with existing evidence of increased GI safety, coupled with huge patient demand, coxibs are heavily used despite these cost concerns.

EVALUATION OF THERAPEUTIC OUTCOMES

Pharmacotherapy monitoring in OA is patient-specific, focusing on patient age, concomitant medications and comorbidities, and the therapy selected. To monitor efficacy, the patient's baseline pain can be assessed with a visual analogue scale, and range of motion for affected joints can be assessed, providing baseline measures to monitor the success of therapy. Baseline radiographs are helpful to document the extent of joint involvement and follow progression of disease with therapy. Additional tests of OA severity may include measurement of grip strength, 50-foot walking time, patient and physician global assessment of OA severity, and the Western Ontario and McMaster Universities Arthritis Index or Stanford Health Assessment Questionnaire to monitor ability to perform activities of daily living. A decrease in the use of analgesics or NSAIDs would suggest a beneficial effect of nonpharmacologic interventions. Lastly, disease-specific quality of life is valuable in assessing clinical response to interventions.⁵

When assessing toxicity of therapy, patients should be asked first if they are having any "problems" with their medications. This open-ended question can be followed with more direct questions relating to the most common adverse effects associated with the respective medication. Symptoms of abdominal pain, heartburn, nausea, or change in stool color provide valuable clues to the presence of GI complications. Patients also should be monitored for the development of hypertension, weight gain, edema, skin rash, and central nervous system adverse effects such as headaches and drowsiness. Baseline serum creatinine, complete blood count, and serum transaminases are repeated at 6- to 12-month intervals to identify GI, renal, hepatic, and hematologic toxicities.

CONCLUSIONS

OA is a very common, slowly progressive disorder that affects diarthrodial joints and is characterized by progressive deterioration of articular cartilage, subchondral sclerosis, and osteophyte production. Clinical manifestations include gradual onset of joint pain, stiffness, and limitation of motion. The primary treatment goals are to reduce pain, maintain function, and prevent further destruction. An individualized approach based on education, rest, exercise, weight loss as needed, and analgesic medication can succeed in meeting these goals. Recommended drug treatment starts with acetaminophen <4 g/day and topical analgesics as needed. If acetaminophen is ineffective, NSAIDs may be used, often providing satisfactory relief of pain and stiffness. Individuals at increased risk for toxicity from NSAIDs,

especially for GI, cardiovascular, or renal events, deserve special attention. Experimental therapy aimed at preventing the progression of OA requires further clinical investigation before entering widespread clinical use.

NOTE ADDED IN PROOF

On September 30, 2004, rofecoxib was withdrawn from the worldwide market by the manufacturer, based on results obtained from the APPROVe (Adenomatous Polyp Prevention on Vioxx) trial. For those on rofecoxib 25 mg daily compared with placebo, risk for confirmed cardiovascular events, including myocardial infarction and stroke, was approximately doubled, beginning after 18 months of treatment.

In addition, on December 9, 2004, the FDA announced a new boxed warning for valdecoxib, stating that serious, at times fatal, skin reactions, including Steven-Johnson syndrome and toxic epidermal necrolysis, have been reported for patients taking valdecoxib. There is also a new bolded warning specifically contraindicating valdecoxib for treating pain following coronary artery bypass graft (CABG) surgery. This was based on a study of more than 1500 patients treated after CABG, where increased cardiovascular risk (myocardial infarction, stroke, and deep vein thrombosis) was seen in those receiving valdecoxib compared with placebo. In addition, reports of problems with celecoxib and naproxen emerged later that month.

Although new coxibs are in development, and valdecoxib and celecoxib remain on the market as this chapter went to press, it appears that all these agents will be the focus of increased scrutiny with regard to their potential cardiovascular and other risks.

GOUT AND HYPERURICEMIA

David W. Hawkins and Daniel W. Rahn

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Asymptomatic hyperuricemia discovered incidentally requires no therapy.
- 2 Acute gouty arthritis may be treated effectively with short courses of high-dose nonacetylated nonsteroidal anti-inflammatory drugs (NSAIDs) or colchicine.
- 3 Intravenous colchicine is rapidly effective but cannot be administered to individuals with renal impairment or extrahepatic biliary obstruction. A single intravenous dose should not exceed 2 to 3 mg, with a cumulative total dose not exceeding 4 to 5 mg per episode.
- 4 Individuals with contraindications to NSAIDs (e.g., active peptic ulcer disease, renal impairment, heart failure, or history of hypersensitivity) or individuals who cannot ingest medications orally may be treated with intravenous corticosteroids or intra-articular corticosteroids.
- 5 Recurrent attacks of gouty arthritis can be prevented effectively through administration of uric acid–lowering therapy.
- 6 Treatment with urate-lowering drugs is considered cost effective for acute gouty arthritis in patients having two or more attacks of gout per year.
- 7 When allopurinol is used for prophylaxis, start with a low dose (100 mg/day) after the acute attack has settled, and adjust the dose every 4 weeks until the goal is reached (serum urate of <6 mg/dL). Give colchicine (0.5 mg twice daily) during the first 3 months of therapy, and stop allopurinol if rash develops or liver function tests become abnormal.
- 8 Uricosuric agents should be avoided in patients with renal impairment (a creatinine clearance below 50 mL/min), a history of renal calculi, and overproduction of uric acid.
- 9 Uric acid nephrolithiasis should be treated with adequate hydration (2 to 3 L/day), a daytime urine-alkalinizing agent, and a 250-mg bedtime dose of acetazolamide.
- 10 Individuals with tophaceous deposits have a large uric acid pool and benefit from allopurinol administration.

The term *gout* describes a disease spectrum including hyperuricemia, recurrent attacks of acute arthritis associated with monosodium urate crystals in leukocytes found in synovial fluid, deposits of monosodium urate crystals in tissues (tophi), interstitial renal disease, and uric acid nephrolithiasis.¹

Hyperuricemia may be an asymptomatic condition with an increased serum uric acid level as the only apparent abnormality. Statistically, hyperuricemia is defined as serum urate concentrations greater than two standard deviations above the population mean. However, for determination of the risk for gout, hyperuricemia is defined as a supersaturated urate concentration.² By this definition, a urate concentration greater than 7.0 mg/dL is abnormal and is associated with an increased risk for gout. This corresponds to a measured value greater than 7.5 mg/dL by most autoanalyzers.

EPIDEMIOLOGY

Population studies have shown that serum urate concentration (and consequently the risk of gout) correlates with age, serum creatinine level, blood urea nitrogen level, male gender, blood pressure, body weight, and alcohol intake. Serum urate concentrations are normally distributed with slight skewing toward higher values. In gout, mean

serum urate concentration values are 6.8 mg/dL for men and 6.0 mg/dL for women.

There is a direct correlation between the serum uric acid concentration and both the incidence and prevalence of gout. The incidence of gout varies from 20 to 35 per 100,000 persons, with an overall prevalence of 1.6 to 13.6 per thousand. Prevalence increases with age, especially in men.¹ Men are affected by gout approximately 10 times more often than women. Although no genetic marker has been isolated for gout, the familial nature of gout strongly suggests an interaction between genetic and environmental factors.

ETIOLOGY AND PATHOPHYSIOLOGY

In humans, uric acid is the end product of the degradation of purines. Uric acid serves no known physiologic purpose and therefore is regarded as a waste product. In lower animals, the enzyme uricase breaks down uric acid to the more soluble allantoin, and thus uric acid does not accumulate. Gout occurs exclusively in humans in whom a miscible pool of uric acid exists. Under normal conditions, the amount of accumulated uric acid is about 1200 mg in men and about 600 mg in women. The size of the urate pool is increased severalfold in individuals with gout. This excess accumulation may result from either overproduction or underexcretion.

OVERPRODUCTION OF URIC ACID

The purines from which uric acid is produced originate from three sources: dietary purine, conversion of tissue nucleic acid to purine nucleotides, and de novo synthesis of purine bases. The purines derived from these three sources enter a common metabolic pathway leading to the production of either nucleic acid or uric acid. Under normal circumstances, uric acid may accumulate excessively if production exceeds excretion. The average human produces about 600 to 800 mg of uric acid each day.

Several enzyme systems regulate purine metabolism. Abnormalities in these regulatory systems can result in overproduction of uric acid.³ Uric acid also may be overproduced as a consequence of increased breakdown of tissue nucleic acids, as with myeloproliferative and lymphoproliferative disorders. Dietary purines play an unimportant role in the generation of hyperuricemia in the absence of some derangement in purine metabolism or elimination.

Two enzyme abnormalities resulting in an overproduction of uric acid have been well described (Fig. 91–1). The first is an increase in the activity of phosphoribosyl pyrophosphate (PRPP) synthetase, which leads to an increased concentration of PRPP. PRPP is a key determinant of purine synthesis and thus uric acid production. The second is a deficiency of hypoxanthine guanine phosphoribosyl transferase (HGPRT).

HGPRT is responsible for the conversion of guanine to guanylic acid and hypoxanthine to inosinic acid. These two conversions require PRPP as the cosubstrate and are important reutilization reactions involved in the synthesis of nucleic acids. A deficiency in the HGPRT enzyme leads to increased metabolism of guanine and hypoxanthine to uric acid, and more PRPP to interact with glutamine in the first step of the purine pathway.⁴ Complete absence of HGPRT results in the childhood Lesch-Nyhan syndrome, characterized by choreoathetosis, spasticity, mental retardation, and markedly excessive production of uric acid. A partial deficiency of the enzyme may be responsible for marked hyperuricemia in otherwise normal, healthy individuals.

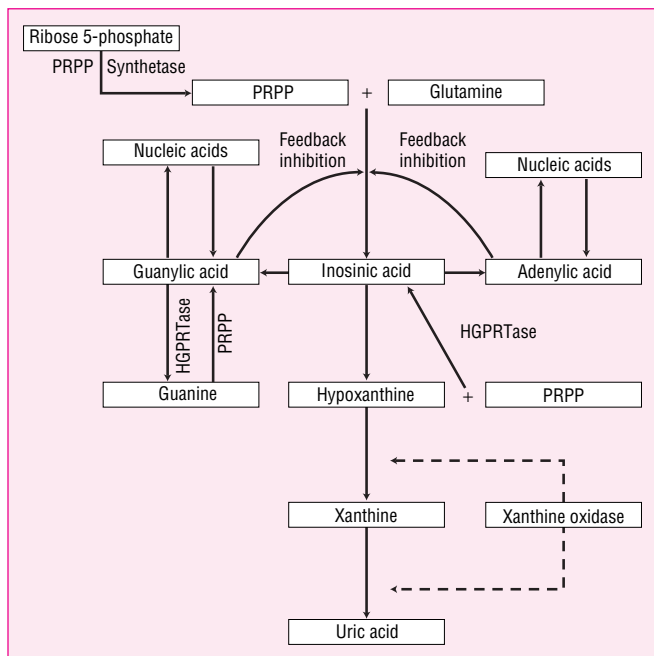

FIGURE 91–1. Purine metabolism.

TABLE 91–1. Conditions Associated with Hyperuricemia

| | |
|---------------------------------|--------------------------|
| Primary gout | Obesity |
| Diabetic ketoacidosis | Sarcoidosis |
| Myeloproliferative disorders | Congestive heart failure |
| Lactic acidosis | Renal dysfunction |
| Lymphoproliferative disorders | Down syndrome |
| Starvation | Lead toxicity |
| Chronic hemolytic anemia | Hyperparathyroidism |
| Toxemia of pregnancy | Acute alcoholism |
| Pernicious anemia | Hypoparathyroidism |
| Glycogen storage disease type 1 | Acromegaly |
| Psoriasis | Hypothyroidism |

UNDEREXCRETION OF URIC ACID

Uric acid does not accumulate as long as uric acid production is balanced with elimination. Uric acid is eliminated in two ways. About two-thirds of the uric acid produced each day is excreted in the urine. The rest is eliminated through the gastrointestinal tract after enzymatic degradation by colonic bacteria.

