Pilocarpine, the parasympathomimetic agent of choice in POAG, is available as an ophthalmic solution, an ocular insert, and a hydrophilic polymer gel (see Table 92–4). Pilocarpine produces similar (20% to 30%) reductions in IOP as those seen with β -blocking agents. Pilocarpine in POAG or “glaucoma suspects” is initiated as 0.5% or 1% solution, one drop three to four times daily. The use of NLO improves response and reduces the need for an every-6-hour dosing frequency. Use of one drop of 2% pilocarpine every 6 to 12 hours and NLO provides optimal response in many patients. Both drug concentration and frequency may be increased if IOP reduction is inadequate. Patients with darkly pigmented eyes frequently require higher concentrations of pilocarpine than patients with lightly pigmented eyes. Concentrations of pilocarpine above 4% rarely improve IOP control in patients other than those with darkly pigmented eyes.

Pilocarpine 4% gel (Pilopine HS) once daily is equivalent to treatment with pilocarpine solution 4% four times daily or timolol 0.5% twice daily. When using every-24-hour dosing of pilocarpine gel, the adequacy of IOP control late in the dosing interval should be confirmed. Ocular adverse effects of pilocarpine include miosis, which decreases night vision and vision in patients with central cataracts. Visual field constriction may be seen secondary to miosis and should be considered when evaluating visual field changes in a glaucoma patient. Pilocarpine ciliary muscle contraction produces accommodative spasm, particularly in young patients still able to accommodate (prepresbyopic). Pilocarpine also may produce frontal headache, brow ache, periorbital pain, eyelid twitching, and conjunctival irritation or injection early in therapy, which tends to decrease in severity over 3 to 5 weeks of continued therapy.

Cholinergics produce a breakdown of the blood–aqueous humor barrier and may result in a worsening of an ocular inflammatory reaction or condition. Systemic cholinergic adverse effects of pilocarpine—such as diaphoresis, nausea, vomiting, diarrhea, cramping, urinary frequency, bronchospasm, and heart block—are rare but may be seen in patients using products with high pilocarpine concentrations (6% to 8%), or those using such products overzealously in treatment of acute angle closure. Other adverse effects associated with direct-acting miotics include retinal tears or detachment, allergic reaction, permanent miosis, cataracts, precipitation of CAG, and rarely, miotic cysts of the pupillary margin.

Carbachol is a potent direct-acting miotic agent; its duration of action is longer than that of pilocarpine (8 to 10 hours) because of resistance to hydrolysis by cholinesterases. This drug also may act as a weak inhibitor of cholinesterase. Patients with an inadequate response to or intolerance of pilocarpine as a result of ocular irritation or allergy frequently do well on carbachol. The ocular and systemic adverse effects of carbachol are similar to but more frequent, constant, and severe than those of pilocarpine.^{1,2,17–19,29,34,35}

The cholinesterase inhibitors used most commonly in the treatment of POAG are the long-acting, relatively irreversible agents demecarium and echothiophate (limited commercial availability; see Table 92–4). These agents are potent inhibitors of pseudocholinesterase, but they also inhibit true cholinesterase. Because of the serious ocular and systemic toxic effects of these agents, the cholinesterase inhibitors are reserved primarily for patients not responding to or those intolerant of other therapy. Because of their cataractogenic properties, most ophthalmologists use these agents only in patients without lenses (aphakia) or those with artificial lenses (pseudophakia). The ocular and periocular parasympathomimetic adverse effects are more common and more severe than with pilocarpine or carbachol.

In addition to the parasympathomimetic effects, the cholinesterase inhibitors may produce severe fibrinous iritis (particularly with the irreversible inhibitors), synechiae, iris cysts, conjunctival thickening, and occlusion of the nasolacrimal ducts. Cataracts occur at high frequency with the use of cholinesterase inhibitors, particularly echothiophate, after about 10 to 18 months of therapy. The incidence of cataracts appears to increase with increasing concentration, with up to 60% of patients developing cataracts at higher concentrations. The inhibition of systemic pseudoacetylcholinesterase by these agents decreases the rate of succinylcholine hydrolysis, resulting in prolonged muscle paralysis. Cholinesterase inhibitors should be discontinued at least 2 weeks before procedures in which succinylcholine is to be used.

The role of cholinesterase inhibitors in glaucoma is limited by the frequency and potential toxicity of these agents. In phakic patients, cholinesterase inhibitors should be administered only if intolerance or failure results with other antiglaucoma medications. Cholinesterase inhibitors have been shown to provide additional IOP-lowering effects when used with β -blockers, CAIs, and sympathomimetic (adrenergic) agents. As with all agents for glaucoma, therapy should be initiated with lower concentrations of these agents. A once-daily administration frequency should be used in most patients unless very high IOP is present.

Use of NLO likely improves response and reduces systemic adverse effects and should be performed by all patients administering cholinesterase inhibitors. These agents should be used with caution in patients with asthma, retinal detachments, narrow angles, bradycardia, hypotension, heart failure, Down's syndrome, epilepsy, parkinsonism, peptic ulcer, and ocular inflammation, as well as in those receiving cholinesterase inhibitor therapy for myasthenia gravis or exposure to carbamate or organophosphate insecticides and pesticides.^{1,2,17–19,29,34,35}

EPINEPHRINE AND DIPIVEFRIN

The mechanism of action by which epinephrine lowers IOP has not been fully elucidated; however, a β_2 -receptor-mediated increase in outflow facility through the trabecular meshwork and the uveoscleral route appears to be the primary mechanism. Compared with β -blockers or miotics, epinephrine and dipivefrin reduce IOP less. With the advent of the better tolerated and more efficacious agents to treat glaucoma, the clinical use of epinephrines has decreased dramatically.

Epinephrine is available as epinephrine hydrochloride and epinephryl borate solutions. The various salts of epinephrine produce equivalent IOP-lowering effects and adverse reactions. Patients with minor ocular irritation from one salt of epinephrine occasionally may benefit from use of another salt because of differences in pH of the commercial solutions.

Use of the prodrug dipivefrin allows use of lower concentrations secondary to improved intraocular absorption (10- to 15-fold higher). The 0.1% dipivefrin produces equivalent IOP reduction to 1% to 2% epinephrine. Dipivefrin therefore may be tolerated by patients unable to tolerate epinephrine solutions, and it is often chosen over other epinephrine products when this class of drugs is indicated.

A factor limiting the usefulness of epinephrine is the high frequency of local ocular adverse effects. Tearing, burning, ocular discomfort, brow ache, conjunctival hyperemia, punctate keratopathy, allergic blepharoconjunctivitis, rare loss of eyelashes, stenosis of the nasolacrimal duct, and blurred vision may occur. Prolonged use (>1 year) may result in deposition of pigment (adrenochrome) in the conjunctiva and cornea. Pigment also may deposit in soft contact lenses, turning them black. These adverse effects occur less

frequently with dipivefrin. Epinephrine may produce mydriasis (particularly when combined with a β -blocker) and may precipitate acute CAG in patients with narrow anterior chambers. A transient increase in IOP may occur with initial therapy, particularly in patients not using other antiglaucoma medications. A relative contraindication to the use of epinephrine (and dipivefrin) is aphakia (i.e., after cataract removal) or lens dislocation because of the development of swelling of the macular portion of the retina. The edema is dose dependent and disappears with drug discontinuation.

Systemic adverse effects of epinephrine include headache, faintness, increased blood pressure, tachycardia, arrhythmias, tremor, pallor, anxiety, and increased perspiration. Epinephrine should be used with caution in patients with cardiovascular diseases, cerebrovascular diseases, aphakia, CAG, hyperthyroidism, and diabetes mellitus, as well as in patients undergoing anesthesia with halogenated hydrocarbon anesthetics. Using NLO with epinephrine and dipivefrin will improve therapeutic response and reduce the risk of systemic adverse effects.^{1,2,17–19,29,34,35}

FUTURE DRUG THERAPIES

It is hoped that new agents, improved formulations, and novel approaches to the reduction of IOP and other methods of prevention of glaucomatous visual field loss will provide more effective and better-tolerated therapies.

Agents that are neuroprotective and act through mechanisms other than IOP reduction are likely to be part of glaucoma therapy in the future.^{13–15,40}

EVALUATION OF THERAPEUTIC OUTCOMES

The ultimate goal of drug therapy in the patient with glaucoma is to preserve visual function through reduction of IOP to a level at which no further optic nerve damage occurs. Because of the poor relationship between IOP and optic nerve damage, no specific target IOP exists. Indeed, drugs used to treat glaucoma may act in part to halt visual field loss through mechanisms separate from or in addition to IOP reduction, such as improvements in retinal or choroidal blood flow. Often a 25% to 30% reduction is desired, but greater reductions (40% to 50%) may be desired in patients with initially high IOPs. For patients with glaucoma, an IOP of less than 21 mm Hg generally is desired, with progressively lower target pressures needed for greater levels of glaucomatous damage. Even lower IOPs (possibly even below 10 mm Hg) are required in patients with very advanced disease, those showing continued damage at higher IOPs, and those with normal-tension glaucoma and pretreatment pressures in the low to middle teens. The IOP considered acceptable for a patient is often a balance of desired IOP and acceptable treatment-related toxicity and patient quality of life.

PATIENT EDUCATION

➤ An important consideration in patients failing to respond to drug therapy is adherence. Poor adherence or nonadherence occurs in 25% to 60% of glaucoma patients.

A large percentage of patients also fail to use topical ophthalmic drugs correctly. Patients should be taught the following procedure:

1. Wash and dry the hands; shake the bottle if it contains a suspension.
2. With a forefinger, pull down the outer portion of the lower eyelid to form a "pocket" to receive the drop.

3. Grasp the dropper bottle between the thumb and fingers with the hand braced against the cheek or nose and the head held upward.
4. Place the dropper over the eye while looking at the tip of the bottle; then look up and place a single drop in the eye.
5. The lids should be closed (but not squeezed or rubbed) for 1 to 3 minutes after instillation. This increases the ocular availability of the drug.
6. Recap bottle and store as instructed.

Note that many patients are physically unable to administer their own eyedrops without assistance. NLO also should be used to improve ocular bioavailability and reduce systemic absorption.^{1,2,17–19,29,34,35} The patient induces NLO for 1 to 3 minutes by closing the eyes and placing the index finger over the nasolacrimal drainage system in the inner corner of the eye. This maneuver, as well as eyelid closure itself, decreases nasolacrimal drainage of drug, thereby decreasing the amount of drug available for systemic absorption by the nasopharyngeal mucosa. The use of NLO may improve drug response significantly, reduce adverse effects, and allow less frequent dosing intervals and the use of lower drug concentrations.

Use of more than one drop per dose increases costs, does not improve response significantly, and may increase adverse effects. When two drugs are to be administered, instillations should be separated by at least 3 to 5 minutes (preferably 10 minutes) to prevent the drug administered first from being washed out. The patient should be taught not to touch the dropper bottle tip with eye, hands, or any surface.

Adherence to glaucoma therapy commonly is inadequate, and it always should be considered as a possible cause of drug therapy failure. Assessment of adherence by health care providers generally is poor, so all patients should be encouraged continually to administer prescribed therapy diligently as instructed. To improve adherence, the patient, family, and care providers should be fully informed of the expectations of therapy and the need to continue therapy despite a lack of symptoms. Possible adverse effects of the medication and ways to reduce them should be discussed. Adherence will be improved by good communication, close monitoring, and use of well-tolerated and convenient drug regimens.^{1,2,17–19,29}

CONCLUSIONS

The glaucomas are a group of primary and secondary diseases, the management of which presents a considerable challenge to the clinician. Successful therapy requires rational use of antiglaucoma medications and patient adherence to the selected regimen, combined with conscientious monitoring for adverse effects and disease progression. The reward for successful therapy is considerable: the maintenance of vision. The overview of the clinical findings, pathology, and drug therapy presented in this chapter provides the clinician with the fundamentals necessary to understand and treat glaucoma.

ALLERGIC RHINITIS

J. Russell May and Philip H. Smith

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Allergic rhinitis is one of the most common diseases. Treatment is justified in most cases because of the potential for complications.
- 2 An immune response to allergens results in release of inflammatory mediators that cause allergic rhinitis symptoms. Therefore patients must be thoroughly knowledgeable about the proper timing and administration of prophylactic regimens.
- 3 Proven therapeutic modalities include avoidance of allergens and pharmacologic management with antihistamines, topical and systemic decongestants, topical steroids, cromolyn sodium, and immunotherapy.
- 4 Immunotherapy can be highly successful, offering long-term benefits, but expense, potential risks, and a major time commitment makes proper patient selection critical.

Rhinitis is inflammation of the nasal mucous membrane. In a sensitized individual, allergic rhinitis occurs when mucous membranes are exposed to inhaled allergenic materials that elicit a specific response mediated by immunoglobulin E (IgE). This response involves the release of inflammatory mediators and is characterized by sneezing, nasal itching, and watery rhinorrhea, often associated with nasal congestion. Itching of the throat, eyes, and ears frequently accompanies allergic rhinitis.

Allergic rhinitis may be regarded as seasonal allergic rhinitis, commonly known as hay fever, or perennial allergic rhinitis (increasingly called “intermittent” and “persistent”). Seasonal rhinitis occurs in response to specific allergens usually present at predictable times of the year, during the plants’ blooming seasons (typically the spring or fall). Seasonal allergens include pollen from trees, grasses, and weeds. Perennial allergic rhinitis is a year-round disease caused by nonseasonal allergens, such as house dust mites, animal dander, and molds, or multiple allergic sensitivities. It typically results in subtle, chronic symptoms. Many patients have a combination of these two types of allergic rhinitis, with symptoms year-round and seasonal exacerbations. About one-third to one-half of sufferers have recognizable seasonal disease with the remainder having perennial or a combination of both.¹

EPIDEMIOLOGY AND ETIOLOGY

- 1 Allergic rhinitis is one of the most common medical disorders found in humans. An estimated 20% to 30% of the American adult population and up to 40% of children are affected, with some believing the percentage to be much higher.^{2,3} It ranks as the sixth most prevalent chronic illness in the United States.¹ Patients are limited in their ability to carry out normal daily functions: higher levels of general fatigue, mental fatigue, anxiety, and depressive disorders are seen.^{4,5}

In addition, the impact of allergic rhinitis goes well beyond these central nervous system issues. Allergic rhinitis is associated with several other serious medical conditions, including asthma, rhinosinusitis, otitis media, nasal polyposis, respiratory infections, and orthodontic malocclusions.²

PREDISPOSING FACTORS

The development of allergic rhinitis is likely influenced by genetics, allergen exposure, and the presence of other risk factors. Allergic rhinitis has a strong genetic predisposition. A family history of allergic rhinitis, atopic dermatitis, or asthma suggests that rhinitis is allergic. The risk of developing allergic disease is approximately 50% for children with one atopic parent and 66% for those with two allergic parents.³

Allergen exposure is another predisposing factor. For allergic rhinitis to occur, an individual must be exposed to a protein that elicits the allergic response in that individual. Many potential sufferers never develop symptoms because they do not come into contact with the allergen that would produce symptoms in them.

Recent evidence suggests microbial exposure in the first years of life could help prevent allergic disease by developing a non-atopic immune response.⁶ Farm children are exposed to higher concentrations of endotoxin, derived from cell walls of gram-negative bacteria, in stables and in dust around the farmhouse. Consumption of non-pasteurized farm milk may cause further exposure. This concept has led to the idea that allergic disease could be prevented by proactively increasing exposure to harmless bacteria early in life (see alternative treatment section below). This could explain why positive skin tests indicating allergen sensitization have been observed more frequently in people in higher socioeconomic classes and people who live in suburban areas.⁷

Other predisposing factors include an elevated serum IgE (>100 international units/mL) before the age of 6 years, eczema, and heavy exposure to second-hand cigarette smoke.⁸

ALLERGENS

Allergens that produce seasonal rhinitis are the protein components of airborne pollen grains, often enzymes, from a variety of trees, grasses, and weeds. Ragweed and grass pollen are the most common offenders in the United States; however, this changes with the geographic region. In general, tree pollens cause symptoms in the spring, grass pollens cause symptoms in the late spring to summer, and weed pollens are the culprits in the late summer to early fall. Patients who are hypersensitive to all three may have overlapping problem periods, and may be described as having perennial rhinitis, when they are actually experiencing prolonged seasonal rhinitis. For this reason and the fact that most patients with seasonal problems are sensitive to at least some of the perennial allergens, many allergists are less often distinguishing between the two types of allergic rhinitis.

To complicate matters further, the antigenic components of many grasses—including fescue, Kentucky bluegrass, orchard, redtop, and timothy—are similar, resulting in cross-allergenicity. Fortunately, most trees that produce many of the offending airborne pollens produce antigenically distinct pollens. These trees include ash, beech, birch, cedar, hickory, maple, oak, poplar, and sycamore. Flowering plants that depend on insect pollination usually do not cause allergic rhinitis.

Mold spores are also important allergens. Spores are present year-round; however, mold growth on decaying vegetation increases seasonally. Just walking through uncut fields or raking leaves can increase exposure. Thus mold spores can be responsible for both perennial and seasonal allergies.

Indoor allergens usually are present perennially; most important among these are house dust mite fecal proteins, animal dander, cockroaches, and certain mold species. Dust mite levels are on the rise, possibly due to the improved construction of energy-efficient homes and offices that result in reduced ventilation and increased humidity, use of wall-to-wall carpeting, and the popularity of cool water detergents and cold water washing.³

PHYSIOLOGY AND PATHOPHYSIOLOGY

NASAL PHYSIOLOGY

Knowledge of nasal physiology aids in the understanding of allergic rhinitis. The nose performs three “air conditioning” functions to prepare incoming gases and their contents for the lungs. During the fraction of a second that air is in the nose, it is heated, humidified, and cleaned. The cleaning process plays a role in the development of allergic rhinitis. As the air passes through the nose, the turbulence throws particulate matter against a mucous blanket. The rhythmic movements of the nasal cilia cause the mucous blanket to move posteriorly at approximately 9 mm/min, where it is eventually swallowed; therefore foreign particles are removed via the gastrointestinal tract and do not reach the lungs.

The vascular tissue in the nose is erectile. Stimulation of sympathetic fibers causes vasoconstriction, reduction in erectile tissue size, and airway widening. Parasympathetic stimulation causes vasodilatation, an increase in erectile tissue size, and airway narrowing.

Located in the nasal mucosa are the mast cells, which participate in the regulation of nasal patency by releasing such mediators as histamine. These are described below.

IMMUNE RESPONSE TO ALLERGENS

2 Allergic reactions in the nose are mediated by antigen-antibody responses, during which allergens interact with specific IgE molecules bound to nasal mast cells and basophils. In allergic people, these cells are increased in both number and reactivity. During inhalation, airborne allergens enter the nose and are processed by lymphocytes, which produce antigen-specific IgE, thereby sensitizing genetically predisposed hosts to those agents. Upon nasal re-exposure, IgE bound to mast cells interacts with airborne allergen, triggering release of inflammatory mediators (Fig. 93–1).⁹

Both immediate and late-phase reactions are observed after allergen exposure. The immediate reaction occurs within minutes, resulting in the rapid release of preformed mediators and newly generated mediators from the arachidonic acid cascade as the mast cell membrane is disturbed (Table 93–1). These mediators of immediate hypersensitivity include histamine, leukotrienes (LTs) C₄, LTD₄, LTE₄, prostaglandin D₂, tryptase, and kinins.⁹ In addition, the mast

FIGURE 93–1. Allergen sensitization and the allergic response. *A.* Exposure to antigen stimulates IgE production and sensitization of mast cells with antigen-specific IgE antibodies. *B.* Subsequent exposure to the same antigen produces an allergic reaction when mast cell mediators are released.

TABLE 93–1. Mast Cell Mediators

| Mediator | Effect |
|---|---|
| Preformed and rapidly released | |
| Histamine | Stimulates irritant receptors Pruritus Vascular permeability Mucosal permeability Smooth muscle contraction |
| Neutrophil chemotactic factor | Influx of inflammatory cells |
| Eosinophil chemotactic factor | Influx of inflammatory cells |

| Platelet-activating factor | Mucus secretion Airway permeability Chemotaxis Vascular permeability |
| Granule matrix contents | |
| Heparin | Anti-inflammatory |
| Tryptase | Protein hydrolysis |
| Kallikrein | Protein hydrolysis |

cell has been found to be a source of several cytokines that probably are relevant to the chronicity of the mucosal inflammation that characterizes allergic rhinitis.¹⁰ Sensory nerve stimulation produces itching, and sneezing occurs via reflex stimulation of efferent vagal pathways. Neuropeptides substance P and calcitonin gene-related peptide from nonadrenergic, noncholinergic nerves affect vascular engorgement directly and via modulation of sympathetic tone. Histamine produces rhinorrhea, itching, sneezing, and obstruction, with the obstruction only partially blocked by H₁- or H₂-blocking agents.¹¹ Nasal obstruction is also caused by kinins, prostaglandin D₂, and LTC₄/LTD₄, and kinins, when directly administered, produce pain rather than itching.¹² These inflammatory mediators also produce vasodilation, increased vascular permeability, and production of nasal secretions.¹³

Four to eight hours after the initial exposure to an allergen, a late-phase reaction occurs in 50% of allergic rhinitis patients.¹⁴ This response, thought to be due to cytokines released primarily by mast cells and thymus-derived helper lymphocytes, is characterized by profound infiltration and activation of migrating cells. This inflammatory response likely is responsible for the persistent, chronic symptoms of allergic rhinitis, including nasal congestion. The inflamed mucosa become hyperresponsive, a state characterized by exacerbation of nasal reactions to nonspecific or irritant triggers. In this state the patient also reacts to increasingly lower amounts of the same allergen.¹⁵

CLINICAL PRESENTATION

SYMPTOMS AND DIAGNOSIS

The patient with allergic rhinitis typically complains of clear rhinorrhea, paroxysms of sneezing, nasal congestion, postnasal drip, and pruritic eyes, ears, nose, or palate. Symptoms of allergic conjunctivitis

are associated more frequently with seasonal than perennial allergic rhinitis, since a majority of the perennial allergens, such as dust mites and molds, are indoors, where air velocity is too low for substantial deposition of allergenic particles on the conjunctivae. However, with heavy exposure from animal or mold allergens, allergic conjunctivitis can be pronounced.

Symptoms secondary to the late-phase reaction, predominantly nasal congestion, begin 3 to 5 hours after antigen exposure and peak at 12 to 24 hours. Subsequent symptoms, both allergic and irritant, are elicited more easily because of the priming effect. For instance, a ragweed-sensitive patient, when exposed to ragweed pollen out of season, responds with modest symptoms and may be very tolerant of irritants such as air pollution or tobacco smoke. During the ragweed season, however, when the nasal mucosa is already inflamed, exposure to small doses of pollen or to irritants to which the patient is usually tolerant elicits a response clinically indistinguishable from his allergy.

Allergic rhinitis is differentiated from other causes of rhinitis by a thorough history, physical examination, and certain diagnostic tests. The medical history consists of a careful description of symptoms, environmental factors and exposures, results of previous therapy, use of other medications, previous nasal injuries, previous nasal or sinus surgery, family history, and the presence of other medical problems. Identification of specific causative allergens may be difficult. For example, a reaction induced by mowing the lawn may not be caused by grass pollens, but by the disturbance of various weeds, molds, or other plants in the lawn. With perennial allergic rhinitis, the cause-effect and temporal relationships are less clear, making the diagnosis more difficult, especially with such covert allergens as house dust mites and molds.

Physical examination may reveal allergic shiners, a transverse nasal crease caused by repeated rubbing of the nose, and adenoidal breathing. Pale, bluish, edematous nasal turbinates coated with thin, clear secretions are characteristic of a purely allergic reaction. Tearing, conjunctival injection and edema, and periorbital swelling may be present. Physical findings are generally less clear-cut in adults.

Nasal scrapings will provide a representative sample of cells infiltrating the nasal mucosa and can be helpful in supporting the diagnosis.¹⁶ Microscopic examination of the nasal smear from an allergic individual typically will show numerous eosinophils. The blood eosinophil count may be elevated in allergic rhinitis, but it is nonspecific and has limited usefulness.¹⁷

Allergy testing can help determine whether a patient's rhinitis is caused by an allergic response to allergens. Immediate-type hypersensitivity skin tests are commonly used for the diagnosis of allergic rhinitis. These skin tests can be performed by the percutaneous route, where the diluted allergen is pricked or scratched into the skin surface, or by the intradermal route, where a small volume (0.01 to 0.05 mL) of diluted allergen is injected between the layers of skin. Percutaneous tests are more commonly performed and are safer and more generally accepted, with intradermal tests reserved for patients requiring confirmation.

In percutaneous testing, a positive control (histamine) and a negative control are essential for correct interpretation. After 15 minutes of the application of the allergen, the site is examined for a positive reaction (defined as a wheal and flare reaction). Because correct testing is done with extremely minute doses, undetectable by nonsensitized individuals, this reaction is evidence of the presence of mast cell-bound IgE specific to the allergen tested. Common allergens are available as standardized allergenic extracts.

Antihistamines and a few other medications interfere with the wheal and flare reaction. First-generation antihistamines should be

stopped 3 days before testing, while second-generation, non-sedating antihistamines should be stopped for 10 days.¹⁸ Medications with antihistamine properties (e.g., sympathomimetic agents, phenothiazines, and tricyclic antidepressants) and H₂-receptor antagonists (e.g., cimetidine, ranitidine, and famotidine) should be discontinued before skin testing. The radioallergosorbent test (RAST) was the first commonly used method for detecting IgE antibodies in the blood that are specific for a given allergen. Several other quantitative assays that include a reference curve calculated against standardized IgE are available.¹⁹ These tests are highly specific but less sensitive than percutaneous tests.

COMPLICATIONS

1 Not only is allergic rhinitis aggravating, it also frequently leads to further complications, particularly if the patient does not receive adequate treatment. Symptoms of untreated rhinitis may lead to inability to sleep, chronic malaise, fatigue, and poor work or school efficiency. Patients often are plagued by loss of smell or taste, with sinusitis or polyps underlying many cases of allergy-related hyposmia. Postnasal drip with cough, hoarseness, and even vocal polyps also can be bothersome.

The role of allergic rhinitis in the development of acute otitis media or chronic middle ear effusion remains controversial. Children with allergic rhinitis appear to be at greater risk of these conditions because of nasal obstruction, insufflation of nasal secretions into the

middle ear via eustachian tube obstruction, and negative middle ear pressure. Hearing problems in children related to middle ear effusion may lead to delayed development of language in young children or school problems in older children.

Structural facial and dental problems can result from chronic allergic rhinitis.^{20,21} The chronic edema and venous stasis may contribute to the development of a high-arched, V-shaped palate. Mouth breathing caused by nasal obstruction can be responsible for dental malocclusion and orthodontic problems. Constant upward rubbing of the nose (allergic salute) can cause a lasting transverse crease across the lower nose; nasal congestion leads to venous pooling and dark circles under the eyes known as *allergic shiners*.

Allergic rhinitis is clearly a risk factor for asthma. As many as 78% of asthma patients have nasal symptoms, while about 38% of allergic rhinitis patients have asthma.³ Asthma is more common in those with perennial than seasonal allergic rhinitis, and it is less likely to be “outgrown” when associated with allergic rhinitis.²²

Recurrent and chronic sinusitis are relatively common complications of allergic rhinitis. The structure of the mucus blanket breaks down, with a severe decrease of water production by serous glands, leaving hair cells trapped in the larger mucus layer. This greatly reduces the clearance of trapped bacteria. This offers ideal breeding grounds and greatly increased growing time for the bacteria. Nasal polyps are less common but nonetheless bothersome; they require specific therapy but may improve with management of the underlying allergic state. Epistaxis also can be a problem; it is related to mucosal hyperemia and inflammation.

TREATMENT: Allergic Rhinitis

DESIRED OUTCOME

The therapeutic goal for patients with allergic rhinitis is to minimize or prevent symptoms. This goal should be accomplished with no or minimal adverse medication effects and reasonable medication expenses. The patient should be able to maintain a normal lifestyle, including participating in outdoor activities, yard work, and playing with pets as desired.

GENERAL APPROACH TO TREATMENT

3 Once the causative allergens and the specific symptoms are identified, management consists of three possible approaches: (1) allergen avoidance, (2) pharmacotherapy for prevention or treatment of symptoms, and (3) specific immunotherapy. The pharmacotherapy for symptoms approach includes several options that are based on patient-specific information (Table 93–2). Figure 93–2 depicts an algorithm for treatment options.

AVOIDANCE

Avoidance of offending allergens is the most direct method of preventing allergic rhinitis, but it is often the most difficult to accomplish, especially for perennial allergens. Mold growth can be reduced by maintaining household humidity below 50% and removing obvious growth with bleach or disinfectant. Patients sensitive to animals will

benefit most by removing pets from the home; however, most animal lovers are reluctant to comply with this approach. Cats may be more of a problem than dogs. Cat allergen is so prevalent and persistent in the air that in one survey 25% of cat-free houses contained detectable cat allergen.²³ Washing cats weekly may reduce allergens but studies have been inconclusive.²⁴ Some dogs display more profuse antigens than do others; clinically, a sensitized person may tolerate one animal better than another.

Efforts to eliminate dust mites should be rigorous, particularly in the bedroom. Exposure to dust mites can be reduced by encasing mattresses and pillows with impermeable covers and washing bed linens in hot water. Washable area rugs are preferable to wall-to-wall carpeting. Acaricide treatment of carpets has been shown to denature the dust mite allergen, but must be done repeatedly, resulting in inconvenience and expense. Atopic infants who are exposed to high levels of dust mites are at increased risk for developing asthma.²⁵ Environmental control of these allergens may be helpful in forestalling further rhinitis and preventing later asthma.

Older central air-filtration systems for houses were expensive and minimally effective. High-efficiency particulate air (HEPA) filters have minimal effect on the dust mite allergens because these allergens are heavy and heavily charged electrically and are not typically floating in the air in the first place. These filters are effective in removing lightweight airborne particulates, including pollen, mold spores, and cat allergen, thus reducing allergic respiratory symptoms.²⁶

Patients with seasonal allergic rhinitis should keep windows closed and minimize time spent outdoors during pollen seasons. Immediate hair washing and change of clothes are recommended upon returning indoors. Use of fans that direct outside air into the

TABLE 93–2. Pharmacotherapeutic Options For Allergic Rhinitis

| Medication Class | Symptoms Controlled | Comments |
|------------------------------------|---|--|
| Antihistamines | | |
| Systemic | Sneezing, rhinorrhea, itching, conjunctivitis | For seasonal allergic rhinitis, begin treatment before allergen exposure. Nonsedating agents should be tried first. If ineffective or too expensive for the patient, the older agents may be used. For perennial allergic rhinitis, use an intranasal steroid as an alternative to or in combination with systemic antihistamines. |
| Ophthalmic | Conjunctivitis | Logical addition to nasal steroids if ocular symptoms are present. |
| Intranasal | Sneezing, rhinorrhea, nasal pruritus | Option for seasonal allergic rhinitis. Warn patients of potential drowsiness. |
| Decongestants | | |
| Systemic | Nasal congestion | Only needed when nasal congestion is present. |
| Topical | Nasal congestion | Only needed when nasal congestion is present. Do not exceed 3–5 days. |
| Intranasal corticosteroids | Sneezing, rhinorrhea, itching, nasal congestion | For seasonal allergic rhinitis, an option when congestion is present. Must begin therapy before allergen exposure. Excellent choice for perennial rhinitis. |
| Mast cell stabilizers | See comments | Prevents symptoms; therefore, for seasonal allergic rhinitis, use before offending allergen’s season starts. For perennial rhinitis, improvement may not be seen for up to 1 month. |
| Intranasal anticholinergics | Rhinorrhea | Reserve for use when above therapies fail or cannot be tolerated. |

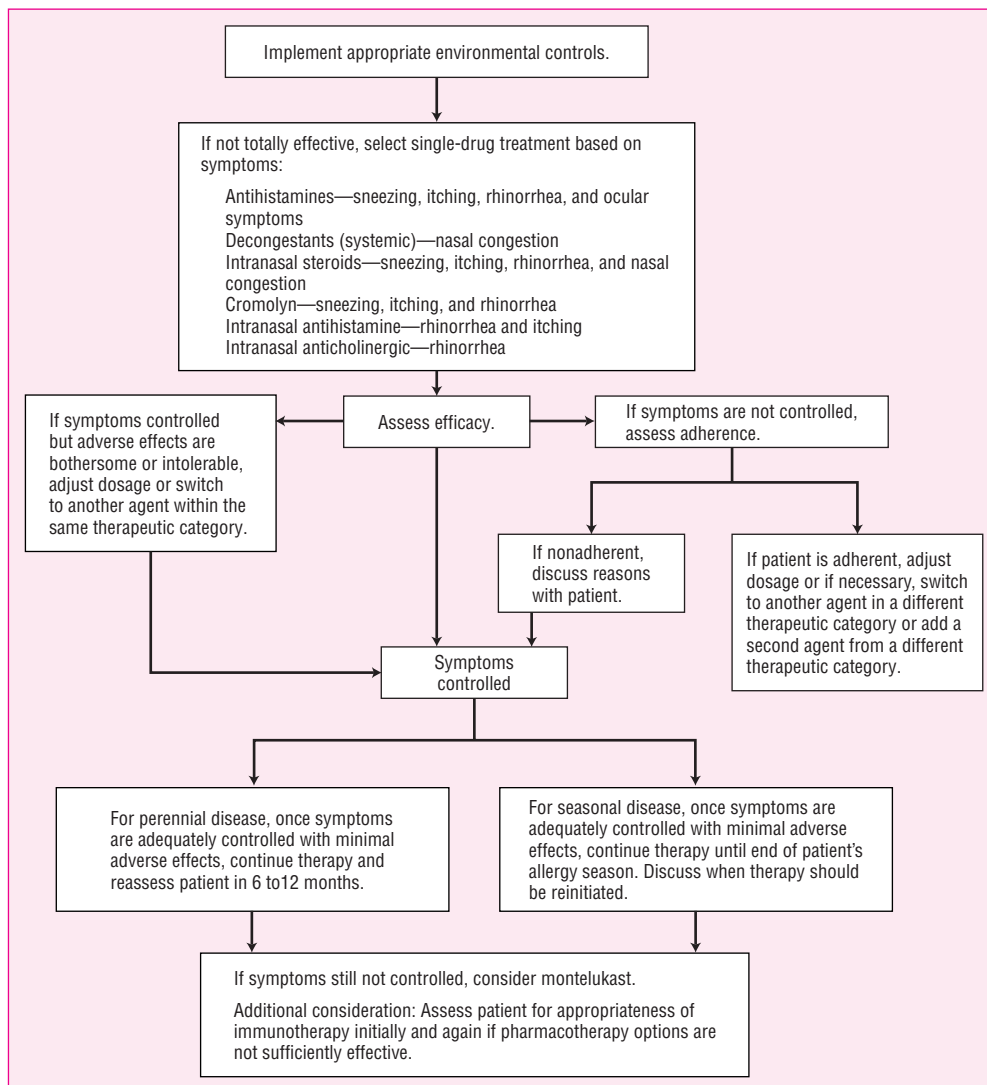

FIGURE 93–2. Treatment algorithm for allergic rhinitis.

TABLE 93–3. Environmental Controls to Prevent Allergic Rhinitis

| |
|--|
| Pollens |
| <ul style="list-style-type: none"> • Keep windows and doors closed during pollen season • Avoid fans that draw in outside air • Use air conditioning • If possible, eliminate outside activities during times of high pollen counts • Shower, shampoo, and change clothes following outdoor activity • Use a vented dryer rather than an outside clothesline |
| Molds |
| <ul style="list-style-type: none"> • Use similar controls as above • Avoid walking through uncut fields, working with compost or dry soil, and raking leaves • Clean indoor moldy surfaces • Fix all water leaks in home • Reduce indoor humidity to <50% if possible |
| House dust mites |
| <ul style="list-style-type: none"> • Encase mattress, pillow, and box springs in an allergen-impermeable cover • Wash bedding in hot water weekly • Remove stuffed toys from bedroom • Minimize carpet use and upholstered furniture • Reduce indoor humidity to <50% if possible |
| Animal allergens (if removal of pet is not acceptable) |
| <ul style="list-style-type: none"> • Keep pet out of patient’s bedroom • Isolate pet from carpet and upholstered furniture • Wash pet weekly |
| Cockroaches |
| <ul style="list-style-type: none"> • Keep food and garbage in tightly closed containers • Take out garbage regularly • Clean up dirty dishes promptly • Use roach traps |
| Other recommendations |
| <ul style="list-style-type: none"> • Do not allow smoking around the patient, in the patient’s house, or in the family car • Minimize the use of wood-burning stoves and fireplaces |

Adapted from American Academy of Allergy.³

house should be avoided. Filter masks can be worn while gardening or mowing the lawn. A summary of recommendations for environmental control is given in Table 93–3.

The few clinical trials on the effectiveness of avoidance measures have been inconclusive.²⁴ These measures are intended to be a part of a comprehensive treatment strategy that will likely include pharmacotherapy and in selected cases, immunotherapy.

PHARMACOLOGIC THERAPY

First-line therapeutic modalities for treating allergic rhinitis are directed at relief of symptoms (see Table 93–2). Antihistamines and decongestants (both oral and topical) generally are used first in treating allergic rhinitis with medications. Several options in these two categories are available without a prescription, but patients will need sound advice to make appropriate choices. Knowledge of pathophysiology and the inflammatory state has led to prophylactic therapy for more severe disease using agents such as cromolyn and topical steroids. However, in attempting to assess the evidence supporting any particular therapy, clinicians have difficulty interpreting the medical literature for a variety of reasons, including lack of uniformity in the research methodologies, inappropriate drug controls, and failure to identify types of rhinitis in study subjects (perennial versus seasonal and allergic versus nonallergic).

Antihistamines

Histamine (H₁)-receptor antagonists are competitive antagonists to histamine. They bind to H₁ receptors without activating them, preventing histamine binding and action. Newer antihistamines may also affect components of the inflammatory response such as histamine release, generation of adhesion molecules, and influx of inflammatory cells. While it was once thought that the older antihistamines had no anti-inflammatory action, some were shown to have these effects as early as the 1950s.²⁷ Antihistamines are available in oral, ophthalmic, and intranasal dosage forms.

The oral antihistamines are the most commonly used and can be divided two major categories: nonselective (first-generation) and peripherally selective (second-generation). Nonselective agents are commonly referred to as *sedating antihistamines*, and peripherally selective agents are referred to as *nonsedating antihistamines*. These generalizing terms can be misleading. Individual agents should be judged on their specific characteristics because variation within these broad categories exists. Also, the nonsedating claim is only valid when the newer agents are used at recommended doses.²⁸ This is of particular concern since some of these antihistamines are now available without a prescription. The mechanism for sedation is not well understood, but its central effect depends on the drugs’ ability to cross the blood-brain barrier. Most older antihistamines are lipid-soluble and cross this barrier easily. The peripherally selective agents have little or no central or autonomic nervous system effects. Table 93–4 lists common antihistamines, their chemical classifications, their relative potential for causing sedation, and their relative anticholinergic effects.

TABLE 93–4. Relative Adverse-Effect Profiles of Antihistamines

| Medication | Relative Sedative Effect | Relative Anticholinergic Effect |
|--|--------------------------|---------------------------------|
| Alkylamine class, nonselective | | |
| Brompheniramine maleate | Low | Moderate |
| Chlorpheniramine maleate | Low | Moderate |
| Dexchlorpheniramine maleate | Low | Moderate |
| Ethanolamine class, nonselective | | |
| Carbinoxamine maleate | High | High |
| Clemastine fumarate | Moderate | High |
| Diphenhydramine hydrochloride | High | High |
| Ethylenediamine class, nonselective | | |
| Pyrilamine maleate | Low | Low to none |
| Tripelennamine hydrochloride | Moderate | Low to none |
| Phenothiazine class, nonselective | | |
| Promethazine hydrochloride | High | High |
| Piperidine class, nonselective | | |
| Cyproheptadine hydrochloride | Low | Moderate |
| Phenindamine tartrate | Low to none | Moderate |
| Phthalazinone class, peripherally selective | | |
| Azelastine (nasal only) | Low to none | Low to none |
| Piperazine class, peripherally selective | | |
| Cetirizine | Low to moderate | Low to none |
| Piperidine class, peripherally selective | | |
| Desloratadine | Low to none | Low to none |
| Fexofenadine | Low to none | Low to none |
| Loratadine | Low to none | Low to none |

Antihistamines are more effective in preventing the actions of histamines than in reversing these actions once they have taken place. Reversal of symptoms is, at least in part, caused by the anticholinergic properties of these drugs. This activity is responsible for the drying effect of antihistamines, which reduces the problem of nasal, salivary, and lacrimal gland hypersecretion. Antihistamines antagonize increased capillary permeability, wheal-and-flare formation, and itching.

In general, the antihistamines are well absorbed, have large volumes of distribution, and are metabolized by the liver. Serum half-lives vary considerably between patients. Also, the therapeutic effects of these agents are more prolonged than might be predicted by their half-lives.

Drowsiness is usually the chief complaint of patients who take antihistamines. It can interfere with a patient's ability to drive a car or operate machinery and may interfere with the patient's ability to function adequately at the workplace. Remember that these problems can also be a reflection of the disease itself. For this reason, many recommend the use of peripherally selective agents as first-line treatment for any patients at high risk for the development of adverse events. This includes patients with renal or hepatic impairment, those with small weights (for whom adult doses may provide larger-than-recommended doses on a milligram per kilogram basis), patients with pre-existing central nervous system or cardiac disorders, patients who require higher doses, and patients who have shown tendencies to overuse nonprescription or prescription medications.²⁷

The sedative effects of antihistamines can be useful in patients who suffer from sleeplessness caused by the symptoms of allergic rhinitis. In these patients, a bedtime dose may prove beneficial. However, they may cause residual daytime sedation, decreased alertness, and performance impairment.²⁴

The logic of preferentially using the newer agents is not clear cut. A recent meta-analysis of performance-impairment trials did not show a clear and consistent distinction between diphenhydramine

and the peripherally selective agents.²⁹ Another study showed that tolerance to sedation secondary to diphenhydramine developed by day 4 of treatment, becoming indistinguishable from placebo,³⁰ but sedation must be distinguished from impairment, as the two are not equivalent.

Anticholinergic (drying) effects contribute to the agents' therapeutic efficacy, but they also cause most adverse effects. Dry mouth, difficulty in voiding urine, constipation, and potential cardiovascular effects may be troublesome. Keep in mind that the differences may be small. Patients with a predisposition to urinary retention (e.g., elderly men and those on concurrent anticholinergic therapy) should use antihistamines with caution. Caution also should be used in patients with increased intraocular pressure, hyperthyroidism, and cardiovascular disease.

Other adverse effects of oral antihistamines include loss of appetite (and paradoxically, weight gain with increased appetite), nausea, vomiting, and epigastric distress.

Antihistamines are only fully effective when taken approximately 1 to 2 hours before anticipated exposure to the offending allergen. If tolerance develops to the therapeutic effect, a change to an agent in a different chemical class may be effective.

Patients should be counseled about the proper use of antihistamines. Adverse effects, especially drowsiness, should be emphasized. Patients should be warned against taking other central nervous system depressants, including the use of alcohol. Patients should be told not to take a double dose when a dose is missed. Taking the antihistamine with meals or at least a full glass of water will help prevent gastrointestinal adverse effects such as nausea, vomiting, and epigastric distress. Patients should check with their health care professional and read labels before taking nonprescription medications. Many cold products and sleep aids contain antihistamines. Patients should be instructed not to use more than one antihistamine at a time. Table 93-5 lists the recommended dosages of the commonly used agents with their prescription status.

TABLE 93-5. Oral Dosages of Commonly Used Oral Antihistamines and Decongestants

| Medication | Availability | Dosage and Interval ^a | |
|--|--------------|---|--|
| | | Adults | Children |
| Nonselective (First-generation) antihistamines | | | |
| Chlorpheniramine maleate, plain ^b | OTC | 4 mg every 6 h | 6-12 y: 2 mg every 6 h 2-5 y: 1 mg every 6 h |
| Chlorpheniramine maleate, sustained-release | OTC | 8-12 mg daily at bedtime or 8-12 mg every 8 h | 6-12 y: 8 mg at bedtime <6 y: Not recommended |
| Clemastine fumarate ^b | OTC | 1.34 mg every 8 h | 6-12 y: 0.67 mg every 12 h |
| Diphenhydramine hydrochloride ^b | OTC | 25-50 mg every 8 h | 5 mg/kg per day divided every 8 h (up to 25 mg per dose) |
| Peripherally selective (second-generation) antihistamines | | | |
| Loratadine ^b | OTC | 10 mg once daily | 6-12 y: 10 mg once daily 2-5 y: 5 mg once daily |
| Fexofenadine | RX | 60 mg twice daily or 180 mg once daily | 6-11 y: 30 mg twice daily |
| Cetirizine ^b | RX | 5-10 mg once daily | >6 y: 5 mg once daily Infants 6-11 mo ^c |
| Oral decongestants | | | |
| Pseudoephedrine, plain | OTC | 60 mg every 4-6 h | 6-12 y: 30 mg every 4-6 h 2-5 y: 15 mg every 4-6 h |
| Pseudoephedrine, sustained-release ^d | OTC | 120 mg every 12 h | Not recommended |

^aDosage adjustment may be needed in renal/hepatic dysfunction. Refer to manufacturers' prescribing information.

^bAvailable in liquid form.

^c0.25 mg/kg orally demonstrated to be safe.³¹

^dControlled-release product available: 240 mg once daily (60-mg immediate-release with 180-mg controlled-release).

Many patients respond to and tolerate the older agents quite well. Because many of the older agents are available generically, they are much less expensive. Patient cost for many of the older nonprescription agents is less than \$5 for a 30-day supply, compared with more than \$20 for some of the nonprescription selective agents, and more than \$70 dollars for the selective prescription-only products. While cost is a concern, patient safety should be the first consideration. Interestingly, in a 2003 survey, the most frequently recommended nonprescription antihistamine to adults by pharmacists was diphenhydramine.³² This may change with the heavy promotion of competing brands of nonprescription loratadine. Loratadine in combination with pseudoephedrine did show up in the survey as the top pharmacists’ pick in the “adult multisymptom allergy” category in that 2003 survey.

For seasonal allergic rhinitis, an intranasal antihistamine, azelastine, is available. Azelastine has been used successfully in patients who did not respond to loratadine.³³ Using the nasal route offers an alternative to switching to another oral antihistamine. Patient satisfaction has been varied because while the product produces rapid symptom relief, patients complain of drying effects, headache, and diminished effectiveness over time. Patients should be warned of the medication’s potential to produce drowsiness, as its systemic availability is approximately 40%.³⁴

Allergic conjunctivitis, often associated with allergic rhinitis, can be treated with an ophthalmic antihistamine such as levocabastine. Since systemic antihistamines usually are also effective for allergic conjunctivitis, levocabastine is a logical addition to nasal steroids when ocular symptoms occur, and is an acceptable approach in patients whose only symptoms involve the eyes.

CLINICAL CONTROVERSY

While many clinicians strongly prefer a peripherally selective agent as the first antihistamine choice, economic considerations still result in the first-line choice of the less expensive and more sedating products by some prescription plans and clinicians.

Decongestants

Topical and systemic decongestants are sympathomimetic agents that act on adrenergic receptors in the nasal mucosa, producing vasoconstriction. Decongestants shrink swollen mucosa and improve ventilation. When nasal congestion is part of the clinical picture, decongestants work well in combination with antihistamines.

Topical Decongestants. Topical decongestants are applied directly to swollen nasal mucosa via drops or sprays. Table 93–6 lists the common topical decongestants and their durations of

TABLE 93–6. Duration of Action of Topical Decongestants

| Medication | Duration (h) |
|--------------------------------|--------------|
| Short-acting | |
| Phenylephrine hydrochloride | Up to 4 |
| Intermediate-acting | |
| Naphazoline hydrochloride | 4–6 |
| Tetrahydrozoline hydrochloride | |
| Long-acting | |
| Oxymetazoline hydrochloride | Up to 12 |
| Xylometazoline hydrochloride | |

action. The use of these agents results in little or no systemic absorption.

Because these agents are extremely effective and are available to patients without a prescription, they are widely used. However, prolonged use of these agents (for more than 3 to 5 days) can result in a condition known as *rhinitis medicamentosa*, or *rebound vasodilation*, with associated congestion. Patients who develop this condition use more spray more often with less response. While the methods used to treat this “addiction” have not been studied formally, several are used commonly. Abrupt cessation works, but it is difficult because of rebound congestion that may leave the patient congested for several days or weeks. Sleeping may become difficult. Nasal steroids have been used successfully, but they take several days to work. Weaning the patient off topical decongestants can be accomplished by decreasing the dosing frequency or the concentration over several weeks. Combining the weaning process with nasal steroids may prove useful.

Other adverse effects of topical decongestants include burning, stinging, sneezing, and dryness of the nasal mucosa.

Patients should be counseled on the use of topical decongestants to prevent rhinitis medicamentosa. Patients should be instructed to use as small a dose as possible as infrequently as possible and only when absolutely necessary (e.g., at bedtime to aid in falling asleep). Duration of therapy always should be limited to 3 to 5 days.

Systemic Decongestants. Oral decongestants are not as effective on an immediate basis as the topical agents, but their effects sometimes last longer and they cause less local irritation.

Also, rhinitis medicamentosa is not a problem with older agents. The most commonly used agent is pseudoephedrine. Usual doses for the regular and sustained-release version are given in Table 93–5. An oral form of phenylephrine is available by prescription only.

Concerns of safety have greatly limited the systemic decongestant options. Pseudoephedrine continues to be the most frequently used and the safest choice. Doses of 180 mg have been shown to produce no measurable change in blood pressure or heart rate.³⁵ In higher doses (210 to 240 mg), pseudoephedrine has raised both blood pressure and heart rate.³⁶ Pseudoephedrine can cause mild central nervous system stimulation, even at therapeutic doses. Stroke, related to oral decongestant use including pseudoephedrine, can occur in patients with hypertension and/or vasospasm.³⁷ Although stroke complications seem to be associated with higher-than-recommended doses, there is also a stroke risk when these agents are taken properly. Severe hypertensive reactions can occur when pseudoephedrine is given concomitantly with monoamine oxidase inhibitors.³⁸ Hypertensive patients should, unless absolutely necessary, avoid systemic decongestants.

Combination Products

Numerous products combine an antihistamine with a decongestant. The combination is rational because of the different mechanisms of action. Both nonselective and peripherally selective antihistamines are available in such combinations. As mentioned previously, patients should read labels to avoid therapeutic duplication.

Nasal Steroids

Nasal steroids are an excellent choice for treating perennial rhinitis, and can be useful in seasonal rhinitis, especially if dosed in advance

TABLE 93–7. Dosage of Nasal Steroids

| Medication | Dosage and Interval |
|--|--|
| Beclomethasone dipropionate | >12 y: 1 inhalation (42 mcg) per nostril 2–4 times a day (maximum, 336 mcg/day) 6–12 y: 1 inhalation per nostril 3 times per day |
| Beclomethasone dipropionate, monohydrate | >12 y: 1–2 inhalations once daily 6–12 y: 1 inhalation per nostril (42 mcg) twice daily to start |
| Budesonide | >6 y: 2 sprays (64 mcg) per nostril in AM and PM or 4 sprays per nostril in AM (maximum, 256 mcg) |
| Flunisolide | Adults: 2 sprays (50 mcg) per nostril twice daily (maximum, 400 mcg) |
| Fluticasone | Children: 1 spray per nostril 3 times a day Adults: 2 sprays (100 mcg) per nostril once daily; after a few days decrease to 1 spray per nostril Children >4 y and adolescents: 1 spray per nostril once daily (maximum, 200 mcg/day) |
| Mometasone furoate | >12 y: 2 sprays (100 mcg) per nostril once daily |
| Triamcinolone acetate | >12 y: 2 sprays (110 mcg) per nostril once daily (maximum, 440 mcg/day) |

of symptoms. Nasal steroids appear to be effective with minimal adverse effects. Some believe that nasal steroids should be recommended as initial therapy over antihistamines because of their high level of efficacy when used properly and along with avoidance of allergens.³⁹ Multiple mechanisms are involved with the effects of nasal steroids on the nasal mucosa: reducing inflammation by reducing mediator release, suppressing neutrophil chemotaxis, reducing intracellular edema, causing mild vasoconstriction, and inhibiting mast cell–mediated late-phase reactions.⁴⁰ Table 93–7 lists the available nasal steroids and their usual doses.

Topical steroids produce only minor adverse effects, most commonly sneezing, stinging, headache, and epistaxis. Despite concerns about safety of systemic steroids, nasal steroids have been found to have no significant association with hypothalamic-pituitary axis suppression, cataract formation, glaucoma, or bone mineral density changes in the doses used for allergic rhinitis. Growth suppression remains a question with some evidence showing that nasal steroids with higher bioavailability (e.g., beclomethasone) may have a greater growth suppression effect than less bioavailable agents.⁴¹ These findings require more study. Most likely, all currently available nasal steroids are safe in the majority of patients and their clinical benefits outweigh any small growth suppressive effect. Other concerns include local infections with *Candida albicans*, which have occurred rarely.

The therapeutic benefits of topical steroids are not immediate. Patients need to understand this to ensure cooperation and continuation of therapy. Some patients notice improvement in a few days, but peak responses may not be observed for 2 to 3 weeks. Once a response is achieved the dosage may be reduced. Blocked nasal passages should be cleared with a decongestant before administration to ensure adequate penetration of the spray. Patients should be advised to avoid sneezing or blowing their noses for at least 10 minutes after administration. Topical steroids should not be used in patients with nasal septum ulcers or recent nasal surgery or trauma.

One additional benefit of nasal steroids in treating allergic rhinitis in individuals with asthma and upper airway conditions is that they

may confer some protection against exacerbations of asthma, leading to fewer emergency room visits. The overall relative risk for an emergency visit among asthma patients who received intranasal steroids was 0.7.⁴² No effect was seen in patients receiving antihistamines.

Other Inhalant Medications

Cromolyn sodium and ipratropium bromide offer two additional approaches for treating allergic rhinitis. Cromolyn sodium is a mast cell stabilizer. Increased interest in this product has resulted from it becoming available without a prescription. Ipratropium bromide is an anticholinergic agent useful in perennial allergic rhinitis.

Cromolyn sodium nasal spray is used for the symptomatic prevention and treatment of allergic rhinitis. It curtails antigen-triggered mast cell degranulation and release of the mediators of allergic reactions, including histamine. Cromolyn sodium has no direct antihistaminic, anticholinergic, or anti-inflammatory properties. Similarly to topical steroids, the most common adverse effects—sneezing and nasal stinging—result from local irritation. The dose in adults and children at least 2 years of age is one spray in each nostril three to four times per day at regular intervals every 4 to 6 hours. Cromolyn sodium must cover the entire nasal lining; therefore patients should be instructed to clear nasal passages before administration. Inhaling through the nose during administration aids in this process. Dosing must be repeated at 6-hour intervals to maintain the effect.

For seasonal rhinitis, treatment with cromolyn sodium should be initiated just before the usual start of the offending allergen's season and continued throughout the season. In perennial rhinitis, the effects may not be seen for 2 to 4 weeks; therefore antihistamines or decongestants may be needed during this initial phase of therapy. As cromolyn sodium begins to work, the need for these medications should decrease.

Ipratropium nasal spray is an anticholinergic agent that exhibits antisecretory properties when applied locally. It provides symptomatic relief of rhinorrhea associated with allergic and other forms of chronic rhinitis. The 0.03% solution is given as two sprays (42 mcg) two to three times daily. The optimal dose should be determined based on the specific patient's symptoms and response. Adverse effects are mild, with the most common being headache, nosebleeds, and nasal dryness.

IMMUNOTHERAPY

4 The first report of the successful use of grass pollen extract injections to treat allergic rhinitis was published in 1911 by Noon.⁴³ The therapy was first called *desensitization*; however, this did not seem appropriate because skin reactivity sometimes remained. The name was later changed to *hyposensitization*. While this term is still used today, *immunotherapy* is used more commonly and is less confusing.

Immunotherapy is the slow, gradual process of injecting increasing doses of antigens responsible for eliciting allergic symptoms in a patient with the hope of inducing tolerance to the allergen when natural exposure occurs. Several mechanisms have been proposed to explain the beneficial effects of immunotherapy, including: induction of IgG antibodies, reduction in specific IgE (long-term), reduced recruitment of effector cells, altered T-cell cytokine balance (a shift from Th1 to Th2), T-cell anergy, and induction of regulatory T cells.⁴⁴

Immunotherapy is expensive, has significant potential risks, and requires a major time commitment from the patient. For these

reasons, it should be considered only in a select group of patients. Candidates for immunotherapy should have a strong history of severe symptoms unsuccessfully controlled by avoidance and pharmacotherapy, or stand to achieve more benefit in other significant ways, such as with asthma. Immunotherapy may postpone the onset of asthma or possibly even prevent it.⁴⁵ Patients who have been unable to tolerate the adverse effects of properly managed drug therapy also should be considered. Patients must be committed to the necessary regular office visits required to complete this long course of therapy.

The effectiveness of immunotherapy for seasonal allergic rhinitis appears to be better than that seen with perennial rhinitis, in part because it is more difficult to determine which allergen is responsible for perennial symptoms, and it is more due to multiple sensitizations. Effectiveness has been shown in a number of clinical studies using a variety of pollen extracts, even in patients with severe disease resistant to pharmacotherapy.⁴⁴ Specific immunotherapy for house dust mites has had good results in appropriately selected patients, while several studies have described marked improvement in patients with allergy to cats. Data indicate that in some patients 3 years of immunotherapy may be sufficient to give lasting benefit.⁴⁶

The selection of antigens should be based on patient history and skin test results. Numerous regimens for administration of selected allergens have been suggested. In general, very dilute solutions are given initially one to two times per week. The concentration is increased until the maximum tolerated dose is achieved. This maintenance dose is continued every 2 to 6 weeks, depending on clinical response. In light of the present understanding of the immunologic results of immunotherapy, it should be given year-round rather than seasonally.

Adverse reactions can occur with immunotherapy and range from mild to life-threatening. Among the most common are mild local reactions, consisting of induration and swelling at the site of the injection. These may be immediate or delayed. Other more serious reactions (e.g., generalized urticaria, bronchospasm, laryngospasm, and vascular collapse) occur rarely; deaths can result from anaphylactic reactions. Severe reactions are treated with epinephrine. Antihistamines and systemic corticosteroids may also be used as adjunctive therapy, and in rare circumstances glucagon may be necessary.

Several patient types have been identified as poor candidates for immunotherapy, including: patients with any medical condition that would compromise the ability to tolerate an anaphylactic-type reaction, patients with impaired immune systems, and patients with a history of nonadherence to therapy.⁴⁷

NEW AND ALTERNATIVE TREATMENT OPTIONS

Montelukast is the first leukotriene receptor antagonist that has received approved labeling for the treatment of seasonal allergic rhinitis. Leukotriene receptor antagonists inhibit the cysteinyl leukotriene receptor. The cysteinyl leukotrienes are among the inflammatory mediators released from mast cells. Montelukast is effective alone or in combination with an antihistamine.⁴⁸ Dosage regimens are given in Table 93–8. While this class represents a therapeutic alternative,

TABLE 93–8. Dosage Regimens for Montelukast in Treatment of Allergic Rhinitis

| Age | Dosage ^a |
|----------------------------------|---|
| Adults and adolescents >15 years | One 10-mg tablet daily |
| Children 6–14 years | One 5-mg chewable tablet daily |
| Children 2–5 years | One 4-mg chewable tablet or oral granule packet daily |

^aThe timing of drug administration can be individualized. If the patient has combined asthma and seasonal allergic rhinitis, the dose should be given in the evening.

studies published to date show them to be no more effective than peripherally selective antihistamines, and less effective than intranasal steroids.⁴⁹

The recent development of monoclonal antibodies directed against the binding site of IgE points to a potentially exciting new way to treat allergic respiratory diseases. Omalizumab, a recombinant humanized anti-IgE monoclonal antibody, is the first to show efficacy in allergic rhinitis.⁵⁰ The actual mechanism of how this agent is thought to work is quite complex.⁵¹ Anti-IgE antibodies bind to the site on the IgE molecule that recognizes the IgE receptor, thereby preventing the IgE molecule from binding to mast cells or basophils. The half-life of IgE antibodies on the mast cell surface is about 6 weeks, and as the antibodies turn over they become available for binding to anti-IgE antibodies. Therefore, by giving repeated doses of omalizumab, the number of IgE antibodies on the mast cell surface can be significantly reduced over time. These new IgE molecules are not eliminated, but remain in circulation as small immune complexes. IgE receptor numbers on basophils and mast cells may be decreased as a result of downregulation. Because of the expensive nature of this therapy, omalizumab’s role has not been defined. Some promising results have been described when it is used in combination with immunotherapy.⁵²

CLINICAL CONTROVERSY

Omalizumab may offer significant long-term benefits to allergic rhinitis patients, but it may prove to be too expensive to gain widespread acceptance.

As mentioned earlier in this chapter, microbial exposure in the early years of life could help prevent allergic disease by developing a non-atopic immune response.⁶ This concept was further studied by administering *Lactobacillus rhamnosus* prenatally to mothers who had at least one first-degree relative or partner with atopic disease (eczema, allergic rhinitis, or asthma) and postnatally for 6 months to their infants.⁵³

CLINICAL CONTROVERSY

Recent evidence shows that probiotics might be useful in preventing the onset of allergic disease, but more research needs to be conducted before use of these products is recommended.

PHARMACOECONOMIC CONSIDERATIONS

The economic impact of allergic rhinitis is enormous. The direct costs have grown significantly over the past few years because of the increasing use of peripherally selective antihistamines and nasal

steroids. The most recent detailed review estimated expenditures of \$3.4 billion annually in the United States, with the majority of this cost attributed to prescription medications and outpatient visits.⁵⁴ Of prescribed medications, 51% were peripherally selective antihistamines, 25% intranasal steroids, and 5% were older antihistamines. A

total of 58% of patients received one or more agents. The mean prescription medication expenditure was \$103 per patient for those on Medicaid, \$155 with private insurance, and \$69 for patients with no insurance. These figures do not include expenditures for nonprescription medications. With various brands and generic equivalents of nonprescription nonsedating products being heavily marketed to consumers, one would guess that usage of these agents would greatly increase. How this will affect the prescription market is unknown.

Direct-to-consumer advertising for prescription-only allergic rhinitis treatment options has also increased significantly. Indirect costs related to missed school or work days and loss of productivity may approach the amount for the direct costs.⁵⁵

The most cost-effective choice of treatment for allergic rhinitis is an individualized decision. Seasonal allergic rhinitis patients who see improvement and can tolerate nonprescription and/or generic antihistamines will experience the least impact on out-of-pocket medical and drug expenses. If these are not effective, the economic picture becomes more complicated. Choices should follow the logical path based on symptoms, tolerance, and efficacy, as described earlier in this chapter.

EVALUATION OF THERAPEUTIC OUTCOMES

With allergic rhinitis, the major outcomes issues include the effect of the disease on a patient's life, the efficacy and tolerability of treatment, and patient satisfaction. Consideration must be given to how the condition is affecting the patient's job or school performance, family and social interactions, and other aspects of quality of life. The drug therapy should prevent or minimize symptoms with minimal or no adverse effects. The patient should not have difficulty obtaining needed medication for financial or other reasons. Patients should be questioned about their satisfaction with the management of their allergic rhinitis. The management should result in minimal disruption to their lives.

Both the Medical Outcomes Study 36-Item Short Form Health Survey and the Rhinoconjunctivitis Quality of Life Questionnaire have been used to evaluate outcomes of treatment for seasonal and perennial allergic rhinitis.^{56–58} These tools go beyond measuring improvement in symptoms and include such items as sleep quality, nonallergic symptoms (e.g., fatigue, poor concentration, and others), emotions, and participation in a variety of activities. How well each of the current treatment modalities performs and how they compare in improving patient outcomes remain to be determined.

Clinicians caring for allergic rhinitis patients should develop a comprehensive pharmaceutical care plan that addresses several areas. Discuss and agree on therapeutic end points for allergic rhinitis, including the patient's acceptable level of symptom relief, onset of symptom relief expectations, and seasonal starts and stops. Discuss adverse drug reaction self-monitoring and prevention based on treatment selection. Assess patient attitude toward adherence to and persistence with oral, ocular, intranasal, or immunologic therapies. Ensure proper matching of treatment to symptoms and intervene with the prescriber if necessary. Conduct seasonal or annual review with patient.

The therapeutic goal for all patients with allergic rhinitis is to minimize or prevent symptoms. Evaluation of success is accomplished primarily through the discussions with the patient, in whom both relief of symptoms and tolerance of drug therapy must be discussed.

ABBREVIATIONS

HEPA: high-efficiency particulate air (filter)
IgE: immunoglobulin E
LT: leukotriene
RAST: radioallergosorbent test

A.

B.

PLATE 1. Macules are circumscribed, flat lesions of any shape or size that differ from surrounding skin because of their color. A. Macules may be the result of hyperpigmentation (A), hypopigmentation, dermal pigmentation (B), vascular abnormalities, capillary dilatation (erythema) (C), or purpura (D). B. The clinical appearance of a drug reaction that has produced an eruption consisting of multiple, well-defined red macules of varying size that blanch upon pressure (diascopy) and are thus due to inflammatory vasodilation. (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, McGraw-Hill, 2003, p 14.)

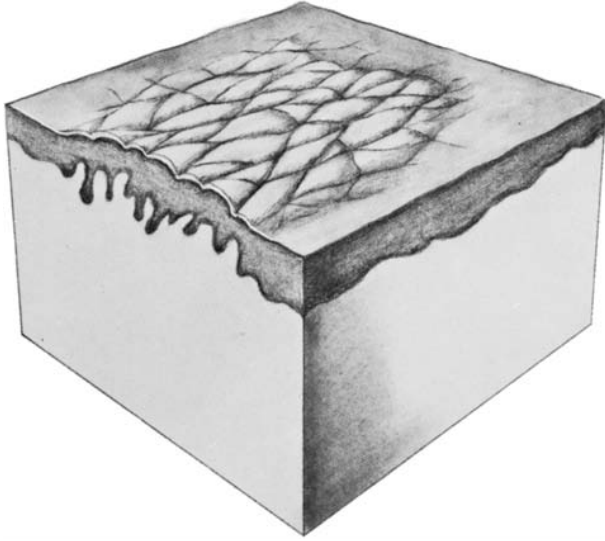

A.

C.

B.

PLATE 2. Papules are small, solid, elevated lesions that are less than 1 cm in diameter. The major portion of a papule projects above the plane of the surrounding skin. A. Papules may result, for example, from metabolic deposits in the dermis (A), from localized dermal cellular infiltrates (B), and from localized hyperplasia of cellular elements in the dermis and epidermis (C). Papules with scaling are referred to as *papulosquamous lesions*, as in psoriasis (see Chap. 96). B. Clinical examples of papules. C. Two well-defined and dome-shaped papules of firm consistency and brownish color, which are dermal melanocytic nevi; multiple, well defined, and coalescing papules of varying size are seen. Their violaceous color, glistening surface, and flat tops are characteristic of lichen planus. (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, McGraw-Hill, 2003, p 15.)

A.

PLATE 3. *A. Plaque* is a mesa-like elevation that occupies a relatively large surface area in comparison with its height above the skin surface. *B. Well-defined, reddish, scaling plaques* can coalesce to cover large areas of the back and buttocks, with some regression in the center as is common in psoriasis (see Chap. 96). *C. Lichenification*, a thickening of the skin and accentuation of skin, can result from repeated rubbing. It develops frequently in patients with atopy, and also occurs in eczematous dermatitis or other conditions associated with pruritus. Lesions of lichenification are not as well defined as most plaques and often show signs of scratching, such as in excoriations and crusts. (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, McGraw-Hill, 2003, p 16.)

B.

C.

A.

C.

B.

PLATE 4. *Nodules* are palpable, solid, round or ellipsoidal lesions. Depth of involvement and/or substantive palpability rather than diameter differentiates a nodule from a papule. *A.* Nodules may be located in the epidermis (*B*) or extend into the dermis or subcutaneous tissue (*A*). *B.* This photograph shows a well-defined, firm nodule with a smooth and glistening surface through which telangiectasia (dilated capillaries) can be seen; there is central crusting indicating tissue breakdown and thus incipient ulceration (nodular basal cell carcinoma). *C.* Multiple nodules of varying size can be seen (melanoma metastases). (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, McGraw-Hill, 2003, p 17.)

A.

C.

B.

PLATE 5. A. *Wheals* are rounded or flat-topped papules or plaques that are characteristically evanescent, disappearing within hours. An eruption consisting of wheals is termed *urticaria* and usually itches. B. Wheals may be tiny papules 3 to 4 mm in diameter, as in cholinergic urticaria. C. Alternatively, wheals may present as large, coalescing plaques, as in allergic reactions to penicillin, other drugs, or alimentary allergens. (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, McGraw-Hill, 2003, p 18.)

A.

B.

PLATE 6. *Vesicles* and *bullae* are the technical terms for blisters. Vesicles are circumscribed lesions that contain fluid, while bullae are vesicles that are larger than 0.5 cm in diameter. A. *Subcorneal vesicles* (A) result from fluid accumulation just below the stratum corneum, while *spongiotic vesicles* (B) result from intercellular edema. B. Multiple translucent subcorneal vesicles are extremely fragile, collapse easily, and thus lead to crusting (*arrows*). These lesions are staphylococcal impetigo. (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, McGraw-Hill, 2003, p 18.)

PLATE 7. Acute dermatitis caused by poison ivy. Note the linear arrangement of lesions typical of phyto dermatitis acquired by inadvertent contact with the plant. The severe vesiculobullous reaction is typical for urushiol, an oily poisonous irritant found in plants of the genus *Toxicodendron*. (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, McGraw-Hill, 2003, p 1167.)

A.

B.

PLATE 8. *A.* This patient has allergic chronic dermatitis involving the dorsal aspects of the hands and the distal forearms, but with minimal involvement of the palms. In this case, contact dermatitis is secondary to use of thiuram present in rubber gloves, prescribed for treatment of an irritant hand dermatitis. *B.* This patient, a florist, has allergic contact dermatitis due to exposure to tuliposide A, the allergen in Peruvian lilies (*Alstroemeria* spp.). Note the more prominent involvement of the palms of the dominant hand. (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, McGraw-Hill, 2003, p 1169.)

PLATE 9. Seborrheic dermatitis with involvement of the nasolabial folds, cheeks, eyebrows, and nose. (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, McGraw-Hill, 2003, p 1199.)

PLATE 10. Seborrheic dermatitis of the upper back. (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, McGraw-Hill, 2003, p 1200.)

PLATE 11. This patient exhibits a striking amiodarone-induced, slate-gray pigmentation of the face. The blue color (ceruloderma) is caused by deposition in the dermis of a brown pigment, which is contained in macrophages and endothelial cells. (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, McGraw-Hill, 2003, p 876.)

PLATE 12. Severe solar damage of the face revealing telangiectasias as well as actinic keratoses at different stages in development, including the flat, pink macules and hyperkeratotic papules. (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, McGraw-Hill, 2003, p 722.)

PLATE 13. This case of squamous cell carcinoma must be differentiated in diagnosis from chondrodermatitis nodularis helioides, which unlike the carcinoma, is painful. (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed., New York, McGraw-Hill, 2003, p 738.)

A.

A.

B.

PLATE 14. A. Basal cell carcinoma, nodular type. B. An ulcerated nodular basal cell carcinoma. (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, McGraw-Hill, 2003, p 749.)

B.

PLATE 15. These two superficial spreading melanomas illustrate the ABCDs of melanoma. A, asymmetry: The lesions are not symmetrical and often have irregular borders. B, border: Note the highly irregular, uneven, and notched border. C, color: The color is variegated with different shades of brown, black, and tan. D, diameter: The diameter is usually (but not always) more than 6 mm in melanomas. (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, McGraw-Hill, 2003, p 925.)

DERMATOLOGIC DRUG REACTIONS,
SELF-TREATABLE SKIN DISORDERS,
AND SKIN CANCER

Nina H. Cheigh

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

As the largest organ of the body, the skin, also known as the integumentary system, is the site of a vast number of pathologic conditions. Patients present with insults to and infections of the skin in a variety of primary care settings, ranging from community pharmacies to emergency departments, requesting evaluation of and advice about skin lesions.

In a survey of patients about the sources of advice they use for skin conditions, pharmacists ranked second, just behind physicians. Interestingly, the advice sought seemed to depend on the nature of the condition, in that patients sought more pharmacist advice on conditions such as dermatitis, psoriasis, skin cancer, and acne.¹ To properly assess a patient, pharmacists and other primary care providers must not only understand clinical presentations of common skin disorders, but they must also be able to quickly identify patients that may need referral for further evaluation by a physician.

In this chapter skin disorders that are self-treatable and dermatologic reactions to medications are presented from a primary care perspective of a pharmacist or other health professional who commonly recommends nonprescription therapies, or refers patients to prescribers or physician specialists. Skin infections are mentioned here, but covered in detail in Chap. 108, on skin and soft tissue infections.

SKIN STRUCTURE AND FUNCTION

The skin has many important functions. Its three layers—the epidermis, dermis, and hypodermis (subcutaneous tissue)—provide a barrier, prevent dehydration, protect from external injury or microorganisms, maintain body temperature, and even express emotions through dilation or constriction of blood vessels. The dermal layer contains most of the structural components of skin, such as mast cells, fibroblasts, collagen, elastic fibers, sweat glands, sebaceous glands, pigment-producing melanin cells, and vasculature.

The hair and nails are considered appendages of the skin. Hair, comprising keratinized epithelial cells, is protein bound and grows in cycles. Scalp hair grows at a rate of approximately 35 mm/day, but this can be affected by various medications and hormones. The nails, also comprised of keratinized cells, have different anatomic components. The nail plate is the main part of the nail, and is highly adherent to the

nail bed, which grows underneath. Generally, toenails tend to grow at a much slower rate than fingernails. Several factors affect the growth of the nails, including genetics, age, and weather.²

PATIENT ASSESSMENT

Before a treat-or-refer recommendation can be made, the pharmacist or other health professional must make a reasoned assessment of the problem and make a presumptive diagnosis (or at least rule out some of the many skin disorders). Several factors affect this decision, including patient age and hormonal status, patient complaint and history, and lesion assessment.

AGE AND HORMONAL STATUS

A primary factor to consider in evaluation is the age of the patient. Changes in the anatomy and physiology of skin and its appendages relate closely to patient age, and for women hormonal status also affects the evaluation.

GERIATRIC CONSIDERATIONS

In addition to wrinkling and dryness, expected age-related skin changes include an increase in uneven pigmentation and thinning of the protective layers, thus predisposing the skin to external injuries. Langerhans cells are reduced by 50% in number, reducing natural immunity to skin cancers. The vascularity of the skin declines, and thus older patients tend to look pale (pallor), feel cold to the touch, and have an increased predisposition to develop certain conditions such as psoriasis, seborrhea, pemphigoid, and candidiasis. Changes in the skin appendages can also occur in the elderly, such as thinning and graying of the hair on the scalp. Women can develop facial hair due to the reduction of estrogen levels. The thickness of the nails is reduced, and nails change in color.

PEDIATRIC CONSIDERATIONS

Certain dermatologic conditions, such as atopic dermatitis, are most likely to occur in children. Also, the rate and amount of absorption

of medications through the skin is higher in children. Infants may not be able to safely metabolize or excrete medications because of immaturity of their hepatic and renal systems. They also have immature sebaceous gland activity, and thus present frequently with seborrheic dermatitis of the scalp, also known as “cradle cap.”

In adolescence, hair appears in new places: the face in boys, and the pubic and other areas in both boys and girls. Sweating and sebaceous gland activity is greater, thus resulting in increased body odor and skin conditions such as acne (see Chap. 96).

HORMONE-RELATED CONSIDERATIONS

Variations in progesterone and estrogen can result in dermatologic disorders as women go through changes and events of their lives.

Menopausal women tend to develop brown hyperpigmentation, or melasma. Women who are on hormone replacement therapy or oral contraceptives also develop these nonspecific brown discolorations on their skin.

Pregnant women develop many changes, including hyperpigmentation of the areola and genitalia. These women can also develop melasma, otherwise commonly known as the “mask of pregnancy.” Most pregnant women develop stretch marks, or striae gravidarum, around the abdomen, thighs, breasts, and buttocks. They can also develop disorders such as pruritic urticarial papules and plaques of pregnancy (PUPPPS). Women who are pregnant also typically notice changes in their hair, as it becomes thinner or thicker, or straighter or curlier.

PATIENT HISTORY

In addition to clues offered by patient age and special conditions such as pregnancy, several key questions can provide insights into the patient’s skin disorder or injury. Getting an accurate history and other information from the patient is critical for ensuring optimal treatment and avoiding undue complications.

THE INTERVIEW

When interviewing the patient, the health care professional should make careful notes of the interaction. Questions that are helpful in assessment include:

- *Are you having other symptoms, such as difficulty breathing, fever, or nausea and vomiting?* When patients present with a rash or skin lesion, the first consideration should be for any potential anaphylaxis or angioedema. Many medications can be responsible for these reactions, and these must be ruled out. If a patient has a severe reaction with difficulty breathing, the patient may require immediate or even emergent referral to an emergency care facility to obtain proper care. Epinephrine, intravenous corticosteroids, or oral prednisone may be needed immediately.
- *Where did the problem first appear? Where are you affected? Did it spread?* Asking where the skin lesions are is important, as it is likely that the entire skin surface is not visible to the health care professional, and the source of the infection may be concealed. For example, although the arms and legs can demonstrate a rash, it would be pertinent to determine if the trunk is also affected, indicating a more systemic cause, as

opposed to an unaffected trunk, which would likely indicate a nonsystemic cause.

- *If they are not visible, what do the lesions look like?* The patient can be asked whether the lesion is painful or itchy, and can thus be assessed for any infection requiring immediate treatment. For example, if the area is oozing, erythematous, and warm to the touch, it is most likely infected. Alternatively, if the lesion is not painful and no other symptoms are present, other conditions are likely present. If appropriate, the lesions can be assessed by the clinician for color, texture, size, and temperature. Also, it is important to note any asymmetry (e.g., the lesion is present on only one side of the body).
- *How long have the lesions been present?* Some patients present after having had a skin condition for quite sometime without seeking any advice. This information is also helpful if the lesions appeared soon after the start of a certain suspected medication.
- *Have the lesions changed in size, shape, color, or consistency?* This question is important in determining any changes that might have occurred with the condition. Most importantly, this question enables evaluation of the patient’s melanoma risk. Typically, any skin lesion that changes in these elements should be further examined by a physician.
- *What do you think the problem may be?* Many patients have some idea as to what the source of their problem may be, so it is helpful to ask this question, and get their opinions and observations.
- *Obtain a general medical and allergy history.* After questioning the patient, the clinician or other health care professional may be able to rule out recently started drugs or new diseases as causes of the patient’s reaction.

LESION ASSESSMENT

If appropriate and acceptable to the patient, the health professional should make a quick visual assessment of the skin lesions. The skin surface should be closely examined, preferably in natural light. As proper diagnosis is based on pattern recognition, the pharmacist or other health professional must understand and demonstrate competence in assessing the lesions (Figs. 94–1 through 94–6, Plates 1 through 6).³ In addition, when referral is needed, the clinician or other health care professional should describe lesions to dermatologists or other physicians in a consistent manner.

SITE DISTRIBUTION AND ARRANGEMENT

Note the area involved (e.g., face, trunk, arms, or legs) and the number of lesions present (single or multiple). The arrangement of the lesions is also helpful, such as stating that the lesions are linear (in a line), grouped, annular (ring-shaped), or serpiginous (resembling a snake). Symmetry or asymmetry should be noted; in skin cancer, lesions are typically asymmetrical.

SURFACE TEXTURE

Unless the lesions are oozing or appear to be infectious (see Fig. 94–6B), they should be palpated with caution. Palpation helps the health care professional determine whether the lesion is smooth or rough, firm or soft, or scaly or crusting.

A

B

FIGURE 94-1. Macules are circumscribed, flat lesions of any shape or size that differ from surrounding skin because of their color. A. Macules may be the result of hyperpigmentation (A), hypopigmentation, dermal pigmentation (B), vascular abnormalities, capillary dilatation (erythema) (C), or purpura (D). B. The clinical appearance of a drug reaction that has produced an eruption consisting of multiple, well-defined red macules of varying size that blanch upon pressure (diascopy) and are thus due to inflammatory vasodilation. See Plate 1. (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, McGraw-Hill, 2003, p 14.)

TYPE OF LESIONS

The size of lesions should be measured. Typically, lesions are described as being less than or greater than 0.5 cm in diameter. A *macule* (see Fig 94-1A) or a *papule* (see Fig. 94-2A) is typically 1 cm or less in diameter, while the term *patch* is sometimes used for larger flat macules (see Fig. 94-1B).

BORDER

Poorly circumscribed lesions are those for which it is hard to tell where the normal skin begins and ends (see Fig. 94-5B), while well-defined lesions have clearer demarcations between healthy skin and lesions (see Fig. 94-5B).

LESIONS AND SKIN COLOR

Lesions should be examined for variations from the patient's predominant skin color. Increased pigmentation (brownish color), loss of pigmentation, redness (erythema), pallor, cyanosis, and yellowing should be noted. Color can be very indicative when underlying systemic diseases are involved. For example, anemia and reduced blood flow can result in decreased skin redness. Cyanosis can indicate reduced cardiac blood flow or lung disease. Jaundice can suggest liver disease.

OTHER FEATURES

An assessment of the nails, hair, and mucous membranes should also be performed as needed and appropriate.

Once the health care professional identifies the specific questions to ask and can provide a reasonable description of the lesion, referral or appropriate therapies can be recommended. As there are hundreds of varieties of dermatologic disorders, here we will focus on common conditions most frequently encountered by the pharmacist and other primary care professionals, with an emphasis on skin disorders that are often treated with nonprescription medications, and on drug-induced skin disorders. Infectious skin conditions are covered in detail in Chap. 108, on skin and soft tissue infections.

ALLERGIC, IRRITANT, AND INFECTION-RELATED SKIN DISORDERS

DERMATITIS

The word *dermatitis* is a general term denoting an inflammatory erythematous rash. Many types of dermatitis have been described, with the most common being atopic dermatitis (see Chap. 97 for a complete discussion) and contact dermatitis. Although atopic dermatitis can occur at any age, it is most common in infants and children, and thus age can be a critical identifier in distinguishing between atopic and contact dermatitis. Atopic dermatitis is also frequently associated with elevated IgE levels and family history of atopic disease, such as dermatitis, allergic rhinitis, and asthma.⁴

CONTACT DERMATITIS

Contact dermatitis is an acute (Fig. 94-7, Plate 7) or chronic (Fig. 94-8, Plate 8) inflammatory skin condition that results from contact of an inciting factor with the skin. Typically, contact dermatitis can be further divided into two major subgroups, allergic or irritant, depending on whether the cause is an antigen (allergen), or irritant, such as an organic substance. In allergies, the antigenic substance triggers the Langerhans cells, and their immunologic responses produce the allergic skin reaction, sometimes several days later. Irritant contact dermatitis is more likely to be the result of a reaction within a few hours of exposure. Although symptoms of either type of contact dermatitis (erythematous vesicles with pruritus) are generally similar, the allergic type can result in more serious erosions or oozing pustules. Common offending agents for contact dermatitis are listed in Table 94-1.⁵

A

C

B

FIGURE 94-2. *Papules* are small, solid, elevated lesions that are less than 1 cm in diameter. The major portion of a papule projects above the plane of the surrounding skin. A. Papules may result, for example, from metabolic deposits in the dermis (A), from localized dermal cellular infiltrates (B), and from localized hyperplasia of cellular elements in the dermis and epidermis (C). Papules with scaling are referred to as *papulosquamous lesions*, as in psoriasis (see Chap. 96). B. Clinical examples of papules. C. Two well-defined and dome-shaped papules of firm consistency and brownish color, which are dermal melanocytic nevi; multiple, well defined, and coalescing papules of varying size are seen. Their violaceous color, glistening surface, and flat tops are characteristic of lichen planus. See Plate 2. (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, McGraw-Hill, 2003, p 15.)

TABLE 94-1. Common Allergens Producing Contact Dermatitis Among People in the United States.

| | |
|------------|------------------|
| Fragrance | Formaldehyde |
| Flavorings | Lanolin (wool) |
| Rubber | Neomycin sulfate |
| Metals | Nickel |
| Adhesives | Paraben mix |
| Glues | Thimerosal |
| Plastics | |

When patients present with symptoms of contact dermatitis, pharmacists and other primary care providers should initially ask key questions about exposure to potentially offending substances. Initial treatment of contact dermatitis should always focus on identification and removal of the offending agent. When this is not possible, the patient should be advised to avoid exposure to those agents considered most likely to be responsible. The second goal of treatment is the relief of symptoms. Products that relieve itching, rehydrate the skin, and decrease weeping of the lesions will provide some immediate relief. The dosage form of topical preparations is determined by the stage of inflammation. In the acute stage, wet dressings are preferred because ointments and creams further irritate the tissue. Astringents such as aluminum acetate, Burow solution, or witch hazel decrease

FIGURE 94-3. *A.* *Plaque* is a mesa-like elevation that occupies a relatively large surface area in comparison with its height above the skin surface. *B.* Well-defined, reddish, scaling plaques can coalesce to cover large areas of the back and buttocks, with some regression in the center as is common in psoriasis (see Chap. 96). *C.* *Lichenification*, a thickening of the skin and accentuation of skin, can result from repeated rubbing. It develops frequently in patients with atopy, and also occurs in eczematous dermatitis or other conditions associated with pruritus. Lesions of lichenification are not as well defined as most plaques and often show signs of scratching, such as in excoriations and crusts. See Plate 3. (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, McGraw-Hill, 2003, p 16.)

weeping from lesions, “dry out” the skin, and provide relief from itching. These agents are applied as wet dressings and should not be used for more than 7 days.

For chronic dermatitis, lubricants, emollients, or moisturizers should be applied after bathing. Soap-free (or mild) cleansers and products containing colloidal oatmeal also contribute to alleviating itch and soothing the skin. If the patient's reaction does not subside within a few days, or further spread occurs, the patient should be referred for specialist follow-up and for prescription therapy with stronger topical corticosteroids and possibly oral corticosteroid therapy.

SEBORRHEIC DERMATITIS

The prevalence of *seborrheic dermatitis* peaks during infancy, and then again during the fourth to seventh decades of life, affecting 3% to 5% of adults in the United States. In infants, seborrheic dermatitis is commonly referred to as “cradle cap.” Typically, this condition occurs around the areas of skin rich in sebaceous follicles, such as the face (Fig. 94-9, Plate 9), ears, scalp, and upper trunk (Fig. 94-10, Plate 10), although it is not classified as a disease of the sebaceous glands per se.⁶

Therapy of seborrheic dermatitis has four major goals: to loosen and remove scales, prevent yeast colonization, control any secondary

FIGURE 94-4. *Nodules* are palpable, solid, round or ellipsoidal lesions. Depth of involvement and/or substantive palpability rather than diameter differentiates a nodule from a papule. *A.* Nodules may be located in the epidermis (*B*) or extend into the dermis or subcutaneous tissue (*A*). *B.* This photograph shows a well-defined, firm nodule with a smooth and glistening surface through which telangiectasia (dilated capillaries) can be seen; there is central crusting indicating tissue breakdown and thus incipient ulceration (nodular basal cell carcinoma). *C.* Multiple nodules of varying size can be seen (melanoma metastases). See Plate 4. (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, McGraw-Hill, 2003, p 17.)

infections, and reduce itching and erythema. Interestingly, the disease typically seems to improve with warmer weather and worsens when the air is colder.

Many topical agents are used to manage seborrheic dermatitis. Depending on what area of the body is affected, the pharmacist or other health professional can assist in selection of proper vehicles (i.e., solutions or shampoos for the scalp). Ingredients such as selenium sulfide, salicylic acid, and coal tar can help soften and remove the scales. Seborrheic dermatitis responds very quickly to low-potency topical corticosteroid preparations, but judicious use is important to avoid long-term adverse effects. Topical ketoconazole 2% can also be used to help control the yeast colonization.⁷

DIAPER DERMATITIS

Diaper dermatitis, or diaper rash, is an acute, inflammatory dermatitis of the buttocks and genital and perineal region. Commonly seen in infants in diapers, this condition, which results in erythematous

patches, erosion of skin, vesicles, and ulcerations, can be seen in adults who wear diapers for incontinence. This reaction is a type of contact dermatitis, as it results from direct fecal and moisture contact with the skin in an occlusive environment.

Treatment of diaper dermatitis includes frequent diaper changes and keeping the area dry. Lukewarm water and mild soap can be used to cleanse the area thoroughly, which should then be allowed to dry. Occlusive agents—such as zinc oxide, titanium dioxide, petrolatum, or any combination of these—should be generously applied to the area before the diaper is applied.

DRUG-INDUCED SKIN DISORDERS

Approximately 2% to 3% of hospitalized patients experience an adverse cutaneous drug reaction, with a higher incidence in older individuals. Almost every commonly used drug has been implicated in producing local and/or systemic drug reactions (Table 94-2).

TABLE 94–2. Types of Drug-Induced Skin Eruptions

| Clinical Presentation | Pattern and Distribution of Skin Lesions | Mucous Membrane Involvement | Implicated Drugs | Treatment |
|----------------------------|--|-----------------------------|--|---|
| Erythema multiforme | Target lesions, limbs | Absent | Anticonvulsants (including lamotrigine), sulfonamide antibiotics, allopurinol, NSAIDs, dapsone | Supportive ^a |
| Stevens-Johnson syndrome | Atypical targets, widespread | Present | As above | Intravenous immunoglobulins, cyclosporine |
| Toxic epidermal necrolysis | Epidermal necrosis with skin detachment | Present | As above | Supportive ^a |
| Pseudoporphyria | Skin fragility, blister formation in photodistribution | Absent | Tetracycline, furosemide, naproxen | Supportive ^a |
| Linger IgA disease | Bullous dermatosis | Present or absent | Vancomycin, lithium, diclofenac, piroxicam, amiodarone | Supportive ^a |
| Pemphigus | Flaccid bullae, chest | Present or absent | Penicillamine, captopril, piroxicam, penicillin, rifampin | Supportive ^a |
| Bullous pemphigoid | Tense Bullae, widespread | Present or absent | Furosemide, penicillamine, penicillins, sulfasalazine, captopril | Supportive ^a |

^aSupportive care includes administration of systemic glucocorticoids until all symptoms of active disease disappear. NSAIDs, nonsteroidal anti-inflammatory drugs.

Typically, these reactions are unpredictable, ranging from mild, self-limiting episodes, to more severe, life-threatening ones. Some reactions are nonallergic, but drug-induced skin reactions tend to be immunologic in origin and relate to hypersensitivity.

Pharmacists and other primary care providers should develop an organized and thorough approach to evaluation of patients with potential drug-induced skin disorders. This process begins with a comprehensive drug history, including episodes of previous drug allergies, and is based on an understanding of the mechanisms involved in drug reactions.

CUTANEOUS DRUG REACTIONS

Maculopapular eruptions are the most common manifestation of drug-induced skin reactions. Lesions tend to resemble those of measles, often involving the trunk or pressure areas, and are frequently symmetrical. These eruptions are classified as either early, appearing within a few hours to 3 days after ingestion of the drug, or late, appearing up to 9 days after the exposure. Most reactions disappear within a few days after discontinuing the agent, and thus symptomatic control of the affected area is the primary intervention. Topical corticosteroids and oral antihistamines can relieve pruritus. In severe eruptions, a short course of systemic corticosteroids may be warranted.

A fixed-drug reaction, typically presenting as an erythematous or hyperpigmented round or oval lesion, usually ranges from a few millimeters to 20 cm in diameter.⁸ Although the lesion can appear anywhere, the oral mucosa or genitalia are the most common sites. If the patient takes the agent again, the drug reaction tends to recur within 30 minutes to 8 hours after rechallenge, in the exact same location, and this is highly indicative of the fixed-drug reaction (lesions may also occur in other locations).⁹ The pathogenesis of fixed-drug reactions is not well understood.

Treatment of fixed-drug reactions involves removal of the offending agent. Rechallenge should be avoided when possible. Other therapeutic measures include the use of corticosteroids, antihistamines to relieve itching, and perhaps cool water compresses on the affected area.⁹

Sun-induced drug eruptions tend to appear similar to a sunburn, and present with erythema, papules, edema, and sometimes vesicle formation. They also appear in areas that tend to be most exposed to sunlight, such as the ears, nose, cheeks, forearms, and hands. Photosensitivity is subdivided into *phototoxicity*, which is defined as a non-immunologic reaction, and a *photoallergic reaction*, which involves an immunologic mechanism and is far less common.¹⁰ Common medications associated with photosensitivity reactions include fluoroquinolones, nonsteroidal anti-inflammatory drugs, phenothiazines, antihistamines, estrogens, progestins, sulfonamides, sulfonylureas, thiazide diuretics, and tricyclic antidepressants.² Typically, patients can achieve symptom resolution by discontinuing the medication.

Patients with photosensitivity reactions should be treated much the same as burn victims would be; management of the “burn” is of primary importance. Some patients benefit from topical corticosteroids and oral antihistamines, but these are relatively ineffective. Systemic corticosteroids, typically oral prednisone at 1 mg/kg per day tapered over 3 weeks, is more effective for these patients. Pharmacists and other health care professionals should encourage the proper use of sunscreen, and recommend a protective product that protects against ultraviolet A and B rays.¹¹

HYPERPIGMENTATION

Many medications can cause changes in skin color. These can be caused by the medication, or may be due to disturbances in melanin production or formation. Depending on the medication, the site of hyperpigmentation can vary. For example, patients receiving

A

B

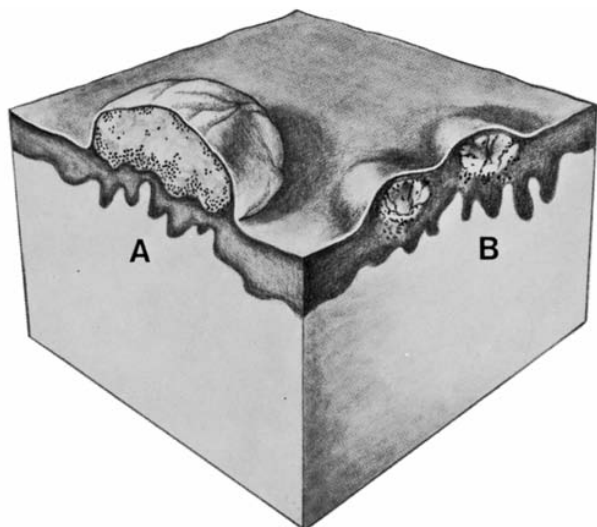

C

FIGURE 94-5. A. *Wheals* are rounded or flat-topped papules or plaques that are characteristically evanescent, disappearing within hours. An eruption consisting of wheals is termed *urticaria* and usually itches. B. Wheals may be tiny papules 3 to 4 mm in diameter, as in cholinergic urticaria. C. Alternatively, wheals may present as large, coalescing plaques, as in allergic reactions to penicillin, other drugs, or alimentary allergens. See Plate 5. (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, McGraw-Hill, 2003, p 18.)

anticonvulsants such as phenytoin, phenobarbital, and carbamazepine report a brown patchy lesion in sun-exposed areas.⁸ Patients who receive anticonvulsant therapy for more than 1 year are at a 10% risk of developing some form of hyperpigmentation related to the medication.¹² Women on oral contraceptives frequently report melasma, or brown, irregularly-shaped macules on the cheeks, forehead, or upper lip. Hormonal changes in estrogen and progesterone as well as sun exposure may cause the increase in melanin deposition.¹³ Other medications commonly associated with skin hyperpigmentation

include antimalarial agents, phenothiazines, tetracyclines,¹⁴ and amiodarone (Fig. 94-11, Plate 11).¹⁵

Patients with drug-induced hyperpigmentation can use skin bleaching creams and/or cosmetic agents that help to even out skin tone. Many such products have been marketed. Hydroquinone or kojic acid are most commonly found in cosmetic agents to aid in bleaching the darkened area of skin. Many times these agents are formulated in conjunction with such agents as α -hydroxy acids, which help to slowly slough off the outermost layer of skin. These patients using bleaching

A

B

FIGURE 94-6. *Vesicles* and *bullae* are the technical terms for blisters. Vesicles are circumscribed lesions that contain fluid, while bullae are vesicles that are larger than 0.5 cm in diameter. *A*. *Subcorneal vesicles* (*A*) result from fluid accumulation just below the stratum corneum, while *spongiotic vesicles* (*B*) result from intercellular edema. *B*. Multiple translucent subcorneal vesicles are extremely fragile, collapse easily, and thus lead to crusting (*arrows*). These lesions are staphylococcal impetigo. See Plate 6. (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, McGraw-Hill, 2003, p 18.)

creams absolutely must use sunscreen, as areas being treated with these creams tend to be even more sun-sensitive.

SKIN CANCERS

Actinic keratoses (AKs) are abnormal keratinocytes that develop in response to prolonged exposure to ultraviolet radiation. These lesions can develop into squamous cell or basal cell carcinomas, and the

FIGURE 94-7. Acute dermatitis caused by poison ivy. Note the linear arrangement of lesions typical of phyto dermatitis acquired by inadvertent contact with the plant. The severe vesiculobullous reaction is typical for urushiol, an oily poisonous irritant found in plants of the genus *Toxicodendron*. See Plate 7. (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, McGraw-Hill, 2003, p 1167.)

presence of suspicious lesions is one of the top reasons that patients seek medical attention for dermatologic disorders.

AK usually presents as a small (2 to 6 mm), erythematous papule that feels flat, rough, or scaly when palpated (Fig. 94-12, Plate 12). It tends to be found in chronically sun-exposed areas, such as the top of the hands, head, neck, and forearms. Typically, patients with AKs are elderly and have fair skin, light-colored eyes, freckles, and a history of significant sun exposure and tend to sunburn easily. Because AKs are likely caused by ultraviolet radiation, sun-preventive measures, particularly in childhood, are of utmost importance.¹⁶ Most commonly, AKs are treated with liquid nitrogen, which will remove the lesion. Another frequently used therapy is topical 5-fluorouracil. Patients who are prescribed topical 5-fluorouracil should be properly counseled, as significant erythema, erosion, crusting, and even ulceration normally occur during treatment.

Squamous cell carcinoma (SCC) is a cutaneous malignancy with estimates of approximately 200,000 cases in the United States in 2001. SCC seems to be more common in advanced age, and twice as common in men as in women. Because of their susceptibility to the negative effects of long-term sun exposure, patients of Celtic ancestry and those with blue or green eyes, red hair, and fair complexion are at the greatest risk of developing SCC.¹⁷ Other risk factors include precursor lesions such as AKs, long-term immunosuppression, and ultraviolet radiation. SCC can appear in many areas, but mainly occurs

A

B

FIGURE 94-8. A. This patient has allergic chronic dermatitis involving the dorsal aspects of the hands and the distal forearms, but with minimal involvement of the palms. In this case, contact dermatitis is secondary to use of thiuram present in rubber gloves, prescribed for treatment of an irritant hand dermatitis. B. This patient, a florist, has allergic contact dermatitis due to exposure to tuliposide A, the allergen in Peruvian lilies (*Alstroemeria* spp.). Note the more prominent involvement of the palms of the dominant hand. See Plate 8. (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, McGraw-Hill, 2003, p 1169.)

in sun-exposed areas such as the head, neck, and dorsal aspect of the hands. Most SCCs appear as a firm, flesh-colored, or erythematous papule or plaque (Fig. 94-13, Plate 13). Some resemble an ulcer. Treatment for SCC is determined by the tumor's risk for metastasis, but commonly involves some form of surgical excision.

Basal cell carcinoma (BCC) is the most common cancer in humans, with an estimated 900,000 cases per year in the United States.¹⁷

FIGURE 94-9. Seborrheic dermatitis with involvement of the nasolabial folds, cheeks, eyebrows, and nose. See Plate 9. (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, McGraw-Hill, 2003, p 1199.)

FIGURE 94-10. Seborrheic dermatitis of the upper back. See Plate 10. (Reprinted with permission from Freedberg IM, et al, eds. Fitzpatrick's Dermatology in General Medicine, 6th ed. New York, McGraw-Hill, 2003, p 1200.)

FIGURE 94-11. This patient exhibits a striking amiodarone-induced, slate-gray pigmentation of the face. The blue color (ceruloderma) is caused by deposition in the dermis of a brown pigment, which is contained in macrophages and endothelial cells. See Plate 11. (Reprinted with permission from Freedberg IM, et al, eds. *Fitzpatrick's Dermatology in General Medicine*, 6th ed. New York, McGraw-Hill, 2003, p 876.)

FIGURE 94-13. This case of squamous cell carcinoma must be differentiated in diagnosis from chondrodermatitis nodularis helicis, which unlike the carcinoma, is painful. See Plate 13. (Reprinted with permission from Freedberg IM, et al, eds. *Fitzpatrick's Dermatology in General Medicine*, 6th ed., New York, McGraw-Hill, 2003, p 738.)

FIGURE 94-12. Severe solar damage of the face revealing telangiectasias as well as actinic keratoses at different stages in development, including the flat, pink macules and hyperkeratotic papules. See Plate 12. (Reprinted with permission from Freedberg IM, et al, eds. *Fitzpatrick's Dermatology in General Medicine*, 6th ed. New York, McGraw-Hill, 2003, p 722.)

BCCs can occur anywhere on the body, but they appear most commonly on the head and neck, usually as a nodular, pigmented lesion (Fig. 94-14, Plate 14). Treatment varies depending on the histology of the lesion, but frequently requires Mohs micrographic surgery, surgical excision, and possible use of topical agents. Topical imiquimod is approved by the Food and Drug Administration for treating BCC of areas other than the face, and this agent resulted in some clearances in a phase II study.¹⁸ Topical 5-fluorouracil has also been used, but needs further evaluation to warrant routine use.

The risk of malignant melanoma is increasing, with a prediction that prevalence could reach 1 in 50 by 2010.¹⁹ Most frequently, melanoma occurs on the back and extremities of white males and females, while in Asians and blacks, it tends to appear on mucous membranes and soles and palms. Risk factors include skin type, sun exposure and response to the sun (i.e., ability to tan), family history, and change in the appearance of moles. The presence of any nonhealing lesion should raise the suspicion of skin cancer. In addition to assessing these risk factors, pharmacists can play a key role in examining the questionable lesion(s) and by assessing the lesion's asymmetry, border, color, diameter, and history, as when a mole changed and led to the appearance of the lesion (Fig. 94-15, Plate 15). Patients who fit these criteria should be further evaluated by a dermatologist.

ACNE VULGARIS

Dennis P. West, Lee E. West, Maria Letizia Musumeci, and Giuseppe Micali

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 In the United States, acne vulgaris is the most common skin disorder, affecting 40 to 50 million people.
- 2 Four primary factors are identified as being involved in the formation of acne lesions: increased sebum production, sloughing of keratinocytes, bacterial growth, and inflammation.
- 3 Acne vulgaris is a disease of the pilosebaceous unit (i.e., the sebaceous glands and adjacent hair follicle).
- 4 Several types of lesions present at the same time in various stages of development, including noninflammatory and inflammatory lesions, scars, and residual hyperpigmentation.
- 5 Most therapeutic interventions function primarily to prevent the formation of new acne lesions and have minimal impact on existing lesions.
- 6 Because most treatments for acne reduce or prevent new eruptions, they may take up to 8 weeks for visible results.
- 7 *Mild acne* usually is managed with topical retinoids alone or with topical antimicrobials, salicylic acid, or azelaic acid. *Moderate acne* may be managed with topical retinoids in combination with oral antibiotics, and if indicated, benzoyl peroxide. *Severe acne* is often managed with oral isotretinoin.
- 8 Minocycline has more adverse effects than the other tetracyclines.

Acne is a common, chronic inflammatory disorder of the pilosebaceous unit in which a microcomedo develops as the initial condition. The most common form of acne is acne vulgaris. Other variants of acne are neonatal acne, adult acne, acne cosmetica, and acne mechanica. These descriptors refer to age of onset or causative factors.

Localization of acne vulgaris on the facial area, especially in an adolescent population, significantly impacts self-esteem. Although acne is self-limiting, it can persist for years and can result in disfigurement and scarring.¹ Acne may also be associated with anxiety, depression, and higher-than-average unemployment rates.² As the emotional impact of acne is not always easy to assess clinically,^{3,4} it is important for the health care professional to educate patients on causes of acne, discussing treatment regimens, and counseling on proper medication use.

EPIDEMIOLOGY

1 In the United States, acne vulgaris is the most common skin disorder, affecting between 40 and 50 million people.³ Acne vulgaris affects approximately 80% of the population between the age of 12 and 25 years,⁵ with no gender, race, or ethnicity prevalence.^{3,6}

Acne age of onset varies, but usually begins at puberty. A form of acne called *adult acne* may first occur after the mid-20s,⁷ affecting females more than males, and with lesions generally distributed in the lower facial area around the mouth, chin, and jaw line.⁸

ETIOLOGY

2 Four primary factors are identified as being involved in the formation of acne lesions: increased sebum production, sloughing of keratinocytes, bacterial growth, and inflammation.^{9–11}

INCREASED SEBUM PRODUCTION

Androgen stimulation is enhanced at puberty and sebaceous glands actively produce sebum. Testosterone, the predominant androgen, and its metabolites along with androstenedione, dehydroepiandrosterone, and dehydroepiandrosterone sulfate, are all increased in acne and apparently capable of enhancing sebaceous gland activity. Anatomic sites for acne tend to be more metabolically active in converting androgens to dihydrotestosterone.

Androgenic activity drives sebum production in the sebaceous glands; however, most acne patients do not have an endocrine abnormality. Acne-affected pilosebaceous units apparently have a hypersensitivity to circulating androgens.⁹ Increased sebum production per se is not necessarily responsible for acne, but may rather be viewed as an underlying factor.

SLOUGHING OF KERATINOCYTES

A primary factor in the development of acne is the process of follicular keratinization. Sloughing of keratinocytes within the hair follicle is a normal process, but in acne, follicular keratinization more readily involves keratinocyte clumping and subsequent plugging of

the hair follicle pore. Increased sloughing of keratinocytes correlates with comedo formation and may be related to influences such as local cytokine modulation, a decrease in sebaceous linoleic acid, and androgen stimulation.^{9,12} Abnormal follicular keratinization may be a primary event, or may be a secondary response to irritation or other factors.

BACTERIAL GROWTH AND COLONIZATION

The mix of “trapped” keratinocytes and sebum provide an environment for the normally-occurring bacteria *Propionibacterium acnes* to flourish.¹³ Although *P. acnes*, a partial anaerobe, resides in the follicle as normal flora, it triggers immune responses such that titers of antibodies to *P. acnes* are higher in patients with severe acne than in non-acne control subjects.

INFLAMMATION AND IMMUNE RESPONSE

Inflammation may be a consequence of increased sebum production, keratinocyte sloughing, and bacterial growth. Also, *P. acnes* may trigger inflammatory acne lesions by producing biologically active mediators and promoting proinflammatory cytokine release.^{14–16}

PATHOPHYSIOLOGY

3 Acne vulgaris is a disease of the pilosebaceous unit (i.e., the sebaceous gland and adjacent hair follicle). Sebaceous glands, predominant on the face, chest, and upper back, respond to androgen stimulation. These glands provide sebum to the follicular canal and eventually to the skin surface through the follicular opening (the pore). Follicular canal contents include keratinocytes, *Propionibacterium acnes* (*P. acnes*), and free fatty acids.

Formation of the primary lesion, the comedo, may be thought of as a plugging of the pilosebaceous follicle. In acne, the follicular canal widens and an increase in cell production may be seen. Sebum mixes with excess loose cells in the follicular canal to form a keratinous plug. The resulting lesion appears as a “blackhead,” or open comedo. The brown or black color is not a result of dirt accumulation, but that of melanin (pigment). Inflammation or trauma to the follicle may lead to formation of a “whitehead,” or closed comedo. If the follicular wall is damaged or ruptured, the contents of the follicle may extrude into dermis and present clinically as a pustule. Closed comedones are of clinical importance since they may become larger, inflammatory lesions secondary to local *P. acnes* activity (Fig. 95–1).⁹ Acne lesions may take months to heal completely, and fibrosis associated with healing may lead to permanent scarring.¹⁷

4 CLINICAL PRESENTATION OF ACNE VULGARIS

Acne lesions typically occur on the face, back, upper chest, and shoulder area. Severity of the disease varies from a mild comedonal form to severe inflammatory necrotic acne.¹⁸ Acne vulgaris is described as mild, moderate, or severe, depending on the type and severity of lesions present. See Table 95–1 for descriptions of mild, moderate, and severe acne.

SYMPTOMS

Generally, the diagnosis of acne vulgaris consists of findings that include a mixture of lesions of acne (e.g., comedones,

FIGURE 95–1. Principal influences in formation of acne lesions.

pustules, papules, nodules, and cysts) on the face, back, or chest. Although there is no precise definition for acne, many practitioners consider the presence of 5 to 10 comedones to be diagnostic.

SIGNS

There may be more than one morphologic type of lesion present (see Table 95–1), in various stages of development, including noninflammatory and inflammatory lesions, scars, and residual hyperpigmentation.¹⁸

NONINFLAMMATORY LESIONS

An open comedo or blackhead is a plug of sebum, keratinocytes, and microorganisms blocking a *dilated* hair follicle opening, whereas a closed comedo or whitehead is a similar plug blocking a *closed* hair follicle opening to the surface of the skin.

INFLAMMATORY LESIONS

- A papule is a well-defined, elevated, palpable, distinct area of skin generally less than 1 cm in diameter involving the epidermis and/or dermis. Papules may not have a change in skin color, but are always raised and may have variable textures.
- A pustule is an elevated, distinct, superficial cavity filled with purulent fluid, typically surrounding a hair follicle.
- A nodule is an elevated, firm, distinct, palpable, round or oval lesion up to 1 cm in diameter which occurs in the dermis and/or hypodermis.

SCARS

Permanent scars may occur as a result of inflammatory acne lesions.

RESIDUAL HYPERPIGMENTATION

Inflammatory acne lesions may trigger noticeable hyperpigmentation that may persist weeks to months after resolution of the lesion.¹

LABORATORY TESTS

There are no laboratory tests to diagnose acne vulgaris. Diagnosis is based on clinical signs. Other dermatologic conditions, such as folliculitis, acne rosacea, and other various acneiform disorders, sometimes may be confused with acne vulgaris.¹⁹

TABLE 95–1. Predominance of Acne Lesion Type by Acne Severity

| Acne Severity | Predominant Lesions | Typical Frequency of Lesion Type | | | | | |
|---------------|---|----------------------------------|-----------------|-----------|-----------|-----------|-----------|
| | | Closed Comedones | Open Comedones | Papules | Pustules | Nodules | Scarring |
| Mild | Noninflammatory lesions (open and closed comedones) | Few to numerous | Few to numerous | Possible | Possible | None | None |
| Moderate | Inflammatory papules and pustules with some noninflammatory lesions | Few to numerous | Few to numerous | Numerous | Numerous | Few | Possible |
| Severe | Inflammatory lesions and scarring with some noninflammatory lesions | Few to numerous | Few to numerous | Extensive | Extensive | Extensive | Extensive |

► TREATMENT: Acne Vulgaris

5 Most therapeutic interventions function primarily to prevent the formation of new acne lesions and have minimal impact on existing lesions. Among the factors that may affect acne are genetics, climate, diet, environment, stress, and physical activity.

Stress seems to aggravate, but not induce, acne.²⁰ In response to stress, immunoreactive nerve fibers may stimulate sebaceous gland activity and provoke inflammatory reactions via mast cells.²¹

The ingestion of iodine may exacerbate acne or induce acneiform lesions.¹⁰ Dietary factors in acne are controversial.

CLINICAL CONTROVERSY

An observational study has concluded that the incidence of acne in Western and non-Western societies is greatly different and suggests that it is not due to genetic influence alone, but most likely occurs due to differences in diet. These authors felt that a non-westernized diet, representing a substantially low glycemic index, influenced a dramatically lower incidence of acne.²² It is disputed whether this conclusion is accurate, since acne is influenced by multiple factors and there are no data to support an effect of glycemic index on acne.^{23,24} Whether proven or not, some clinicians feel that diet is a factor in skin conditions, including acne, and needs to be further addressed.²⁵

■ GENERAL APPROACH TO TREATMENT

6 Severity, lesion types,¹⁸ scarring, and skin discoloration, as well as previous treatment history, helps to determine a treatment approach to acne vulgaris (see Table 95–1).^{9,11,26,27} Most treatments reduce or prevent new eruptions and may take up to 8 weeks to produce visible results. During the first few weeks of therapy, acne may appear to worsen as existing acne lesions may resolve more rapidly. Patients must understand the need to continue therapy for optimal outcome.

7 Patient education with emphasis on goals, realistic expectations, and dangers of overtreatment is important to optimize therapeutic outcomes. Treatment regimens are targeted to types of lesions and acne severity.^{9,18} Mild acne usually is managed with topical retinoids alone or with topical antimicrobials, salicylic acid, or azelaic acid. Moderate acne may be managed with topical retinoids in combination with oral antibiotics, and if indicated, benzoyl peroxide.²⁷ Severe acne is often managed with oral isotretinoin.

Initial treatment is aimed at reducing lesion count and will vary in duration from a few months to a few years, depending on severity and response to treatment. Once control is achieved, chronic indefinite treatment may be required. Therapy with both topical and systemic antibiotics should be for the minimum duration necessary to achieve control of acne, in order to minimize the likelihood of resistance.^{9,26,27}

Topical treatment forms include creams, lotions, solutions, gels, and disposable wipes. Responses to different formulations may be dependent on skin type and individual preferences:

- Oily to normal skin types may tolerate gels, solutions, and lotions.
- Normal skin may tolerate gels, solutions, lotions, and creams.
- Normal to dry skin may tolerate lotions and creams.

Ointments are not typically included in topical acne therapy due to their occlusive nature and possible induction of acne cosmetica.

Systemic treatment is required in patients with moderate to severe acne, especially when acne scarring is a possibility.²⁸

Antibiotics such as tetracyclines and macrolides are the agents of choice for papulopustular acne. In severe papulopustular and nodulocystic/conglobate acne, oral isotretinoin is the treatment of choice. Hormonal therapy represents an alternative effective regimen in female patients.

NONPHARMACOLOGIC THERAPY

Scrubbing the skin with abrasive scrubs or excessive face washing does not necessarily open or cleanse pores. Follicular plugging originates too deeply to be affected by superficial epidermal scrubbing, which often leads to skin irritation.

Since surface cleansing with soap and water primarily affects sebum and bacteria on the surface of the skin and has minimal impact within the follicle, cleansing has a relatively small impact on the treatment of acne.

To avoid skin irritation and dryness during some acne therapies, it is important to use gentle, nondrying cleansing agents.

PHARMACOLOGIC THERAPY

Recently, worldwide consensus statements regarding management and treatment of acne have been widely distributed to improve and optimize outcomes. See Table 95–2 for highlights of consensus statements from The Global Alliance to Improve Outcomes in Acne.⁹ Figure 95–2 provides acne treatment algorithms based on acne severity. See Table 95–3 for the action spectra of selected acne treatments.

TABLE 95–2. Treatment Guidelines for Acne Vulgaris

| Therapy | Recommendations |
|---------------------|---|
| Topical retinoids | <ul style="list-style-type: none"> • Should be primary treatment for most forms of acne vulgaris • Use early for best results • Should be applied to the entire affected area • Combine with antimicrobial therapy when inflammatory lesions are present • Essential part of maintenance therapy |
| Hormonal therapy | <p>Excellent choice for women who also need oral contraceptives for gynecologic reasons</p> <ul style="list-style-type: none"> • Use early in female patients with moderate to severe acne or with symptoms of seborrhea, acne, hirsutism, or alopecia • Useful as part of combination therapy in women with or without endocrine abnormalities • Sometimes used in women with late-onset acne |
| Oral isotretinoin | <p><i>Indications:</i></p> <ul style="list-style-type: none"> • Severe nodulocystic acne • Severe acne variants • Inflammatory acne with scarring, after conventional therapy has failed • Moderate to severe acne, especially frequently relapsing cases • Acne with severe psychological distress <p><i>Typical dose:</i></p> <ul style="list-style-type: none"> • 0.5–1.0 mg/kg daily in two divided doses, with cumulative dose of 120–150 mg/kg per treatment course (4–6 months) • A lower dose (<0.5 mg/kg) may be used but is associated with a higher relapse rate • Patient counseling is critical |
| Combination therapy | <ul style="list-style-type: none"> • Should be used when inflammatory lesions are present • Speeds clearing and provides greater resolution of both inflammatory lesions and comedones • Topical retinoid should be started at the initiation of antimicrobial therapy • Antibiotic should be discontinued when inflammatory lesions resolve adequately • If this is not possible, then switch to a combination agent with benzoyl peroxide plus an antibiotic • Continue use of topical retinoid to maintain remission of new acne lesions when antibiotic therapy is discontinued |

From the consensus recommendations from *The Global Alliance to Improve Outcomes in Acne*.⁹

■ TOPICAL AGENTS: FIRST-LINE THERAPIES

■ Benzoyl Peroxide

Superficial inflammatory acne is typically treated with benzoyl peroxide (BPO), a nonantibiotic antibacterial agent that is rapidly bacteriostatic and possibly bactericidal against *P. acnes*.²⁹ Its antibacterial mechanism of action is uncertain, although BPO is decomposed on the skin by cysteine, liberating free oxygen radicals that oxidize bacterial proteins.³⁰ BPO increases the sloughing rate of epithelial cells, loosens the follicular plug structure, and thus possesses some degree of comedolytic activity. An advantage to using topical BPO is that *P. acnes* resistance is not known to develop.^{9,27}

BPO is available in soaps, lotions, creams, washes, and gels, in concentrations ranging from 1% to 5%;⁹ 10% concentrations are not significantly more efficacious, but may be more irritating. Gel formulations have better stability and are usually most potent, while lotions, creams, and soaps are weaker. Gels are usually based on alcohol, propylene glycol, or water; the alcohol-based preparations generally cause more dryness and irritation. Fair or moist skin usually is more sensitive to irritation from BPO; thus patients should be advised to apply medication to dry skin (at least 30 minutes after washing) to decrease irritation.

Cleansing dosage forms (washes) that contain antiacne ingredients such as α -hydroxy acids, BPO, or salicylic acid are available. BPO cleansers may be considered for adolescent boys, both to enhance compliance and to cover large skin areas such as the chest and back.⁹

Dryness and irritation from a primary irritant such as BPO may limit therapy in some patients; allergic contact dermatitis (delayed-type hypersensitivity reaction) has also been reported.³¹

To limit irritation and increase patient tolerance of BPO, one may initiate therapy with a low-potency formulation (2.5%), and increase either strength (5% to 10%) or application frequency (every other day, each day, and then twice a day). To minimize irritation potential, BPO should be applied to cool, clean, dry skin, no more frequently than twice daily. Use should be discontinued if excessive irritation or allergy occurs. One disadvantage is that BPO may bleach or discolor some fabrics (clothing, bed linen, or towels). Tolerability and effectiveness are enhanced when used in combination with other agents such as topical retinoids, clindamycin, and erythromycin.^{9,27,29,32}

■ Retinoids

Topical retinoids—tretinoin, adapalene, tazarotene, and in some countries topical isotretinoin, motretinide, retinaldehyde, and retinoyl- β -glucuronide⁹—should be used as first-line therapy for mild to moderate inflammatory acne and comedonal acne. They are also preferred agents for maintenance therapy to minimize antibiotic use in acne therapy.⁹ To optimize efficacy in moderate inflammatory acne, topical retinoids should be combined with topical antibiotics or BPO.^{27,33}

■ Tretinoin

Tretinoin, a topical vitamin A analogue, is a comedolytic agent that increases cell turnover in the follicular wall and decreases cohesiveness of cells, leading to extrusion of existing comedones and inhibition of the formation of new comedones,³⁰ and may reduce the number of inflammatory acne lesions.²⁷ Tretinoin significantly decreases the number of cell layers in the stratum corneum from about 14 to about 5.³⁰

In a 12-week study of tretinoin, the reduction of lesion counts ranged from 32% to 81% for noninflammatory lesions, and 17% to 71% for inflammatory lesions (22% to 83% for the total lesion count).²⁷ Comparing tretinoin 0.025% gel or 0.025% cream with vehicles only in a once-daily application regimen, tretinoin was significantly more effective in reducing both inflammatory and noninflammatory lesions.^{34,35}

Tretinoin is available as 0.05% solution (most irritating), 0.01% and 0.025% gels, and 0.025%, 0.05%, and 0.1% creams (least irritating).⁹ Treatment initiation with 0.025% cream usually is recommended for mild acne in patients with easily irritated and nonoily skin, 0.01% gel for moderate acne in easily irritated skin with oily complexion, and 0.025% gel for moderate acne with nonsensitive and oily skin. A “flare” of acne may appear suddenly after initiation of treatment, followed by clinical clearing in about 8 to 12 weeks.³⁰

Once control is established, therapy should be continued at the lowest effective concentration and at the maximum effective interval sufficient to minimize acne exacerbations.

Concomitant use of an antibacterial agent with tretinoin can decrease keratinization, inhibit *P. acnes*, and decrease inflammation. In addition, both BPO and tretinoin have shown additive or synergistic

effects in the treatment of inflammatory acne.³⁶ A regimen of BPO each morning and tretinoin at bedtime may enhance efficacy and be less irritating than either agent used alone.³⁶ By slowly increasing application frequency from every other day, to daily, and then twice daily, tolerance to tretinoin may be increased. Increased sensitivity to sun exposure, wind, cold, and other irritants may also be evident in patients using tretinoin.

Two reformulations of tretinoin include a porous bead (0.01% gel) (microspheres) and liquid polymer (0.025% cream and 0.025% gel). These are less irritating than standard vehicles for tretinoin. In the topical gel formulation containing polyolprepolymer-2, tretinoin penetration was significantly reduced while epidermal deposition was enhanced, compared with a commercially available gel preparation at the same concentration. Polyolprepolymer-2 promotes retention of drug molecules on the skin surface and in the upper layers of the skin.³⁷

In a double-blind 12-week study, tretinoin microsphere gel demonstrated faster onset of action than adapalene, including a greater reduction in comedone counts at week 4; yet reductions in acne lesions at 12 weeks were similar with the two drugs, and an increased incidence of dryness and peeling was associated with tretinoin.³⁸

Another formulation is a microsphere delivery system consisting of macroporous beads 10 to 15 micrometers in diameter that are loaded with tretinoin. Gradual release of active ingredient after topical application depends on mechanical rubbing, temperature, pH, and other factors.³⁹ Tretinoin 0.1% gel microsphere, tretinoin 0.025% gel, tazarotene 0.1% gel, and adapalene 0.1% gel all showed equivalent facial tolerability in a split-face study.³⁹ In another variation, a formulation of liposomally encapsulated tretinoin showed potentially better tolerance than gel dosage forms, yet demonstrated equivalent efficacy.⁴⁰

Adverse reactions to tretinoin—such as skin irritation, erythema, and peeling—will vary depending on individual skin type and dosage form used. Allergic contact dermatitis is rare and much less common than with BPO. Teratogenicity risk with topical retinoids remains controversial.

CLINICAL CONTROVERSY

During treatment with topical tretinoin, plasma tretinoin concentrations are typically less than endogenous levels, and apparently do not affect endogenous levels of tretinoin or its metabolites or alter plasma vitamin A levels. However, controversy continues with regard to teratogenicity and embryotoxicity risk versus benefit issues in the use of topical retinoids during pregnancy.^{41,42}

■ Adapalene

Adapalene, a third-generation retinoid,⁹ is a retinoid-mimetic compound (a naphthoic acid derivative), available as 0.1% gel, cream, alcoholic solution, and pledgets. It has selective affinity for retinoic acid receptor (RAR) subtypes RAR- β and RAR- γ found in the epidermis,^{43,44} and has comedolytic, keratolytic, and anti-inflammatory activity.^{11,44,45} Vehicle-controlled and comparative studies have demonstrated the utility of adapalene in treatment of acne.^{43,45,46}

Adapalene is indicated for mild to moderate acne vulgaris. Adapalene 0.1% gel may be used as an alternative to tretinoin 0.025% gel to achieve better tolerability in some patients.^{46,47} Adapalene coadministered with a topical or oral antibiotic represents a rational therapy for moderate forms of acne.¹¹

In a double-blind 12-week study, tretinoin microsphere gel demonstrated faster onset of action than adapalene, including a greater reduction in comedone counts at week 4. Yet reductions in acne lesions at 12 weeks were similar with the two drugs, and an increased incidence of dryness and peeling was associated with tretinoin.³⁸

Adapalene may also be an alternative in treating some patients of color since it produces less skin irritation and subsequent discoloration than the first-generation topical tretinoin products.¹¹

■ Tazarotene

Tazarotene, a prodrug and a synthetic acetylenic retinoid, is converted to its active form, tazarotenic acid, after topical application. This new-generation retinoid also selectively binds to RARs and can alter expression of genes involved in cell proliferation, cell differentiation, and inflammation.⁴⁴

Tazarotene is used in the treatment of mild to moderate acne vulgaris and has comedolytic, keratolytic, and anti-inflammatory action. Tazarotene 0.1% and 0.05% gel and cream have been shown to be more effective than vehicle in the treatment of acne vulgaris.^{48,49} The 0.1% gel was slightly more effective than the 0.05% gel in decreasing lesion counts, with treatment success rates of 68% and 51% of patients, respectively.³

Once-daily tazarotene gel may be more effective than once-daily tretinoin in reducing papules and open comedones, with equal efficacy against closed comedones.^{50,51} Efficacy is comparable to adapalene, but its local tolerance by daily application is similar to tretinoin. In addition, tazarotene was studied for its efficacy with short contact application. Once-daily short contact applications significantly reduced irritation potential, yet maintained therapeutic equivalency to standard application regimens.⁵²

Both 0.1% and 0.05% concentrations had acceptable tolerability profiles, with no serious adverse events.⁴⁹ Dose-related local adverse effects include erythema, pruritus, stinging, and burning.⁴

■ Erythromycin

Erythromycin in topical form in concentrations of 1% to 4% with or without the addition of zinc is effective against inflammatory acne. Zinc combination products possibly enhance penetration of erythromycin into the pilosebaceous unit.⁵³

Combinations of erythromycin and BPO have shown greater efficacy in treating acne than a combination of erythromycin and tretinoin.³³ Development of *P. acnes* resistance to erythromycin may be reduced by combination therapy with BPO.

Topical erythromycin, usually applied twice daily, is formulated as a gel, lotion, solution, and disposable pad. Reduction of the percentage of free fatty acids in sebum has been noted with the use of topical erythromycin.⁵³

■ Clindamycin

Topical clindamycin inhibits *P. acnes* and provides comedolytic as well as anti-inflammatory activity.⁵⁴ It is available in gel, lotion, solution, and disposable pad formulations, and is usually applied twice daily. Combination with BPO increases efficacy.⁵⁵ Though rare, diarrhea and pseudomembranous colitis may occur secondary to topical clindamycin.⁵⁶

■ Azelaic Acid

Azelaic acid has a dicarboxylic acid structure that confers antibacterial, anti-inflammatory, and comedolytic activity.⁵⁴ Azelaic acid is useful for treating mild to moderate acne in patients who do not tolerate BPO. It is useful in treating postinflammatory hyperpigmentation since it also has skin-lightening properties.⁵⁷

Azelaic acid has no likelihood of bacterial resistance, systemic adverse effects, or photosensitivity reactions. Although uncommon, adverse effects, usually transient, include burning, pruritus, stinging, and tingling.^{9,27}

Azelaic acid is available in a 20% cream formulation. Application is usually twice daily on clean, dry skin.

■ TOPICAL AGENTS: SECOND-LINE THERAPIES

■ Motretinide

Motretinide, also available outside the U.S., is a topical aromatic ester retinoid with an efficacy profile similar to low-dose tretinoin concentrations, but with somewhat less irritant potential.²⁷

■ Retinaldehyde

Retinaldehyde is biotransformed into all-*trans*-retinoic acid and induces biologic effects including comedolytic activity⁵⁸ similar to those of topical tretinoin when administered at comparatively lower concentrations.⁹

After topical application of retinaldehyde 0.1% gel or its vehicle every morning and erythromycin 4% lotion every evening in the treatment of acne for 8 weeks, comedones and microcysts were significantly improved with retinaldehyde combined with erythromycin, but not with erythromycin alone. In both treatment groups, papules and pustules were reduced significantly. Local tolerance is satisfactory.⁵⁹

■ Retinoyl- β -Glucuronide

Retinoyl- β -glucuronide is a naturally occurring, biologically active metabolite of vitamin A. A 0.16% retinoyl- β -glucuronide cream has been shown to be effective against inflammatory and noninflammatory acne lesions⁶⁰ with comparable efficacy to tretinoin, but with less irritation potential and comparatively fewer other adverse effects than with tretinoin.

■ Isotretinoin

Isotretinoin is available outside the U.S. as a gel formulation; it does not reduce sebum secretion as does oral isotretinoin. Used topically, the effectiveness of isotretinoin is similar to that of other topical retinoids, but it causes somewhat less skin irritation.²³ It reduces non-inflammatory lesions from 46% to 78% and inflammatory lesions from 24% to 55% after 12 to 14 weeks of treatment.²⁷

■ Keratolytic Agents

In addition to keratolytic activity, salicylic acid, sulfur, and resorcinol are mildly antibacterial.

Salicylic acid has comedolytic and anti-inflammatory action.²⁶ Also known as β -hydroxy acid, it is deemed a more effective comedolytic than most α -hydroxy acids.¹³ In addition, it increases penetration of other substances, and in low concentrations is bacteriostatic and fungistatic.²⁷

Although evidence for efficacy in the treatment of acne is conflicting, each agent has been classified as safe and effective by an advisory review panel of the FDA. Some combinations of these agents may be considered synergistic (e.g., sulfur and resorcinol, salicylic acid, BPO). Keratolytic products, in the concentration allowed, may be less irritating than BPO and tretinoin; however, they are not considered as effective comedolytic agents, as are BPO and tretinoin.

Disadvantages of these agents include the odor created by hydrogen sulfide on reaction of sulfur with the skin, the brown scale from use of resorcinol, and the possibility of salicylism from repeated and widespread use of sufficient concentrations of salicylic acid on highly permeable (inflamed and/or abraded) skin.⁵⁶

■ Corticosteroids

Topical corticosteroids can be applied in very selected patients with very inflammatory acne for short periods of time. They may play a role in reducing flare-up reactions in severe conglobate acne and for reduction of granuloma pyogenicum–like lesions under systemic isotretinoin treatment.²⁷

■ Chemical Peeling

Light chemical peels may be useful in some acne patients to reduce superficial scarring and hyperpigmentation.⁶¹ Chemical peeling targets the interfollicular epidermis.²⁷

Some currently available substances for chemical peeling include: α -hydroxy acids (glycolic acid), salicylic acid, and trichloroacetic acid.⁶¹ Salicylic acid is lipid soluble and may penetrate into sebum-laden follicles more readily than water-soluble α -hydroxy acids. Salicylic acid may also have some ability to reduce the inflammatory component of acne.^{9,26} Patients with sensitive skin types tolerate salicylic acid peels.⁶²

■ Dapsone

Topical dapsone, exhibiting antibacterial and anti-inflammatory properties, is being investigated for effectiveness in the treatment of acne.⁶³

■ SYSTEMIC AGENTS: FIRST-LINE THERAPY—SEVERE NODULAR/CONGLOBATA

■ Isotretinoin

As an oral retinoid, isotretinoin is the most effective sebosuppressive agent that affects all of the etiologic factors involved in inflammatory acne, including induction of atrophy of the sebaceous gland with decreased sebum production and change in sebum composition, inhibition of *P. acnes* growth within follicles, inhibition of inflammation, and altered patterns of keratinization within follicles (decreased size and increased differentiation).^{64,65} These characteristics make it the treatment of choice in severe nodulocystic acne.⁶⁶ It may be used

TABLE 95–4. Principal Adverse Effects of Oral Isotretinoin

| Adverse Effect | Response |
|--------------------------------|---|
| Teratogenicity | Contraindicated during pregnancy |
| Depression | Patient monitoring and counseling; antidepressants |
| Dryness | |
| Mouth | Hard candy |
| Eyes | Eyedrops; avoid contact lenses if possible during treatment course |
| Nose | Lubricant |
| Skin | Nondrying gentle skin cleansers; non-comedolytic moisturizers |
| Lips | Lip moisturizer with sunscreen |
| Muscle and joint pain | Nonsteroidal anti-inflammatory drugs |
| Alopecia | Reversible when drug discontinued or dose decreased |
| Hypertriglyceridemia | Reversible when drug discontinued or dose decreased |
| Acne flare at start of therapy | Continue therapy |
| Photosensitivity | Use sunscreens (moisturizing), protective clothing, and sun avoidance |

in patients who have failed conventional treatment, those who have scarring acne, those who have chronic relapsing acne, and those who have acne with severe psychological distress.⁶⁷

Adverse effects from orally administered isotretinoin are numerous, frequent, and often dose related.⁶⁸ About 90% of patients receiving isotretinoin therapy suffer from mucocutaneous effects. Drying of the mucosa of the mouth, nose, and eyes is the most common problem, with relatively rare involvement of the genito-anal mucosa. Cheilitis and skin desquamation occurs in more than 80% of patients. Less frequently, the conjunctiva and nasal mucosa are affected. Table 95–4 shows selected responses to some of the adverse effects of oral isotretinoin.

Disturbances in lipid metabolism also may occur, resulting in transitory increase of blood values for cholesterol and triglycerides.⁶⁷ Liver function and serum lipids should initially be monitored, typically at baseline and at weeks 4 and 8.⁶⁹ Serious adverse effects of isotretinoin therapy include: increased creatine phosphokinase and blood glucose, as well as photosensitivity, pseudotumor cerebri, excess granulation tissue, hepatomegaly with abnormal liver function tests, bone abnormalities, arthralgias, muscle stiffness, and headaches.⁷⁰

Hyperlipidemia, diabetes mellitus, and severe osteoporosis are relative contraindications for oral isotretinoin. The drug may very occasionally produce significant mood changes, depression, and other significant psychiatric adverse effects. Although relationship to drug therapy is controversial, current recommendations are that patients be counseled about and screened for depression during therapy.^{71,72}

Isotretinoin dosing guidelines range from 0.5 to 1 mg/kg per day, but the cumulative dose taken by patients during a treatment course may be the major factor influencing long-term outcome.⁷³ Optimal results generally have occurred when cumulative doses have attained a range of 120 to 150 mg/kg.⁷³

A 6-month course of therapy is sufficient for most patients, but it has been observed that an initial dose of 1 mg/kg per day for 3 months, then reduced to 0.5 mg/kg per day, and if possible, to 0.2 mg/kg per day for 3 to 9 additional months will optimize the therapeutic outcome.²⁸ Generally, after 2 to 4 weeks of treatment, a 50% reduction of the pustules can be expected. Pustules clear more rapidly than papules or nodules. Improvement continues during the posttreatment period. In female patients contraception is required because of teratogenicity,⁶⁸ recommended to begin 1 month before therapy, continuing during the entire period of treatment, and for up to 3 months after discontinuation of isotretinoin.⁶⁸

Although costs of therapy with isotretinoin are greater in the first year, isotretinoin can be more cost effective than long-term antibiotic treatment.⁷⁴

■ SYSTEMIC AGENTS: FIRST-LINE THERAPY—MODERATE PAPULAR PUSTULAR/NODULAR

■ Macrolide Antibiotics

The macrolide antibiotics (erythromycin, azithromycin, and clindamycin) exhibit anti-inflammatory properties in patients with acne.

Erythromycin can be used for patients who require systemic antibiotics, but cannot tolerate tetracyclines, or who acquire bacterial strains resistant to tetracyclines.^{75,76} The dosage is usually 1 g/day with meals to minimize gastrointestinal intolerance. Zinc combination products possibly enhance penetration of erythromycin into the pilosebaceous unit.⁵³ Erythromycin's efficacy is similar to tetracycline, but it induces higher rates of bacterial resistance.^{75,76} Development of erythromycin resistance by *P. acnes* may be reduced by combination therapy with BPO.

Azithromycin, an azalide antibiotic and derivative of erythromycin, is a safe and effective alternate treatment of moderate to severe inflammatory acne. With a half-life of 68 hours, it may be intermittently dosed three times a week.⁷⁷ One study using pulse therapy, 500 mg daily for 3 to 4 consecutive days every week for 4 weeks, demonstrated efficacy similar to other systemic antibacterial agents.⁷⁸ Adherence is high with this regimen, and phototoxicity and resistance have not been reported.⁷⁸

Clindamycin is very effective in the treatment of acne, but has disadvantages for long-term therapy due to the possible induction of pseudomembranous colitis. For this reason, its use in acne is uncommon.

■ Tetracyclines

The tetracyclines are effective in reducing *P. acnes*.⁷⁹ In addition to their antibacterial effects, they reduce the amount of keratin in sebaceous follicles and inhibit chemotaxis, phagocytosis, complement activation (by the alternate pathway), and cell-mediated immunity.⁸⁰ Tetracyclines also appear to have an affinity for inflammatory cells and

bacteria, resulting in higher drug concentration in areas of inflamed skin.

Adverse reactions involving the gastrointestinal tract may occur with the tetracyclines. Drawbacks to the use of tetracyclines include hepatotoxicity and predisposition to superinfections (vaginal candidiasis), and very rarely benign intracranial hypertension. All tetracyclines are photosensitizing, and a sun protection plan should be used. Also, these agents should not be used in children under 10 years of age or in pregnant women because the risk of tooth discoloration when used in children and inhibition of skeletal growth in the developing fetus. Emergence of resistant strains of *P. acne*,⁷⁵ adverse events, and adherence issues associated with long-term systemic tetracycline use have led to new treatment approaches.

Adverse effects of tetracyclines include resistant bacteria, folliculitis, candidiasis, gastrointestinal upset, and phototoxic effects. Tetracyclines must not be combined with systemic retinoids because of the increased probability for development of intracranial hypertension. Tetracycline is used in the treatment of moderate to severe acne vulgaris. It is the least expensive of the tetracyclines and therefore often prescribed for initial therapy.³⁰ A common initial approach includes tetracycline 1 g daily (500 mg twice daily), 1 hour before meals; after 1 or 2 months, when marked improvement of inflammatory lesions is observed, the dose may be decreased to 500 mg every day, for another 1 or 2 months.⁷⁵ Drawbacks to the use of tetracycline include also a drug–food interaction with dairy products.

Doxycycline is commonly used in the treatment of moderate to severe acne vulgaris. It is more effective and produces less resistance than tetracycline. The initial dosage is usually 100 or 200 mg daily, followed after improvement by 50 mg/day as a maintenance dose; it may be taken with food even though it is more effective when taken 30 minutes before meals. Subantimicrobial-dose doxycycline (20 mg) has been investigated in a double-blind, placebo-controlled trial in the treatment of moderate facial acne. Positive outcomes were achieved with no development of resistant organisms or change in normal skin flora.^{81,82} Adverse effects include resistant bacteria, folliculitis, candidiasis, gastrointestinal upset, and phototoxic effects such as photonycholysis.⁸³

Minocycline is another commonly prescribed oral antibiotic used in the treatment of moderate to severe acne vulgaris. It is more effective than tetracycline because of greater lipid solubility and enhanced penetration into tissue and sebaceous follicles.⁸⁴ It is dosed similarly to doxycycline (100 mg/day or 50 mg twice daily) and on an indefinite basis in selected patients.

8 Of the tetracyclines, minocycline has the most reported adverse effects.⁸⁵ Neither tetracycline nor doxycycline contain an amino acid side chain found in minocycline that has potential to form a reactive metabolite. Perhaps related to this, in addition to usual tetracycline adverse effects, minocycline may cause vestibular toxicity, discoloration of skin and visceral tissues,⁸⁶ discoloration of the gums, drug-induced lupus erythematosus,⁸⁶ interstitial nephritis/hepatic failure/systemic eosinophilia,⁸⁶ hypersensitivity syndromes,⁸⁵ serum sickness–like illness,⁸⁵ severe fever,⁸⁷ depersonalization symptoms,⁸⁸ and cutaneous hyperpigmentation of at least four distinct types:⁸⁹

1. Blue-black pigmentation confined to sites of scarring or inflammation on the face
2. Blue-gray circumscribed pigmentation of normal skin of the lower legs and forearms
3. Diffuse muddy brown pigmentation of normal skin accentuated in sun-exposed areas
4. Circumscribed blue-gray pigmentation within acne scars confined to the back

SYSTEMIC AGENTS: SECOND-LINE THERAPY

Cotrimoxazole

Cotrimoxazole (trimethoprim-sulfamethoxazole) or trimethoprim alone may be used for treating patients who do not tolerate tetracycline and erythromycin or in cases of resistance to these antibiotics.⁹⁰ The adult dosage is usually 800 mg sulfamethoxazole and 160 mg trimethoprim twice daily.

Hormonal Therapy

Hormonal therapy is useful in treating acne in women with elevated or normal serum androgens. It may also be warranted for female patients with severe seborrhea, clinically apparent androgenic alopecia, seborrhea/acne/hirsutism/alopecia syndrome, late-onset acne, and with proven ovarian or adrenal hyperandrogenism.⁹¹

Hormonal therapy is absolutely contraindicated in women who want to become pregnant due to the risk of sexual organ malformation in a developing fetus.²⁸

Antiandrogens, or androgen-receptor blockers, should be avoided during pregnancy.⁹ Both cyproterone and spironolactone should be used for acne only in women, because they lead to feminization in men.⁹²

Cyproterone Acetate

Cyproterone acetate (CPA), the most widely used antiandrogen compound, is not available in the United States. It is a progestational agent that blocks the androgen receptors and also inhibits the synthesis of adrenal androgens. In Europe and Canada, CPA is widely used in women for the treatment of acne, with or without signs of hyperandrogenism, and as an oral contraceptive formulation (CPA 2 mg with ethinyl estradiol 35 mcg or 50 mcg).⁹³

Adverse effects include menstrual abnormalities, breast tenderness and enlargement, nausea and vomiting, fluid retention, leg edema, headache, and melasma.

Chlormadinone Acetate

Chlormadinone acetate (2 mg), alone or in combination with 50 mcg ethinyl estradiol or 50 mcg mestranol in a contraceptive pill, is available in several European countries and is slightly less efficacious than CPA.⁹⁴

Spironolactone

Spironolactone, an antiandrogen and inhibitor of 5 α -reductase, reduces sebum production and improves acne at dosages of 50 to 200 mg twice daily in patients with acne resistant to conventional therapy.⁹¹ Most commonly, it is used in countries where other antiandrogen drugs are not available.

Adverse effects are dose dependent and can be lessened by initiating therapy with doses as low as 25 mg/day. They include potential hyperkalemia, irregular menses, breast tenderness, headache, and fatigue.²⁶

■ Drospirenone

Drospirenone, a derivative of spironolactone, has been introduced in Europe as another antiandrogen agent that may prove to be useful in some patients.⁹³

■ Flutamide

Flutamide, a drug approved for treatment of prostate cancer, blocks the androgen receptor. It is used in combination with oral contraceptives in seborrhea and acne therapy for females.⁹² The dose is usually 250 to 500 mg twice daily over 6 months.

Flutamide use is limited due to reports of fatal hepatitis requiring monitoring of liver function during therapy.⁹² Pregnancy must be avoided due to the risk of feminization of a male fetus.⁹

■ Estrogens

Estrogens are indicated in female patients with clinical evidence of hyperandrogenism. They suppress the ovarian production of androgens. They are of limited use because the dose of estrogen required for suppression of sebum production is greater than that required to suppress ovulation. Response to 0.035 to 0.050 mcg of ethinyl estradiol or its esters occurs in some women, but higher doses are often required.⁹⁵ Breast examinations and Pap smears may be recommended in women receiving long-term estrogen therapy; other serious adverse effects such as clotting and hypertension are possible but very rare in young healthy females.

■ Oral Contraceptives

Oral contraceptives containing two agents, an estrogen and a progestin, are used as an alternate treatment for moderate acne in women.⁹⁵

Oral contraceptives decrease free testosterone levels by increasing sex hormone-binding globulin, leading to a decrease in sebum production,^{12,95} and they inhibit the ovarian production of androgens by suppressing ovulation.

Common adverse effects of oral contraceptives include nausea and vomiting, breast tenderness, headache, spotting and breakthrough bleeding, edema of the venous system of the lower extremities, decreased libido, increased appetite, and weight gain. A transient flare of inflammatory acne may also accompany the initiation of therapy. The most serious adverse effect of oral contraceptives, thromboembolism, has been greatly reduced by the use of lowered doses of estrogens.⁹¹

■ Gonadotropin-Releasing Hormone Agonists

Gonadotropin-releasing hormone agonists (buserelin, nafarelin, and leuprolide), available as injectable drugs or nasal spray, suppress the production of ovarian androgens and are efficacious in acne. By reducing estrogen, they can produce menopausal symptoms (headache and bone loss). They have not been approved for treatment of acne.⁹¹

■ Corticosteroids

Low-dose corticosteroids (prednisone, prednisolone, or dexamethasone) are indicated in patients with adrenal hyperandrogenism or acne fulminans.

■ Dapsone

Oral dapsone, a sulfone, has been used for treatment of acne conglobata (a rare condition that is highly inflammatory; onset usually occurs in adults) and acne inversa (chronic lesions in the axillary and groin areas).⁶³

PHARMACOECONOMIC CONSIDERATIONS

Although costs of therapy with oral isotretinoin are greater than with other therapeutic choices in the first year, this option can be more cost-effective than long-term antibiotic treatment.⁷⁴

EVALUATION OF THERAPEUTIC OUTCOMES

See Tables 95–5 through 95–9 for prototypical examples of pharmaceutical care plans in the evaluation of therapeutic outcomes for each grade of acne severity.

TABLE 95–5. Typical Pharmaceutical Care Plan for Mild Comedonal Acne

| Mild comedonal | Baseline | 2 wk | 1 mo | 2 mo | 3 mo | 4 mo | 5 mo | 6 mo | 9 mo | 12 mo | Every 12 mo |

PSORIASIS

Dennis P. West, Lee E. West, Laura Scuderi, and Giuseppe Micali

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Exogenous trigger factors such as climate, stress, alcohol, smoking, infection, trauma, and drugs may aggravate psoriasis.
- 2 As a result of pathogenic T-cell production and activation, psoriatic epidermal cells proliferate at a rate sevenfold faster than normal epidermal cells.
- 3 In general, psoriatic lesions are characterized by sharply demarcated, erythematous papules and plaques often covered with silver-white scales.
- 4 Goals of treatment are usually directed at skin normalization: reduction or clearing of erythema, papules, and plaques, as well as scales.
- 5 A variety of topical (most commonly salicylic acid, corticosteroids, anthralin, and/or vitamin D analogues) and systemic (most often acitretin but also cyclosporine, tacrolimus, methotrexate, mycophenolate mofetil, sulfasalazine, 6-thioguanine, and/or hydroxyurea) pharmacotherapeutic agents can be used for treating psoriasis, with treatment determined by the severity of a patient's condition and the probability of controlling long-term symptoms with minimal adverse effects. Biologic therapies (infliximab, etanercept, alefacept, or efalizumab) and photochemotherapy (photochemotherapy using ultraviolet A light; PUVA) provide additional options, especially for patients with severe or refractory cases.
- 6 Combination, rotational, and sequential therapy is commonly used in treatment of psoriasis to achieve a response, increase effectiveness of treatment, or enable lowering of doses of individual agents.

Psoriasis is a common chronic inflammatory skin disorder characterized by recurrent exacerbations and remissions of thickened, erythematous, and scaling plaques. The clinical appearance of psoriasis may be cosmetically disfiguring, and the disease may be physically and emotionally debilitating, especially for patients with severe disease.

EPIDEMIOLOGY

Psoriasis is universal in occurrence and affects up to 3% of the American population. Approximately 25% of affected patients have severe conditions.¹ The disorder occurs in all racial groups but is most prevalent in Caucasians. It is equally common in males and females. Two peaks of age of onset have been described: the greatest incidence is between 20 and 30 years, and a smaller peak occurs between 50 and 60 years of age;² however, the age of onset is widely variable from infancy to old age. Although rarely life-threatening, psoriasis has an adverse physical and emotional impact on quality of life.^{3,4}

ETIOLOGY

Psoriasis is a complex and multifactorial disease due to the interaction between environmental factors (exogenous or endogenous antigens) and a specific genetic background. The antigens involved in disease development are not completely known or understood.⁵

GENETIC FACTORS

There is a significant genetic component in psoriasis, but the exact mode of inheritance is uncertain.⁶ Most patients with psoriasis have at least one immediate relative with the disorder.⁷ Some studies have shown that the development and severity of psoriasis is influenced by gender of the contributing parent. One study showed an earlier age of onset when the disease was inherited from the father.⁸

Monozygotic twins have a higher concordance for psoriasis than dizygotic twins.

A number of genetic loci have been identified by genome-wide linkage scans and two loci have been replicated: *PSORS1* on chromosome 6, within the major histocompatibility complex, and *PSORS2* on chromosome 17q. *PSORS1* accounts for an estimated 30% to 50% of the genetic contribution to psoriasis.⁹

Studies of histocompatibility antigens in psoriatic patients indicate statistically significant associations on the B, C, and D loci, more specifically, HLA-B13, HLA-B17, and HLA-B37.²

The most significant association is with HLA-Cw6, where the relative likelihood for developing psoriasis is 9 to 15 times normal.² Identification of multiple loci for psoriasis susceptibility indicates that psoriasis is a genetically heterogeneous disease with different genetic causes.

EXOGENOUS TRIGGER FACTORS

- 1 Factors such as climate, stress, alcohol, smoking, infection, trauma, and drugs may aggravate psoriasis. Warm seasons and

sunlight reportedly improve psoriasis in 80% of patients, whereas 90% report worsening in cold weather. In addition, stress worsens psoriasis in up to 40% of patients; however, the exact role stress plays in exacerbation of psoriasis is uncertain. Alcohol seems to have a greater influence on the progression of psoriasis in men, and the association between smoking and psoriasis seems to be stronger in women.¹⁰

Infection has been identified retrospectively as a common precipitating factor in psoriasis.¹¹ About 25% of patients have initial onset of the disease after clinically documented infections, and more than one half have exacerbations within 3 weeks after an upper respiratory infection. A variant known as guttate (small drop-like plaques) psoriasis is often associated with infections of group A β -hemolytic streptococci.¹¹

Psoriatic lesions may develop at the site of injury on normal-appearing skin (Koebner response). This response may be induced by a variety of trauma that includes rubbing, venipuncture, bites, surgery, and mechanical pressure. The mechanism for a Koebner response is unknown, is not unique to psoriasis, and yet occurs in a majority of psoriatic patients. Duration of time between injury and lesion development may vary from a day to several weeks.

Lithium carbonate, β -adrenergic blocking agents, some anti-malarial agents, nonsteroidal anti-inflammatory drugs, angiotensin-converting enzyme inhibitors, tetracyclines, and interferons are among the most commonly reported drugs to exacerbate psoriasis or to trigger psoriasiform lesions.¹²

PATHOPHYSIOLOGY

IMMUNOLOGIC MECHANISMS

Recently, much attention has been directed to cell-mediated immune mechanisms in psoriasis. A central role for activated T cells has been demonstrated by response to drugs that block T-cell activation, migration, or cytokine secretion in psoriasis.¹³

Cutaneous inflammatory T-cell-mediated immune activation requires two T-cell signals that are mediated via cell-cell interactions by surface proteins and by antigen-presenting cells (APC) such as dendritic cells or macrophages.

The “first signal” is the interaction of the T-cell receptor with antigen presented by the APC. Table 96–1 lists cell surface proteins important to this first signal.

The “second signal,” also called *costimulation*, is mediated through various surface interactions. Both signals are essential for initial activation of T cells in psoriasis.¹⁴

Once T cells are activated, they migrate from lymph nodes and the circulation into skin. Specific cell surface proteins on T cells and vascular endothelium including selectins, integrins, and other adhesion molecules mediate this movement. The best understood cellular interaction is the relationship between LFA-1 on T cells and intercellular adhesion molecule-1 on endothelial cells. Once in the skin, activated T cells secrete various cytokines that induce the pathologic changes of psoriasis.¹⁵ Cytokines are proteins secreted by immune cells that bind to very specific receptors on the cell surface, influencing keratinocytes and other cells to produce pathologic changes characteristic of psoriasis.

The cytokine profile in psoriasis is known as a T-helper cell type 1 (Th1) response; this subset of T cells produces primarily interferon- γ (IFN- γ) and interleukin (IL)-2.¹⁶ Other local cells, including keratinocytes and local neutrophils, are induced to produce other cytokines, including tumor necrosis factor- α (TNF- α)¹⁷ and interleukin

TABLE 96–1. Cell Surface Proteins Mediating Cell-Cell Interactions via the First Signal Prior to Costimulation (Second Signal)

| Protein Abbreviation | Protein |
|----------------------|--|
| Anti-CD11a | Monoclonal antibody toward the α chain (CD11a) of LFA-1 |
| APC | Antigen-presenting cells |
| CD2 | Cluster of differentiation 2 |
| CD3 | Cluster of differentiation 3 |
| CD4 | Cluster of differentiation 4 |
| CD28 | Cluster of differentiation 28 |
| CTCL | Cutaneous T-cell lymphoma |
| DAB | β Subunit of diphtheria toxin |
| Fab | Fraction antibody binding |
| Fc | Fraction crystallizable |
| ICAM | Intercellular adhesion molecule |
| ICAM-1 | Intercellular adhesion molecule-1 |
| IFN- α | Interferon- α |
| IFN- γ | Interferon- γ |
| IL-2 | Interleukin-2 |
| IL-2/DAB | Interleukin-2 combined with diphtheria toxin β subunit |
| IL-4 | Interleukin-4 |
| IL-8 | Interleukin-8 |
| IL-10 | Interleukin-10 |
| LFA-1 | Lymphocytic function-associated antigen-1 |
| LFA-3 | Lymphocytic function-associated antigen-3 |
| LFA-3/TIP | Recombinantly-engineered LFA-3/ig G1 human fusion protein |
| MHC | Major histocompatibility complex |
| PASI | Psoriasis activity and severity index |
| Th1 | T-helper cells type 1 |
| Th2 | T-helper cells type 2 |
| TNF- α | Tumor necrosis factor- α |

(IL)-8,¹⁸ which are believed to be important in the pathophysiology of psoriasis. All of these cytokines are important in the development of psoriasis and represent possible targets of biologic therapies.

Cytokines and chemokines with a currently recognized potential role in psoriasis include: granulocyte-macrophage colony-stimulating factor; regulated on activation, normal T-cell expressed and secreted (RANTES; causes keratinocyte proliferation); epidermal growth factor and monokine induced by interferon- γ (MIG; increases neutrophil migration); IL-8 and inducible protein-10 (increases differentiation of type 1 T cells); IL-12 and macrophage inflammatory protein-3 α (MIP-3 α ; produces angiogenesis); IL-1 and thymus- and activation-regulated chemokine (TARC; produces epidermal hyperplasia); IL-6 (increases other chemokine release); INF- γ (increases upregulation of adhesion molecules on endothelial cells); TNF- α ; and vascular endothelial growth factor (VEGF).

DEFECTS IN THE EPIDERMAL CELL CYCLE

As a result of pathogenic T-cell production and activation, psoriatic epidermal cells proliferate at a rate sevenfold faster than normal epidermal cells. The germinative cell population increases in psoriatic skin, and duration of the epidermal cell cycle is calculated at 37.5 hours (versus 300 hours in normal skin). Lesion-free skin in psoriatic patients generally is considered to be involved because epidermal proliferation is elevated in apparently normal skin of psoriatic patients.¹⁹

CLINICAL PRESENTATION OF PSORIASIS

GENERAL

Although psoriasis is a nonmalignant, hyperproliferative epidermal cell disorder, it results in accumulated, immature, excessively thickened skin that is manifested as plaques.

SYMPTOMS

Psoriatic lesions are relatively asymptomatic; however, pruritus is a complaint in about 25% of patients. Severe, widespread psoriasis may involve symptomatology similar to that of exfoliative dermatitis, which may include fever and chills. Psoriatic arthritis is a distinct clinical entity in which both psoriatic lesions and inflammatory arthritis-like symptoms occur. Classically, distal interphalangeal joints and adjacent nails are involved, but knees, elbows, wrists and ankles also may be involved.