A decline in the urinary excretion of uric acid to a level below the rate of production leads to hyperuricemia and an increased miscible pool of sodium urate. Almost all the urate in plasma is freely filtered across the glomerulus. The concentration of uric acid appearing in the urine is determined by multiple renal tubular transport processes in addition to the filtered load. Evidence favors a four-component model including glomerular filtration, tubular reabsorption, tubular secretion, and postsecretory reabsorption.²

Approximately 90% of filtered uric acid is reabsorbed in the proximal tubule, probably by both active and passive transport mechanisms. There is a close linkage between proximal tubular sodium reabsorption and uric acid reabsorption, so states that enhance sodium reabsorption (e.g., dehydration) also lead to increased uric acid reabsorption. The exact site of tubular secretion of uric acid has not been determined; this too appears to involve an active transport process. Postsecretory reabsorption occurs somewhere distal to the secretory site.

Factors that decrease uric acid clearance or increase its production will result in an increase in serum urate concentration. Some of these factors are listed in Table 91–1. Drugs that decrease renal clearance of uric acid through modification of filtered load or one of the tubular transport processes are listed in Table 91–2. By enhancing renal urate reabsorption, insulin resistance is also associated with gout.⁵

The pathophysiologic approach to the evaluation of hyperuricemia requires determining whether the patient is overproducing or underexcreting uric acid. This can be accomplished by placing the patient on a purine-free diet for 3 to 5 days and then measuring the amount of uric acid excreted in the urine in 24 hours. Normal individuals produce 600 to 800 mg of uric acid daily and excrete less than 600 mg in urine. Individuals who excrete more than 600 mg on a purine-free diet may be considered overproducers. Hyperuricemic individuals who excrete less than 600 mg of uric acid per 24 hours

TABLE 91–2. Drugs Capable of Inducing Hyperuricemia and Gout

| | | |
|------------------------|--------------|-----------------|

on a purine-free diet may be classified as underexcretors of uric acid. However, it is very difficult in clinical practice to maintain someone on a purine-free diet for several days. On a regular diet, excretion of greater than 1000 mg per 24 hours reflects overproduction; less than this is probably normal.

PRESENTATION OF ACUTE GOUTY ARTHRITIS

GENERAL

Gout typically involves acute attacks of arthritis, nephrolithiasis, gouty nephropathy, and aggregated deposits of sodium urate (tophi) in cartilage, tendons, synovial membranes, and elsewhere.

SIGNS AND SYMPTOMS

Fever; intense pain, erythema, warmth, and swelling of involved joints
 Excruciating pain, swelling, and inflammation involving one or more joints, most commonly starting in the great toe, but sometimes involving other joints of the extremities

LABORATORY TESTS

Elevated serum uric acid levels; leukocytosis

OTHER DIAGNOSTIC TESTS

None

CLINICAL PRESENTATION

1 Gout is a disease diagnosed by symptoms rather than laboratory tests of uric acid. In fact, asymptomatic hyperuricemia discovered incidentally generally requires no therapy.

ACUTE GOUTY ARTHRITIS

Acute attacks of gouty arthritis are characterized by rapid onset of excruciating pain, swelling, and inflammation. The attack typically is monarticular at first, most often affecting the first metatarsophalangeal joint (great toe) and then, in order of frequency, the insteps, ankles, heels, knees, wrists, fingers, and elbows. In one-half of initial attacks, the first metatarsophalangeal joint is affected. Of gouty patients, 90% experience attacks in the great toe at some point in their disease.

The predilection of acute gout for peripheral joints of the lower extremity is probably related to the low temperature of these joints combined with high intra-articular urate concentration. Synovial effusions are postulated to occur transiently in weight-bearing joints in the course of a day with routine activity. At night, water is reabsorbed from the joint space, leaving behind a supersaturated solution of monosodium urate, which can precipitate attacks of acute arthritis. Attacks generally begin at night with the patient awakening from sleep in excruciating pain.

The development of crystal-induced inflammation involves a number of chemical mediators causing vasodilation, increased vascular permeability, and chemotactic activity for polymorphonuclear leukocytes.⁶ Phagocytosis of urate crystals by the leukocytes results in rapid lysis of cells and a discharge of proteolytic enzymes into the cytoplasm. The ensuing inflammatory reaction is associated with intense joint pain, erythema, warmth, and swelling. Fever is common, as is leukocytosis. Untreated attacks may last from 3 to 14 days before spontaneous recovery.

Although acute attacks of gouty arthritis may occur without apparent provocation, a number of conditions may precipitate an attack. These include stress, trauma, alcohol ingestion, infection, surgery, rapid lowering of serum uric acid by ingestion of uric acid-lowering agents, and ingestion of certain drugs known to elevate serum uric acid concentrations. The diagnosis is best accomplished by aspiration of synovial fluid from the affected joint and identification of intracellular crystals of monosodium urate monohydrate in synovial fluid leukocytes. Other crystal-induced arthropathies that may resemble gout on clinical presentation are caused by calcium pyrophosphate dihydrate crystals (pseudogout) and calcium hydroxyapatite crystals, which are associated with calcific periarthritis, tendinitis, and arthritis.^{7,8}

URIC ACID NEPHROLITHIASIS

Nephrolithiasis occurs in 10% to 25% of patients with gout.⁹ Factors that predispose individuals to uric acid nephrolithiasis include excessive urinary excretion of uric acid, an acidic urine, and a highly concentrated urine. The risk of renal calculi approaches 50% in individuals whose renal excretion of uric acid exceeds 1100 mg/day. In addition to pure uric acid stones, hyperuricosuric individuals are at increased risk for mixed uric acid-calcium oxalate stones and pure calcium oxalate stones. Uric acid stones are usually small, round, and radiolucent. Uric acid stones containing calcium are radiopaque.⁹

Uric acid has a negative logarithm of the acid ionization constant of 5.5. Therefore when the urine is acidic, uric acid exists primarily in the un-ionized, less soluble form. At a urine pH of 5.0, urine is saturated at a uric acid level of 15 mg/dL. When the urine pH is 7.0, the solubility of uric acid in urine is increased to 200 mg/dL.¹⁰ In patients with uric acid nephrolithiasis, urinary pH typically is less than 6.0 and frequently less than 5.5. When an acidic urine is saturated with uric acid, spontaneous precipitation of stones may occur.

GOUTY NEPHROPATHY

There are two types of gouty nephropathy: acute uric acid nephropathy and chronic urate nephropathy.¹¹ In acute uric acid nephropathy, acute renal failure occurs as a result of blockage of urine flow secondary to massive precipitation of uric acid crystals in the collecting ducts and ureters. This syndrome is a well-recognized complication in patients with myeloproliferative or lymphoproliferative disorders and is a result of massive malignant cell turnover, particularly after initiation of chemotherapy.

Chronic urate nephropathy is caused by the long-term deposition of urate crystals in the renal parenchyma. Microtophi may form, with a surrounding giant cell inflammatory reaction. A decrease in the kidney's ability to concentrate urine and the presence of proteinuria may be the earliest pathophysiologic disturbances. Hypertension and nephrosclerosis are common associated findings. Although renal failure occurs in a higher percentage of gouty patients than expected, it is not clear that hyperuricemia per se has a harmful effect on the kidney. The chronic renal impairment seen in individuals with gout may result largely from the co-occurrence of hypertension, diabetes mellitus, and atherosclerosis.

TOPHACEOUS GOUT

Tophi (urate deposits) are uncommon in the general population of gouty subjects and are a late complication of hyperuricemia. The most common sites of tophaceous deposits in patients with recurrent acute

gouty arthritis are the base of the great toe, helix of the ear, olecranon bursae, Achilles tendon, knees, wrists, and hands.² Eventually, even the hips, shoulders, and spine may be affected. In addition to caus-

ing obvious deformities, tophi may damage surrounding soft tissue, cause joint destruction and pain, and even lead to nerve compression syndromes including carpal tunnel syndrome.

► TREATMENT: Gout and Hyperuricemia

The goals in the treatment of gout are to terminate the acute attack, prevent recurrent attacks of gouty arthritis, and prevent complications associated with chronic deposition of urate crystals in tissues.¹² Patients should be advised to reduce their dietary intake of saturated fats and meats high in purines (e.g., organ meats).¹³

■ ACUTE GOUTY ARTHRITIS

2 Acute attacks of gouty arthritis may be treated successfully with colchicine or any of a variety of nonsteroidal anti-inflammatory drugs (NSAIDs) (Fig. 91–2).

Colchicine can be given orally or parenterally. Unless contraindications exist or the patient has renal insufficiency, the usual oral dose is 1 mg initially, followed by 0.5 mg every 2 hours until the joint symptoms subside, until the patient develops abdominal discomfort or diarrhea, or until a total dose of 8 mg has been administered.¹⁴ About 75% to 95% of patients with acute gouty arthritis respond favorably to colchicine when ingestion of the drug is begun within 24 to 48 hours of the onset of joint symptoms.¹⁵ If the initiation of colchicine is delayed longer than 48 hours after the onset of acute symptoms, the probability of success with the drug diminishes substantially.

The major problem associated with the use of oral colchicine is that it causes gastrointestinal side effects in 50% to 80% of patients before the relief of the attack.

3 This high incidence of gastrointestinal side effects may be circumvented by administering colchicine intravenously. Except in patients with renal insufficiency, the initial intravenous dose of colchicine is 2 mg. If relief is not obtained, an additional 1-mg dose may be given at 6 and 12 hours to a total dose of 4 mg for a specific attack. The colchicine should be diluted with 20 mL normal saline before administration to minimize sclerosis of the vein. The intravenous administration of colchicine eliminates most of the gas-

trointestinal symptoms associated with the oral dose, but subjects the patient to the risk of local extravasation, which can cause inflammation and necrosis of the surrounding tissue. Very small, difficult-to-inject veins and renal impairment represent relative contraindications to intravenous colchicine therapy.

Because of the risk of bone marrow toxicity, colchicine should be discontinued for 7 days following initial therapy with either oral or intravenous administration. Colchicine should not be used intravenously in individuals who are neutropenic, have severe renal impairment (a creatinine clearance of <10 mL/min), or have combined renal and hepatic insufficiency. The dose should be decreased by 50% in individuals with renal insufficiency (a creatinine clearance of 10 to 50 mL/min) and limited to a total dose of 2 mg in patients receiving oral maintenance colchicine.¹⁶

Indomethacin is as effective as colchicine in the treatment of acute gouty arthritis. Because acute gastrointestinal toxicity occurs far less frequently with indomethacin than with colchicine, it is preferred. Side effects unique to indomethacin include headache and dizziness. All NSAIDs have been implicated in the cause of gastric ulceration and bleeding, but with short-term therapy, this is not likely.

For treatment of acute gouty arthritis, indomethacin may be begun with a relatively large dose for the first 24 to 48 hours and then tapered over 3 to 4 days to minimize the risk of recurrent attacks. For example, 75 mg of indomethacin should be given initially, followed by 50 mg every 6 hours for 2 days and then 50 mg every 8 hours for 1 or 2 days.

A number of other NSAIDs (e.g., naproxen, fenoprofen, ibuprofen, and piroxicam) are also effective in relieving the inflammation of acute gout. There is no evidence that any given NSAID is superior to all the others in the management of acute gout.¹⁷ All NSAIDs should be used with caution in individuals with a history of acid peptic disease, heart failure, chronic renal failure, or coronary artery disease. Selective cyclooxygenase-2 inhibitors, such as celecoxib and valdecoxib, can be used as an alternative for patients who cannot tolerate nonselective cyclooxygenase inhibitors (see note at end of Chap. 90 for information on problems with these agents that emerged while this chapter was in production).¹⁸

4 Corticosteroids may be used to treat acute attacks of gouty arthritis, but they are reserved primarily for resistant cases or for patients with a contraindication to colchicine and NSAID therapy.¹⁷ Doses of 40 to 80 USP units of adrenocorticotropic hormone gel are given intramuscularly every 6 to 8 hours for 2 to 3 days, and then the doses are reduced in stepwise fashion and discontinued. Intra-articular administration of triamcinolone hexacetonide in a dose of 20 to 40 mg may be useful in treating acute gout limited to one or two joints.¹⁹ Prednisone may be administered orally in doses of 30 to 60 mg for 3 to 5 days in patients with multiple-joint involvement. Because rebound attacks may occur on steroid withdrawal, the dose should be tapered gradually by 5-mg decreases over 10 to 14 days and discontinued.