SIGNS

In general, psoriatic lesions are characterized by sharply demarcated, erythematous papules and plaques often covered with silver-white scales. Initial lesions are usually small papules that enlarge over time and coalesce into plaques,

sometimes as serpiginous or geographic forms. If the covering scale is removed, a salmon-pink to erythematous lesion is exposed, perhaps with punctate bleeding from prominent dermal capillaries (Auspitz sign).

Psoriatic lesions vary in appearance depending on the anatomic site and the variant of psoriasis. The most common type of psoriasis is psoriasis vulgaris. Scalp involvement may vary from diffuse scaling on an erythematous scalp to thickened plaques with exudation, microabscesses and fissures. Trunk, back, arm, and leg lesions may appear as generalized, scattered, discrete, guttate (resembling drops or spots), or large plaques. Palms, soles, face, and genitalia may be commonly involved. Affected nails often are pitted with subungual keratotic material. Yellowing under the nail plate also may be seen.

LABORATORY TESTS

Skin biopsy of lesional skin is useful in confirming the diagnosis.

OTHER DIAGNOSTIC TESTS

None

► TREATMENT: Psoriasis

4 Goals of treatment of psoriasis are directed at skin normalization: reduction or clearing of erythema, papules, and plaques, as well as scales. Reduction or clearing of skin signs as a treatment objective leads to normalized cosmesis and improvement in quality of life. A goal of therapy is to achieve resolution of lesions, but partial clearing is sometimes acceptable when using regimens with decreased toxicity and increased patient acceptability.

The Psoriasis Area and Severity Index (PASI) serves as a uniform method to determine the amount of body surface area affected, along with the degree of erythema, induration, and scaling. Mild psoriasis is considered to have a PASI score of less than 12, moderate involvement is PASI 12 to 18, and severe psoriasis is PASI greater than 18.

The National Psoriasis Foundation advocates that PASI 50 (50% decrease from baseline) is a clinically relevant end point when assessing efficacy of treatment. As a new class of agents, the biologic agents were required to demonstrate a PASI 75 decrease for approval by the Food and Drug Administration. No prior nonbiologic agents were required to meet such a high standard to be approved.

■ GENERAL APPROACH TO TREATMENT

Although the exact cause of psoriasis is unknown, in a majority of patients, pharmacotherapy is usually effective in establishing good clinical control. Psoriasis may be a lifelong relapsing and remitting disease, so therapy should be selected with careful consideration of long-term adverse effects. Major points for consideration include the extent and site of disease involvement, the patient's age, and concurrent associated diseases.

5 Drug treatments for psoriasis, discussed in detail below, include the following:

Topical therapy:

- Keratolytics

- Coal tar
- Corticosteroids
- Anthralin
- Vitamin D analogues (calcipotriene and calcitriol)
- Tazarotene
- Immunomodulators (tacrolimus and pimecrolimus)

Systemic therapy:

- Acitretin
- Cyclosporine
- Tacrolimus
- Methotrexate
- Mycophenolate mofetil
- Sulfasalazine
- 6-Thioguanine
- Hydroxyurea

Biologic therapy:

- Infliximab
- Etanercept
- Alefacept
- Efalizumab

Photochemotherapy:

- PUVA

NONPHARMACOLOGIC THERAPY

■ EMOLLIENTS

Emollients are frequently used during therapy-free periods to minimize skin dryness that may lead to early recurrence. These agents hydrate stratum corneum and minimize cutaneous transepidermal water loss (evaporation). Hydration causes the stratum corneum to

swell and flattens the surface contour. Emollients effective as moisturizers decrease binding forces within the horny layer, enhance desquamation, and eliminate scaling. Emollients also may increase pliability of the skin, have antipruritic activity, and possess mild vasoconstrictor activity.

As lotions, creams, or ointments, emollients often need to be applied several times per day (about four times per day) to achieve a beneficial response. Adverse effects of emollients include folliculitis and allergic or irritant contact dermatitis.

BALNEOTHERAPY

Balneotherapy (and climatotherapy) is a therapeutic approach that consists of bathing in waters containing certain salts, often combined with natural exposure to the sun. Certain areas around the world have been targeted as excellent places to receive balneotherapy (or climatotherapy); the Dead Sea is salt filled, located below sea level, and capable of enhancing exposure to a natural ultraviolet A (UVA) light source. The Kangal hot spring in Turkey and the Blue Lagoon in Iceland are also notable salt-containing waters. The salts in these waters are a mixture of salts that reduce activated T cells in skin and are remittive for psoriasis. Reduction in serum manganese and lithium levels is significant after bathing with Dead Sea salt, an effect believed to be related to effectiveness of the salts.²⁰

ULTRAVIOLET B PHOTOTHERAPY

Ultraviolet B (UVB) light (290 to 320 nm) continues to be an important phototherapeutic intervention for psoriasis.

Exposure to UV light by natural sunlight has been used to treat psoriasis for centuries. At the beginning of the twentieth century patients were treated with topical, occlusive coal tar all day and night, removing the tar just before exposure to a hot quartz mercury vapor lamp (Goeckerman therapy).⁷ Subsequent development of various forms of UVB phototherapy have led to the use of more precise wavelengths within the UVB range in order to achieve an optimal therapeutic benefit for psoriasis.

The most effective wavelength of UVB for treatment of psoriasis is 310 to 315 nm, and this has led to the development of a UVB

“narrow-band” (NB) light source, in which 83% of the UVB emission is at 310 to 313 nm.²¹ Numerous clinical trials have demonstrated efficacy of NB-UVB for the treatment of plaque-type psoriasis.²²

Numerous topical and systemic psoriatic therapies (discussed individually below) are used adjunctively to hasten and improve the response to UVB phototherapy. Several studies showed an advantage to combining short-contact anthralin with UVB.²³ The addition of calcipotriene also improved results compared to UVB alone.²⁴ Emollients enhance efficacy of UVB and may be applied to the skin just before treatments for this purpose.²³ UVB phototherapy has also produced more effective results when added to systemic psoriatic treatments, such as methotrexate and retinoids.²⁵

EXCIMER LASER PHOTOTHERAPY

Lasers have been used for the treatment of psoriasis with variable results. Most laser therapy has been ineffective, while excimer lasers, which generate a 308-nm UVB wavelength, have some efficacy at clearing psoriasis and inducing moderately prolonged remissions.^{26,27} Unfortunately, this approach to therapy is limited to treatment of individual, isolated plaques. The excimer laser has some advantages over traditional NB-UVB phototherapy, including the capability to successfully treat psoriatic plaques with fewer treatments and with a smaller UV radiation dose. Moreover, it may have a lower risk of carcinogenicity and photoaging.²⁸

PHARMACOLOGIC THERAPY

Topical treatments of first choice for mild to moderate psoriasis include keratolytics, corticosteroids, vitamin D analogues (calcipotriene, calcitriol, and tacalcitol), and tazarotene. The systemic treatment of first choice for moderate to severe psoriasis is acitretin. See Tables 96–2 and 96–3 for topical and systemic psoriasis treatment guidelines.

Multiple pharmacotherapeutic approaches to psoriasis management include first-line therapy for mild to moderate psoriasis with topical agents. In severe psoriasis, photochemotherapy and

TABLE 96–2. Selected Topical Psoriasis Treatment Guidelines

| Active Ingredient | Regimen | Selected Adverse Effects |
|-------------------|--|---|
| Emollients | About 4 times/day | Folliculitis, allergic or irritant contact dermatitis |
| Salicylic acid | 2–3 times/day | Irritation, salicylism with symptoms of nausea, vomiting, tinnitus, or hyperventilation |
| Coal tar | Apply in the evening, allowing to remain through the night | Irritation, photoreactions, unpleasant odor, staining skin and clothing |
| Corticosteroids | 2–4 times/day | Local tissue atrophy, degeneration, and striae; epidermal thinning; acneiform eruptions; bacterial or fungal skin infections; glucocorticoid systemic effects |
| Calcipotriene | 1–2 times/day, no more than 100 g/wk | Burning and stinging (10% of patients), irritant contact dermatitis |
| Anthralin | Usually applied in the evening, allowed to remain overnight; short-contact regimens may also be used | Stains skin and clothing; irritation |
| Tazarotene | 1 time/day, usually in the evening | Pruritus, burning, stinging, and erythema |

TABLE 96–3. Selected Systemic Psoriasis Treatment Guidelines

| Active Ingredient | Regimen | Selected Adverse Effects |
|-----------------------|---|--|
| Acitretin | 25–50 mg/day until lesions have resolved | Hypervitaminosis A (dry lips/cheilitis, dry mouth, dry nose, dry eyes/conjunctivitis, dry skin, pruritus, scaling, and hair loss), hepatotoxicity, skeletal changes, hypercholesterolemia, hypertriglyceridemia |
| Cyclosporine | 2.5–4 mg/kg per day in 2 divided doses; may increase to 5 mg/kg per day in 1 month if no response | Nephrotoxicity, malignancies, hypertension, hypomagnesemia, hyperkalemia, alterations in liver function tests, elevations of serum lipids, gastrointestinal intolerance, paresthesias, hypertrichosis, gingival hyperplasia |
| Methotrexate | 7.5–15 mg per week, increased incrementally by 2.5 mg every 2 to 4 weeks until response; maximal doses are approximately 25 mg/wk | Anemia, leukopenia, thrombocytopenia, hepatotoxicity, gastrointestinal upset, nausea, vomiting, mucosal ulceration, stomatitis, malaise, headaches, pulmonary toxicity |
| Tacrolimus | 0.05 mg/kg daily, with increases to 0.10 mg/kg daily at 3 weeks and to 0.15 mg/kg daily at 6 weeks, depending on results | Nephrotoxicity, immunosuppression, gastrointestinal upset, diarrhea, nausea, paresthesias, hypertension, tremor, insomnia |
| Mycophenolate mofetil | 500 mg 4 times a day, up to maximum of 4 g/day | Gastrointestinal toxicity (diarrhea, nausea, vomiting), hematologic effects (anemia, neutropenia, thrombocytopenia), viral and bacterial infections; lymphoproliferative disease or lymphoma can occur |
| Sulfasalazine | 3–4 g/day for 8 weeks | Gastrointestinal upset |
| 6-Thioguanine | 80 mg twice weekly, increased by 20 mg every 2–4 weeks; maximum dose 160 mg/3 times week | Bone marrow suppression; gastrointestinal complications including nausea and diarrhea; elevation of liver function tests |
| Hydroxyurea | 1 g/day; may increase to 2 g/day | Bone marrow toxicity with leukopenia or thrombocytopenia, cutaneous reactions, leg ulcers, megaloblastic anemia |
| Infliximab | 5 or 10 mg/kg for 3 intravenous infusions at weeks 0, 2, and 6 | Headaches, fever, chills, fatigue, diarrhea, pharyngitis, upper respiratory and urinary tract infections; hypersensitivity reactions (urticaria, dyspnea, hypotension); lymphoproliferative disorders |
| Etanercept | 50 mg subcutaneously twice a week | Local reaction at the injection site (20% of patients); respiratory tract and gastrointestinal infections, abdominal pain, nausea and vomiting, headaches, rash; serious infections (including tuberculosis) and malignancies are rare |
| Alefacept | 15 mg intramuscularly once weekly | Pharyngitis, influenza-like symptoms, chills, dizziness, nausea, headache, injection site pain and inflammation, and nonspecific infection; opportunistic infections and malignancy are rare |
| Efalizumab | 1 mg/kg subcutaneously once weekly | Headache, nausea, chills, nonspecific infection, pain, fever, and asthenia; no evidence drug causes organ toxicity, serious infection, or malignancy |

systemic agents, including biologic therapies, are used. Psoriasis treatment regimens now include combination, rotational, and sequential therapy.

■ COMBINATION, ROTATIONAL, AND SEQUENTIAL THERAPY

6 Frequently, monotherapy with a systemic agent does not provide optimal outcomes. Combination therapy of systemic agents with other modalities may enhance therapeutic benefit. In addition, the dose of each agent may often be reduced when used in combination that may result in lower toxicity.²⁹

Combinations may include:

- Acitretin + UVB
- Acitretin + photochemotherapy using ultraviolet A light (PUVA)
- Methotrexate + UVB
- PUVA + UVB
- Methotrexate + cyclosporine

Although combination therapies with biologic agents may be clinically useful, they are still being evaluated for safety and efficacy.

In addition to combination therapy, biologic agents may also be used in rotational therapy. Patients may receive a biologic regimen for a limited period of time and are then switched to a nonbiologic regimen, continuing on a rotational basis. One objective of rotational therapy is to minimize cumulative drug toxicity.

Sequential therapy is another treatment strategy designed to optimize therapeutic outcome. It involves rapid clearing of psoriasis with aggressive therapy by an agent such as cyclosporine, followed by a transitional period in which a safer drug such as acitretin is introduced at maximal dosing. Subsequently, a maintenance period with acitretin in lower doses, or if necessary, acitretin in combination with UVB or PUVA, may be continued.³⁰

Pharmacotherapeutic approaches to the treatment of psoriasis are shown in the treatment algorithm (Fig. 96–1).

■ TOPICAL THERAPY: FIRST-LINE AGENTS

■ Keratolytics

Keratolytic agents are used to remove scale, smooth the skin, and decrease hyperkeratosis. The mechanism of action of salicylic acid, one of the most commonly used keratolytics, is disruption in corneocyte-to-corneocyte cohesion in the abnormal horny layer of psoriatic skin.

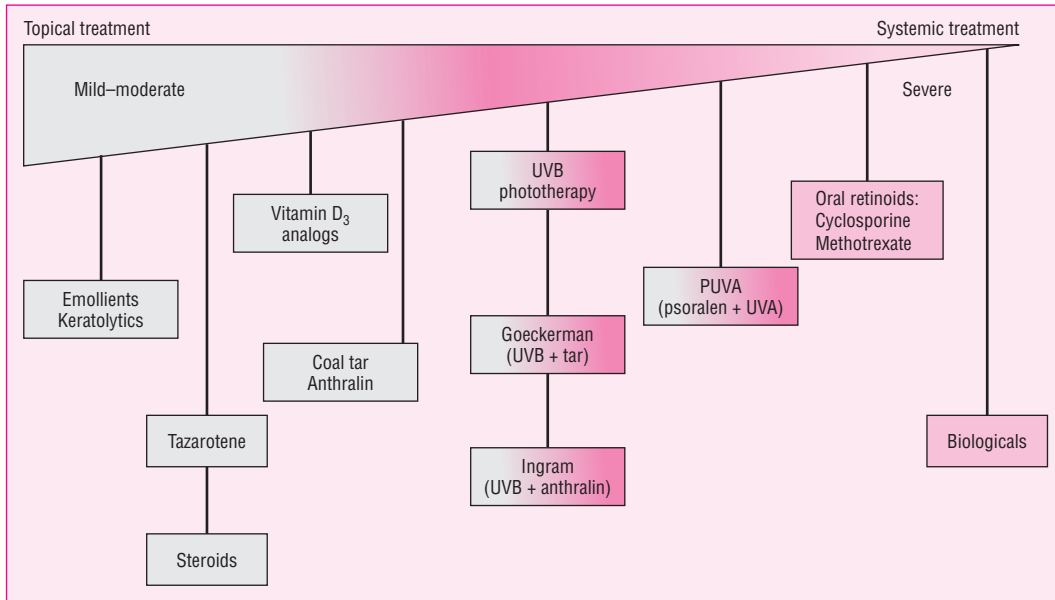

FIGURE 96-1. Psoriasis treatment spectrum.

For this reason, salicylic acid is especially useful at anatomic sites where thick scales are present.³¹

When applied to large, inflamed areas of skin, salicylic acid may induce salicylism, with symptoms of nausea, vomiting, tinnitus, and hyperventilation. Salicylate poisoning in small children is potentially more serious than in older people because they are at higher risk of developing metabolic acidosis. Several fatal cases of percutaneous salicylate intoxication have been reported in children under 3 years of age.³²

The keratolytic effect of salicylic acid enhances penetration and efficacy of some other topical agents such as corticosteroids.⁵

Salicylic acid, as a gel or lotion, is usually applied two to three times a day in concentrations of 2% to 10%.

■ Corticosteroids

Topical corticosteroids are the most widely used agents in the treatment of psoriasis in the United States. They are often used to decrease erythema, scaling, and pruritus. Topical vasoconstricting potencies of corticosteroids are ranked by the Stoughton-Cornell classification in seven classes (Table 96-4). Class I steroids are very high-potency products such as clobetasol propionate 0.05%, halobetasol propionate, and betamethasone dipropionate.²³

High-potency agents are used primarily as alternatives to systemic adrenocorticoid therapy when local therapy is feasible. Examples of conditions for which very-high-potency products are used include thick, chronic psoriatic plaques. They should be used for finite periods of time (as short as possible) and on relatively small body surface areas.

Class VII steroids are agents with the lowest level of vasoconstricting potency (e.g., hydrocortisone 1%). They have a weak anti-inflammatory effect and are safest for long-term application. These products are also the safest products for use on the face and intertriginous areas, in infants and young children, and with occlusion when necessary and appropriate.

Intermediate classes include products with a medium-potency ranking and are used in moderate inflammatory dermatoses. Medium-

potency preparations may be used on the face and intertriginous areas for limited periods of time.²³

The mechanism of action of corticosteroids in psoriasis is not fully understood.³³ Topical corticosteroids appear to inhibit phospholipase A, and to thus reduce levels of arachidonic acid, prostaglandins, and leukotrienes in skin. Moreover, steroid receptors have been identified in skin, with synthesis and mitosis of DNA in epidermal cells being inhibited by topical corticosteroids as demonstrated by decreased epidermal proliferation.³⁴

Topical corticosteroid adverse reactions are not uncommon. Local tissue atrophy, epidermal and dermal degeneration, and striae are manifestations of corticosteroid effect on collagen synthesis and fibroblast growth. If detected early, atrophy and striae may be reversible on drug discontinuation, but in numerous cases of prolonged therapy with high-potency agents, these atrophic changes may be long lasting. Thinning of the epidermis may result in visibly distended capillaries (telangiectasias) and purpura. Acneiform eruptions and masking of symptoms of bacterial or fungal skin infections also have been reported with topical corticosteroid use.

Systemic consequences of topical corticosteroid use include risk of suppression of the hypothalamic-pituitary-adrenal axis, hyperglycemia, and development of cushingoid features. Avoidance of prolonged therapy with very-high-potency agents minimizes the risk of these adverse effects. Tachyphylaxis and rebound flare of psoriasis after abrupt cessation of topical corticosteroid therapy may also occur. With proper monitoring, topical corticosteroids are a safe and effective adjunctive approach to psoriasis treatment.³⁵

Topical corticosteroids are available in ointments, creams, lotions, gels, sprays, shampoos, and mousses. An ointment is considered the most clinically effective dosage form in psoriasis treatment because it consists of an oily phase that is occlusive and conveys a hydrating effect. Due to the lipophilicity of ointments, penetration of corticosteroid into dermis is enhanced, resulting in increased vasoconstriction.

Ointments are not suitable for use in areas such as the axilla, groin, or other intertriginous areas where maceration and folliculitis may develop secondary to the occlusive effect. Creams—typically emulsified products with an aqueous phase—are preferred by some

TABLE 96–4. Selected Corticosteroid Products Useful for Treating Psoriasis

| Corticosteroids | Dosage Forms | Strength (%) | USP Potency Ratings ^a | Vasoconstrictive Potency Rating ^b |
|--------------------------------|---|-----------------------|----------------------------------|--|
| Alclometasone dipropionate | Cream | 0.05 | Low | VI |
| | Ointment | 0.05 | Low | V |
| Amcinonide | Lotion, ointment | 0.1 | High | II |
| | Cream | 0.1 | High | III |

| | Cream, ointment | 0.5 | High | III |
| Topical aerosol | 0.015 | Medium | — | |

^aUSP ratings are low, medium, high, and very high.^bVasoconstriction potency scale is I (highest) to VII (lowest)—denotes unknown vasoconstrictive properties.

patients as more cosmetically desirable. They may be used in intertriginous areas even though their lower oil content makes them more drying than ointments.

Topical corticosteroids are applied 2 to 4 times daily during long-term therapy.

■ Vitamin D Analogues

Vitamin D, important in cellular and systemic calcium metabolism, also inhibits keratinocyte differentiation and proliferation, suggesting a role in the treatment of hyperkeratotic skin disease. Vitamin D and its analogues provide anti-inflammatory benefits by inducing a shift towards Th2 cytokine expression, with a decrease in IL-8 and increase in IL-10.³⁶ Moreover, it induces inhibition of nuclear factor- κ B protein in lymphocytes, leading to a reduced transcription of IL-2.¹⁹

However, use of vitamin D has been limited by its propensity to cause hypercalcemia. This has driven the development of analogues of vitamin D with less effect on calcium homeostasis. Calcipotriene binds to vitamin D receptors as does vitamin D, but it is 100 times less active on systemic calcium metabolism because of its rapid local metabolism. Its long-term effect on altered calcium homeostasis is unknown. On average, improvement is seen within 2 weeks of treatment with calcipotriene, with approximately 70% of patients demonstrating marked improvement after 8 weeks of therapy. Adverse effects of calcipotriene include lesional and perilesional irritation, occurring in approximately 10% of treated patients and consisting of mild burning and stinging. Irritant contact dermatitis is reported to occur more commonly on the face.³⁷ Calcipotriene, available in a 0.005% concentration as a cream, ointment, and solution, is generally applied 1 to 2 times/day (no more than 100 g/wk).

Calcitriol (1,25-dihydroxyvitamin D₃) is another analogue used in the treatment of mild to moderate plaque psoriasis. As demonstrated in several open-label or randomized, double-blind, controlled trials, calcitriol is effective in improving or clearing psoriatic plaques. A 0.03% formulation showed clearance or considerable improvement in 89% of patients.³⁸

Tacalcitol (1 α , 24-dihydroxyvitamin D₃) is a biologically active hormone derived from vitamin D. In a study of 157 patients with chronic plaque psoriasis, tacalcitol ointment applied once daily during a 6-month treatment period decreased mean PASI score by 67% and body area affected from 13.3% to 8.8%. Reported adverse effects of tacalcitol are limited to local, transient, mild irritation.³⁹

■ Tazarotene

Tazarotene, a synthetic retinoid, is a prodrug that exerts its pharmacologic activity when hydrolyzed to its active metabolite, tazarotenic acid. Like other topical retinoids, it modulates keratinocyte proliferation and differentiation.^{40,41}

Treatment with 0.1% gel, applied once daily, results in substantial reduction in the severity of scaling and plaque thickness during 12-week treatments. The 0.1% gel is somewhat more efficacious, but the 0.05% formulation is associated with less irritation.^{40,41} Based on the results of clinical trials, tazarotene is effective for the treatment of mild to moderate plaque psoriasis.^{40,42}

Predominant treatment-related adverse effects are mild to moderate pruritus, burning, stinging, or erythema. These local reactions have been shown to be dose- and frequency-related.^{42,43} Tazarotene is often used in combination with topical corticosteroids to decrease

the incidence of local adverse events and to increase efficacy.⁷ Application of the gel to eczematous skin or to more than 20% of body surface area is not recommended because this may lead to extensive systemic absorption.⁴²

Tazarotene is available as a 0.05 or 0.1% gel and cream, and is applied once a day, usually in the evening.

■ TOPICAL THERAPY: SECOND-LINE AGENTS

■ Coal Tar

The use of tar as coal tar, shale tar, or wood tar has a long history in antipsoriatic therapy. In recent years, wood and shale tars have fallen out of use because they demonstrate relatively less efficacy than coal tar. Coal tar contains numerous hydrocarbon compounds formed from distillation of bituminous coal.

Although the mechanism of action is not fully understood, coal tar, when applied to normal skin, stimulates transient epidermal hyperplasia followed by a cytostatic effect with epidermal thinning. There is evidence that UVB light-activated topical coal tar forms photoadducts with epidermal DNA, thereby inhibiting DNA synthesis. This down-regulated epidermal proliferation rate approaches a normal rate of proliferation and leads to reduction in plaque elevation.⁴⁴

Coal tar treatment is a burdensome, time-consuming treatment with disadvantages that include local irritation, unpleasant odor, staining of skin and clothing, and increased sensitivity to UV light, including the sun. The risk of carcinogenicity is low; however, there are cases indicating a higher rate of nonmelanoma skin cancers in patients chronically exposed to tar and UV light.⁴⁵

Coal tar preparations of 2% to 5% tar are available in lotions, creams, shampoos, ointments, gels, and solutions. It also may be used in bath water. It is generally applied in the evening and allowed to remain in skin contact through the night.

■ Anthralin

Anthralin, an anthrone derivative of chrysarobin, was introduced under the name dithranol in Great Britain decades ago. Chronic plaque-type and guttate psoriasis respond better than other variants to anthralin treatment. Topical anthralin, particularly with UV light, is long established as an effective approach to the treatment of psoriasis.¹⁹

Anthralin possesses antiproliferative activity on human keratinocytes, inhibiting DNA synthesis by intercalation between DNA strands.⁴⁶ It induces nuclear factor- κ B (NF- κ B) in murine keratinocytes. Since NF- κ B is involved in the transcription of proinflammatory cytokines such as IL-6, IL-8, and TNF- α , these findings may be helpful in explaining the irritant properties of anthralin. Other hypotheses support the role of anthralin-generated free radicals in producing both antipsoriatic effects and irritation.

The patient must apply anthralin products only to affected areas of skin because contact with uninvolved skin may result in excessive and unwanted irritation and staining. Skin staining usually disappears within 1 to 2 weeks of discontinuation. Staining of affected plaques is a positive response sign because cell turnover has been slowed enough to take up the stain.

Inflammation, irritation, and staining of skin and clothing (via oxidation and binding to keratins) are often therapy-limiting effects.

Fortunately, anthralin exerts its clinical effects at low cellular concentrations; classic anthralin therapy starts with low

concentrations (0.1% to 0.25%) and gradually proceeds to higher concentrations (0.5% to 1%). Short-contact anthralin therapy regimens are alternative modes of application with decreased local adverse effects. Higher concentrations of anthralin (1% to 5%) in water-soluble vehicles are applied to lesions for a short period of time (application for 10 to 20 minutes).¹⁹

Anthralin traditionally was formulated in stiff paste bases to provide adherence to plaques. Subsequently, cream and ointment formulations have been developed that are more cosmetically appealing and appear to be equivalent in efficacy. Usually it is applied in the evening and allowed to remain overnight.

■ Immunomodulators

Pimecrolimus and tacrolimus are calcineurin inhibitors capable of exerting a local immunomodulating effect that may serve to normalize hyperproliferation of epidermis. As topical agents, tacrolimus and pimecrolimus are approved for the treatment of atopic dermatitis; however, regulatory approval regarding the efficacy of these agents in psoriasis is yet to be completed.

■ SYSTEMIC THERAPY: FIRST-LINE AGENTS

■ Acitretin

Acitretin, an oral retinoid, is the active metabolite of etretinate and has demonstrated clinical effects similar to etretinate, but with fewer adverse effects.²⁹ Acitretin is indicated for the treatment of severe psoriasis, including erythrodermic and generalized pustular types, but is more useful as an adjunct in the treatment of plaque psoriasis. In contrast to the fast-acting cyclosporine and methotrexate, acitretin resolves psoriatic lesions more slowly.

Acitretin has a shorter half-life than etretinate. Its mechanism of action is not completely understood; it may achieve benefits by acting on retinoid receptors in the keratinocyte nucleus to correct abnormal cell differentiation.⁴⁷

Acitretin has shown good results when combined with other psoriatic therapies, including PUVA and UVB, cyclosporine, and methotrexate.⁴⁸ The combination of acitretin and PUVA is highly effective and provides faster and more complete clearance, as well as allowing a decrease in the doses of both agents, thereby limiting the risk of adverse effects.²⁹

Adverse effects are dose dependent. They include hypervitaminosis A (i.e., dry lips/cheilitis, dry mouth, dry nose, dry eyes/conjunctivitis, dry skin, pruritus, scaling, and hair loss), hepatotoxicity, skeletal changes, hypercholesterolemia, and hypertriglyceridemia. To counteract hyperlipidemic effects, gemfibrozil has been studied for concomitant use with acitretin. In addition, acitretin is a known teratogen and thus is contraindicated in females who are pregnant or who plan pregnancy within the 3 years following drug discontinuation.⁴⁹

Absorption is enhanced when taken with food. Concurrent ingestion of alcohol converts acitretin to etretinate, which has a longer half-life.

An initial recommended dose of acitretin is 25 to 50 mg once daily, with therapy continued until lesions have resolved. A dosage of 50 mg/day is typically required for plaque psoriasis, and even at this relatively high dose, acitretin is only moderately effective. It is better tolerated when taken in conjunction with a meal.

■ SYSTEMIC THERAPY: SECOND-LINE AGENTS

■ Cyclosporine

An effective immunosuppressive agent that inhibits the first phase of T-cell activation, cyclosporine is used in the treatment of both cutaneous and arthritic manifestations of severe psoriasis.⁵⁰ It also inhibits the release of inflammatory mediators from mast cells, basophils, and polymorphonuclear cells.⁵¹

A meta-analysis of 579 patients with severe psoriasis treated with either 2.5 or 5 mg/kg per day of cyclosporine for 10 to 12 weeks found that the PASI decreased by 70% and 72%, respectively.⁵² An oral microemulsion formulation of cyclosporine has shown a better pharmacokinetic profile, resulting in a more consistent and predictable rate of absorption than the original formulation.^{5,53}

Cyclosporine is nephrotoxic with prolonged use. Published studies have demonstrated interstitial fibrosis and renal tubular atrophy on kidney biopsy specimens in patients treated for more than 2 years with cyclosporine. To decrease the risk of nephrotoxicity, the dose of cyclosporine should be kept below 5 mg/kg per day.^{54,55} In addition, use for more than 2 years of cumulative treatment may increase the risk of malignancy, including skin cancers and lymphoproliferative disorders.²⁹ One study has suggested that cyclosporine renders malignancies more aggressive. Other complications include hypertension, hypomagnesemia, hyperkalemia, decreased liver function, elevation of serum lipids, gastrointestinal intolerance, paresthesias, hypertrichosis, and gingival hyperplasia.^{51,54}

See Chap. 87 on solid organ transplantation for a discussion of drug interactions involving cyclosporine.

The typical dose of cyclosporine is usually between 2.5 and 5 mg/kg per day.

■ Tacrolimus

Tacrolimus is a macrolide immunosuppressive agent indicated for the prevention of organ transplant rejection and useful as an alternative treatment in severe recalcitrant psoriasis. Tacrolimus, like cyclosporine, inhibits T-cell activation.⁷

Adverse effects include diarrhea, nausea, paresthesias, hypertension, tremor, and insomnia. Other toxicities with topical tacrolimus—including renal insufficiency and immunosuppression—have been rarely reported.⁵⁶

See Chap. 87 on solid organ transplantation for a discussion of drug interactions involving tacrolimus.

In recalcitrant plaque-type psoriasis, patients receive tacrolimus at oral doses of 0.05 mg/kg per day (increased up to 0.15 mg/kg per day as needed).⁵⁷

■ Methotrexate

Methotrexate, a common antimetabolite, was introduced several decades ago for the treatment of psoriasis and remains an effective therapeutic approach. It is a synthetic analogue of folic acid that acts as a competitive inhibitor of the enzyme dihydrofolate reductase, that is responsible for the conversion of dihydrofolate to tetrahydrofolate. Tetrahydrofolate is an essential cofactor for the synthesis of thymidylate and purine nucleotides required for DNA and RNA synthesis.⁵⁸

Methotrexate inhibits replication and function of T and B cells and suppresses secretion of various cytokines such as IL-1, IFN- γ ,

and TNF- α . It also suppresses epidermal cell division. Methotrexate is indicated in patients with moderate to severe psoriasis.

Methotrexate is particularly beneficial for patients with psoriatic arthritis. It is also indicated for patients that are refractory to topical or ultraviolet therapy.²⁹ Methotrexate should be avoided in patients with active infections because of its immunosuppressive activity.⁵⁹

Methotrexate is associated with nausea and vomiting as well as mucosal ulceration, stomatitis, malaise, headaches, macrocytic anemia, and pulmonary toxicity. Nausea and macrocytic anemia can be ameliorated by administering oral folic acid in doses of 1 to 5 mg/day.

Bone marrow toxicity that leads to leukopenia, anemia, and thrombocytopenia has been shown to be induced by methotrexate. A serious long-term adverse effect is hepatotoxicity. Consequently, methotrexate should typically be avoided in patients with liver disease. Risk factors for hepatotoxicity include a history of excessive alcohol consumption, hepatitis, persistent elevated liver function tests, and family history of inheritable liver disease.⁵⁸

Malignant lymphomas have been reported in several patients treated with methotrexate. In some cases, lymphomas regressed when methotrexate was discontinued, strongly suggesting a causal relationship.⁶⁰ Methotrexate is contraindicated in pregnant women because it is teratogenic.⁵⁸

Drug interactions may potentiate methotrexate toxicity. For example nonsteroidal anti-inflammatory drugs can reduce renal clearance of methotrexate, resulting in toxic levels.⁶¹ Table 96–5 lists selected drugs that interact with, and increase toxicity of, methotrexate.

The starting methotrexate dose is 7.5 to 15 mg per week, and this is increased incrementally by 2.5 mg every 2 to 4 weeks until a response is evident. Maximal doses are typically about 25 mg per

TABLE 96–5. Interacting Drugs that Increase the Toxicity of Methotrexate

| Mechanism | Drug |
|---|---|
| Additive or synergistic toxicity | Ethanol |
| | Pyrimethamine |
| | Trimethoprim-sulfamethoxazole |
| Decreased renal elimination of methotrexate | Aminoglycosides |
| | Cephalothin |
| | Colchicines |
| | Cyclosporine |
| | Nonsteroidal anti-inflammatory drugs (naproxen and ibuprofen) |
| | Penicillins |
| | Phenylbutazone |
| | Probenecid |
| | Salicylates |
| | Sulfonamides |
| | Displacement of methotrexate from protein binding |
| Phenytoin | |
| Probenecid | |
| Retinoids | |
| Salicylates | |
| Sulfonamides | |
| Sulfonyleureas | |
| Tetracycline | |
| Hepatotoxicity | Ethanol |
| | Retinoids |
| | Dipyridamole |
| Intracellular accumulation of methotrexate | Dipyridamole |

week.⁵⁶ It can be administered orally, subcutaneously, or intramuscularly. It is renally excreted and should therefore not be administered to patients with impairment of kidney function.

■ **Mycophenolate Mofetil**

Mycophenolate mofetil, a semisynthetic morpholinoester of mycophenolic acid, initially was used to prevent acute rejection after renal and cardiac transplantation, but it is now used as part of combination therapy in moderate to severe psoriasis and other autoimmune dermatoses. It reversibly blocks de novo synthesis of guanine nucleotides required for DNA and RNA synthesis. The drug has been shown to have a specific lymphocyte antiproliferative effect.^{62,63} Oral mycophenolate mofetil, as well as topical mycophenolic acid, may undergo further clinical studies to establish efficacy in the treatment of patients with severe psoriasis.⁶⁴

Commonly reported adverse effects of mycophenolate mofetil include gastrointestinal toxicity (diarrhea, nausea, and vomiting), hematologic effects (anemia, neutropenia, and thrombocytopenia), and an increased incidence of viral and bacterial infections. Lymphoproliferative disease or lymphoma has developed in up to 1% of patients who received mycophenolic acid with other immunosuppressive agents.

See Chap. 87 on solid organ transplantation for a discussion of drug interactions involving mycophenolate mofetil.

Mycophenolate mofetil is usually administered in 500-mg doses four times a day; the dosage can be increased up to 4 g/day.

■ **Sulfasalazine**

Sulfasalazine, commonly used in the treatment of inflammatory bowel disease and rheumatoid arthritis, is selectively used as an alternative treatment, particularly in patients with concurrent psoriatic arthritis. Sulfasalazine is an anti-inflammatory agent that inhibits 5-lipoxygenase. When used as a single agent in the treatment of psoriasis, it is not as effective as is therapy with methotrexate, PUVA, or acitretin. One possible advantage of sulfasalazine therapy compared with other systemic treatments is its relatively high margin of safety. The usual dose of oral sulfasalazine is 3 to 4 g/day for 8 weeks.⁷

See Chap. 89 on rheumatoid arthritis for a discussion of drug interactions involving sulfasalazine.

■ **6-Thioguanine**

A purine analog that acts as an antimetabolite in the S-phase of cell division, 6-thioguanine is approved for treatment of leukemia, but has been used as an alternative treatment for psoriasis for decades when conventional therapies have failed.⁶⁵ It appears to be less hepatotoxic than methotrexate and therefore may be more useful in treating hepatically-compromised patients with severe psoriasis.

Adverse effects of 6-thioguanine include bone marrow suppression, gastrointestinal complications including nausea and diarrhea, and elevation of liver function tests.

See Chap. 124 on cancer treatment and chemotherapy, for a discussion of drug interactions involving 6-thioguanine.

The typical dose of 6-thioguanine is 80 mg twice weekly, increased by 20 mg every 2 to 4 weeks. Its maximum dose is considered to be 160 mg three times a week.

■ Hydroxyurea

Hydroxyurea inactivates the enzyme ribonucleotide reductase, inhibiting cell synthesis in the S-phase of the DNA cycle. An antimetabolite that is primarily used to treat hematologic malignancies, it has been used for the treatment of psoriasis for more than 3 decades.²⁹ It is selectively used, particularly in those with liver disease who would be at risk of adverse effects with other antipsoriatic agents. However, hydroxyurea is less effective than methotrexate.⁷

Adverse effects of hydroxyurea are bone marrow toxicity with leukopenia or thrombocytopenia, cutaneous reactions, leg ulcers, and megaloblastic anemia.

See Chap. 124 on cancer treatment and chemotherapy for a discussion of drug interactions involving hydroxyurea.

The typical dose of hydroxyurea is 1 g/day, with gradual increase to 2 g/day as needed as tolerated. Improvement is gradual, usually seen after 4 weeks of therapy.⁷

■ BIOLOGIC THERAPY

The field of biologic therapy is expanding rapidly as a result of advances in recombinant DNA technology, microbiology, and immunology. In dermatology, biologic therapies—primarily immunomodulating agents designed to alter immune responses—are the basis for treatment of cutaneous diseases such as psoriasis and atopic dermatitis. These agents, produced in vitro through recombinant DNA technology, fall into three categories: (1) recombinant human cytokines, (2) humanized monoclonal antibodies, and (3) molecular receptors that can bind target molecules.⁶⁶

The biologic agents currently used in moderate to severe psoriasis treatment are infliximab, etanercept, alefacept, and efalizumab.

CLINICAL CONTROVERSY

While some authors seem to successfully argue the advantages of remittive therapy in a potentially lifelong disorder,⁶⁷ others hypothesize the notion that biologic agents are excessively costly and that less expensive alternatives need development.⁶⁸ Despite the annual cost, given careful oversight, patient quality of life can be dramatically improved with an acceptable risk:benefit ratio if remittive therapy is accomplished with a biologic agent.

In psoriasis, biologic agents typically act through one or more of the following mechanisms: (1) elimination of activated T cells, (2) inhibition of T-cell activation, (3) interference with T-cell trafficking to the skin, (4) neutralization of the effects of Th1-type cytokines, and (5) induction of immune deviation by introducing Th2-type cytokines.⁶⁶

■ Infliximab

Infliximab is a chimeric monoclonal antibody (immunoglobulin G₁; IgG₁) directed against TNF- α . It binds with high affinity to the soluble and transmembranous forms of TNF- α and inhibits binding of TNF- α with its receptors. TNF- α is believed to play an important role in the pathogenesis of psoriasis. Increased amounts of TNF- α have been found in psoriatic lesions. The proposed mechanism of action

of TNF- α includes stimulation of synthesis of numerous cytokines and induction of the expression of intracellular adhesion molecules on endothelial cells and keratinocytes.⁶⁹

Infliximab is approved for treatment of rheumatoid arthritis and Crohn's disease, but has been studied for use in psoriasis. One double-blind, randomized, placebo-controlled clinical trial studied the effectiveness and safety of infliximab in patients with moderate to severe psoriasis. A good response was seen in 82% and 91% of patients treated with infliximab 5 mg/kg or 10 mg/kg, respectively. Median time to response for all patients receiving infliximab was 4 weeks. The investigators concluded that patients treated with infliximab had a high degree of clinical improvement with rapid response rate, similar to that observed with cyclosporine therapy.⁷⁰

The most common adverse effects of infliximab are headaches, fever, chills, fatigue, diarrhea, pharyngitis, upper respiratory and urinary tract infections, and hypersensitivity reactions (urticaria, dyspnea, and hypotension). Infliximab has been also associated with infections and lymphoproliferative disorders. It is not associated with end-organ toxicity, and blood counts, liver enzyme levels, kidney function, and complement values can be expected to remain normal during treatment. This gives it a major advantage over other systemic psoriasis treatments.

Infliximab is administered in three doses at weeks 0, 2, and 6, of 5 mg/kg or 10 mg/kg by slow intravenous infusion.⁷⁰

■ Etanercept

Etanercept, another TNF- α blocker, is a genetically engineered fusion protein that combines the extracellular domain of the TNF- α receptor with the Fc region of human IgG₁. Etanercept binds free and membrane-bound TNF- α , competitively interfering with the interaction of TNF- α with cell-bound receptors, and inhibits the effects of this cytokine on target cells. Unlike the chimeric infliximab, etanercept is fully humanized, thereby minimizing the risk of immunogenicity.⁷¹

Etanercept has been approved in several countries for subcutaneous treatment of rheumatoid arthritis and psoriatic arthritis. Safety and efficacy of etanercept for psoriatic arthritis and psoriasis were demonstrated in a 12-week randomized, double-blind, placebo-controlled trial of twice-weekly subcutaneous injections of etanercept 25 mg. The median reduction in PASI in the treatment group was 46%, compared with 8.7% in the placebo group.⁷²

Adverse effects of etanercept include a local reaction at the injection site (20% of patients), respiratory tract and gastrointestinal infections, abdominal pain, nausea and vomiting, headaches, and rash. Serious infections (including tuberculosis) and malignancies have rarely been observed.

Etanercept is usually given in doses up to 50 mg subcutaneously twice a week.

■ Alefacept

Alefacept is a dimeric fusion protein that combines the first extracellular domain of human LFA-3 with the Fc portion of human IgG₁. The LFA-3 segment of alefacept binds specifically to CD2 on T cells to prevent costimulatory signals delivered by LFA-3 and thereby inhibit cutaneous T-cell activation and proliferation. Alefacept also induces selective apoptosis of memory-effector T cells and produces a dose-dependent decrease in circulating total lymphocytes.^{7,73}

TABLE 96–6. Skin Classification Based on Reaction to Sun Exposure

| Skin Type | Description | Generalized Characteristics |
|-----------|--------------------------------------|--|
| 1 | Always burns easily, never tans | Light skin color, often blue eyes, very light skin |
| 2 | Usually burns easily, tans minimally | Light skin color, often blue eyes, fair skin |
| 3 | Burns moderately, tans gradually | Light brown skin |
| 4 | Burns minimally, tans readily | Moderate brown skin or olive skin |
| 5 | Rarely burns, tans profusely | Deeply pigmented, dark olive skin |
| 6 | Never burns | Darkly pigmented, brown or black skin |

From Lindelof et al.⁸³

Alefacept is approved for treatment of moderate to severe plaque psoriasis in patients and is also effective for the treatment of psoriatic arthritis.⁷⁴ Significant clinical response is achieved after about 3 months of therapy, and improvements are relatively long lasting.

Alefacept is well tolerated and its safety profile is equivalent to that of placebo. The most common adverse events are mild and include pharyngitis, influenza-like symptoms, chills, dizziness, nausea, headache, injection site pain and inflammation, and nonspecific infection; the frequency of these effects is low. Also, the drug produces no increase in the rate of opportunistic infections or malignancies.⁷⁵ Weekly visits to a physician's office for drug administration and CD4 T-cell monitoring are required, and not all patients respond to treatment.

Alefacept is administered by intramuscular injection in once-weekly doses of 15 mg for 12 weeks.

■ Efalizumab

Efalizumab is a humanized monoclonal antibody (IgG₁) against CD11- α integrin. CD11- α /CD18 comprise subunits of LFA-1, a T-cell surface molecule important in T-cell activation, T-cell migration into skin, and cytotoxic T-cell function.⁷⁶

Clinical studies with efalizumab have shown efficacy with few adverse effects. In an open-label, multicenter, dose-escalating study of repeated intravenous infusions of efalizumab over 7 weeks in 39 subjects with moderate to severe psoriasis, the individuals who were exposed to the optimum dose (1 mg/kg weekly) showed a mean decrease in PASI of 47%.⁷⁷ A subcutaneous formulation is under investigation.

The most frequent adverse effects of efalizumab are mild to moderate influenza-like complaints such as headache, nausea, chills, nonspecific infection, pain, fever, and asthenia; however, organ toxicity, serious infections, and malignancies have not been reported.⁷⁸

The usual dose is 1 mg/kg subcutaneously once weekly.

■ PHOTOCHEMOTHERAPY

UVA combined with oral methoxsalen is a photochemotherapeutic approach to treatment of psoriasis. Although burdensome, photochemotherapy is an important treatment consideration for patients with moderate to severe psoriasis, when time needed to treat and risk factors are balanced with potential benefit.

The mechanism of action of both UVB and PUVA in treating psoriasis is thought to be immunomodulatory. Phototherapy apparently

modulates expression of cellular adhesion molecules and induces T-cell apoptosis.⁷⁹

Candidates for PUVA therapy usually have moderate to severe, incapacitating psoriasis unresponsive to conventional topical and systemic therapies. A recent comparison of PUVA and NB-UVB involved 100 patients, 51 treated with NB-UVB and 49 receiving PUVA, with the results clearly favoring PUVA. Of these patients, 84% cleared with 16 PUVA treatments, whereas 63% cleared with 25 treatments of NB-UVB.⁸⁰

Adverse effects from oral methoxsalen include nausea, dizziness, and headache. Long-term adverse effects from combined psoralen (methoxsalen) and UV light include actinic skin damage, solar elastosis, dry and wrinkled skin, and hyperpigmentation or hypopigmentation. An increased risk of skin cancers, both squamous cell carcinoma and melanoma, exists after PUVA therapy, and is correlated with the cumulative UVA exposure.⁸¹ Although the proportion of patients with malignant melanoma has remained small, an increase in malignant melanoma has been observed in patients who received more than 250 PUVA sessions.

Oral methoxsalen is usually dosed with milk or food to minimize risk of nausea and gastrointestinal upset.

Systemic PUVA is approved for the treatment of psoriasis. It consists of oral ingestion of a potent photosensitizer such as methoxsalen (8-methoxypsoralen) at a constant dose (0.6 to 0.8 mg/kg) and variable doses of UVA, depending on patient skin type and history of previous response to ultraviolet radiation⁷ (see Table 96–6 for skin type classifications⁸³). Approximately 2 hours after ingesting psoralen, the patient is exposed to UVA light. Photochemotherapy is performed two or three times a week. In most patients, control and partial clearing occurs by the twenty-fifth treatment.

Another method—one that may have less carcinogenic potential—is to topically deliver the photosensitizer (methoxsalen) to the skin by addition to the bath water (bath PUVA) instead of through systemic administration.⁸³ Major advantages of this therapy are minimal risk of systemic effects and the overall reduction of UVA dose to one-fourth that required with conventional PUVA. A reduction in the risk of nonmelanoma skin cancer has also been demonstrated.

CLINICAL CONTROVERSY

Although PUVA is apparently not responsible for any increased incidence of internal malignancy,⁸⁴ risk:benefit considerations with regard to melanoma and nonmelanoma skin cancers indicate an increased risk for melanoma,⁸⁵ but no increase for nonmelanoma skin cancers, according to some authors,⁸⁶ despite development of increased numbers of lentiginos. Other investigators report an increased incidence of nonmelanoma skin cancers in association with PUVA.⁸⁷

PHARMACOECONOMIC CONSIDERATIONS

Outpatient costs for a patient with mild to moderate psoriasis may run as high as \$4,000 per patient per year. Psoriasis is a chronic disease with patients either requiring treatment or being in remission. Patients with severe psoriasis may be disabled. A patient with early onset of psoriasis may require treatment for more than 50 years.

By effectively controlling psoriasis, costs to patients, lost work days, and health plan costs may be reduced.

EVALUATION OF THERAPEUTIC OUTCOMES

See Tables 96–2 and 96–3 for pharmaceutical care guidelines and Fig. 96–1 for treatment algorithm based on severity of psoriasis.

ABBREVIATIONS

APC: antigen-presenting cell
 IFN- γ : interferon- γ
 IgG₁: immunoglobulin G₁
 IL-2: interleukin-2
 IL-8: interleukin-8
 IL-10: interleukin-10
 MIG: monokine induced by interferon- γ
 MIP-3 α : macrophage inflammatory protein-3 α
 NB-UVB: narrow-band ultraviolet B
 NF- κ B: nuclear factor- κ B
 PASI: Psoriasis Area and Severity Index
 PUVA: photochemotherapy using ultraviolet A light
 RANTES: regulated on activation, normal T-cell expressed and secreted
 TARC: thymus- and activation-regulated chemokine
 Th1: T-helper cell type 1
 TNF- α : tumor necrosis factor- α
 UVA: ultraviolet A
 UVB: ultraviolet B
 VEGF: vascular endothelial growth factor

ATOPIC DERMATITIS

Nina H. Cheigh

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Atopic dermatitis has increased in prevalence in recent years by two- to threefold, particularly in industrialized countries, along with an associated increase in prevalence of other IgE-mediated diseases such as allergic rhinitis and asthma.
- 2 Atopic dermatitis most often initially presents during infancy but can occur at any age.
- 3 Clinical presentation differs according to age. Infants typically have face, trunk, and neck involvement, while older children and adults present with lesions in the antecubital and popliteal fossa and on the hands and face.
- 4 Patients with atopic dermatitis are extremely susceptible to allergens and other triggering factors, including aeroallergens (dander, grass, mold, and pollen), food (eggs, peanuts, soy, and milk), detergents and soaps, chemicals, varying humidities, temperature, and emotional stress.
- 5 Most patients with atopic dermatitis have elevated serum IgE levels as well as eosinophilia. But pathogenesis also involves a complex process of interactions among lymphocytes, macrophages, and mast cells.
- 6 Control of atopic dermatitis flare-ups includes identification and elimination of trigger allergens, as well as maintenance of skin patency.
- 7 Topical corticosteroids and emollients are the mainstay for treatment of atopic dermatitis.
- 8 Topical immunomodulators, tacrolimus, and pimecrolimus provide new options for patients with mild to severe cases of atopic dermatitis.
- 9 In severe, refractory cases, atopic dermatitis can be treated with ultraviolet radiation, oral corticosteroids, cyclosporine, azathioprine, methotrexate, and interferon- γ .

Atopic dermatitis (AD), a common pervasive inflammatory skin condition, is notorious for creating a vicious cycle of itching and scratching. Chronic, relapsing, itchy and inflamed skin is the hallmark symptom of AD (also known as atopic eczema).¹ The condition is characterized by an itch so unbearable that patients often find that they must scratch until the itch is replaced by pain. Although the term “atopy” is widely accepted throughout clinical medicine to describe a person’s susceptibility to hay fever, asthma, and atopic dermatitis, there is no precise definition or marker of atopy.² Certainly there is an association among these chronic conditions, as some 80% of children with AD eventually develop allergic rhinitis or asthma, or have a family history of one or both of these conditions.^{3,4}

EPIDEMIOLOGY

1 A recent and substantial increase in prevalence of AD has been well documented over a wide variety of age groups and geographic locations.^{5,6} Approximately 10% to 15% of children under the age of 5 years have been afflicted with AD at some stage in more developed countries.⁶ Levels of air pollution, industrialization and urbanization, dietary modifications, and higher socioeconomic class are some of the factors that have been attributed to this increase in prevalence.⁵ Although approximately one-half of AD cases are diagnosed during the first year of life, AD typically is a long-term condition, with one third of patients having symptoms that continue into

adulthood.⁷ However, those with severe symptoms and early onset have a greater likelihood for a more pervasive course of disease.

Many times, AD is not perceived as a major illness and is frequently dismissed as a minor skin condition. However, studies have demonstrated considerable financial, emotional, and social impact on families of those with moderate or severe AD.⁸ An Australian study reported results of significantly more stress in taking care of a child with moderate or severe AD than that involved with care of a child with insulin-dependent diabetes.⁹ Disturbed or lack of sleep has also been reported.¹⁰ In the United States, AD accounts for 4% of emergency department visits. The health systems of all countries are burdened with the economic load of AD’s direct and indirect costs of treatment and social morbidity.¹¹

ETIOLOGY

Despite important contributions of research into the cause of AD, the complicated genetic, environmental, and immunologic mechanisms that produce AD are not completely understood. The hereditary component of AD’s etiology is particularly strong, as children with one affected parent have a 60% likelihood of having an atopic disease. If both parents are afflicted, the child has an 80% chance of developing an atopic condition.¹² Paternal AD and asthma are stronger contributors to this risk, in contrast to maternal history. Most patients with AD are found to have elevated eosinophils and serum

immunoglobulin (Ig) E levels—findings commonly found in patients with allergic rhinitis or asthma—and 80% of children with AD eventually develop one of these other immunologic/allergic diseases. Children with AD more frequently develop severe asthma than do asthmatic children without AD.⁵

Almost every immunocyte—including Langerhans cells, monocytes, macrophages, lymphocytes, mast cells, and keratinocytes—have some demonstrated abnormality in patients with AD.¹³ In addition, AD skin is characterized by an elevated transepidermal water loss and lower skin barrier functions, and for this reason patients must use proper cleansing and moisturizing techniques to maintain skin integrity.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

2 Intense itching (pruritus) and skin reactivity are the hallmarks of AD.¹⁴ Typically, three different types of skin lesions are associated with AD: acute, subacute, and chronic.

The acute rash lesions are intensely pruritic, erythematous papules and vesicles over erythematous skin. These itchy lesions are subsequently associated with scratching that results in excoriations and exudates. Subacute lesions are typically thicker, paler, scaly, erythematous, and excoriated plaques. Chronic lesions are characterized by thickened plaques, accentuated skin markings (lichenification), and fibrotic papules. Most patients exhibit all three lesion types. At all phases, the atopic skin usually has a dry luster.¹

3 AD, often referred to as infantile eczema, commonly involves the extensor surfaces of the extremities, trunk, face, scalp, and neck.¹⁵ Although infantile eczema commonly subsides in severity, it often causes the adult to develop a tendency for inflammatory, erythematous, pruritic reactions when exposed to irritants. When AD presents in older children or adults, the lesions are present in the flexural areas of the antecubital (inside the elbow) and popliteal (behind the knee) fossae. Atopic skin is associated with xerosis, which is recognized as a fine scaling, noninflamed skin involving large areas of the body. Atopic skin has a genetically determined decreased ability for keratinocytes to bind water, thus producing dry skin regardless of the weather.¹⁶ The atopic epidermis not only triggers pruritus, but also results in an abnormal protective layer, predisposing the patients to irritation from allergens.

DIAGNOSIS

Hanifin and Rajka¹⁴ published the first major and minor diagnostic criteria for AD in 1980. These diagnostic criteria include the presence of pruritus, with three of more of the following:

1. History of flexural dermatitis, or dermatitis of the face in children younger than 10 years of age
2. History of asthma or allergic rhinitis in the child or a first-degree relative
3. History of generalized xerosis (dry skin) within the past year
4. Visible flexural eczema
5. Onset of rash before 2 years of age

5 If a diagnosis of AD cannot be made, the presenting symptoms can be indicative of a wide array of other conditions and differential diagnoses, and thus referral to a specialist is warranted.¹⁷ Although elevated IgE and peripheral eosinophilia are found in most patients with AD, no single laboratory test can be relied upon for diagnosis of

AD, as some patients do not present with such abnormalities.¹⁷ Skin prick tests or enzyme-linked immunosorbent assay tests can be used to aid in identification and exclusion of allergic triggers, but these are not specific or sensitive enough to be diagnostic.

Not only is there a lack of absolute diagnoses or laboratory tests, a lack of standardization in objective severity scales hampers classification of the disease. Of the systems available, the SCORAD index, adapted by the European Task Force on Atopic Dermatitis,¹⁸ was previously the most often used, but it demonstrated interobserver variation. As such, research is continuing to identify a better system for classifying patients.¹⁹

ALLERGEN TRIGGERS

4 Immunologic triggers that contribute to AD development include food allergens and aeroallergens. A variety of allergens cause approximately 85% of AD patients to demonstrate an immediately positive skin test of serum IgE antibody.¹ However, AD is not a purely IgE-type of condition, as this would indicate presence of an immediate hypersensitivity mast-cell mechanism.

Instead, type 2 T-helper (Th2) cells, found in atopic individuals, play an important role in the condition.²⁰ Studies have demonstrated flaring of AD on exposure to various aeroallergens such as horse dander, grass, and ragweed pollen.¹ Although variation in performance and evaluation of these tests is difficult to avoid, patch tests with allergens can result in eczematous reactions.³

The most common household aeroallergens are dust mites, cat dander, and molds. Dust mites, a commonly encountered allergen, occur in more than 45% of American homes in a concentration exceeding that needed for sensitization.²⁰ Even so, simple steps can reduce the amount of dust mites in homes.

Food allergy is also a contributing factor to AD, and generally, the more severe the AD and younger the patient, the more likely food allergy is the cause of the symptoms.²¹ Egg, milk, peanut, soy, and wheat are noted to account for almost 90% of food allergy in children with AD.²² Even so, almost one-third of the children with AD and food allergies will “outgrow” the condition over 1 to 3 years.²³ But given this, it is essential that patients (parents) are properly instructed on how to read labels for “hidden sources” of allergenic foods. Patients should be rechallenged at certain times to determine whether they have truly outgrown their food allergy.²²

The question remains as to whether breast-feeding helps prevent allergy, but this cannot be ethically studied. Human breast milk is the most hypoallergenic substance that can be used to nourish infants, but no evidence shows that either prolonged breast-feeding or manipulations of a mother’s diet during lactation protects in the development of AD in infants with a family history of atopy.²⁴ In infants with a strong family history of AD, thus putting them at high risk, occurrence of AD may be decreased during the first 4 years of life by prolonged breast-feeding (4 to 6 months), and introduction of solid foods at a later point in development (after 4 months of age).²⁵

In stressful situations, in which the patient is frustrated or embarrassed, itching, sweating, and scratching are more likely.¹ Stress itself does not cause AD, but it can exacerbate the condition.²⁶ Stress management, relaxation, and behavioral modification may be important.

Knowing that atopic patients are more susceptible to irritants, there should be an attempt to identify and remove the common irritants. Soaps, detergents, abrasive clothing, smoke, and exposure to extremes in temperature and humidity can be aggravating factors. Although UV light may be beneficial to some patients, sunscreens should be used to avoid sunburns. Care should be used in selection, as many chemical sunscreens can cause contact dermatitis. In

addition, as modernization and “Westernization” occurs, people spend the majority of their time in modern buildings with reduced ventilation. This has resulted in an increased load of chemical vapors and gases, along with indoor house dust mites and mold.²⁵

COMPLICATIONS

Atopic skin also has a predisposition for increased microbial organisms, namely *Staphylococcus aureus*, which is found in more than

90% of AD skin lesions.¹³ Patients with AD are also more prone to herpes simplex infections than the general population.²⁷ These viral infections can spread locally or become generalized. In addition, fungal pathogens, particularly *Malassezia furfur* or *Pityrosporum ovale*, have been identified.

Patients with AD can also present with eyelid dermatitis, nipple dermatitis, and cheilitis of the lips.²⁸ Eyelid dermatitis and chronic blepharitis are commonly associated with AD, and can result in visual impairment from corneal scarring. Other ocular complications include atopic keratoconjunctivitis, vernal conjunctivitis, and keratoconus.¹

► TREATMENT: Atopic Dermatitis

Currently, AD cannot be cured. As such, this condition requires a management plan, including identification and avoidance of external triggers, maintenance of skin patency, and use of several therapeutic options for symptomatic relief. Therapy should be individu-

alized, and a multipronged approach should be initiated. Reduction of symptoms, prevention of recurrent flares, and modification of the course of the disease is the best long-term strategy for managing AD (Fig. 97–1).

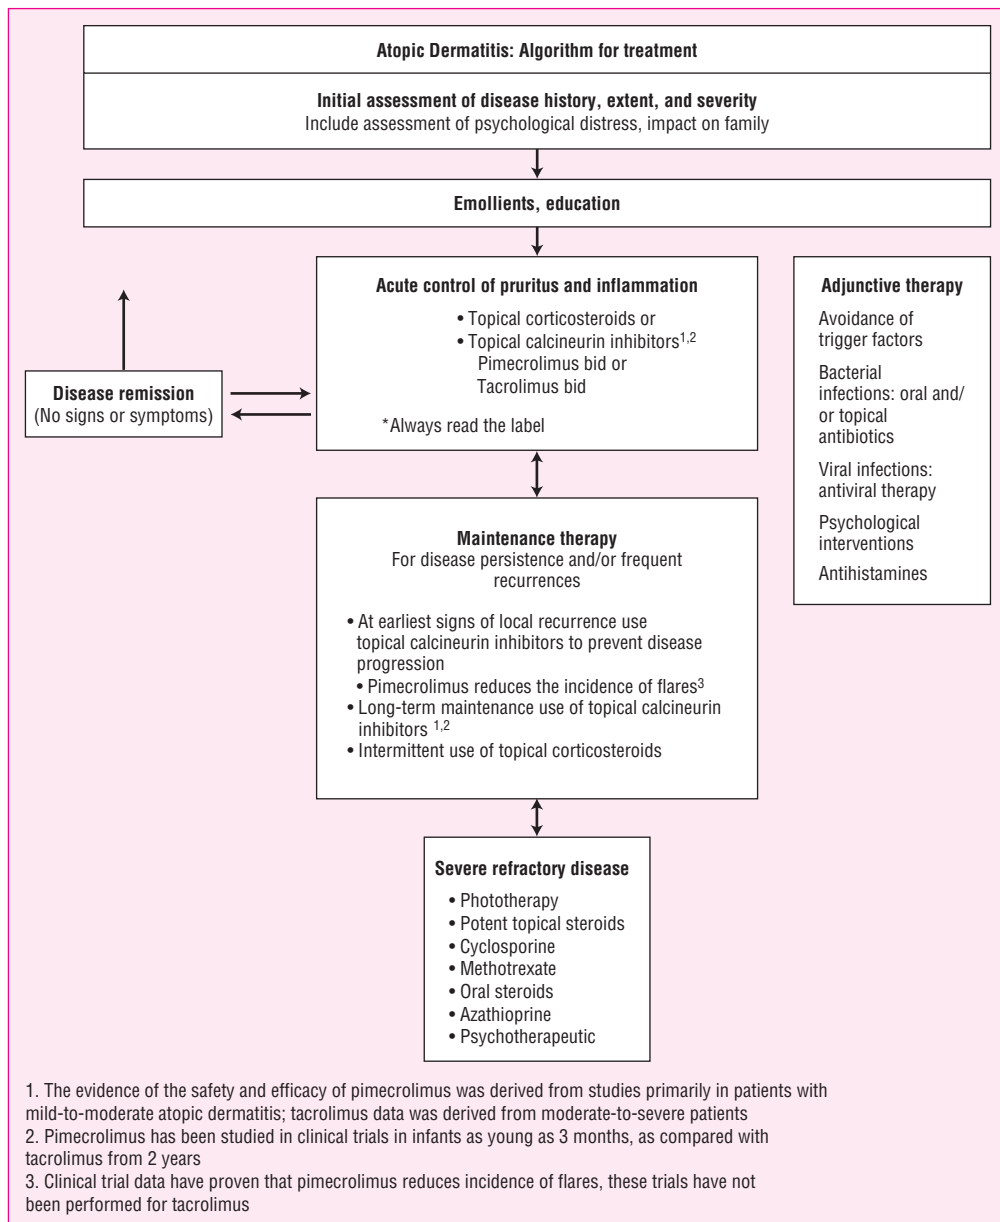

FIGURE 97–1. Treatment of atopic dermatitis

■ NONPHARMACOLOGIC THERAPY

6 Given that patients with AD are more susceptible to irritants than normal individuals, possible aggravating factors that may trigger a flare-up should be identified. Recommendations can include avoiding extraneous perfumed or dyed soaps and detergents, using a second rinse cycle for laundry, avoiding extremes of temperature fluctuations, and otherwise being cognizant of potential allergens. Sunscreens should be used in patients with AD, but judicious use of nonchemical agents (e.g., physical sunscreens such as titanium or zinc oxide products) are probably less likely to cause further irritation or contact dermatitis.¹

The epidermis of atopic skin has a reduced capability of holding moisture. This inherently dry skin is also exacerbated by external changes, including variations in weather and allergen exposures. Thus the importance of maintaining proper skin patency cannot be overstressed, as slight irritations to atopic skin can result in microfissures, which act as portals of entry for various pathogens.¹⁷

7 Simple, nonpharmacologic, preventive measures should be recommended for all patients with AD. Clinicians should be attuned to the various types of moisturizer classes, including occlusives, humectants, and emollients. Each has a different mechanism of action on the epidermis, and thus treatment should be tailored to an individual patient need. Generally speaking, an ointment is more occlusive than a cream or a lotion, and thus can retain more moisture in contact with the skin. Avoidance of extraneous fragrances, dyes, and preservatives, as well as understanding a potential role of excipient contact allergy is also of importance in emollient selection (Table 97–1).

■ PHARMACOLOGIC THERAPY

■ TOPICAL CORTICOSTEROIDS

Topical corticosteroids have been the standard approach for treating the inflammation and pruritus of AD. Typically used in short-term reactive treatment of acute flare-ups, topical corticosteroids must be supplemented with emollients. Clinicians unfamiliar with topical corticosteroids find them a challenge to use, due to the numerous types, strengths, generic versus brand name formulations, and the wide variety of ways to use the products. The corticosteroids are ranked according to potency depending on vasoconstrictor assays (see Table 96–4 in Chap. 96, on psoriasis). Most commonly, the highest-

TABLE 97–1. Nonpharmacologic Management of Atopic Dermatitis

- Identify and eliminate potential allergens
- Reduce frequency of bathing; bathe every other day
- Use of tepid water in baths
- Avoidance of irritating soaps (dyes, fragrances, and preservatives can all contribute to further exacerbations)
- Avoid washcloths or irritating scrubs
- Air dry skin and gently pat dry
- Application of emollient (preferably an ointment or cream, again watching for dyes, fragrances, and preservatives) within 3 minutes after bathing
- Keep fingernails short and clean to prevent scratching
- Consider cotton gloves to prevent scratching at night
- Use of cotton sheets and pajamas
- Avoid harsh laundry detergents (some may contain allergens)
- Moisturize as often as necessary to keep skin soft and pliable (at least twice a day)

TABLE 97–2. Topical Corticosteroid Use in Atopic Dermatitis

Potency of the steroid depends upon the vasoconstrictive properties

- Typically, with high-potency steroids:
Use no longer than 3 weeks
Use on thickened lesions
Not for use on face, skinfolds, or mucous membranes

The vehicle is as important as the steroid concentration

- Occlusives can increase percutaneous absorption
- Ointments are stronger than creams, which are stronger than lotions
- Gels may be beneficial for hairy or oily areas

Use with moisturizers

- Apply corticosteroid first
- The goal is to increase moisturizers while decreasing corticosteroid use

potency steroids are used for short periods of time (generally less than 3 weeks) for acute flare-ups of AD or for lichenified (thickened) lesions. Because of their potential adverse effects, these steroids should not be used on the face, mucous membranes, eyelids, or skinfold areas.¹⁷ Moderate-strength steroids may be used for more chronic AD, typically on the trunk or extremities. Low-potency steroids are usually used in children.

The vehicle in which the steroid is incorporated is also of importance. As in emollients, ointments are far better at occluding the epidermis, and thus provide enhanced percutaneous absorption of the corticosteroid compared with the cream of the same strength. Ointments may be a better choice for a lichenified lesion or when an acute flare-up is being treated, as the enhanced occlusion will result in better absorption.¹⁷ Other methods of occlusion—such as use of plastic wrap, tight-fitting clothes, or diapers—may also increase the absorption significantly, which is advantageous when absorption is desired, but that is not always the case.²⁹ The vehicle can also be chosen based on the area of the body. For example, if application is required on hairy areas such as the scalp or beard, a solution or gel may be more aesthetically pleasing. These are important considerations when recommending a corticosteroid, or when counseling a patient on its appropriate use.

Typically, most corticosteroids are applied once to twice daily. Should the steroid be used in conjunction with other topical agents, including moisturizers, the corticosteroid should be applied first, rubbed in well, and followed by the other product. A good rule of thumb is that approximately 30 g of cream or ointment can cover the average-sized adult once. Thus if treatment needs to be twice daily to the entire body for 2 weeks, the average adult will go through 2 pounds of topical corticosteroid. Failure to respond to topical corticosteroid use is sometimes simply due to inadequate application.¹

Concerns about adverse effects from topical steroids have resulted in restrictions of its use on certain anatomic areas and its use in children. Both health care providers' and patients' lack of confidence in the safety of topical corticosteroid use has resulted in undertreatment and nonadherence.¹⁷ The potential for adverse effects with these products depends a variety of factors. The concentration applied, the amount applied, how often it is applied, and for how long it is applied can be important factors to consider. Long-term topical corticosteroid use primarily results in cutaneous abnormalities such as skin atrophy, striae, hypopigmentation, and steroid-induced acne. Systemic effects, namely hypothalamic-pituitary-adrenal axis suppression, growth retardation, and other adrenal abnormalities have been reported and thus have resulted in limiting topical steroid use in children (Table 97–2).^{7,17}

■ ANTIHISTAMINES

Antihistamines are used to attempt to break the itch-scratch cycle that results from the pruritus of AD. Despite frequent use of antihistamines, few clinical studies support their efficacy, most likely because not all pruritus is mediated by histamine.^{1,17} Because pruritus is worse at night, the sedating antihistamines (i.e., hydroxyzine or diphenhydramine) can offer an advantage by facilitating sleep, whereas the newer nonsedating antihistamines have shown variable results.

One tricyclic antidepressant, doxepin, inhibits both H₁ and H₂ receptors, and it has been used for treating adults with AD in doses of 10 to 75 mg at night and up to 75 mg twice daily. This may be beneficial in those atopic patients who have some depression as well.^{1,17,30} Topical antihistamines, such as 5% doxepin cream or diphenhydramine cream, also have demonstrated neutral results, but are generally not recommended because of high cutaneous sensitization from excipient ingredients in the formulation.¹⁷

■ TOPICAL IMMUNOMODULATORS

8 Topical calcineurin inhibitors, including tacrolimus and pimecrolimus, have added a new dimension to treatment of AD. Unlike corticosteroids, these agents offer a more long-term option, as they can be used on all parts of the body for prolonged periods without fear of corticosteroid-induced adverse effects. These agents form a complex that results in inhibition of calcineurin, which normally initiates T-cell activation. Through inhibition, the complex subdues the inflammatory component of AD (Table 97-3).³¹

Although the structures of both of these compounds are similar, pimecrolimus is more lipophilic than tacrolimus, and this reduces its cutaneous penetration.^{31,32} Studies show that both compounds can be used long-term without skin atrophy occurring.^{33,34}

A number of studies have demonstrated the short-term and long-term effectiveness of topical tacrolimus 0.03% and 0.1% ointment in AD for children and adults.³¹ When used twice daily, tacrolimus significantly reduced pruritus, cleared lesions, and otherwise improved quality of life. Since the 0.1% formulation is no more effective than the 0.03% concentration, the lower strength is preferred in children with moderate or severe AD,³⁵ but both strengths are used in adults with AD in those severity categories.³¹

The most common patient complaints with topical tacrolimus therapy are transient itching and burning at the site of application. Although no data support the practice, many clinicians recommend pretreatment with topical corticosteroids to prevent or reduce tacrolimus-induced burning and erythema. Systemic adverse effects of tacrolimus, while well documented with oral therapy, have not been observed in patients using the topical ointment for AD.³⁶ Patients who receive long-term systemic immunosuppressants are prone to devel-

oping actinic keratoses, viral warts, and nonmelanoma skin cancers. Although there are no such reports from topical use, the judicious use of adequate sun protection should be stressed in patients receiving topical tacrolimus for AD.

Topical pimecrolimus 1% cream is safe and effective for treating long-term AD.³¹ Preliminary evidence also indicates a potential for use in the treatment of allergic and irritant contact dermatitis.³⁷ Topical pimecrolimus has been evaluated in both children and infants as young as 3 months of age. These multicenter, randomized, double-blind trials found that flare-ups were prevented and overall disease severity reduced.^{38,39} When pimecrolimus is used as first-line therapy for acute AD, the need for corticosteroids can be reduced or eliminated. Even when steroids are needed for flare-ups, the duration of steroid use can be significantly shortened.⁴⁰ Thus pimecrolimus is increasingly accepted as a first-line therapy and effective means of reducing the amount of corticosteroid needed for managing AD.⁴¹

Pharmacokinetic studies have evaluated the systemic concentrations of pimecrolimus when the agent is administered topically in children. These studies concluded that pimecrolimus is well tolerated locally, and systemic effects were not seen.^{42,43} Currently, the FDA has approved pimecrolimus cream 1% twice daily for use in mild to moderate AD in children older than 2 years of age and adults.

Although no direct comparative data exist, tacrolimus may be more effective in clearing severe cases of AD than is pimecrolimus.³¹ However, increased transient local burning with topical tacrolimus, possibly reflecting its higher immunosuppressant activity, might indicate an increased possibility of skin cancers, as these are more common when skin immunity is impaired. Other areas that require further study are the use of each of these agents in combination regimens and use of these calcineurin inhibitors as maintenance therapy for AD supplemented with corticosteroids during acute flare-ups.^{7,31}

■ TAR PREPARATIONS

Coal tar preparations reduce itching and inflammation of the skin.¹ These products have been used in combination with topical corticosteroids, as adjuncts so that lower strengths of corticosteroid can be used effectively, and in conjunction with ultraviolet light therapies. These preparations are available as crude coal tar (1% to 3%), or liquor carbonis detergens (5% to 20%). At times, coal tar is compounded by pharmacists into various concentrations and sometimes with topical corticosteroids.

Coal tar preparations should not be used on acute oozing lesions, as this would result in stinging and irritation.⁴⁴ The strong odor of coal tar products and their staining of clothing are limiting factors. Patients can be instructed to use the product at bedtime and wash it off in the morning. In addition, folliculitis and photosensitivity have been reported.

■ THERAPIES FOR REFRACTORY CONDITIONS

■ WET DRESSINGS WITH OCCLUSION

Cool wet dressings or total body wraps placed directly onto the skin can be effective in relieving itching, particularly at night. Wet wraps used in conjunction with topical corticosteroids can be used for acute flares or chronic, lichenified lesions.⁴⁴ Skin maceration, fissures, and subsequent infections can occur, and thus these occlusive dressings should be limited to severe, chronic lesions. Tepid compresses applied to skin for 20 minutes four to six times daily can aid in drying out the oozing lesions.

TABLE 97-3. Topical Immunomodulator Use in Atopic Dermatitis

|--|
| <ul style="list-style-type: none"> • Tacrolimus (Protopic) 0.1% ointment: for moderate to severe AD in adults not responding adequately to other therapies • Tacrolimus 0.03% ointment: for moderate to severe AD in children over 2 years old • Pimecrolimus (Elidel) 1% cream: for mild to moderate AD in children and adults (it has been studied in infants as young as 3 months) |
| <p>Applied twice daily May be used for longer term Can result in reduction in flare-ups</p> |

■ ULTRAVIOLET LIGHT

9 Ultraviolet light can have phototherapeutic benefits to patients with severe AD. Though natural sunlight can be a source, ensuring that the sunlight is not associated with high heat or humidity (which can exacerbate the condition further) is difficult. Thus short-wave UVB therapies can be useful as adjunctive therapy in chronic recalcitrant AD.⁴⁵ At times, higher-intensity UVA therapy has been therapeutic in acute exacerbations, and the mechanism indicates that eosinophils and epidermal Langerhans cells may be targets for high-intensity UVA.⁴⁶ Photochemotherapy with oral methoxypsoralen followed by UVA may be indicated in patients with severe, widespread AD, particularly in corticosteroid failure.⁴⁷ Adverse effects, ranging from erythema and pigmentation to premature photoaging and cutaneous malignancies are possible, and thus caution should be used in assessing risks versus benefits of therapy.

■ SYSTEMIC IMMUNOSUPPRESSANTS

If aggressive topical therapy and phototherapy fail to control AD symptoms, the systemic immunosuppressant agents can play a role. Given that AD is a T-cell-mediated disease with involvement from Langerhans cells, eosinophils, and mast cells, immunosuppressant agents are logical agents to use in treatment of severe, refractory, or extensive disease. However, because of their possible adverse effects, judicious use of systemic immunosuppressants is warranted.⁴⁸

■ Systemic Corticosteroids

Oral corticosteroids, such as prednisone, may be indicated in the treatment of severe chronic AD.^{1,17} Typically, a short course can be used to control a severe flare. Proper tapering is necessary, as misuse of the medications can result in dramatic improvement of symptoms, followed by a significant rebound flare upon discontinuation of the medication.¹⁷ Long-term use can cause the well-recognized adverse effects of systemic corticosteroids, including hypertension, growth stunting and developmental delays, and cushingoid features. Thus use of these agents, particularly in children, should be limited to severe conditions that do not respond to safer treatments.⁴⁸ Concomitant and proper use of intensified skin care, particularly of topical corticosteroid and emollient use during therapy, is also of utmost importance.

■ Cyclosporine

Although cyclosporine is not currently approved by the FDA for use in psoriasis, it has been effective in treating many other immunologically based skin diseases.⁴⁸ Similarly to systemic corticosteroids, rebound flare-ups of AD are possible with cyclosporine use. Oral cyclosporine can be used on a short-term basis for severe, recalcitrant disease in adults at a dose of 5 mg/kg per day,^{48,49} and slightly lower doses, 3 mg/kg per day, can be used with caution in children.

Tolerability in children is good, and most common adverse effects are limited to abdominal pain and headaches.⁵⁰ Adverse effects such as renal toxicity were mild and reversible in a long-term multicenter study of safety of cyclosporine use in adults.⁵¹ Even so, appropriate monitoring parameters—electrolytes, renal function, complete blood counts, fasting lipid profiles, and uric acid levels—should be measured at baseline and periodically. Cyclosporine is also involved

in many drug-drug interactions, and careful monitoring is required (see Chap. 87 on solid organ transplantation).

■ Azathioprine

Azathioprine, a purine analogue, is another systemic immunosuppressant that may be helpful in severe cases of AD. Its main disadvantage, compared with cyclosporine, is a delayed onset of action of 4 to 6 weeks. Most reports of azathioprine use have been in uncontrolled, open, retrospective trials, and the use of inconsistent regimens in these trials makes determination of dosing schedules difficult. Despite numerous adverse effects—including myelosuppression, hepatotoxicity, and gastrointestinal disturbances—azathioprine can be helpful in reduction of AD disease activity.⁴⁸

■ Antimetabolites

Mycophenolate mofetil (MMF), an immunosuppressant used in organ transplant, has cleared refractory symptoms of AD in short-term, open-label studies.¹ Since dose finding and well-controlled studies are not available for MMF use in AD, the agent should be used with caution and discontinued if the patient does not respond within 4 to 8 weeks of therapy.^{1,48}

Methotrexate, an antimetabolite, is a folic acid antagonist that is primarily used as an antineoplastic agent and in the treatment of psoriasis and rheumatoid arthritis. Although no controlled studies have examined its use in AD, anecdotal evidence supports its effectiveness at a dosage of 2.5 mg/day given four times a week.^{1,48,52} Because of its myelosuppressive effects, patient hematologic parameters should be closely monitored. Other adverse effects include hepatotoxicity, pulmonary toxicity, and gastrointestinal toxicity. Folic acid supplementation should also be instituted during methotrexate therapy, and addition of this nutrient does not compromise methotrexate effectiveness.

■ Interferon- γ

Interferon- γ , a known inhibitor of Th2 cells, has been considered a logical choice in suppressing the IgE responses in AD, and several multicenter, double-blind, placebo-controlled trials have demonstrated clinical improvement with its use in AD.^{1,48} However, interferon injections are expensive and may be associated with flu-like symptoms such as fever, chills, headache, myalgia, arthralgia, nausea, vomiting, and diarrhea.⁵³ Further controlled studies are warranted before its routine use for AD patients can be recommended.

CLINICAL CONTROVERSY

AD and contact dermatitis (both the irritant and allergic types) are eczematous diseases with very similar pathologies. Although AD, unlike contact dermatitis, maintains an important genetic component, evidence is increasing that these diseases are closely related. The current consensus is that atopic and acute contact dermatitis are both immune-mediated, and AD increases one's susceptibility to irritant contact dermatitis. More investigations are needed, but understanding the possible links between AD and contact dermatitis can aid clinicians in understanding the pathophysiology, diagnosis, and treatment of patients who are ailing from these diseases.⁵⁴

EVALUATION OF THERAPEUTIC OUTCOMES

The overall goal for managing patients with AD is to control the condition by preventing flare-ups and to produce a better quality of life without disease- or treatment-related complications. Patients with AD and their caregivers should consult with health care practitioners for assistance with identifying and eliminating trigger factors and allergens and nonpharmacologic management of the disease. All patients with AD should be counseled on the importance of emollient use and other measures for proper skin care.

Depending on the severity of AD, some patients may need maintenance treatment with low-strength topical corticosteroids. Currently, topical corticosteroids are the mainstay for treatment of flare-ups associated with AD. However, patients can be quite concerned about use of corticosteroids. One recent study showed that 73% of patients worried about using topical corticosteroids for fear of adverse effects; 24% of the patients were concerned enough that they did not adhere to recommendations for corticosteroid treatment.⁵⁵

Patients older than 16 years who present with AD should be patch tested for possible contact dermatitis.¹⁷ Health care practitioners should also inform patients of the possibility of problematic bacterial, viral, or herpetic skin infections with AD and during its treatment.

ABBREVIATIONS

AD: atopic dermatitis
 Ig: immunoglobulin
 MMF: mycophenolate mofetil
 Th2: type 2 T-helper cells

HEMATOPOIESIS

William P. Petros and Solveig Ericson

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- ◀1 Leukocytes are subdivided into specific cell types which have important functional differences.
- ◀2 All hematopoietic cells are thought to be generated from one common type of cell (stem cell).
- ◀3 Blood concentrations of some hematopoietic cell types may not be reflective of total body content.
- ◀4 Cytokines such as colony-stimulating factors are important regulators of hematopoiesis.
- ◀5 The kinetics of hematopoietic cells vary with cell type, maturity, pathophysiology, and external stimuli.
- ◀6 Both the number of cells and other cofactors determine the clinical consequences of neutropenia or anemia.

Hematopoiesis is defined as the formation and maturation of blood cells and their derivatives. There is a tremendous daily turnover rate of cells in this system, with more than 6 billion cells produced per kilogram of body weight every 24 hours.¹ These accelerated processes result in vastly exaggerated and rapid responses to the slightest perturbation.

In humans, hematopoiesis takes place primarily in the bone marrow. Hematopoietic cells were among the first to be evaluated for their biologic function and pattern of maturation, and recent identification of the protein molecules (cytokines) that regulate this system has yielded an extraordinary amount of new information regarding its control. The process of continual hematopoietic cell production is complicated, involving interactions between immature cells, the surrounding microenvironment, and cytokines.

HEMATOPOETIC SYSTEM

The hematopoietic system consists of three primary cell components: leukocytes, platelets, and erythrocytes. The first group encompasses a functionally diverse group of cells that includes neutrophils, eosinophils, basophils, monocytes/macrophages, lymphocytes, and plasma cells. Typical concentrations of mature hematopoietic cells found in the peripheral blood of adults are shown in Table 98–1.

LEUKOCYTES

NEUTROPHILS (SEGS AND BANDS)

- ◀1 The major functions of neutrophils (also known as polymorphonuclear leukocytes) are to prevent pathogenic microorganism invasion and to localize and kill these microorganisms if they

do invade the body. These effects are mediated by a series of events, including migration to the site (chemotaxis), recognition/attachment to the invader, phagocytosis, lysosomal fusion, degranulation, and local generation of oxidants (respiratory burst) and degrading enzymes (Fig. 98–1).² A neutrophil is attracted to the site of infection by chemotactic factors. Once migration to the site has occurred, the neutrophil ingests the opsonized microorganism. (Opsonization is the process whereby antibody and complement coat the microorganism, allowing for increased neutrophil recognition.) Following ingestion or phagocytosis, the cytoplasmic granules within the neutrophil fuse with the phagosome or phagocytosed microorganism, thereby initiating degranulation and release of enzymes. These degrading enzymes kill the microorganism through oxygen reduction. Secretion of these enzymes may also result in localized host tissue injury. The actions of cytokines such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) may intensify neutrophil activity.³

EOSINOPHILS

Although eosinophils are less efficient than neutrophils, they elicit similar effector functions. Eosinophil activity is directed primarily against large invaders, such as helminths and other parasites that cannot be phagocytized. During an allergic reaction, activated mast cells secrete chemicals that attract and stimulate eosinophils, which in turn produce substances that neutralize or degrade the reaction products of mast cells. Unfortunately, the eosinophil constituents may also damage normal tissue and cause secondary histamine release. High concentrations of eosinophils for prolonged periods may result in damage to the cardiac and central nervous systems, with possible pulmonary and dermatologic involvement.⁴

TABLE 98-1. Average (Normal Range) Adult Blood Cell Concentrations

| | | |
|---------------------------------------|--------|------------------|
| White cell count ($\times 10^9/L$) | | 7.8 (4.4–11.3) |
| Red cell count ($\times 10^{12}/L$) | Male | 5.21 (4.52–5.90) |
| | Female | 4.60 (4.10–5.10) |
| Hemoglobin ^a (g/dL) | Male | 15.7 (14.0–17.5) |
| | Female | 13.8 (12.3–15.3) |
| Hematocrit | Male | 0.46 (0.42–0.50) |
| | Female | 0.40 (0.36–0.45) |
| Mean corpuscular volume (fL/red cell) | | 88.0 (80.0–96.1) |
| Platelet count ($\times 10^9/L$) | | 311 (172–450) |

^aMay be 0.5–1.0 g/dL lower in black patients.

BASOPHILS AND MAST CELLS

Through a massive release of their granule contents upon stimulation, basophils and mast cells function as mediators of inflammatory processes. The released chemicals include heparin, histamine, and other substances. The mediator may be vasoactive, bronchoconstrictive, and/or chemotactic (attractive) for eosinophils.^{5,6}

MONOCYTES/MACROPHAGES

Derived from the granulocyte-monocyte colony-forming unit, monocytes are peripheral cells in transit from the bone marrow to tissues. Once in the tissues, under the influence of local factors, monocytes become macrophages. Macrophages exist in the liver (Kupffer cells),

spleen, lymph nodes, microglial (CNS) cells, skin (Langerhans cells), and bone.

Monocytes and macrophages perform a variety of functions, including initiation of immune responses for recognition by lymphocytes, regulation of immune response intensity, phagocytosis of foreign invaders, tumor cytotoxicity, degradation of cellular debris, and secretion of peptide molecules called monokines (a subclassification of cytokines).⁷ Examples of monokines include interferons, tumor necrosis factor, and interleukin-1 (IL-1). Monokines and other cytokines regulate the activity of these cells.

LYMPHOCYTES

The primary functions of lymphocytes are to control and be the effector cells for the immune system. Many of these cells also are important synthetic sites for various cytokines. Lymphocytes can be functionally divided into cells that display cell-mediated immunity (T cells) and those that are responsible for humoral immunity (B cells; Table 98-2). Several different T-cell subtypes are found in peripheral blood. These include the cytotoxic suppressor T cells (CD8), which attack intracellular pathogens and regulate the size and duration of the immune response, as well as helper T cells (CD4). The latter cells are responsible for delayed hypersensitivity, stimulation of B-cell differentiation (maturation), and antibody production, in addition to regulation of inflammatory reactions. B lymphocytes ultimately become plasma cells, which produce immunoglobulin specific for an antigen attached to the cell's surface.

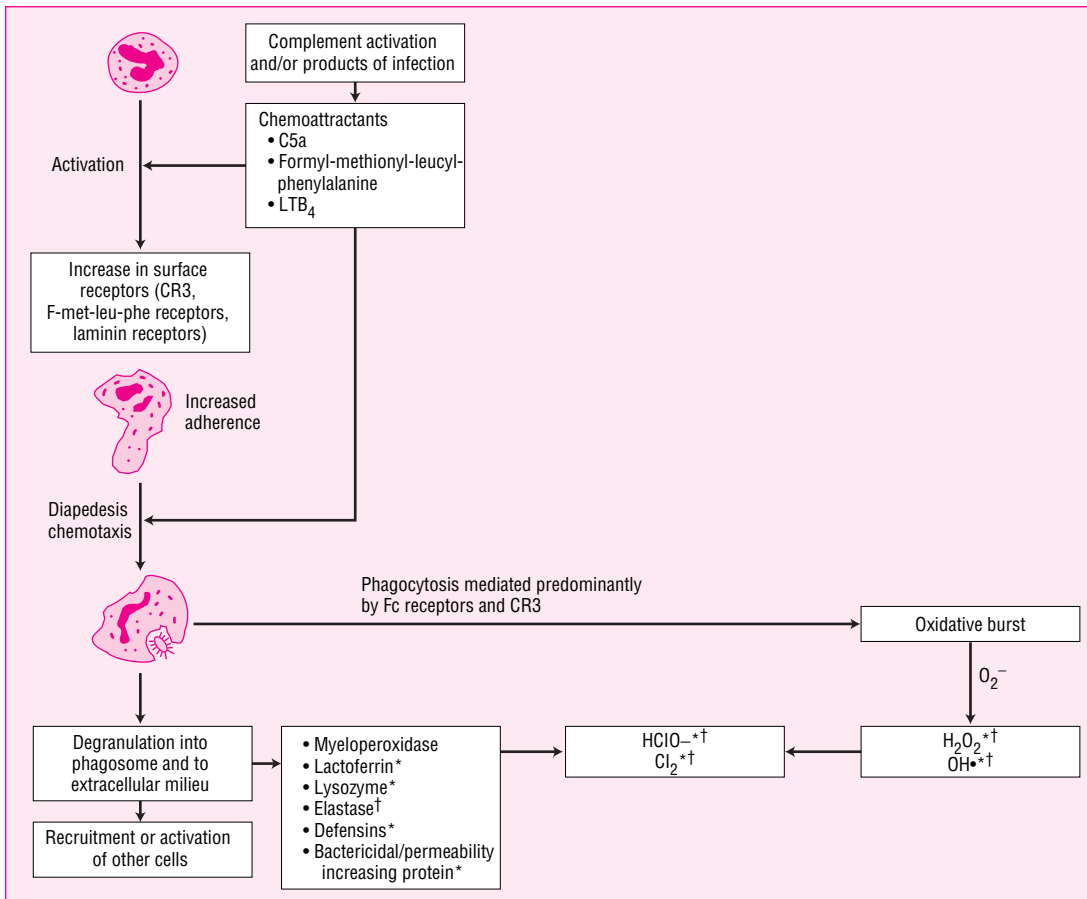

FIGURE 98-1. Neutrophil responses to infection or inflammation. *Microbicidal. †Damage to host tissues.

TABLE 98–2. Lymphocyte-Mediated Immune Function**Cellular immunity (T cells)**

1. Provides resistance against intracellular pathogens such as viruses, protozoa, fungi, and bacteria
2. Mediates allogeneic transplant rejection
3. Responsible for contact dermatitis
4. Provides autologous reaction to tumor cells

Humoral immunity (B cells)

1. Serves as major component of allergic reactions and other autoimmune diseases
2. Aids in eradication of encapsulated bacteria
3. Inactivates circulating toxins
4. May play role in antitumor reactions

Null cells are a separate subset of lymphocytes that lack surface markers of B or T origin. These cells, also referred to as large granular lymphocytes, are thought to perform functions such as direct cytotoxicity to foreign entities, and they act either alone (natural killer cells) or in concert with immunoglobulin (antibody-dependent cellular cytotoxicity).^{8,9} (Further details regarding lymphocytes are found in Chap. 84, on the immune system.)

PLATELETS

There are several mechanisms by which platelets (thrombocytes) interact to facilitate blood coagulation. These include localization of the thrombus and provision of a specific receptor site for clotting factors, as well as the necessary phospholipid surface for the conversion of prothrombin to thrombin, and protection of thrombin from antithrombin. The process begins with a vascular injury that causes platelets to adhere to the exposed collagen fibers of the damaged wall as blood flows out. These events require the presence of other plasma proteins, namely von Willebrand factor. Platelets then aggregate through a process that is calcium dependent. Following aggregation, various platelet mediators are released (thromboxane, serotonin, and platelet factor V), resulting in the formation of an irreversible platelet aggregate with subsequent formation of a stable fibrin cross-linked clot.^{10,11}

ERYTHROCYTES

The primary function of the erythrocyte is to carry oxygen from the lungs to the peripheral tissues. Its optimal design enables efficient oxygen transport via the hemoglobin molecule. The general metabolic state of the patient and local factors control oxygen release.

Some drugs selectively accumulate in erythrocytes, resulting in substantial differences when comparing blood to plasma drug concentrations. In a few instances, enzymes found in erythrocytes (e.g., aldehyde dehydrogenase) may impact on the systemic metabolism of drugs.

HEMATOPOIETIC STRUCTURE AND COMPARTMENTS

Embryonic development of hematopoietic tissue occurs in the yolk sac mesenchyme, with fetal transition occurring in the liver and spleen. Very immature hematopoietic cells can also appear in umbilical cord blood, but not many are evident in the peripheral blood of adults.¹² The ultimate location of immature hematopoietic cells is in the bone marrow. The average adult has approximately 1.7 L of bone marrow, which provides an optimal environment for the development and proliferation of hematopoietic cells.

The hematopoietic bone marrow is located primarily in the central portion of the pelvis, ribs, vertebrae, skull, and femoral and humeral epiphyses. The anatomic structure of the bone marrow is characterized by the central venous marrow sinus, which is linked by coarse vascular sinusoids that intertwine a reticulin mesh where the cells are suspended. Thus hematopoiesis occurs in the extravascular marrow spaces, which also contain endothelial cells, fibroblasts, macrophages, and adipocytes, collectively termed bone marrow stroma.¹³ Stromal cells are thought to be important hematopoietic components, providing growth factors, collagen, and cell adhesion proteins.¹⁴ When these cells are combined with accessory cells (lymphocytes/monocytes) and cytokines, the mixture is referred to as the hematopoietic microenvironment.

Egress of more mature cells from the bone marrow occurs through the endothelial cell barrier. Release of cells such as neutrophils may be stimulated by complement, steroids, or endotoxin. Immature (progenitor) cells that may ultimately become any one of the blood cellular components can be mobilized from the bone marrow into peripheral blood by the administration of a cytotoxic chemotherapy drug (e.g., cyclophosphamide)¹⁵ or a colony-stimulating factor (G-CSF or GM-CSF).¹⁶ This process is commonly referred to as “priming” the bone marrow for peripheral blood progenitor or stem cell transplantation (see Chap. 134).

2 The least mature hematopoietic cell, accounting for only a fraction of a percentage of bone marrow cells, is referred to as the stem cell. Because these cells have the unique potential to ultimately become any of the mature hematopoietic cells, they are termed pluripotent. Importantly, they have self-renewal capacity (Fig. 98–2).¹⁷ Extensive research has been conducted describing the morphologic and immunologic characteristics indicative of the earliest stem cell, but investigators have yet to arrive at a consensus model. Only a small percentage of these cells is likely to be dividing at any one time, and thus most are dormant in the cell cycle.

Stem cell renewal and differentiation occur within the bone marrow under the influence of the marrow microenvironment. Stromal endothelial cells, fibroblasts, and fat cells (adipocytes) are necessary to support stem cell proliferation and division by providing anchorage for adhesion and secreting various hematopoietic growth factors necessary for differentiation. It is the characteristics of the local microenvironment (cellular matrix and growth factor concentrations) that influence the differentiation of a particular hematopoietic lineage, favoring it over another.

The next step in hematopoietic cell differentiation is thought to be represented by committed pluripotent stem cells that can still differentiate into any cell line (red blood cells [RBCs], white blood cells [WBCs], and platelets); however, they have a limited capacity for self-renewal (see Fig. 98–2).

Cells that differentiate can proceed to either myeloid or lymphoid cell precursors (oligopotent progenitors). These cells may ultimately become B or T lymphocytes in the case of lymphoid cells. Myeloid progenitors may become granulocytes, erythrocytes, macrophages, or megakaryocytes, as displayed in Fig. 98–2. Nomenclature for immature hematopoietic cells often uses terms developed during *in vitro* experiments of cell proliferation. Thus the term *burst-forming unit* (BFU) or *colony-forming unit* (CFU) is added to the suffix of the cell lines ultimately produced by the specific cell.

Leukocytes found in the peripheral blood can generally be classified into neutrophils (the most frequently occurring blood leukocyte, subdivided into the more mature segs and less mature bands), lymphocytes, monocytes, eosinophils, basophils, and the tissue derivative of basophils, mast cells. Immature neutrophils such as metamyelocytes are rarely seen in peripheral blood. Strictly speaking, the group of

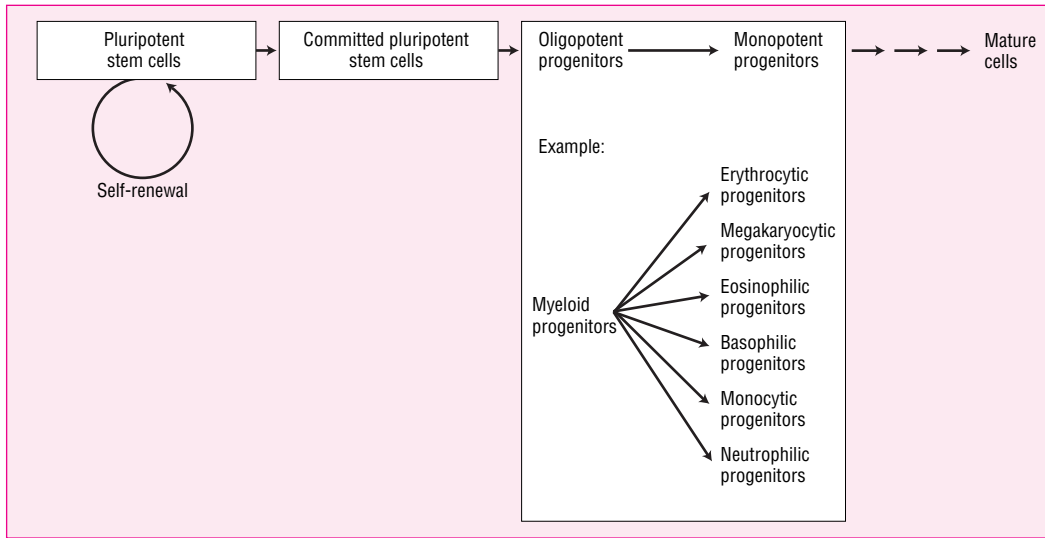

FIGURE 98-2. Rudimentary model of hematopoiesis, displaying the basic steps a cell may take from its inception as a stem cell in the bone marrow, through stages in which it can become multiple (oligopotent) or only one specific (monopotent) type of mature blood cell.

cells referred to as granulocytes includes neutrophils, eosinophils, and basophils, although common use tends to include only the neutrophils. The terminally differentiated leukocytes, which are usually not seen in blood, include the macrophage or histiocyte (derived from monocytes) and plasma cells (derived from B lymphocytes).

Most of the body’s neutrophils and neutrophilic precursors reside in the bone marrow (approximately 9 billion cells) in contrast to the circulation (approximately 700 million). Similarly, only 1% of the eosinophils in the body are found in peripheral blood, whereas the skin, lungs, and gastrointestinal tract are the preferred sites of residence.⁴ There is no marrow reserve pool of monocytes. Neutrophil development in the bone marrow begins with the stem cell and proceeds through intermediate precursors, such as the myeloblast, promyelocyte, myelocyte, and metamyelocyte.

Only a small fraction of the total body pool of lymphocytes resides in the blood. Immature T cells are evident in the circulation on their way to full maturation in the thymus. Mature B lymphocytes express surface immunoglobulin, which functions as an antigen receptor. Most of these cells migrate from the bone marrow to areas such as the lymph nodes (dense collections of lymphocytes, plasma cells, and macrophages that are supplied by postcapillary venules and drained by a system of efferent lymphatics) and spleen, where antigenic stimulation results in specific immunoglobulin production.¹³ Approximately 75% of blood lymphocytes are T cells; 15% null cells, and 10% B cells. Various antigens expressed on the surface of leukocytes, depending on the degree of cell maturity and function, are termed clusters of differentiation (CD).

Progenitor cells that give rise to platelets are referred to as colony-forming unit megakaryocytes. Megakaryocytes account for only 0.05% to 0.02% of marrow cells. Morphologic changes in both the cytoplasm and nucleus accompany the maturation of megakaryocytes. Therefore, at differing stages of maturation, it is possible to see granules, organelles, and increasing segmentation of the nucleus. Cells in this lineage progress through three stages of development: commitment, proliferation, and differentiation, similar to that of leukocytes.^{18,19} Receptors for the cytokine thrombopoietin (TPO) are expressed on both megakaryocytes and platelets, as well as hematopoietic stem cells.

The term *erythron* has been used to describe collectively the erythropoietic cellular pathway, composed of all cells involved in erythropoiesis, starting with the earliest committed erythroid progenitor and ending with the mature circulating RBC. The earliest cell committed to the erythroid lineage is known as a BFU-E (erythroid).

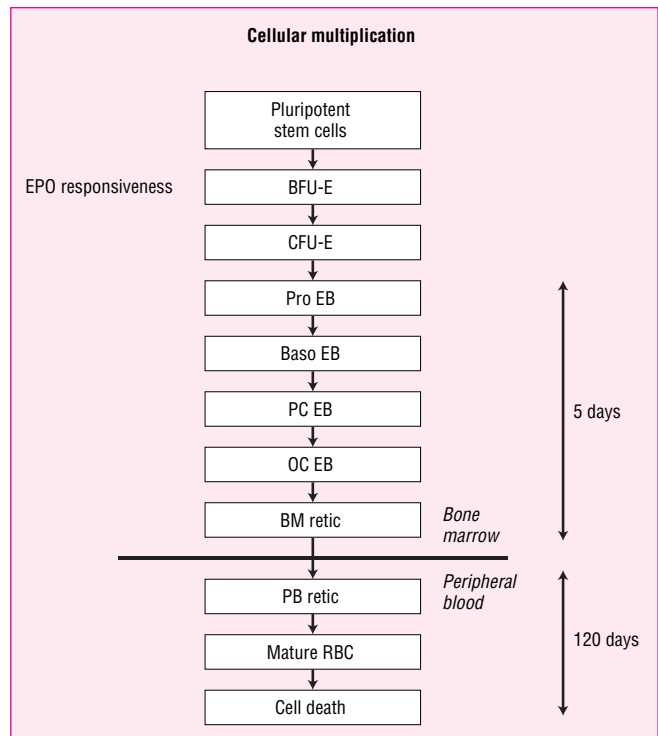

FIGURE 98-3. Proposed differentiation pattern of cells into mature erythrocytes with identification of various immature cell types. In addition, the cells that may be stimulated by the cytokine erythropoietin (EPO) are identified. BM, bone marrow; BFU, burst-forming unit; CFU, colony-forming unit; E, erythroid; EB, erythroblast; OC, orthochromatophilic; PB, peripheral blood; PC, polychromatophilic; RBC, red blood cell; retic, reticulocyte.

Through in vitro culture systems, one BFU-E can proliferate into several hundred progeny. These cells are followed in differentiation by the CFU-E cell, and subsequently by the nucleated normoblast and the immediate RBC precursor, the circulating anuclear reticulocyte as outlined in Fig. 98–3. The remaining RNA is typically lost from the RBC within 2 days of its appearance in the peripheral blood; thus the mature cell does not synthesize new proteins such as enzymes.²⁰

The erythrocyte precursor cell types display a continuum of changes in shape, hemoglobin concentration, Rh antigen, and erythropoietin (EPO) receptor expression with maturity. However, mature erythrocytes express significantly lower EPO receptor density than do proerythroblasts.²¹

Neonatal RBCs contain primarily fetal hemoglobin. Adult hemoglobin, 85% of which is synthesized in the erythropoietic marrow, replaces the fetal hemoglobin within a few months. Hemoglobin-synthesizing cells must have mitochondria; therefore its synthesis cannot occur in the mature erythrocyte. Genetic alterations in hemoglobin structure may dramatically alter the stability or solubility of the hemoglobin and also cell confirmation. The characteristic biconcave-disk shape of the normal RBC is approximately 8×2 μm . Pathologic alterations in plasma lipids may affect the outer phospholipid membrane of the RBC, thus changing the cell's shape and survival. Blood types are characterized by the antigenic structure of the external surface of the cell membrane. The interactions of antibodies with RBC surface antigens affect the membrane function, integrity, and phagocytosis of the cells.

NATURAL REGULATION OF CELL PROLIFERATION AND DIFFERENTIATION

The generic model of cell maturation presented in Fig. 98–2 includes a population of stem cells, thought to be capable of self-renewal, that provides the initial cell (committed progenitor) for subsequent maturation, differentiation (i.e., commitment to a cell line), and expansion into all blood cell types. This is followed by an initial differentiation step when a cell is produced (oligopotent progenitor) that will ultimately become one of only several mature blood cell types. Finally, monopotent progenitors are noted in which differentiation is restricted to one cell type. The latter cells then undergo a series of maturation steps, ultimately resulting in a mature cell.

STEM CELLS

4 The action of a stem cell in self-renewing rather than differentiating and the selection of lineage by a multipotential progenitor cell during the differentiation process are thought to be stochastic (random) events. Conversely, the survival and proliferation of the subsequent progenitor cells are thought to be regulated by the group of cytokines referred to as colony-stimulating factors (also known as CSFs, hematopoietins, hematopoietic cytokines, or hematopoietic growth factors).²² Receptors for a variety of CSFs are present on the surface of stem cells, which agrees with in vitro studies demonstrating stimulatory activity for cytokines such as stem cell factor (SCF), IL-1, IL-6, G-CSF, IL-10, IL-11, IL-12, IL-13, TPO, basic fibroblast growth factor, and leukemia inhibitory factor, when present in combinations. Whether or not the therapeutic use of a CSF that is thought to act primarily on more mature cells will exhaust (deplete) the stem cell pool over the course of multiple cycles of therapy is under active debate and study.²³ Proposed “cascades” of hematopoiesis are represented in Fig. 98–3 through 98–6. Inserted within some figures are the

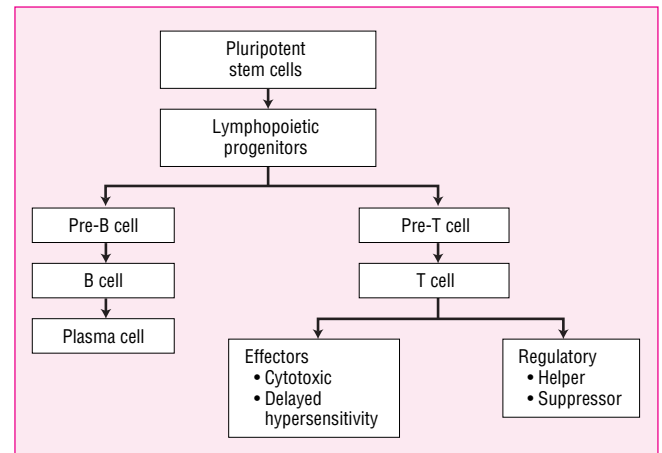

FIGURE 98–4. Pattern of lymphocyte maturation and differentiation into T and B cells. The plasma cell is a factory for antibodies, whereas the T cells have both effector and regulatory functions on the immune system.

suspected sites in the process where CSFs are thought to interact by promoting the production, proliferation, and survival of hematopoietic cells. These schema are simple representations of a system of complex interactions between stimulatory and inhibitory cytokines that may not be adequately described by the in vitro models used thus far to define them. (Details regarding the clinical pharmacology of individual CSFs are presented in Chap. 124.)

Immature bone marrow precursor cells such as the myeloblast (first recognizable cell of granulocytic differentiation), promyelocyte, myelocyte, and erythroblast are thought to be capable of replication. This is in contrast to most mature hematopoietic cells, which are incapable of division. Exceptions to the latter statement include monocytes, macrophages, and tissue mast cells. Evaluation of reasons for

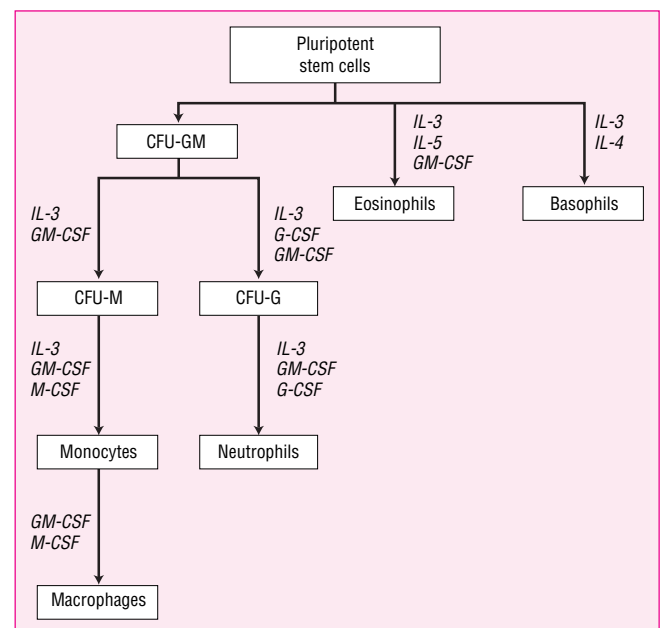

FIGURE 98–5. Maturation of precursor cells into granulocytes and macrophages, including some intermediate precursor cells (CFU-GM, G, and M). The colony-stimulating factors (CSFs) that affect the more terminal (mature) pathways are also shown. (CSFs that regulate immature cell types are not displayed.) CFU, colony-forming unit; G, granulocyte; M, monocyte.

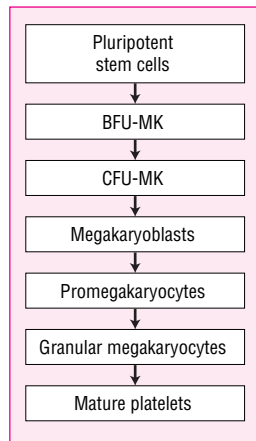

FIGURE 98-6. Maturation steps of megakaryocyte precursors prior to becoming mature platelets. BFU, burst-forming unit; CFU, colony-forming unit; MK, megakaryocyte.

a change in hematopoietic cellular concentration over time must be conducted with a thorough knowledge of the mechanisms of both cellular production and destruction.

NEUTROPHILS

Blood neutrophils are in constant exchange with an equal number of “marginated” cells. The latter are stuck to the walls of vessels in the peripheral blood, liver, lungs, and spleen. Therefore, demargination or the opposite, increased adhesion, can dramatically change the peripheral neutrophil concentration, even though cell production remains constant. A variety of stimuli can result in demargination, including infection, exercise, epinephrine, corticosteroids, and sickle cell anemia.²⁴ Conversely, transient neutropenia can occur via stimulation of margination by conditions such as malaria, some viral infections, and onset of hemodialysis.²⁵

Normally, it takes 14 days for neutrophil production and differentiation in the bone marrow. It is believed that G-CSF, GM-CSF, and IL-3 are important regulatory molecules of neutrophil production (see Fig. 98-5). A healthy adult will produce approximately 1.6 billion neutrophils per kilogram body weight per day.²⁶ As blood neutrophils are totally replaced at least twice in each 24-hour period, the average circulation time for any one cell is approximately 6 to 12 hours. Most of this removal is thought to be for effector functions in the tissues and not simply an elimination process.

5 The total number of noncirculating (i.e., storage) neutrophils is more than 15 times the number in blood. Absolute storage cell numbers are subject to alteration by prior exposure to chemotherapy or deficiency in cofactors required for their synthesis (e.g., folate). When conditions call for an acute increase in blood neutrophils, the pattern of cells thus changes to one more similar to that in the marrow (i.e., band concentration increases relative to seg concentration; normal ratio <0.1 to 0.3).²⁷ This phenomenon, often referred to as a “shift to the left,” denotes a circulating neutrophil population made of less mature cells. Infectious processes frequently provoke such a shift, as well as an increased outflow of cells from storage forms in the bone marrow, but extreme cases may require so many granulocytes at the infection site that marrow pools are depleted, resulting in neutropenia. Cytokine expression, and thus hematopoiesis, may be impaired in the elderly, resulting in a reduced ability to tolerate myelosuppressive chemotherapy.²⁸

EOSINOPHILS

The typical blood circulation time for an eosinophil is approximately 6 hours, but it may survive weeks within tissues. Cytokines thought to be important in eosinophil production or function include IL-1, IL-3, GM-CSF, G-CSF, and perhaps most important, IL-5. Corticosteroids cause a transient margination of eosinophils and inhibit release of mature cells from the bone marrow.⁴

MONOCYTES AND MACROPHAGES

Both macrophages and T lymphocytes secrete cytokines that stimulate monocytopoiesis.²⁹ Examples of cytokines that act on relatively mature monocytes include macrophage colony-stimulating factor (M-CSF) and GM-CSF. Blood monocytes have a shorter marrow transit time than neutrophils (6 vs. 13 days, respectively), and there is no monocyte reserve in the marrow.²⁷ The peripheral blood turnover of these cells is much slower (circulation half-life, 3 days) than for neutrophils; similarly, tissue macrophages are thought to be very long-lived. Macrophages may be able to produce their own progeny as well as attract additional monocytes for differentiation in the local environment.

LYMPHOCYTES

Immature T cells produced in the bone marrow ultimately migrate to the thymus, where they both expand and mature into immunologically competent cells (see Fig. 98-4). A variety of cytokines, including IL-2, IL-4, and IL-7, facilitate lymphopoiesis, whereas others such as transforming growth factor- β may decelerate this process.³⁰ T lymphocytes are probably the longest lived hematopoietic cell, as there is experimental evidence that the life span of some is more than 10 years.

The term *lymphokine* is used to describe cytokines secreted by T cells. Lymphokines such as IL-2 are important in both activation and proliferation of the immune response, while monokines are also important regulators of lymphocyte development. T and B lymphocytes have important interactions with each other in both lymphocyte development and activation, which seem necessary for immunocompetence. There is some evidence for age-associated reductions in circulating helper and suppressor T cells and B cells.³¹

PLATELETS

Thrombopoiesis is the term used to describe the process of platelet production. The bone marrow manufactures 40,000 platelets/mL of blood each day. Proliferation and differentiation of platelet precursors are thought to be primarily influenced by cytokines such as IL-6, IL-11, leukemia inhibitory factor, and perhaps most specifically, by thrombopoietin (TPO or megakaryocyte growth and development factor; see Fig. 98-6).^{32,33} Other hematopoietins that may act in concert, producing synergistic effects include IL-3, IL-1, GM-CSF, EPO, and SCF.³⁴ The platelet survival time is a clinical test that can estimate the rate of platelet turnover.³⁵ In healthy individuals, this time is 9.5 ± 0.6 days.³⁶

ERYTHROCYTES

The normal life span of a RBC is approximately 100 to 120 days, with a circulating cell turnover rate of 1% per day. Thus a typical adult produces approximately 200 billion reticulocytes every day. Conditions such as anemia or hypoxemia primarily stimulate the renal peritubular

interstitial cells to produce EPO by interaction with the renal oxygen sensor. The degree of elevation in blood EPO concentrations is dependent on the severity of anemia or hypoxemia. This in turn recruits RBC precursors and shortens the normal time for differentiation if adequate cofactors such as iron, folate, and vitamin B₁₂ are present. Although the overall time for differentiation is shortened (as is the duration of time that a reticulocyte spends in the marrow), the RBC's blood maturation time is lengthened. The increase in EPO concentrations is relatively quick (within hours), but the effects on marrow transpire over several days. The ultimate increase in RBC mass occurs at an even slower pace, generally over weeks to months (see Fig. 98–3). Multiple other endogenous cytokines are also thought to play a role in either stimulating or inhibiting erythropoiesis by acting on the early progenitors. These include GM-CSF, G-CSF, IL-1, IL-3, IL-6, IL-9, SCF, and some stromal proteins.²¹

Adequate production of RBCs for a degree of anemia is best assessed by evaluation of the number of circulating reticulocytes. Although the normal range is approximately 0.4% to 1.7% of the RBCs, this percentage would obviously be higher in anemic patients with adequate productive capacity. The calculation of a corrected reticulocyte count involves multiplying the percentage of circulating reticulocytes by the hemoglobin concentration and dividing the result by the normal hemoglobin level expected for a healthy patient with similar characteristics. Additional correction accounts for the increased life span of reticulocytes in the peripheral blood, depending directly on the patient's degree of anemia. Figure 98–7 displays correction factors that can be used to accommodate these changes.³⁷

Direct assessment of erythropoiesis in the bone marrow can be performed by estimating the myeloid:erythroid cell ratio from a marrow aspirate. The range of the normal adult ratio is 3:1 to 5:1, but changes in erythroid or myeloid production can obviously influence the ratio. RBCs lose flexibility with age and eventually undergo lysis or are phagocytized and removed by the monocyte-macrophage system (primarily via the spleen). Accelerated red cell destruction can be grossly quantitated by determining increases in plasma concentrations of bilirubin and lactate dehydrogenase.³⁷

Although clinical laboratories measure RBC concentrations with excellent accuracy, the most useful tool for assessment of the blood's

FIGURE 98–7. Correction of hematocrit with the marrow and blood reticulocyte maturation times. With a hematocrit of 45, the blood reticulocytes circulate for 1 day, whereas reduction in hematocrit to 15 results in a 2.5-day circulation time. The numbers found under the blood reticulocyte concentrations can be used as a correction factor in evaluation of reticulocyte concentrations. (From Hillman et al.³⁷)

oxygen-carrying capacity is the hemoglobin concentration because of the variability in RBC size. The average RBC and hemoglobin concentrations in healthy adult male and female patients are approximately 5.21 and $4.60 \times 10^6/\text{mm}^3$, respectively; and 15.7 and 13.8 g/dL, respectively. Variations in normal concentrations will also be evident, depending on age, menstruation status, race, environmental factors, and pregnancy.³⁸

DISEASE-ASSOCIATED HEMATOPOIETIC CHANGES

NEUTROPHILS

6 The usual definition of neutropenia is an absolute neutrophil count below $1,800/\text{mm}^3$ in white patients, $1,400/\text{mm}^3$ in black patients, and $1,500/\text{mm}^3$ for children 1 month to 10 years old. Clinical manifestations of neutropenia (i.e., infection) are not typically evident without other cofactors until the concentration drops below $1,000/\text{mm}^3$.³⁹ Accompanying factors that may influence the risk of infection for a particular patient include skin and mucous membrane integrity; vascular tissue supply; nutritional status; and lymphocytopenia, monocytopenia, or hypogammaglobulinemia. Persistent agranulocytosis ($<500/\text{mm}^3$ or no measurable neutrophils) is almost uniformly fatal without the use of supportive antibiotics.

Disorders resulting in defective granulopoiesis can be subdivided into those that result in marrow aplasia or diseases that replace the normal neutrophilic component (see Chap. 102 for drug-induced neutropenia). Diseases associated with granulopoietic suppression include viral infection, tuberculosis, anorexia, autoimmune diseases (e.g., systemic lupus erythematosus), Felty's syndrome (rheumatoid arthritis, splenomegaly, and leukopenia), myelodysplastic syndromes, and leukemias.^{39,40} A congenital form of severely defective neutrophil production (Kostmann's syndrome) has been described that is possibly a result of defective regulation of the late-acting hemopoietin G-CSF.⁴¹ Patients with the rare disorder of cyclic neutropenia display periodic wide fluctuations in the WBCs at approximately 3-week intervals that last for 3 to 6 days. Other forms of chronic neutropenias may occur with adequate marrow stores and can be relatively benign in symptomatology.

Neutrophilia is typically defined as an absolute neutrophil count greater than $7,500/\text{mm}^3$ of blood and is sometimes referred to as a leukemoid reaction, if extreme.²⁴ Acute neutrophilia may be a result of emotional or physical stimuli (e.g., exercise, seizures, labor, pain, or temperature changes), infections, inflammation or tissue necrosis, or drugs or toxins (e.g., CSFs, epinephrine, corticosteroids, lithium, vaccines, or endotoxin). Chronic causes of increased neutrophilia include persistent infections, inflammation, malignancies, drugs, metabolic or endocrine disorders, cigarette smoking, hereditary or congenital abnormalities, and myeloproliferative diseases such as polycythemia vera.²⁴

EOSINOPHILS

Eosinophilia (absolute count greater than $700/\text{mm}^3$) may result from neoplastic processes, parasitic or fungal infections, gastrointestinal disorders, malignancies, dermatitis, granulomatous disorders (e.g., sarcoidosis or Wegener's granulomatosis), or collagen-vascular diseases in addition to the more typical cause, allergic reactions.⁴² One mechanism that may be common to several of these etiologic factors is antigenic stimulation of T cells, which produces a cytokine (IL-5) that mediates eosinophil proliferation.⁴³ Infections may cause

eosinopenia; however, its significance is not thought to be of concern in that setting.

BASOPHILS

Basophilia occurs frequently in patients with myeloproliferative disorders and in association with inflammatory reactions and diseases. Viral infections, iron deficiency, or lung cancer can sometimes increase basophil counts. Mastocytosis is usually evident only on analysis of tissue or bone marrow mast cells. Causes include hypersensitivity reactions, malignancy, osteoporosis, and chronic liver or renal disease.

MONOCYTES

Monocytosis ($>800/\text{mm}^3$ of blood) occurs with some infections (e.g., tuberculosis, histoplasmosis, toxoplasmosis, bacterial endocarditis, and salmonellosis), collagen vascular diseases (rheumatoid arthritis and systemic lupus erythematosus), gastrointestinal disorders (ulcerative colitis and alcoholic liver disease), leukemias, and up to 60% of nonhematologic malignancies, whereas abnormally low monocyte concentrations occur in patients with hairy cell leukemia or aplastic anemia.⁴⁴

LYMPHOCYTES

Significant reductions in lymphocyte concentration ($<1000/\text{mm}^3$ of blood) can be evident without apparent cause or in a variety of diseases, including acute inflammatory disorders, severe uremia, immune deficiency diseases such as systemic lupus erythematosus, chronic infections such as tuberculosis or human immunodeficiency virus (HIV) infection, malignancies, and connective tissue diseases.⁴⁵ Lymphocytosis ($>4000/\text{mm}^3$) may occur with mononucleosis, pertussis, measles, or chickenpox, and in lymphoid malignancies. A progressive increase in mature lymphocytes may be indicative of chronic lymphocytic leukemia. Increased levels of atypical lymphocytes may occur in patients with infections (e.g., mononucleosis, hepatitis, or cytomegalovirus), allergic reactions, or lymphomas.⁴⁶

PLATELETS

Both qualitative and quantitative platelet disorders have important pathophysiologic consequences. Thrombocytopenia, defined as a platelet count less than $150,000/\text{mm}^3$, may result from a defect in production, increased sequestration, or accelerated destruction.⁴⁷

Certain stimuli may damage the marrow by reducing the number of megakaryocytes available. Drugs, chemicals, radiation, and infection are among the potential causes of marrow injury. Diseases that produce general bone marrow failure or those that invade the bone marrow may result in thrombocytopenia. Examples of the latter include cancers such as leukemia, lymphoma, myelofibrosis, myelodysplasia, and metastatic solid tumors (breast and prostate cancer), and infections such as those caused by mycobacteria. Suboptimal platelet production may also result from defects in maturation seen with vitamin B₁₂ and/or folate deficiency or in congenital syndromes.⁴⁸

Alteration in platelet distribution may also result in thrombocytopenia. Splenomegaly is the most frequent cause of increased platelet sequestration.

Owing to its accelerated destruction of platelets, idiopathic thrombocytopenic purpura (ITP) is a common cause of thrombocytopenia. Antiplatelet antibodies combine with platelets in ITP, thus

sensitizing them to removal by the immune system. Accelerated platelet destruction can also occur in patients with connective tissue disorders. Approximately 14% of patients with systemic lupus erythematosus experience thrombocytopenia similar to ITP.

ERYTHROCYTES

Suboptimal erythropoiesis can be classified by changes in the size of RBCs noted on examination of the peripheral blood. Because the excretory and endocrine functions of the kidney usually mirror each other, renal dysfunction can lead to anemia by reduction in EPO production, resulting in a normochromic, normocytic pattern. Other causes of insufficient erythropoiesis include replacement of bone marrow by fibrosis, solid tumors, or leukemia, as well as defects in erythroid maturation. Relative deficiencies in the cofactors required for heme-RBC synthesis such as iron, folate, and vitamin B₁₂ may also be important contributors. Structurally, RBC macrocytosis denotes defects in the maturation of the nucleus, whereas microcytosis is indicative of cytoplasmic defects (reduced hemoglobin synthesis). (A detailed description regarding the pathogenesis and treatment of anemic disorders is found in Chap. 99.)

Exaggerated erythropoiesis with increased RBC mass (polycythemia) can be mistaken for a reduction in plasma volume. Symptoms are not always immediately evident, but may progress to reduced tissue oxygenation, thrombosis, and congestive heart failure. The most common cause is hypoxia; alternative causes can be grouped according to their ability to stimulate EPO production. EPO (or a similar cytokine) may be produced in response to genetic alterations or a variety of malignancies, including angioblastoma, hepatomas, and hypernephroma.⁴⁹ Polycythemia vera, a malignancy of the bone marrow stem cells, results in an increased sensitivity of RBC precursors to stimulation by EPO and is accompanied in many patients by thrombocytosis and leukocytosis.

CLINICAL USES OF HEMATOPOIETIC CELLS

HEMATOPOIETIC STEM CELL TRANSPLANTATION

High-dose chemotherapy with or without irradiation is beneficial in the treatment of a number of malignant diseases (see Chap. 134). The dose of chemotherapy that can be administered, however, is limited by hematopoietic toxicity that can result in prolonged periods of pancytopenia with the attendant risks of serious infection and bleeding. The infusion (transplantation) of hematopoietic stem cells following the high-dose therapy can overcome this hematopoietic toxicity, resulting in subsequent repopulation of the bone marrow and recovery of hematopoiesis. Bone marrow transplantation (BMT) involves the removal of bone marrow from the donor, administration of intensive doses of chemotherapy (with or without irradiation) to the recipient, and infusion of the donor bone marrow (stem cells) to the recipient. If the donor and recipient are the same individual (i.e., the patient serves as his or her own donor), the procedure is termed autologous BMT. If the marrow comes from another individual, the procedure is termed allogeneic BMT. Most allogeneic donors are human leukocyte antigen (HLA)-matched siblings, but the use of alternative donors such as HLA-matched related volunteer donors or umbilical cord blood cells is increasing.

Allogeneic transplantation is complicated by the immune recognition of host tissues by donor T lymphocytes, resulting in a syndrome called graft-versus-host disease (GVHD). Because immune

recognition of tumor cells also occurs (graft-versus-tumor effect), the relapse rates associated with allogeneic transplants are lower than those associated with autologous transplants for similar disease stages. Allogeneic transplantation is commonly used for diseases primarily involving the bone marrow, such as acute and chronic leukemias, aplastic anemia, thalassemia, and severe combined immunodeficiency syndrome.

Autologous transplantation is commonly used in non-Hodgkin's lymphoma, Hodgkin's disease, multiple myeloma, and a relatively small subset of patients with solid tumors. A number of laboratory techniques are evolving to allow the bone marrow harvested for autologous transplantation to expand in the laboratory prior to infusion and to cleanse the marrow of potential malignant cell contamination.

Small numbers of hematopoietic progenitor (stem) cells capable of reconstituting hematopoiesis circulate in the blood under normal circumstances.⁵⁰ Commonly referred to as peripheral blood progenitor cells (PBPCs), these circulating progenitor cells increase in number during recovery from myelosuppressive chemotherapy or after treatment with cytokines such as G-CSF or GM-CSF.^{16,51} These cells can be collected by a process called leukapheresis and stored for reinfusion following high-dose chemotherapy. Hematopoietic recovery is generally more rapid following rescue with PBPCs as compared with rescue with bone marrow. Potential tumor cell contamination may also be less with PBPC transplants. The use of PBPCs has essentially replaced the use of autologous bone marrow, and allogeneic transplants of PBPCs are becoming more common.

Cytokine-mobilized PBPC transplants from allogeneic donors have been shown to result in more rapid white cell and platelet engraftment and shorter hospital stays than bone marrow transplants.⁵² The incidence of acute GVHD is not increased, but there is a significant increase in the incidence of chronic GVHD with PBPC. Relapse rates and overall survival rates are similar with the use of allogeneic PBPC or bone marrow.

Only about one-third of patients who would otherwise be eligible for allogeneic BMT have HLA-matched related donors. One alternative is the use of closely HLA-matched, unrelated donor marrow. The National Marrow Donor Program (NMDP) is a registry of volunteer marrow donors now containing more than 4 million members. By coordinating the activities of a network of donor, collection, and transplant centers, the NMDP facilitates the identification of potential donors and the procurement of marrow. Unrelated donor marrow transplants are associated with an increased incidence of GVHD compared to related donor transplants; however, recent advances in tissue typing and donor matching and GVHD prophylaxis have resulted in comparable overall survival rates for many diseases.

Grafts of PBPCs from unrelated donors are also increasingly used for transplantation. The cells are collected by leukapheresis after mobilization of PBPCs by giving the donor G-CSF. This spares the donor from potential complications related to general or spinal anesthesia and pain associated with bone marrow harvest. Unrelated PBPC transplants are associated with more rapid engraftment compared to unrelated BMT, with no increase in GVHD or relapse rates.⁵³

Many patients do not have HLA-matched family members or unrelated donors in the marrow registries. An alternative for these patients is the use of human umbilical cord blood, which contains hematopoietic stem cells capable of reconstituting bone marrow function following high-dose chemotherapy.⁵⁴ An almost unlimited number of cord blood donors is potentially available, because the cord and its associated blood are commonly discarded following delivery.

There are cord blood banks in which cord blood cells are HLA-typed, cryopreserved, and made available for transplantation for appropriate recipients. To date, the majority of cord blood progenitor cell transplantations performed have been in children because of the relatively small number of cells available from a cord blood unit, although the number of cord blood transplantations performed in adults is increasing. A major problem with cord blood transplants is a more prolonged period of neutropenia (often greater than 1 month.) This leads to additional infectious complications and associated morbidity. Laboratory methods to expand the number of progenitor cells in cord blood units are under investigation. Cord blood transplants are thought to lead to less GVHD than transplants from matched unrelated bone marrow donors with similar degrees of matching, and they may prove to be an important source of progenitor cells for transplantation in the near future.

The application of allogeneic transplantation has been limited to younger patients without comorbid conditions secondary to the toxicity of the myeloablative preparative regimen and the allogeneic bone marrow graft. Recently, a number of centers have reported successful allogeneic engraftment following nonmyeloablative, immunosuppressive conditioning regimens.^{55,56} The goal of this approach is to establish donor hematopoiesis and a graft-versus-tumor effect while minimizing toxicity. These transplants can be offered to older patients and to patients with diminished end-organ function. This approach has also been used for patients with disorders that may be responsive to immune-based therapy, such as renal cell carcinoma.

ADOPTIVE IMMUNOTHERAPY

Experiments involving the administration of immune system cells for the purpose of cancer treatment (adoptive immunotherapy) have been conducted for well over a decade; however, the clinical benefit has only recently been substantiated. As described earlier, nonspecific, total depletion of donor T cells following high-dose chemotherapy and stem cell reinfusion produces fewer graft-versus-host effects, but attenuated anticancer responses. However, it has been shown that careful attention to the T-cell dose and timing of infusion may maximize the potential for beneficial immunologic responses and minimize graft-versus-host effects. It has been found that the administration of allogeneic donor lymphocyte infusions to patients with leukemia relapse following myeloablative stem cell transplantation has anticancer efficacy in diseases such as chronic myelogenous leukemia (65% complete response), acute nonlymphocytic leukemia, or myelodysplastic syndrome (25% complete response).⁵⁷ Some of these remissions have prolonged durability. Similar strategies have been utilized in nonmyeloablative stem cell transplantation. The complications of donor lymphocyte infusions include the obvious risk of GVHD, but the condition does not develop in all patients who have clinical benefit. This mode of therapy can also result in marrow aplasia for approximately 20% of patients; however, it is self-limiting or treatable with G-CSF in most cases.

GENE THERAPY

Hematopoietic progenitor cells are the focus of intense research in gene therapy. The self-renewal capacity of these cells makes them an obvious target for delivering corrective genetic information for a variety of both hematologic and metabolic inherited disorders, such as sickle cell anemia, thalassemia, immunodeficiency syndromes, and glycogen storage diseases.

TRANSFUSION AND BLOOD PRODUCT SUPPORT

Advances in blood banking and transfusion support have been critical to the improved outcome of therapy for patients with hematologic and malignant diseases. Platelet transfusions are indicated for the prevention and treatment of bleeding. In general, prophylactic platelet transfusions are not indicated for platelet counts above 10,000 cells/mm³ unless the patient is febrile or actively bleeding. Platelets are available as pooled random donor concentrates obtained from RBC donations (six to eight donors per transfusion) or single-donor platelets collected by apheresis.

Administration of multiple platelet transfusions increases the risk of developing a platelet-refractory state termed alloimmunization. This effect is thought to be an immune-mediated reaction to HLA antigens on donor platelets or WBC contaminants. A common method of identifying such patients is evaluation of platelet counts within an hour of transfusion. For example, a 1-m² person should obtain an increase in platelet concentration between 7,000 and 11,000/mm³ for each unit of platelet concentrate administered (in the absence of other risk factors such as infection, splenomegaly, etc). The diagnosis can be confirmed by *in vitro* demonstration of platelet antibodies. The use of leukocyte filters prior to storage of donated platelets or UV irradiation of the product has been shown to decrease the development of alloimmunization and refractoriness to platelet transfusions. Leukocyte filters also decrease the risk of transmission of cytomegalovirus and febrile transfusion reactions. Treatment of alloimmunized patients often entails use of platelets obtained from single donors (to lessen exposure to HLA), or use of HLA-compatible or platelet cross-match-compatible donors. Unfortunately, such approaches are not always effective and additional therapies (plasma exchange or intravenous immunoglobulin) have been added with some limited success.

Packed RBC transfusions are indicated to keep hemoglobin levels above 7 to 8 g/dL to maintain adequate oxygen-carrying capacity. Each unit of packed RBCs should increase the hemoglobin level by approximately 1 g/dL unless active blood loss is evident. RBCs should also be filtered to reduce the risk of nonhemolytic, febrile transfusion reactions. Patients who are candidates for bone marrow transplantation should receive blood products that have been irradiated with 2,500 cGy to prevent transfusion-associated GVHD.

Fresh frozen plasma contains the components of the coagulation system and is indicated for the replacement of deficient coagulation factors II, V, VII, X, XI, and XIII. Factor VIII and IX deficiencies are treated with specific factor concentrates. Fresh frozen plasma is also used for the rapid reversal of warfarin anticoagulation and in the treatment of disseminated intravascular coagulation. Thrombotic thrombocytopenic purpura is treated by means of therapeutic plasma exchange with fresh frozen plasma as the replacement fluid. Cryoprecipitate, which contains factor VIII, von Willebrand's factor, and fibrinogen, is indicated for the treatment of von Willebrand's disease that does not respond to desmopressin acetate, and for fibrinogen replacement (see Chap. 100).

INTRAVENOUS IMMUNOGLOBULIN

Pharmaceutical products containing immunoglobulin for intravenous use in humans are pooled from blood collection in over 1,000 donors for each lot of drug. The high number of donors provides a wide diversity in the capability of the antibodies to react with antigenic targets. Products are similar in content of each IgG subclass; however, the titers against specific antigens vary between manufacturers (as do other pharmaceutical characteristics, such as osmolality).

CLINICAL CONTROVERSIES

Intravenous immunoglobulin products vary by the number of donors utilized to produce the product, titers for specific antigens, and methods used for purification. Products are often marketed and selected based on these criteria; however, the clinical relevance of each is unclear.

The IV administration of immunoglobulin has been used in a variety of hematologic disorders, but for most of these situations, it is still considered experimental or indicated only when other therapeutic options have been exhausted. Patients with deficient immunoglobulin production (e.g., agammaglobulinemia or hypogammaglobulinemia) or function (e.g., chronic lymphocytic leukemia, multiple myeloma, and children with HIV) may benefit from this therapy, with the goal of raising the immunoglobulin G level such that there is less chance for bacterial infection (>500 mg/dL). This approach has other pharmacologic properties as well, including blockade of Fc receptors, modification of complement activation, and modulation of the immune response by anti-idiotypic antibodies.⁵⁸ It is also beneficial for patients with ITP who are at high bleeding risk or need higher platelet counts prior to surgery.⁵⁹ Posttransplant prophylaxis (approximately 3 months) with Ig given IV is also sometimes used in patients receiving allogeneic hematopoietic stem cell transplantation for prevention of bacterial sepsis and acute GVHD. The IV treatment with Ig may benefit patients whose platelet counts do not increase substantially despite transfusions, owing to the formation of alloantibodies. A number of immunoglobulin products are available that provide more specific immunity toward selected antigens. These pharmaceuticals are generated from individuals who have been exposed to the antigen and thus developed antibody "titers" more specific to the infectious agent. Products include: botulism immunoglobulin, cytomegalovirus immunoglobulin, hepatitis B immunoglobulin, rabies immunoglobulin, respiratory syncytial virus immunoglobulin, tetanus immunoglobulin, and varicella-zoster immunoglobulin.

ABBREVIATIONS

BFU: burst-forming unit
 BMT: bone marrow transplantation
 CD: cluster of differentiation
 CFU: colony-forming unit
 CSF: colony-stimulating factor
 EPO: erythropoietin
 G-CSF: granulocyte colony-stimulating factor
 GM-CSF: granulocyte-macrophage colony-stimulating factor
 GVHD: graft-versus-host disease
 HIV: human immunodeficiency virus
 HLA: human leukocyte antigen
 IL: interleukin
 ITP: idiopathic thrombocytopenic purpura
 MCSF: macrophage colony-stimulating
 NMDP: National Marrow Donor Program
 PBPC: peripheral blood progenitor cell
 RBC: red blood cell
 SCF: stem cell factor
 TPO: thrombopoietin
 WBC: white blood cells

ANEMIAS

Beata Ineck, Barbara J. Mason, and E. Gregory Thompson

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Anemias are a group of diseases characterized by a decrease in either the hemoglobin (Hgb) or the volume of red blood cells (RBCs), which results in decreased oxygen-carrying capacity of the blood.
- 2 Anemias are often a sign of underlying pathology. Therefore a rapid diagnosis of the cause of the anemia is essential.
- 3 Patients with acute-onset anemias are most likely to present with tachycardia, light-headedness, and dyspnea; those with chronic anemia often present with weakness, fatigue, headache, vertigo, faintness, sensitivity to cold, pallor, and loss of skin tone.
- 4 Iron deficiency anemia (IDA) is characterized by decreased levels of ferritin (most sensitive marker) and serum iron, as well as decreased transferrin saturation; the Hgb and hematocrit (Hct) fall late in the disease. Total iron-binding capacity (TIBC) is increased. RBC morphology includes hypochromia and microcytosis. Most patients with IDA are adequately treated with oral ferrous (Fe^{2+}) sulfate therapy, although parenteral iron therapy is necessary in select patient populations.
- 5 Vitamin B_{12} deficiency, a macrocytic anemia, can be due to inadequate intake, decreased absorption, or inadequate utilization. Anemia caused by a lack of intrinsic factor, resulting in decreased vitamin B_{12} absorption, is called pernicious anemia. Vitamin B_{12} levels and the reticulocyte count are usually low. Neurologic symptoms are often present. Oral or parenteral therapy may be used for replacement therapy.
- 6 Folic acid deficiency, a macrocytic anemia, results from inadequate intake, decreased absorption, hyperutilization, or inadequate utilization. Treatment consists of the oral administration of folic acid, even in patients with absorption problems. Adequate folic acid intake is essential in women of childbearing years to decrease the risk of neural tube defects in their children.
- 7 Anemia of chronic disease (ACD) is a diagnosis of exclusion. It results from chronic inflammation, infection, or malignancy, and can occur as early as 1 to 2 months after the onset of these processes. The serum iron level is usually decreased, but in contrast to IDA, the serum ferritin concentration is normal or increased and TIBC is usually decreased. Treatment is aimed at correcting the underlying pathology.
- 8 Anemia is a common complication in critically ill patients and is almost universally found in this patient population. Contributing factors include sepsis, frequent blood samples, surgical blood loss, immune-mediated functional iron deficiency, decreased erythropoietin (EPO) production, reduced RBC life span, and gastrointestinal bleeding. Low serum iron, TIBC, and a low iron:TIBC ratio result. Serum ferritin is normal to high. The role of EPO in treatment is yet to be defined.
- 9 One of the most prevalent clinical problems observed in the elderly is anemia, although it is not an inevitable outcome of aging. The anemia is associated with an increased risk of mortality, poor health, and decreased physical functioning. Those with iron deficiency may have concurrent folic acid or vitamin B_{12} deficiency.
- 10 IDA is a leading cause of infant morbidity and mortality in the world. The age of the child can yield some clues to the etiology of the anemia. Age- and sex-adjusted norms need to be utilized in interpretation of lab results in pediatric patients. Primary prevention of IDA is the goal. A therapeutic trial of oral iron is the standard of care. EPO may be used in anemia of prematurity (AOP).
- 11 Hemolytic anemia results in decreased survival time of RBCs secondary to destruction in the spleen or circulation. Hemolytic anemias are normocytic and normochromic, with increased levels of reticulocytes, lactate dehydrogenase, and indirect bilirubin. Treatment is directed towards correcting or controlling the underlying pathology.

This chapter will provide an overview of anemia. This first section will present definitions and classification systems. A review of basic aspects of erythropoiesis, followed by laboratory evaluation of the anemia patient will then be discussed. The general similarities in the clinical presentation of the anemic patient will be presented in the text.

INTRODUCTION

According to the World Health Organization, anemia is second only to tuberculosis as the world's most prevalent and costly public health issue. Anemia defined as Hgb <13 g/dL in men or <12 g/dL in women (as recommended by the World Health Organization) occurs in

TABLE 99–1. Classification Systems for Anemias

| | |
|---|---|
| I. Morphology | |
| Macrocytic anemias | Gastritis |
| Megaloblastic anemias | Hemorrhoids |
| Vitamin B ₁₂ deficiency | Chronic hemorrhage |
| Folic acid deficiency anemia | Vaginal bleeding |
| Microcytic, hypochromic anemias | Peptic ulcer |
| Iron deficiency anemia | Intestinal parasites |
| Genetic anomaly | Aspirin and other nonsteroidal anti-inflammatory agents |
| Sickle cell anemia | Excessive RBC destruction |
| Thalassemia | Extracorporeal (outside the cell) factors |
| Other hemoglobinopathies (abnormal hemoglobins) | RBC antibodies |
| Normocytic anemias | Drugs |
| Recent blood loss | Physical trauma to RBC (artificial valves) |
| Hemolysis | Excessive sequestration in the spleen |
| Bone marrow failure | Intracorporeal factors |
| Anemia of chronic disease | Heredity |
| Renal failure | Disorders of hemoglobin synthesis |
| Endocrine disorders | Inadequate production of mature RBCs |
| Myeloplastic anemias | Deficiency of nutrients (B ₁₂ , folic acid, iron, protein) |
| II. Etiology | Deficiency of erythroblasts |
| Deficiency | Aplastic anemia |
| Iron | Isolated (often transient) erythroblastopenia |
| Vitamin B ₁₂ | Folic acid antagonists |
| Folic acid | Antibodies |
| Pyridoxine | Conditions with infiltration of bone marrow |
| Central—caused by impaired bone marrow function | Lymphoma |
| Anemia of chronic disease | Leukemia |
| Anemia of the elderly | Myelofibrosis |
| Malignant bone marrow disorders | Carcinoma |
| Peripheral | Endocrine abnormalities |
| Bleeding (hemorrhage) | Hypothyroidism |
| Hemolysis (hemolytic anemias) | Adrenal insufficiency |
| III. Pathophysiology | Pituitary insufficiency |
| Excessive blood loss | Chronic renal disease |
| Recent hemorrhage | Chronic inflammatory disease |
| Trauma | Granulomatous diseases |
| Peptic ulcer | Collagen vascular diseases |
| | Hepatic disease |

RBC, red blood cell.

approximately 3.4 million Americans based on self-reported data from the National Center for Health Statistics. The highest prevalence is in women, African-Americans, the elderly, and low-income persons. Laboratory data from the second National Health and Nutrition Examination Survey (NHANES) reports anemia prevalence as 5.7% in infants, 5.9% in teenage girls, 5.8% in young women, and 4.4% in elderly men.¹ Prevalence data is confounded by the lack of a standardized definition of anemia. Since no guidelines for screening for the presence of anemia in the elderly exist, the incidence of anemia may be even greater than suspected.²

There is increasing evidence that anemia is not an innocent by-stander. It appears to have an impact on both length and quality of life.³ Retrospective and observational studies in hemodialysis patients and congestive heart failure patients suggest that anemia is an independent risk factor for mortality.⁴ In addition, anemia significantly influences morbidity, as shown in patients with end-stage renal disease, chronic kidney disease, and congestive heart failure.⁵ The data regarding quality of life in anemic patients stems mainly from cancer patients.⁶ The effect of treatment of anemia on patient outcomes needs to be the focus of research with each specific type of anemia. Global goals of treatment for anemic patients are to alleviate signs and symptoms, correct the underlying etiology, and prevent recurrence of anemia.

❖ Anemias are a group of diseases characterized by a decrease in either Hgb or RBCs, resulting in reduced oxygen-carrying

capacity of the blood. Anemias can result from inadequate RBC production, increased RBC destruction, accelerated loss of RBC mass, or they can be a manifestation of a host of systemic disorders such as infection, chronic renal disease, or malignancy. Since anemias are often a sign of underlying pathology, a rapid diagnosis of the cause of the anemia is essential.

❖ Anemias can be classified on the basis of the morphology of the RBCs, etiology, or pathophysiology. Table 99–1 gives some examples of anemias in these classifications. IDA, ACD, and anemias associated with vitamin B₁₂ and folic acid deficiency will be the emphasis of this chapter. Characteristic changes in the size of the RBC seen in erythrocyte indices can be the first step in the morphologic classification and understanding of the anemia.

Anemias are classified by RBC size as macrocytic, normocytic, or microcytic. Vitamin B₁₂ deficiency and folic acid deficiency are both macrocytic anemias. An example of a microcytic anemia is iron deficiency, whereas a normocytic anemia may be the result of recent blood loss or chronic disease. In many patients more than one anemia and etiology may occur at the same time. Inclusion of the underlying cause of the anemia makes diagnostic terminology easier to understand (e.g., microcytic anemia secondary to iron deficiency).

Microcytic anemias are pathogenically a result of a quantitative deficiency in Hgb synthesis, usually due to iron deficiency or impaired iron utilization. This results in the formation of erythrocytes containing insufficient Hgb. Microcytosis and hypochromia are the

morphologic abnormalities that provide evidence of impaired Hgb synthesis. Macrocytic anemias can be divided into megaloblastic and nonmegaloblastic anemias. The type of macrocytic anemia can be distinguished microscopically with a peripheral blood smear examination. Megaloblasts are distinctive cells that express a biochemical abnormality of retarded DNA synthesis, resulting in unbalanced cell growth. Megaloblastic anemias affect all hematopoietic cell lines. The most common cause of megaloblastic anemia is vitamin B₁₂ and/or folate deficiency. Nonmegaloblastic macrocytic anemias may be due to membrane cholesterol defects, so white blood cells and platelets may look normal. Nonmegaloblastic anemias do not have a common pathogenic mechanism and may be macrocytic or normocytic. This type of macrocytic anemia may be due to etiologies such as liver disease, hypothyroidism, hemolytic anemia, and alcoholism.

MATURATION AND DEVELOPMENT OF RED BLOOD CELLS

In adults, RBCs are formed in the marrow of the vertebrae, ribs, sternum, clavicle, pelvic (iliac) crest, and the proximal epiphyses of the long bones. In children, most bone marrow space is hematopoietically active to meet increased RBC requirements.

In normal RBC formation, a pluripotent stem cell yields an erythroid burst-forming unit. EPO and cytokines such as interleukin-3 and granulocyte-macrophage colony-stimulating factor stimulate this cell to form an erythroid colony-forming unit in the marrow. The erythroid colony-forming unit is very sensitive to EPO and produces proerythroblasts. Subsequent divisions yield basophilic erythroblasts, polychromatic erythroblasts, pyknotic erythroblasts, reticulocytes, and finally an erythrocyte. During this process, the nucleus becomes smaller with each division, finally disappearing in the normal erythrocyte (Fig. 99–1). Hgb and iron are incorporated into

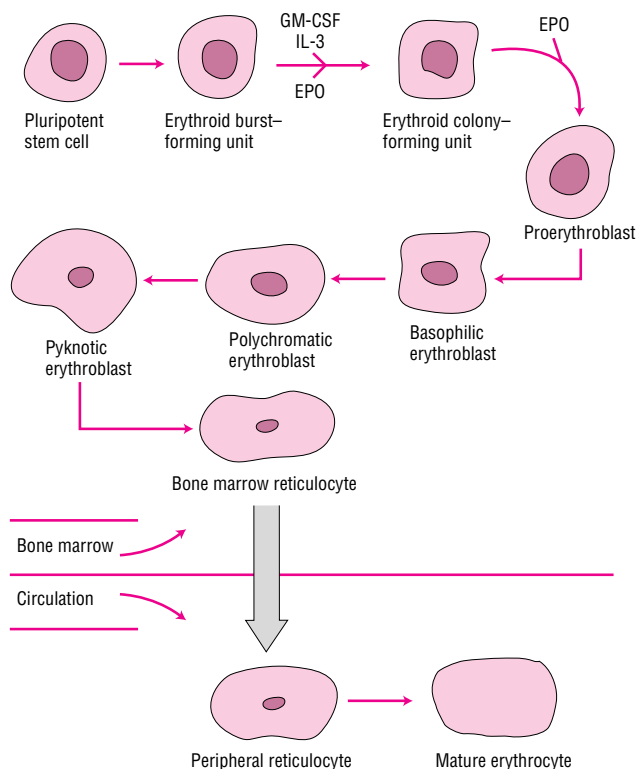

FIGURE 99–1. Erythrocyte maturation sequence. EPO, erythropoietin; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL-3, interleukin-3.

the gradually maturing RBC, which is eventually released from the marrow into the circulating blood as a reticulocyte. The maturation process usually takes about 1 week. Several days are then necessary for the reticulocyte to lose its nucleus and become an erythrocyte. The circulating erythrocyte is a non-nucleated, nondividing cell. More than 90% of the protein content of the erythrocyte consists of the oxygen-carrying molecule Hgb. Erythrocytes compose 40% to 50% of the total blood volume and have a normal survival time of 120 days.

STIMULATION OF ERYTHROPOIESIS

The hormone EPO, 90% of which is produced by the kidneys, initiates and stimulates the production of RBCs. Erythropoiesis is driven by a feedback loop. The main mechanism of action of EPO is to prevent apoptosis, or programmed cell death, of erythroid precursor cells and to allow their proliferation and subsequent maturation. A decrease in tissue oxygen concentration signals the kidneys to increase the production and release of EPO into the plasma, which (1) stimulates stem cells to differentiate into proerythroblasts, (2) increases the rate of mitosis, (3) increases the release of reticulocytes from the marrow, and (4) induces Hgb formation. In normal circumstances, the RBC mass is kept at an almost constant level by EPO matching new erythrocyte production to the natural rate of loss of RBCs. Accelerated Hgb synthesis makes it possible to achieve the critical Hgb concentration necessary for RBCs to mature more rapidly, and a feedback mechanism stops further RBC nucleic acid synthesis, causing an earlier release of reticulocytes. Early appearance of large quantities of reticulocytes in the peripheral circulation (reticulocytosis) is another indication of increased RBC production.

SYNTHESIS OF HEMOGLOBIN

Hgb consists of a protein component with two α and two β chains; each chain is linked to a heme group consisting of a porphyrin ring structure with an iron atom chelated at its center, which is capable of binding oxygen. The initial step in the synthesis of heme from the substrate succinyl CoA and glycine requires the presence of pyridoxine phosphate (vitamin B₆) as a catalyst. Following its synthesis in the cytoplasmic mitochondria of the RBC, heme diffuses into the extra-mitochondrial space, combines with the completed α and β chains, and forms Hgb.

Under normal conditions, the body produces approximately 6.25 g of Hgb daily. If the bone marrow functions at maximal capacity, the normal RBC survival time of 120 days can decrease to 18 to 20 days before an anemia develops. When hemolytic destruction of RBCs exceeds marrow production capacity and anemia develops, the Hgb value decreases to a steady-state level at which production is equal to destruction. Hgb values in these hemolytic anemias, such as sickle cell anemia, (see Chap. 101 on sickle cell anemia) will remain stable unless other factors further shorten the RBC life span.

The affinity of Hgb for oxygen is influenced by three intracellular components and by temperature. Increasing hydrogen ion concentration (decreasing pH), carbon dioxide, and 2,3-bisphosphoglycerate, together with increased temperature, all enhance the ability of Hgb to release oxygen into tissue by decreasing oxygen affinity. This physiologic compensation also increases plasma volume which can increase tissue perfusion.

BODY IRON

The normal iron content of the body is about 3 to 4 g. Approximately 2.5 g of the iron exists in the form of Hgb, whereas about 400 mg

exists as iron-containing proteins such as myoglobin and cytochromes. Another 3 to 7 mg of iron is bound to transferrin in plasma, while the remaining iron exists as storage iron in the form of ferritin or hemosiderin. Due to the toxicity of inorganic iron, the body has an intricate system for iron absorption, transport, storage, assimilation, and elimination.

ABSORPTION OF IRON

Iron is best absorbed in its ferrous (Fe²⁺) form. The normal daily Western diet contains approximately 12 to 15 mg of iron, mainly in the ferric (Fe³⁺) nonabsorbed form. After being ionized by stomach acid and then reduced to the Fe²⁺ state, iron is absorbed primarily in the duodenum, and to a smaller extent in the jejunum, via intestinal mucosal cell uptake. Subsequently, it is transferred across the cell into the plasma.⁷ Iron absorption is not directly correlated to iron intake. As physiologic iron levels decrease, gastrointestinal absorption of iron increases.

The daily recommended dietary allowance for iron is 8 mg in adult males and postmenopausal females, and 18 mg in menstruating females. Children require more iron due to growth-related increases in blood volume, and pregnant women have an increased iron demand brought about by fetal development. However, iron overload does not occur, as only the amount of iron lost per day is absorbed. The amount of iron absorbed from food depends on the body stores, the rate of RBC production, the type of iron provided in the diet, and the presence of any substances that may enhance or inhibit iron absorption.

Heme iron, found in meat, fish, and poultry, is about three times more absorbable than the nonheme iron found in vegetables and dietary supplements. Forty percent of iron from animal sources is in the heme form.⁷ Heme and nonheme iron are absorbed by different receptors on the intestinal mucosa. The iron content of some foods high in iron is shown in Table 99–2. Gastric acid and other dietary components such as ascorbic acid increase the absorption of nonheme iron. Dietary components that form insoluble complexes with iron (phytates, tannates, and phosphates) decrease absorption.⁸ Phytates, a natural component of grains, brans, and some vegetables, can form poorly absorbed complexes and partially explain the increased prevalence of IDA in poorer countries, where grains and vegetables compose a disproportionate amount of the normal diet, with the more readily absorbable heme iron lacking in the diet. Though the mechanism is unknown, calcium inhibits absorption of both heme and nonheme iron. Epidemiologic studies show a correlation between milk intake and prevalence of iron deficiency.⁹ Finally, because gastric acid improves iron absorption, patients who have undergone a gastrectomy or have achlorhydria will have decreased iron absorption.