■ NEPHROLITHIASIS

9 The medical management of uric acid nephrolithiasis includes hydration sufficient to maintain a urine volume of

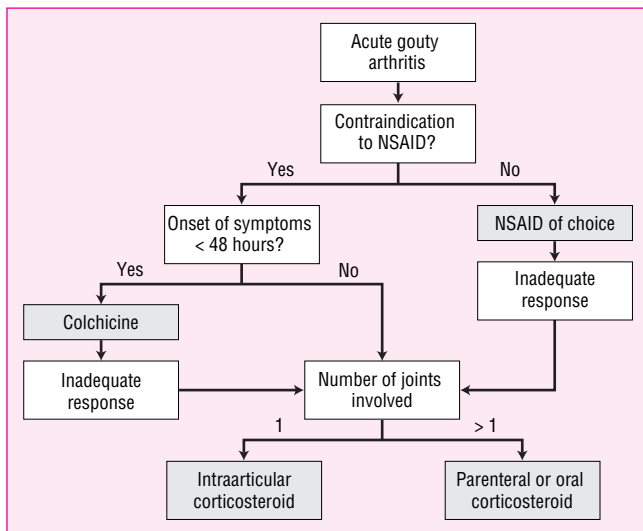

FIGURE 91–2. Treatment algorithm for acute gouty arthritis.

2 to 3 L/day, alkalization of urine, avoidance of purine-rich foods, moderation of protein intake, and reduction of urinary uric acid excretion.

Maintenance of a 24-hour urine volume of 2 to 3 L with an adequate intake of fluids is desirable for all gouty patients, but especially for those with excessive (>1 g/day) uric acid excretion. Alkalinizing agents should be used with the objective of making the urine less acidic. Urine pH should be maintained at 6 to 6.5. In this pH range, up to 85% of uric acid will be in the form of the soluble urate ion.

Reduction of urine acidity can be accomplished by the administration of sodium bicarbonate or Shohl's solution (40 g citric acid and 98 g sodium citrate per liter). With the former, 2 to 6 g/day is given in equally divided doses at 6- to 8-hour intervals. A dose of 20 to 60 mL of Shohl's solution per day, given in three or four divided doses, provides an equivalent amount of alkali. If use of a sodium salt is contraindicated, potassium citrate may be used instead.

One must keep in mind that older patients with uric acid kidney stones also may have hypertension, congestive heart failure, or renal insufficiency, and obviously should not be exposed to overload with alkalinizing sodium salts or unlimited fluid intake. Acetazolamide, a carbonic anhydrase inhibitor, produces rapid and effective urinary alkalization and sometimes is used in conjunction with alkali therapy. When a 250-mg dose of acetazolamide is given at bedtime, the excretion of an acidic urine in the early morning hours is avoided. The usual tachyphylaxis (rapid tolerance) to this drug is obviated by a daily repletion dose of bicarbonate.

Since the advent of allopurinol, a low-purine, low-protein diet in the patient with uric acid lithiasis is no longer as critical as it once was; however, it is still advisable to instruct the patient to avoid foods rich in purine and to limit protein to no more than 90 g/day. Such a diet is still palatable and reduces appreciably the amount of uric acid in the urine.

The mainstay of drug therapy for recurrent uric acid lithiasis is allopurinol. It is effective in reducing both serum and urinary uric acid levels, thus preventing the formation of calculi. Allopurinol is also recommended as prophylactic treatment in patients who will receive cytotoxic agents for the treatment of lymphoma or leukemia. The marked increase in uric acid production associated with cytotoxicity of a neoplasm predisposes a patient to the development of uric acid nephrolithiasis.

PROPHYLACTIC THERAPY

5 After the first attack of acute gouty arthritis or after the passage of the first renal stone, a decision to institute prophylactic therapy must be entertained. If the first episode was mild and responded promptly to treatment, the patient's serum urate concentration was elevated only minimally, and the 24-hour urinary uric acid excretion was not excessive (<1000 mg/24 hours on a regular diet), then prophylactic treatment can be withheld. Some patients never have a second attack or a second stone. Others may not experience a second gouty episode for 5 to 10 years. Therefore a wait-and-see attitude seems justified in patients who meet these conditions.⁷

6 On the other hand, if the patient had a severe attack of gouty arthritis, a complicated course of uric acid lithiasis, a substantially elevated serum uric acid level (>10 mg/dL), or a 24-hour urinary excretion of uric acid of more than 1000 mg, then prophylactic treatment should be instituted immediately after resolution of the acute episode. Prophylactic therapy is also appropriate for patients with frequent attacks (more than two or three per year) of gouty arthritis,

even if the serum uric acid concentration is normal or only minimally elevated.

7 Recurrences of acute gouty arthritis may be prevented with continuous low-dose daily oral colchicine or by uric acid-lowering therapy with either uricosuric agents or inhibition of xanthine oxidase with allopurinol. Combination therapy consisting of colchicine plus a uricosuric agent or allopurinol may be employed in resistant cases. The choice of treatment depends on the serum urate concentration, the amount of uric acid excreted in a 24-hour period, and the renal function status of the patient.

Prophylactic therapy with low-dose oral colchicine, 0.5 to 0.6 mg twice daily, may be effective in preventing recurrent arthritis in patients with no evidence of visible tophi and a normal or slightly elevated serum urate concentration.¹⁴ Patients do not become resistant to or tolerant of daily colchicine, and if they sense the beginning of an acute attack, they should increase the dose to 1 mg every 2 hours; in most instances the attack will abort after 1 or 2 mg of colchicine. If the serum urate concentration is within the normal range and the patient has been symptom-free for 1 year, maintenance colchicine may be discontinued. The patient should be advised, however, that discontinuation of the treatment program may be followed by an exacerbation of acute gouty arthritis.

Patients with a history of recurrent acute gouty arthritis and a significantly elevated serum uric acid concentration probably are best managed with uric acid-lowering therapy. Colchicine at a dose of 0.5 mg twice daily should be administered during the first 6 to 12 months of antihyperuricemic therapy to minimize the risk of acute attacks that may occur during initiation of uric acid-lowering therapy. The therapeutic objective of antihyperuricemic therapy is to reduce the serum urate concentration below 6 mg/dL, well below the saturation point.

Reduction of the serum urate concentration can be accomplished pharmacologically by increasing the renal excretion of uric acid or by decreasing its synthesis. The drugs used most widely to increase uric acid excretion are probenecid and sulfapyrazone. Several other uricosuric drugs are available in Europe, but they have not been approved for use in the United States.

URICOSURIC DRUGS

8 Uricosuric drugs increase the renal clearance of uric acid by inhibiting the renal tubular reabsorption of uric acid. Therapy with uricosuric drugs should be started at a low dose to avoid marked uricosuria and possible stone formation. The maintenance of adequate urine flow and alkalization of the urine with sodium bicarbonate or Shohl's solution during the first several days of uricosuric therapy further diminish the possibility of uric acid stone formation. Probenecid is given initially at a dose of 250 mg twice a day for 1 to 2 weeks and then 500 mg twice a day for 2 weeks. Thereafter the daily dose is increased by 500-mg increments every 1 to 2 weeks until satisfactory control is achieved or a maximum dose of 2 g is reached. The initial dose of sulfapyrazone is 50 mg twice a day for 3 to 4 days and then 100 mg twice a day, increasing the daily dose by 100-mg increments each week up to 800 mg/day.

The major side effects associated with uricosuric therapy are gastrointestinal irritation, rash and hypersensitivity, precipitation of acute gouty arthritis, and stone formation. These drugs are contraindicated in patients who are allergic to them and in patients with impaired renal function (a creatinine clearance <50 mL/min), a history of renal calculi, and in patients who are overproducers of uric acid; for such patients, allopurinol should be used.

■ XANTHINE OXIDASE INHIBITOR

Currently, allopurinol is the only drug approved for use in inhibiting uric acid synthesis. Both allopurinol and its major metabolite, oxypurinol, are xanthine oxidase inhibitors and thus impair the conversion of hypoxanthine to xanthine and xanthine to uric acid. Allopurinol also lowers the intracellular concentration of PRPP. Because of the long half-life of its metabolite, allopurinol can be given once daily. An oral daily dose of 300 mg usually is sufficient. Occasionally, as much as 600 to 800 mg/day may be necessary.

Allopurinol is the antihyperuricemic drug of choice in patients with a history of urinary stones or impaired renal function, in patients who have lymphoproliferative or myeloproliferative disorders and need pretreatment with a xanthine oxidase inhibitor before initiation of cytotoxic therapy to protect against acute uric acid nephropathy, and in patients with gout who are overproducers of uric acid. The major side effects of allopurinol are skin rash, leukopenia, occasional gastrointestinal toxicity, and increased frequency of acute gouty attacks with the initiation of therapy. An allopurinol hypersensitivity syndrome characterized by fever, eosinophilia, dermatitis, vasculitis, and renal and hepatic dysfunction is a rare side effect, but is associated with a 20% mortality rate.¹⁸

CLINICAL CONTROVERSY

To reduce the risk of developing the allopurinol hypersensitivity syndrome, some experts believe that the dose of allopurinol should be adjusted based on the patient's creatinine clearance.

■ ASYMPTOMATIC HYPERURICEMIA

Questions are often raised regarding the indications for drug therapy for asymptomatic hyperuricemia. The purported benefits from treatment include prevention of acute gouty arthritis, tophi formation, nephrolithiasis, and chronic urate nephropathy. The first three complications are easily controlled should they develop; therefore antihyperuricemic therapy is not warranted to prevent these conditions.

CONCLUSION

Hyperuricemia may lead to acute arthritis, chronic gout, or kidney stones or remain asymptomatic. Asymptomatic hyperuricemia need not be treated, especially if the serum urate concentration remains below 10 mg/dL.

Acute gouty arthritis requires either colchicine or an NSAID to treat the underlying inflammatory condition. The management of uric acid kidney stones includes hydration and alkalinization of the urine. Prevention of recurrent gouty arthritis or recurrent nephrolithiasis and treatment of chronic gout require hypouricemic therapy with either a uricosuric drug or allopurinol. Allopurinol is the hypouricemic drug of choice in patients with a history of uric acid stones or renal insufficiency and in patients known to be overproducers of uric acid.

ABBREVIATIONS

HGPRT: hypoxanthine guanine phosphoribosyl transferase
NSAID: nonsteroidal anti-inflammatory drug
PRPP: phosphoribosyl pyrophosphate (synthetase)

The prevention of urate nephropathy might be a stronger indication because it is irreversible even with proper treatment. Available data indicate, however, that gouty nephropathy is extremely rare in the absence of clinical gout, and evidence that elevation of uric acid by itself may cause renal disease is weak and inconclusive.^{20,21} As discussed previously, renal impairment is very rare in the absence of concurrent hypertension and atherosclerosis. In addition, it is unclear whether uric acid-lowering therapy protects renal function in such individuals. Available data thus do not justify therapy for most patients with asymptomatic hyperuricemia.

CLINICAL CONTROVERSY

While asymptomatic hyperuricemia is not generally treated, some clinicians have begun recommending treatment to reduce the risk of coronary artery disease. Hyperuricemia is associated with both hypertension and coronary artery disease, and patients with elevated uric acid levels and hypertension are at increased risk of cardiovascular morbidity and mortality.

■ PHARMACOECONOMIC CONSIDERATIONS

Assuming no treatment of asymptomatic hyperuricemia, pharmacoeconomic considerations apply only to the management of the acute and chronic clinical manifestations of gout.