TABLE 99–2. Good Sources of Iron

| Food | Serving Size | Amount (mg) |
|------------------------|----------------|-------------|
| Total cereal | 1 cup | 18 |
| Grape-nuts cereal | 1 cup | 18 |
| Instant Cream of Wheat | 1 cup | 8.2 |
| Instant plain oatmeal | 1 cup | 6.7 |
| Wheat germ | 1 oz. | 2.6 |
| Broccoli | 1 medium stalk | 2.1 |
| Baked potato | 1 medium | 2.7 |
| Raw tofu | ½ cup | 4 |
| Lentils | ½ cup | 3.3 |
| Beef chuck | 3 ounces | 3.2 |

INCORPORATION OF IRON INTO HEME

A specific plasma transport protein called transferrin delivers iron to the bone marrow for incorporation into the Hgb molecule. Transferrin enters cells by binding to transferrin receptors, which circulate and then attach to cells needing iron. Conversely, there are fewer transferrin receptors on the surface of cells not currently in need of iron, thus preventing iron-replete cells from receiving excess iron.¹⁰

Circulating transferrin is normally about 30% saturated with iron. Transferrin delivers extra iron to other body storage sites, such as the liver, marrow, and spleen, for later use. This iron is stored within macrophages as ferritin or hemosiderin. Ferritin consists of a Fe³⁺ hydroxyphosphate core surrounded by a protein shell called apoferritin. Hemosiderin can be described as compacted ferritin molecules with an even greater iron:protein shell ratio. Physiologically it is a more stable, but less available, form of storage iron.

NORMAL DESTRUCTION OF RED BLOOD CELLS

Phagocytic breakdown destroys older blood cells, primarily in the spleen, but also in the marrow (Fig. 99–2). Amino acids from the globin chains return to an amino acid pool; heme oxygenase acts on the porphyrin heme structure to form biliverdin and to release its iron. Iron returns to the iron pool to be reused while biliverdin is further catabolized to bilirubin. The bilirubin is then released into the

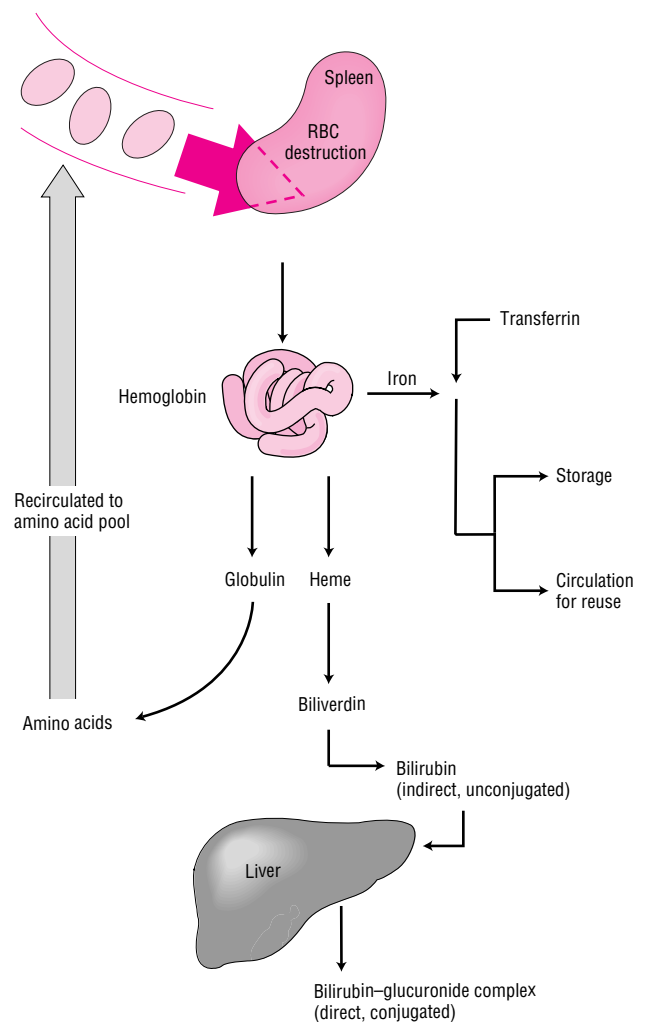

FIGURE 99–2. Destruction of red blood cells (RBCs).

plasma where it binds to albumin and is transported to the liver for glucuronide conjugation and excretion via bile. If the liver is unable to perform the conjugation, as seen with intrinsic liver disease or oversaturation of conjugation enzymes by excessive cell hemolysis, the result is an elevated indirect (unconjugated) bilirubin. Should there be an obstruction in the biliary excretion pathway for the already conjugated bilirubin, an elevated direct bilirubin would result. Comparison of direct and indirect bilirubin values helps to determine if the defect in bilirubin clearance occurs before or after bilirubin enters the liver. The Hgb in RBCs, which is destroyed by intravascular hemolysis, becomes attached to haptoglobin and is carried back to the marrow for processing in the normal manner.

DIAGNOSIS OF ANEMIA

GENERAL PRESENTATION

History, physical examination and laboratory testing are utilized in the evaluation of the anemic patient. The work-up determines if the patient is bleeding, if there is evidence for increased RBC destruction, if the bone marrow is suppressed, or if the patient is iron deficient and if so why. A previous abnormal blood exam may suggest a congenital problem. Occupation, social habits, travel history, and diet are all important in identifying causes of anemia. Additionally, information about concurrent nonhematologic disease states and a drug ingestion history are essential when evaluating the cause of the anemia (see Chap. 102, on drug-induced hematologic disorders). Past history of blood transfusions, liver disease, and exposure to toxic chemicals should also be obtained.

Anemias are a sign of disease, so clinical presentation may relate to the underlying pathology. The presenting signs and symptoms of anemias depend on the rate of development and the age of the patient, as well as the cardiovascular status of the patient. Severity of symptoms does not always correlate with the degree of the anemia.¹¹ If the myocardium is healthy and the anemia evolves slowly, the combined effects of the shift in the oxygen dissociation curve and increased cardiac output may allow acclimatization at very low Hgb concentrations. Mild anemia is often associated with no clinical symptoms and is often found incidentally upon obtaining a complete blood count (CBC) for other reasons. The signs and symptoms in elderly patients with anemia may be attributed to their age or concomitant disease states. Levels of Hgb tolerated by younger persons may not be tolerated by the elderly. Premature infants with anemia may be asymptomatic or have tachycardia, poor weight gain, increased supplemental oxygen needs, or increased episodes of apnea or bradycardia.

PRESENTATION OF ANEMIA

GENERAL

- Patients may be asymptomatic or have vague complaints.
- Patients with vitamin B₁₂ deficiency may develop neurologic consequences.
- In ACD, the signs and symptoms of the underlying disorder often overshadow those of the anemia.

SYMPTOMS

- Decreased exercise tolerance
- Fatigue
- Dizziness
- Irritability

- Weakness
- Palpitations
- Vertigo
- Shortness of breath
- Chest pain
- Neurologic symptoms such as numbness and paresthesias often present in vitamin B₁₂ deficiency.

SIGNS

- Tachycardia
- Pale appearance (most prominent in conjunctivae)
- Decreased mental acuity
- Increased intensity of some cardiac valvular murmurs
- Diminished vibratory sense in vitamin B₁₂ deficiency

LABORATORY TESTS

- Hemoglobin, hematocrit, and RBC indices may remain normal early in the disease and then decrease as the anemia progresses.
- Low serum iron in IDA and ACD
- Ferritin levels are low in IDA and normal to increased in ACD.
- High TIBC in IDA, low TIBC in ACD
- MCV elevated in vitamin B₁₂ deficiency and /folate deficiency
- Vitamin B₁₂ and folate levels are low in their respective types of anemia.
- Homocysteine elevated in vitamin B₁₂ deficiency and folate deficiency
- Methylmalonic acid elevated in vitamin B₁₂ deficiency

OTHER DIAGNOSTIC TESTS

- Schilling test determines deficiency in intrinsic factor.
- Bone marrow testing with iron staining can indicate low iron levels in IDA and an abundance of iron in ACD.

3 Anemia of rapid onset is most likely to present with cardiorespiratory symptoms such as tachycardia, palpitations, angina, hypotension, light-headedness, and breathlessness due to decreased oxygen delivery to tissues or from hypovolemia in those with acute bleeding. With severe intravascular blood volume loss, peripheral vasoconstriction and central vasodilation preserve blood flow to vital organs. Over time systemic small vessel dilation increases tissue oxygenation. Vascular compensation results in decreased systemic vascular resistance, increased cardiac output, and tachycardia. With acute hemolysis and fall in RBC mass, there is some decrease in blood volume, but not in plasma volume.

If the onset is more chronic in nature, the presenting symptoms may include fatigue, weakness, headache, symptoms of heart failure, vertigo, faintness, sensitivity to cold, pallor, and loss of skin tone. Traditional anemia signs such as pallor have limited sensitivity and specificity and may be misinterpreted. In chronic bleeding there is time for equilibration with extravascular space and total blood volume will remain normal. Some of these physiologic effects, such as effects on respiratory function demonstrated by measurements of maximal oxygen consumption, may serve as end points of clinical benefit of treating anemia.

Manifestations of IDA include glossal pain, smooth tongue, reduced salivary flow, pica (compulsive eating of nonfood items), and pagophagia (compulsive eating of ice). These symptoms usually do

TABLE 99–3. Normal Hematologic Values

not appear until the Hgb concentration falls below 8 or 9 g/dL. IDA has negative effects on psychomotor and mental development in infants, children, and adolescents.¹² Additionally, maternal IDA can result in low birth weight infants and preterm delivery.¹³

Clinically, patients with vitamin B₁₂ deficiency may be pale and mildly icteric, and they may develop gastric mucosal atrophy. Neurologic findings in vitamin B₁₂ deficiency, which often precede hematologic findings, may be partly due to the impairment of the conversion of homocysteine to methionine, as methionine is necessary for the production of choline and choline-containing phospholipids.¹⁴ Neurologic findings are found in 75% to 95% of individuals with clinically apparent vitamin B₁₂ deficiency. The occurrence of neurologic findings is inversely correlated with the degree of anemia.¹⁵ The neurologic findings include numbness and paresthesias as the earliest findings, then peripheral neuropathy, ataxia, diminished vibratory sense, increased deep tendon reflexes, decreased proprioception, imbalance, and demyelination of the dorsal columns and corticospinal tract develop.¹⁶ Psychiatric findings include irritability, personality changes, memory impairment, dementia, depression, and infrequently, psychosis. Other reported symptoms include glossitis, muscle weakness, dysphagia, and anorexia.

Symptoms associated with folate deficiency are similar to those seen in patients with vitamin B₁₂ deficiency, with the absence of neurologic symptoms. Although the symptoms of anemia will improve with folate replacement and a partial hematologic response will occur, the neurologic manifestations of vitamin B₁₂ deficiency will not be reversed with folic acid replacement therapy and consequently may become irreversible if not treated.

LABORATORY EVALUATION

The initial evaluation of anemia involves a CBC, including RBC indices; a reticulocyte index; examination of a peripheral blood smear; and examination of a stool sample for occult blood. The results from the preliminary evaluation determine the need for other studies.

Table 99–3 shows normal hematologic values. By definition, anemia is present in males if the Hct is less than 41% or the Hgb is less than 13 g/dL, while females have a Hct less than 36% or a Hgb less than 12 g/dL.

Figure 99–3 provides a broad, general algorithm for the diagnosis of anemias based on laboratory data. There are many exceptions and additions to this algorithm, but it can serve as a guide to the typical presentation of the most common types and causes of anemia. Algorithms such as this are less useful in the presence of more than one cause of anemia.

HEMOGLOBIN

Values given for Hgb represent the amount of Hgb per volume of whole blood. The higher values seen in males are due to stimulation of RBC production by androgenic steroids, and to a lesser extent due to the decrease in Hgb in females caused by blood loss during menstruation. The level of Hgb can be used as a very rough estimate of the oxygen-carrying capacity of blood. Hgb levels may be diminished because of a decreased quantity of Hgb per RBC or because of a decrease in the actual number of RBCs.

HEMATOCRIT

Expressed as a percentage, Hct is the actual volume of RBCs in a unit volume of whole blood. In general, it is about three times the Hgb value. An alteration in this ratio may occur with abnormal cell size or shape and often indicates the pathology. A low Hct indicates a reduction in either the number or size of RBCs, or an increase in plasma volume.

RED BLOOD CELL COUNT

The RBC count is an indirect estimate of the Hgb content of the blood, as it is an actual count of RBCs per unit of blood.

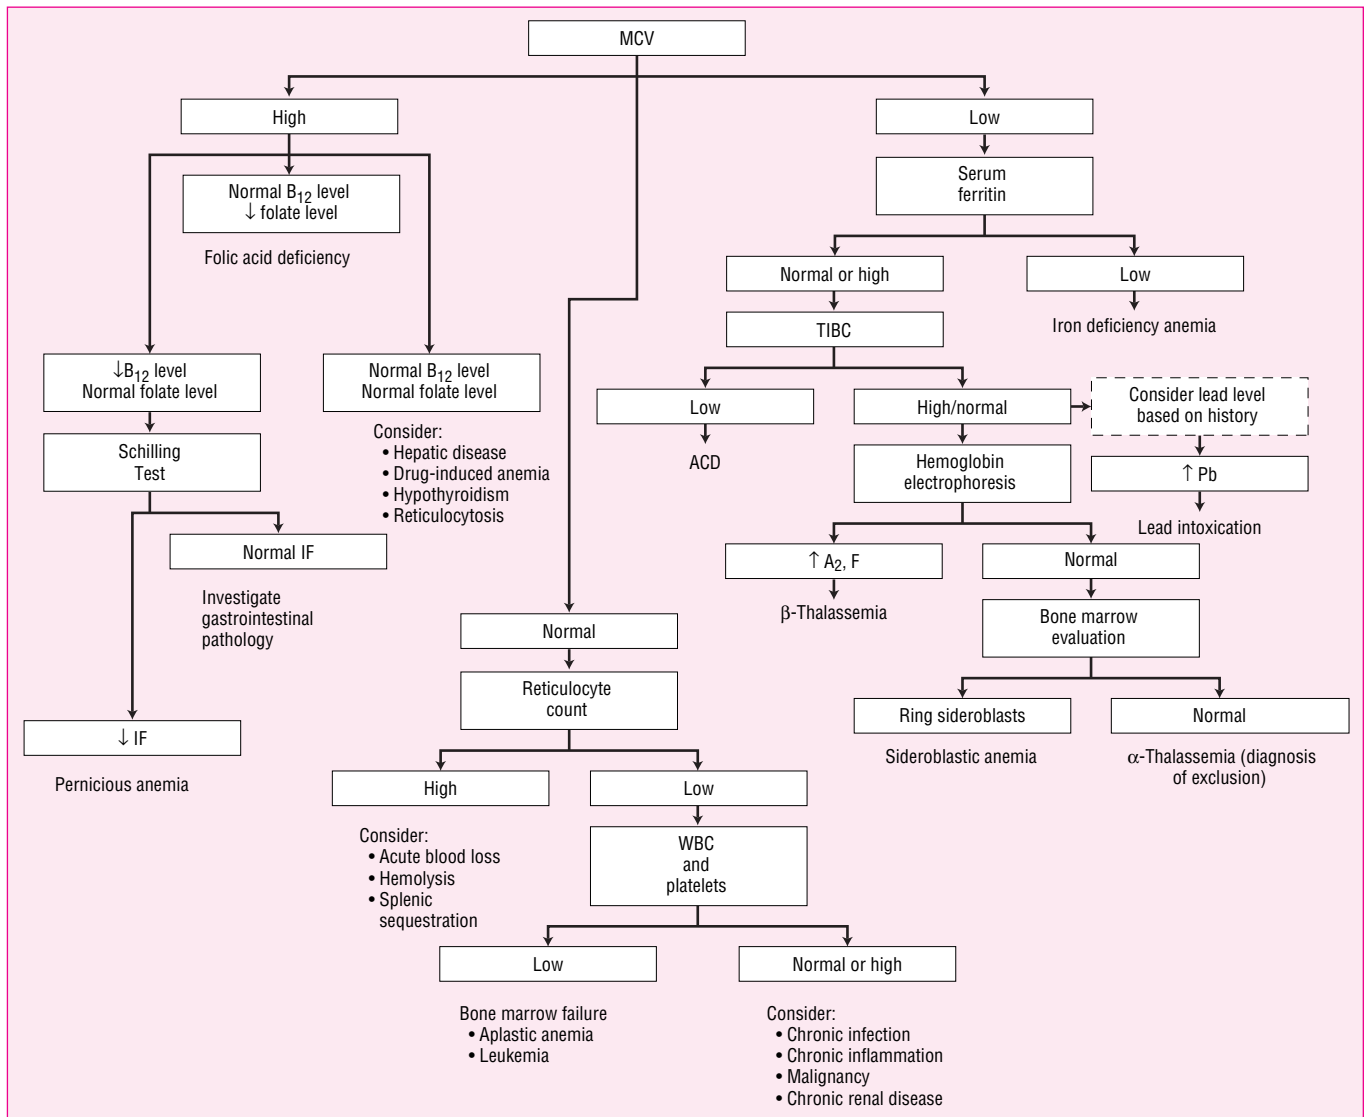

FIGURE 99-3. General algorithm for the diagnosis of anemias. ↑, increased; ↓, decreased; ACD, anemia of chronic disease; A₂, hemoglobin A₂; F, hemoglobin F; IF, intrinsic factor; MCV, mean corpuscular volume; Pb, lead; TIBC, total iron-binding capacity; WBC, white blood cells.

RED BLOOD CELL INDICES

Wintrobe indices describe the size and Hgb content of the RBCs, and are calculated from the Hgb, Hct, and RBC count. RBC indices, such as mean corpuscular volume (MCV) or mean corpuscular hemoglobin (MCH) for example, are single mean values that do not express the variation that may occur in cells.

Mean Corpuscular Volume (Hct/RBC Count)

MCV represents the average volume of RBCs. Cells are said to be macrocytic if they are larger than normal, microcytic if they are smaller than normal, and normocytic if their size falls within normal limits. Folic acid and vitamin B₁₂ deficiency anemias yield macrocytic morphology, whereas iron deficiency and thalassemia are examples of microcytic anemias. A falsely elevated MCV occurs with reticulocytosis because reticulocytes are larger than erythrocytes. The MCV is also falsely elevated in the presence of cold agglutinins and hyperglycemia. When IDA (decreased MCV) is accompanied by folate deficiency (increased MCV), failure to understand that the MCV rep-

resents an average RBC size creates the potential for overlooking the real cause of the anemia.

Mean Corpuscular Hemoglobin (Hgb/RBC Count)

The percent volume of Hgb in an RBC is the MCH. Two morphologic changes, microcytosis or hypochromia, can reduce the MCH. A microcytic cell contains less Hgb because it is a smaller cell, whereas a hypochromic cell has a low MCH because of the decreased amount of Hgb present in a normocytic cell. Cells can be both microcytic and hypochromic, as seen with IDA, and the MCH alone cannot distinguish between microcytosis and hypochromia. The most common cause of an elevated MCH is macrocytosis (e.g., vitamin B₁₂ or folate deficiency).

Mean Corpuscular Hemoglobin Concentration (Hgb/Hct)

The weight of Hgb per volume of cells is the mean corpuscular Hgb concentration (MCHC). Because the MCHC is independent of cell size, it is more useful than the MCH in distinguishing between

microcytosis and hypochromia. A low MCHC always indicates hypochromia; a microcyte with a normal Hgb concentration will have a low MCH, but a normal MCHC. A decreased MCHC is seen most often in association with IDA.

TOTAL RETICULOCYTE COUNT

Although an indirect assessment, the total reticulocyte count is an indication of new RBC production. In a normal situation, 1% of RBCs are replaced daily; this represents a reticulocyte count of 1%. The reticulocyte count in normocytic anemia can differentiate hypoproliferative marrow from a compensatory marrow response to an anemia. A lack of reticulocytosis in anemia indicates that a lesion that interferes with RBC production is responsible. Occasionally, a patient's Hct decreases while the absolute number of reticulocytes remains the same, resulting in a falsely elevated reticulocyte percentage. Multiplying the reticulocyte percentage by the patient's Hct and then dividing the product by an average normal Hct (for men or women) produces a corrected percentage of reticulocytes (see Chap. 98 on hematopoiesis).

RED BLOOD CELL DISTRIBUTION WIDTH

The higher the RDW, the more variable the size of the RBCs. The RDW increases in early IDA because of the release of large, immature, nucleated RBCs to compensate for the anemia, but this change is not specific for IDA. The RDW can also be helpful in the diagnosis of a mixed anemia. A patient can have a normal MCV, yet have a wide RDW. This would indicate presence of microcytes and macrocytes, which would yield a "normal" average RBC size. Use of RDW to distinguish IDA from ACD is not recommended.

PERIPHERAL SMEAR

The peripheral blood smear is an inexpensive tool that can supplement other clinical data, or in some cases, provide enough data alone to establish a diagnosis. Peripheral smears provide information on the functional status of the bone marrow and defects in RBC production. Additionally, it provides information on variations in cell size (anisocytosis) and shape (poikilocytosis). Automated blood counters, used for the complete blood count, can flag specific RBC changes which can be confirmed on a peripheral blood smear. Blood smears are placed on a microscope slide following precise preparation techniques and stained as appropriate. Morphologic examination includes assessment of size, shape, and color. The extent of anisocytosis correlates with increased range of cell sizes, and poikilocytosis suggests a defect in the maturation of RBC precursors in the bone marrow. The detected abnormalities can then suggest pathology.

SERUM IRON

The level of serum iron is the concentration of iron bound to transferrin. Normally, transferrin is about one-third bound (saturated) to iron. Unfortunately, the serum iron level of many patients with IDA remains within the lower limits of normal, as it takes a considerable amount of time to deplete iron stores, giving a false-negative test result. There is also a 20% to 30% diurnal variation in serum iron levels (higher in the morning, lower in the afternoon) as well as a 20% to 25% day-to-day variation among individuals.¹⁷ Variability results from technical and physiologic influences. Serum iron levels are decreased by infection and inflammation. Consequently, as a diagnostic tool, serum iron levels are best interpreted in conjunction with the TIBC. The serum iron

level decreases with IDA and ACD, and it increases with hemolytic anemias and iron overload.

TOTAL IRON-BINDING CAPACITY

An indirect measurement of the iron-binding capacity of serum transferrin, the TIBC evaluation is performed by adding an excess of iron to plasma to saturate all transferrin with iron. The excess (unbound) iron is then removed and the serum iron concentration is determined. Unlike the serum iron level, the TIBC does not fluctuate over hours or days. The finding of a low serum iron level and a high TIBC indicates IDA. The TIBC is actually a measurement of the protein serum transferrin, which can be affected by a variety of factors. Patients with infection, malignancy, inflammation, liver disease, and uremia may have a decreased TIBC and a decreased serum iron level, which is consistent with the diagnosis of ACD. Oral contraceptive use and pregnancy can increase TIBC because the serum transferrin production is increased with a variety of other proteins.

PERCENTAGE TRANSFERRIN SATURATION

The ratio of the serum iron level to the TIBC indicates transferrin saturation. It reflects the extent to which iron-binding sites are vacant on transferrin and indicates the amount of iron readily available for erythropoiesis. It is expressed as a percentage, as described in the following formula: Transferrin saturation = (Serum iron/TIBC) × 100.

Normally transferrin is 20% to 50% saturated with iron. In IDA, transferrin saturation of 15% or lower is commonly seen. Although it is a commonly used measure of iron deficiency, it is a less sensitive and specific marker than ferritin levels.

SERUM FERRITIN

The concentration of ferritin (storage iron) in the serum is proportional to total iron stores, and consequently is a reliable indicator of body iron stores. Ferritin levels indicate the amount of iron stored in the liver, spleen, and bone marrow cells. Therefore it is the best indicator of iron deficiency or iron overload. Low serum ferritin levels are virtually diagnostic of IDA, as they decrease only in association with IDA. In contrast, serum iron levels may decrease both in IDA and in ACD. Serum ferritin is an acute phase reactant, so chronic infection or inflammation can raise its concentration independent of iron status, masking depleted tissue stores. This limits the specificity and the utility of the serum ferritin if it is normal or high in a chronically ill patient.

FOLIC ACID

The results of folic acid measurements may vary depending on the assay method used. Decreased serum folic acid levels indicate a folate deficiency megaloblastic anemia that may coexist with a vitamin B₁₂ deficiency anemia. An erythrocyte folic acid level is less volatile than serum levels, as it is slow to decrease in an acute process such as drug-induced folic acid deficiency, and slow to increase with oral folic acid replacement. However, the clinical utility of determining the erythrocyte folic acid level is questionable, and the procedure should be reserved for cases in which the clinician suspects folic acid depletion and the serum folic acid may be falsely elevated or depleted.

VITAMIN B₁₂

Low levels of vitamin B₁₂ (cyanocobalamin) indicate vitamin B₁₂ deficiency. However, a deficiency may exist prior to the recognition of

low serum levels, as serum values are maintained at the expense of vitamin B₁₂ tissue stores. Since vitamin B₁₂ deficiency and folate deficiency may overlap, it is recommended to determine serum level of both vitamins. Vitamin B₁₂ levels may be falsely low with folate deficiency, pregnancy, use of oral contraceptives, congenital deficiency of serum haptocorrins, and in multiple myeloma.¹⁸

SCHILLING TEST

The purpose of the rarely used Schilling urinary excretion test is to diagnose vitamin B₁₂ deficiency anemia caused by a B₁₂ absorption defect resulting from a lack of intrinsic factor (pernicious anemia). The patient first receives an oral dose of radiolabeled vitamin B₁₂. Two hours later, the patient receives a large intramuscular dose of nonlabeled vitamin B₁₂ to saturate plasma transport proteins. Any excess vitamin B₁₂ that is not taken up by the transport proteins or stored in the liver will be excreted in the urine. A 24-hour urine collection is then measured for radioactivity. If sufficient gastrointestinal intrinsic factor is being produced, the radiolabeled B₁₂ will be absorbed.

If oral absorption is impaired, part 2 of the test is conducted 5 to 7 days later. The second stage of the Schilling test differentiates inadequate secretion of intrinsic factor by the stomach from an abnormality in absorption by the ileum. Radiolabeled vitamin B₁₂ is administered orally with a sufficient amount of intrinsic factor. Results within the normal range indicate that the defect is in the production of intrinsic factor as opposed to other causes of vitamin B₁₂ deficiency such as dietary deficiency or small bowel pathology. Generally, abnormal results for stage 1 followed by a normal result in stage 2 is consistent with pernicious anemia.

If the results in part 2 are still low, then the third stage of the test is conducted to determine whether the cause of the deficiency is due to bacterial overgrowth or ileal disease. The patient is given 250 mg of tetracycline four times daily for 10 days. Tetracycline reduces the intestinal bacteria in blind loop syndrome. Blind loops occur when a segment of the intestine is not contiguous with the rest of the gastrointestinal tract, which necessarily occurs with some surgical procedures. The loops are subject to bacterial overgrowth that may lead to malabsorption. If the excretion of radiolabeled vitamin B₁₂ improves after the tetracycline, a malabsorptive syndrome related to intestinal bacteria is confirmed.

HOMOCYSTEINE

Vitamin B₁₂ and folate are both required for conversion of homocysteine to methionine. Increased serum homocysteine may help define vitamin B₁₂ or folate deficiency. Homocysteine levels can also be elevated in vitamin B₆ deficiency, renal failure, hypothyroidism, and in persons with a genetic defect in cystathionine β -synthase.¹⁹ Additionally, elevated levels have been caused by medications including nicotinic acid, theophylline, methotrexate, and L-dopa.

METHYLMALONIC ACID

A vitamin B₁₂ coenzyme is needed to convert methylmalonyl coenzyme A to succinyl co-enzyme A. Patients with vitamin B₁₂ deficiency almost always have increased urinary excretion of methylmalonic acid (MMA). MMA is a more specific marker for vitamin B₁₂ deficiency compared to homocysteine. MMA levels are not elevated in folate deficiency, as folate does not participate in MMA metabolism. Levels of both MMA and homocysteine are usually elevated prior to the development of hematologic abnormalities and reductions in serum vitamin B₁₂ levels.¹⁸ MMA levels need to be interpreted cau-

tiously in patients with renal disease and hypovolemia, as it may be elevated due to decreased urinary excretion.

COOMBS TEST

Antiglobulin tests, also called Coombs tests, indicate hemolytic anemia caused by an immune response. A direct Coombs test detects antibodies bound to erythrocytes, whereas an indirect Coombs test measures antibodies present in the serum. A positive finding in a direct Coombs test is usually indicative of antibody-mediated hemolysis.

ERYTHROPOIETIN LEVELS

Healthy individuals require 10 to 30 milliunits/mL of EPO to maintain normal Hgb and Hct concentrations. Endogenous EPO levels can increase 100- to 1,000-fold during hypoxia or anemia. This marked increase does not occur in patients with end-stage renal disease, patients receiving chemotherapy, and patients with acquired immunodeficiency syndrome (AIDS), especially those taking azidothymidine. These patients will have an EPO response that is insufficient to correct their anemia.

SPECIFIC ANEMIAS

IRON DEFICIENCY ANEMIA

EPIDEMIOLOGY

Iron deficiency is the most common nutritional deficiency in developing and developed countries and it is estimated that over 500 million people worldwide have IDA.^{1,20} Data from the Third NHANES indicates IDA is prevalent in 1% to 2% of adults.²¹

Prevalence data varies because screening uses a simple Hgb test, arbitrary normals are used, and selection of samples in population surveys tends to lead to errors. The normal ranges for Hgb and Hct are so wide that a patient may lose up to 15% of their RBC mass and still have a Hct within the normal range.

ETIOLOGY

Iron deficiency results from prolonged negative iron balance or failure to meet increased physiologic iron need. The speed of iron deficiency development depends on an individual's initial iron stores and balance between iron absorption and loss. Multiple etiologic factors are usually involved.

In less industrialized nations, the risks for developing IDA are largely related to dietary factors. Diets limited in meat or fresh fruits and vegetables or diets high in substances that form complexes with iron may result in IDA. Other causes of IDA include chronic illnesses, inflammatory conditions like rheumatoid arthritis, and malabsorptive syndromes. Situations that increase the demand for iron are frequent blood donations, endurance sports, menstruation, pregnancy and lactation, infancy, and adolescence.²² Iron deficiency in pregnant women is so common that the Centers for Disease Control (CDC) and Prevention guidelines recommend low-dose iron supplements (30 mg/day) to be initiated at the woman's first prenatal visit for the primary prevention of IDA. At diagnosis, the cause of IDA must be considered a consequence of blood loss until proven otherwise. More than 50% of adults with IDA have some form of gastrointestinal bleeding. Blood loss may occur as a result of many disorders, including trauma,

hemorrhoids, peptic ulcers, gastritis, gastrointestinal malignancies, diverticular disease, copious menstrual flow, nosebleeds, or postpartum bleeding. Occult blood loss from a single gastrointestinal lesion has been shown to be a frequent cause of “idiopathic” IDA.²³ Diseases contributing to the development of IDA include various malignancies, usually in the gastrointestinal tract, and renal disease. Additionally, the possibility of multifactorial causes must always be considered. Medication history, specifically about use of recent or past iron or hematinics, alcohol, corticosteroids, aspirin, and nonsteroidal anti-inflammatory drugs is a vital part of the history. Other possible causes of hypochromic, microcytic anemia include ACD, thalassemia, sideroblastic anemia, and heavy metal (mostly lead) poisoning (see Fig. 99–3). Patients with a past medical history significant for IDA should be periodically re-evaluated for iron deficiency.

PATHOPHYSIOLOGY

Iron is vital to the function of all cells. It is a critical element in iron-containing enzymes such as the mitochondria’s cytochrome system.²⁴ Without iron, cells lose their capacity for electron transport and energy metabolism. IDA is associated with abnormal neurotransmitter function and altered immunologic and inflammatory defenses. This is because in addition to iron’s role in oxygen transport and delivery, iron is a cofactor for oxidative metabolism, dopamine and DNA synthesis, and free radical function in neutrophils.²⁵ The balance of iron metabolism is designed to conserve iron for reutilization. The margin between the amount of iron available for absorption and the body’s iron requirement is narrow for growing infants and female adults, which explains why IDA prevalence is highest in these populations. Risk of iron deficiency is related to levels of iron loss, iron intake, iron absorption, and physiologic demands. Iron deficiency is usually the result of a long period of negative iron balance. Manifestations of iron deficiency occur in several stages and three stages have been described: prelatent, latent, and IDA. Prelatent refers to a reduction in iron stores without reduced serum iron levels, and can be assessed with serum ferritin measurement. In this first stage, iron stores can be depleted without causing anemia. The stores allow iron to be utilized when there is an increased need for Hgb synthesis. Once stores are depleted, there is still adequate iron from the daily RBC turnover for Hgb synthesis. Further iron losses would make the patient vulnerable to anemia development. Latent iron deficiency occurs when iron

stores are depleted, but Hgb is above the lower limit of normal for the population, yet may be reduced for a given patient. This can be determined by serial CBC measurements. Findings would include reduced transferrin saturation and increased TIBC. IDA occurs when the Hgb falls to less than normal values. Deficiency progresses to the classic hypochromia and microcytosis of iron-deficient erythropoiesis.

LABORATORY FINDINGS

4 Abnormal laboratory findings in patients with IDA generally include low serum iron and ferritin levels and a high TIBC.²⁶ The first apparent sign of iron deficiency is the increased RDW, although it is not specific to IDA. In the early stages of IDA, the RBC size is not changed. Low ferritin concentration is the earliest and most sensitive indicator of iron deficiency. The disadvantage of using ferritin to evaluate iron stores is that renal or liver disease, malignancies, infection, or inflammatory processes may elevate the measured values, and these values may not correlate with iron stores in the bone marrow.²⁷ The Hgb, Hct, and RBC indices usually remain normal.

In the later stages of IDA, the Hgb and Hct fall below normal values, and a microcytic, hypochromic anemia develops. Microcytosis may precede hypochromia, as erythropoiesis is programmed to maintain normal Hgb concentration in deference to cell size. As a consequence, even slightly abnormal Hgb and Hct levels may indicate significant depletion of iron stores and should not be ignored. In terms of RBC indices, MCV reduction occurs earlier in iron-deficient hematopoiesis than reduction in Hgb concentration.

As noted earlier, transferrin saturation (i.e., serum iron level divided by the TIBC) is also useful in assessing IDA. Low values likely indicate IDA, although low serum transferrin saturation values may also be present in inflammatory disorders. Fortunately, the TIBC usually helps to differentiate the diagnosis in these patients: a TIBC greater than 400 mcg/dL suggests IDA, whereas values below 200 mcg/dL usually represent inflammatory disease. With continued progression of IDA, anisocytosis occurs and poikilocytosis develops, as seen on peripheral smear and indicated by increased RDW. In rare cases, a bone marrow examination can be performed to assess bone marrow iron stores. Bone marrow examination reveals absent iron stores in IDA. Documentation of decreased hemosiderin can confirm the diagnosis of IDA. In microcytic anemias due to all other causes, iron stores are detectable.

► TREATMENT: Iron Deficiency Anemia

The severity and cause of IDA determines the approach to treatment.

Treatment is focused on replenishing iron stores. Since iron deficiency can be an early sign of other illnesses, treatment of the underlying disease may aid in the correction of the iron deficiency.

■ DIETARY SUPPLEMENTATION AND THERAPEUTIC IRON PREPARATIONS

Treatment of IDA usually consists of dietary supplementation and administration of therapeutic iron preparations. As discussed earlier, iron is poorly absorbed from vegetables, grain products, dairy products, and eggs; it is best absorbed from meat, fish, and poultry. Beverages have also been shown to affect iron absorption. It is recommended that meat, orange juice, and other ascorbic acid-rich foods be included in meals, while milk and tea be consumed in moderation between meals.

In most cases of IDA, oral administration of iron therapy with soluble Fe²⁺ iron salts is appropriate.²⁸

CLINICAL CONTROVERSY

Daily Fe²⁺ sulfate is not tolerated by all and can be difficult to administer in populations of developing nations. Weekly rather than daily supplements have been used with conflicting efficacy results. The weekly approach follows the natural pattern of mucosal cell iron turnover.

Fe²⁺ sulfate, succinate, lactate, fumarate, glycine sulfate, glutamate, and gluconate are all about equally absorbed. The addition of copper, cobalt, molybdenum, or other minerals, as well as hematinics provides no advantage but adds expense. The carbonyl iron may be advantageous because of lower risk of death in cases of accidental overdose. Iron is best absorbed in the reduced Fe²⁺ form, with maximal absorption occurring in the duodenum, primarily due

TABLE 99–4. Oral Iron Products

| Salt | Elemental Iron Percentage | Elemental Iron Provided |
|------------------------------|---------------------------|---|
| Ferrous sulfate | 20% | 60–65 mg/324–325 mg tablet 18 mg iron/5 mL syrup 44 mg iron/5 mL elixir 15 mg iron/0.6 mL drop |
| Ferrous sulfate (exsiccated) | 30% | 65 mg/200 mg tablet 60 mg/187 mg tablet 50 mg/160 mg tablet |
| Ferrous gluconate | 12% | 36 mg/325 mg tablet 27 mg/240 mg tablet |
| Ferrous fumarate | 33% | 33 mg/100 mg tablet 63–66 mg/200 mg tablet 106 mg/324–325 mg tablet 15 mg/0.6 mL drop 33 mg/5 mL suspension |
| Polysaccharide iron complex | 100% | 150 mg capsule 50 mg tablet 100 mg/5 mL elixir |
| Carbonyl iron | 100% | 50 mg caplet |

to the acidic medium of the stomach. The presence of mucopolysaccharide chelator substances prevent the iron from precipitating and maintains the iron in a soluble form. In the alkaline environment of the small intestines, iron tends to form insoluble complexes that are unavailable for absorption. Slow-release or sustained-release iron preparations do not undergo sufficient dissolution until reaching the small intestines, which significantly reduces iron absorption and can attenuate the hematinic effects.²⁹ This is especially true when enteric-coated preparations are used in achlorhydric patients. The dose of iron replacement therapy depends on the patient's ability to tolerate the administered iron. Tolerance of iron salts improves with a small initial dose and gradual escalation to the full dose. In patients with IDA, it is generally recommended that approximately 200 mg of elemental iron be administered daily, usually in two or three divided doses to maximize tolerability.³⁰ However, if patients cannot tolerate this daily dose of elemental iron, smaller amounts of elemental iron, such as a single 325-mg tablet of Fe²⁺ sulfate, is usually sufficient to replace iron stores, albeit at a slower rate. Table 99–4 shows the percentage of elemental iron of commonly available iron salts. The percentage of iron absorbed progressively decreases as the dose increases, but the absolute amount absorbed increases. Iron should be preferably administered at least 1 hour prior to meals, as food interferes with its absorption. Many patients must take their iron with food, as they experience nausea and diarrhea when iron is administered on an empty stomach. Gastrointestinal side effects are usually dose-related and are similar among iron salts when equivalent amounts of elemental iron are administered. Administration of smaller amounts of iron with

each dose may minimize these adverse effects. H₂-blockers or proton pump inhibitors that reduce gastric acidity may impair iron absorption (see Table 99–5 for drug interactions with iron).

Adverse reactions to therapeutic doses of iron are primarily gastrointestinal in nature and consist of a dark discoloration of feces, constipation or diarrhea, nausea, and vomiting. Failure to develop at least some of these symptoms, even mildly, may indicate noncompliance. If these side effects become intolerable, the total daily dose may be decreased to 110 to 120 mg of elemental iron or the dose may be taken with meals. As noted, however, the administration of iron with meals reduces the amount of iron absorbed by more than one-half.

Failure to respond to appropriate treatment regimens necessitates re-evaluation of the patient's condition. Occasionally a "therapeutic trial of iron" approach will be used to confirm a presumptive diagnosis of IDA. Common causes of treatment failure include poor patient compliance, inability to absorb iron, incorrect diagnosis, continued bleeding, or a concurrent condition that blocks full reticulocyte response. Even when iron deficiency is present, response may be impaired when a coexisting cause for anemia exists. Rarely, patients may not be able to absorb iron, most often due to previous gastrectomy or celiac disease. Malabsorption can be ruled out by the iron test, in which plasma iron levels are determined at half-hour intervals for 2 hours following the administration of 50 mg of elemental iron as liquid Fe²⁺ sulfate. If plasma iron levels increase by more than 50 mcg during this time, absorption is satisfactory. Regardless of the form of oral therapy used, treatment must be continued 3 to 6 months after the

TABLE 99–5. Iron Salt–Drug Interactions

| Drugs that Decrease Iron Absorption | Object Drugs Affected by Iron |
|---|--|
| Al-, Mg-, and Ca ²⁺ -containing antacids | Levodopa ↓ (chelates with iron) |
| Tetracycline and doxycycline | Methyl dopa ↓ (decreases efficacy of methyl dopa) |
| H ₂ antagonists | Levothyroxine ↓ (decreased efficacy of levothyroxine) |
| Proton pump inhibitors | Penicillamine ↓ (chelates with iron) |
| Cholestyramine | Fluoroquinolones ↓ (forms ferric ion-quinolone complex) |
| | Tetracycline and doxycycline ↓ (when administered within 2 hours of iron salt) |
| | Mycophenolate ↓ (decreases absorption) |

TABLE 99–6. Comparison of Parenteral Iron Preparations

| | Sodium Ferric Gluconate | Iron Dextran | Iron Sucrose |
|--------------------------|---|--|---|
| Amount of elemental iron | 62.5 mg iron/5 mL | 50 mg iron/mL | 20 mg iron/mL |
| Molecular weight | Ferlecit: 289,000–444,000 daltons | InFeD: 165,000 daltons DexFerrum: 267,000 daltons | Venofer: 34,000–60,000 daltons |
| Composition | Ferric oxide hydrate bonded to sucrose chelates with gluconate in a molar rate of 2 iron molecules to 1 gluconate molecule | Complex of ferric hydroxide and dextran | Complex of polynuclear iron hydroxide in sucrose |
| Preservative | Benzyl alcohol 9 mg/5 mL 20% (975 mg in 62.5 mg iron) | None | None |
| Indication | Treatment of iron deficiency anemia in patients undergoing chronic hemodialysis who are receiving supplemental erythropoietin therapy | Treatment of patients with documented iron deficiency in whom oral therapy is unsatisfactory or impossible | Treatment of iron deficiency anemia in patients undergoing chronic hemodialysis who are receiving supplemental epoetin alfa therapy |
| Warning | No black box warning; hypersensitivity reactions | Black box warning: anaphylactic-type reactions | Black box warning: anaphylactic-type reactions |
| IM injection | No | Yes | No |
| Usual dose | 125 mg (10 mL) diluted in 100 mL normal saline, infused over 60 minutes; may also be administered as a slow IV injection (rate of 12.5 mg/min). | 100 mg undiluted at a rate not to exceed 50 mg (1 mL) per min | 100 mg into the dialysis line at a rate of 1 mL (20 mg of iron) undiluted solution per minute |
| Treatment | 8 doses × 125 mg = 1,000 mg | 10 doses × 100 mg = 1,000 mg | Up to 10 doses × 100 mg = 1,000 mg |
| Common adverse effects | Cramps, nausea and vomiting, flushing, hypotension, rash, pruritus | Pain and brown staining at injection site, flushing, hypotension, fever, chills, myalgia, anaphylaxis | Leg cramps, hypotension |

anemia is resolved to allow for repletion of iron stores and to avoid relapse.

■ PARENTERAL IRON THERAPY

When there is evidence of iron malabsorption or intolerance to orally administered iron, or when long-term noncompliance is a problem, parenteral iron therapy may be warranted. Patients with significant blood loss who refuse transfusions and in whom oral iron therapy is not possible may also require parenteral iron therapy. Parenteral iron does not lead to a quicker hematologic response than oral iron.³¹ The ideal parenteral iron supplement would be safe, efficacious, convenient, and maintain consistent patient outcomes. There are currently three different parenteral iron preparations available in the U.S.: iron dextran, sodium ferric gluconate, and iron sucrose (Table 99–6). They differ in their molecular size, degradation kinetics, bioavailability, and side-effect profiles. Although toxicity profiles of these agents differ, clinical studies indicate that each is efficacious.³² Most of the recent IV iron research has been done in hemodialysis patients.³³ The dextran parenteral preparation(s) have been associated with deaths due to anaphylactic reactions. These reactions may be related to immune reactions to the iron-carbohydrate or iron-dextran complex. Another theory for the anaphylaxis may be the high-molecular-weight dextran component, which may be antigenic even when not complexed to iron. The safety profile of iron is largely assessed by spontaneous reports to the Food and Drug Administration, as well as via retrospective and open-label prospective studies. Data suggests that Fe³⁺ gluconate and iron sucrose are safer than iron dextran.³⁴ The concern with parenteral iron is that iron may be released too quickly and overload the ability of transferrin to bind it, leading to free iron reactions resulting in interference with neutrophil function.

Iron dextran, a complex of Fe³⁺ hydroxide and the carbohydrate dextran, contains 50 mg of iron/mL and may be given via the IM or IV route. Different brands of iron dextran are available and differ in their molecular weight. They are not substitutable.³⁵

Iron dextran must be processed by macrophages for the iron to be biologically available. The absorption and metabolism varies with the route and amount of drug given. Absorption of an IM dose of iron dextran occurs in two phases. During the first 72 hours, iron dextran is absorbed primarily through the lymphatics into the left superior vena cava. A smaller amount is absorbed directly through the IM capillary network into the blood.³⁶ A second, slower phase involves uptake of the iron dextran complex by macrophages, with subsequent transport through the lymphatics into the blood. The macrophages phagocytize the iron dextran complex and cleave the dextran moiety, making free iron available to the body as circulating iron, transferrin-bound iron, or storage iron (ferritin and hemosiderin). Iron dextran can remain within these cells for many months. About 60% of an IM dose of iron dextran is absorbed after 3 days, and up to 90% is absorbed within 3 weeks.³⁷ The remainder is absorbed slowly over several months or longer.

When iron dextran is given IV, the iron is taken up immediately by the reticuloendothelial system.³⁸ Small to intermediate IV doses (50 to 500 mg of elemental iron) can be cleared from the plasma within 3 days of administration. In contrast, larger IV doses of iron dextran (500 mg of elemental iron) are processed by the reticuloendothelial system at a constant rate of 10 to 20 mg/h.³⁹ Doses this large are associated with increased plasma concentrations of iron dextran for as long as 3 weeks.

The iron dextran package insert carries a black box warning regarding the risk of anaphylaxis and requires a test dose before administration of the repletion dose. Methods of IV administration include multiple slow injections of undiluted iron dextran solution or an infusion of a diluted preparation. This latter method is often referred

TABLE 99–7. Equations for Calculating Doses of Parenteral Iron**In patients with iron deficiency anemia:**

Adults + children over 15 kg

$$\text{Dose (mL)} = 0.0442 (\text{desired Hgb} - \text{observed Hgb}) \\ \times \text{LBW} + (0.26 \times \text{LBW})$$

$$\text{LBW males} = 50 \text{ kg} + (2.3 \times \text{inches over 5 ft})$$

$$\text{LBW females} = 45.5 \text{ kg} + (2.3 \times \text{inches over 5 ft})$$

Children 5–15 kg

$$\text{Dose (mL)} = 0.0442 (\text{desired Hgb} - \text{observed Hgb}) \\ \times W + (0.26 \times W)$$

Hgb = hemoglobin

mL = milliliter

W = weight

LBW = lean body weight

In patients with anemia secondary to blood loss (hemorrhagic diathesis or long-term dialysis):

$$\text{mg of iron} = \text{blood loss} \times \text{hematocrit}$$

where blood loss is in milliliters and hematocrit is expressed as a decimal fraction.

to as total dose infusion. The IM administration of iron dextran should take place via Z-tract injection technique (a technique to handle IM injections of irritating substances with minimal tracking of the medication through surrounding tissues) to minimize staining of the skin. Because each IM dose is limited to 2 mL (100 mg of iron), multiple injections are often required. Daily IM doses should not exceed 25 mg in patients less than 5 kg, 50 mg in patients less than 10 kg, and 100 mg in all other patients. Problems with IM administration include patient discomfort, sterile abscesses, tissue necrosis, or atrophy. In addition, up to 30% of an administered dose remains physiologically unavailable. For these reasons, the IV route is the preferred parenteral route of administration.

Equations for calculating the appropriate dose of parenteral iron in patients with IDA or those with anemia secondary to blood loss can be found in Table 99–7. When given by IV administration, the dose should not exceed 50 mg of iron per minute (1 mL/min). It is suggested that all patients considered for an iron dextran injection receive a test dose of 25 mg IM or IV, or a 5- to 10-minute infusion of the diluted solution. Patients should then be observed for more than 1 hour for untoward reactions. If an anaphylaxis-like reaction were to occur, it generally responds to IV epinephrine, diphenhydramine, and corticosteroids. Patients receiving total dose infusions can have the remaining solution infused during the next 2 to 6 hours if the test dose is tolerated.

Total replacement doses of IV iron dextran have been given as a single dose, diluted in 250 to 1000 mL normal saline or 5% dextrose in water and infused over 4 to 6 hours. A test dose is still required. The ability to give a total dose infusion is a benefit of iron dextran over the other parenteral iron products. Iron dextran is best utilized when smaller frequent doses of sodium ferric gluconate or iron sucrose are impractical, such as with peritoneal dialysis.

If the patient receives a total dose infusion, there is an increased possibility of adverse reactions such as arthralgias, myalgias, flushing, malaise, and fever. Other adverse reactions of iron dextran include staining of the skin, pain at the injection site, allergic reactions, and rarely anaphylaxis. Patients most likely to experience adverse effects with iron dextran include individuals with a history of allergies, asthma, or inflammatory diseases. Patients with pre-existing immune-mediated diseases such as active rheumatoid arthritis or systemic lupus erythematosus are considered at high risk for adverse reactions because of their hyperreactive immune response capabilities.

Sodium ferric gluconate is a complex of iron bound to one gluconate and four sucrose molecules in a repeating pattern. The molecular weight is 289,000 to 440,000 daltons and it is available in an aqueous solution. Pharmacokinetically, there is no direct transfer of iron from the Fe^{3+} gluconate to the transferrin. It is taken up quickly by the reticuloendothelial system and has a half-life of about 1 hour in the bloodstream. It is supplied in 5-mg ampules containing 62.5 mg of elemental iron. It has been available in Europe since 1959, but was recently introduced in the U.S. It is FDA-indicated for iron supplementation in hemodialysis patients. The parenteral drug exposure differences between countries makes it difficult to compare allergy and anaphylaxis reports for sodium ferric gluconate complex and iron dextran. Sodium ferric gluconate appears to produce fewer anaphylactic reactions than does iron dextran. According to the package insert, a test dose of sodium ferric gluconate is not required; however, when utilized, it is given as 2 mL IV (25 mg elemental iron) in 50 mL normal saline over 60 minutes. Although sodium ferric gluconate may be administered undiluted as a slow IV injection (up to 12.5 mg/min), it is most commonly administered 10 mL IV (125 mg elemental iron) in 100 mL normal saline over 1 hour. Most hemodialysis patients require a minimum total of 1 g of elemental iron over eight dialysis sessions to replete their stores. Side effects for sodium ferric gluconate include cramps, nausea, vomiting, flushing, hypotension, loin pain, intense upper gastric pain, rash, and pruritus.

Iron sucrose is a polynuclear iron (III) hydroxide in sucrose complex with a molecular weight of about 34,000 to 60,000 daltons, and is available in 5-mL single-dose vials. Each vial contains 100 mg (20 mg/mL) of iron sucrose. Following IV administration of iron sucrose, the iron is released directly from the circulating iron sucrose to the transferrin, and is taken up in the reticuloendothelial system and metabolized. The half-life is approximately 6 hours with a volume of distribution similar to that of iron dextran. For adults on hemodialysis, it is administered at an IV dose of 100 mg one to three times per week to a total dose of 1000 mg in 10 doses. It can be given IV directly into the dialysis line by slow injection (20 mg iron [1 mL] per minute) or infusion without the requirement for a test dose. For infusion, it needs to be diluted in normal saline (maximum 100 mL) immediately prior to use and infused over a minimum of 15 minutes. Iron sucrose injection should not be administered concomitantly with oral iron preparations, as it will reduce the absorption of oral iron. Adverse effects include leg cramps and hypotension. Iron sucrose has been shown to be well tolerated, but with less-than-expected efficacy at maintaining Hgb levels above 11 g/dL and transferrin saturation above 25%.⁴⁰ Also, about 50% of patients studied experienced serum ferritin levels greater than 1,100 ng/mL, suggesting iron overload. The reduced hematologic response and development of high serum ferritin levels may be due to oversaturation of transferrin and the release of free iron. Varying doses of iron sucrose may not produce these results. Overall, iron sucrose has been shown to be safe and efficacious.⁴¹

TRANSFUSIONS

Another form of IDA treatment involves blood transfusions. The decision to manage anemia with blood transfusions is based on the evaluation of risks and benefits.⁴² This form of therapy requires extreme caution with existing cardiovascular compromise. Once Hct decreases to less than 30%, the oxygen-carrying capacity in older patients drops precipitously, predisposing them to ischemia. Tachycardia, angina, ischemic patterns on electrocardiogram, cerebrovascular insufficiency, postural hypotension, and prerenal azotemia are strong indications

that transfusions are necessary to maintain the Hct above 30%. An exception to this treatment option relates to the patient who has developed low Hct values over extended time periods. These patients often demonstrate cardiac compromise after transfusion despite Hct levels

in the 20s. Therapy in these patients should consist of iron therapy, followed by transfusion only if necessary. Guidelines for transfusion in perisurgical anemias exist.⁴³ They suggest 6 to 8 g/dL of Hgb as a threshold for treatment, with no benefit above 10 g/dL.

EVALUATION OF THERAPEUTIC OUTCOMES

A positive response to a trial of oral iron therapy would result in a modest reticulocytosis in 5 to 7 days, with an increase in Hgb at a rate of about 2 to 4 g/dL every 3 weeks until Hgb is normalized. As the Hgb level approaches normal, the rate of increase slows progressively. A Hgb response of less than 2 g over a 3-week period is unacceptable and warrants further evaluation. If the patient does not develop reticulocytosis, it is necessary to re-evaluate the diagnosis or iron replacement therapy.

Iron therapy should continue for a period sufficient for complete restoration of iron stores. Serum ferritin concentrations should return to the normal range prior to iron discontinuation. The time interval required to accomplish this goal varies, although at least 3 to 6 months of therapy is usually warranted.⁴⁴ Patients with negative iron balances caused by bleeding may require iron replacement therapy for only 1 month after correction of the underlying lesion, whereas patients with recurrent negative balances may require long-term treatment. This latter group may require as little as 30 to 60 mg of elemental iron daily.

When large amounts of parenteral iron are administered, either by total dose infusion or by multiple IM or IV doses, the patient's iron status should be closely monitored. Patients receiving regular IV iron should be monitored for clinical or laboratory evidence of iron toxicity or overload. Iron overload may be indicated by abnormal liver function tests, serum ferritin greater than 800 ng/mL or a transferrin saturation greater than 50%. Serum ferritin and transferrin saturation should be measured in the first week after doses of 100 to 200 mg, and at 2 weeks after larger IV iron doses. Hgb and Hct should be measured weekly, and serum iron and ferritin levels should be measured at least monthly. Serum iron values may be obtained reliably 48 hours after IV dosing.

MEGALOBLASTIC ANEMIAS

Macrocytic anemias are divided into megaloblastic and nonmegaloblastic anemias. Macrocytosis, as seen in megaloblastic anemias, is due to abnormalities in DNA metabolism resulting from a deficiency in vitamin B₁₂ or folate, as well as due to various drugs such as hydroxyurea, zidovudine, cytosine arabinoside, methotrexate, azathioprine, 6-mercaptopurine, or cladribine.

In vitamin B₁₂ or folate deficiency anemia, megaloblastosis results from interference in folic acid– and vitamin B₁₂–interdependent nucleic acid synthesis in the immature erythrocyte. The rate of RNA and cytoplasm production exceeds the rate of DNA production. The maturation process is retarded, resulting in immature large RBCs (macrocytosis). Synthesis of the RNA and DNA necessary for cell division depends on a series of reactions catalyzed by vitamin B₁₂ and folic acid, as they have a role in the conversion of uridine to thymidine. As shown in Fig. 99–4, dietary folates are absorbed in this process and converted (A) to 5-methyl tetrahydrofolate, which is then converted via a B₁₂-dependent reaction (B) to tetrahydrofolate (C). After gaining a carbon, tetrahydrofolate is converted to a folate cofactor (D), 5,10-methyl-tetrahydrofolate, used by thymidylate synthetase (E) in the

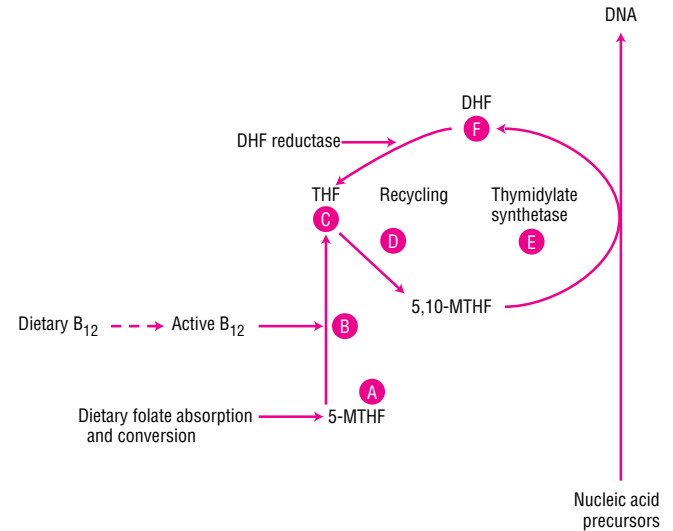

FIGURE 99–4. Drug induced megaloblastosis. DHF, dihydrofolate; 5-MTHF, 5-methyl-tetrahydrofolate; 5,10-MTHF, 5,10-methyl-tetrahydrofolate THF, tetrahydrofolate.

biosynthesis of nucleic acids. The 5,10-methyl-tetrahydrofolate cofactor is converted to dihydrofolate (F) during biosynthesis. Normally, dihydrofolate reductase reduces dihydrofolate back to tetrahydrofolate (C), which can again pick up a carbon and be recycled to produce more 5,10-methyl-tetrahydrofolate (D).

Although vitamin B₁₂ deficiency and folate deficiency are the most common causes of macrocytosis, other factors need to be considered if these deficiencies are not found to exist. Other causes of macrocytosis include: (1) a shift to immature or stressed RBCs as seen in reticulocytosis, aplastic anemia, and pure RBC aplasia; (2) a primary bone marrow disorder such as myelodysplastic syndromes, congenial dyserythropoietic anemias, and large granular lymphocyte leukemia; (3) lipid abnormalities as seen with liver disease, hypothyroidism, or hyperlipidemia, and lastly; (4) unknown mechanisms resulting from alcohol abuse and multiple myeloma. Alcoholism is a common cause of macrocytosis, as approximately 90% of alcoholics have macrocytosis prior to the appearance of an anemia.⁴⁵ Even with adequate folate and vitamin B₁₂ levels plus the absence of liver disease, patients may present with an alcohol-induced macrocytosis. Cessation of alcohol ingestion results in resolution of the macrocytosis within a couple of months.

VITAMIN B₁₂ DEFICIENCY ANEMIA

Epidemiology

Adult-onset pernicious anemia has an estimated annual incidence of 100 per 1 million population in the United States, and is slightly more common in women. However, the incidence may be underestimated due to the aging population and universal use of gastric acid-suppressing agents, as these agents may inhibit vitamin B₁₂ absorption. Older adults have an estimated prevalence reaching 40%.⁴⁶

Etiology

5 The three major causes of vitamin B₁₂ deficiency are inadequate intake, malabsorption syndromes, and inadequate utilization. Inadequate dietary consumption of vitamin B₁₂ is rare. It usually occurs only in patients who are strict vegans and their breast-fed infants, chronic alcoholics, or elderly patients with a “tea and toast” diet due to financial limitations or poor dentition. Decreased absorption of vitamin B₁₂ is seen in patients with pernicious anemia. It is caused by the absence of intrinsic factor due to either autoimmune destruction of the gastric parietal cells or atrophy of the gastric mucosa. It is most commonly seen in Europeans of northern descent and African-Americans. A deficiency in intrinsic factor limits vitamin B₁₂ absorption, but is rarely diagnosed in patients less than 35 years of age. Another cause accounting for up to 50% of deficiencies later in life is the inability of vitamin B₁₂ to be cleaved and released from the proteins in food due to inadequate gastric acid production.⁴⁷ Conditions leading to this phenomenon include subtotal gastrectomy, atrophic gastritis resulting in decreased acid pepsin production, and prolonged use of acid suppression therapy. Supplemental cobalamin is well absorbed in these individuals, as it is not protein bound. Additionally, the treatment of *Helicobacter pylori* may improve vitamin B₁₂ status, as it is a cause of chronic gastritis.⁴⁸ Vitamin B₁₂ deficiency may also result from overgrowth of bacteria in the bowel that utilizes vitamin B₁₂, or from injury or removal of ileal receptor sites where vitamin B₁₂ and the intrinsic factor complex are absorbed. Blind loop syndrome, Whipple’s disease, Zollinger-Ellison syndrome, tapeworm infestations, intestinal resections, tropical sprue, surgical resection of the ileus, pancreatic insufficiency, inflammatory bowel disease, advanced liver disease, tuberculosis, and Crohn’s disease may all contribute to the development of vitamin B₁₂ deficiency.⁴⁹

Pathophysiology

Vitamin B₁₂ is necessary for DNA synthesis, is important in metabolic reactions involving folic acid, and is essential in maintaining the integrity of the neurologic system. It is a water-soluble vitamin obtained exogenously by ingestion of meat, fish, poultry, dairy products, and fortified cereals. Body stores, which are found primarily in the liver, range from 2 to 5 mg. The recommended daily allowance is 2.4 mcg in adults and is slightly higher in pregnant or breast-feeding women. The average Western diet contains 5 to 30 mcg of vitamin B₁₂, of which 1 to 5 mcg is absorbed. It takes several years for a vitamin B₁₂ deficiency to develop following vitamin deprivation, due to efficient enterohepatic circulation of the vitamin.

After the stomach’s acidic environment facilitates the breakdown of vitamin B₁₂ bound to food, the vitamin B₁₂ binds to the intrinsic factor released by the stomach’s parietal cells. The secretion of intrinsic factor generally corresponds to the release of hydrochloric acid and serves as a cell-directed carrier protein similar to transferrin for iron. This complex, resistant to degradation, forms in the duodenum and allows for subsequent absorption of vitamin B₁₂ in the terminal ileum. The cobalamin-intrinsic factor complex is taken up into the ileal mucosal cell, the intrinsic factor is discarded, and the cobalamin is transferred to transcobalamin II, which serves as a transport protein. This complex is secreted into the circulation and is taken up by the liver, bone marrow, and other cells. Transcobalamin II has a short half-life of 1 hour and is rapidly cleared from the blood. Consequently, most circulating cobalamin is bound to serum haptocorrins (formerly transcobalamin I and transcobalamin III) whose function is unknown. However, it should be noted that an alternate pathway for vitamin B₁₂ absorption independent of intrinsic factor or an intact ter-

iminal ileum accounts for a small amount of vitamin B₁₂ absorption.⁵⁰ This alternate pathway involves passive diffusion and accounts for approximately 1% absorption of the ingested vitamin B₁₂.

Cobalamin is also a crucial cofactor in the conversion of homocysteine to methionine. When this reaction is impaired, folate metabolism is disturbed, resulting in folate-deficient tissues, and consequently, megaloblastic erythropoiesis.

Laboratory Findings

In macrocytic anemias, the MCV is usually elevated to 110 to 140 fL, but some patients deficient in vitamin B₁₂ may have a normal MCV. Mild leukopenia and thrombocytopenia are often present, as DNA synthesis derangements affect all cells in the bone marrow. Advanced cases of vitamin B₁₂ deficiency may result in pancytopenia. A peripheral blood smear demonstrates macrocytosis accompanied by hypersegmented polymorphonuclear leukocytes (one of the earliest and most specific indications of this disease), oval macrocytes, anisocytosis, and poikilocytosis. Serum lactate dehydrogenase and indirect bilirubin levels may be elevated as a result of hemolysis or ineffective erythropoiesis. Serum iron concentrations and transferrin saturation are usually elevated, although iron levels may be low in some patients with pernicious anemia.⁵¹ Other laboratory findings include a low reticulocyte count, low serum vitamin B₁₂ level (<100 pg/mL), and low Hct (sometimes as low as 10% to 15%).⁵¹ If a bone marrow biopsy is performed, marked erythroid hyperplasia and megaloblastic changes in the cells of erythroid lineage will be observed.

In the early stages of vitamin B₁₂ deficiency, classic signs and symptoms of megaloblastic anemia may not be evident and serum levels of vitamin B₁₂ may be within normal limits. Therefore measurement of MMA and homocysteine is useful, as these parameters are often the first to change.⁵² Increased levels of serum MMA and homocysteine may be evident, as both of these are involved in enzymatic reactions dependent on vitamin B₁₂, and a deficiency in vitamin B₁₂ allows for accumulation of these precursors. Elevations in MMA are more specific for vitamin B₁₂ deficiency, while elevated homocysteine can be indicative of either vitamin B₁₂ or folic acid deficiency, but offers greater specificity for folate plasma levels. Low levels of vitamin B₁₂ result in hyperhomocysteinemia, which the majority of data suggest is an independent risk factor for cerebrovascular, peripheral vascular, coronary, and venous thromboembolic disease. Hyperhomocysteinemia may also be linked to dementia and Alzheimer’s disease.⁵³

All patients with a suspected low vitamin B₁₂ level should be screened. Vitamin B₁₂ values below 150 pg/mL in a patient with macrocytosis, hypersegmented polymorphonuclear leukocytes, peripheral neuropathy, or dementia, is diagnostic of B₁₂ deficiency, even though the Schilling test results may be normal. About one-third of patients with pernicious anemia will not demonstrate macrocytosis if their condition is complicated by iron deficiency, thalassemia, or a predominant neurologic involvement.

Vitamin B₁₂ values of 200 to 300 pg/mL are suggestive of depletion, and the patient should undergo repeated testing in 1 to 3 months. A Schilling test may be performed to diagnose pernicious anemia, but the utility of this test is questionable and rarely alters the clinical management of the vitamin B₁₂ deficiency. The Schilling test was once performed to determine whether vitamin B₁₂ needed to be replaced via an oral or parenteral route, but evidence now suggests oral replacement is as efficacious as parenteral supplementation due to the vitamin B₁₂ absorption pathway independent of intrinsic factor. Limitations to the test include its complicated protocol, the need for

a 24-hour urine collection, difficulty in obtaining radiolabeled vitamin B₁₂, and difficulty in interpreting results in patients with renal insufficiency.⁵⁰

Other potentially useful tests include antibody testing and serum gastrin levels. Positive anti-intrinsic factor antibodies may be present in approximately half of patients with pernicious anemia, but is highly specific for the disease.¹⁸ Additionally, an estimated 85% of patients have anti-parietal cell antibodies, but they are nonspecific, as 3% to 10% of healthy patients have these antibodies.¹⁸ Fasting serum gastrin levels are elevated in more than 70% of patients with cobalamin deficiency and may be useful in assessing patients with borderline

serum cobalamin levels.⁵⁴ If the results of the Schilling test are normal and the serum gastrin level is elevated, this is suggestive of food-cobalamin malabsorption. When evaluating low serum vitamin B₁₂ levels, one should rule out other causes besides dietary deprivation and malabsorption. For example, levels may be falsely low in patients receiving antibiotics, anticonvulsants, cytotoxic agents, oral contraceptives, and high-dose vitamin C. In addition, conditions that can result in falsely low vitamin B₁₂ levels include multiple myeloma, malignancy, aplastic anemia, a deficiency in serum haptocorrins, gastrectomy, the third trimester of pregnancy, and radioisotope exposure studies.

▶ **TREATMENT: Vitamin B₁₂ Deficiency Anemia**

The goals of treatment for vitamin B₁₂ deficiency include reversal of hematologic manifestations, replacement of body stores, and the prevention or reversal of neurologic manifestations. Early treatment is of paramount importance to reverse any neurologic symptoms present, as they may be irreversible if the deficiency is not detected for 6 to 12 months. Permanent disabilities may range from mild paresthesias and numbness to memory loss and outright psychosis. In addition to replacement therapy, any underlying etiology that is treatable, such as bacterial overgrowth, should be remedied. In the rare cases of nutritional deficiency, the oral or parenteral administration of vitamin B₁₂ is beneficial. Patients should also be counseled on the types of foods high in vitamin B₁₂ content (Table 99–8). The oral administration of vitamin B₁₂ can also be used effectively to treat pernicious anemia or cobalamin deficiency due to ileal resection, but in much larger doses than those used to treat other causes of vitamin B₁₂ deficiency. Oral replacement therapy can be utilized due to the aforementioned alternate pathway, independent of intrinsic factor. Oral doses may be initiated at 1 to 2 mg daily for 1 to 2 weeks, followed by 1-mg daily, since doses less than 0.5 mg may result in variable absorption.⁵⁵ The 1-mg cobalamin tablets are available over

the counter. The only contraindications to oral replacement therapy include inability to take medications orally, diarrhea, or vomiting. A commonly used initial parenteral vitamin B₁₂ regimen consists of daily injections of 1,000 mcg of cyanocobalamin for 1 week to saturate vitamin B₁₂ stores in the body and to resolve clinical manifestations of the deficiency. Afterwards, it can be given weekly for 1 month and monthly thereafter for maintenance. Hydroxocobalamin is a less popular formulation of parenteral vitamin B₁₂ that is available. Its low utilization rate may be due to the possibility of antibody development to the hydroxocobalamin-transcobalamin II complex in some patients. Parenteral therapy is preferred for patients exhibiting neurologic symptoms until resolution of symptoms and hematologic indices, since the most rapid-acting therapy is necessary.⁵⁶ If converting patients from the parenteral to the oral form of cobalamin, 1 mg of oral cobalamin daily can be initiated on the due date of the next injection.

In addition to the oral and parenteral form, vitamin B₁₂ is available in an intranasal gel formulation. This form may be advantageous for patients who are homebound, have cognitive impairment, or are experiencing dysphagia. Intranasal administration should be avoided in patients with nasal diseases or those receiving medications intranasally in the same nostril. Additionally, patients should avoid administering the gel 1 hour before or after the ingestion of hot foods or beverages, as cobalamin absorption may be impaired. The efficacy of the nasal gel formulation has not been well studied and it should only be used for maintenance therapy once hematologic parameters have normalized.

Potential adverse effects with vitamin B₁₂ replacement therapy are rare. Uncommon side effects include hyperuricemia and hypokalemia. Rebound thrombocytosis may precipitate thrombotic events. Another side effect of vitamin B₁₂ therapy is sodium retention. This effect is more likely to occur in the patient with compromised cardiovascular status, because of an expansion in intravascular volume secondary to the sudden increase in the production of RBCs. Rare cases of anaphylaxis with parenteral administration of cobalamin have been reported.

TABLE 99–8. Good Sources of Vitamin B₁₂

| Food | Serving Size | Amount (mcg) |
|------------------------------------|--------------|--------------|
| Beef liver, cooked | 3 oz | 60 |
| Breakfast cereal, fortified (100%) | ¾ cup | 6 |
| Rainbow trout, cooked | 3 oz | 5.3 |
| Sockeye salmon, cooked | 3 oz | 4.9 |
| Beef, cooked | 3 oz | 2.1 |
| Breakfast cereal, fortified (25%) | ¾ cup | 1.5 |
| Haddock, cooked | 3 oz | 1.2 |
| Clams, breaded and fried | ¾ cup | 1.1 |
| Oysters, breaded and fried | 6 pieces | 1 |
| Tuna, canned in water | 3 oz | 0.9 |
| Milk | 1 cup | 0.9 |
| Yogurt | 8 oz | 0.9 |

Evaluation of Therapeutic Outcomes

Most patients respond rapidly to vitamin B₁₂ therapy. The patient will experience an improvement in strength and well-being within a few days. If glossitis is present, improvement is seen within 24 hours. Bone marrow becomes normoblastic after 24 hours, but is not evident in the plasma for another 7 days. Reticulocytosis is evident in 2 to 5 days and peaks around day 7. Hgb begins to rise after the first week and the leukocyte and platelet counts normalize

after about 7 days. Hypersegmented neutrophils persist for about 2 weeks. A CBC count and a serum cobalamin level is usually drawn 1 to 2 months after the initiation of therapy and 3 to 6 months thereafter for surveillance monitoring. Homocysteine and MMA levels should be repeated 2 to 3 months after the initiation of replacement therapy to evaluate for normalization of levels, although levels begin to decrease in 1 to 2 weeks. Failure to observe these findings usually indicates an incorrect diagnosis or other factors

contributing to the anemia such as iron deficiency or thalassemia trait. The neuropsychiatric signs and symptoms can be reversible if they are of less than 6 months' duration, but 6 months of replacement therapy or longer may be necessary before improvement is noted.⁴⁴ If permanent neurologic damage has resulted, progression should cease with replacement therapy. Demands for iron may be greater during the initiation of therapy as a result of increased erythropoiesis.⁵⁷

FOLIC ACID DEFICIENCY ANEMIA

Epidemiology

Folic acid deficiency is one of the most common vitamin deficiencies in the United States, largely due to its association with excessive alcohol intake and pregnancy. Requirements for folate in pregnancy are about five times higher than normal daily requirements.

Etiology

6 Major causes of folic acid deficiency include inadequate intake, decreased absorption, hyperutilization, and inadequate utilization. Since folic acid deficiency is associated with poor eating habits, it is common in elderly patients, alcoholics, food faddists, the poverty stricken, and those who are chronically ill or in demented states. Folic acid absorption may decrease in patients who have malabsorption syndromes or those who have received certain drugs. In addition to poor dietary habits associated with alcoholics, alcohol also interferes with folic acid absorption, interferes with folic acid utilization at the cellular level, and decreases hepatic stores of folic acid.

Hyperutilization of folic acid may occur when the rate of cellular division is increased as is seen during pregnancy; hemolytic anemia; myelofibrosis; malignancy; chronic inflammatory disorders such as Crohn's disease, rheumatoid arthritis, or psoriasis; long-term dialysis; burn patients; and growth spurts seen in adolescence and infancy. This can lead to anemia, particularly when the daily intake of folate is borderline, resulting in inadequate replacement of folate stores.

Several drugs (e.g., sulfasalazine, trimethoprim-sulfamethoxazole, and methotrexate) have been reported to cause a folic acid deficiency megaloblastic anemia. These drugs either interfere with folate absorption or inhibit the dihydrofolate reductase enzyme necessary for conversion of dihydrofolate to its active tetrahydrofolate form (see Chap. 102, on drug-induced blood dyscrasias).

Phenytoin may induce a megaloblastic anemia, as the levels of serum folic acid decrease up to 40% in about half of all patients treated with the anticonvulsant. The progression to overt megaloblastic anemia occurs in less than 1% of patients. Since folic acid doses as low as 1 mg/day may affect serum phenytoin levels, routine supplementation is not generally advised. This decline in phenytoin concentration is usually evidenced within the first 10 days and may diminish the phenytoin levels by 15% to 50%.⁵⁸

► TREATMENT: Folic Acid Deficiency Anemia

Therapy for folic acid deficiency consists of the administration of exogenous folic acid in order to induce hematologic remission, replace body stores, and resolve signs and symptoms. In the majority of cases, 1 mg daily is sufficient to replace stores except in cases of deficiency due to malabsorption, in which case doses up to 5 mg daily may be necessary. Synthetic folic acid is almost completely absorbed by the gastrointestinal tract and is converted to tetrahydrofolate with-

Pathophysiology

Folic acid is a water-soluble vitamin readily destroyed by cooking or processing. It is necessary for the production of nucleic acids, proteins, amino acids, purines, and thymine, and hence DNA and RNA. It acts as a methyl donor to form methylcobalamin, which is used in the remethylation of homocysteine to methionine. Because humans are unable to synthesize total daily folate requirements, they depend on a dietary source of this vitamin. Major dietary sources of folate include fresh, green, leafy vegetables, citrus fruits, yeast, mushrooms, dairy products, and such animal organs as liver and kidney. Most folate in food is present in the polyglutamate form, which needs to be broken down into the monoglutamate form prior to absorption in the small intestine. Once absorbed, dietary folate must be converted to tetrahydrofolate through a cobalamin-dependent reaction in order to achieve its active state. Additionally, in 1997 the U.S. government mandated the fortification of grain products with folic acid with the desire to increase the dietary intake of folate by 100 mcg of folate per person daily. This amount of supplementation was chosen to decrease the incidence of neural tube defects without masking occult vitamin B₁₂ deficiency. Even though body demands for folate are high, owing to high rates of RBC synthesis and turnover, the minimum daily requirement is 50 to 100 mcg. In the general population, the recommended daily allowance for folate is 400 mcg in nonpregnant females, 600 mcg for pregnant females, and 500 mcg for lactating females.⁵⁹ On average, Americans ingest 200 to 300 mcg of folate per day. The body stores approximately 5 to 10 mg of folate, primarily in the liver; therefore cessation of dietary folate intake results in depletion of body stores in a relatively short period of time. Folate is distributed to the other tissues primarily via enterohepatic recirculation. The methylated form of folate is reabsorbed from the bile into the serum. As it enters the tissues, including erythrocytes, it endures for the remaining life span of the cell.

Laboratory Findings

It is of paramount importance to rule out vitamin B₁₂ deficiency when folate deficiency is detected, as symptoms are similar. Laboratory changes associated with folate deficiency are similar to those seen in vitamin B₁₂ deficiency, except vitamin B₁₂ levels are normal. Decreases occur in the serum folate level (<3 ng/mL) within a few days of dietary folate limitations. The RBC folate level (<150 ng/mL) also declines and may be a better indicator of deficiency, as levels remain constant throughout the life span of the erythrocyte. Serum folate levels are sensitive to short-term changes such as dietary restrictions or alcohol intake, which may result in a short-term decline in serum levels with adequate tissue stores. It should be noted that an estimated 60% of patients with pernicious anemia have falsely low RBC folate levels, in all probability due to the requirement of cobalamin for the normal transfer of methyltetrahydrofolate from plasma to cells.¹⁸ Additionally, if serum or erythrocyte folate levels are borderline, serum homocysteine is usually increased with a folic acid deficiency. If serum MMA levels are also elevated, vitamin B₁₂ deficiency needs to be ruled out.

out cobalamin. Therapy should continue for approximately 4 months if the underlying cause of the deficiency can be identified and corrected. This treatment period allows a sufficient amount of time for all folate-deficient RBCs to be cleared from the circulation. Long-term folate administration may be necessary in chronic conditions associated with increased folate requirements as listed previously. It is also recommended that patients with a folic acid deficiency be placed on

diets containing foods high in folate (Table 99–9). Low-dose folate therapy (500 mcg daily) may be administered when anticonvulsant drugs produce a megaloblastic anemia and may make it unnecessary to discontinue the anticonvulsant. Adverse effects have not been reported with folic acid doses used for replacement therapy.

Although megaloblastic anemia during pregnancy is rare, the most common cause is folate deficiency. The condition usually manifests itself as an underweight, premature infant and suboptimal health for the mother. Folic acid supplementation (800 to 1,000 mcg daily) prior to conception and during pregnancy reduces the incidence of neural tube defects in the general population.⁶⁰ Women who have previously given birth to offspring with neural tube defects or those with a family history of neural tube defects should ingest 4 mg of folic acid daily.⁵⁸ Finally, it has been suggested that supplementation with 10 mg of folic acid daily may reduce the incidence of cleft lip.⁶¹ It is clearly essential that women in their childbearing years maintain adequate folic acid intake.

TABLE 99–9. Good Sources of Folate

| Food | Serving | Amount (mcg) |
|--------------------|-------------------|--------------|
| Chicken liver | 3.5 oz | 770 |
| Cereal | 1/2 to 1 1/2 cups | 100–400 |
| Lentils, cooked | 1/2 cup | 180 |
| Chickpeas | 1/2 cup | 141 |
| Asparagus | 1/2 cup | 132 |
| Spinach, cooked | 1/2 cup | 131 |
| Black beans | 1/2 cup | 128 |
| Pasta | 2 oz | 100–120 |
| Kidney beans | 1/2 cup | 115 |
| Lima beans | 1/2 cup | 78 |
| White rice, cooked | 3/4 cup | 60 |
| Tomato juice | 1 cup | 48 |
| Brussels sprouts | 1/2 cup | 47 |
| Orange | 1 medium | 47 |

Evaluation of Therapeutic Outcomes

Symptomatic improvement, as evidenced by increased alertness, appetite, and cooperation, often takes place early during the course of treatment. Reticulocytosis occurs within 2 to 3 days and peaks within 5 to 8 days after beginning therapy. Hct begins to rise within 2 weeks and should reach normal levels within 2 months. The MCV initially increases because of an increase in reticulocytes, but then gradually decreases to normal.

ANEMIA OF CHRONIC DISEASE

EPIDEMIOLOGY

ACD is one of the most common forms of anemia seen clinically and is especially important in the differential diagnosis of iron deficiency. Since ACD, as the name implies, is associated with other prominent disease states, the usual signs and symptoms are often overshadowed. The diagnosis of ACD is usually one of exclusion, with particular emphasis on the possibility of IDA as the primary anemia or as a coexistent anemia with ACD because of chronic disease–associated conditions (e.g., gastrointestinal blood loss from aspirin, other nonsteroidal anti-inflammatory agents, or steroids) or malignancy-associated bleeding. ACD is often observed in patients with diseases that last longer than 1 to 2 months, although it can occur in conditions with a fairly rapid onset of several weeks, such as a pneumonia. It can also coexist with anemia of renal disease, IDA, chemotherapy-induced anemia, and AIDS-related anemia. Anemia is the most common hematologic abnormality associated with human immunodeficiency virus (HIV), and the yearly incidence of developing anemia increases with disease progression.⁶² Table 99–10 lists common diseases associated with ACD.

ETIOLOGY

ACD is one response to the stimulation of the cellular immune system by various underlying disease processes. ACD commonly develops in AIDS patients, especially those with opportunistic infections or malnutrition, and is associated with increased morbidity and mortality. It may also be due to drugs used to treat AIDS and associated illness.⁶³ HIV contributes to abnormalities of hematopoiesis. Infection of progenitor cells is just one factor involved in HIV-induced bone marrow suppression.

PATHOPHYSIOLOGY

ACD is a hypoproliferative anemia that has traditionally been associated with infectious or inflammatory processes, tissue injury, or conditions associated with the release of proinflammatory cytokines. Alternative names include anemia of inflammation and cytokine-mediated anemia. The pathogenesis of the anemia of chronic disorders is based on three abnormalities: shortened erythrocyte survival, impaired marrow response, and disturbance of iron metabolism. Pathologically, the RBCs have a shortened life span, and the bone marrow’s capacity to respond to EPO is inadequate to maintain normal Hgb concentration. The cause of this defect is still uncertain, but appears to involve a block in the release of iron from the reticuloendothelial cells of the marrow. Various cytokines, such as interleukin-1, interferon-γ, and tumor necrosis factor released during these illnesses may inhibit the production or action of EPO or the production of RBCs.⁶⁴

TABLE 99–10. Diseases Causing Anemia of Chronic Disease

| |
|---|
| Common causes |
| Chronic infections |
| Tuberculosis |
| Other chronic lung infections |
| Human immunodeficiency virus |
| Subacute bacterial endocarditis |
| Osteomyelitis |
| Chronic urinary tract infections |
| Chronic inflammation |
| Rheumatoid arthritis |
| Systemic lupus erythematosus |
| Rheumatoid (collagen vascular) diseases |
| Inflammatory osteoarthritis |
| Gout |
| Chronic inflammatory liver diseases |
| Malignancies |
| Carcinoma |
| Lymphoma |
| Leukemia |
| Multiple myeloma |
| Less common causes |
| Alcoholic liver disease |
| Congestive heart failure |
| Thrombophlebitis |
| Chronic obstructive lung disease |
| Ischemic heart disease |

LABORATORY FINDINGS

No definitive test will confirm a diagnosis of ACD, and the diagnosis is often overlooked.²⁷ The practitioner should maintain a high index of suspicion in any patient with a chronic disease. ACD may coexist with IDA and folic acid deficiency, as many of these patients will have poor dietary intake or gastrointestinal blood loss. Examination of the bone marrow reveals an abundance of iron, suggesting

the release mechanism for iron is the central defect. Patients with ACD usually have a decreased serum iron level, but unlike those with IDA, their serum ferritin level is normal or increased and their TIBC decreased. Generally, ACD is normocytic and normochromic. With ACD, hypochromia usually precedes microcytosis, with the opposite finding in IDA. Erythrocyte survival may be reduced in patients with ACD, but a compensatory erythropoietic response usually does not occur.

▶ TREATMENT: Anemia of Chronic Disease

The treatment of ACD is somewhat less specific than the treatment of other anemias. Focus should be on treating the underlying disorder and correcting reversible causes of anemia. Direct approaches to correction of anemia may not be needed. During inflammation, oral or parenteral iron therapy is ineffective. Transfusions of RBCs are effective, but should be limited to situations in which oxygen transport is inadequate due to concomitant medical problems. The Hgb level necessitating a RBC transfusion varies from 8 to 10 g/dL based on factors such as cost, convenience, and risk of infectious complications. Assessment of the symptomatic state should always be considered before blood products are administered.

Exogenous EPO (or epoetin alfa) has been used to stimulate erythropoiesis in patients with ACD, as a relative EPO deficiency exists for the degree of anemia. Use should be considered in patients with compromised cardiovascular status, although patients with chronic disease may have a relatively impaired response to epoetin alfa. The dosage is 50 to 100 units per kilogram three times a week. The dosage can be increased to 150 units per kilogram per dose if no increase in Hgb concentration occurs after 6 to 8 weeks. Response to EPO varies depending on dose and cause of the anemia. EPO treatment is effective when the marrow has an adequate supply of iron, cobalamin, and folic acid.

Treatment of anemia in HIV-infected patients starts with therapy of HIV and correction of reversible causes of anemia.⁶⁵ For zidovudine-treated HIV-infected patients, an initial IV or subcuta-

neous dose of 100 units/kg, three times per week for 8 weeks is suggested. If response is not satisfactory based on decreased transfusion requirements or increased Hct after 8 weeks of therapy, the dose is increased by 50 to 100 units/kg, three times per week. Dosage adjustments in increments of 50 to 100 units/kg three times a week can be made to a maximum of 300 units/kg per dose three times a week. The dose should be discontinued when the Hct is greater than 40%. Treatment should then be restarted at a 25% dosage reduction when Hct decreases to 36%. A simplified weekly regimen of 40,000 units of subcutaneously administered EPO has been given successfully to some patients with HIV-associated anemia.⁶⁶

Most patients tolerate EPO therapy well. Iron deficiency can occur in patients treated with EPO and close monitoring of iron levels is necessary. Oral iron supplementation should be given if transferrin saturation drops to 20% or the serum ferritin level drops below 100 ng/mL. Some patients develop “functional” iron deficiency, in which the iron stores are normal, but the supply of iron to the erythroid marrow is less than that necessary to support the demand for RBC production. Therefore many practitioners routinely supplement EPO therapy with oral iron therapy. The hypertension commonly seen in end-stage renal disease patients on EPO is far less common in AIDS patients. More common toxicities of EPO administration include nausea, headache, fever, bone pain, and fatigue. Other adverse effects to monitor include seizures, thrombotic events, and allergic reactions such as rash or local reactions at the injection site.

EVALUATION OF THERAPEUTIC OUTCOMES

An easy way to monitor the immediate effect of increased endogenous or exogenous EPO is an increase in blood reticulocyte count in the first few days. Baseline iron status should be checked before and during treatment, as many patients on EPO require supplemental iron therapy. The optimal form and schedule of iron supplementation is not known. A fall in Hgb during EPO therapy usually signifies development of an infection or iron depletion. Baseline and periodic monitoring of iron, TIBC, transferrin saturation, or ferritin levels may be useful in maximizing iron repletion and limiting the need for epoetin. EPO patients who do not respond clinically by 12 weeks should not be continued on EPO.

ANEMIA OF CRITICAL ILLNESS

EPIDEMIOLOGY

8 Anemia is a common complication in critically ill patients and is almost universally found in this patient population.^{67,68}

ETIOLOGY

Factors that may contribute to anemia in critically ill patients include sepsis, frequent blood samples, surgical blood loss, immune-mediated

functional iron deficiency, decreased production of endogenous EPO, reduced RBC life span, and gastrointestinal bleeding. Deleterious effects of anemia may include increased risk of cardiac-related morbidity and mortality, and decreased oxygen-carrying capacity with risk of multiple organ deterioration. Consequences of anemia in critically ill patients may be enhanced due to increased metabolic demands of critical illness. Additionally, it is difficult to wean anemic patients from mechanical ventilation.

PATHOPHYSIOLOGY

In anemia of critical illness, alteration in the mechanism for RBC replenishment and homeostasis occurs. The effect of cytokines on EPO may partly explain anemia of critical illness, as they are associated with a blunting of the erythropoietic response in this population.⁶⁹ In addition, the cytokines seem to directly inhibit RBC production and stimulate iron binding proteins that sequester iron and limit RBC production.⁶⁹ Impaired RBC production by the bone marrow contributes to the development and persistence of anemia.

LABORATORY FINDINGS

Anemia of critical illness is similar to ACD. Lab findings frequently seen in anemia of critical illness are low serum iron, TIBC, and iron:TIBC ratio. Serum ferritin is normal to high and EPO levels

are usually slightly decreased despite the presence of anemia, with minimal reticulocyte response.^{67,69} This differs from patients with

IDA who generally have elevated EPO concentrations in response to a low Hct.

► TREATMENT: Anemia of Critical Illness

Patients with anemia of critical illness need the necessary substrates of iron, folic acid, and vitamin B₁₂ for RBC production in order for the physiologic response for anemia correction to occur. Iron stores are usually insufficient to meet physiologic demands, hence the administration of supplemental iron in the oral or parenteral form is necessary to support erythropoiesis. Parenteral iron is often utilized in this population, as often patients are on enteral therapy or there are concerns regarding inadequate iron absorption. The disadvantage of parenteral therapy is the theoretical risk of infection.⁷⁰ The low iron concentrations in critically ill patients may be a defense mechanism, as microbes require iron for sustenance. Therefore diminished iron levels may inhibit bacterial growth.

The pathophysiology of anemia of critical illness would lead to the hypothesis that treatment with pharmacologic doses of EPO might be beneficial. Few randomized, controlled trials have evaluated the role of EPO in critically ill patients, and these have resulted in mixed findings regarding EPO's ability to decrease transfusion requirements.⁶⁹ A recently published literature review found that EPO cannot be recommended to reduce the need for RBC transfusions in critically ill patients with anemia.⁷¹ Even though EPO administration

may reduce the need for transfusions, improved clinical outcomes may not result. Further investigation is necessary to define the role of EPO in critically ill patients, as well as to better define optimal dosing and end points for therapy.

Many critically ill patients receive RBC transfusions, although the actual benefits of increasing Hgb in this patient population has not been clearly established. Stored RBCs may not function as well as endogenous blood. Although RBC transfusions may increase oxygen delivery to tissues, the cellular oxygen may or may not increase.⁷² Transfusion practices vary in intensive care units, with clinicians using different Hgb concentrations as thresholds for administering transfusions. Recent data have suggested that RBC transfusions may decrease the likelihood of survival in some subgroups of critically ill patients.⁷³ Decisions to use transfusions must include a discussion of the risks of transfusions, including immunosuppression, immunosaturation, microthrombosis, and virus transmission. Additional immediate risks of transfusions include infections, infusion reactions, and transfusion-related acute lung injury. Lastly, the clinician must take into consideration administrative, logistic, and economic factors.⁷⁴

EVALUATION OF THERAPEUTIC OUTCOMES

Treatment of anemia of critical illness has nonspecific goals of therapy. The role of monitoring RBCs, Hgb, Hct, EPO levels, and reticulocyte counts remains to be determined. Outcomes used in EPO studies are transfusion requirements and transfusion independence. Morbidity, mortality, and length of stay are also assessed. Adverse effects such as risk of thrombotic events must be monitored. More research is needed to determine whether reduction in RBC transfusions and increases in Hgb will result in improved clinical outcomes.

ANEMIA IN THE ELDERLY

EPIDEMIOLOGY

9 One of the most common clinical problems observed in the elderly is anemia. Anemia is a prevalent and increasing problem in the elderly, with approximately 12% of people aged 60 and over affected.⁷⁵ The number of cases increases with age with the highest prevalence in men 85 and older.² Prior to the age of 55, the incidence of anemia is higher in women (3% in men vs. 6% in women aged 50 to 54), whereas after this point the prevalence appears to be higher in men (at 65 years of age, prevalence is found to be 21% in men and 16% in women).⁷⁶ Elderly patients with the highest incidence of anemia are those that are hospitalized, followed by residents of nursing homes and institutions at an estimated rate of 31% to 40%.⁵⁴ The lowest incidence is seen in elderly patients that are community dwellers. Although the incidence of anemia is high in the elderly, it should not be alleged as an inevitable outcome of aging, as an underlying cause can be identified in approximately 80% of patients.⁷⁵ Undiagnosed and untreated anemia can have severe ramifications and is affiliated with an increased risk of mortality, poor health, and decreased physical function. Additionally, it can cause neurologic, cognitive,

and cardiovascular complications. Anemia may also be an indication of serious diseases such as gastrointestinal cancer. Various studies have indicated the risk of mortality is increased among elderly with anemia.⁷⁵

PATHOPHYSIOLOGY

Data have indicated that aging is associated with a progressive reduction in hematopoietic reserve, which makes individuals more susceptible to developing anemia in times of hematopoietic stress.⁷⁷ Although Hgb levels may remain normal, the diminished marrow reserve leaves the elderly patient more susceptible to other causes of anemia. Additionally, renal insufficiency is common in elderly patients and this may reduce the ability of the kidneys to produce EPO. Patients often have a normal creatinine level but a diminished glomerular filtration rate. It has been suggested that a deficiency in endogenous EPO develops when the GFR falls below 50% of the normal range.

ETIOLOGY

In the acute ward setting, the top three causes of anemia in the elderly have been identified as chronic disease (35%), unexplained cause (17%), and iron deficiency (15%), whereas in community-based outpatient clinics the most prevalent causes are unexplained (36%), infection (23%), and chronic disease (17%).⁷⁶ Risk factors for the development of anemia in the elderly include race and ethnicity with the highest prevalence in elderly blacks, those with serum albumin and serum creatinine abnormalities, and recent hospitalization or placement in an institution.⁵⁴

In general, the anemia is hyporegenerative and represents an inability of the older hematopoietic system to replace the peripheral blood loss. The unexplained causes may be due to inadequate

diagnostic evaluation or due to absolute or relative EPO deficiency. Absolute deficiency may be associated with renal insufficiency, whereas relative deficiency may be due to the body's inability to provide adequate response to declining Hgb levels.⁷⁶

Another common problem in the elderly is vitamin B₁₂ deficiency, with the most common causes of clinically overt deficiency due to pernicious anemia, small bowel disease, and food-cobalamin malabsorption. A preclinical deficiency in vitamin B₁₂ is seen in 5% to 30% of all seemingly healthy elderly patients and is predominantly metabolic in expression, although subtle neurologic and cognitive defects may be present.⁵⁴

One often-overlooked major factor that may contribute to anemia in the older population is nutritional status. Cross-sectional studies demonstrate a higher prevalence of anemia in low socioeconomic populations, as well as a high prevalence of other nutritional deficiencies. Thus nutritional deficiencies not usually severe enough to affect the hematopoietic system in the younger population may account for anemia in the aged. Edentulous or infirm elderly who may be too ill to prepare their meals are at risk for nutritional folate deficiency. However, unlike cobalamin levels, it has been demonstrated that folate levels increase rather than decline with age.⁷⁸ This may be due to the dramatic increase in folate supplements used by the elderly, especially in white women, as well as the fortification of the American diet with folic acid.⁷⁹

Other common anemias in the elderly include IDA and ACD. Iron malabsorption may occur after total gastrectomy. Bleeding with resultant iron deficiency in the elderly may be due to carcinoma, ulcer, atrophic gastritis, drug-induced gastritis, postmenopausal vaginal bleeding, or bleeding hemorrhoids. Elderly women have a much lower incidence of IDA as compared to younger, menstruating women. Until proven otherwise, iron deficiency in the elderly should be considered a sign of chronic blood loss. ACD is more common in the elderly, as diseases that contribute to ACD such as

cancer, infection, and rheumatoid arthritis are more prevalent in this population.

LABORATORY FINDINGS

Elderly males may have lower Hgb levels, but it is not known if this is secondary to physiologic reasons or increased prevalence of anemia. Low levels may be due to decreased androgen secretion in men or age-related changes in stem cells. For practical purposes, it is best to use usual adult reference values for labs in the elderly and realize that some mild anemias may go unexplained.

A CBC, including a peripheral smear and reticulocyte count, should be performed in any elderly patient with symptoms that may be attributed to anemia, along with a physical exam to look for signs of renal or hepatic failure as well as to evaluate for gastrointestinal or genitourinary blood loss. If the reticulocyte count is adequate, blood loss or RBC destruction should be suspected, whereas a low level will indicate decreased RBC production. With a low reticulocyte count, RBC indices should be evaluated and if the MCV is >100 fL, further evaluation should be performed to discern vitamin B₁₂ deficiency and folate deficiency as possible causes. A vitamin B₁₂ deficiency may be present even when plasma levels of vitamin B₁₂ are within normal range, but elevated levels of MMA will detect the deficiency. A refractory macrocytic anemia in the elderly should raise suspicion of a myelodysplastic or leukemic syndrome.

If the MCV is <100 fL, further studies should be evaluated to determine if possible causes are iron deficiency or ACD.

With IDA, laboratory abnormalities are similar to those discussed above in the microcytic anemia section. However, serum iron and TIBC decrease with age, making the transferrin saturation ratio less useful in the elderly. MCVs and mean cell Hgb concentrations may appear normal even in the presence of IDA, as patients may have concurrent vitamin B₁₂ or folate deficiency anemias.

▶ TREATMENT: Anemia in the Elderly

Depending on the type of anemia unveiled, treatment in the elderly is the same as that specified for each type of anemia previously discussed in this chapter. With IDA it is essential to treat the underlying cause if known (i.e., bleeding) as well as with iron supplementation in the dose of 50 to 100 mg of elemental iron three times a day if tolerated. Vitamin B₁₂ deficiency is treated with parenteral or oral

vitamin B₁₂ supplementation, while folic acid deficiency is treated with folic acid, generally at a dose of 1 mg daily. ACD does not have any specific treatment except to resolve the underlying cause. EPO is helpful in some patients with ACD at a dosage of 50 to 100 units/kg three times a week and adjusted upwards if response is inadequate.

EVALUATION OF THERAPEUTIC OUTCOMES

Reticulocytosis usually starts within 1 week of oral supplementation with iron. If the reticulocyte count rises but the anemia does not improve, inadequate absorption of iron or continued blood loss needs to be considered. Also, with any form of anemia, symptomatic improvement should be evident shortly after starting therapy. Additionally, Hgb/Hct should begin to rise within a few weeks of initiating therapy.

ANEMIA IN PEDIATRIC POPULATIONS

EPIDEMIOLOGY

◀ IDA is a leading cause of infant morbidity and mortality in the world. In the United States, the prevalence of IDA among children is declining due to improved iron supplementation.¹ Data from the third NHANES indicated that 9% of children ages 12 to 36 months in the United States had iron deficiency and 3% had IDA.⁸⁰ Another

source states that as many as 20% of children in the United States and 80% of children in developing countries will have anemia prior to the age of 18 years.¹³ Peak requirements for iron absorption occur during puberty. The prevalence of iron deficiency is highest among premature or low-birth-weight infants; children living below the poverty level; African-American and Mexican-American children; and infants fed only non-iron fortified formulas. An anemia of prematurity can occur 3 to 12 weeks after birth in infants less than 32 weeks' gestation and spontaneously resolves by 3 to 6 months. The prevalence of vitamin B₁₂ deficiency has been identified as 1 in 1,255 for levels <100 pg/mL and 1 in 200 for levels of <200 pg/mL, with the lowest levels in non-Hispanic whites.⁸¹

PATHOPHYSIOLOGY

In contrast to anemias in adults, which tend to be manifestations of some broader underlying pathology, anemias in the pediatric

population are more often due to a primary hematologic abnormality.⁸² The amount of iron present at birth depends on gestational length and weight. Erythropoiesis normally decreases after birth. A concurrent decrease in EPO production results in a physiologic anemia at 2 to 9 weeks of age. Iron stores are mostly depleted by age 6 months, while the blood volume is doubling from 4 to 12 months.

ETIOLOGY

The age of the child can yield some clues about the etiology of the anemia. The optimal amount of nutritional iron and folate required varies in an individual, based on life cycle stages. Two peak periods place children at risk of developing IDA, with the first being during late infancy and early childhood, when children undergo rapid body growth, have low levels of dietary iron, and exhaust stores accumulated during gestation. The second peak period is recognized during adolescence, when rapid growth, poor diets, and onset of menses occurs.⁸³

During the first 5 to 6 months, the normal term infant is iron replete. Conditions in the newborn period that can lead to IDA may include prematurity, administration of EPO for AOP, or insufficient dietary intake. Premature infants are at increased risk of IDA because of a smaller total blood volume, increased blood loss through phlebotomy, and poor gastrointestinal absorption. However, iron deficiency can only occur after the birth weight has doubled in premature infants.¹³ Factors leading to unbalanced iron metabolism in infants include insufficient iron intake, decreased absorption, early introduction of cow's milk, cow milk intolerance, medications, and malabsorption. However, dietary deficiency of iron in the first 6 to 12 months of life is less common today because of the increased use of iron supplementation during breast-feeding and use of iron-fortified formulas. Iron deficiency becomes more prominent when children change to regular diets. Blood loss and hemolysis are other common causes of anemia in neonates.

Day care attendance at an earlier age may result in a higher incidence of anemia due to frequent infections. Anorexia associated with infection can lead to decreased ingestion of iron-containing foods and infection can also decrease erythropoiesis. When screening for iron deficiency in young children, a careful dietary history can help identify children at risk. Dietary deficiency has been defined as one or more of the following: less than five servings each of meat, grains, vegetables, and fruit per week; more than 16 oz of milk per day; or daily intake of fatty snacks, sweets, or more than 16 oz of soft drinks. High iron needs and the tendency to eat fewer iron-

containing foods contribute to the etiology of iron deficiency during adolescence.⁸⁴

Other causes of microcytic anemia include thalassemia, lead poisoning, and sideroblastic anemia. Homeopathic or herbal medication use may place children at risk for lead exposure, as may exposure to paint or certain cooking materials. Normocytic anemias in children include infection with human parvovirus B19 and glucose-6-phosphate dehydrogenase deficiency, while macrocytic anemias are caused by deficiencies in vitamin B₁₂ and folate, chronic liver disease, hypothyroidism, and myelodysplastic disorders. Folic acid deficiency is usually due to inadequate dietary intake; however, human and cow's milk provide adequate sources. Folic acid deficiency may be seen in infants and children who primarily consume goat's milk or health food milk alternatives, as well as in children with insufficient intake of green leafy vegetables.⁸³ Vitamin B₁₂ deficiency due to nutritional reasons is rare, but may occur due to a congenital pernicious anemia.

LABORATORY FINDINGS

When evaluating lab values in pediatric patients, it is imperative to use age- and sex-adjusted norms. It is also important to know that many blood samples are capillary samples, such as heel- or fingersticks, that may have slightly different results than venous samples.

In regular well child checks for infants, screening of the Hgb or Hct level is obtained between 6 and 12 months of age, and further testing is not pursued unless an abnormality is found.¹³ If an abnormality is found, a CBC should be ordered to evaluate the MCV to determine whether the anemia is microcytic, normocytic, or macrocytic. Additionally, a peripheral smear and reticulocyte count is recommended for further differentiation if necessary. The peripheral smear can indicate the etiology based on RBC morphology, and the reticulocyte count helps differentiate between decreased RBC production and increased RBC destruction. More complete studies would include serum iron, ferritin, TIBC, and transferrin saturation. Mild hereditary anemias may produce a mild hypochromic, microcytic anemia which can be confused with IDAs. The RDW may be high with iron deficiency and is more likely to be normal with thalassemia. Lab features of AOP include normocytic normochromic cells, low reticulocyte count, and decreased RBC presence in bone marrow. Serum concentrations of EPO are low. Laboratory diagnosis of vitamin B₁₂ deficiency in children is similar to that of adults, and includes a CBC, measurement of vitamin B₁₂, and MMA and homocysteine levels. Serum or erythrocyte folate levels would also be measured if a folic acid deficiency anemia is suspected.

► TREATMENT: Anemia in Pediatric Populations

Primary prevention of IDA in infants, children, and adolescents is the most appropriate goal since delays in mental and motor development are potentially irreversible. In April of 1998, the CDC published revised recommendations to prevent and control iron deficiency in the United States, focusing on children and women of childbearing age.⁸⁵

Interventions likely to prevent anemia include diverse foods with bioavailable forms of iron, food fortification for infants and children, and individual supplementation. Routine screening for iron deficiency in nonpregnant adolescents is only recommended for those with risk factors. These include significant physical activity (especially adolescent female athletes), vegetarian diets, malnutrition, low body weight, chronic illness, or history of heavy menstrual blood loss. Utilizing the four questions listed in Table 99–11 can identify patients at risk for

the development of IDA.⁷ Patients answering “no” to one of the first three questions may be at risk for iron deficiency.

TABLE 99–11. Questions to Assess Adequacy of Dietary Iron Intake

1. Do you consume two or more portions of meat, fish, chicken, nuts, seeds, or legumes per day?
2. Do you eat at least six servings of grain per day?
3. Do you generally eat at least one serving of fruits or vegetables at the same meal that includes grains or beans?
4. Do you take a calcium supplement at every meal?

From Ross.⁷

AOP is usually treated with red blood cell transfusions. Premature infants fed human milk need 2 mg/kg per day iron supplementation. EPO may be used in AOP, keeping in mind that EPO pharmacokinetics are influenced by the developmental age of the infant. EPO has limited efficacy in decreasing the requirement for transfusions, making it a controversial treatment approach. Infants on full enteral feedings treated with EPO need iron supplements in doses of 6 mg/kg per day.

For infants aged 9 to 12 months with a mild microcytic anemia, it may be most cost effective to give a therapeutic trial of iron. Fe²⁺ sulfate at a dose of 3 mg/kg of elemental iron once or twice daily between meals for 4 weeks is recommended as the standard of care. In children that respond, iron should be continued for 2 to 3 months to

replace storage iron pools, along with dietary intervention and patient education. If the anemia recurs, the work-up should include sources of occult blood loss. Higher doses of oral iron (6 mg/kg per day of elemental iron divided into two or three daily doses) are administered to older children. Parenteral iron therapy has a limited role and is rarely necessary.

For the macrocytic anemias in children, parenteral or oral folate may be administered in a dose of 1 to 3 mg daily, while vitamin B₁₂ deficiency due to congenital pernicious anemia would require lifelong vitamin B₁₂ supplementation.⁸² Dose and frequency need to be titrated according to clinical response and laboratory values. No data are currently available regarding the use of oral vitamin B₁₂ supplementation in children.

EVALUATION OF THERAPEUTIC OUTCOMES

Children with anemia as identified by labs are usually treated with further evaluation performed only if treatment response is inadequate. Therapeutic outcomes are assessed in children by checking Hgb, Hct, and RBC indices at 6 to 8 weeks after initiation of iron therapy. In premature infants, Hgb or Hct should be monitored weekly. Reticulocyte counts should be checked at 4 to 6 weeks after birth. Reticulocyte count, Hct, and absolute neutrophil counts are measured before and 1 to 2 weeks after starting EPO treatment. EPO is held for an absolute neutrophil count of less than 1,000 units/L. Serum ferritin levels may help evaluate infants not responding. Use of EPO in premature infants is not associated with the side effects frequently seen in adults.

HEMOLYTIC ANEMIA

PATHOPHYSIOLOGY

◀ Hemolytic anemia results from decreased survival time of RBCs secondary to destruction in the spleen or circulation. The severity of hemolytic anemia varies with the mechanism. Hemolysis may be mild, chronic, and compensated, or lifelong or acute, severe, and life-threatening.

The normal 120-day life span of a RBC comes from its inherent flexibility in passing through the microvasculature and spleen without disruption of the cell membrane or sequestration and phagocytosis by reticuloendothelial cells. Hemolysis, as defined by an RBC life span of less than 120 days, results from one of three primary defects that are intrinsic or extrinsic in origin: (1) membrane defects, (2) alterations in Hgb solubility or stability, and (3) changes in intracellular metabolic processes. Intrinsic defects are intracorporeal changes and are often genetically determined; extrinsic defects, or extracorporeal changes, are usually the cause of acquired hemolytic anemia. Acquired disorders result mainly from a direct effect on the membrane and less often from alterations in Hgb or metabolism. Table 99–12 lists examples of the different classes of hemolytic anemias.

Causes of hemolytic anemia in the younger patient differ from those in the elderly patient. Most younger patients exhibit congenital disease, whereas older patients most often experience autoimmune hemolytic anemia. A positive Coombs test is diagnostic in the latter group.

Alterations in Hgb solubility or stability, as seen with sickle cell anemia and the thalassemias, cause cell deformations leading to hemolysis (see Chap. 101 on sickle cell disease).

Finally, alterations in cell metabolism (enzymopathies) lead to hemolytic disease by changing cell dimensions and Hgb solubility.

The two major metabolic pathways necessary for normal RBC metabolism are the hexose monophosphate shunt pathway, with its associated enzyme systems, and the Embden-Myerhof pathway of anaerobic glycolysis. The former is responsible primarily for maintaining Hgb in the reduced state and thus preventing the formation of methemoglobin, while the latter metabolizes glucose to lactic acid, which leads to adenosine triphosphate formation.

The most common metabolic abnormality resulting in a hemolytic syndrome is glucose-6-phosphate dehydrogenase (G6PD) deficiency in the hexose monophosphate shunt pathway (see Chap. 102 on drug-induced hematologic disorders). Hgb is oxidized to methemoglobin and then to sulfhemoglobin. Heinz bodies of denatured Hgb form, resulting in damage to the RBC membrane. Hemolysis results from the action of the spleen and reticuloendothelial system, which normally removes damaged cells. The disease more typically occurs in whites of Mediterranean descent upon exposure to oxidant drugs (e.g., sulfamethoxazole and dapsone) and chemicals or with infection.

Some drugs and ingested toxins such as nitrofurantoin, cancer chemotherapy agents, phenazopyridine, sulfones, amyl nitrate, mothballs, paraquat, and hydrogen peroxide can cause direct oxidative damage to erythrocytes (see Chap. 102 on drug-induced hematologic disorders).

LABORATORY FINDINGS

Hemolytic anemias tend to be normocytic and normochromic. An increased reticulocyte count is evidence of an attempt to maintain RBC mass. A peripheral blood smear may reveal sickle cells, target cells, spherocytes, elliptocytes, and fragmented RBCs. Decreased haptoglobin is seen, caused by increased hemoglobin-haptoglobin

TABLE 99–12. Common Classes of Hemolytic Anemias

Intrinsic (intracorporeal; usually genetically inherited)

- Membrane defect
 - Spherocytosis and elliptocytosis
- Hemoglobin defect
 - Sickle cell anemia
 - Thalassemia syndrome
- Metabolic defect
 - Glucose-6-phosphate dehydrogenase (G6PD) deficiency
 - Many other enzyme deficiencies

Extrinsic

- Membrane defect
 - Autoimmune hemolytic anemias
 - Oxidants, may cause unstable hemoglobin to clump

complex formation. Lactate dehydrogenase increases secondary to release from RBCs; however, this is a very nonspecific enzyme.

Hemoglobinuria may result and an increase in indirect bilirubin often occurs.

► TREATMENT: Hemolytic Anemia

Therapy for hemolytic anemia consists of managing the underlying cause of the anemia. Clearly, avoidance of precipitating oxidant medications and chemicals in patients with G6PD deficiency is essential. Currently, there is no specific therapy that compensates for this en-

zyme deficiency. Steroids and other immunosuppressive agents have been used for management of autoimmune hemolytic anemias. In some instances, a splenectomy is indicated in an attempt to reduce RBC destruction.

ANEMIAS CAUSED BY ABNORMAL HEMOGLOBIN SYNTHESIS

A defect in Hgb synthesis, as well as acquired defects in EPO precursor cell metabolism, may cause changes in iron incorporation, producing a cell with an excess of nonheme iron within the cytoplasm. Called sideroblasts, these cells cause sideroblastic anemia, which is usually microcytic. Sideroblastic anemia can be congenital (hereditary, sex-linked in males) or acquired. The acquired forms can be either primary or secondary to drugs, toxins (e.g., lead or alcohol), or other disease states. Reduced copper content of the blood, known as hypocupremia, has long been associated with sideroblastosis. Excess zinc intake causes sideroblastic anemia by binding preferentially to copper, impairing copper absorption and leading to hypocupremia.⁸⁶ Primary acquired sideroblastic anemia is usually classified as myelodysplastic syndrome and may eventually transform into acute myeloblastic leukemia in some patients.

Other hereditary defects in heme synthesis can lead to an overproduction of heme precursors resulting in porphyria. The most common form, acute intermittent porphyria (AIP), results from a hereditary (autosomal dominant) partial deficiency in the enzyme uroporphyrinogen I synthetase, which is responsible for converting porphobilinogen to uroporphyrinogen. This deficiency inhibits the normal feedback mechanism of porphyrin synthesis, leading to an excess production of the heme intermediate pigments uroporphyrin I and coproporphyrin I. These products can be detected in abnormal amounts in urine and feces to confirm the diagnosis of AIP.

Neuropsychiatric, neuromuscular, autonomic dysfunction, and intense abdominal pain characterize AIP. In the liver, this enzyme deficiency results in the increased inducibility of abnormal heme intermediates by certain drugs. Drugs and agents known to induce hepatic cytochrome P450 enzymes or to increase hepatic heme turnover are theoretically capable of precipitating porphyria. Barbiturates, estrogens, alcohol, and heavy metals such as lead have been documented to induce porphyria in genetically susceptible people.^{87–89}

Genetic expression of an abnormal amino acid substitution in either the α or β globin chains can lead to a variety of hemoglobinopathies causing hemolytic diseases such as sickle cell anemia and thalassemia (see Chap. 101 on sickle cell disease). Four genes control α -chain production, and two genes regulate β -chain production. Thalassemias result when these genes are defective. If three or four α genes or both β genes are not functioning properly, a major thalassemia, which is often incompatible with life, develops. Fortunately, thalassemia minor (trait) is more common. The trait results from deficiencies in one or two α genes or one β gene. For example, if α genes are affected, normal β chains would accumulate in the cell and damage the membrane. This cell would then be prematurely cleared from the circulation, exacerbating the anemia. Surviving cells have inadequate Hgb and are microcytic and hypochromic.

The thalassemias are widely disseminated throughout parts of Africa, the Mediterranean region, the Middle East, the Indian sub-

continent, and southeast Asia, but occur sporadically in all racial groups.⁹⁰ Specifically, β -thalassemia is well recognized in persons of Greek and Italian descent while the α -thalassemic syndromes have an increased prevalence in African-American, American Indian, and Asian groups. It is frequently asymptomatic and requires no treatment. It is unusual for patients to need transfusions or EPO and the use of iron supplementation is not needed unless the patient has excessive blood loss and confirmed iron deficiency. It is important to distinguish thalassemia from IDA to avoid inappropriate iron therapy, as the excess iron may be deleterious and lead to possible organ damage. Although both are microcytic, the MCV tends to be much lower with thalassemia than with IDA. Also, target cells may be seen on the peripheral smear in patients with thalassemia. Finally, in contrast to patients with IDA, ferritin levels are normal or increased in patients with thalassemia. Hundreds of these abnormal Hgb diseases exist and are best diagnosed by Hgb electrophoresis.

PHARMACOECONOMIC CONSIDERATIONS

Anemia has an independent impact on many clinical, functional, and economic indicators, and evidence suggests that treatment can improve patient outcomes. The implications of treating anemia are becoming increasingly recognized and the elderly are one subset of patients where this can be appreciated.⁹¹ The cost of the comorbidities associated with anemia in the elderly is significant, as it has been linked to an increased risk of falls, dementia, depression, and general functional disability that increases the demand for long-term care services.⁹² However, the causal link between anemia and the costs of the above diseases is not known. Data to date have indicated that the treatment of anemia in elderly patients with renal failure and congestive heart failure is beneficial.⁹² However, more research is needed to assess the costs and benefits of therapies in individuals and in groups, especially when treatment of mild anemia is considered.⁹³

Although the direct medical costs of anemia are unknown, the direct costs of drug treatment must be weighed with the indirect costs associated with anemia.⁹⁴ The costs of laboratory tests used to diagnose anemia, the role of screening for anemia, and the prevention of anemia are all components that necessitate consideration in the pharmacoeconomic analysis. Anemia practice guidelines within medical subspecialties must take pharmacoeconomics into consideration as they are developed. Additionally, the frequency of blood transfusions must be considered, as it impacts cost and therapeutic decision making in patients.

For IDA, IV iron, though costly, has superior bioavailability compared with oral preparations. In select individuals the bioavailability advantage of parenteral iron over oral iron can be the difference in the achievement of a successful outcome. The benefits of using combination oral iron products designed to enhance absorption is probably not warranted.

In regard to vitamin B₁₂ deficiency, the average wholesale price for oral cyanocobalamin tablets and the IM injections is inexpensive. However, significant costs are added to the parenteral route, including the cost of a physician or nurse's visit for injection or home health visit. Additionally, many elderly patients may have difficulties attending additional clinic appointments due to transportation difficulties. An IM injection of cyanocobalamin costs between \$10 and \$25 for an in-office visit and between \$60 and \$100 for administration via home health care provider. A 90-day supply of 1-mg oral tablets can be purchased over the counter for approximately \$5. The disadvantage of the nasal gel is its cost as compared to the oral or parenteral route, with a 2-month supply costing approximately \$60.

For ACD, EPO is effective and safe, but expensive. Cost of IV iron is low compared with the cost of EPO. Since most patients are not symptomatic from this type of anemia, patients may actually feel no improvement with therapy. Symptom severity should be considered in the decision to use EPO. One study in patients with heart failure found use of erythropoietin to be highly cost-effective.⁹⁵ Transfusion use for ACD as an alternative to EPO must take into consideration cost, convenience, and risk of complications.

Total costs associated with EPO have not been evaluated for anemia of critical illness. Doses used for anemia of critical illness have been 40,000 units weekly, which costs approximately \$400. The cost of an RBC unit transfusion is about \$400, and two or three doses of EPO are needed to avoid one RBC transfusion. Future studies may need to assess the cost per unit of RBC saved, since these variables differ from institution to institution.

Other pharmacoeconomic factors to consider include morbidity and mortality of transfusion reactions, related infections, potential for medical errors, and availability of RBCs as a resource. Length of ICU and total hospital stay and length of time on mechanical ventilation are also key factors.

ABBREVIATIONS

ACD: anemia of chronic disease
 AIDS: acquired immunodeficiency syndrome
 AIP: acute intermittent porphyria
 AOP: anemia of prematurity
 CBC: complete blood count
 CDC: Centers for Disease Control and Prevention
 EPO: erythropoietin
 Fe²⁺: ferrous iron
 Fe³⁺: ferric iron
 G6PD: glucose-6-phosphate dehydrogenase
 Hct: hematocrit
 Hgb: hemoglobin
 HIV: human immunodeficiency virus
 IDA: iron deficiency anemia
 MCHC: mean corpuscular hemoglobin concentration
 MCH: mean corpuscular hemoglobin
 MCV: mean corpuscular volume
 MMA: methylmalonic acid
 NHANES: National Health and Nutrition Examination Survey
 RBC: red blood cell
 RDW: red blood cell distribution width
 TIBC: total iron-binding capacity
 WBC: white blood cells

COAGULATION DISORDERS

Betsy Bickert and Janet L. Kwiatkowski

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Hemophilia is an inherited bleeding disorder resulting from a congenital deficiency in factor VIII or IX.
- 2 The goal of therapy for hemophilia is to arrest bleeding when it occurs and to prevent bleeding episodes and their long-term complications.
- 3 Recombinant factor concentrates are usually first-line treatment for moderate and severe hemophilia because they have the lowest risk of infection.
- 4 The goal of therapy for von Willebrand disease is to improve von Willebrand factor and factor VIII levels.
- 5 Factor VIII concentrates that contain von Willebrand factor are the agents of choice for the treatment of type 3 von Willebrand disease, some type 2 von Willebrand disease, and for serious bleeding in type 1 von Willebrand disease.
- 6 Desmopressin acetate is often effective for the treatment of type 1 von Willebrand disease. It may also be effective for the treatment of some forms of type 2 von Willebrand disease.
- 7 The optimal approach for patients with disseminated intravascular coagulation remains to be determined. The goal of treatment is to diagnose and treat the underlying disease.
- 8 Prophylactic use of phytonadione can effectively prevent vitamin K–dependent bleeding in the newborn.

Coagulation disorders result from a decreased number of platelets, decreased function of platelets, coagulation factor deficiency, or enhanced fibrinolytic activity. A series of complex actions and reactions of procoagulant and anticoagulant events regulate blood flow. Maintenance of blood flow involves the interplay of four major components: (1) the vessel wall, (2) platelets, (3) the coagulation system, and (4) the fibrinolytic system.

The traditional view of the coagulation cascade consisted of intrinsic, extrinsic, and common pathways. Coagulation could be initiated via either the intrinsic or extrinsic pathways as depicted in Fig. 100–1. The extrinsic pathway is initiated by the exposure of tissue during trauma. The intrinsic pathway is initiated when circulating factor XII comes in contact with the subendothelial membrane. These two pathways converge at the activation of factor X, forming the common pathway. While the historical model in Fig. 100–1 shows the basic dependency of the various coagulation factors, it does not reflect the interactions with platelets and the endothelium. Thus it has been replaced by the cell-based model depicted in Fig. 100–2 that more accurately describes these interactions. This is known as the tissue factor pathway because it recognizes the central role of tissue factor in coagulation.

REGULATION OF HEMOSTASIS

COAGULATION FACTORS

Twelve plasma proteins are considered coagulation factors (Table 100–1). The coagulation factors can be divided into three groups on the basis of biochemical properties. These groups include vitamin K–dependent factors (II, VII, IX, and X), contact activation factors

(XI and XII, prekallikrein, high-molecular-weight kininogen), and thrombin-sensitive factors (V, VIII, XIII, and fibrinogen).

Coagulation factors circulate as inactive precursors (zymogens). Coagulation of blood entails a cascading series of proteolytic reactions. At each step, a clotting factor undergoes limited proteolysis and becomes an active protease (designated by a lowercase “a,” as in Xa). These coagulation factors play key roles in the coagulation pathway.

VESSEL WALL AND PLATELETS

Blood vessel walls and activated platelets play central roles in primary hemostasis. Damage to a vessel wall initiates vasoconstriction and the exposure of collagen and tissue factor to blood. This exposure initiates coagulation via the tissue factor pathway.

Platelet function in response to vascular injury includes four phases: (1) adhesion, (2) secretion, (3) aggregation, and (4) elaboration of procoagulant activity. Release of von Willebrand factor from activated platelets and fibrinogen from the endothelium causes adhesion of platelets at the site. Platelets release granular contents, such as adenosine diphosphate and thromboxane A₂ that lead to platelet aggregation. A platelet plug is formed that occludes the blood vessel lesion. Activated coagulation factors are generated at the site of bleeding on the activated platelets. Factor XIIIa cross-links fibrin and stabilizes the clot.¹

Unbound factors IIa, IXa, Xa, XIa, and XIIa are inactivated by antithrombin when they migrate to the endothelial cell surface. Heparin and heparin-like substances present on the surface of endothelial cells enhance the inhibitory capacity of antithrombin.¹ Thrombomodulin binds thrombin and activates protein C. Activated protein C and its cofactor, protein S, are vitamin K–dependent proteins

FIGURE 100-1. Cascade model of coagulation demonstrates activation via the intrinsic or extrinsic pathway. This model shows successive activation of coagulation factors proceeding from the top to the bottom where thrombin and fibrin are generated. PK, Prekallikrein; HK, high-molecular weight kininogen; TF, tissue factor. (Reproduced from Roberts HR et al. *Molecular biology and biochemistry of the coagulation factors and pathways of hemostasis*. In: Beutler et al. *Williams Hematology*, 6th ed. New York, McGraw-Hill, 2001, pp 1409–1434.)

that inactivate factor Va and VIIIa on the endothelial cell surface. These interactions localize the clotting to the site of injury and prevent clotting in the intact vascular system.

TISSUE FACTOR PATHWAY

Tissue factor is a membrane protein found in organs and surrounding the vasculature. Tissue factor is exposed to blood as a consequence of vessel wall damage or inflammatory cytokine release from vascular cells or monocytes.² Coagulation is initiated when factor VIIa binds to exposed or expressed tissue factor (see Fig. 100–2). The factor VIIa–tissue factor complex activates factors IX and X. Activated platelets form complexes with factor IXa-factor VIIIa (tenase) and factor

FIGURE 100-2. Cell-based model of hemostasis. TF, tissue factor; TFPI, tissue factor pathway inhibitor; vWF, von Willebrand factor. (Reproduced from Roberts HR et al. *Molecular biology and biochemistry of the coagulation factors and pathways of hemostasis*. In: Beutler et al. *Williams Hematology*, 6th ed. New York, McGraw-Hill, 2001, pp 1409–1434.)

Xa-factor Va (prothrombinase).² Tenase activates factor X and prothrombinase converts prothrombin to thrombin. Thrombin activates platelets and catalyzes the conversion of fibrinogen to fibrin. Thrombin also amplifies coagulation by activating factors V, VIII, and XI.

FIBRINOLYSIS

The coagulation system regulates fibrin clot formation, whereas the fibrinolytic system dissolves the polymerized clot and restores blood flow. As a regulatory mechanism to maintain blood flow, the fibrinolytic system removes fibrin deposits and prevents formation of unnecessary fibrin clots. It also contributes to the localized repair of damaged endothelium.

Plasminogen is the primary compound of the fibrinolytic enzyme system. Plasminogen activators (tissue plasminogen activator and urokinase plasminogen activator) are released in response to thrombin, venous stasis, physical exercise, or ischemia.³ Activators convert plasminogen to plasmin in the presence of fibrin. Plasmin enzymatically digests fibrin, dissolves the clot, and releases a number of fibrin degradation products. The interaction between plasminogen activators, plasminogen, and fibrin restricts the fibrinolytic activity to the site of the clot. Plasminogen-activator inhibitor type 1 (PAI-1) blocks the plasminogen activators while antiplasmin directly inhibits circulating plasmin to prevent systemic fibrinolysis.³

TABLE 100-1. Blood Coagulation Factors

| Factor ^a | Synonym | Biologic Half-life | Blood Product Source |
|---------------------|----------------------------------|--------------------|--|
| I | Fibrinogen | 100–150 h | Cryoprecipitate (200–300 mg/bag) |
| II | Prothrombin | 50–80 h | FFP, plasma, PCC |
| V | Proaccelerin | 24 h | FFP |
| VII | Proconvertin | 6 h | Recombinant VIIa, FFP, plasma, PCC |
| VIII | Antihemophilic factor | 12 h | FFP, PCC, factor concentrates, cryoprecipitate |
| IX | Christmas factor | 24 h | FFP, PCC, factor concentrates |
| X | Stuart-Power factor | 25–60 h | FFP, plasma, PCC |
| XI | Plasma thromboplastin antecedent | 40–80 h | FFP, plasma |
| XII | Hageman factor | 50–70 h | |
| XIII | Fibrin-stabilizing factor | 150 h | FFP, plasma, cryoprecipitate |

^aCoagulation factors are numbered with roman numerals in order of their discovery. The most common synonyms are listed. Factor III (tissue factor) and factor IV (calcium ions) have been omitted. There is no factor VI. FFP, fresh frozen plasma; PCC, prothrombin complex concentrate.

SIMPLE LABORATORY TESTS

The diagnosis of coagulation disorders can be established from a detailed clinical history, a physical examination, and laboratory test results. The most common screening tests include bleeding time, prothrombin time, activated partial thromboplastin time, thrombin time, and platelet count.¹ The results of these standard laboratory procedures can distinguish bleeding disorders caused by defects in the intrinsic, extrinsic, and common coagulation pathways (see Fig. 100–1), or from alterations in the number of functioning platelets. Specific assays of individual coagulation factors and platelet function tests can be performed after abnormalities are identified by initial screening tests. The following is a brief review of widely available tests. These tests are summarized in Table 100–2.

BLEEDING TIME

Bleeding time assesses platelet and capillary function. Bleeding time reflects the time to cessation of bleeding following a standardized skin cut. Patients with an abnormal bleeding time but a normal platelet count are arbitrarily designated as having qualitative abnormalities of platelet function. Such patients include those with von Willebrand disease, those who have recently ingested various antiplatelet drugs (i.e., aspirin), those with renal failure, those with fibrinogen disorders or with abnormal blood vessels.

PROTHROMBIN TIME

The prothrombin time (PT) assesses the function of the extrinsic system and common pathway of the coagulation system.⁴ In particular,

the test measures the activity of the vitamin K–dependent proteins (factors II, VII, IX, and X, and proteins C and S). Prothrombin time reflects the time required for fibrin strands to appear after the addition of tissue thromboplastin to a patient’s plasma. Thus the PT yields evidence about the current synthetic capacity of the liver, the adequacy of vitamin K absorption, and the inhibition of clotting factor synthesis by warfarin. Prothrombin time is expressed as an International Normalized Ratio to normalize the values due to variability of the test reagents.⁴

ACTIVATED PARTIAL THROMBOPLASTIN TIME

The activated partial thromboplastin time (aPTT) measures the activity of the intrinsic system and common pathway (factors II, V, X, VIII, IX, XI, XII, high-molecular-weight kininogen, prekallikrein, and fibrinogen). aPTT reflects the time required for a fibrin clot to form after a partial thromboplastin, calcium, and an activating agent are added to the patient’s plasma. aPTT is widely used for monitoring heparin therapy.

THROMBIN TIME

The thrombin time measures the conversion of fibrinogen to fibrin and is affected by quantitative and qualitative abnormalities of fibrinogen and the presence of thrombin inhibitors or fibrinogen degradation products. The thrombin time measures the time required for the formation and the appearance of the fibrin clot after thrombin is added to plasma. It may be used to monitor the effect of systemic fibrinolytic therapy and can be modified for monitoring heparin therapy.

TABLE 100–2. Laboratory Procedures

| Procedure | Identifies | Cause of Prolonged Value | Clinical Manifestations |
|--|--|--|--|
| Bleeding time | Platelet number and function | Thrombocytopenia Inherited qualitative platelet defects von Willebrand disease Antiplatelet drugs Factor V or XI deficiency Afibrinogenemia | Bleeding from the gums Easy bruising Bleeding following surgery or tooth extraction Epistaxis Menorrhagia |
| Prothrombin time (PT) | Factors I, II, V, VII, X | Newborn Vitamin K deficiency Inherited factor deficiencies Warfarin Liver disease Lupus anticoagulant ^a Afibrinogenemia | Bleeding following surgery, trauma, etc Easy bruising |
| Activated partial thromboplastin time (aPTT) | Factors I, II, V, VIII, IX, X HMWK Prekallikrein Factor XII Factor XI | Inherited factor deficiencies Lupus anticoagulant ^a Heparin therapy Liver disease Afibrinogenemia | Joint and muscle bleeding Bleeding after surgery, trauma, etc No bleeding manifestations Increased incidence of thrombotic disease possible with factor XII deficiency Variable bleeding tendency Bleeding following surgery, trauma, etc |
| Thrombin time (TT) | Fibrinogen Inhibitors of fibrin aggregation | Afibrinogenemia Heparin therapy | Lifelong hemorrhagic disease |

^aBleeding manifestations dependent on factor levels.
HMWK, high-molecular-weight kininogen.

CONGENITAL COAGULATION DISORDERS

HEMOPHILIA

1 Hemophilia is a bleeding disorder that results from a congenital deficiency in a plasma coagulation protein. Hemophilia A (classic hemophilia) is caused by a deficiency of factor VIII, while hemophilia B (Christmas disease) is caused by a deficiency of factor IX. The incidence of hemophilia A is approximately 1 in 5,000 male births.⁵⁻⁷ Hemophilia B occurs less commonly, with only one-fourth the incidence of hemophilia A.^{5,7} There are no significant racial differences in the incidence of hemophilia.

Thirty percent of severe hemophilia patients have a negative family history, presumably representing a spontaneous mutation. Both hemophilia A and hemophilia B are recessive X-linked diseases; that is, the defective gene is located on the X chromosome. In general, the disease affects only males, while females are carriers. Affected males have the abnormal allele on their X chromosome and no matching allele on their Y chromosome. Thus their sons would be normal (assuming the mother is not a carrier), and their daughters would be obligatory carriers. Female carriers have one normal allele, and therefore do not usually have a bleeding tendency. Sons of a female carrier and a normal male have a 50% chance of being hemophiliacs, whereas daughters have a 50% chance of being carriers. Thus there is a “skipped generation” mode of inheritance in which the female carriers, who are the children of hemophiliacs, do not express the disease, but can pass it on to the next male generation.

Hemophilia has been observed in a small number of females. This can occur if both factor VIII or IX genes are defective, if a female patient has only one X chromosome, as in Turner’s syndrome,⁸ or if the normal X chromosome is excessively inactivated through a process called lyonization.

In 1984, researchers isolated and cloned the human factor VIII gene.^{9,10} It is a large gene, consisting of 186 kilobases (kb).^{5,10} More than 800 unique mutations in the factor VIII gene, including point mutations, deletions, and insertions, have been reported (<http://europium.csc.mrc.ac.uk>). Deletions and nonsense mutations are often associated with the more severe forms of factor VIII deficiency, because no functional factor VIII is produced. In 1993, researchers identified an inversion in the factor VIII gene at intron 22 that accounts for about 45% of severe hemophilia A gene abnormalities.¹¹ That discovery has greatly simplified carrier detection and prenatal diagnosis for families with this gene mutation. A more recently discovered inversion mutation involving intron 1 of the factor VIII gene accounts for an additional 5% of severe hemophilia mutations.¹²

The factor IX gene, cloned and sequenced in 1982,¹³ consists of only 34 kb and thus is significantly smaller than the factor VIII gene.^{5,9} Unlike the factor VIII gene in patients with severe hemophilia A, the factor IX gene in patients with hemophilia B has no predominant mutation. Direct gene mutation analysis is simpler in hemophilia B because of the smaller gene size, and to date more than 800 different mutations have been reported (www.kcl.ac.uk/ip/petergreen/haemBdatabase.html). Most of these mutations are single base pair substitutions. Approximately 3% of factor IX gene mutations are deletions or complex rearrangements, and the presence of these mutations is associated with a severe phenotype.¹⁰

Hemophilia B Leiden is a rare variant in which factor IX levels are initially low, but rise at puberty. This phenotype results from a mutation in the promoter region of the gene that is apparently ameliorated by the action of testosterone.^{5,14} The identification of this genotype is clinically important, because it confers a better prognosis.

CLINICAL PRESENTATION

The characteristic bleeding manifestations of hemophilia include ecchymoses, bleeding into joint spaces (hemarthroses), muscle hemorrhages, and excessive bleeding after surgery or trauma. The severity of clinical bleeding generally correlates with the degree of deficiency of factor VIII or factor IX. Factor VIII and factor IX activity levels are usually measured in units per milliliter with 1 unit/mL representing 100% of the factor found in 1 mL of normal plasma. Normal plasma levels range from 0.5 to 1.5 units/mL.⁵ Patients with less than 0.01 unit/mL (1%) of either factor are classified as severe hemophiliacs; those with 0.01 to 0.05 unit/mL (1% to 5%) are moderate hemophiliacs, and those with greater than 0.05 unit/mL (5%) are mild hemophiliacs (Table 100-3). Patients with severe disease often experience frequent spontaneous hemorrhages and joint space bleeding, while those with moderate disease have excessive bleeding following trauma and rarely experience spontaneous hemarthroses. Patients with mild hemophilia may have so few symptoms that their condition is undiagnosed for many years, and they usually have excessive bleeding only after significant trauma or surgery. Occasionally those with severe disease (less than 1% factor activity) may not display a severe phenotype; conversely, some with milder forms of the disease may have more severe bleeding symptomatology. Patients with hemophilia usually present with clinical manifestations after the age of 1 year, when they begin to walk and increase their risk of bleeding.

TABLE 100-3. Laboratory and Clinical Manifestations of Hemophilia

| | Severe (<0.01 units/mL) | Moderate (0.01-0.05 units/mL) | Mild (>0.05 units/mL) |
|--|----------------------------|----------------------------------|---|
| Age at onset | ≤1 year | 1-2 years | 2 years-adult |
| Neonatal symptoms | | | |
| PCB: | Usually | Usually | Rare |
| ICH: | Occasionally | Uncommonly | Rare |
| Muscle/joint hemorrhage | Spontaneous | Minor trauma | Minor trauma |
| CNS hemorrhage | High risk | Moderate risk | Rare |
| Postsurgical hemorrhage (without prophylaxis) | Frank bleeding, severe | Wound bleeding, common | Wound bleeding, with factor <0.3 units/mL |
| Oral hemorrhage following trauma, tooth extraction | Usual | Common | Often |

Normal range of factor VIII/IX activity level is 0.5-1.5 units/mL (50%-150%). 1 unit/mL corresponds to 100% of the factor found in 1 mL of normal plasma. CNS, central nervous system; ICH, intracranial hemorrhage; PCB, postcircumcisional bleeding.

CLINICAL PRESENTATION OF HEMOPHILIA

SIGNS AND SYMPTOMS

Ecchymoses
Hemarthrosis (especially knee, ankle, and elbow)
Joint pain
Joint swelling and erythema
Decreased range of motion
Muscle hemorrhage
Swelling
Pain with motion of affected muscle
Signs of nerve compression
Potential life-threatening blood loss, especially with thigh bleeding
Mouth bleeding with dental extractions or trauma
Genitourinary bleeding
Hematuria
Intracranial hemorrhage (spontaneous or following trauma), with headache, vomiting, change in mental status, and focal neurologic signs
Excessive bleeding with surgery

LABORATORY TESTING

Prolonged aPTT
Decreased factor VIII/factor IX level
Normal PT
Normal platelet count
Normal von Willebrand factor antigen and activity

DIAGNOSIS

The diagnosis of hemophilia should be considered in any male with unusual bleeding. A family history of bleeding is also helpful in the diagnosis, but this is absent in up to one-third of patients.¹⁵ Brothers of patients with hemophilia should be screened; sisters should have carrier testing.

Recent advances in molecular genetic analysis have greatly improved the accuracy of carrier status evaluation. Thus female relatives of patients with hemophilia who are at risk of being carriers for the disorder should be tested. Additionally, the appropriate factor level should be measured in female carriers to identify those with levels less than 0.3 units/mL (30%) who might themselves be at risk of bleeding.

Patients with severe hemophilia A should be tested for the common factor VIII gene inversions. If the patient has this mutation, family members should undergo testing to determine if they also have the mutation and thus are carriers. In those patients with hemophilia A who lack the inversion mutation, other methods to determine the carrier status of their family members are available.¹⁶ Techniques to determine carrier status in families with hemophilia B are similar, although no predominant mutation like the factor VIII inversion has been found. The smaller size of the factor IX gene facilitates direct DNA mutational analysis.¹⁶

Hemophilia can be diagnosed prenatally by chorionic villus sampling in the tenth to eleventh gestational week or by amniocentesis after 15 weeks' gestation.^{5,17} Fetal blood can be sampled and assayed directly for factor VIII levels by the eighteenth to twentieth week of gestation.^{5,17} This procedure is less useful for diagnosing factor IX deficiency, because factor IX levels are physiologically low in fetuses and infants.⁵

► TREATMENT: Hemophilia

The comprehensive care of hemophilia requires a multitude of health care professionals. The patient is best managed in specialized centers with trained personnel and appropriate laboratory, radiologic, and pharmaceutical services. The health care team includes hematologists, orthopedic surgeons, nurses, physical therapists, dentists, genetic counselors, psychologists, pharmacists, case managers, and social workers.

Patients with hemophilia should receive routine immunizations, including immunization against hepatitis B. Hepatitis A vaccine is also recommended for patients with hemophilia because of the risk (albeit small) of transmitting the causative agent through factor concentrates.¹⁸ The use of a small-gauge needle can prevent excessive bleeding. Some health care providers advocate giving immunizations subcutaneously rather than intramuscularly to decrease the risk of hematoma formation.

A few special considerations apply to the perinatal care of male infants of hemophilia carriers. Intracranial or extracranial hemorrhage has been estimated to occur in 1% to 4% of newborns with hemophilia.^{19,20} Vacuum extraction and forceps delivery increase the risk of cranial bleeding. Elective cesarean section has not prevented intracranial bleeding. There is no clear consensus on the optimal mode of delivery or the use of prophylactic factor replacement in male infants of hemophilia carriers.¹⁹ Circumcision should be postponed until a diagnosis of hemophilia is excluded. Factor levels can be assayed from cord blood samples or from peripheral venipuncture. Arterial puncture should be avoided because of the risk of hematoma formation.

◀ Intravenous factor replacement therapy to treat or prevent bleeding is the mainstay of treatment for hemophilia. It is common

for families to learn how to treat patients with factor concentrate at home. Parents may learn to infuse factor for younger children, and older children and adult patients may learn self-administration. Home health care nursing support may also be helpful, particularly for the youngest patients in whom venous access may be difficult. Administration of factor at home is more convenient for families and allows for earlier treatment of acute bleeding episodes. However, serious bleeding episodes always require medical evaluation.

■ HISTORY OF HEMOPHILIA TREATMENT

Therapy for hemophilia has undergone dramatic advances over the past few decades. Fifty years ago, the administration of fresh frozen plasma was the only available treatment. The introduction of cryoprecipitate in the early 1960s allowed more specific therapy for hemophilia A.^{5,7} Intermediate-purity factor VIII and IX concentrates became available in the 1970s.^{5,7} Plasma-derived factor concentrates are made from the donations of thousands of people. Contamination of plasma pools with hepatitis B, hepatitis C, and the human immunodeficiency virus (HIV) during the late 1970s and early 1980s resulted in transmission to most patients with severe hemophilia. Since the mid-1980s, plasma-derived concentrates have been manufactured with a variety of virus-inactivating techniques including dry heat, pasteurization, and treatment with chemicals (e.g., solvent detergent mixtures).⁷ Since 1986, no transmission of HIV through factor concentrates to patients with hemophilia in the United States has been reported.^{5,7}

Protein purification, introduced in the 1990s, produced high-purity concentrates with increased amounts of factor VIII or factor IX relative to the product’s total protein content. Recombinant factor VIII and then factor IX also became available.⁵ The first-generation recombinant factor VIII products utilize human and animal proteins in culture and add human albumin as a protein stabilizer.⁷ Second-generation recombinant factor VIII concentrates removed albumin as a protein stabilizer, and the third-generation products lack human and animal proteins in the culture media.²¹ Finally, gene therapy for the treatment of hemophilia is now in the early stages of clinical trials.

HEMOPHILIA A

Table 100–4 summarizes the factor VIII products currently available in the United States. Most patients are treated with high-purity products. In general, products that have the lowest risk of transmitting infectious disease should be used. Thus recombinant products are generally used when available, rather than plasma-derived products.

RECOMBINANT FACTOR VIII

Derived from cultured Chinese hamster ovary cells or baby hamster kidney cells transfected with the human factor VIII gene,²² recombinant factor VIII is produced from DNA technology. Because it is not derived from blood donations, the risk of transmitting infections through the administration of recombinant factor VIII is low. For this reason, recombinant products are generally favored over plasma-derived products. There is still a small risk of viral infection of the cell lines used to produce the clotting factor.²³ Furthermore, human and/or animal proteins are utilized in the production process of some recombinant products.²¹ Therefore these products have a theoretical risk of transmitting infection, although hepatitis and HIV infection have never been reported with their use.⁵ The presence of parvovirus B19 DNA has been reported in recombinant factor VIII products.²⁴ First-generation recombinant factor VIII products contain human albumin as a stabilizing protein.⁷ Second-generation recombinant factor VIII products add sucrose instead of human albumin as a stabilizer, but human albumin is utilized in the culture process. One second-generation product (ReFacto) has the B domain of the factor VIII gene

TABLE 100–4. Factor Concentrates

| Brand Name | Product Type | Viral Inactivation or Exclusion Method | Other Contents |
|---------------------------------|------------------------------|--|--|
| Factor VIII concentrates | | | |
| Alphanate | Plasma | Solvent detergent, dry heat | Albumin, heparin, vWF |
| Hemophil M | Plasma | Solvent detergent, monoclonal antibody | Albumin |
| Humate-P | Plasma | Pasteurization | Albumin, vWF |
| Koāte-DVI | Plasma | Solvent detergent, dry heat | Albumin, heparin, vWF |
| Monarc-M | Plasma | Solvent detergent, monoclonal antibody | Albumin |
| Monoclate P | Plasma | Pasteurization, monoclonal antibody | Albumin |
| Advate | Recombinant | None | Albumin |
| Bioclate | Recombinant | None | Albumin |
| Helixate FS | Recombinant | Solvent detergent | Albumin (fermentation only); sucrose |
| Kogenate | Recombinant | Monoclonal antibody | Albumin |
| Kogenate FS | Recombinant | Solvent detergent, monoclonal antibody | Albumin (fermentation only); sucrose |
| Recombine | Recombinant | Monoclonal antibody | Albumin |
| ReFacto | Recombinant B domain deleted | None | Albumin (fermentation only); sucrose |
| Factor IX concentrates | | | |
| AlphaNine SD | Plasma | Solvent detergent, filtered | Heparin |
| Mononine | Plasma | Monoclonal antibody, ultrafiltration | Heparin |
| Benefix | Recombinant | None | |
| APCC | | | |

| Hyate:C | Porcine VIII | Freeze-dried | Citrate |

APCC, activated prothrombin complex concentrate; PCC, prothrombin complex concentrate; vWF, von Willebrand factor.

deleted, yielding a smaller protein product.²⁵ This B domain does not appear to be necessary for coagulation function. Third-generation recombinant factor VIII products contain no human protein in either the culture or in the stabilization processes.²¹

Clinical trials have demonstrated that recombinant factor VIII products are comparable in effectiveness to the plasma-derived products.²⁵ The risk of developing an inhibitory antibody to factor VIII in patients with severe hemophilia A with the use of recombinant factor VIII is 28% to 33%.²⁵ This risk is higher than that reported with plasma-derived products. The difference may be partly attributable to more frequent screening for inhibitors in the recombinant product trials, with the detection of transient inhibitors that might have been missed in the trials with plasma-derived products.²⁶ However, the incidence of high-responding inhibitors, which are clinically significant, was higher in trials with the use of recombinant factor VIII compared with the use of a single plasma-derived product.²⁶

■ PLASMA-DERIVED FACTOR VIII PRODUCTS

Several different plasma-derived factor VIII products are available (see Table 100–4). These products are derived from the plasma of thousands of donors, and therefore potentially can transmit infection. Donor screening, testing plasma pools for evidence of infection, viral reduction through purification steps, and viral inactivation procedures (e.g., dry heat, pasteurization, and solvent detergent treatment) have all resulted in a safer product.²¹ No cases of HIV transmission from factor concentrates have been reported since 1986.⁵ However, there have been isolated reports of hepatitis C infection with the use of plasma-derived products.⁵ Additionally, there have been outbreaks of hepatitis A viral infections associated with plasma-derived products, likely because solvent detergent treatment does not inactivate this nonenveloped virus.¹⁸ Parvovirus has also been reported to be present in both plasma-derived and recombinant factor VIII products.^{24,27} Finally, there remains concern about the possibility for infection with as yet unidentified viruses that currently used methods would not inactivate.

Factor VIII concentrates can be classified according to their level of purity, which refers to the specific activity of factor VIII in the product. Cryoprecipitate is a low-purity product, containing a specific factor VIII activity level of less than 5 units/mg of protein.⁵ This product is no longer considered a primary treatment for factor VIII deficiency in countries where factor VIII concentrates are available, because cryoprecipitate does not undergo a viral inactivation process. Intermediate-purity products have a specific activity of factor VIII of 1 to 10 units/mg of protein, while high-purity products have a specific activity of 50 to 1,000 units/mg of protein.⁵ Ultrahigh-purity plasma-derived products are prepared with monoclonal antibody purification steps and have a specific activity of 3,000 units/mg of protein prior to the addition of albumin as a stabilizer.

■ FACTOR VIII CONCENTRATE REPLACEMENT

Appropriate dosing of factor VIII concentrate depends on several considerations, including the half-life of the infused factor, the patient's body weight, and the volume of distribution. The presence or absence of an inhibitory antibody to factor VIII and the titer of this antibody also influence treatment. Recovery studies, which measure the immediate postinfusion factor level, and survival studies, which assess the half-life of the factor, can establish patient-specific pharmacokinetics. The location and magnitude of the bleeding episode determine the

percent correction to target, as well as the duration of treatment. Serious or life-threatening bleeding requires peak factor levels of greater than 0.75 to 1 unit/mL (75% to 100%), while less severe bleeding may be treated with a goal of 0.3 to 0.5 unit/mL (30% to 50%) peak plasma levels. Table 100–5 provides general guidelines for the management of bleeding in different locations.

Factor VIII is a large molecule that remains in the intravascular space. Therefore the plasma volume, approximately 50 mL/kg, can be used to estimate the volume of distribution.²⁸ In general, each unit of factor VIII concentrate infused per kilogram of body weight yields a 2% rise in plasma factor VIII levels. The following equation may be used to calculate an initial dose of factor VIII:

$$\text{Factor VIII (units)} = (\text{desired level} - \text{baseline level}) \\ \times 0.5 \times (\text{weight in kilograms})$$

The baseline level is usually omitted from the equation because it is negligible compared to the desired level. The half-life of factor VIII ranges from 8 to 15 hours.²⁸ It is generally necessary to administer half of the initial dose approximately every 12 hours to sustain the desired level of factor VIII. A single treatment may be adequate for minor bleeding such as mouth bleeding or slight muscle hemorrhages. However, because of the potential for long-term joint damage with hemarthroses, 2 or 3 days of treatment are often recommended for these bleeds. Serious bleeding episodes may require maintenance of 70% to 100% factor activity for a week or longer. As previously mentioned, factor VIII dosing depends on several variables and each case must be considered individually. Individual pharmacokinetics may help guide treatment, particularly for serious bleeding episodes.

Alternatively, factor VIII may be administered as a continuous infusion when prolonged treatment is required, such as in the perioperative period or for serious bleeding episodes. Infusion rates ranging from 2 to 4 units/kg per hour are usually employed in fixed dose continuous infusion protocols, with the aim of maintaining a steady-state level of 60% to 100%.^{29,30} The administration of factor concentrate via continuous infusion may reduce factor requirements by 20% to 50%, because unnecessarily high peaks of factor VIII that occur with bolus injections are avoided.³⁰ A gradual decrease in factor VIII clearance during the first 5 to 6 days of treatment contributes to the lower factor concentrate requirements.²⁹ Daily factor level monitoring can help determine the appropriate rate of infusion.

The administration of factor VIII concentrate via continuous infusion has been shown to be safe and effective,²⁹ and it may be more convenient than bolus therapy for hospitalized patients. The advantages of continuous infusion include the maintenance of a steady-state plasma level, with avoidance of potentially subtherapeutic trough levels, and a reduction in cost associated with decreased factor requirements. A potential side effect with continuous infusion is thrombophlebitis at the delivery site. Concomitant infusion of saline or the addition of heparin (2 to 5 units/mL) to the infusion bag can minimize this risk.^{29,30} Bacterial contamination of the concentrate is another theoretical concern. However, studies have shown that the products can remain sterile for more than a week if prepared and kept under appropriate conditions.²⁹ Finally, concerns about the stability of the formulations appear to be unwarranted in that most of the high-purity factor VIII concentrates have been shown to remain stable for at least 7 days after reconstitution.³⁰

■ OTHER PHARMACOLOGIC THERAPY

Treatment with 1-desamino-8-D-arginine vasopressin (desmopressin acetate) is often adequate for minor bleeding episodes in patients with

TABLE 100–5. Guidelines for Factor Replacement Therapy for Hemorrhage in Hemophilia A and B

| Site of Hemorrhage | Desired Hemostatic Factor Level (% of Normal) | Comments |
|------------------------|---|---|
| Joint | 50%–70% | Rest/immobilization/physical therapy rehabilitation following bleed; several doses may be necessary to prevent or treat target joint |
| Muscle | 30%–50% for most sites 70%–100% for thigh, iliopsoas, or nerve compression | Risk of significant blood loss with femoral/retroperitoneal bleed; bed rest for iliopsoas or other retroperitoneal bleeding |
| Oral mucosa | 30%–50% | May try antifibrinolytic or topical thrombin prior to factor replacement for minor bleeding; higher factor levels may be needed for tongue swelling or risk of airway compromise; antifibrinolytic therapy should be used following factor replacement; do not use with APCCs or PCCs |
| Gastrointestinal | Initially 100%, then 30% until healing occurs | Endoscopy is highly recommended; antifibrinolytic therapy may be useful |
| Hematuria | 30% if no trauma 70%–100% if traumatic | If no pain or trauma, consider bed rest and fluids for 24 hours; factor should be given if hematuria persists; evaluate if hematuria persists; if trauma to abdomen or back, perform imaging and give aggressive factor replacement |
| Central nervous system | Initially 100%, then 50%–100% for 10–14 days | Anticonvulsants may be given preventively with neurologic follow-up; lumbar puncture requires prophylactic factor coverage |
| Trauma or surgery | Initially 100%, then 50% until wound healing complete | Perioperative and postoperative management plan must be in place preoperatively; evaluation for inhibitors is crucial prior to elective surgery |

APCC, activated prothrombin complex concentrate; PCC, prothrombin complex concentrate.

mild hemophilia A. A synthetic analog of the antidiuretic hormone vasopressin, desmopressin causes release of von Willebrand factor and factor VIII from endogenous storage sites. It appears to be most effective in those with higher baseline factor VIII levels (0.1 to 0.15 units/mL).³¹ The recommended dose of desmopressin is 0.3 mcg/kg diluted in 50 mL of normal saline and infused IV over 15 to 30 minutes.^{5,31} Patients with mild or moderate hemophilia A should have a desmopressin trial performed to determine their response to this medication. At least a twofold rise in factor VIII to a minimal level of 0.3 units/mL within 60 minutes is considered an adequate response.³² In adults with mild hemophilia A, the response rate to desmopressin has been reported to be 80% to 90%.³² One study reported a lower response rate of 57% in pediatric patients with mild hemophilia A.³² Furthermore, the response rate was related to age; the mean age of those who responded to desmopressin was 5.2 years compared with 3 years for those who failed to respond. Seven of the eleven children who failed to respond to desmopressin initially demonstrated an adequate response when the desmopressin challenge was repeated at an older age.

The infusion of desmopressin may be repeated daily for up to 2 to 3 days. Tachyphylaxis, an attenuated response with repeated dosing, may develop after that. The factor increase after the second dose of desmopressin is approximately 30% lower than after the initial dose.³¹

Factor concentrate therapy may be necessary if the patient requires further treatment. Factor levels should be measured to ensure that an adequate response has been achieved. Treatment with desmopressin will not result in hemostasis for patients who have severe hemophilia and for those who are only marginally responsive. Also, it should not be used as primary therapy for life-threatening bleeding episodes such as intracranial hemorrhage or for major surgical procedures when a minimum factor VIII concentration of 0.7 to 1 unit/mL is required.³¹

Desmopressin may be administered intranasally via a concentrated nasal spray.³¹ It effectively increases factor VIII levels, but its peak effect occurs 60 to 90 minutes after administration, somewhat longer than with desmopressin administered intravenously.^{5,31,33} The dosage is one spray (150 mcg) for children who weigh less than 50 kg and two sprays (300 mcg) for those who weigh more than 50 kg.³³ The nasal spray may serve as an alternative to the intravenous formulation, especially in patients with mild bleeding episodes.