In a cost-effectiveness analysis in patients with nontophaceous recurrent gouty arthritis, urate-lowering therapy was found to reduce costs if patients experienced two or more recurrent attacks per year.²² Generic allopurinol was associated with a lower incremental cost-effectiveness ratio than were either probenecid or sulfinpyrazone.

◀10 In the case of chronic tophaceous gout, a need to continue long-term therapy with a urate-lowering drug clearly exists. Allopurinol generally is less expensive than uricosuric therapy and may be more effective. Comparative trials are lacking. For severe cases, combination therapy may be indicated. Many clinicians will add colchicine to the regimen to reduce the likelihood of precipitating acute gouty arthritis, but this does not appear to be a cost-effective measure.

GLAUCOMA

Timothy S. Lesar, Richard G. Fiscella, and Deepak Edward

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Primary open-angle glaucoma (POAG) or ocular hypertension (OHT) is more prevalent than closed- or narrow-angle glaucoma.
- 2 In any form of glaucoma, reduction of intraocular pressure (IOP) is essential.
- 3 IOP is a very important risk factor for glaucoma, but the most important considerations are progression of glaucomatous changes in the back of the eye (optic disk and nerve fiber layer) and visual field changes when diagnosing and monitoring for POAG or OHT.
- 4 Fundus changes often occur before visual field changes are exhibited.
- 5 Recent studies have demonstrated that reduction in IOP will prevent progression or even onset of glaucoma.
- 6 Newer medications have simplified treatment regimens for patients. Prostaglandin analogs are considered the most potent topical medications for reducing IOP and flattening diurnal variations.
- 7 Local adverse events are common with topical glaucoma medications, but patient education and reinforcing adherence are essential to prevent glaucoma progression.

The glaucomas are a group of ocular disorders that lead to an optic neuropathy characterized by changes in the optic nerve head (optic disk) that is associated with loss of visual sensitivity and field. Increased intraocular pressure (IOP), a traditional diagnostic criterion for glaucoma, is thought to play an important role in the pathogenesis of glaucoma, but is no longer a diagnostic criterion for glaucoma.^{1–10} Two major types of glaucoma have been identified: open angle and closed angle. Open-angle glaucoma accounts for the great majority of cases. Either type can be a primary inherited disorder, congenital, or secondary to disease, trauma, or drugs, and can lead to serious complications.^{11–16} Both primary and secondary glaucomas may be caused by a combination of open-angle and closed-angle mechanisms (Table 92–1).

BASIC CONCEPTS

AQUEOUS HUMOR DYNAMICS AND IOP

An understanding of IOP and aqueous humor dynamics will assist the reader in understanding the drug therapy of glaucoma.^{1,2,17–19}

Aqueous humor is formed in the ciliary body and its epithelium (Figs. 92–1 and 92–2) through both filtration and secretion. Because ultrafiltration depends on pressure gradients, blood pressure and IOP changes influence aqueous humor formation. Osmotic gradients produced by active secretion of sodium and bicarbonate, and possibly other solutes such as ascorbate from the ciliary body epithelial cells into the aqueous humor, result in movement of water from the pool

of ciliary stromal ultrafiltrate into the posterior chamber, forming aqueous humor. Carbonic anhydrase (primarily isoenzyme type II), α - and β -adrenergic receptors, and sodium- and potassium-activated ATPases are found on the ciliary epithelium and appear to be involved in this secretion of the solutes sodium and bicarbonate.

Receptor systems controlling aqueous inflow have not been elucidated fully. Pharmacologic studies suggest that β -adrenergic agents increase inflow, whereas α_2 -adrenergic-blocking, α -adrenergic-blocking, β -adrenergic-blocking, dopamine-blocking, carbonic anhydrase-inhibiting, and adenylate cyclase-stimulating agents decrease aqueous inflow. Aqueous humor produced by the ciliary body is secreted into the posterior chamber at a rate of approximately 2 to 3 $\mu\text{L}/\text{min}$. The pressure in the posterior chamber produced by the constant inflow pushes the aqueous humor between the iris and lens and through the pupil into the anterior chamber of the eye^{1,2,17–22} (see Fig. 92–2).

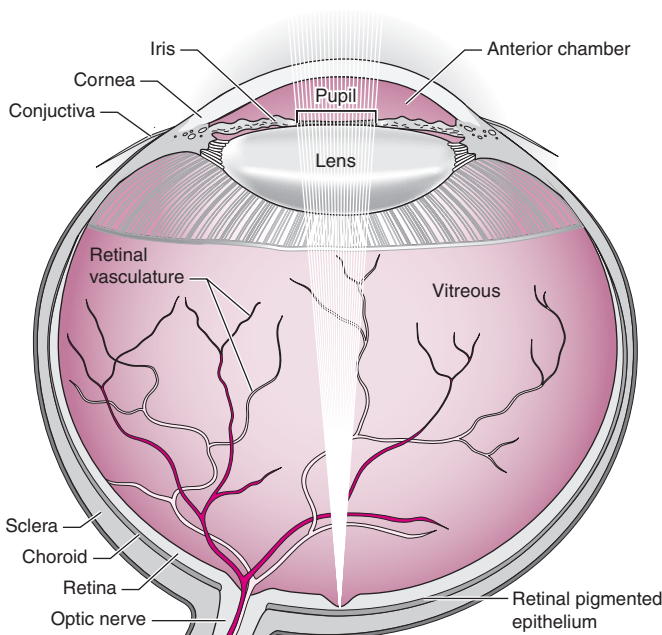

Aqueous humor in the anterior chamber leaves the eye by two routes: (1) filtration through the trabecular meshwork (conventional outflow) to Schlemm's canal (80% to 85%) and (2) through the ciliary body and the suprachoroidal space (uveoscleral outflow or unconventional outflow). Cholinergic agents such as pilocarpine increase outflow by physically opening the meshwork pores secondary to ciliary muscle contraction. The uveoscleral outflow of aqueous humor is also increased by prostaglandin analogs, and β - and α_2 -adrenergic agonists. Constant inflow of aqueous humor from the ciliary body and resistance to outflow result in an IOP great enough to produce an outflow rate equal to the inflow rate (see Fig. 92–2).

- III. Congenital glaucoma

The median IOP measured in large populations is 15.5 ± 2.5 mm Hg; however, the distribution of pressures around the mean is skewed to the right (toward higher readings). IOP is not constant and changes with pulse, blood pressure, forced expiration or coughing, neck compression, and posture. IOP is measured by tonometry: indentation tonometry, applanation tonometry, or a noncontact method using an air pulse. These methods may result in slightly different pressure readings. IOPs consistently greater than 21 mm Hg are found in 5% to 8% of the general population. The incidence increases with age such that “abnormal” (i.e., >22 mm Hg) IOP is found in 15% of those 70 to 75 years of age. Intermittently high IOP (>40 mm Hg) is found in patients with closed-angle glaucoma (CAG). The increased IOP in all types of glaucoma results from the decreased facility for aqueous humor outflow through the trabecular meshwork. Aqueous humor production in primary open-angle glaucoma (POAG) is normal.^{1,2,17–19}

IOP demonstrates considerable circadian variation (often referred to as *diurnal* IOP or the IOP during the daily 24-hour cycle) primarily because of changes in the rate of aqueous humor formation.

**FIGURE 92–1.** Anatomy of the eye.

This circadian variation results in a minimum IOP at approximately 6 PM and a maximum IOP at awakening, although some studies have suggested that both healthy and glaucoma patients may have their highest IOP at night after falling asleep.²⁰ Low systemic blood pressure in conjunction with high IOPs (decreased ocular perfusion pressure) at night can result in optic nerve head damage.²⁰ Generally, the circadian IOP variation is usually less than 3 to 4 mm Hg; however, it may be greater in patients with glaucoma. This circadian variation and the poor relationship of IOP with visual loss make measurement of IOP a poor screening test for glaucoma.

Although increased IOP within any range is associated with a higher risk of glaucomatous damage, it is both an insensitive and non-specific diagnostic and monitoring tool. Of individuals with IOP between 21 and 30 mm Hg, only 0.5% to 1% per year will develop optic disk changes and visual field loss (i.e., glaucoma) over 5 to 15 years. However, more subtle retinal damage, such as alteration of color vision or decreased contrast sensitivity, occurs in a higher percentage of patients with IOPs greater than 21 mm Hg, and the incidence of visual field defects increases to as high as 28% in individuals with IOPs above 30 mm Hg. For a given abnormal IOP, the incidence of glaucoma increases with age. In patients with pre-existing optic nerve damage, the worse the existing damage, the more sensitive the eye is to a given IOP. As many as 20% to 30% of patients with glaucomatous visual field loss have an IOP of less than 21 mm Hg (called *normal-tension glaucoma*, referring to the normal IOP). Thus the absolute IOP is a less precise predictor of optic nerve damage. More direct measurements of therapeutic outcome such as optic disk examination and visual-field evaluation also must be used as monitors of disease progression.^{1–7,17–24} Taking the above factors into consideration, glaucoma medications that provide maximal reduction of IOP over 24 hours and have minimal influence on blood pressure may be advantageous in treating glaucoma patients.

OPTIC DISK AND VISUAL FIELDS

The optic disk is the portion of the optic nerve ophthalmoscopically visible as it leaves the eye. It consists of approximately one million retinal ganglion nerve cell axons, blood vessels, and supporting connective tissue structures (lamina cribrosa). The small depression within the disk is termed the *cup* (Fig. 92–3). A normal physiologic cup does not extend beyond the optic nerve rim and has a varying diameter of less than one-third to one-half that of the disk (cup:disk ratio 0.33 to 0.5). The common alterations of the optic disk found in glaucoma are listed in Table 92–2. These disk changes result from optic nerve axonal degeneration and remodeling of the supporting structures. As the nerve axons die, the cup becomes larger in relation to the whole disk. A loss of retinal nerve fiber layer visibility might be visualized in glaucoma patients with detectable visual field loss. This pattern of changes is consistent with visual field losses and loss of visual sensitivity seen in glaucoma.^{1,2,17–24}

Determination of the visual field allows assessment of optic nerve damage and is an important monitoring parameter in treatment. However, visual field changes lag behind optic disk changes, and a loss of 25% to 35% of retinal ganglion cells is usually required before detectable visual field defects are noted. The peripheral visual field is measured using a visual field instrument called a *perimeter*. Characteristic visual field loss occurs in glaucoma (Fig. 92–4; see also Table 92–2), but loss of central visual acuity usually does not occur until late in the disease. Other indicators such as color vision changes and contrast sensitivity may allow earlier and more sensitive detection of glaucomatous changes.^{1,2}

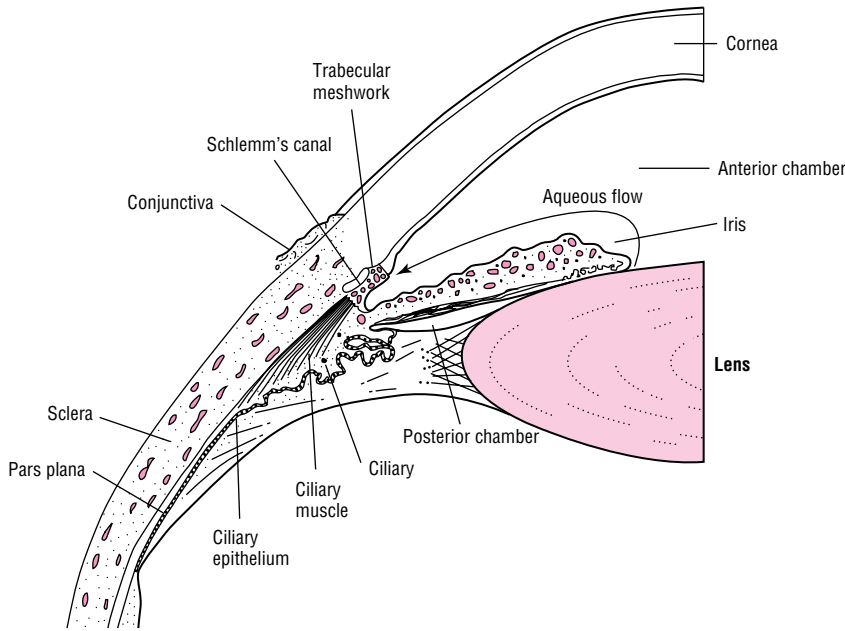

FIGURE 92-2. Anterior chamber of the eye and aqueous humor flow.

GENETICS

A number of major gene loci associated with POAG have been identified. The molecular mechanism of how mutations in any of these genes result in increased IOP with loss of visual field has not been elucidated. One gene, *GLC1A*, codes for the trabecular meshwork–induced glucocorticoid response protein, also commonly known as *myocilin*, in the trabecular meshwork. Its function and role in POAG is under active investigation. Discovery of mutations in the optineurin gene were reported in about 17% of patients in families with autosomal-dominant inherited normal-tension glaucoma patients, but the mutation is likely responsible for less than 0.1% of all glaucomas.^{25–26} It is hoped that improved understanding of the genetic origins of POAG will lead to new diagnostic tools and therapies that target the underlying causes of the disease.^{1,2,25,26}

United States and 6.7 million worldwide will have bilateral blindness as a result. The prevalence rate varies with age, race, diagnostic criteria, and other factors. In the United States, open-angle glaucoma occurs in 1.5% of the population over 30 years of age, 1.3% of whites and 3.5% of blacks. The incidence of open-angle glaucoma increases with increasing age. The incidence of the disease in patients 80 years of age is 3% in whites and 5% to 8% in blacks.

ETIOLOGY OF OPEN-ANGLE GLAUCOMA

◀ The specific cause of glaucomatous optic neuropathy is presently unknown. Previously, increased IOP was considered to be the sole cause of the damage; however, it is now recognized that IOP is only one of many factors associated with the development

EPIDEMIOLOGY OF OPEN-ANGLE GLAUCOMA

◀ Glaucoma affects up to 3 million individuals in the United States and 66.8 million individuals worldwide, of whom 135,000 in the

and progression of glaucoma.¹⁻¹⁰ Increased susceptibility of the optic nerve to ischemia, a reduced or dysregulated blood flow, excitotoxicity, autoimmune reactions, and other abnormal physiologic processes are likely additional contributory factors. The final outcome of these processes is believed to be apoptosis of the retinal ganglion cells, which results in axonal degeneration, and finally permanent loss of vision.¹¹⁻¹⁶ Interestingly enough, there appears to be a fair amount of similarity between neuronal cell death by apoptosis in Alzheimer’s

disease and glaucoma.¹³ Indeed, open-angle glaucoma may represent a number of distinct diseases or conditions that simply manifest the same symptoms. Susceptibility to visual loss at a given IOP varies considerably; some patients do not demonstrate damage at high IOPs, whereas other patients have progressive visual field loss despite an IOP in the normal range (normal-tension glaucoma).

Although IOP poorly predicts which patients will have visual field loss, the risk of visual field loss clearly increases with increasing IOP within any range. In fact, recent studies have demonstrated that lowering IOP, no matter what the pretreatment IOP, reduces the risk of glaucomatous progression or may even prevent the onset to early glaucoma in patients with ocular hypertension.³⁻⁷

The mechanism by which a certain level of IOP increases the susceptibility of a given eye to nerve damage remains controversial. Multiple mechanisms are likely to be operative in a spectrum of combinations to produce the death of retinal ganglion cells and their axons in glaucoma. Pressure-sensitive astrocytes and other cells in the optic disk supportive matrix may produce changes and remodeling of the disk, resulting in axonal death. Vasogenic theories suggest that optic nerve damage results from insufficient blood flow to the retina secondary to the increased perfusion pressure required in the eye, dysregulated perfusion, or vessel wall abnormalities, and results in degeneration of axonal fibers of the retina. Another theory suggests that the IOP may disrupt axoplasmal flow at the optic disk.

Recently, focus on the mechanisms of the retinal ganglion cell apoptosis and the role of excessive glutamate and nitric oxide found in glaucoma patients has broadened the focus of drug therapy research to include evaluation of agents that act as neuroprotectants.¹²⁻¹⁵ Such agents may be particularly useful in patients with normal-pressure glaucoma, in whom pressure-independent factors may play a relatively larger role in disease progression. These agents would target risk factors and underlying pathophysiologic mechanisms of disease other than IOP.¹¹⁻¹⁶

PATHOPHYSIOLOGY OF OPEN-ANGLE GLAUCOMA

3 As stated previously, optic nerve damage in POAG can occur at a wide range of intraocular pressures, and the rate of progression is highly variable. Patients may exhibit pressures in 20 to 30 mm Hg range for years before any disease progression is noticed in the optic disk or visual fields. That is why open-angle glaucoma is often referred to as the “sneak thief of sight.”

CLINICAL PRESENTATION OF GLAUCOMA

GENERAL

Glaucoma can be detected in otherwise asymptomatic patients, or patients can present with characteristic symptoms, especially vision loss. POAG is a chronic, slowly progressive disease found primarily in patients older than 50 years, while CAG is more typically associated with symptomatic acute episodes.

SYMPTOMS

POAG: None until substantial visual field loss occurs

CAG: Nonsymptomatic or prodromal symptoms (blurred or hazy vision with halos around lights that is caused by a hazy, edematous cornea, and occasionally headache) may be present. Acute episodes produce symptoms associated with a cloudy, edematous cornea, ocular pain or discomfort, nausea, vomiting, abdominal pain, and diaphoresis.

SIGNS

POAG: Disk changes and visual field loss (see Table 94-2); IOP can be normal or elevated (>21 mm Hg)

CAG: Hyperemic conjunctiva, cloudy cornea, shallow anterior chamber, and occasionally an edematous and hyperemic optic disk; IOP is generally elevated markedly (40 to 90 mm Hg) when symptoms are present.

LABORATORY TESTS

None

OTHER DIAGNOSTIC TESTS

Emerging tests include retinal nerve fiber analyzers or confocal scanning laser tomography of the optic nerve.

CLINICAL PRESENTATION OF OPEN-ANGLE GLAUCOMA

POAG is a bilateral, genetically determined disorder constituting 60% to 70% of all glaucomas and 90% to 95% of primary glaucomas (see clinical presentation box). An increased IOP is not required for diagnosis of POAG. Symptoms do not present until substantial visual field constriction occurs. Central visual acuity typically is maintained, even in the late stages of the disease. Even though POAG is a bilateral disease, it may have greater progression and severity in one eye.

4 Detection and diagnosis involve evaluation of the optic disk and retinal nerve fiber layer, assessment of the visual fields, and measurement of IOP. The presence of characteristic disk changes and visual field loss with or without increased IOP confirms the diagnosis of glaucoma. Typical disk changes and field loss occurring at an IOP of less than 21 mm Hg account for 20% to 30% of patients and are referred to as *normal-tension glaucoma*. Elevated IOP (>21 mm Hg) without disk changes or visual field loss is observed in 5% to 7% of individuals (known as *glaucoma suspects*) and is referred to as *ocular hypertension* (OHT). New technologies such as retinal nerve fiber analyzers or confocal scanning laser tomography of the optic nerve head may allow early identification of signs of glaucomatous retinal changes in ocular hypertensives, thus allowing for earlier initiation of therapy.^{1-3,17}

Secondary open-angle glaucoma has many causes, including systemic diseases, trauma, surgery, rubeosis, lens changes, ocular inflammatory diseases, and medications. A system for classifying secondary glaucomas into pretrabecular, trabecular, and posttrabecular forms has been proposed. This classification allows drug therapy to be chosen on the basis of the pathogenic mechanism involved. In pretrabecular forms, a normal meshwork is covered that does not permit aqueous humor outflow. Trabecular forms of secondary glaucoma result from either an alteration of meshwork or an accumulation of material in the intertrabecular spaces. The posttrabecular forms result primarily from disorders causing increased episcleral venous blood pressure.^{1,2,15-17}

PROGNOSIS OF OPEN-ANGLE GLAUCOMA

5 In most cases of POAG, the overall prognosis is excellent when it is discovered early and treated adequately. Even patients with advanced visual field loss can have continued visual field loss reduced if the IOP is maintained at low enough pressures (often <10 to 12 mm Hg). Progression of visual field loss still occurs in 8% to 20% of patients despite reaching standard therapy IOP goals. However, in untreated patients or in those failing to achieve target IOP reduction, up to 80% have continued visual field loss. Estimates of progression

to bilateral blindness in treated patients range from 4% to 22%. Thus the keys to medical treatment of POAG are an effective, well-tolerated drug regimen, close monitoring of therapy, and adherence. Medications will control IOP successfully in 60% to 80% of patients over a 5-year period. Availability of newer, highly effective, well-tolerated agents may improve the prognosis further.^{1,2,5,17-19,23-28}

EPIDEMIOLOGY OF CLOSED-ANGLE GLAUCOMA

The incidence of closed-angle glaucoma varies by ethnic group, with higher incidence in individuals of Inuit, Chinese, and Asian-Indian descent. Incidence rates of 1% to 4% have been reported in these populations.^{1,2}

ETIOLOGY OF CLOSED-ANGLE GLAUCOMA

Primary CAG accounts for 5% or less of primary glaucomas; however, when CAG occurs, it may need to be treated as an emergency to avoid visual loss. CAG results from mechanical blockage of the (usually normal) trabecular meshwork by the peripheral iris. Partial or complete blockage of the meshwork occurs intermittently, resulting in extreme fluctuations between normal IOP with no symptoms, and very high IOP with symptoms of acute CAG. Between attacks of CAG, the IOP is usually normal unless the patient has concomitant open-angle glaucoma or nonreversible blockage of the meshwork with synechiae (“creeping” angle closure) that develops over time in the narrow-angle eye. Primary CAG occurs in patients with inherited shallow anterior chambers, which produce a narrow angle between the cornea and iris or tight contact between the iris and lens (pupillary block). The presence of a narrow angle is determined mainly by visualization of the angle by gonioscopy. Other tests for CAG involve provocation of an angle-closure–induced IOP increase. These tests, which attempt to produce angle closure through mydriasis (darkroom test or mydriasis test), or gravity (prone test), are rarely performed in the clinical setting.

Two major types of classic, reversible primary CAG have been described: CAG with pupillary block and CAG without pupillary block. CAG with pupillary block results when the iris is in firm contact with the lens. This produces a relative block of aqueous flow through the pupil to the anterior chamber (pupillary block), resulting in a bowing forward of the iris, which blocks the trabecular meshwork. CAG with pupillary block occurs most commonly when the pupil is in mid-dilation. In this position, the combination of pupillary block and relaxed iris allows the greatest bowing of the iris; however, angle closure may occur during miosis or mydriasis.

CAG without pupillary block occurs in patients with an abnormality called a *plateau iris*. The ciliary processes in these cases are situated anteriorly, which indent the iris forward and cause closure of the trabecular meshwork, especially during mydriasis. The mydriasis produced by anticholinergic drugs or any other drug results in precipitation of both types of CAG glaucoma, whereas drug-induced miosis may produce pupillary block.

PATHOPHYSIOLOGY OF CLOSED-ANGLE GLAUCOMA

The mechanism of IOP elevation in CAG is clearer than that of POAG. In CAG, a physical blockage of trabecular meshwork is present. In many cases, single or multiple episodes of excessively high IOP (>40 mm Hg) result in optic nerve damage. Very high IOP (>60 mm Hg) may result in permanent loss of visual field within a matter of hours to days.