Very few adverse effects are associated with desmopressin. The most commonly observed side effect is facial flushing.³¹ Less frequently reported side effects include mild headaches, increased heart rate, and decreased blood pressure. Thrombosis is a rare complication associated with desmopressin.⁵ Because of its antidiuretic effects, desmopressin also has the potential to cause water

retention, which may lead to severe hyponatremia. This may be a particular problem in children less than 1 to 2 years old, in whom hyponatremic seizures have been reported.^{5,31} Therefore desmopressin should be used with caution in this age group.^{31,32} Patients with congestive heart failure may also be at increased risk of developing hyponatremia with the use of desmopressin.³¹ Mild fluid restriction and monitoring of urine output are also recommended with desmopressin administration.⁵

Antifibrinolytic therapy inhibits clot lysis and therefore is a useful adjunctive therapy in the treatment of hemophilia. These antifibrinolytic agents are particularly beneficial in the treatment of oral bleeding because of the high concentration of fibrinolytic enzymes present in saliva. Two currently available antifibrinolytics are aminocaproic acid and tranexamic acid. Aminocaproic acid is given at a dosage of 100 mg/kg (maximum 6 g) every 6 hours and may be administered orally or intravenously.⁵ The dosage of tranexamic acid is 25 mg/kg (maximum 1.5 g) orally every 8 hours or 10 mg/kg (maximum 1 g) intravenously every 8 hours.^{5,34}

■ HEMOPHILIA B

Therapeutic options for hemophilia B have improved greatly over the past several years, first with the development of monoclonal antibody-purified plasma-derived products, and then with the licensure of recombinant factor IX. Products that are currently available in the United States for treatment of hemophilia B are listed in Table 100-4.

■ RECOMBINANT FACTOR IX

First marketed in the United States in 1996,^{5,7} recombinant factor IX is produced in Chinese hamster ovary cells transfected with the factor IX gene. Blood and plasma products are not used to produce recombinant factor IX nor to stabilize the final product; thus recombinant factor IX has an excellent viral safety profile.³⁵ Clinical trials have shown the product to be safe and efficacious in the treatment of acute bleeding episodes and in the management of bleeding associated with surgical procedures.^{36,37} Although the half-life of recombinant factor IX is similar to that of the plasma-derived products, recovery is approximately 28% lower.³⁷ As a result, doses of recombinant factor IX concentrate must be higher than those of plasma-derived products to achieve equivalent plasma levels. Because individual pharmacokinetics may vary, recovery and survival studies should be performed to determine optimal treatment. Recombinant factor IX is often considered the treatment of choice for hemophilia B.

■ PLASMA-DERIVED FACTOR IX PRODUCTS

High-purity factor IX plasma concentrates have been available in the United States since the early 1990s.⁵ These products are derived from plasma through biochemical purification and monoclonal immunoaffinity techniques. Other viral inactivation measures, such as solvent detergent or chemical treatment, are also employed.

Before the high-purity products were approved for use, hemophilia B patients had been treated with factor IX concentrates that also contained other vitamin K-dependent proteins (factors II, VII, and X), known as prothrombin complex concentrates (PCCs). These products contain small amounts of activated factors generated during processing, and their use has been associated with thrombotic

complications, including deep venous thrombosis, pulmonary embolism, myocardial infarction, and disseminated intravascular coagulation (DIC).^{38,39} The risk of such complications is highest in patients who are receiving high or repeated doses of PCCs, in those who have liver disease, in neonates, and in patients who have experienced crush injuries or who are undergoing major surgery.³⁹ Concomitant use of PCCs and antifibrinolytics should be avoided because of the risk of thrombosis.

Because of the lower purity of PCCs and their thrombogenic potential, these products are not first-line treatment for hemophilia B, although they are still used in the treatment of patients with hemophilia A or B who have developed inhibitory antibodies against factor VIII or factor IX, respectively. High-purity factor IX concentrates have excellent efficacy in the treatment of bleeding episodes and in the control of bleeding associated with surgical procedures.⁴⁰ Their viral safety profile has also been reported to be excellent,⁴⁰ and the risk of thromboembolic complications is low.⁵

■ FACTOR IX CONCENTRATE REPLACEMENT

Factor IX is a relatively small protein. Unlike factor VIII, it is not limited to the intravascular space, but also passes into the extravascular compartment.²⁸ This results in a volume of distribution that is approximately twice that of factor VIII. In general, for plasma-derived factor IX concentrates, each unit of factor IX infused per kilogram of body weight yields a 1% rise in the plasma level of factor IX (range, 0.67% to 1.28%).²⁸ The following equation can be used to calculate the initial dose:

$$\text{Plasma-derived factor IX (units)} = (\text{desired level} - \text{baseline level}) \times (\text{weight in kilograms})$$

As with the similar calculation for factor VIII dosing, the baseline level term can be omitted from the formula. Because the recovery of recombinant factor IX is approximately 20% lower than that of the plasma-derived products, the following adjustment is made:

$$\text{Recombinant factor IX (units)} = (\text{desired level} - \text{baseline level}) \times 1.2 \times (\text{weight in kilograms})$$

A recovery study to determine optimal dosing is recommended for patients who receive recombinant factor IX because of the wide interpatient variability in pharmacokinetics.

Because the half-life of factor IX is approximately 24 hours, dosing can be less frequent than with factor VIII. Table 100-5 provides general guidelines for dosing factor IX, based on the site and severity of the bleeding episode. As with factor VIII replacement therapy, individual pharmacokinetics may vary, and monitoring the patient's factor IX levels helps optimize therapy.

■ PROPHYLACTIC REPLACEMENT THERAPY

Traditionally, factor concentrates for hemophilia patients have been given on demand, as the bleeding episode occurs. However, recurrent joint bleeding can damage the joint and lead to the development of severe physical disability. Thus it would be preferable to prevent bleeding episodes and avoid the resultant damage. Known as prophylactic factor replacement therapy, this approach entails the regular

infusion of concentrate to maintain the deficient factor at a minimum of 0.01 unit/mL (1%).

In effect, prophylactic replacement therapy converts severe hemophilia into a milder form of the disease. The rationale for this approach is that patients with moderate hemophilia rarely experience spontaneous hemarthroses, and they have a much lower incidence of chronic arthropathy. Patients with hemophilia A usually require 25 to 40 units of factor VIII per kilogram of body weight, given every other day or three times a week.⁴¹ For hemophilia B, the usual dosage is 25 to 40 units/kg of factor IX given twice weekly instead of three times weekly because of the longer half-life of factor IX.^{5,42}

Primary prophylaxis is regular replacement therapy started at a young age (usually before the patient is 2 years old), prior to the onset of joint bleeding.⁴¹ The results of primary prophylaxis have been very promising. In the Swedish experience, children who began prophylaxis at 1 to 2 years of age experienced almost no bleeding episodes and had normal joint examinations and radiographs over a 5-year period.^{41–43} Secondary prophylaxis begins after significant joint bleeding has already occurred. It is associated with a significant reduction in the number of joint bleeding episodes and a better clinical and orthopedic outcome.^{41,44} However, radiographic evidence of joint disease rarely improves and often progresses despite the institution of secondary prophylaxis.⁵ Therefore it may not be possible to avoid chronic arthropathy when prophylaxis is initiated after significant joint bleeding has already occurred; this supports a need for earlier intervention.

CLINICAL CONTROVERSY

Hemophilia patients may receive prophylactic factor concentrate therapy to prevent or decrease bleeding episodes or they may receive on-demand factor concentrate therapy in response to a bleeding episode. In addition, prophylaxis may be primary or secondary. Controversy exists over whether the benefits of prophylaxis justify the cost, as well as the appropriate time to initiate prophylaxis.

Prophylactic replacement therapy is now in widespread use in Europe. Although the Medical and Scientific Advisory Council of the National Hemophilia Foundation of the United States has recommended primary prophylaxis beginning at 1 to 2 years of age for children with severe hemophilia,⁵ this therapeutic approach has not yet been widely accepted in the United States. There are several disadvantages associated with prophylactic regimens that may be responsible for this lack of acceptance. Perhaps most important is the high cost of prophylactic replacement therapy. Factor requirements have been estimated to be two- to threefold higher with prophylactic regimens than with treatment on demand.^{41,45} The use of individual pharmacokinetics to titrate dosage may help to lessen costs.⁴¹ Other issues to consider are the inconvenience to families and the possible difficulties with compliance. Central venous lines may be necessary for the frequent administration of factor concentrates, particularly in children less than 3 to 5 years old, the age targeted for initiation of primary prophylaxis regimens. Potential complications of central venous access include surgical risks, infection, and catheter-related deep venous thrombosis.^{46,47} Catheter-related sepsis has been reported to occur in up to 50% of patients with hemophilia who have central lines.⁴⁷ Catheter-related infectious complications appear to be more common in hemophilia patients who have developed inhibitory antibodies.⁴⁶ Finally, there are concerns that the routine use of primary prophylaxis may overtreat some patients with severe hemophilia who do not have a severe clinical phenotype. Prospective, randomized studies and more formal cost-effectiveness analyses are needed to determine the rela-

tive benefits and optimal timing of prophylactic factor replacement therapy.

TREATMENT OF INHIBITORS IN HEMOPHILIA

Neutralizing antibodies to factor VIII and IX, known as inhibitors, develop in a subset of patients with hemophilia, challenging the management of these patients. The development of inhibitors is probably the most common serious complication of factor replacement therapy. The reported incidence of inhibitor development has varied considerably, depending on the population studied, the study design, the method of detection, and the frequency and duration of testing. Inhibitor formation has been reported to occur in 4% to 20% of patients with factor VIII deficiency, and in up to 52% of patients with severe factor VIII deficiency.⁴⁸ The reported prevalence of inhibitors is much lower in hemophilia B, occurring in only 1% to 4% of patients.⁴⁸

Most inhibitors develop in childhood, often after relatively few exposure days.²⁶ Patients with severe hemophilia are much more likely to develop inhibitors than those with milder forms of the disease.²⁶ A possible explanation is that the low levels of factor produced in patients with mild and moderate hemophilia may induce immune tolerance in these individuals. In contrast, factor levels are undetectable in patients with severe hemophilia, and infused factor VIII, regarded as a foreign protein, may provoke an antibody response. Similarly, in patients with severe hemophilia there is a higher rate of inhibitor development (23% to 40%) in those with mutations that result in undetectable plasma factor VIII levels than in those with missense mutations and small deletions (3% to 13%) when circulating, albeit abnormal, protein is present.⁴⁹ The rate of inhibitor formation varies even among patients with identical mutations, which suggests that host factors modify the risk. One possibility is that HLA genotype may influence the risk of inhibitor formation, but studies have been inconclusive.²⁶

Inhibitors are usually immunoglobulins of the IgG subclass that are directed against the factor coagulant portion of the complex. The presence of an inhibitor is suspected when there is a decreased clinical response to factor replacement. It may also be discovered incidentally on routine laboratory screening. Inhibitors are measured with the Bethesda assay, and titers are reported in Bethesda units (BU). One BU is the amount of inhibitor needed to inactivate half of the factor VIII or factor IX in a mixture of inhibitor-containing plasma and pooled normal plasma.⁴⁸ Patients with inhibitors to factor VIII or factor IX are divided into two groups: low responders, who have low levels of inhibitors (<10 BU/mL) and generally have little or no rise in antibody titers after exposure to the factor; and high responders, who have higher inhibitor levels (>10 BU/mL) and develop an increase in antibody titer after exposure (anamnestic response).⁴⁸

The treatment of patients with inhibitors is twofold, involving treatment of acute bleeding episodes as well as treatment directed at eradicating the inhibitor. The inhibitor titer, the site and magnitude of bleeding, and the patient's past response to therapy determine the approach to treatment. For patients with a low inhibitor titer, administration of high doses of the specific factor can often control bleeding episodes. Two to three times the usual replacement dose and more frequent dosing intervals are often necessary to overcome the antibody. Factor level monitoring and clinical assessments help to evaluate the adequacy of treatment. Additional supportive measures, such as immobilization and the administration of antifibrinolytic agents, should be employed, where appropriate.

In the presence of a high-titer inhibitor, it may be impossible to administer enough factor VIII or factor IX to neutralize the antibody

and achieve a hemostatic plasma level. Therefore the approach to treatment of bleeding episodes in these patients is to use agents that bypass the factor to which the antibody is directed. These include PCCs, activated PCCs, and recombinant activated factor VII.

PCCs contain the vitamin K–dependent factors II, VII, IX, and X. Small quantities of activated factors VII and IX are present in these products. Activated PCCs (aPCCs) contain greater quantities of the activated factors.⁵⁰ The usual dosage is 50 to 100 units/kg administered every 12 to 24 hours, depending on the severity of the bleeding episode.⁴⁸ The maximum dose should not exceed 200 units/kg per day. The use of PCCs and aPCCs, when not restricted to one or two doses, is effective in obtaining hemostasis in approximately 80% of bleeding episodes in patients with inhibitors, and aPCCs appear to be more effective than PCCs.⁵⁰ As previously mentioned, there is a risk of serious thrombotic complications including pulmonary emboli, deep venous thrombosis, and myocardial infarction associated with the use of PCCs and aPCCs.⁵⁰ Additionally, because these products contain trace amounts of factor VIII and larger amounts of factor IX, they can stimulate an anamnestic response in patients with hemophilia A, and more commonly, in those with hemophilia B.^{38,50} Other minor side effects include dizziness, nausea, hives, flushing, and headaches.⁵⁰ Patients with factor IX inhibitors may occasionally develop severe allergic reactions in response to infusion of factor IX–containing products; therefore these patients should be monitored closely.⁵¹

A newer bypassing agent, recombinant factor VIIa, is thought to be hemostatically active only at the site of tissue injury where tissue factor is present; thus the risk of systemic thrombotic events associated with this agent is minimal.⁵² Additionally, because recombinant VIIa is not a plasma-derived product, both viral transmission and anamnestic responses to factor VIII or factor IX are unlikely.^{38,50} The initial dose for bleeding episodes ranges from 35 to 120 mcg/kg.^{50,52} Doses of 70 mcg/kg or higher are more effective, and often a dose of 90 to 120 mcg/kg is used for the treatment of patients with hemophilia and inhibitors.⁵² A drawback is the product's short half-life, which necessitates dosing every 2 hours. The continuous infusion of recombinant factor VIIa, which may be more convenient and cost-effective, has been successful, although studies are limited.⁵⁰ Recombinant factor VIIa appears to be efficacious in controlling bleeding episodes and in managing hemophilia during surgical procedures.⁵⁰ Patients treated with bypassing agents must be monitored clinically, because there are no laboratory tests that directly measure the effectiveness of the treatment.

Porcine factor VIII is an alternative therapeutic option for patients who have hemophilia A and inhibitors. In general, porcine factor VIII is most useful when the inhibitor titer is less than 50 BU.^{28,48} The recommended initial dose is 50 to 100 units/kg for those with inhibitor titers less than 50 BU.²⁸ The rationale is that porcine factor VIII is enough like human factor VIII to participate in the coagulation cascade, yet most factor VIII inhibitors have absent or only weak neutralizing activity against nonhuman factor VIII. However, cross-reactivity with porcine factor VIII does occur, and there is also the potential for developing a high titer of antibody against porcine factor VIII. Although the rise in antibody titer is generally lower than that seen with the administration of human factor VIII,⁴⁸ anamnestic rises in inhibitor titers to both porcine and human factor VIII may occur and can limit future use.^{38,50} Other potential side effects include severe allergic reactions and thrombocytopenia.^{38,48,50} Supply problems may limit the availability of this product. Because of these limitations, porcine factor VIII is usually indicated only after recombinant factor VIIa and PCC have failed or when hemorrhages are severe.⁴⁸ An advantage to porcine factor VIII is that treatment response may be monitored with factor VIII levels.

The ideal therapy for patients with hemophilia and inhibitors is to eradicate the inhibitor so that future treatment with factor VIII or factor IX concentrates is possible. Immune tolerance therapy, which involves the regular infusion of high doses of the factor to which the antibody is directed, may accomplish this eradication. A variety of different dosing regimens, ranging from 25 units/kg every other day to more than 200 units/kg every day have been employed. Some treatment protocols include adjunctive immunomodulatory therapy, such as the administration of cyclophosphamide, prednisone, and intravenous immune globulin.⁵³ The overall success rate is 50% to 70% and it is best in patients with low inhibitor titers and in those whom the inhibitor has recently developed.^{5,54} Weeks to years of therapy may be required to eradicate the antibody. Unfortunately, immune tolerance therapy is costly, time-consuming, and often requires the placement of a central venous catheter.⁵ Once achieved, however, immune tolerance facilitates the management of bleeding episodes with specific factor replacement therapy. Rituximab, an anti-CD20 monoclonal antibody, has been used in a few patients with acquired factor VIII inhibitors with some success.⁵⁵ The mechanism of action involves the rapid depletion of circulating B cells, which produce antibodies, including the anti-factor VIII antibody. The use of rituximab in patients with hemophilia and inhibitors has yet to be tested on a large scale.

Figure 100–3 summarizes the therapeutic options in the management of hemophilia A patients with inhibitors. The same algorithm can be applied to the management of hemophilia B patients, except that factor IX should be substituted for factor VIII. The use of porcine factor VIII is not indicated for the inhibitors in hemophilia B.

GENE THERAPY IN HEMOPHILIA

The use of gene therapy for hemophilia A and B is currently under investigation. A number of different viral and nonviral vectors have been used to transfer the recombinant factor gene to human cells, such as liver and muscle cells.^{56,57} Even low levels of factor expression through gene therapy should reduce bleeding episodes in patients with severe hemophilia, a rationale for gene therapy similar to that for prophylactic factor replacement. Furthermore, given that there is a broad range of physiologically normal factor levels, very tight regulation of gene expression is not necessary. The safety and efficacy of this approach to treatment remain to be determined. Potential benefits to gene therapy include patient convenience, viral safety, and decreased cost. Possible drawbacks to gene therapy include a risk of inhibitor formation, tumorigenesis related to integration of the viral vector, possible germline transmission, and concerns about long-term gene expression.^{56,57}

PAIN MANAGEMENT IN HEMOPHILIA

Pain, both acute and chronic, can be a common occurrence for patients with hemophilia. The likely cause of acute pain is bleeding, and control of the bleeding episode should ease the pain. Chronic pain may be the result of permanent joint changes. Surgical intervention may help to alleviate the pain, as may an intensive physical therapy program.⁵⁸ The intra-articular administration of dexamethasone may also be useful.⁵⁹ Acetaminophen may be used, although narcotic analgesia may be required for more severe pain. Nonsteroidal anti-inflammatory drugs impair platelet function and may increase the risk of bleeding in patients with hemophilia, although these drugs have been used for the management of chronic arthropathy.

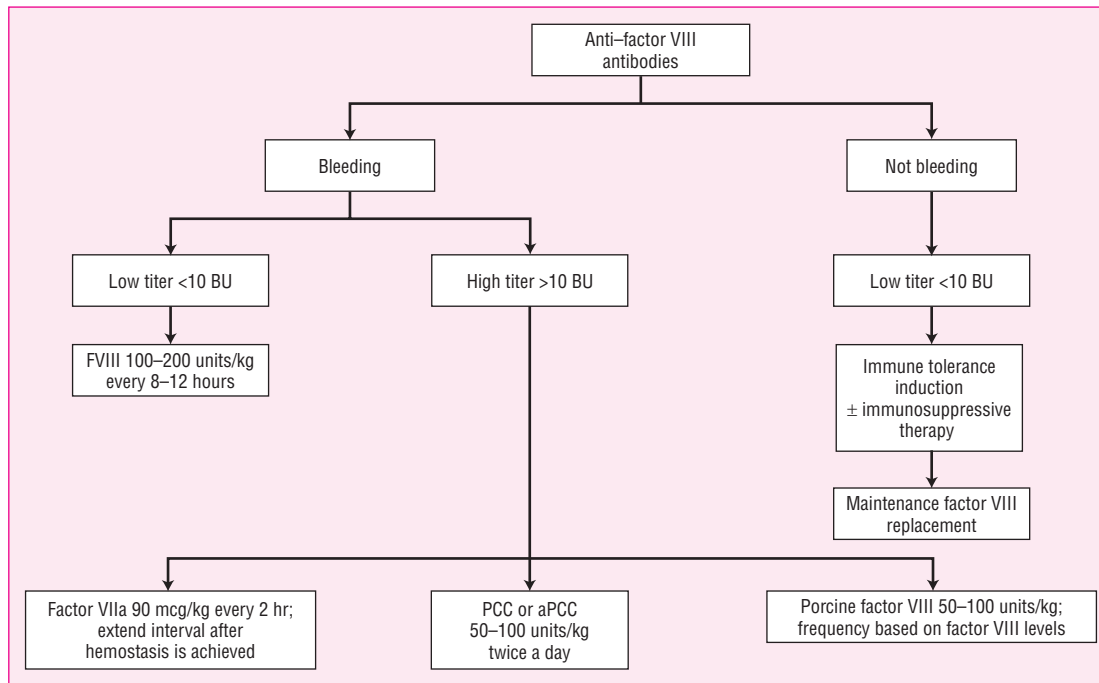

FIGURE 100-3. Treatment algorithm for the management of patients with hemophilia A and factor VIII antibodies. BU, Bethesda unit; PCC, prothrombin complex concentrate; aPCC, activated prothrombin complex concentrate.

Cyclooxygenase-2 inhibitors have less antiplatelet activity and may be an option for pain management.

■ SURGERY IN HEMOPHILIA

The goal of treatment of the patient with hemophilia undergoing a surgical procedure is to maintain factor levels of at least 0.5 to 0.7 unit/mL (50% to 70%) during surgery and in the postoperative period in

order to prevent excessive bleeding. Intermittent dosing or continuous infusion factor replacement may accomplish this goal. Before surgery, factor concentrate is usually infused to obtain a plasma level of 1 unit/mL (100%).⁶⁰ Replacement therapy is continued to maintain plasma levels greater than 0.5 unit/mL (50%) for 5 to 7 days or longer, depending on the type of surgery. Preoperative evaluation for elective procedures should include the measurement of an inhibitor titer and assessment of the recovery and half-life of infused factor in the patient. Elective surgery should not proceed unless therapeutic plasma levels can be obtained.

EVALUATION OF THERAPEUTIC OUTCOMES

The main goal in the treatment of hemophilia is to control and prevent bleeding episodes and their long-term sequelae, such as chronic arthropathies. Pharmacologic and nonpharmacologic interventions should be aimed at achieving this goal. Treatment response can be monitored through clinical parameters, such as cessation of bleeding and resolution of symptoms. It may also be useful to determine plasma factor levels, particularly for severe bleeding episodes. Home therapy for the administration of factor concentrates is common among these patients, because this approach can lead to earlier treatment and more independence for the patient. Diaries in which the patient documents symptoms, the dose of factor replacement, adjuvant therapies used, and treatment response can help the caregiver evaluate the success of home therapy. Monitoring the number and type of bleeding episodes and measuring trough plasma factor levels makes it possible to evaluate the adequacy of prophylactic regimens. Physical examination with evaluation of joint range of motion and radiographs of target joints indicates the long-term success of preventing and treating arthropathies.

Clinicians should check for the development of inhibitors, especially in patients with severe disease and exposure to factor concentrates, at least yearly and with any suspicion of poor treatment

response. The development of inhibitors challenges the management and control of bleeding episodes. A full understanding of the clinical situation and the titer of the inhibitor are mandatory to address all treatment options for each patient. Because there is no laboratory test to measure the effectiveness of therapy in this scenario, close clinical monitoring for worsening or resolution of the symptoms is essential to optimize the outcome.

VON WILLEBRAND DISEASE

The most common congenital bleeding disorder, von Willebrand disease has a prevalence of 1% to 2%.⁶¹ It refers to a family of disorders caused by a quantitative and/or qualitative defect of von Willebrand factor, a glycoprotein that plays a role in both platelet aggregation and coagulation. Unlike hemophilia, von Willebrand disease has an autosomal inheritance pattern, resulting in an equal frequency of disease in males and females.

The gene for von Willebrand factor is located on chromosome 12 and is 178 kb in length.⁶¹ Transcription and translation produce a large primary product that subsequently undergoes complex modifications, resulting in von Willebrand factor multimers of various sizes with

molecular weights ranging from 500 to 20,000 kd.⁶¹ Von Willebrand factor is synthesized in endothelial cells where it is either stored in Weibel-Palade bodies or secreted constitutively. It is also synthesized in megakaryocytes and stored in alpha granules, from which it is released following platelet activation.⁶¹

Von Willebrand factor is important for both primary and secondary hemostasis. In response to vascular injury, it promotes platelet adhesion by interacting with the glycoprotein Ib receptor on platelets.^{61,62} It can also facilitate platelet aggregation by binding to the platelet glycoprotein IIb/IIIa receptor, although fibrinogen is the main ligand for this receptor.^{61,62} The highest-molecular-weight von Willebrand factor multimers appear to be the most important in platelet adhesion because their large surface area contains numerous binding sites for various ligands and receptors. An additional function of von Willebrand factor is that it is the carrier molecule for circulating factor VIII, protecting it from premature degradation and removal.⁶¹ A deficiency of von Willebrand factor thus reduces the half-life of factor VIII, causing decreased plasma factor VIII levels as well. Therefore von Willebrand factor plays a dual role in hemostasis, affecting both platelet function and coagulation.

CLASSIFICATION OF VON WILLEBRAND DISEASE

As shown in Table 100–6, von Willebrand disease consists of a heterogeneous group of disorders that can be classified into three major subtypes. Types 1 and 3 are associated with quantitative defects in von Willebrand factor, while type 2 mutations refer to functional abnormalities in von Willebrand factor. The determination of the disease subtype is important, because it influences treatment.

Type 1 von Willebrand disease is the most common type, accounting for 59% to 76% of cases.⁶¹ It is characterized by a mild to moderate reduction in the level of von Willebrand factor (although its multimeric structure is normal) and a similar reduction in the level of factor VIII. It is usually inherited in an autosomal dominant fashion with variable penetrance and expression.⁶³ Bleeding symptoms are often only very mild to moderate.⁶¹

Type 2 von Willebrand disease, diagnosed in 9% to 30% of affected patients, is characterized by a qualitative abnormality of von Willebrand factor.⁶¹ Bleeding manifestations may be more severe than with type 1 disease. Inheritance is most often autosomal dominant, but may be recessive.⁶³ Type 2 von Willebrand disease may be further subdivided into four variants. Type 2A is the most frequent subtype and is characterized by a reduced von Willebrand factor–platelet interaction and an absence of high- and intermediate-molecular-weight factor multimers. Type 2B is a less common variant in which there is an abnormal von Willebrand factor that has an increased affinity for the platelet glycoprotein Ib receptor. This is associated with thrombocytopenia, which is usually mild. In addition, there are usually no high-molecular-weight forms of von Willebrand factor.⁶³ Type 2M

arises from a qualitative defect in von Willebrand factor that impairs its binding to platelets; it is similar to type 2A, except that there is no measurable reduction in the high-molecular-weight multimers.⁶³ Finally, type 2N von Willebrand disease (Normandy) is a rare form of the disease in which von Willebrand factor has a markedly reduced affinity for factor VIII. This leads to a moderate to severe reduction of factor VIII plasma levels with normal von Willebrand factor levels.⁶³

Type 3 von Willebrand disease refers to a severe quantitative variant of the disease in which von Willebrand factor is nearly undetectable and factor VIII levels are very low. It is often inherited in an autosomal recessive fashion.⁶¹ The clinical phenotype is severe, reflecting major deficits in primary hemostasis and coagulation. There is also a platelet-type pseudo–von Willebrand disease in which von Willebrand factor is normal, but there is a defect in the platelet glycoprotein Ib receptor that causes an increased affinity for normal von Willebrand factor.⁶¹ As a result, it is phenotypically similar to type 2B disease, but should be distinguished from it because the treatment is different.

Acquired von Willebrand disease is a rare bleeding disorder that is similar to the congenital form of the disease. It has been reported primarily in association with autoimmune disorders, such as systemic lupus erythematosus, lymphoproliferative disorders, and neoplastic disease.⁶¹ Certain medications also have been associated with acquired von Willebrand disease, including valproic acid, dextran, and ciprofloxacin.⁶⁴ Bleeding manifestations vary from mild to severe, and the condition often resolves with treatment of the underlying disease. In the acquired disease, von Willebrand factor appears to be synthesized in normal amounts, but then is rapidly removed from plasma by anti–von Willebrand factor antibodies, adsorption to tumor cells, or other mechanisms.^{61,64}

CLINICAL PRESENTATION OF VON WILLEBRAND DISEASE

Clinical manifestations are variable; some patients are asymptomatic.

Mucocutaneous bleeding: epistaxis, gingival bleeding with minor manipulation, menorrhagia

Easy bruising

Postoperative bleeding

DIAGNOSIS

When a patient has a lifelong history of mucocutaneous bleeding and a family history of abnormal bleeding, the clinician should suspect von Willebrand disease. Several different laboratory tests are helpful in the diagnosis of the hemostatic abnormality. Initial screening tests include determinations of PT, aPTT, and bleeding time, as well as a platelet count. The PT is normal, whereas the aPTT may be prolonged in relation to the reduction in plasma factor VIII levels. The platelet count is usually normal, although thrombocytopenia is common in type 2B and platelet-type pseudo–von Willebrand disease. The bleeding time, which measures platelet function, is often prolonged, but may be normal in patients with milder forms of the disease.

Specific laboratory tests to investigate the possible presence of von Willebrand disease include measurement of von Willebrand factor antigen (vWF:Ag) level, factor VIII assay, determination of ristocetin cofactor activity, and von Willebrand factor multimer analysis. Plasma concentrations of von Willebrand factor increase with cigarette smoking, exercise, pregnancy, and infection, as well as with the use of certain medications, such as corticosteroids, birth control pills, and desmopressin.⁶⁵ Repeated test measurements may be

TABLE 100–6. Von Willebrand Disease

| |
|---|
| <i>von Willebrand factor (vWF)</i> |
| The large multimeric glycoprotein that is necessary for normal platelet adhesion, a normal bleeding time, and stabilizing factor VIII. |
| <i>von Willebrand factor antigen (vWF:Ag)</i> |
| The antigenic determinant(s) on vWF measured by immunoassays; usually low in types 1 and 2; virtually absent in type 3. |
| <i>Ristocetin cofactor activity</i> |
| Functional assay of vWF activity based on platelet aggregation with ristocetin. Reduced by the same degree as vWF:Ag in types 1 and 3, but to a greater extent in type 2 disease (except 2B). |

necessary to make the diagnosis because of physiologic variations in plasma levels.

Electroimmunoassay, immunoradiometric assay, or enzyme-linked immunosorbent assay can be used to quantify vWF:Ag.⁶¹ Because vWF:Ag levels are known to vary with different ABO blood types,⁶⁶ interpretation requires reference to values specific for the patient's blood type. The vWF:Ag level is usually low in types 1 and 2 von Willebrand disease and virtually absent in type 3 disease. Factor VIII levels are normal or mildly decreased in patients with type 1 or 2 disease and very low (<10%) in those with type 3 disease.⁶¹ Ristocetin, an antibiotic that causes platelet aggregation in the presence of functional von Willebrand factor, is used to measure von Willebrand factor activity. The assay is performed by mixing platelet-free patient plasma, normal formalin-fixed platelets, and ristocetin,

and then quantitating the extent of platelet agglutination. Ristocetin cofactor activity is usually reduced in parallel to vWF:Ag levels in types 1 and 3, and decreased to a greater extent than vWF:Ag in type 2 disease (except type 2B).⁶³ Ristocetin-induced platelet agglutination is useful to further distinguish type 2B disease, as a low concentration of ristocetin induces excessive aggregation in type 2B disease.

Von Willebrand factor multimers can be analyzed by separating them by size on an agarose gel. All multimer sizes are present in type 1 disease, while a reduction in intermediate- and high-molecular-weight multimers is characteristic of type 2 disease. Type 3 patients lack all types of von Willebrand factor multimers. A summary of the laboratory findings in the various types of von Willebrand disease is provided in Table 100–6.

▶ TREATMENT: von Willebrand Disease

4 The specific type of von Willebrand disease, as well as the location and severity of bleeding, determine the approach to treatment. Local measures, including pressure, ice, and topical thrombin, can often control superficial bleeding. Systemic treatment is used for bleeding that cannot be controlled in this manner and for the prevention of bleeding with surgery. The goal of systemic therapy is to correct the platelet adhesion and coagulation defects. This may be accomplished by stimulating the release of endogenous von Willebrand factor or by administering products that contain von Willebrand factor and factor VIII. General guidelines for the treatment of von Willebrand disease are shown in Fig. 100–4.

■ REPLACEMENT THERAPY

5 The treatment of choice for patients with types 2B, 2M, and 3 von Willebrand disease and for patients with type 1 or 2A von Willebrand disease who are unresponsive to desmopressin is replacement therapy with plasma-derived von Willebrand factor–containing products.⁶⁰ Several virus-inactivated, intermediate- or high-purity factor VIII concentrates contain sufficient amounts of functional von Willebrand factor.⁶⁰ Ultrahigh-purity (monoclonal antibody-derived) plasma-derived products and recombinant factor VIII products

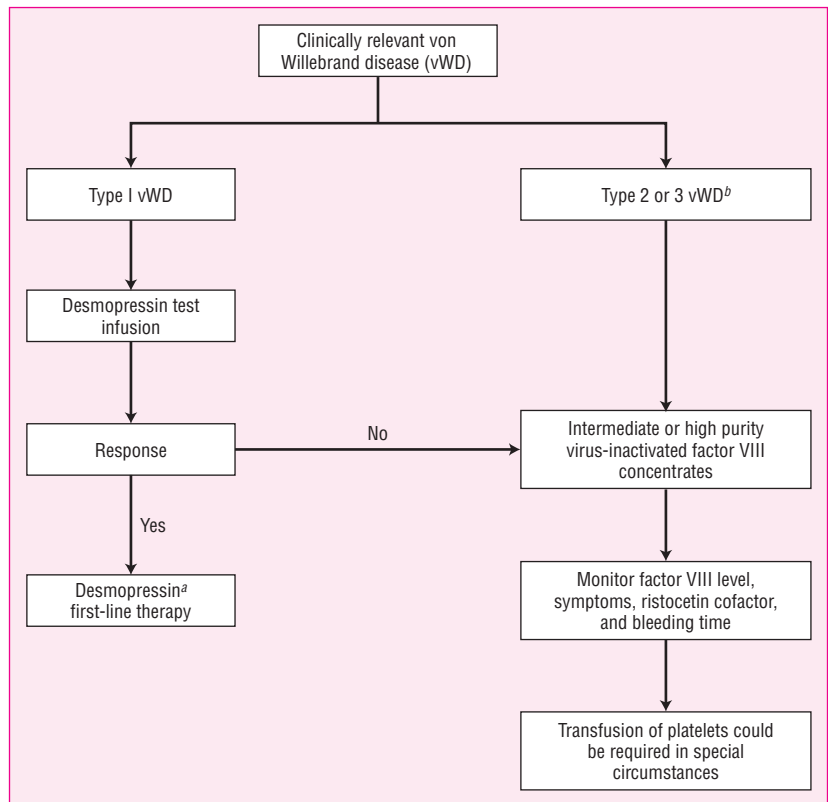

FIGURE 100–4. Guidelines for the treatment of von Willebrand disease. ^aUse factor VIII concentrate for life-threatening bleeding. ^bSome patients with type 2 or 3 von Willebrand disease may respond to desmopressin.

TABLE 100-7. Replacement Therapy in von Willebrand Disease^a

| Condition | Therapy |
|---------------------------------------|--|
| Major surgery | Maintain factor VIII level $\geq 50\%$ for 1 week Prolonged treatment in type 3 patients (> 7 days) |
| Minor surgery | Maintain factor VIII level $\geq 50\%$ for 1–3 days Maintain factor VIII level $> 20\%$ – 30% for an additional 4–7 days |
| Dental extraction | Single infusion to achieve factor VIII level $> 50\%$ Desmopressin prior to procedure for type I |
| Spontaneous or posttraumatic bleeding | Usually single infusion of 20–40 units/kg |

^aThe yield of factor VIII after first infusion is similar to that observed in hemophilia A (about 2% increment over baseline amount for every 1 unit/kg of factor VIII infused).

contain only negligible amounts of von Willebrand factor and are inadequate for the treatment of von Willebrand disease. A very high-purity plasma-derived von Willebrand factor concentrate and a recombinant von Willebrand factor product are currently in clinical trials.⁶² Because these von Willebrand factor concentrates do not contain appreciable factor VIII, concomitant administration of a factor VIII-containing product may be necessary for patients with severe disease and low levels of factor VIII.⁶² Cryoprecipitate contains approximately 80 to 100 units of von Willebrand factor per unit, and it was the mainstay of therapy for von Willebrand disease in the past.⁶¹ However, because cryoprecipitate is not virally inactivated, it is seldom used as first-line treatment. General guidelines for the dosing of replacement therapy in patients with von Willebrand disease unresponsive to desmopressin are provided in Table 100-7.

OTHER PHARMACOLOGIC THERAPY

6 Desmopressin stimulates the endothelial cell release of von Willebrand factor and factor VIII.⁶⁰ It is effective for patients with von Willebrand disease who have adequate endogenous stores of functional von Willebrand factor. This group includes most patients with type 1 disease and some patients with type 2A disease. Conversely, desmopressin is not appropriate for patients with type 3 disease, who lack stores of von Willebrand factor.

OTHER CONGENITAL FACTOR DEFICIENCIES

In addition to deficiencies in factors VIII and IX, congenital deficiencies in fibrinogen; in factors II, V, VII, X, XI, and XIII; as well as combinations of factor deficiencies have been reported.⁶⁷ Contact factor abnormalities, including deficiencies in factor XII and prekallikrein, prolong the aPTT, but do not lead to any bleeding diathesis. It is important to identify these disorders so that treatment is not inappropriate. The only contact factor deficiency associated with bleeding symptoms is factor XI deficiency. Also known as hemophilia C, this deficiency is particularly common in people of Ashkenazi Jewish descent.^{67,68} Bleeding manifestations are variable. Bleeding does not usually occur spontaneously, but there may be excessive bleeding after trauma or surgery. Most other deficiencies are inherited as autosomal recessive disorders and are rare. Some patients with abnormal molecules,

CLINICAL CONTROVERSY

Some hematologists find desmopressin beneficial in treating patients with type 2B von Willebrand disease, while others feel it may exacerbate thrombocytopenia.

Desmopressin also is not usually recommended for the treatment of type 2B disease, because the release of additional abnormal von Willebrand factor may exacerbate thrombocytopenia.⁶¹ However, desmopressin has been reported to be beneficial in some patients with type 2B disease.⁶¹ If desmopressin is used for type 2B disease, close monitoring is necessary.

The dose of desmopressin for von Willebrand disease is identical to that used in the treatment of mild factor VIII deficiency, 0.3 mcg/kg diluted in 30 to 50 mL of normal saline and given intravenously over 15 to 30 minutes.⁶⁰ In general, patients with von Willebrand disease have a better response to desmopressin than those with hemophilia, with an average three- to fivefold rise in von Willebrand factor and factor VIII levels.⁶¹ These levels remain elevated for about 6 to 8 hours. The response to desmopressin in a given patient is usually consistent, and a trial of desmopressin should establish if the medication is likely to be effective for the individual. Desmopressin is preferable to the use of plasma-derived products for patients who have an adequate response because desmopressin does not carry a risk of viral transmission. An added benefit is that desmopressin is substantially less costly than the plasma-derived products. (For a discussion of the side effects of desmopressin, see the section on the treatment of hemophilia A.)

Desmopressin can be administered every 12 to 24 hours, but the response diminishes with repeated treatment. After three to four doses, desmopressin is often no longer effective, and alternative replacement therapy may be necessary if prolonged treatment is required. Laboratory monitoring, including vWF:Ag measurements, factor VIII assays, ristocetin cofactor activity assessments, and clinical examinations, will help determine the adequacy of treatment.

The intranasal administration of desmopressin, at the same dosage as that used in mild factor VIII deficiency, can be useful in the treatment of mild bleeding episodes. One or two doses administered at the start of menses may be helpful in controlling menorrhagia.⁶² Oral contraceptives may be very effective in controlling this symptom as well.^{61,62} Inhibitors of the fibrinolytic system may be of special value in those tissues rich in plasminogen activators, such as the mouth, especially with tooth extractions.⁶¹ Antifibrinolytic agents may also be used in the management of epistaxis, gastrointestinal bleeding, and menorrhagia. However, these agents should be avoided in urinary tract bleeding, because of the risk of thrombosis and obstruction.⁶²

such as fibrinogen, may have an increased tendency to develop thromboembolic disease. Most of these deficiencies are treated with fresh frozen plasma, although newer specific concentrates are becoming available. Cryoprecipitate, which is rich in fibrinogen, may be used to treat patients with fibrinogen deficiency or dysfunctional fibrinogen (dysfibrinogenemias).

COMPLICATIONS OF REPLACEMENT THERAPY

Transmission of blood-borne viruses is always a concern when blood and blood-derived products are used. The infection of a large number of hemophiliac patients with hepatitis viruses and HIV during the 1980s prompted the development of virucidal methods to inactivate infectious agents.^{5,7} All currently available plasma-derived factor concentrates come from screened donors and undergo viral

inactivation procedures in an effort to reduce the risk of viral transmission. Heat treatment, which includes dry and wet heat, is one method of viral inactivation. Wet heat is applied while the concentrate is in suspension or in solution (pasteurization) and appears to be more effective than dry heat.^{5,7} Other methods of viral inactivation include chemical (solvent detergent) and affinity chromatography with monoclonal antibodies. Solvent detergent treatment inactivates lipid-coated viruses such as HIV and hepatitis B and C, but it is not effective against nonenveloped viruses, including hepatitis A.^{5,7,69,70} Outbreaks of hepatitis A associated with factor concentrates have occurred.^{69,70} Another nonenveloped virus that has been identified in plasma-derived products, parvovirus B19,¹⁵ may be particularly important for patients with hemophilia and HIV infection because it can cause chronic anemia in patients with immune deficiency.⁶⁹ Although concern has arisen, to date there has been no evidence of transmission of variant Creutzfeldt-Jakob disease from plasma-derived products.¹⁵

Other complications associated with factor administration include allergic reactions, fever, chills, urticaria, and nausea. PCCs and aPCCs also have the potential to cause thromboembolic complications, including deep vein thrombosis, pulmonary embolism, myocardial infarction, and DIC, likely related to the presence of activated factors.³⁹ Antifibrinolytic agents should be avoided in patients receiving PCCs or aPCCs to avoid thrombotic complications.

Porcine factor VIII, used in the treatment of patients with inhibitors to factor VIII, is not known to transmit human viruses. However, allergic-type reactions (e.g., fever, chills, skin rashes, nausea, and headaches) have been reported.^{38,48} Patients who experience these reactions may be treated with hydrocortisone and/or diphenhydramine. Thrombocytopenia is another potential complication of porcine factor VIII use.^{38,48}

Recombinant factor VIII has a low risk of viral transmission. Adverse effects of these products include metallic taste, mild dizziness, mild rash, burning at the infusion site, and a small drop in blood pressure.²²

PHARMACOECONOMIC CONSIDERATIONS

Treatment of severe hemophilia is often expensive, with a substantial portion of the cost related to the expense of factor concentrates.⁷¹ The highly purified plasma-derived products and recombinant factor concentrates are considerably more expensive than the low- and intermediate-purity products. However, the viral safety of recombinant products must be weighed against the added cost. Recombinant products are often used, particularly for children with hemophilia. With prophylactic factor replacement regimens to prevent chronic arthropathy becoming more widespread, factor usage and cost of treatment have greatly increased over that for on-demand therapy.⁷² The positive impact on patient lifestyle must be weighed against the drawbacks of cost, the potential need for permanent venous access, and patient compliance. Finally, the use of immune tolerance therapy is associated with extremely high factor usage and cost, but with the potential benefit of eradicating an inhibitor. A formal cost-benefit analysis has suggested that this therapy may be cost-effective over the patient's lifetime.⁷¹

As noted earlier, the optimal management of von Willebrand disease starts with adequate identification of the patient's disease type. Desmopressin is considerably less expensive than plasma-derived factor VIII concentrates.⁶¹ It should be the treatment of choice for all patients responsive to the test dose because of its viral safety, reduced cost, and ease of administration.

ACQUIRED COAGULATION DISORDERS

DISSEMINATED INTRAVASCULAR COAGULATION

The systemic activation of coagulation that results from DIC leads to clot formation in the microvasculature, often with compensatory bleeding owing to biodegradation of coagulation factors and platelets. Although the causes for DIC can be diverse, the pathophysiology leading to DIC is the same once the triggering event occurs (Fig. 100-5).

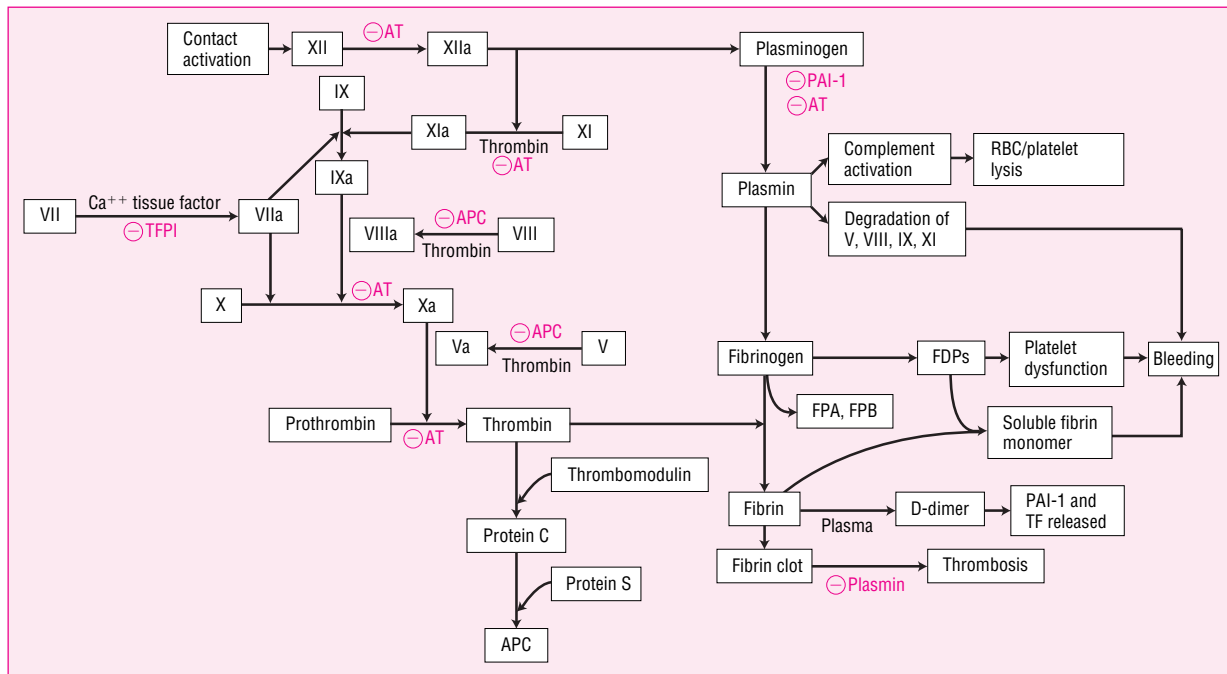

FIGURE 100-5. Pathophysiology of disseminated intravascular coagulation. APC, activated protein C; AT, antithrombin; FDP, fibrin degradation products; FPA, FPB, fibrinopeptides A and B; PAI-1, plasminogen activator type 1; RBC, red blood cell; TFPI, tissue factor pathway inhibitor.

An overwhelming insult leads to the formation of thrombin and plasmin beyond the control of the regulatory systems. Once thrombin is formed, it leads to the cleavage of fibrinopeptide A and B from fibrinogen, leaving a fibrin monomer. The monomer polymerizes into a clot, leading to microvascular and macrovascular thrombosis while consuming platelets by trapping them in the clots. Thrombosis will ultimately decrease blood flow to multiple organs, leading to organ damage. Plasmin cleaves fibrinogen into fibrin(ogen) degradation products (FDP), which can combine with the fibrin monomer before polymerization. This forms a soluble fibrin monomer, impairing hemostasis and leading to hemorrhage. Also, some of the FDPs may adhere to platelets, causing platelet dysfunction that may contribute to clinically significant hemorrhage. In addition, plasmin is a proteolytic enzyme that can degrade factors V, VIII, IX, XI, and other plasma proteins. Circulation of plasmin can activate the complement system, leading to red blood cell and platelet lysis. The activated complement system also increases vascular permeability that can cause hypotension and shock.⁷³

Complicating this process is an intricate web of feedback systems. Thrombin induces activation of factors V and XI, while it also activates protein C that inhibits the activation of the same. Antithrombin is a serine protease that mediates the antithrombotic effect of heparin. It also inhibits the activation of thrombin, plasmin, and factors IXa, Xa, XIa, and XIIa.⁷⁴ Acute DIC is characterized by a rapid and extensive depletion of coagulation factors and inhibitors, as well as excessive fibrinolysis in an attempt to compensate for microvascular clotting. Normally, a balanced dynamic process of clotting and fibrinolysis operates to prevent organ dysfunction, bleeding, or clotting. In acute DIC, excessive intravascular coagulation overcomes the normal inhibitory processes. In subacute or chronic DIC, the balance between depletion and synthesis of coagulation factors in the circulation may make the diagnosis difficult, as patients may be asymptomatic, bleeding, and/or forming thromboses.

In summary, bleeding problems observed during DIC can be the result of the consumption of coagulation factors during clotting, the depletion or dysfunction of platelets, interference in fibrin formation by FDPs, and lysis of clots by plasmin. In parallel with the bleeding process, thrombosis is occurring, and the extent of microvascular obstruction will determine the degree of organ damage.

CLINICAL PRESENTATION OF DISSEMINATED INTRAVASCULAR COAGULATION

GENERAL

Underlying illness as described in Table 100–8

SIGNS AND SYMPTOMS

Bleeding, thrombosis or both
Petechiae and purpura
Peripheral cyanosis
Hemorrhagic bullae

LABORATORY TESTS

Elevated D-dimer
Decreased antithrombin
Decreased fibrinogen
Thrombocytopenia
Decreased protein C and protein S
Increased fibrinopeptides A and B
Elevated prothrombin fragments 1 and 2
Evidence of end-organ dysfunction or failure

TABLE 100–8. Conditions Associated with Disseminated Intravascular Coagulation

| | |
|---------------------------------------|--|
| Cardiovascular | Obstetrics (Continued) |
| Acute myocardial infarction | Fatty liver of pregnancy |
| Angiopathy | Placental abruption |
| Aortic aneurysm | Preeclampsia/eclampsia |
| Aortic balloon assist devices | Retained fetus syndrome |
| Giant hemangiomas | Pulmonary |
| Peripheral vascular disease | syndrome |
| Postcardiac arrest | syndrome |
| Prosthetic devices | Empyema |
| Raynaud's syndrome | Hyaline membrane disease |
| Infectious | Pulmonary embolism |
| Arbovirus | Pulmonary infarction |
| <i>Aspergillus</i> | Tissue injury |
| <i>Candida albicans</i> | Burns |
| Cytomegalovirus | Crush injuries |
| Ebola virus | Extensive surgery |
| Gram-negative bacteria | Head trauma |
| Gram-positive bacteria | Multiple trauma |
| Herpesvirus | Miscellaneous |
| Histoplasma | Acid-base imbalance |
| Human immunodeficiency virus | Acute liver failure |
| Influenza | Amphetamines |
| Kala-azar | Anaphylaxis |
| Malaria | Autoimmune diseases |
| <i>Mycobacteria</i> | Cholestasis |
| <i>Mycoplasma</i> | Chronic inflammatory diseases |
| Paramyxoviruses | Collagen vascular disease |
| Rocky Mountain spotted fever | Craniotomy |
| Rubella | Extracorporeal circulation |
| Typhoid | Extracorporeal membrane oxygenation |
| Varicella | Fat embolism |
| Variola | Heat stroke |
| Intravascular hemolysis | Hemorrhagic telangiectasia |
| Hemolytic transfusion reaction | Hepatitis |
| Hemolytic uremic syndrome | Leukemia |
| Minor hemolysis | Lightning strikes |
| Massive transfusion | Near drowning |
| Newborn | Organic solvent poisoning |
| Birth asphyxia | Paroxysmal nocturnal hemoglobinuria |
| Hypothermia | Peritoneovenous or pleurovenous shunts |
| Meconium or amniotic fluid aspiration | Polycythemia rubra vera |
| Necrotizing enterocolitis | Renal vascular disorders |
| Respiratory distress syndrome | Severe anoxia |
| Shock | Snake bite |
| Obstetrics | Solid tumors |
| Abortion | Transplant rejection |
| Amniotic fluid embolism | |

LABORATORY DIAGNOSIS

The basis for a diagnosis of DIC is a combination of laboratory test results in the setting of a known causative clinical disorder.^{73,75} The relative importance of any particular laboratory test is controversial. Routine tests of blood coagulation, including prothrombin time and aPTT, are unreliable and of minimal use. The PT and aPTT are usually prolonged, but may be decreased or normal.⁷³ The thrombin time is usually prolonged because of the absolute decrease in fibrinogen as well as the presence of FDPs, which inhibit the conversion of fibrinogen to fibrin.⁷³

Liver disease may cause a decreased synthesis of coagulation factors, and the subsequent abnormal laboratory results can be difficult to differentiate from DIC. Increased levels of FDPs are not specific to DIC, but elevated levels occur in 85% to 100% of patients with DIC.⁷³ Because FDPs are metabolized in the liver and excreted by the kidney, organ damage may increase the level of FDPs.⁷⁶ However, an increased FDP level may help to identify compensated DIC, as it may be the only abnormal laboratory result. D-dimer is formed when plasmin digests cross-linked fibrin; thus the level of D-dimer is a more specific measure of FDPs and should be elevated only in DIC.⁷⁷

Fibrinogen levels and platelet counts are usually decreased in patients with DIC. Fifty percent of patients have schistocytes (red blood cell fragments) in fulminant DIC.⁷³ Unfortunately, these findings may also be evident in patients with severe liver disease with hypersplenism. Depressed antithrombin, protein C, and protein S levels are seen in most patients. Severe initial decreases in antithrombin

levels occur in septic DIC. Activity levels below 50% to 60% correlate with poor outcome.⁷⁴

Since thrombin cleaves fibrinopeptides A and B from fibrinogen, the levels of fibrinopeptides A and B should be elevated in patients with DIC. Initial studies have shown a good correlation between an elevated level of fibrinopeptide A and DIC, but other inflammatory conditions such as systemic lupus erythematosus, infections, and thrombosis may also result in elevated levels, thus decreasing the specificity of this test. Elevated prothrombin 1 and 2 indicates factor Xa generation, and is a reliable DIC marker, indicating procoagulant activation.⁷³

Factor VIII and V levels should be decreased in DIC, but results of these tests may be quite variable because of the systemic activation of the coagulation system. The most specific findings of DIC are a low platelet count associated with an elevated D-dimer level, fibrinopeptide A, and prothrombin 1 and 2, along with depressed antithrombin and fibrinogen levels.

► TREATMENT: Disseminated Intravascular Coagulation

⚠ If unrecognized and left untreated, DIC may lead to death as a result of hemorrhage or thrombosis. However, because of the different mechanisms and clinical manifestations that can occur with DIC, there is some controversy regarding optimal treatment. Even so, there is a consensus that the most important step in the treatment of DIC is treatment of the underlying disease.^{73,75,77,78} In a pregnant woman with placental abruption or retained placenta in whom the disease is self-limited, delivery of the fetus with the products of conception usually returns hemostasis to normal. In those patients who have overwhelming sepsis or shock, antibiotics and treatment of hypotension are the mainstays of therapy. In patients who are receiving maximum treatment for the underlying condition, but in whom the process is worsening or in whom bleeding develops, additional treatments may be used.

The efficacy of transfusing fresh frozen plasma or platelets has not been proven in randomized clinical trials, but is rational for patients who are bleeding or require invasive procedures.⁷⁵ Fresh frozen plasma replaces clotting factors, fibrinogen, protein S, protein C, and antithrombin. If hypofibrinogenemia is severe, cryoprecipitate may be useful as a concentrated source of fibrinogen. Although it has been argued that replacement of coagulation factors may worsen the situation, in practice this does not appear to make the situation worse, and it frequently improves hemostasis.

Trials of antithrombin concentrate in the treatment of DIC from various causes show some beneficial effect on improving DIC score, decreasing duration of DIC, or improving end-organ function.^{74,75} A meta-analysis of a number of well-designed studies demonstrated a trend toward decreased mortality (from 56% to 44%).⁷⁵ In addition to variable efficacy, antithrombin is an expensive product with only intermittent availability. Therefore restricting its use to patients at high risk for morbidity and mortality should be considered.

CLINICAL CONTROVERSY

Heparin use in patients with disseminated intravascular coagulation may prevent the formation of new blood clots. The most common complication of heparin therapy is bleeding, so some clinicians find it too risky to justify its use.

Anticoagulation is controversial in patients with DIC.^{75,77} The main pathogenic factor of DIC is considered to be the generation

of intravascular thrombin. Interference of thrombin activity by an agent such as heparin appears to be a logical therapeutic step. The main advantage of heparin is that it can prevent further thrombosis and consumption of hemostatic factors, but it has no influence on an already established microthrombus within the vasculature. Because the major complication of heparin therapy is bleeding, some experts argue against its use in patients with an existing bleeding disorder. There are numerous anecdotal reports of improvement in individual patients, but controlled clinical studies are lacking. Heparin has not been shown to reduce morbidity or mortality in uncontrolled series.⁷⁵ Heparin rarely restores the coagulopathy to normal, although both the deficiency of coagulation factors and the thrombocytopenia may improve. If the patient does not respond to the replacement of coagulation factors, the addition of heparin may improve the coagulopathy by forming the heparin-antithrombin complex to inhibit thrombin.

Heparin is given subcutaneously or as a continuous IV infusion. The dosage of heparin for DIC is controversial, ranging anywhere from full-dose to low-dose heparin.^{75,77} Full-dose heparin in adults requires that 5,000 units be administered as an IV bolus, followed by a continuous infusion at 1,000 units per hour or according to a weight-based heparin-dosing regimen. Some experts advocate low-dose heparin, such as an infusion of 500 units per hour in adults, and adjusting the dose based on clinical and laboratory data. Low-dose heparin given subcutaneously has been used with success. Monitoring of heparin therapy is difficult because the aPTT is often elevated before the initiation of heparin therapy. Therefore it is best to follow D-dimer and fibrinogen levels.

Anticoagulation is contraindicated in patients with life-threatening or serious bleeding (e.g., intracranial, retroperitoneal, or pericardial). Patients with symptomatic thromboemboli, extensive fibrin deposition, persistent coagulation abnormalities despite replacement of hemostatic factors, solid tumors, or chronic DIC may benefit from heparin therapy.^{75,79} Historically, an infusion of low-dose heparin, 7.5 units/kg per hour, has been used in patients with acute promyelocytic leukemia (APML), along with the administration of platelets, fresh frozen plasma, and cryoprecipitate.⁷⁹ The availability of differentiating agents may decrease or prevent the need for anticoagulation of these patients.⁷⁷ Patients with solid tumors who are symptomatic from a thrombosis should receive an infusion of heparin, 15 units/kg per hour. Once asymptomatic, heparin can be administered subcutaneously.

In two uncontrolled trials, patients tolerated the use of low-molecular-weight heparin well, and this approach showed a possible beneficial outcome.⁷⁵ A randomized, double-blind study compared the efficacy of dalteparin with that of low-dose heparin. Dalteparin was more effective at improving bleeding symptoms, but there was no difference in mortality.⁷⁵

Antifibrinolytics, such as aminocaproic acid, have been used in patients in whom the dominant clinical picture is one of excessive fibrinolysis.⁷⁵ Because aminocaproic acid can increase fibrin deposition, many experts believe that it is usually contraindicated. In patients with chronic liver disease who manifest dominant fibrinolysis, attempts to inhibit the fibrinolytic system have generally been unsuccessful. Patients with APML may benefit from an antifibrinolytic, as hyperfibrinolysis is the dominant clinical feature of their condition. Tranexamic acid and aminocaproic acid have shown benefits in patients with APML.⁷⁵

EVALUATION OF THERAPEUTIC OUTCOMES

The management of DIC is surrounded by controversy, and the optimal approach to these patients is still to be determined. Diagnosis and treatment of the underlying disease should be the goal in all cases. Determination, if possible, of the dominant process (i.e., hemorrhage vs. thrombosis) can help focus the treatment approach. This is often impossible, however, so clinicians institute replacement therapy of the deficient clotting factors and attempt to control the clotting problems with agents such as heparin.

Risk versus benefit, as well as any contraindications, should be considered at the start of any given therapy for each patient. Monitoring therapy for DIC with laboratory tests can be difficult, because the underlying process can cause a variety of laboratory abnormalities. For example, monitoring the effect of heparin by using the aPTT can be a complex task, especially when the patient has an abnormal baseline aPTT; in this case, monitoring fibrinogen and D-dimer may be more useful in detecting any need to adjust therapy. In addition, it is important to combine laboratory parameters with clinical assessment to make rational treatment adjustments. Aggressive hemodynamic stabilization and other supportive measures to prevent organ failure are also important in the overall management and prognosis of patients with DIC.

VITAMIN K DEFICIENCY

Vitamin K is a cofactor for the activation of factors II, VII, IX, and X.⁸⁴ When vitamin K deficiency occurs, the inactive precursors of these coagulation factors that do not bind calcium accumulate in the plasma. Vitamin K is also necessary for the active forms of proteins C and S, which inhibit factor Va and VIIIa. In most clinical situations, vitamin K deficiency causes a bleeding diathesis as a result of the marked deficiency of factors II, VII, IX, and X.

Vitamin K is a fat-soluble vitamin. Vitamin K₁, phytonadione, is found in green vegetables. Bacteria in the large intestine produce vitamin K₂, the menaquinones, which require bile salts to be solubilized and absorbed.⁸⁴

HEMORRHAGIC DISEASE OF THE NEWBORN

Newborns are vitamin K-deficient at birth, although not completely because some maternal vitamin K crosses the placenta.⁸⁵ The level may continue to fall during the neonatal period because the infant's gut has not had sufficient time to undergo bacterial colonization. Breast

critically ill patients may develop vitamin K deficiency. In addition, patients with DIC may consume vitamin K and may need supplementation to replenish stores. Other treatment modalities may include the use of protein C concentrate; lepirudin; anti-tissue factor antibody; recombinant tissue factor pathway inhibitor; thrombomodulin; or thrombin inhibitors such as dermatan sulfate, anti-plasminogen activator inhibitor type 1, and dithiocarbamates.^{75,77,80,81}

Activated protein C modulates coagulation as shown in Fig. 100-5. The activation of protein C may be impaired during sepsis. Drotrecogin alfa (activated protein C) administration resulted in an absolute reduction in mortality of 6.1% from severe sepsis without undue bleeding in carefully chosen adult patients.⁸² Strategies for use in adults have been developed to target appropriate patients⁸³ while pediatric data are forthcoming. Patients must be carefully chosen to minimize bleeding complications and optimize benefits.

milk contains a low vitamin K content in comparison to infant formulas, and therefore breast-fed infants are more vulnerable to developing vitamin K deficiency. In addition, the plasma concentrations of the vitamin K-dependent factors are physiologically low in infants.⁸⁶ Vitamin K deficiency in neonates can cause intracranial hemorrhage and bleeding from the umbilical cord or the gastrointestinal tract.⁸⁵

Bleeding within 24 hours of birth, early vitamin K-dependent bleeding, is usually the result of maternal ingestion of anticonvulsants, warfarin, rifampin, or isoniazid. Treatment of these women prior to delivery with vitamin K may decrease the incidence of hemorrhagic disease of the newborn among their offspring.⁸⁵ Classic vitamin K-dependent bleeding usually appears during the first week of life, and it results from the lack of prophylactic vitamin K administration at birth. Risk factors identified for late vitamin K-dependent bleeding, which occurs at 2 to 12 weeks, include cholestatic liver disease, exclusive breast-feeding, and failure to give adequate vitamin K at birth.⁸⁵ The use of oral vitamin K at birth is also associated with a higher incidence of late vitamin K-dependent bleeding. It has been suggested that the intramuscular route of administration allows the vitamin K to act as a depot preparation, and may explain the lower rate of late vitamin K-dependent bleeding with this route.⁸⁵

The levels of vitamin K-dependent coagulation factors are low at birth. Without adequate vitamin K, these levels may fall even further. In this situation, the PT and the aPTT are prolonged, but the thrombin time, fibrinogen level, and platelet count are normal. Most infants achieve adult levels by 3 months of age if intramuscular phytonadione was received at birth.⁸⁵

8 In the United States, infants usually receive 1 mg of phytonadione intramuscularly at birth for prophylaxis. Most infants build up vitamin K₁ and K₂ stores in the liver during the first month of life. The speed of repletion depends on the amount of milk or formula received. Oral supplementation results in late vitamin K-dependent bleeding if not given for a prolonged course. Controversy has arisen over whether the high plasma vitamin K levels achieved with intramuscular injection may lead to an increased incidence of childhood cancer. This risk has not been substantiated and the benefits of widespread use outweigh the minimal risk.⁸⁷ Fresh frozen plasma is used to treat hemorrhages.

MALABSORPTION

Patients may become vitamin K-deficient because of poor nutrition or malabsorption. A careful dietary history is important in this

regard. Broad-spectrum antibiotics may sterilize the large intestine and prevent vitamin K₂ production.⁸⁸

Vitamin K absorption depends on both bile acids and pancreatic enzymes to create micelles. Malabsorption resulting from diseases of the small intestine or pancreas—such as cystic fibrosis, Crohn’s

disease, ulcerative colitis, cholestatic liver disease, celiac disease, amyloidosis, Whipple’s disease, and short-bowel syndrome—may cause abnormal development in children, weight loss, muscle wasting, steatorrhea, vitamin deficiencies, and anemia. Significant malabsorption can occur even without the symptoms of diarrhea or steatorrhea.

► TREATMENT: Vitamin K Deficiency

Phytonadione is used to treat vitamin K deficiency. The dose, frequency, and duration of vitamin K depend on the severity of the deficiency and the patient’s response. Vitamin K may be administered orally, intramuscularly, subcutaneously, or intravenously. After an oral dose of vitamin K₁, the blood coagulation factors increase within 6 to 12 hours. When administered parenterally, the PT may take 12 to 24 hours to normalize, although improvement usually occurs within 1 to 2 hours. Failure to correct the PT after 48 hours should raise suspicion about the etiology of the coagulation abnormality (e.g., liver disease).

The appropriate route of administration depends on the severity and the cause of the vitamin K deficiency. For instance, in patients with severe hypoprothrombinemia, it is best to avoid the intramus-

cular route because of the risk of forming a hematoma. Because of the rare anaphylactic reaction associated with the intravenous route of administration, this route is often restricted to patients who are thrombocytopenic or unable to absorb the drug via the gastrointestinal tract.⁸⁹ Vitamin K can be administered subcutaneously to those patients without intravenous access. Bleeding patients should receive fresh frozen plasma as a source of vitamin K–dependent factors to ensure immediate correction.

Patients with malabsorption or obstructive jaundice may require the parenteral administration of vitamin K. Phytonadione 10 mg weekly is usually sufficient in adults. Patients on long-term total parenteral nutrition should receive it daily in the multivitamin additive.

COAGULOPATHY AND LIVER DISEASE

Bleeding disorders can be associated with acute or chronic liver disease. The degree of coagulopathy correlates with the degree of hepatocellular disease. The liver synthesizes the blood coagulation factors and inhibitors of coagulation (e.g., antithrombin and proteins C and S). All clotting factors except factor VIII are decreased in liver failure.⁹⁰ The ability of the liver to clear activated clotting factors and their degradation products is reduced with liver failure.⁹⁰ Primary fibrinolysis occurs due to a decline in the level of the inhibitors of plasmin activation.⁹⁰ Platelet count and function are decreased in patients with liver disease. The development of DIC may potentially worsen the coagulopathy.

The PT, the aPTT, and the thrombin time are useful in screening for a deficiency of liver-dependent factors. The PT is sensitive to deficiencies in the vitamin K–dependent factors. The aPTT helps to

determine deficiencies in factor IX, as well as some other factors. The thrombin time can help to detect hypofibrinogenemia, dysfibrinogenemia, and the presence of FDPs that interfere with fibrin polymerization. Because defects in polymerization may occur before severe hypofibrinogenemia, this may be an indication of the degree of liver dysfunction. The level of D-dimer should be normal unless DIC is present.

Factor V is synthesized by hepatic cells, but is not dependent on vitamin K. Therefore it may be useful in distinguishing vitamin K deficiency from liver disease. Deficiency of antithrombin occurs with severe hepatocellular disease and may contribute to the development of DIC. In acute hepatic failure, the level of plasminogen may be low, reflecting decreased synthesis or increased catabolism associated with DIC. The level of factor VIII is usually normal or elevated in liver disease, whereas it is decreased in DIC.

► TREATMENT: Coagulopathy and Liver Disease

Treatment of the coagulopathy associated with liver disease is recommended for overt bleeding or for the correction of coagulation parameters (e.g., PT and aPTT) prior to an invasive procedure. Major bleeding may occur with normal coagulation parameters secondary to esophageal varices or peptic ulcer disease. To ensure that vitamin K deficiency is not contributing to the abnormalities, adults may receive 10 mg of vitamin K for one or more days.

When a patient bleeds in association with a coagulopathy, replacement therapy with platelets and fresh frozen plasma may decrease bleeding. Fresh frozen plasma supplies all of the missing coagulation factors, but fluid overload may be a serious problem. If fluid overload becomes an issue, plasma exchange may be considered. If the patient has ascites, the half-life of many of these factors is decreased, and it is difficult to correct the coagulopathy. PCCs can be given, but they may increase the risk of intravascular coagula-

tion and cause DIC if it is not already present. In general, the use of these concentrates is not recommended. Only when the administration of fresh frozen plasma does not correct the coagulopathy and the patient continues to have serious bleeding should PCCs be considered.

The use of heparin and antifibrinolytic drugs is controversial. The administration of aminocaproic acid may be successful, especially with mucosal bleeding. Heparin has not been demonstrated to improve survival in acute liver failure and may exacerbate bleeding. Antithrombin concentrates have been evaluated in fulminant liver failure. They had no benefit on mortality, clinical complications, or coagulation laboratory findings. Desmopressin may decrease the bleeding time in patients with liver failure.⁹⁰ The administration of recombinant factor VIIa has successfully corrected coagulation parameters and stopped bleeding in patients with liver disease.⁹¹

ABBREVIATIONS

aPCC: activated prothrombin complex concentrate
 APLM: acute promyelocytic leukemia
 aPTT: activated partial thromboplastin time
 BU: Bethesda unit

SICKLE CELL DISEASE

C.Y. Jennifer Chan and Reginald Moore

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Sickle cell disease is an inherited disorder caused by a defect in the gene for hemoglobin. Patients may have one defective gene (sickle cell trait) or two defective genes (sickle cell disease).
- 2 Although most often seen in persons of African ancestry, other ethnic groups can be affected.
- 3 Sickle cell disease involves multiple organ systems.
- 4 Prophylaxis against pneumococcal infection reduces death during childhood.
- 5 Hydroxyurea has been shown to decrease the incidence of painful crises. However, the patient population that receives hydroxyurea should be carefully monitored.
- 6 Chronic transfusion therapy programs have been shown to be beneficial in decreasing the occurrence of stroke in children with sickle cell disease.
- 7 Patients with fever greater than 38.5°C should be evaluated and appropriate antibiotics should include coverage for encapsulated organisms, especially pneumococcal.
- 8 Pain episodes can usually be managed at home. Hospitalized patients usually require parenteral analgesics. Analgesic options include opioids, nonsteroidal anti-inflammatory agents, and acetaminophen. The patient characteristics and the severity of the crisis should determine the choice of agent and regimen.

1 Sickle cell syndromes, which can be divided into sickle cell disease (SCD) and sickle cell trait (SCT), are a group of hereditary disorders characterized by the presence of sickle hemoglobin (HbS) in red blood cells. SCT is the heterozygous inheritance of one normal and one sickle hemoglobin (HbAS) gene. Individuals with SCT are usually asymptomatic. SCD can be of homozygous or compounded heterozygous inheritance. Homozygous HbS (HbSS) is called sickle cell anemia (SCA); whereas heterozygous inheritance of HbS compounded with another mutation results in sickle-hemoglobin C (HbSC), sickle β -thalassemia (HbS β^+ -thal and HbS β^0 -thal), and some other rare phenotypes such as sickle O-Arab.

This complex disorder was first described in the literature by Herrick in 1910. Since then, much progress has been made in identifying the molecular and functional defects, as well as understanding the relationship between genotypes and clinical severity of the disease.^{1,2}

SCD is a chronic illness with significant burden for family and society.³ Frequent crisis episodes can interrupt schooling and result in employment difficulties. Acute complications of the disease can be unpredictable, rapidly progressive, and life-threatening. Later in life, chronic organ damage may develop. Due to the complexity and seriousness of the illness, it is essential that comprehensive care is available and that providers involved must have a good understanding of the disease and its management options.⁴

are identified as carriers. The most common SCD genotype is HbSS (~45%), followed by HbSC (~25%), HbS β^+ -thalassemia (~8%), and HbS β^0 -thalassemia (~2%). Other variants account for less than 1% of patients.^{5,6}

Sickle cell gene mutation offers partial protection against serious malarial infection. Abnormal red blood cells (RBCs) are less easily parasitized by *Plasmodium falciparum* than normal RBCs. Consequently, persons with heterozygous sickle gene (SCT) have a selective advantage in regions (tropical areas) where malaria is endemic. The incidence of the sickle gene in a population correlates with the historical incidence of malaria.

2 SCD is most common in people with African heritage, with a frequency of about 1 in 400 for SCD and 8% for SCT in African-Americans. The prevalence is higher in Africa, where an estimated 120,000 babies are born with SCD each year. The prevalence rate of SCT in Africa varies across regions, with a higher rate in western, central, and eastern Africa (10% to 30%) but lower in northern and southern Africa (0% to 5%). Hemoglobin C (HbC) appears primarily in the inhabitants of western and northern Africa or in descendants of people from this area. About 2% to 3% of African-Americans carry HbC gene (HbC-trait).⁵⁻⁸

Other areas with sickle mutation are the Arabian Peninsula, Indian subcontinent, and the Mediterranean region. HbS has been reported in up to 25% in certain Middle Eastern populations and greater than 30% in Greece and Cyprus. Genetic analysis shows that the mutation found in Arabic patients is different from those of African descent. Sickle gene mutation variants have been associated with different geographic locations and may be responsible for variations in clinical manifestations. In Africa, the variants are Senegal (Atlantic West Africa), Benin (Central West Africa), Bantu (Central African

EPIDEMIOLOGY

More than 50,000 Americans have sickle cell disease and approximately 2000 infants with SCD are identified each year in the United States. In addition, for every 1 infant with SCD, about 50 infants

FIGURE 101-1. Sickle gene inheritance scheme for both parents with sickle cell trait (SCT). A, normal hemoglobin; S, sickle hemoglobin. Possibilities with each pregnancy: 25% normal (AA); 50% SCT (AS); 25% sickle cell anemia (SS).

Republic), and Cameroon. The Arab-Indian haplotype is seen in certain areas of Saudi Arabia and India.⁸⁻¹⁰

ETIOLOGY

Normal hemoglobin (HbA) is composed of two α chains and two β chains ($\alpha_2\beta_2$). The biochemical defect that leads to the development of HbS involves the substitution of valine for glutamic acid as the sixth amino acid in the β -polypeptide chain. Another type of abnormal hemoglobin, hemoglobin C (HbC), is produced by the substitution of lysine for glutamic acid as the sixth amino acid in the β -chain. Structurally, the α -chains of HbS, HbA, and HbC are identical. Therefore it is the chemical differences in the β -chain that explain sickling and its related sequelae.^{2,7}

Sickle cell anemia (SCA) is a form of SCD in which the patient has inherited both genes that code for formation of HbS, one from each parent (HbSS). Figures 101-1, 101-2, 101-3, and 101-4 illustrate the possibility of inheritance with each pregnancy for the offspring of parents with normal hemoglobin (HbA), SCT, and SCA. If both parents are carriers, the offspring will have a 25% risk of having SCD and 50% risk of being a carrier (see Fig. 101-1). β -Thalassemia can

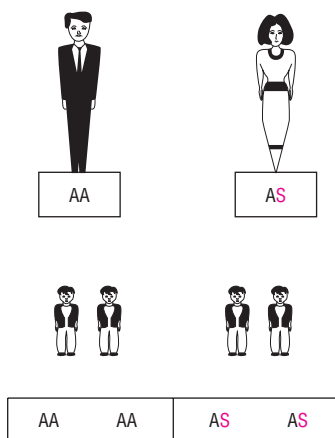

FIGURE 101-2. Sickle gene inheritance scheme for 1 parent with sickle cell trait (SCT) and 1 parent with no sickle cell gene. A, normal hemoglobin; S, sickle hemoglobin. Possibilities with each pregnancy: 50% normal (AA); 50% SCT (AS).

FIGURE 101-3. Sickle gene inheritance scheme for 1 parent with sickle cell trait (SCT) and 1 parent with sickle cell anemia (SCA). A, normal hemoglobin; S, sickle hemoglobin. Possibilities with each pregnancy: 50% SCA (SS); 50% SCT (AS).

be found in conjunction with HbS. Since patients with HbSS and HbS β^0 -thalassemia do not have normal β -globulin production, they usually have a more severe course than those with HbSC and HbS β^+ -thalassemia. As discussed earlier, several haplotypes characterize the sickle gene, resulting in differing clinical and hematologic courses. Included among these types are the three most commonly found in the United States: the Bantu haplotype, characterized by severe disease; the Senegal haplotype, characterized by mild disease; and the Benin haplotype, characterized by a course intermediate to that of the other two haplotypes. Although there are a number of other haplotypes seen around the world, the remaining major types include Saudi Arabian and Cameroon. Both of these types usually follow milder courses of illness.^{2,7-11}

PATHOPHYSIOLOGY

To understand the pathophysiology of SCD, one must understand the normal physiology of RBC production. Normal adult RBCs contain 33 to 35 g/dL hemoglobin, predominantly HbA (96%). Other forms of hemoglobin are HbA₂ (2% to 3%) and fetal hemoglobin (<2%). Fetal

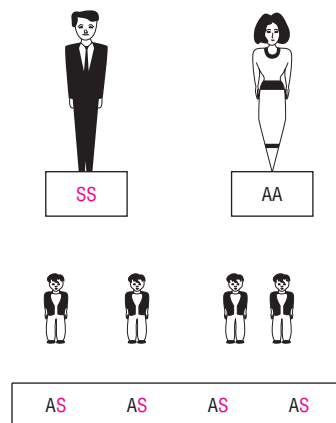

FIGURE 101-4. Sickle inheritance scheme for 1 parent without sickle cell gene and 1 parent with sickle cell anemia (SCA). A, normal hemoglobin; S, sickle hemoglobin. Possibilities with each pregnancy: 100% SCT (AS).

hemoglobin (HbF) is present predominantly in fetal RBCs. Instead of β chains in HbA or HbS, HbF contains 2 gamma chains ($\alpha_2\gamma_2$). The switch from production of γ chains to β chains occurs shortly before birth. A few red cell clones remain to produce HbF postnatally. Increased production of HbF is seen under severe erythroid stress, such as anemia, hematopoietic stem cell transplant or chemotherapy. Both water and hemoglobin content in the RBCs determine the mean corpuscular hemoglobin concentration (MCHC). Passive diffusion and active transport regulate intracellular cation and volume contents, which determine the intracellular viscosity of RBC. Normal RBCs are biconcave shape and able to deform to squeeze through capillaries (Fig. 101–5). As RBCs age, MCHC increases, deformability decreases, and the cells are removed by the reticuloendothelial system.¹²

In the pathogenesis of SCD, three known problems are primarily responsible for various clinical manifestations: impaired circulation, destruction of RBCs, and stasis of blood flow. These three problems probably relate directly to two major disturbances involving RBCs: polymerization and membrane damage (Fig. 101–6).