One type of CAG, known as “creeping” angle closure, occurs in patients with narrow angles in which the iris adheres to the trabecular meshwork and may result in continuously increased IOP in ranges more similar to those of POAG, and the clinical behavior is similar to POAG, with individuals differing in the degree and rapidity of visual loss from any given elevated IOP.¹

CLINICAL PRESENTATION OF CLOSED-ANGLE GLAUCOMA

Patients with untreated CAG typically experience intermittent non-symptomatic or prodromal symptoms brought on by precipitating events (see clinical presentation box). Increased IOP during such prodromal episodes is not great enough or long enough to produce the other symptoms of a full-blown attack. Such prodromal attacks last 1 to 2 hours, at which time pupillary block is broken by further mydriasis or miosis; or when miosis or mydriasis occurs in patients with plateau iris. The rate at which IOP increases may be a determinant of when full-blown symptoms occur. Visual fields demonstrate generalized constriction or typical glaucomatous defects. In prolonged attacks, total loss of vision may occur if the IOP is high enough. Tonometry reveals IOPs as high as 40 to 90 mm Hg. Patients who have developed adhesions between the iris and meshwork (anterior synechiae) may have chronic IOP elevation with intermittent spikes of high IOP when angle closure occurs.

DRUG-INDUCED GLAUCOMA

A number of medications have been associated with increased IOP or carry labeling that cautions against use of the medication in glaucoma patients. The potential for a medication to produce or worsen glaucoma depends on the type of glaucoma and whether or not the patient is treated adequately.²⁵

Patients with treated, controlled POAG are at minimal risk of induction of an increase in IOP by systemic medications with anticholinergic properties or vasodilators; however, in patients with untreated glaucoma or uncontrolled POAG, the potential of these medications to increase IOP should be considered. Topical anticholinergic agents used to produce mydriasis may result in an increase in IOP. Potent anticholinergic agents such as atropine or homatropine are most likely to increase IOP. Weaker anticholinergics, such as tropicamide, that produce less cycloplegia are less likely to increase IOP and are favored, along with phenylephrine, when mydriasis is desired in POAG patients. Inhaled, nasal, topical, or systemic glucocorticoids may increase IOP in both normal individuals and patients with POAG.

Patients with POAG appear to be particularly susceptible to glucocorticoid-induced increases in IOP. Glucocorticoids reduce the facility of aqueous humor outflow through the trabecular meshwork. The decreased facility of outflow appears to result from the accu-

TABLE 92–3. Drugs That May Induce or Potentiate Increased Intraocular Pressure

Open-angle glaucoma

Ophthalmic corticosteroids (high risk)
Systemic corticosteroids

Venlafaxine
Topiramate
Tetracyclines (low risk)
Carbonic anhydrase inhibitors (low risk)
Monoamine oxidase inhibitors (low risk)
Topical cholinergics (low risk)

mulation of extracellular material blocking the trabecular channels. The potential of a glucocorticoid to increase IOP is related to its anti-inflammatory potency and intraocular penetration. Thus patients should be treated with the lowest potency and dose and for the shortest time possible when steroids are indicated.

In patients predisposed to CAG (i.e., narrow anterior chambers), angle closure may be produced by any drug that causes mydriasis (e.g., anticholinergics). A wide range of sulfa compounds cause idiosyncratic reactions that result in anterior choroidal effusions with anterior movement of the iris and lens, resulting in angle closure. The topical use of anticholinergics or sympathomimetic agents most likely will result in angle closure. Systemic and inhaled anticholinergic and sympathomimetic agents also must be used with caution in such patients. As discussed previously, potent miotic agents such as echothiophate may produce angle closure by increasing pupillary block. Drugs associated with potentiation of glaucoma are listed in Table 92–3.

► TREATMENT: Ocular Hypertension

Treatment of the patient with possible glaucoma (ocular hypertension; i.e., patients with IOP >22 mm Hg) is less controversial than it was in the past, with the recent results of the Ocular Hypertensive Treatment Study (OHTS).³ The OHTS helped to identify risk factors for treatment. Patients with intraocular pressures higher than 25 mm Hg, vertical cup:disk ratio of more than 0.5, and central corneal thickness of less than 555 micrometers are at greater risk for developing glaucoma. Risk factors such as family history of glaucoma, black ethnicity, severe myopia, and patients with only one eye must also

be taken into consideration when deciding which individuals need treatment.

Patients without risk factors typically are not treated and are monitored for the development of glaucomatous changes. Patients with significant risk factors usually will be treated with a well-tolerated topical agent such as a β -blocking agent, an α_2 -agonist (brimonidine), a topical carbonic anhydrase inhibitor (CAI), or a prostaglandin analog, depending on individual patient characteristics. Optimally, therapy is initiated in one eye to assess efficacy and tolerance. Use of second- or

third-line agents (e.g., pilocarpine or epinephrine) when first-line agents fail to reduce IOP depends on the risk-benefit assessment of each patient. The cost, inconvenience, and frequent adverse effects of combination therapies, anticholinesterase inhibitors, and oral CAIs result in an unfavorable risk-benefit ratio in patients with possible glaucoma.²⁹

The goal of therapy is to lower the IOP to a level associated with a decreased risk of optic nerve damage, usually at least a 20% if not a 25% to 30% decrease from the baseline IOP. Greater decreases may be required in high-risk patients or those with higher

initial IOPs. Drug therapy should be monitored by measurement of IOP, examination of the optic disk, assessment of the visual fields, and evaluation of the patient for drug adverse effects and compliance with therapy. Patients who are unresponsive to or intolerant of a drug should be switched to an alternative agent rather than given an additional drug. Many clinicians prefer to discontinue all medications in patients failing to respond adequately to simple topical therapy, closely monitor for development of disk changes or visual field loss, and treat again when such changes occur.^{1,2,17–19,29}

▶ TREATMENT: Open-Angle Glaucoma

All patients with elevated IOP and characteristic optic disk changes and/or visual field defects not due to other factors (i.e., glaucoma by definition) should be treated. Recent findings that one in five patients with “normal” IOP and glaucomatous retinal nerve findings (i.e., normal-tension glaucoma) do not have progression of visual field loss if left untreated have prompted recommendations to monitor normal-tension glaucoma patients without immediate threat of loss of central vision, and treat only when progression is documented. Some controversy exists as to whether the initial therapy of glaucoma should be surgical trabeculectomy (filtering procedure), argon laser trabeculectomy, or medical therapy.^{1,2,17,18} Presently, drug therapy remains the most common initial treatment modality.

Drug therapy of patients with documented glaucomatous change with either elevated or normal IOP is initiated in a stepwise manner (Fig. 92–5), starting with lower concentrations of a single well-tolerated topical agent. The goal of therapy is to prevent further visual loss. A “target” IOP is chosen based on a patient baseline IOP and the amount of existing visual field loss. Typically, an initial target IOP reduction of 30% is desired. Greater reductions may be desired in patients with very high baseline IOPs or advanced visual field loss. Patients with normal baseline IOPs (normal-tension glaucoma) may have target IOPs of less than 10 to 12 mm Hg.

CLINICAL CONTROVERSY

How much should the IOP be reduced in patients who may have POAG? Although the major clinical trial (OHTS³) required a 20% reduction in IOP for patients with ocular hypertension, many clinicians believe a further lowering of IOP may be more beneficial in preventing the progression of ocular hypertension to glaucoma. The American Academy of Ophthalmology (AAO) Preferred Practice Guidelines suggest 20% to 30% IOP lowering. It remains to be seen if a more aggressive approach earlier in the treatment of the POAG suspect would be more beneficial.

■ PHARMACOTHERAPEUTIC APPROACH

6 Medications most commonly used to treat glaucoma are the nonselective β -blockers, the prostaglandin analogs (latanoprost, travoprost, and bimatoprost), brimonidine (an α_2 -agonist), and the fixed combination product of timolol and dorzolamide.^{21–22}

Before 1996, a β -blocker was used provided no contraindications existed, because this class of drugs has a long history of successful use, providing a combination of clinical efficacy and tolerability. The newer agents, in particular the prostaglandin analogs, brimonidine, and topical CAIs, are also considered suitable first-line therapy or

alternative initial therapy in patients with contraindications to or other concerns with β -blockers (see Fig. 92–5). Pilocarpine and epinephrine (or dipivefrin) are used commonly as third-line therapies because of their increased frequency of adverse effects or reduced efficacy.

Therapy optimally is started as a single agent in one eye (except in patients with very high IOP or advanced visual field loss) to evaluate drug efficacy and tolerance. Monitoring of therapy should be individualized: Initial response to therapy is typically done 4 to 6 weeks after the medication is started. A monocular trial of medication is recommended when possible. Once IOPs reach acceptable levels, the IOP is monitored every 3 to 4 months (more frequently after any change in drug therapy).

Visual fields and disk changes are typically monitored annually, or earlier if the glaucoma is unstable or there is suspicion of disease worsening. Patients should always be questioned regarding adherence to and tolerance of prescribed therapy. Initial IOP response does not predict long-term IOP control. Using more than one drop per dose does not improve response, but increases the likelihood of adverse effects and the cost of therapy. When using more than one medication, separation of drop instillation of each agent by at least 5 to 10 minutes is suggested to provide optimal ocular contact for each agent.

The value of an agent with which the patient has shown a drop in IOP following an initial response can be measured by discontinuing the medication completely and determining if an increase in IOP occurs. Patients responding to but intolerant of initial therapy may be switched to another drug or to an alternative dosage form of the same medication. For patients failing to respond to the highest tolerated concentrations of an initial drug, a switch to an alternative agent after 1 day of concurrent therapy should be considered. Alternatively, if only a partial response occurs, addition of another topical drug to be used in combination is a possibility. A number of drugs or drug combinations may need to be tried before an effective and well-tolerated regimen is identified. Because of the frequency of adverse effects, carbachol, topical cholinesterase inhibitors, and oral CAIs are considered last-line agents to be used in patients who fail less toxic combination topical therapy.

CLINICAL CONTROVERSY

The AAO has not designated any agent as the drug of choice for initiation of glaucoma treatment. Many clinicians in recent years have used the prostaglandin analogs because they are dosed once daily and achieve the best pressure reduction. However, others believe that even though the β -blockers are less potent in reducing IOP, they should still be used as initial agents because they are dosed once or twice daily, and are available as generic products and are therefore more cost effective.

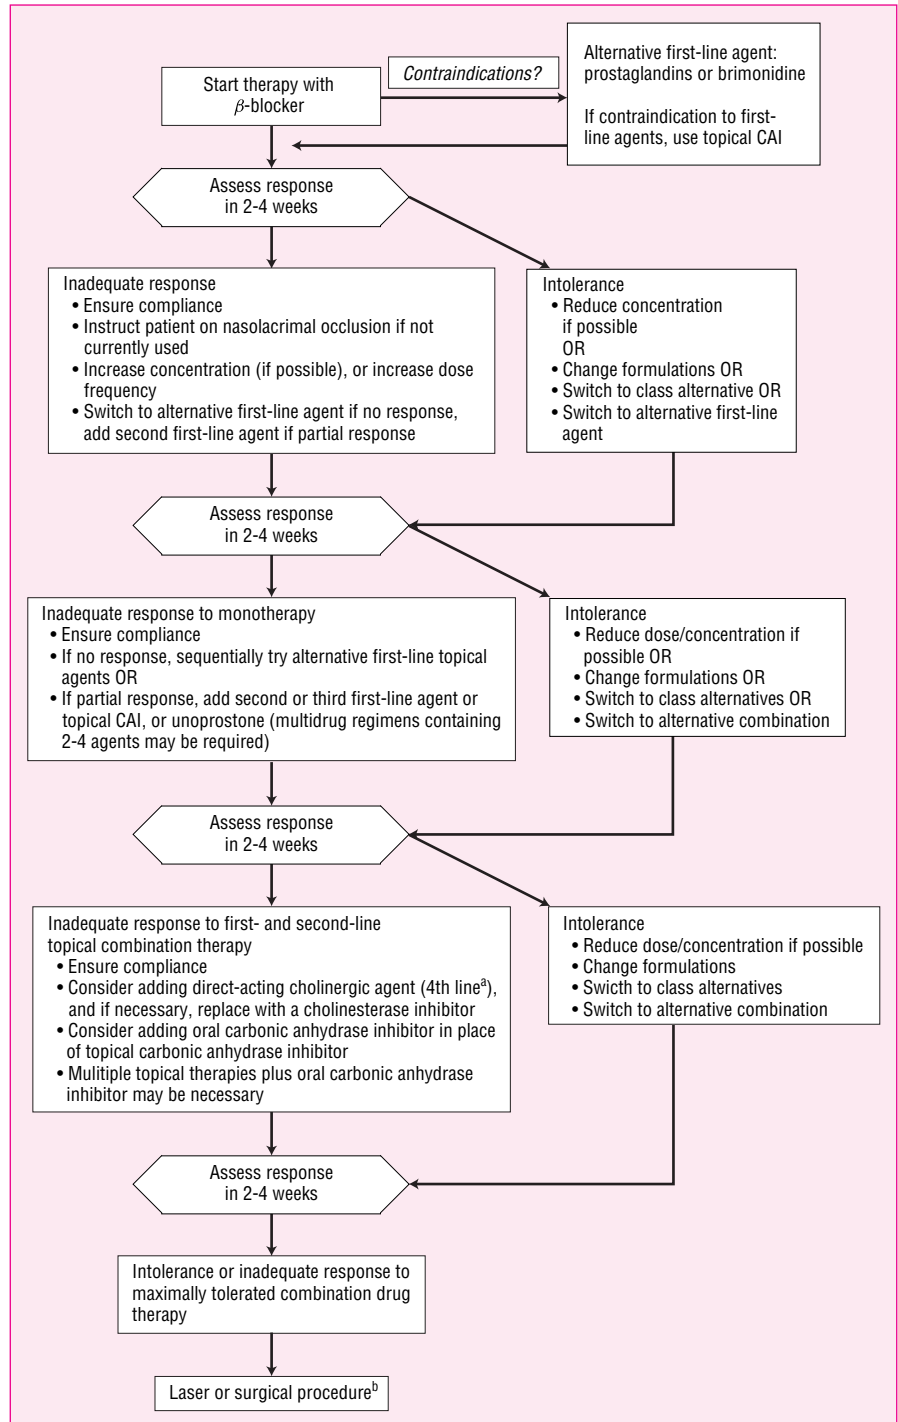

FIGURE 92–5. Algorithm for the pharmacotherapy of open-angle glaucoma.
^aFourth-line agents not commonly used any longer.
^bMost clinicians believe laser procedure should be performed earlier (e.g., after 3 drug maximum, poorly adherent patient).

NONPHARMACOLOGIC THERAPY: LASER AND SURGICAL PROCEDURES

When drug therapy fails, is not tolerated, or is excessively complicated, surgical procedures such as laser trabeculoplasty (argon [ALT] or selective [SLT]) or a surgical trabeculectomy (filtering procedure) may be performed to improve outflow. Laser trabeculoplasty is usually an intermediate step between drug therapy and trabeculectomy. Procedures with higher complication rates, such as those involving place-

ment of draining tubes or destruction of the ciliary body (cyclodestruction), may be required when other methods fail^{1,2,25} (see Fig. 92–2). Surgical methods for reduction of IOP involve the creation of a channel through which aqueous humor can flow from the anterior chamber to the subconjunctival space (filtering bleb), where it is reabsorbed by the vasculature. A major reason for failure of the procedure is healing and scarring of the site. Modification of the healing process to maintain patency is possible with the use of antiproliferative agents. The antiproliferative agents 5-fluorouracil and mitomycin C are used in patients undergoing

glaucoma-filtering surgery to improve success rates by reducing the inflammatory response and fibroblast proliferation. Although used most commonly in patients with increased risk for suboptimal

surgical outcome (after cataract surgery and a previous failed filtering procedure), use of these agents also improves success in low-risk patients.^{30–33}

► TREATMENT: Closed-Angle Glaucoma

The goal of initial therapy for acute CAG with high IOP is rapid reduction of the IOP to preserve vision and to avoid surgical or laser iridectomy on a hypertensive, congested eye. Iridectomy (laser or surgical) is the definitive treatment of CAG; it produces a hole in the iris that permits aqueous humor flow to move directly from the posterior chamber to the anterior chamber, opening up the block at the trabecular meshwork. Drug therapy of an acute attack typically involves administration of pilocarpine, hyperosmotic agents, and a secretory inhibitor (a β -blocker, α_2 -agonist, prostaglandin $F_{2\alpha}$ analog, or a topical or systemic CAI). With miosis produced by pilocarpine, the peripheral iris is pulled away from the meshwork. Although traditionally the drug of choice, pilocarpine used as initial therapy is controversial. Miotics may worsen angle closure by increasing pupillary block and producing anterior movement of the lens because of drug-induced accommodation.

At IOPs greater than 60 mm Hg, the iris may be ischemic and unresponsive to miotics; as the pressure drops and the iris responds, miosis occurs. During this time, the urge to use excessive amounts of pilocarpine must be resisted. The dose of pilocarpine commonly used is a 1% or 2% solution instilled every 5 minutes for two or three doses and then every 4 to 6 hours. However, many practitioners withhold application of pilocarpine until the IOP has been reduced by other

agents, and then apply a single drop of 1% to 2% pilocarpine to produce miosis. In either case, the unaffected contralateral eye should be treated with the miotic every 6 hours to prevent development of angle closure. An osmotic agent also commonly is administered because these drugs produce the most rapid decrease in IOP. Oral glycerin 1 to 2 g/kg can be used if an oral agent is tolerated; if not, intravenous mannitol 1 to 2 g/kg should be used. Osmotic agents reduce IOP by withdrawing water from the eye secondary to the osmotic gradient between the blood and the eyes. These drugs are among the first-line agents in the short-term treatment of CAG or other forms of acute very high IOP elevations. Topical corticosteroids often are used to reduce the ocular inflammation and reduce the development of synechiae in CAG eyes. In classic CAG, once the IOP is controlled, pilocarpine may be given every 6 hours until iridectomy is performed. Patients failing therapy altogether will require an emergency iridectomy.

Peripheral iridectomy essentially “cures” primary CAG without significant synechiae. Long-term drug therapy is not used unless IOP remains high due to the presence of synechiae blocking the trabecular meshwork or concurrent POAG. In such cases, the pharmacotherapeutic approach is essentially identical to that for the POAG patient, or laser or surgical procedures are performed.^{1,2}

PHARMACOLOGIC AGENTS USED IN GLAUCOMA

β -BLOCKING DRUGS

The topical β -blocking agents are one of the most commonly used antiglaucoma medications (Table 92–4). β -Blockers lower IOP by 20% to 30% with a minimum of local ocular adverse effects. These are commonly the agents of first choice in treating POAG if no contraindications exist.^{1,2,17–19,34–36}

The β -blocking agents produce ocular hypotensive effects by decreasing the production of aqueous humor by the ciliary body without producing substantial effects on aqueous humor outflow facility. The mechanism by which β -blockers decrease aqueous humor inflow remains controversial, but it is most frequently attributed to β_2 -adrenergic receptor blockade in the ciliary body.

Five ophthalmic β -blockers are presently available: timolol, levobunolol, metipranolol, carteolol, and betaxolol. Timolol, levobunolol, and metipranolol are nonspecific β -blocking agents, whereas betaxolol is a relatively β_1 -selective agent. Carteolol is a nonspecific blocker with intrinsic sympathomimetic activity (ISA). Despite differences in potency, selectivity, lipophilicity, and ISA, the five agents reduce IOP to a similar degree, although betaxolol has been reported to produce somewhat less lowering of IOP than timolol and levobunolol. Levobunolol may be more effective than timolol and betaxolol in reducing post-cataract surgery IOP increases. Levobunolol solution is more effective in controlling IOP than other agents when given as aqueous solutions on a once-daily schedule (up to 70% of patients). Timolol in the form of a gel-forming solution (Timoptic-XE) provides equivalent IOP control with once-daily administration when compared with the same concentration of the

aqueous solution administered twice daily. The choice of a specific β -blocking agent generally is based on differences in adverse-effect potential, individual patient response, and cost. Long-term treatment with topical β -blockers results in tachyphylaxis in 20% to 25% of patients. The mean IOP reduction from baseline may be smaller in patients receiving topical β -blockers with concurrent systemic β -blockers.²⁹

Local adverse effects with β -blockers usually are tolerable, although stinging on application occurs commonly, particularly with betaxolol solution (less with betaxolol suspension) and metipranolol. Other local effects include dry eyes, corneal anesthesia, blepharitis, blurred vision, and rarely, conjunctivitis, uveitis, and keratitis. Some local reactions may be a result of preservatives used in the commercially available products. Switching from one agent to another or switching the type of formulation may improve tolerance in patients experiencing local adverse effects.

Systemic effects are the most important adverse effects of β -blockers. Drug absorbed systemically may produce decreased heart rate, reduced blood pressure, negative inotropic effects, conduction defects, bronchospasm, central nervous system effects, and alteration of serum lipids, and may block the symptoms of hypoglycemia. The β_1 -specific agents betaxolol and possibly carteolol (due to ISA) are less likely to produce the systemic adverse effects caused by β -adrenergic blockade, such as the cardiac effects and bronchospasm, but a real risk still exists. The use of timolol as a gel-forming liquid or betaxolol as a suspension allows for administration of less drug per day, and therefore reduces the chance for systemic adverse effects compared with the aqueous solutions.

Because of their systemic adverse effects, all ophthalmic β -blockers should be used with caution in patients with pulmonary

TABLE 92–4. Topical Drugs Used in the Treatment of Open-Angle Glaucoma

| Drug | Pharmacologic Properties | Common Brand Names | Dose Form | Strength (%) | Usual Dose ^a | Mechanism of Action |
|--|--|--------------------------------------|------------------|--------------------------------|--|--|
| β-Adrenergic blocking agents | | | | | | |
| Betaxolol | Relative β_1 -selective | Generic | Solution | 0.5 | 1 drop twice a day | All reduce aqueous production of ciliary body |
| | | Betoptic-S | Suspension | 0.25 | 1 drop twice a day | |
| Carteolol | Nonselective, ISA | Generic | Solution | 1 | 1 drop twice a day | |
| Levobunolol | Nonselective | Betagan | Solution | 0.25, 0.5 | 1 drop twice a day | |
| Metipranolol | Nonselective | OptiPranolol | Solution | 0.3 | 1 drop twice a day | |
| Timolol | Nonselective | Timoptic, Betimol | Solution | 0.25, 0.5 | 1 drop every day—one to two times a day | 1 drop every day ^a |
| | | Timoptic-XE | Gelling solution | 0.25, 0.5 | | |
| Nonspecific adrenergic agonists | | | | | | |
| Dipivefrin | Prodrug | Propine | Solution | 0.1 | 1 drop twice a day | Increased aqueous humor outflow |
| α_2-Adrenergic agonists | | | | | | |
| Apraclonidine | Specific α_2 -agonists | Iopidine | Solution | 0.5, 1 | 1 drop two to three times a day | Both reduce aqueous humor production; brimonidine known to also increase uveoscleral outflow |
| Brimonidine | | Alphagan P | Solution | 0.15 | 1 drop two to three times a day | |
| Cholinergic agonists | | | | | | |
| Direct-acting | | | | | | |
| Carbachol | Irreversible | Carboptic, Isopto Carbachol | Solution | 0.75, 1.5, 2.25, 3 | 1 drop two to three times a day | All increase aqueous humor outflow through trabecular meshwork |
| Pilocarpine | Irreversible | Isopto Carpine, Pilocar, Pilopine HS | Solution | 0.25, 0.5, 1, 2, 4, 6, 8, 10 | 1 drop two to three times a day 1 drop four times a day | |
| | | | Gel | 4 | Every 24 h at bedtime | |
| Cholinesterase inhibitors | | | | | | |
| Echothiophate | | Phospholine iodide | Solution | 0.125 | Once or twice a day | |
| Carbonic anhydrase inhibitors | | | | | | |
| Topical | | | | | | |
| Brinzolamide | Carbonic anhydrase type II inhibition | Azopt | Suspension | 1 | Two to three times a day | All reduce aqueous humor production of ciliary body |
| Dorzolamide | | Trusopt | Solution | 2 | Two to three times a day | |
| Systemic | | | | | | |
| Acetazolamide | | Generic | Tablet | 125 mg, 250 mg | 125–250 mg two to four times a day | |
| | | | Injection | 500 mg/vial | 250–500 mg | |
| | | Diamox Sequels | Capsule | 500 mg | 500 mg twice a day | |
| Dichlorphenamide | | Daranide | Tablet | 50 mg | 25–50 mg one to three times a day | |
| Methazolamide | | Generic | Tablet | 25 mg, 50 mg | 25–50 mg two to three times a day | |
| Prostaglandin analogs | | | | | | |
| Latanoprost | Prostaglandin F _{2α} analog | Xalatan | Solution | 0.005 | 1 drop every night | Increases aqueous uveoscleral outflow and to a lesser extent trabecular outflow |
| Bimatoprost | Prostamide analog | Lumigan | Solution | 0.03 | 1 drop every night | |
| Travoprost | | Travatan | Solution | 0.004 | 1 drop every night | |
| Combinations | | | | | | |
| Timolol-dorzolamide | | Cosopt | Solution | Timolol 0.5% Dorzolamide 2% | 1 drop twice daily | |

^aUse of nasolacrimal occlusion will increase number of patients successfully treated with longer dosage intervals.

ISA, Intrinsic sympathomimetic activity.

diseases, sinus bradycardia, second- or third-degree heart block, congestive heart failure, atherosclerosis, diabetes, and myasthenia gravis, as well as in patients receiving oral β -blocker therapy. Use of nasolacrimal occlusion (NLO; see section on patient education for description) technique during administration reduces the risk or severity

of systemic adverse effects as well as optimizes response. Overall, β -adrenergic blocking agents are well tolerated by most patients, and most potential problems can be avoided by appropriate patient evaluation, drug choice, and monitoring of drug therapy. In patients failing or having an inadequate response to single-drug therapy with a

β -blocking agent, the addition of a CAI, parasympathomimetic agent, prostaglandin analog, or an α_2 -adrenergic receptor agonist usually will result in additional IOP reduction. Epinephrine or dipivefrin added to a β -blocking agent (particularly nonspecific β -blockers) usually results in only minimal additional IOP reduction.^{1–3,17–19,29}

α_2 -ADRENERGIC AGONISTS

Brimonidine and the less lipid-soluble and less receptor-selective apraclonidine are α_2 -adrenergic agonists structurally similar to clonidine. Apraclonidine is indicated and brimonidine is effective for prevention or control of postoperative or postlaser treatment increases in IOP, and both are indicated in the treatment of open-angle glaucoma. Brimonidine is considered a first-line or adjunctive agent in the therapy of POAG, and apraclonidine is seen as a second-line or adjunctive therapy.

Use of apraclonidine has fallen dramatically because of a high incidence of loss of control of IOP (tachyphylaxis) and a more severe and prevalent ocular allergy rate.

α_2 -Agonists reduce IOP by decreasing the rate of aqueous humor production (some increase in uveoscleral outflow also occurs with brimonidine). The drugs reduce IOP by 18% to 27% at peak (2 to 5 hours) and by 10% at 8 to 12 hours. Comparative trials demonstrate a reduction in IOP similar to that obtained with 0.5% timolol. Use of brimonidine 0.2% every 8 to 12 hours appears to provide maximum IOP-lowering effects in long-term use. Use of NLO (see section on patient education, below) may improve response and allow the longer dosing frequency (i.e., every 12 hours). Combinations of α_2 -agonists with β -blockers, prostaglandin analogs, or CAIs produce additional IOP reduction.

An allergic-type reaction characterized by lid edema, eye discomfort, foreign-object sensation, itching, and hyperemia occurs in approximately 30% of patients with apraclonidine. Brimonidine produces this adverse effect in up to 8% of patients. This reaction commonly necessitates drug discontinuation. Systemic adverse effects with brimonidine include dizziness, fatigue, somnolence, dry mouth, and possibly a slight reduction in blood pressure and pulse. α_2 -Agonists should be used with caution in patients with cardiovascular diseases, renal compromise, cerebrovascular disease, and diabetes, as well as in those taking antihypertensives and other cardiovascular drugs, monoamine oxidase inhibitors, and tricyclic antidepressants.

Brimonidine is also contraindicated in infants because of apneic spells and hypotensive reactions. In terms of overall efficacy and tolerability, brimonidine approximates that achieved with β -blockers.^{1,2,17–19,29}

Brimonidine-purite 0.15% is a formulation of brimonidine in a lower concentration than the original product, and it contains a less toxic preservative than the most commonly employed benzalkonium chloride. The newer formulation is as effective as the original because the more neutral pH of brimonidine-purite allows for higher concentrations of brimonidine in the aqueous humor.²⁹

CLINICAL CONTROVERSY

Many animal trials demonstrate that brimonidine has excellent neuroprotective properties.^{12–15} Some clinicians believe that one of the major advantages of using brimonidine lies in its potential neuroprotective properties. However, neuroprotection has not been demonstrated in human trials.

PROSTAGLANDIN ANALOGS

The prostaglandin analogs, including latanoprost, travoprost, bimatoprost, and unoprostone, reduce IOP by increasing the uveoscleral and to a lesser extent trabecular outflow of aqueous humor. Some differences in receptor sites and mechanisms of action may exist between the two prostaglandins (latanoprost and travoprost), the prostamide (bimatoprost), and the docosanoid (unoprostone) classes. Bimatoprost may be slightly more effective in lowering IOP, getting a larger percentage of patients to lower IOPs, and in patients unresponsive to latanoprost.^{29,37–39}

Reduction in IOP with once-daily doses of prostaglandin $F_{2\alpha}$ analogs (a 25% to 35% reduction) is often greater than that seen with timolol 0.5% twice daily. In addition, nocturnal control of IOP is improved compared with timolol. Interestingly, administration of prostaglandin $F_{2\alpha}$ analogs twice daily may reduce the IOP comparably to once-daily dosing. The drugs are administered at nighttime, although they are probably as effective if given in the morning.

Unoprostone 0.15% reduces IOP somewhat less than prostaglandin analogs and requires twice-daily administration. Prostaglandin analogs are well tolerated and produce fewer systemic adverse effects than timolol. Local ocular tolerance generally is good, but ocular reactions such as punctate corneal erosions and conjunctival hyperemia do occur. Local intolerance occurs in 10% to 25% of patients with these agents.

With prostaglandin analogs, altered iris pigmentation occurs in 15% to 30% of patients, particularly those with mixed-color irises (blue-brown, green-brown, blue-gray-brown, or yellow-brown eyes), which become more brown in color over 3 to 12 months. The change in iris pigmentation will often appear within 2 years, and long-term consequences of this pigment change appear to be mostly cosmetic. Hypertrichosis and increased eyelash pigmentation also have been reported.

These agents have been associated with uveitis, and caution is recommended in patients with ocular inflammatory conditions. Cystoid macular edema also has been reported. Cases of worsening of herpetic keratitis have been reported.

Prostaglandin analogs can be used in combination with other antiglaucoma agents for additional IOP control, due to their unique mechanism of action. Given their excellent efficacy and side-effect profile, prostaglandin analogs provide effective monotherapy or adjunctive therapy in patients not responding to or tolerating other agents. Many glaucoma experts have advocated the use of prostaglandin analogs as first-line therapy in POAG. Long-term studies of these agents are ongoing, but they appear to be safe, efficacious, and well tolerated in glaucoma therapy. The present role of unoprostone is not well delineated.^{17–19,29,37,38}

CARBONIC ANHYDRASE INHIBITORS

TOPICAL AGENTS

CAIs reduce IOP by decreasing ciliary body aqueous humor secretion. CAIs appear to inhibit aqueous production by blocking active secretion of sodium and bicarbonate ions from the ciliary body to the aqueous humor.^{1,2,29} Topical CAIs such as dorzolamide and brinzolamide are well tolerated and are indicated for monotherapy or adjunctive therapy of open-angle glaucoma and ocular hypertension. Relatively specific inhibitors of carbonic anhydrase enzyme II such as dorzolamide and brinzolamide reduce IOP by 15% to 26%.

Topical CAIs generally are well tolerated. Local adverse effects include transient burning and stinging, ocular discomfort and transient blurred vision, tearing, and rarely, conjunctivitis, lid reactions, and photophobia. A superficial punctate keratitis occurs in 10% to 15% of patients. Brinzolamide produces more blurry vision but is less stinging than dorzolamide. Systemic adverse effects are unusual despite the accumulation of drug in red blood cells. Because of their favorable adverse-effect profile, topical CAIs provide a useful alternative agent for monotherapy or adjunctive therapy in patients with inadequate response to or who are unable to use other agents. The drugs may add additional IOP reduction in patients using other single or multiple topical agents. The usual dose of a topical CAI is one drop every 8 to 12 hours. Administration every 12 hours produces somewhat less IOP reduction than administration every 8 hours. Use of NLO should optimize response to CAI given at any interval.^{1,2,17–19,29,34,36} The combination product timolol 0.5% and dorzolamide 2% (Cosopt) is dosed twice daily and produces equivalent IOP lowering to each product dosed separately.

SYSTEMIC AGENTS

Systemic CAIs are indicated in patients failing to respond to or tolerate maximum topical therapy. Systemic and topical CAIs should not be used in combination because no data exist concerning improved IOP reduction, and the risk for systemic adverse effects is increased. Oral CAIs reduce aqueous humor inflow by 40% to 60% and IOP by 25% to 40%. The available systemic CAIs (see Table 92–4) produce equivalent IOP reduction but differ in potency, adverse effects, dosage forms, and duration of action. Despite their excellent effects on elevated IOP of any etiology, the systemic CAIs frequently produce intolerable adverse effects. As a result, CAIs are considered third-line agents in the treatment of POAG.

On average, only 30% to 60% of patients are able to tolerate oral CAI therapy for prolonged periods. Intolerance to CAI therapy results most commonly from a symptom complex attributable to systemic acidosis and including malaise, fatigue, anorexia, nausea, weight loss, altered taste, depression, and decreased libido. Other adverse effects include renal calculi, increased uric acid, blood dyscrasias, diuresis, and myopia. Elderly patients do not tolerate CAIs as well as younger patients. The three available CAIs produce the same spectrum of adverse effects; however, the drugs differ in the frequency and severity of the adverse effects listed. Acetazolamide (standard or sustained-release capsules) and methazolamide are considered the best-tolerated CAIs.

CAIs should be used with caution in patients with sulfa allergies (all CAIs, topical or systemic, contain sulfonamide moieties), sickle-cell disease, respiratory acidosis, pulmonary disorders, renal calculi, electrolyte imbalance, hepatic disease, renal disease, diabetes mellitus, or Addison's disease. Concurrent use of a CAI and a diuretic may rapidly produce hypokalemia. High-dose salicylate therapy may increase the acidosis produced by CAIs, whereas the acidosis produced by CAIs may increase the toxicity of salicylates.^{1,2,17–19,21,29,34,35}

PARASYMPATHOMIMETIC AGENTS

The parasympathomimetic (cholinergic) agents reduce IOP by increasing aqueous humor trabecular outflow. The increase in outflow is a result of physically pulling open the trabecular meshwork secondary to ciliary muscle contraction, thereby reducing resistance to outflow. These agents may reduce uveoscleral outflow. Cholinergics agents work well to decrease IOP, but their use as primary or even adjunctive agents in the treatment of glaucoma has decreased

significantly because of local ocular adverse effects and/or frequent dosing requirements.