The solubility of HbS and HbA are the same when oxygenated. Due to increased hydrophobicity as a result of valine substituting glutamic acid, solubility of deoxygenated HbS is reduced to 17 g/dL. Saturation of deoxy-HbS leads to intermolecular binding and formation of thin bundles of fibers, which initially are unstable but with

FIGURE 101–5. Elongated sickle and normal discoid shaped red blood cells.

time, increased binding of deoxy-HbS results in cross-linking fibers and stable polymers. This process is influenced by MCHC, temperature, intracellular pH, and the amount of HbS. Polymerization allows deoxygenated hemoglobin molecules to exist as a semisolid gel that protrudes into the cell membrane, leading to distortion of RBCs (sickled shape) and loss of deformability. The presence of sickled RBCs increases blood viscosity and encourages sludging in the capillaries and small venous vessels. Such obstructive events lead to local tissue hypoxia, which tends to accentuate the pathologic process.

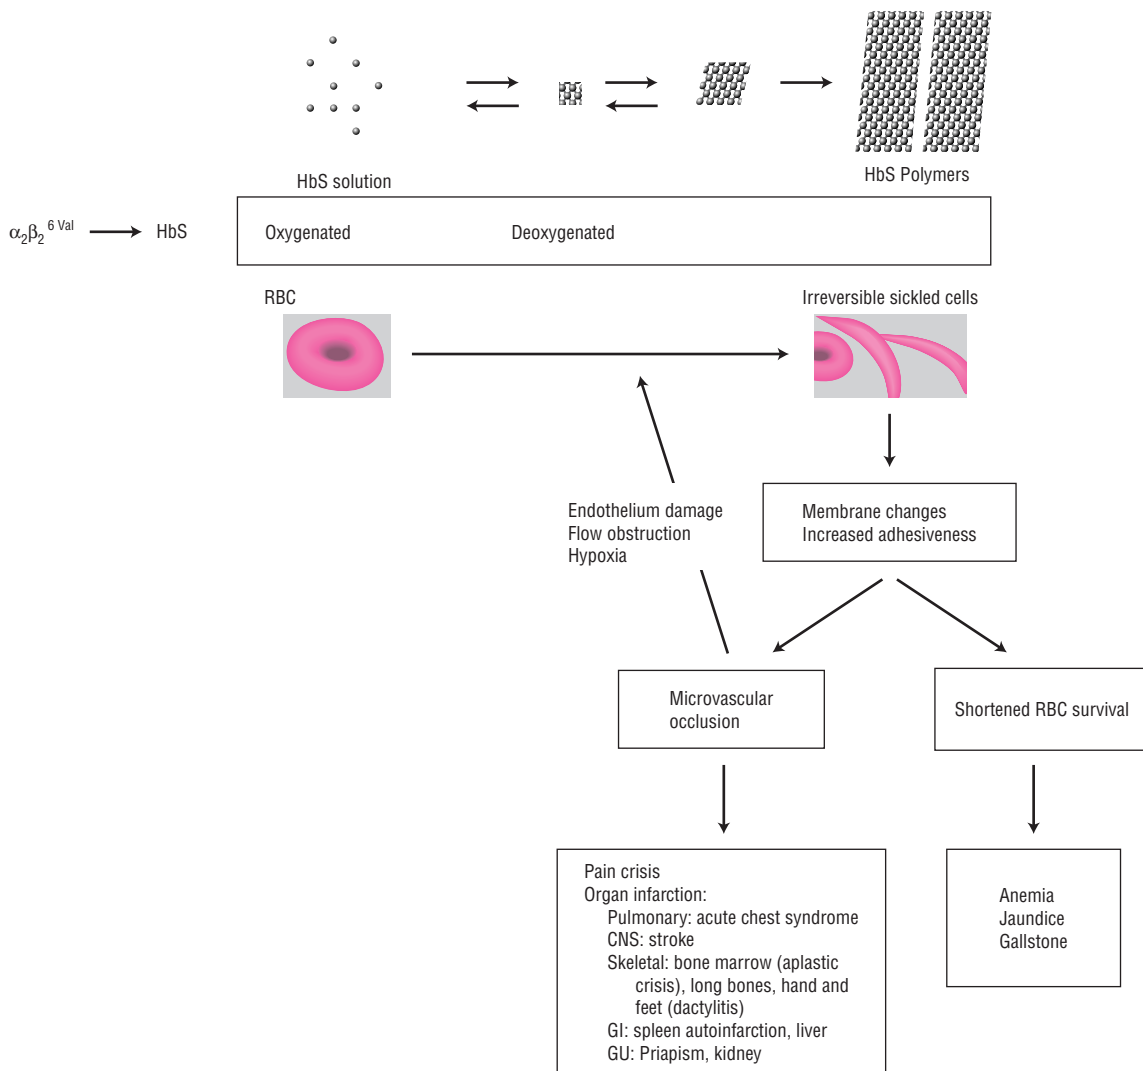

FIGURE 101–6. Pathophysiology of sickle cell disease.

When reoxygenated, polymers within the RBCs are lost, and the RBCs eventually return to normal shape. This process contributes to the vaso-occlusive manifestation in that HbS is able to squeeze into microvasculature when oxygenated, but becomes sickled when deoxygenated. The cycle of sickling and unsickling results in damage to the cell membrane, loss of membrane flexibility, and rearrangement of surface phospholipids. Membrane damage also alters ion transport, resulting in loss of potassium and water, which lead to a dehydrated state that enhances the formation of sickled forms. After continual repetitions of the process, the RBC membrane develops into a more rigid form, irreversibly sickled cells (ISC). Unlike the reversible sickle cells, which have normal morphology when oxygenated, ISCs are elongated cells and remain sickled when oxygenated. More rigid membranes of HbS-containing RBC retard their flow, particularly through the microcirculation. In addition, sickled RBCs tend to adhere to vascular endothelial cells, which further increases polymerization and obstruction.

Intermolecular binding and polymer formation are reduced by fetal hemoglobin (HbF) and to a lesser degree by HbA₂. RBCs that contain HbF sickle less readily than cells without. ISCs, not surprisingly, have a low HbF level. Increased levels of HbF, as in the case of the Saudi Arabian genotype, results in more benign forms of SCD. The amount of HbF and HbA₂ in relation to HbS influences clinical manifestations and explains the variability in severity among different SCD genotypes.

Intravascular destruction of sickle cells may occur at an accelerated rate. The stresses of circulation, and repetitive sickle-unsickle cycles are likely to lead to cell fragmentation. Damage to the cell membrane promotes cell recognition by macrophages. Rigid ISCs are easily trapped, resulting in short circulatory survival and chronic hemolysis. The typical sickled cell survives for about 10 to 20 days, while life spans of normal RBCs are 100 to 120 days.

Factors in addition to sickling may be responsible for the pathogenesis of a number of the clinical manifestations associated with SCD. Obstruction of blood flow to the spleen by sickle cells can result in functional asplenia, defined as the loss of splenic function with an intact spleen. These patients may also have deficient opsonization. Impaired splenic function increases susceptibility to infection by encapsulated organisms, particularly pneumococcal disease. Coagulation abnormalities in SCD may be the result of continuous activation of the hemostatic system or disorganization of the membrane layer.^{7,9,12–14}

CLINICAL PRESENTATION

SCD is usually identified by routine neonatal screening programs. The sensitivity and specificity of screening methods, most commonly by isoelectric focusing, are excellent. For infants with a positive screening result, confirmation testing should be performed prior to 2 months of age. Even with universal screening, infants with SCD are sometimes not identified at birth because of extreme prematurity, prior blood transfusion, inability to contact family, or clerical errors.⁴

3 SCD involves multiple organ systems and its clinical manifestations vary greatly between and among genotypes (Table 101–1). Persons with SCT are usually asymptomatic, although some clinical signs and symptoms can occur. Sickling of RBCs in the renal medulla results in loss of ability to maximally concentrate urine. Patients with such impairment may be at risk of dehydration during periods in which the body normally conserves water. Microscopic hematuria has been seen and gross hematuria can occur after heavy exercise. An increased incidence of urinary tract infection in women, especially during pregnancy, has been reported. In general, trait carriers are not considered

TABLE 101–1. Clinical Features of Sickle Cell Trait and Common Sickle Cell Disease

| Type | Clinical Features |
|-------------------------------|--|
| Sickle cell trait (SCT) | Rare painless hematuria; normal Hgb level; heavy exercise under extreme conditions may provoke gross hematuria and complications |
| Sickle cell anemia (SCA) | Pain crises, microvascular disruption of organs (spleen, liver, bone marrow, kidney, brain, and lung), gallstone, priapism, leg ulcers; anemia (Hgb 7–10 g/dL) |
| Sickle hemoglobin C | Painless hematuria and rare aseptic necrosis of bone; vaso-occlusive crises are less common and occur later in life; other complications are ocular disease and pregnancy-related problems; mild anemia (Hgb 10–12 g/dL) |
| Sickle β^+ -thalassemia | Rare crises; milder severity than sickle cell disease because production of HbA; Hgb 10–14 g/dL with microcytosis |
| Sickle β^0 -thalassemia | No HbA production; severity similar to SCA; Hgb 7–10 g/dL with microcytosis |

to have clinical disease, but should be cautious when participating in exercise under extreme conditions, such as high altitude or military training.^{5,13}

The feature presentations of SCD are hemolytic anemia and vaso-occlusion. In patients who are homozygous for HbS, anemia usually appears from 4 to 6 months after birth. Symptoms are delayed because the infant's RBCs contain mainly HbF at birth. As RBC turnover occurs during those early months, cells containing HbS gradually replace those containing HbF, which typically leads to attacks of pain frequently accompanied by fever. Pneumonia and splenomegaly are also common findings. Infants can also present with pain and swelling of the hands and feet, commonly referred to as “hand-and-foot syndrome” or dactylitis.^{4,5}

The usual clinical signs and symptoms associated with SCA include chronic anemia; fever and pallor; arthralgia; scleral icterus; abdominal pain; weakness; anorexia; fatigue; enlargement of the liver, spleen, and heart; and hematuria.

Laboratory findings include low hemoglobin (Hgb) level and increased reticulocyte, platelet, and white blood cell (WBC) counts. The peripheral blood smear demonstrates sickle forms (see Fig. 101–5). Presentation of patients with HbSC disease is less severe than that of SCA, and is characterized primarily by mild anemia (Hgb levels above 9 g/dL), infrequent episodes of pain, persistence of splenomegaly into adult life, and excessive target cells in the peripheral blood smear. In patients with heterozygous HbS and β -thalassemia gene, severity of disease depends on the thalassemia gene involved.^{5,7,13}

Patients with SCD experience delayed growth and sexual maturation. Both height and weight are usually below average, and the poor growth cannot be explained by nutritional factors alone. Fertility problems tend to occur more often, and some menstrual abnormalities are more prevalent in female SCD patients than in normal women. Other typical physical characteristics include a protuberant abdomen with exaggerated lumbar lordosis, usually an asthenic appearance with rather long extremities and tapered fingers, and frequently a barrel-shaped chest.^{4,5}

The previously high mortality rate of early childhood has been reduced for patients with SCD with availability of public health programs and comprehensive care.⁴ The median survival rate is estimated

TABLE 101–2. Acute Complications of Sickle Cell Disease (SCD)**Infection^a**

Clinical features: SCD carries a high risk for overwhelming sepsis due to functional asplenia and failure to make antibodies against encapsulated organisms; patients should be evaluated for temperature greater than 38.5°C. A low threshold for empiric therapy is recommended.

Pathogens: *Streptococcus pneumoniae* (most common), *Haemophilus influenzae*, *Salmonella*, *Mycoplasma pneumoniae*, *Chlamydia*, and viruses (parvovirus B19)

Evaluation: Physical examination, complete blood count (CBC) with reticulocyte, urinalysis, chest x-ray, and cultures (blood, urine, and throat); lumbar puncture if toxic-looking or presenting with signs of meningitis; needle aspirate in patients with findings suggestive of osteomyelitis

Cerebrovascular accidents (stroke)^b

Clinical features: Incidence is four times higher for HbSS than HbSC. Initial episode most often occurs during the first 10 years of life. “Silent infarcts” as evidenced by changes on magnetic resonance imaging (MRI) have been reported in 21.8% of HbSS and may be associated with increased risk of stroke and decreased neurocognitive function.

Cause: Most common is cerebrovascular occlusion. Other causes include intracranial hemorrhage, cardiac embolism, infection, and clotting disorders. *Signs and symptoms:* Headache, vomiting, stupor, hemiparesis, aphasia, visual disturbances, and seizure; transient ischemic attack is a strong predictor for stroke. Behavioral and performance changes may be present in patients with asymptomatic infarction.

Evaluation: Perform computed tomography (CT) scan and MRI for evaluation of acute event. Perform magnetic resonance angiography for asymptomatic infarction. Perform transcranial Doppler to detect abnormal velocity and identify high-risk patients. Perform electroencephalography if there is a history of seizure.

Acute chest syndrome (ACS)^c

Clinical features: ACS occurs in 15% to 43% of patients and is responsible for up to 25% of deaths. Risk factors include young age, low HbF level, high Hgb and WBCs, winter seasons, and reactive airway disease. Recurrences are up to 80% and can lead to chronic lung diseases in adulthood.

Signs and symptoms: New infiltration on X-ray accompanied by fever, cough, dyspnea, chest pain, hypoxia, leukocytosis. Can progress to acute respiratory distress syndrome and death.

Cause: Exact cause remains unknown but pulmonary sickling resulting in infarction is the key element. Proposed etiologies include: infectious (*S. pneumoniae*, *H. influenzae*, *Chlamydia*, *Mycoplasma*, and viral) and noninfectious (fat embolization from bone infarction, hypoventilation secondary to pain, narcotics, etc).

Evaluation: Close monitoring of pulmonary status, blood gases (if indicated), oxygen saturation, chest x-ray, blood and sputum cultures, CBC, bronchoscopy with lavage (if needed)

Priapism^d

Clinical features: Priapism is defined as a painful and unwanted erection, which is classified as stuttering (less than 3 hours, often multiple episodes) or prolonged (more than 3 hours). Up to 89% of males with SCD will have at least one episode by age 20. The mean age of the initial episode is 12 years of age. Repeated episodes can cause fibrosis and impotence.

Cause: Sickling in the sinusoids of the penis

Signs and symptoms: Prepubertal children often present with stuttering priapism. Older males can present with prolonged episodes that last for days and should be managed as medical emergencies. Urinary obstruction can occur in severe cases.

Evaluation: Physical examination; monitor duration of episode and for signs of urinary retention.

to be 42 years for males and 48 years for females for HbA, and 60 years for males and 68 years for females for HbSC.⁵ Predictors for severe disease in children who are less than 10 years of age include dactylitis before 1 year of age, an average Hgb level less than 7 g/dL in the second year of life, and WBC count greater than 13,700/mm³ in the absence of infection. Risk factors for early death in adults with SCD include acute complications such as pain crisis, anemic events, acute chest syndrome, renal failure, and pulmonary disease (Tables 101–2 and 101–3).^{5,15–17} Today, with longer survival for SCD, chronic manifestations of the disease contribute to the morbidity later in life (Table 101–4).

COMPLICATIONS**ACUTE COMPLICATIONS**

For acute complications of SCD, see Table 101–2.

FEVER AND INFECTION

Functional asplenia and failure to make antibodies against encapsulated organisms contribute to the high risk of overwhelming sepsis

in patients with SCD. The most common pathogen is *Streptococcus pneumoniae*. Other encapsulated organisms are *Haemophilus influenzae* and *Salmonella*, and the latter has been known to cause osteomyelitis and pneumonia in SCD. *Mycoplasma pneumoniae* should be considered in older children with infiltrates on chest x-ray. Viral infections (e.g., influenza and parvovirus B19) can result in severe morbidity.^{1,5,18,19}

All SCD patients with fever greater than 38.5°C must be evaluated to determine the extent of sepsis; work-up may include physical examination, complete blood count with reticulocyte count, blood culture, chest x-ray, urinalysis, and urine culture. Lumbar puncture may be needed, especially in young children and toxic-looking children. A low threshold for empiric therapy compared to that in the general population is recommended.^{1,5,13}

NEUROLOGIC

Neurologic abnormalities can occur in both adults and children. Vaso-occlusive processes occasionally lead to cerebrovascular occlusion that manifests itself as the signs and symptoms of stroke, such as drowsiness, paralysis, transitory or permanent blindness, aphasia, visual disturbances, spinal cord infarction, and convulsions. The onset

TABLE 101–3. Sickle Cell Crisis

Vaso-occlusive Pain Crisis^a

Clinical features: Acute painful infarction without changes in Hgb; almost all patients with SCA will have episodes of acute pain. Recurrent acute crises result in bone, joint, and organ damage and chronic pain. Vaso-occlusive crisis most commonly involves the bones, liver, spleen, brain, lungs, and penis. Acute long bone pains may be accompanied by signs of inflammation, making it difficult to differentiate from osteomyelitis. Abdominal involvement may resemble a surgical abdomen. Precipitating factors include infection, extreme weather conditions, dehydration, and stresses.

Signs and symptoms: Deep throbbing pain; local tenderness, erythema, and swelling may be seen. Fever and leukocytosis are common. Dactylitis usually occurs in young infants. Jaundice and increased transaminases present if liver is involved.

Evaluation: Frequent physical examination, complete blood count (CBC), reticulocyte, and urinalysis; based on symptomatology, the following may be needed: needle aspiration to rule out osteomyelitis, abdominal studies (x-ray, computed tomography scan, etc), liver function tests, bilirubin, culture, and chest x-ray.

Aplastic crisis^b

Clinical features: Acute decrease in Hgb with decreased reticulocyte count (usually less than 1%); transient suppression of RBC production in response to bacterial or viral infection, most common being parvovirus B19

Signs and symptoms: Headache, fatigue, dyspnea, pallor, and tachycardia; may also present with fever, upper respiratory or gastrointestinal infection symptoms.

Evaluation: CBC, reticulocyte count, x-ray, cultures (blood, urine, and throat), parvovirus titers

Acute splenic sequestration crisis^c

Clinical features: Acute exacerbation of anemia due to sequestration of large blood volume by the spleen. More commonly seen in patients with functioning spleens (e.g., infants and adults with HbSC disease); onset often is associated with viral or bacterial infections; recurrences are common and can be fatal.

Signs and symptoms: Sudden onset of fatigue, dyspnea, and distended abdomen; rapid decrease in Hgb and Hct with elevated reticulocyte count, abdominal pain, splenomegaly, vomiting, hypotension, and shock

Evaluation: Close monitoring of vital signs, spleen size, and oxygen saturation, CBC, reticulocyte, and cultures

TABLE 101–4. Chronic Complications of Sickle Cell Disease (SCD)

| System | Complications |
|------------------------|--|
| Auditory | Sensorineural hearing loss due to sickling in cochlear vasculature with hair cell damage |
| Cardiovascular | Cardiomegaly, myocardial ischemia, murmurs, and abnormal electrocardiogram; patients with SCD have lower blood pressure (BP) than the normal population; normal BP values for SCD should be used for diagnosis of hypertension (“relative” hypertension); heart failure usually is related to fluid overload |
| Dermatologic | Painful leg ulcers; failure to heal occurs in 50% of patients; recurrences are common |
| Genitourinary | Renal papillary necrosis, hematuria, hyposthenuria, proteinuria, nephritic syndrome, tubular dysfunction, chronic renal failure, impotence |
| Growth and development | Delay in growth (weight and height) and sexual development; decreased fertility; increased complications during pregnancy; depression may be more prevalent than in general population, especially in patients with unstable disease |
| Hepatic and biliary | Cholelithiasis, biliary sludge, acute and chronic cholecystitis, and cholestasis (can be progressive and life-threatening) |
| Neurologic | “Silent” brain lesions on magnetic resonance imaging are associated with poor cognitive and fine motor functions; pseudotumor cerebri (case report) |
| Ocular | Retinal or vitreous hemorrhage, retinal detachment, transient or permanent visual loss; central retinal vein occlusion |
| Pulmonary | Pulmonary fibrosis, pulmonary hypertension, cor pulmonale |
| Renal | Hematuria, hyposthenuria (inability to concentrate urine maximally), tubular dysfunction, enuresis during early childhood, acute renal failure can also occur |
| Skeletal | Aseptic necrosis of ball-and-socket joints (shoulder and hip); prostheses may be needed due to permanent damage; bone marrow hyperplasia resulting in growth disturbances of maxilla and vertebrae |
| Spleen | Asplenia (autosplenectomy or surgical splenectomy) |

From Fixler et al,¹ National Institutes of Health,⁵ Dover et al,¹³ Kral et al,²¹ Vichinsky et al,²⁷ Gladwin et al,³⁰ Henry et al,³¹ Mukisi-Mukaza et al,³² Hasan et al,³³ Babalola et al,³⁴ de Montalembert et al,³⁵ Hassan et al,³⁶ and Schatz et al.³⁷

is usually sudden, but occasionally may be gradual. Milder symptoms may occur as a result of vascular stasis. Some patients recover rapidly and completely, while others are left with permanent neurologic deficits. In addition, some patients who have SCA with no prior history of stroke have been found to have changes on magnetic resonance imaging of the brain that suggests infarction or ischemia. These “silent infarcts” have been reported to occur in up to 21.8% of HbSS patients and may be associated with increased risk of stroke and decreased neurocognitive functions.^{1,13,20–22}

ACUTE CHEST SYNDROME

Acute chest syndrome (ACS) is the leading cause of death among patients with SCD. It is characterized by acute new pulmonary infiltrate, other respiratory symptoms (such as cough, dyspnea, chest pain, fever, and wheezing), and an equivocal response to antibiotic therapy. As many as one-half of patients with SCD develop ACS at least once. Pulmonary infarcts often involve the lower lobes of the lungs and are a frequent cause of pleural effusions. Pneumonia occurs most often in the middle and upper lobes. These pulmonary manifestations must be recognized early and managed aggressively because the patient may rapidly progress to pulmonary failure and death.^{23–27}

PRIAPISM

Sickling in the sinusoids of the penis can cause priapism, a sustained painful erection that may last several hours or days. Impotence has been reported after repeated episodes. ASPEN (association of sickle cell disease, priapism, exchange transfusion, and neurological events) syndrome has occurred in some patients with priapism after partial exchange transfusion. The syndrome can range from headaches and seizures to obtundation requiring ventilation.^{1,5,13}

SICKLE CELL CRISIS

Chronic hemolytic anemia in the SCD patient is periodically interrupted by crises, particularly in childhood (see Table 101–3). Patients with HbSS disease experience crises more often than do patients with HbSC disease or some other variants. Although fever, infections, dehydration, hypoxia, acidosis, and sudden temperature alterations can precipitate crises, multiple factors often contribute to development of a crisis.

Vaso-Occlusive Pain Crisis

The most common type of crisis is the vaso-occlusive crisis, which is usually characterized by pain affecting the involved areas, without changes in hemoglobin. Laboratory changes that may be seen include leukocytosis, increased serum levels of fibrinogen, and decreased serum pH and bicarbonate level. Dactylitis (hand-and-foot syndrome) occurs in infancy and early childhood, and is characterized by redness and swelling of the dorsal aspects of the hands, feet, fingers, and toes. The episodes are painful, but there usually is no permanent damage. Children most likely to develop severe SCD later in life are those who experience dactylitis, along with severe anemia and noninfectious leukocytosis during the first 2 years of life.^{1,5,13,28}

Aplastic Crisis

Aplastic crisis is characterized by a decrease in the reticulocyte count and a rapidly developing severe anemia. The bone marrow is hypoplastic. There may be associated pain. The crisis is thought to be caused by a viral infection, particularly B19 parvovirus.^{1,5,13,29}

Splenic Sequestration Crisis

This is a sudden massive enlargement of the spleen resulting from the sequestration of blood from the reticuloendothelial system. There is a dramatic fall in hematocrit and hemoglobin concentration, with no evidence of marrow failure or accelerated hemolysis. The trapping of the sickled RBCs by the spleen also leads to a drop in circulating blood volume, which can result in hypotension and shock. The condition is most often seen in infants and children, as their spleens are intact. These crises can cause sudden death in young children. Repeated infarctions lead to autosplenectomy as the disease progresses; therefore the incidence declines as adolescence approaches.^{1,5,13}

CHRONIC COMPLICATIONS

SCD manifests in a variety of chronic problems involving multiple organs (see Table 101–4). Pulmonary hypertension has been reported to be a risk factor for death in adult patients with SCD.³⁰ Headache is a symptom associated with acute neurologic events; however, pseudotumor cerebri presenting with severe headache and blurred vision was recently reported.³¹ Destructive bone and joint problems are common. Aseptic necrosis, particularly of the femoral or humeral heads, causes permanent damage and disability. Patients with SCD also have an increased incidence of osteomyelitis; the organism most often responsible is *Salmonella*. In addition to necrosis of joints, chronic leg ulcers can become a difficult skeletal problem. The inner aspect of the lower leg just above the ankle is the site most often affected. Ulcers are often seen after trauma or infection; they are usually slow to heal, taking several weeks to a year.^{1,5,32}

Ocular problems seen in patients with SCD include transient monocular blindness, visual field defects from retinal hemorrhage, retinal detachment, vitreous hemorrhage, venous microaneurysms, and neovascularization. The incidence of proliferative retinopathy in SCD patients varies from 5% to 10%. Vaso-occlusion in the eye can occur as early as 20 months and clinically detectable retinal diseases usually occur during adolescence and early adulthood. Despite the less systemic manifestations, patients with HbSC develop serious retinal complications more often and earlier. Annual examination with retinal evaluation is recommended for patients with SCD to prevent blindness from retinopathy and other complications.^{5,33,34}

Cholelithiasis is a common occurrence in the SCD patient. It is the result of the chronic hemolysis that results in increased bilirubin production, leading to biliary sludge and/or stone formation. Cholecystitis, exemplified by pain in the right iliac fossa, can be confused with abdominal pain crisis.^{1,5}

As with any anemia, cardiovascular abnormalities, including cardiac enlargement and various murmurs, can occur in patients with SCD. Patients complain of various degrees of exertional dyspnea, tachycardia, and palpitation owing to the decreased oxygen-carrying capacity of the blood.^{5,35}

Renal complications include unilateral hematuria and hyposthenuria (inability to concentrate urine maximally). Enuresis, as a result of increased urine production, is a common complaint. Death from renal disease is unusual among younger patients, but does occur among older patients with SCD.^{1,5}

Depression may be more prevalent than in the general population, especially in patients with unstable disease.^{36,37} Delay in growth and sexual development are seen in patients with SCD. Adults with SCD have decreased fertility. Finally, pregnancy introduces an increased risk for the mother with SCD and for the fetus. The anemia of SCD may lead to intrauterine growth retardation. Preterm labor and premature delivery are common occurrences in mothers with SCD,

and the risk of spontaneous abortion is increased. The incidence of preeclampsia is also higher than in mothers who do not have SCD. The periodicity of past pain crisis is predictive of the likely events during pregnancy, although some patients may experience increased frequency of pain crisis during pregnancy. The presentation of such patients is similar to that of nonpregnant patients—severe localized or generalized pain, low-grade fever, and mild leukocytosis.^{1,5}

CONTINUING CARE AND SUPPORT

Patients with SCD require lifelong multidisciplinary care. All patients with SCD should receive regularly scheduled comprehensive medical evaluations. The goals of the comprehensive care are reduction of

hospitalizations, complications, and mortality. Due to the complexity of the disease, a multidisciplinary team is needed to provide medical care, education, counseling, and psychosocial support. Appropriate comprehensive care can have a positive impact on both longevity and general quality of life. This care includes the use of traditional prophylactic and general symptomatic supportive care, as well as the use of newer, more specific therapies aimed at altering hematologic capacity and function.^{1,5}

Treatment for patients with SCD involves the use of general measures to meet the unique demands for increased erythropoiesis. Additional interventions may be aimed at preventing or treating complications of the disease. When crises occur, the type and severity of the crisis determines the appropriate therapeutic plan. A treatment overview is shown in Table 101–5.^{1,5,13,20,26–28,38–79}

TABLE 101–5. Management of Sickle Cell Disease

| Options and Comments | |
|---------------------------------|--|
| Health maintenance | |
| Infection prophylaxis | <ul style="list-style-type: none"> • Pneumococcal vaccines (PCV 7 and PPV 23) • Penicillin prophylaxis for children less than 5 years old • Annual influenza vaccine |
| Induction of fetal hemoglobin | <ul style="list-style-type: none"> • Hydroxyurea is the primary agent • Other agents are butyrates (arginine butyrate and sodium phenylbutyrate), decitabine, clotrimazole, and erythropoietin • Combination HbF inducers have been proposed |
| Chronic transfusion therapy | <ul style="list-style-type: none"> • Primary indication: stroke prevention in pediatric patients • May also reduce pain crisis and acute chest syndrome • Goal: maintain HbS less than 30% |
| Future prospects | |
| Transplantation | <ul style="list-style-type: none"> • May potentially cure the disease • Most experience is with HLA-matched donors; umbilical cord blood transplantation is being evaluated |
| Crises and complications | |
| Fever and infection | <ul style="list-style-type: none"> • Broad-spectrum antibiotic: cefotaxime or ceftriaxone (clindamycin for cephalosporin allergy); vancomycin for staphylococcal and resistant pneumococcal organisms • Fluids • Acetaminophen or ibuprofen for fever |
| Stroke | <ul style="list-style-type: none"> • Exchange transfusion • Initiate chronic transfusion therapy to prevent recurrent strokes |
| Acute chest syndrome | <ul style="list-style-type: none"> • Broad-spectrum antibiotics (include <i>Mycoplasma</i> coverage) • Bronchodilator if wheezing or history of reactive airway disease • Fluids • Pain management • Transfusion |
| Priapism | <ul style="list-style-type: none"> • Hydration • Pain management • Urology consult for other options (intra-penile injection or surgery) |
| Aplastic crisis | <ul style="list-style-type: none"> • Supportive care • Transfusion for severe symptomatic anemia |
| Sequestration crisis | <ul style="list-style-type: none"> • Transfusion • Broad-spectrum antibiotic • Splenectomy in severe cases |
| Pain crises | <ul style="list-style-type: none"> • Hydration • Analgesics |

TABLE 101–6. Pneumococcal Immunization for Children with Sickle Cell Disease

| Recommended Schedule | |
|---|--|
| Previously unvaccinated | |
| Age 2–6 months | PCV 7 (Pneumovax): 3 doses 6–8 wk apart; then 1 dose at 12–15 months |
| Age 7–11 months | PCV 7 (Pneumovax): 2 doses 6–8 wk apart; then 1 dose at 12–15 months |
| Age ≥12–23 months | PCV 7 (Pneumovax): 2 doses 6–8 wk apart |
| Age 24–59 months | PCV 7 (Pneumovax): 2 doses 6–8 wk apart PPV 23 (Pneumovax): 2 doses; first dose at least 6–8 wk after last PCV 7 dose; second dose 3–5 years after the first PPV 23 dose |
| Age 5 years or older | PCV 7 (Pneumovax): 1 dose PPV 23 (Pneumovax): 2 doses; first dose at least 6–8 wk after last PCV 7 dose; second dose 3–5 years (for those age 10 years or younger) or more than 5 years (for those age 10 years or older) after the first PPV 23 dose |
| Previously vaccinated | |
| Age 12–23 months, incomplete PCV 7 series | PCV 7 (Pneumovax): 2 doses 6–8 wk apart |
| Age 24–59 months, received four doses of PCV 7 | PPV 23 (Pneumovax): 2 doses; first dose at least 6–8 wk after last PCV 7 dose; second dose 3–5 years after the first PPV 23 dose |
| Age 24–59 months, three doses PCV 7 given before 24 months of age | PCV 7 (Pneumovax): 1 dose PPV 23 (Pneumovax): 2 doses; first dose at least 6–8 wk after last PCV 7 dose; second dose 3–5 y after the first PPV 23 dose |
| Age 24–59 months, 1 dose PPV 23 given | PCV 7 (Pneumovax): 2 doses 6–8 wk apart; first dose at least 8 wk after PPV 23 dose PPV 23 (Pneumovax): second dose 3–5 years after first PPV 23 |
| Age 5 years or older, received PPV 23 | PCV 7 (Pneumovax): 1 dose 6–8 wk after PPV 23 If only received 1 dose of PPV 23 (Pneumovax): Second dose 6–8 wk after PCV 7 and 3–5 years (for those age 10 years or less) or more than 5 years (for those age 10 years or older) after the first PPV 23 dose |

PCV 7, 7-valent pneumococcal conjugated vaccine; PPV 23, 23-valent pneumococcal polysaccharide vaccine. From Advisory Committee on Immunization Practices,³⁹ Committee on Infectious Diseases,⁴⁰ and Sickle Cell Disease Care Consortium.⁴¹

HEALTH MAINTENANCE

IMMUNIZATIONS

Administration of routine immunizations as recommended by the American Academy of Pediatrics is crucial. In addition to the routine immunizations, SCD patients 6 months and older should also receive influenza vaccine annually. Meningococcal vaccine is also recommended for patients greater than 2 years of age undergoing splenectomy.^{38–40}

Patients with SCD have impaired splenic function, which increases their susceptibility to infection by encapsulated organisms, particularly pneumococci. Prior to the routine use of penicillin prophylaxis and the development of pneumococcal vaccines, invasive pneumococcal disease was 20- to 100-fold more common in children with SCD than in healthy children. Even with these interventions, some groups of children with SCD continue to have a high rate of invasive pneumococcal infections.^{18,38}

4 Two different pneumococcal vaccines are available. The 7-valent pneumococcal conjugate vaccine (PCV 7; Prevnar) induces good antibody responses in infants. Immunization with the PCV 7 is recommended for all children less than 24 months of age. Infants should receive the first dose between 6 weeks and 6 months. Two additional doses should be given at approximately 2-month intervals, followed by a fourth dose at age 12 to 15 months. The 23-valent pneumococcal polysaccharide vaccine (PPV 23; Pneumovax 23) was not recommended for use in children less than 2 years of age because

of poor antibody response. To cover for different serotypes, the immunization schedule for children with sickle cell disease should include both pneumococcal vaccines. PPV 23 should be given at 2 years of age or older, administered approximately 2 months after the last dose of the PCV 7. An additional dose of the PPV 23 administered 3 to 5 years later should be considered. The recommended immunization schedule and catch-up schedule for PCV 7 and PPV 23 are presented in Table 101–6.^{39–41}

CLINICAL CONTROVERSY

Some sickle cell centers administer a third dose of PPV 23. Meningococcal vaccine is recommended by the American Academy of Pediatrics for asplenic patients, but its routine use for nonsurgical asplenic patients varies among centers.

PENICILLIN

4 Penicillin prophylaxis until at least 5 years of age is also recommended in children with SCD, even if they have been immunized with the 7-valent vaccine as prophylaxis against pneumococcal infections. Prophylactic treatment should begin at 2 months of age or earlier. An effective regimen that yields an 84% decrease in observed incidence of pneumococcal infections is penicillin V potassium at a dosage of 125 mg orally twice daily until the age of 3 years, followed by 250 mg twice daily until the age of 5 years. An alternate regimen

is benzathine penicillin, 600,000 units given intramuscularly every 4 weeks for children age 6 months to 6 years, and 1.2 million units every 4 weeks for those over 6 years of age for whom continued therapy is warranted. Patients who are allergic to penicillin can be given erythromycin 20 mg/kg per day twice daily. Penicillin prophylaxis is not routinely needed in older children, based on a study demonstrating no benefit over placebo beyond the age of 5. However, continuation of oral pneumococcal prophylaxis should be handled on a case-by-case basis, especially in patients with a history of invasive pneumococcal infection or surgical splenectomy.^{1,5,13,39–42}

CLINICAL CONTROVERSY

Routine penicillin prophylaxis is controversial in HbS β^+ -thalassemia patients.

FOLIC ACID

Patients with SCD have an increased demand for folic acid because of accelerated erythropoiesis. Megaloblastic changes have been reported, but the actual incidence of megaloblastic anemia in association with SCD is unknown. Conflicting data on serum folate levels have been reported. In children and adolescents, one study reported normal folate stores in SCD patients without receiving supplemental folic acid, and another study reported that 15% of patients had low folate levels despite daily supplementation. A trial of folate supplementation in infants and young children has not shown any beneficial effect on growth or acute events. In general, folic acid supplementation at a dose of 1 mg/day is recommended in adult patients, women who are contemplating pregnancy, and patients of all ages with chronic hemolysis.^{5,13,43–45}

FETAL HEMOGLOBIN INDUCERS

Fetal hemoglobin (HbF) has a direct effect on polymer formation. Increases in HbF levels significantly decrease RBC sickling and RBC adhesion. Epidemiologic studies have demonstrated the direct relationship between HbF concentration and severity of the disease. Patients with low HbF levels have more frequent crises and higher mortality. Based on these observations, HbF induction has become a treatment modality for patients with SCD.^{6,13}

HYDROXYUREA

Hydroxyurea, a chemotherapeutic agent, stimulates the production of HbF, resulting not only in increased HbF levels, but also increases in the number of HbF-containing reticulocytes and intracellular HbF. Its antineoplastic activity involves prevention of DNA synthesis by blocking ribonucleoside conversion to deoxyribonucleotides. The exact mechanism on HbF production is unknown, but it may be directly or indirectly related to erythropoiesis in that cyto-reduction in the bone marrow results in alteration of RBC differentiation toward macrocytosis and HbF production. Recent studies show that hydroxyurea increases nitric oxide (NO) levels, which suggests its effect on HbF may be mediated by stimulation of NO-dependent guanylyl cyclase, which induces γ -globin expression.^{46–48} This new finding provides the rationale for the development of NO as a treatment modality for SCD.⁴⁹ In addition to increased HbF, hydroxyurea has other beneficial effects, including reduction of neutrophils and monocytes, possession of antioxidant properties, alteration of RBC membrane properties, increased red cell deformability by increased intracellular water con-

tent, decreased red cell adhesion to endothelium, and increased NO, a regulator involved in physiologic disturbances.^{5,46–48,50}

Hydroxyurea is useful in the prevention of painful crises and has been approved by the FDA for adult patients based on a double-blind, placebo-controlled study called the Multicenter Study of Hydroxyurea in Sickle Cell Anemia (MSH). In this study of 299 adult SCD patients, hydroxyurea significantly reduced the frequency of painful episodes, the incidence of ACS, the need for blood transfusions, and the number of hospitalizations.⁵⁰ The number of crises was 44% lower in those who received hydroxyurea, declining from an average of 4.5 to an average of 2.5 crises per year. The incidence of severe crises, defined as those requiring hospitalization, was also lower, with a median rate of 2.4 severe crises per year in the placebo group versus 1 severe crisis in the hydroxyurea group. The risk of ACS was also significantly reduced in patients receiving hydroxyurea. Of the 152 patients in the hydroxyurea group, 25 (16.4%) developed ACS, as compared with 51 (34.7%) of the 147 patients in the placebo group. Blood transfusion requirements were decreased by 34% in the hydroxyurea group. The study was terminated early after interim analyses revealed the significant benefits. The incidence of death, stroke, and hepatic sequestration in the hydroxyurea and placebo groups was not significantly different during the 29-month evaluation period. However, a follow-up study of 233 of the 299 patients reported a 40% reduction in mortality with hydroxyurea over a 9-year period.⁵¹ The patients enrolled in the study were adult populations with moderate to severe SCD in adult populations. Therefore its benefits may not be applicable to patients with milder disease, such as HbSC.

Although not FDA approved, hydroxyurea is also used in selected children and adolescents with SCD. A phase I/II study of hydroxyurea in pediatric patients (Pediatric Hydroxyurea in Sickle Cell Anemia) reported similar benefits as in adults with no adverse effects on growth and development. A pilot study in infants demonstrated that the agent is well tolerated. Both studies involved smaller number of pediatric patients. Another study, BABY HUG, supported by the National Heart, Lung and Blood Institute will be available to evaluate if hydroxyurea therapy is effective in prevention of chronic end-organ damage in young children with SCA.^{5,52–54}

The most common side effect of hydroxyurea is bone marrow suppression. In the MSH trial, 14 of 152 patients in the hydroxyurea group and 6 of 147 patients in the placebo group required permanent discontinuation of treatment due to medical reasons. Temporary discontinuation of therapy occurred in almost all patients because of bone marrow suppression, which usually recovered within 2 weeks.⁵⁰ Long-term side effects of hydroxyurea therapy in patients with SCD are not fully known. Myelodysplasia, acute leukemia, and chronic opportunistic infection associated with T-lymphocyte abnormalities have been reported.^{13,41,55} In the 9-year follow-up study, 3 of 233 patients who received hydroxyurea have developed cancer.⁵¹ However, only 23 of those patients received more than 8 years therapy, a duration that had been associated with an increased risk of acute leukemia.⁵⁶ Therefore longer follow-up is needed to determine its carcinogenic or leukemogenic effects. Teratogenicity is another concern, as high-dose hydroxyurea has been shown to be teratogenic in animals. Normal pregnancies resulting in no birth defects have been reported in at least 15 women receiving hydroxyurea.^{13,41}

Clinical indications for hydroxyurea use include frequent painful episodes, severe symptomatic anemia, a history of ACS, or other severe vaso-occlusive complications.^{13,41} It has not been proved that hydroxyurea will prevent organ damage or reverse previous damage. Splenic regeneration, however, has been reported in adult patients who received the agent. Hydroxyurea does not appear to prevent neurologic complications, but preserved cognitive performance has been

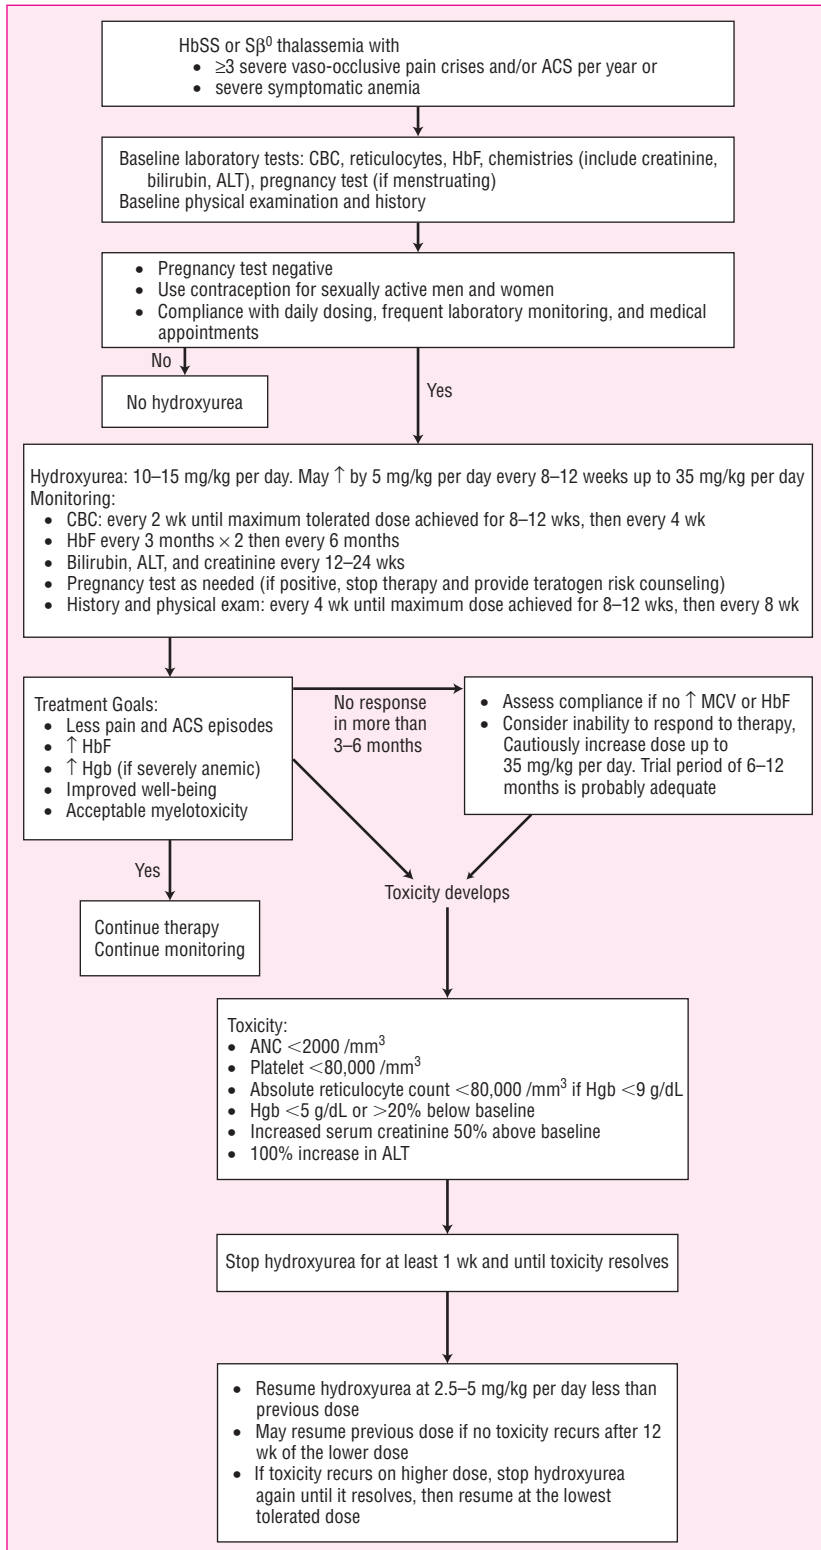

FIGURE 101–7. Hydroxyurea use in sickle cell disease. ACS, acute chest syndrome; ALT, alanine aminotransferase; ANC, absolute neutrophil count; CBC, complete blood cell count; HbF, fetal hemoglobin; Hgb, hemoglobin; HbSS, homozygous sickle hemoglobin; MCV, mean corpuscular volume. (From Dover et al¹³ and Sickle Cell Disease Care Consortium.⁴¹)

reported. As mentioned previously, decreases in mortality have been reported in adult sickle cell patients in a 9-year follow-up study.^{30,51}

Hydroxyurea is available in 200-, 300-, 400-, and 500-mg capsules. For children who are unable to swallow capsules, liquid preparations (100 mg/mL) can be prepared extemporaneously. The starting dose for hydroxyurea is 10 to 15 mg/kg per day as a single daily dose (Fig. 101–7). The dosage can be increased after 8 to 12 weeks if

the patient has not experienced intolerable adverse effects and blood counts are stable. Hydroxyurea dosage should be individualized based on response and toxicity. In general, 3 to 6 months of daily administration are required before improvement is observed. Compliance with medication use can be an issue. Since the mean corpuscular volume (MCV) generally increases as the level of HbF increases, monitoring the MCV is an inexpensive and convenient method of monitoring

response. With close monitoring, hydroxyurea can be increased by 5 mg/kg per day up to 35 mg/kg per day, the maximal prescribed dose in the MSH study.^{13,50}

5 Patients receiving hydroxyurea should be closely monitored for toxicity. Blood counts should be checked every 2 weeks during dose titration and every 4 to 6 weeks thereafter. Treatment should be interrupted if hematologic indices fall below the following values: absolute neutrophil count, 2000/mm³; platelet count, 80,000/mm³; hemoglobin, 5 g/dL; or reticulocytes, 80,000/mm³ if the hemoglobin concentration is less than 9 g/dL. Other laboratory abnormalities warranting temporary discontinuation of therapy are a 50% increase in serum creatinine and a 100% increase in transaminase.

After recovery has occurred, treatment should be resumed at a dose that is 2.5 to 5 mg/kg per day lower than the dose associated with toxicity. If no toxicity occurs after 12 weeks with the lower dose, the dose may be increased by 2.5 to 5 mg/kg per day. A given dose that twice produces a toxic hematologic response should not be tried again. Failure to see an increase in the MCV with hydroxyurea therapy may indicate that the marrow is unable to respond, the hydroxyurea dose is inadequate, or the patient is noncompliant.^{13,41}

BUTYRATE

Butyrate, a naturally occurring fatty acid, increases HbF by altering gene expression, which leads to increased gamma globin chain production. Unlike hydroxyurea, butyrate does not appear to be cytotoxic.

Butyrate has been studied in small number of adult patients. Initial trials administering butyrate by continuous infusion showed an increase not only in HbF, but also in total Hgb and in the number of cells containing HbF. However, a sustained effect or an associated clinical benefit has not been observed. A later study utilizing arginine butyrate as a pulse regimen demonstrated a sustained increase in HbF and reduction of hospitalized days in a small number of adult patients. In that study, adult patients received a 4-day course of arginine butyrate, followed by a 10- to 24-day drug-free period before the administration of the next dose. Arginine butyrate was given at a daily dose of 250 to 500 mg/kg over 6 to 12 hours. Although the results are encouraging, the need for intravenous administration may prevent wide use of the regimen.⁵⁷

Oral sodium penylbutyrate has been used for years in young children with urea cycle disorders. At high doses, side effects include transient fluid retention, rashes, and unusual body odor. Increased HbF levels were seen in patients with SCA who received both high-dose (15 to 20 g/day) and low-dose (1 to 11 g/day) regimens. In the study of low-dose sodium penylbutyrate, increased HbF was seen within 5 weeks, but may not be sustained. The studies of butyrate involved a small number of patients. More clinical trials are needed to determine the optimal dosage and regimen.^{5,58}

5-AZA-2'-DEOXYCYTIDINE (DECITABINE)

5-Azacytidine and 5-aza-2'-deoxycytidine (decitabine) induce HbF by inhibiting methylation of DNA, thus preventing the switch from γ - to β -globin production. Decitabine has a more favorable safety profile and is a more potent methylation inhibitor than 5-azacytidine. Virtually abandoned in the past because of concerns regarding the cytotoxicity of 5-azacytidine, decitabine has now been studied in a small number of patients with SCD who did not respond to hydroxyurea. In one study, 5-aza-2'-deoxycytidine was given at a dose of 0.2 mg/kg one to three times a week subcutaneously to eight adult patients resistant or intolerant to hydroxyurea. An increase in fetal hemoglobin was seen in all patients. In addition, reduction of adhesion was reported with the RBC adhesion study. The only significant toxicity reported

was neutropenia. This agent may have a role in treating patients who fail to respond to hydroxyurea.^{5,59}

COMBINATIONS OF HEMOGLOBIN F INDUCERS

Erythropoietin therapy has been used in only a limited number of patients with SCD and the clinical results have been inconsistent; therefore its routine use in these patients cannot be recommended. When used in combination with hydroxyurea, erythropoietin increases HbF levels to a greater extent than hydroxyurea alone. This suggests that there may be a role for addition of erythropoietin therapy in patients who do not respond to hydroxyurea alone, although more studies are needed. Other proposed combinations are hydroxyurea combined with either penylbutyrate or clotrimazole, based on their different mechanisms of action.^{13,47,58}

CLOTRIMAZOLE

Clotrimazole, an antifungal agent, causes a decrease in cell density by blocking cation transport channels in the erythrocyte membrane. The decrease seen, however, is less than that demonstrated with hydroxyurea therapy. It is unclear whether this agent will be clinically useful in the treatment of SCA.⁴⁷

CHRONIC TRANSFUSION THERAPY

Transfusions play an important role in the management of SCD. In acute illness, transfusions can be life-saving and will be discussed in a later section. Maintenance transfusion programs are used to prevent serious complications of SCD. The primary indication for chronic transfusion is stroke prevention. Chronic transfusions help prevent stroke and stroke recurrence in children.

6 In children who had a stroke, chronic transfusions are successful in reducing stroke recurrence from approximately 50% to about 10% over 3 years.⁶⁰⁻⁶² Since the first stroke in SCD is usually devastating, transfusions have been used to prevent the first stroke. In one trial, prophylactic transfusions significantly reduced the incidence of first stroke over a 2-year period in children 2 to 16 years of age with abnormal transcranial Doppler (TCD) ultrasonography. Stroke occurrence rate was reduced from 16% in patients receiving standard care to 2% in those who received prophylactic transfusions.⁶³

Chronic transfusions may also reduce the incidence of vaso-occlusive pain and ACS, and prevent progression of organ damage. Reversal of pre-existing organ dysfunction has been reported. Improved quality of life, energy levels, exercise tolerance, and growth and sexual development have also been reported. Selected patients in whom chronic transfusion should be considered are patients with transient ischemic attack, abnormal TCD, severe or recurrent ACS, debilitating pain, splenic sequestration, recurrent priapism, chronic organ failure, intractable leg ulcers, severe chronic anemia with cardiac failure, and complicated pregnancies.^{5,41}

The goal of transfusions is to achieve and maintain an HbS concentration of less than 30% of total hemoglobin. Frequency of transfusions is adjusted to maintain the desired HbS levels and is usually every 3 to 4 weeks. After 4 years of therapy without development of complications, many clinicians give transfusions less frequently and allow the HbS concentration to rise to 50% of total hemoglobin.^{4,5,41} The optimal duration of chronic transfusion therapy is not known. For secondary prevention, current recommendations are to continue transfusion for at least 5 years or until age 18. A study is underway to determine when transfusions can be safely stopped for primary stroke prevention.⁵

Although the benefits of transfusion therapy are relatively clear in some clinical situations, the usefulness of this therapy in other situations remains controversial. Therefore the risks of transfusion therapy must be weighed against possible benefits. The risks associated with transfusion therapy include alloimmunization (sensitization to the blood received), hyperviscosity, viral transmission, volume overload, iron overload, and transfusion reactions. Alloimmunization occurs in 18% to 36% of SCD patients who receive blood transfusions. The use of leukocyte-reduced RBC transfusions or HLA-matched units in chronically transfused patients may reduce the risk of alloimmunization. Transfusion-related infections also remain a concern. All patients should be immunized with hepatitis A and B vaccines. Presently, hepatitis C is considered the most serious risk associated with transfusion therapy, with an infection rate of approximately 1 in every 100,000 transfusions. The risk of contracting acquired immunodeficiency syndrome from blood transfusions, while still of concern, has decreased with routine blood screening. Iron overload is another complication of transfusions and patients should be counseled to avoid excess dietary iron. Abnormal liver biopsy results showing mild to moderate inflammation or fibrosis have been reported. Chelation therapy with deferoxamine should be considered after more than 1 year of chronic transfusions or when serum ferritin is greater than 1500 to 2000 ng/mL. Deferoxamine has been associated with oto- and ocular toxicity and growth failure. Therefore patients receiving chelation therapy should have yearly ophthalmologic and auditory examinations.^{5,13,41,64}

Unique to the population with SCD is a constellation of features that may occur in response to blood transfusion; this is often referred to as the sickle cell hemolytic transfusion reaction syndrome. This syndrome includes manifestations of an acute or delayed transfusion reaction due to alloimmunization. Delayed reaction can occur 5 to 20 days after transfusion. During the hemolytic reaction, the patient develops symptoms suggestive of a pain crisis, or symptoms worsen if the patient is already in crisis. The patient may also develop an anemia posttransfusion that is more severe than previously observed because of the rapid drop in hemoglobin and hematocrit, accompanied by a suppression of erythropoiesis. Alloantibodies and autoantibodies that formed as a result of past transfusions can serve as a trigger, causing a return of symptoms in the postrecovery period. Subsequent transfusions may further worsen the clinical situation due to the presence of autoimmune antibodies. There may be no serologic explanation for the hemolytic transfusion reaction. Recovery, as evidenced by reticulocytosis with a gradual increase in the hemoglobin level, may occur only after the withholding of further transfusions. Although some patients tolerate further transfusions after recovery, others may experience a recurrence of the hemolytic transfusion reaction.^{3,5,13,41}

FUTURE PROSPECTS

ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Currently, allogeneic hematopoietic stem cell transplantation (HSCT) is the only therapy that provides a cure for patients with SCD. A report of a multicenter trial of allogeneic HSCT in 50 patients with SCD showed a 94% survival rate and 84% event-free survival. All of the patients in the study were less than 16 years of age, had symptomatic SCD, and had an HLA-identical sibling donor. Two patients died from chronic graft-versus-host disease, and one died of intracranial hemorrhage. Of the 47 surviving patients, 5 experienced graft rejection and recurrent SCD. These rejections occurred a median of 5.1 months after transplantation.^{65,66} One recent study in 24 children with severe SCD reported that pretransplant use of hydroxyurea appeared to be associated with a lower incidence of rejection or failure of engraftment.⁶⁷ Based on these data and worldwide experience, it appears that a stable engraftment of donor cells can eradicate or arrest the clinical manifestations of SCD.

The best candidates for allogeneic HSCT are SCD patients who are younger than 16 years of age; have severe complications such as refractory pain, stroke, or recurrent ACS; and have an HLA-matched donor. Although allogeneic HSCT in young children before organ damage and alloimmunization occur may be associated with an increased success rate, disease progression is unpredictable, making it difficult to determine the optimal time for transplantation. The risks associated with allogeneic HSCT must be carefully considered, as the transplant-related mortality rate is about 5% to 10% and graft rejection is about 10%. Approximately 5% of patients developed grade III–IV acute or extensive chronic graft-versus-host disease. Other risks associated with allogeneic HSCT are secondary malignancies, and recently there was a case of transmission of chronic myeloid leukemia to a peripheral blood stem cell recipient who was a sickle cell patient. Efforts to decrease the posttransplant risk of seizures or intracranial bleeding include prophylactic anti-convulsant therapy, aggressive platelet support, and stringent patient selection.^{5,41,66,68,69}

Experience with unrelated or HLA-mismatched related donor transplant is very limited. Data on transplantation in thalassemia patients do not support the use of these alternate sources at this point. Umbilical cord blood is another donor source. Its advantages include a lower incidence of severe graft-versus-host disease and the potential of using umbilical cord blood from unrelated donors; however, such advantages are balanced by longer duration for engraftment and a higher rate of graft rejection.^{5,41,69}

► TREATMENT: Sickle Cell Disease

■ GENERAL MANAGEMENT

Parents and older children should be educated on the signs and symptoms of complications and conditions that require urgent evaluation. During acute illness, patients should be evaluated promptly, as deterioration can occur rapidly. Keeping a balanced fluid status is essential because both dehydration and fluid overload can worsen complications associated with SCD. Oxygen saturation by pulse oximetry should be maintained at least 92% or at baseline. New or increasing supplemental oxygen requirements should be investigated.^{5,13,41}

■ EPISODIC TRANSFUSIONS FOR ACUTE COMPLICATIONS

Indications for red cell transfusions include (1) acute exacerbation of baseline anemia, such as aplastic crisis if the anemia is severe, hepatic or splenic sequestration, or severe hemolysis; (2) severe vaso-occlusive episodes, such as ACS, stroke, or acute multiorgan failure; and (3) preparation for procedures that require the use of general anesthesia or ionic contrast. Other patients in whom transfusions may be useful include patients with complicated obstetric problems, refractory leg ulcers, or refractory and protracted painful episodes or severe

priapism. Transfusion can be done by simple transfusion or partial exchange transfusion. If simple transfusion is used, volume overload leading to congestive heart failure can occur if anemia is corrected too rapidly in patients with severe anemia. In addition, increases in Hgb levels to greater than 10 to 11 g/dL may cause hyperviscosity and should be avoided.^{5,41}

■ INFECTION AND FEVER

Patients with SCD should be evaluated as soon as possible for any fever greater than 38.5°C. Evaluation should be initiated as outlined in Table 101–2. Criteria for hospitalization include an infant less than 1 year old, history of previous bacteremia or sepsis, temperature greater than 40°C, WBC greater than 30,000/mm³ or less than 5000/mm³ and/or platelets less than 100,000/mm³, and evidence of other acute complications or toxic appearance. Outpatient management can be considered in older nontoxic children with reliable family caregivers. Antibiotic choice should provide adequate coverage for encapsulated organisms.

➤ Ceftriaxone should be used for outpatient management because it provides coverage for 24 hours. If admitted, cefotaxime can also be used. For patients with cephalosporin allergy, clindamycin may be used. Vancomycin should be considered for toxic-appearing children or if *Staphylococcus* is suspected. A macrolide antibiotic should be added if mycoplasma pneumonia is suspected. Penicillin prophylaxis should be discontinued while receiving broad-spectrum antibiotics. Acetaminophen or ibuprofen may be used for fever control. Increased fluid requirements may be needed due to dehydration and/or increased insensible loss.^{1,4,5,13,41}

■ CEREBROVASCULAR ACCIDENTS

Patients with acute neurologic events must be hospitalized and monitored closely. Physical and neurologic examination should be performed every 2 hours. Acute treatment for children should include exchange transfusion or simple transfusion to maintain Hgb at approximately 10 g/dL and HbS less than 30%, anticonvulsants for patients with a history of seizure, and therapy for increased intracranial pressure if needed. Chronic transfusion therapy should be initiated for children with ischemic stroke as discussed above. In adults presenting with ischemic stroke, thrombolytic therapy should be considered if less than 3 hours since onset of symptoms.^{1,4,5,13,41}

■ ACUTE CHEST SYNDROME

Patients with ACS should use incentive spirometry frequently (e.g., at least every 2 hours). In incentive spirometry, the patient tries to take long, slow, deep breaths. A visual indicator on the spirometer indicates when the patient achieves the targeted flow rate or volume. In addition to spirometry, proper management of pain is important. The goal is to provide relief while avoiding analgesic-induced hypoventilation. Appropriate fluid therapy is important as overhydration may cause pulmonary edema and exacerbate respiratory distress. Early use of broad-spectrum antibiotics, including a macrolide or quinolone, is also recommended. Studies indicate that infection is common with ACS, and may involve gram-positive, gram-negative, or atypical bac-

teria. Oxygen therapy is indicated for all patients who are hypoxic or in acute distress. In a patient with a history of reactive airway disease or wheezing on examination, a trial of bronchodilators is appropriate. Transfusions are often used in the treatment of acute lung disease.^{5,13,27,70}

Steroids may decrease inflammation and endothelial cell adhesion. Use of glucocorticoids has been associated with decreases in hospital stay, transfusions, and need for other supportive care. However, higher readmission rates for SCA-related complications was also reported. Another promising therapy is the use of NO. NO inhalation relaxes and dilates blood vessels. Its hematologic effects include inhibition of platelet aggregation and reduced polymerization tendency of HbS. Marked improvement of pulmonary status and cardiac output have been reported in a patient with ACS. Both inhaled NO and oral L-arginine, the precursor of NO, are being evaluated for management of ACS.^{27,71}

■ PRIAPISM

Stuttering priapism, episodes that last a few minutes to 2 hours, resolve spontaneously. Prolonged episodes lasting more than 2 to 3 hours require prompt medical attention. The initial goals of treatment are to provide appropriate analgesic therapy, reduce anxiety, produce detumescence, and preserve testicular function and fertility. Treatment given within 4 to 6 hours can usually reduce erection. Aggressive hydration and adequate pain control should be initiated. Use of ice packs is not recommended. Although transfusions have been given to these patients, the usefulness of this therapeutic intervention has not been established.^{1,5,72}

CLINICAL CONTROVERSY

Some clinicians transfuse patients to maintain an HbS level less than 30% to prevent recurrent priapism. Duration of such regimens should be limited to 6 to 12 months.

Clinicians have used both vasoconstrictors and vasodilators in the treatment of priapism. Vasoconstrictors, such as phenylephrine or epinephrine, are thought to work by forcing blood out of the corpus cavernosum into the venous return. Epinephrine use has been associated with increases in heart rate and blood pressure. In one prospective nonrandomized unblinded study, aspiration followed by intrapenile irrigation with epinephrine was effective and well tolerated. In that study, as much blood as possible was aspirated from the corpus cavernosum, and the area was irrigated with a 1:1,000,000 solution of epinephrine.⁷³ The priapism resolved in 37 of the 39 occasions in which it was used. The therapy was well tolerated with no serious immediate or long-term side effects. On two occasions, a small intrapenile hematoma formed after treatment.

Vasodilators, such as terbutaline and hydralazine, induce relaxation of the smooth muscle of the vasculature. It is suggested that this relaxation allows oxygenated arterial blood to enter the corpus cavernosum, which displaces or washes out the damaged sickle cells that are stagnant in the corpus cavernosum. Terbutaline has been used to treat priapism, but it has not been formally studied in patients with SCA. Surgical interventions used in severe refractory priapism have included a variety of shunt procedures. These surgical procedures have been successful in some cases, but they have a high failure rate and serious complications, which include skin sloughing, cellulitis, and urethral fistulas.⁵

Modalities to prevent priapism are limited and not well studied. Pseudoephedrine (30 or 60 mg/day given orally at bedtime) and leuprolide, a gonadotropin-releasing hormone, have been used to decrease the number of recurrent episodes of priapism. Hydroxyurea therapy may also be useful. Recently, low-doses of an antiandrogen, bicalutamide, have been used in two patients with SCD and one patient with spinal cord injury for treatment of recurrent and refractory priapism without major side effects.^{5,13,41,74}

MANAGEMENT OF CRISES

APLASTIC CRISIS

Treatment of aplastic crisis is primarily supportive and most patients recover spontaneously. The patient may need blood transfusions if anemia is severe or symptomatic. Reticulocyte count helps to determine if there is red cell production and the need for transfusions. The most common cause for aplastic crisis is acute infection with human parvovirus B19. Parvovirus is contagious; therefore infected patients should be placed in isolation. In addition, contact with pregnant health care providers should be avoided because parvovirus infection during the midtrimester of pregnancy may result in hydrops fetalis and stillbirth.^{4,5,13,41}

SEQUESTRATION CRISIS

Splenic sequestration crisis is a major cause of mortality in young patients with SCD. The sequestration of RBCs in the spleen may result in a rapid drop of hematocrit, leading to hypovolemia, shock, and death. Immediate treatment is red cell transfusion to correct hypovolemia. Broad-spectrum antibiotic therapy, which includes coverage for pneumococci and *H. influenzae*, may also be beneficial, because infection may precipitate crises.^{4,5,13,41}

Recurrent episodes are common; approximately 50% in one study, and are associated with mortality. Options for management of recurrence include observation, chronic transfusion, and splenectomy. Observation is common in adults because they tend to have milder episodes. Increased risk of invasive infection after splenectomy is a concern in young children. Chronic transfusion may allow delaying splenectomy and temporarily restore splenic function, but it is associated with its own risks. Splenectomy is probably indicated, even after a single sequestration crisis, if that event is life-threatening. Splenectomy should be considered after repetitive episodes, even if they are less serious. For children less than 2 years of age, chronic blood transfusions have been recommended to prevent sequestration and to delay splenectomy until the age of 2, when the risk of post-splenectomy septicemia is less. Finally, splenectomy should also be considered for patients with chronic hypersplenism.^{1,4,5,13}

VASO-OCCLUSIVE PAIN CRISIS

Hydration and analgesia are the mainstays of treatment for vaso-occlusive (painful) crises (Table 101–7). Mild pain crisis may be treated on an outpatient basis with rest, increased fluid intake, warm compresses, and oral analgesics. Hospitalization is necessary for moderate to severe crisis. Since infection can precipitate crises, an infectious etiology should be ruled out and appropriate empiric therapy should be initiated in patients with fever or patients who are critically ill. In patients who are anemic, transfusion to maintain the Hgb level

at baseline may be needed. Fluid replacement given intravenously or orally at 1.5 times the maintenance requirement is recommended. Close monitoring of fluid status is essential as aggressive hydration, particularly with sodium-containing fluids, may lead to volume overload, ACS, and heart failure.^{4,5,13,41}

There is great variability in the frequency and severity of acute pain episodes associated with SCD. Thus the pain should be assessed and analgesic therapy should be tailored for each patient. Pain scales can be useful to quantify the degree of pain. Several pain assessment tools are available. Unfortunately, they have not been validated for sickle cell pain. The health care provider should choose one tool appropriate for age and use it routinely to assess pain. Other useful information to guide choice of analgesics should include previous effective agents and their dosages, response to therapy and previous clinical course, and duration of pain crisis.^{28,75–77}

8 Aggressive therapy to relieve pain and enable the patient to attain maximum functional ability should be initiated in patients with pain crisis. Treatment of mild to moderate pain should include the use of nonsteroidal anti-inflammatory drugs (NSAIDs) or acetaminophen, unless there are contraindications to their use. Ketorolac is the only injectable NSAID available and is useful for patients requiring intravenous therapy. Due to concerns about gastrointestinal bleeding, it is recommended to limit the duration of therapy to 5 days or less. When acetaminophen is used, it is important to review the total dose of acetaminophen administered in patients who may also be receiving the agent for fever or other acetaminophen-containing product for pain. If mild to moderate pain persists, an opioid should be added. Effective combination therapy, such as an NSAID combined with an opioid, may enhance analgesic efficacy while decreasing side effects.^{28,75–77}

Severe pain should be treated aggressively until the pain is tolerable. Commonly used opioids include morphine, hydromorphone, fentanyl, and methadone. The weak opioids, codeine and hydrocodone, are used to manage moderate pain. Meperidine has no advantages as an analgesic. Its duration of action is short compared to the half-life of the metabolite, normeperidine. The accumulation of normeperidine can cause central nervous system side effects, ranging from dysphoria to seizures. Therefore it is recommended that meperidine should only be used for a very brief duration in patients who are allergic or intolerant to other opioids.^{28,75–77}

Both prior history and current assessment are important considerations when managing pain crisis. For patients whose typical crisis improves in a short time, preparations with a short duration of action are appropriate. For patients whose crises require many days to resolve, sustained-release preparations combined with a short-acting product for breakthrough pain are more appropriate. If the patient has been on long-term opioid therapy at home, tolerance may develop. In these cases, the pain of acute crises can be treated with a different potent opioid or a larger dose of the same medication. Intravenous administration provides a rapid onset of action and therefore is preferred for severe pain. Intramuscular injections should be avoided. Children may actually deny pain because of fear of injections. Analgesics should be titrated to pain relief. In patients with continuous pain, the analgesic should be given as a scheduled dose or continuous infusion. Continuous infusion has the advantage of less fluctuation of blood levels between dosing intervals. As-needed dosing is only appropriate for breakthrough pain. Patient-controlled analgesia (PCA) is commonly utilized. When used properly, PCA allows patients (or their families) to have control over pain therapy and minimizes the lag time between perception of pain and administration of analgesics. The transdermal fentanyl patch has also been used successfully. Its role in sickle cell pain crisis remains uncertain due to its long duration of 12 to 16 hours to achieve therapeutic effect and

TABLE 101–7. Management of Acute Pain of SCD**Principles**

- Treat underlying precipitating factors
- Avoid delays in analgesia administration
- Use pain scale to assess severity
- Choice of initial analgesic should be based on previous pain crisis pattern, history of response, current status, and other medical conditions
- Schedule pain medication; avoid as-needed dosing
- Provide rescue dose for breakthrough pain
- If adequate pain relief can be achieved with one or two doses of morphine, consider outpatient management with a weak opioid; otherwise hospitalization is needed for parenteral analgesics
- Frequently assess to evaluate pain severity and side effects; titrate dose as needed
- Treating adverse effects of opioids is part of pain management
- Consider nonpharmacologic intervention
- Transition to oral analgesics as the patient improves; choose an oral agent based on previous history, anticipated duration, and ability to swallow tablets; if sustained-release products are used, a fast-release product is also needed for breakthrough pain

Analgesic regimens

Mild to moderate pain:

Acetaminophen with codeine

Dose based on codeine—children: 1 mg/kg per dose every 6 h; adult: 30–60 mg/dose

Hydrocodone + acetaminophen

Dose based on hydrocodone—children: 0.2 mg/kg per dose every 6 h; adults: 5–10 mg/dose

Anti-inflammatory agents

Use with caution in patients with renal failure (dehydration) and bleeding

Ibuprofen—children: 10 mg/kg every 6–8 h; adult: 200–400 mg/dose

Naproxen: 5 mg/kg every 12 h; adult 250–500 mg/dose

Ibuprofen + hydrocodone: Each tablet contains 200 mg ibuprofen and 7.5 mg hydrocodone per tablet; only for older children who can swallow tablets

Moderate to severe pain:

Morphine: 0.1–0.15 mg/kg per dose every 3–4 h for children; 5–10 mg/dose for adults

Continuous infusion: 0.04–0.05 mg/kg per h; titrate to effect

Hydromorphone: 0.015 mg/kg per dose every 3–4 h for children; 1.5–2 mg/dose for adults

Continuous infusion: 0.004 mg/kg per h; titrate to effect

Intravenous anti-inflammatory agents:

Ketorolac: 0.5 mg/kg up to 30 mg/dose every 6 h

Patient-controlled analgesics:

Morphine: 0.01–0.03 mg/kg per h basal; demand 0.01–0.03 mg/kg every 6–10 min; 4 h lock out 0.4–0.6 mg/kg

Hydromorphone: 0.003–0.005 mg/kg per h basal; demand 0.03–0.05 mg/kg every 6–10 min; 4 h lock out 0.06–0.08 mg/kg

Rescue therapy:

For breakthrough, give 1/4 to 1/2 of the scheduled dose as bolus every 1–2 h; assess amount of rescue dose used in 8–12 h and readjust scheduled dose or infusion rate as needed

Other adjunct therapy:

Hydration, heating pads, relaxation, and distraction

Stool softener and/or stimulants for constipation

Antihistamine for itching

Antiemetics for nausea or vomiting

From Yale,²⁸ Jacob et al,⁷⁵ Berde et al,⁷⁶ Stinson et al,⁷⁷ Christensen et al,⁷⁸ and Elander et al.⁷⁹

fixed dosage form, which makes it difficult to titrate the dose. Other alternative pain management techniques such as physical therapy and relaxation therapy can be helpful as adjunct therapy.^{28,75–78}

The most common issue leading to suboptimal pain control in children with SCA is the suspicion of addiction. This obstacle is especially common in adolescents. In one study, 53% of emergency physicians believed that 20% of SCD patients are addicted to analgesics. Elander and associates interviewed 51 SCD patients and utilized symptoms described in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* to assess substance dependence.⁷⁹ They reported that when pain-related symptoms are included, 31% met criteria for substance dependence, but when symptoms are restricted those that are not pain-related, only 2% met the criteria for substance dependence. Another barrier for effective pain control is the difference in perception between patients, family, and health care providers. Patients with SCD often suffer from chronic pain and they may cope with the pain by being inactive. Patients who have inad-

equate pain control may exhibit anxiety and drug-seeking behavior for fear of pain. Tolerance to narcotics can also be misinterpreted as drug addiction by health care providers and families. Aggressive pain control, frequent monitoring of pain during crises, and tapering medication according to response are factors that minimize physical dependence.^{28,75–79}

■ Agents Under Development: Purified Poloxamer 188

Poloxamer 188 (Flocor), a highly purified poloxamer, is an agent currently being evaluated under orphan drug status for the management of vaso-occlusive pain crisis in SCD. It acts as a surfactant and normalizes the RBC to its nonadhesive state. In addition, it enhances blood flow in ischemic areas by blocking RBC aggregation. The antiadhesive and hemorheologic properties result in improved blood flow, increased oxygen delivery, and decreased cell injury. A Phase III

clinical study conducted in adults and children aged 8 to 65 years old with vaso-occlusive crises reported a faster resolution. Patients younger than 15 years and those who were receiving hydroxyurea

therapy were two groups that appeared to have the most beneficial effect.⁸⁰ Another Phase III study in patients younger than 15 years with vaso-occlusive crisis has been planned.⁸¹

PHARMACOECONOMIC CONSIDERATIONS

Being a chronic condition, SCD has a significant impact on health care costs. Pharmacoeconomic considerations should include newborn screening, cost of managing acute and chronic complications, and the economic impact of new treatment modalities. Early penicillin prophylaxis prevents pneumococcal sepsis in infants. Newborn screening targeted at African-Americans has been shown to be cost-effective. Whether it is cost-effective to screen all infants depends on the prevalence of high-risk infants in the area. The estimated annual cost through universal screening programs ranged from \$1,402 in Mississippi to \$304,215 in Vermont per case identified. In general, universal screening identifies more infants with disease, prevents more deaths, and may provide for a certain degree of cost-effectiveness since targeted screening may not detect all infants with the disease.^{8,82}

Hospitalization is an important societal financial burden. A 1996 national estimate reported the average cost per hospitalization to be \$6300, which totals a cost of \$475 million per year. Studies conducted in various regions have shown that a small number of patients consume a disproportionate amount of care as a result of severe illness, and most of the total cost results from hospitalization. Patients who are not being followed in settings that provide comprehensive medical care tend to acquire higher costs for emergency room and hospital visits. Another study examining relationships between socioeconomic factors and geographic distribution in Alabama reported that utilization of comprehensive care was lower for those living in rural areas. Using a mathematical model and data available from studies, researchers estimated lifetime costs for SCA and other hemoglobinopathies to be \$83,200 for patients with early diagnoses and \$78,400 for late diagnosis.^{3,8,83–85}

Newer therapies, diagnostic methods such as TCD, and chronic transfusions further increase cost. The cost of a year of hydroxyurea therapy has been estimated to be \$2000. Utilizing the data from the MSH trial, Moore and colleagues reported that the average annual cost for medical care was lower in the hydroxyurea group as compared with the placebo group (\$12,160 vs. \$22,020). Hospitalization due to pain crisis accounted for the highest cost in both groups and was lower for the hydroxyurea group (\$12,160 vs. \$17,290). Allogeneic HSCT can potentially cure the disease, and if successful can reduce long-term costs, but it requires a high up-front cost. The new therapies, although expensive, may keep patients out of emergency departments and inpatient beds, improving the cost-effectiveness of those therapies over a patient's lifetime.^{7,86}

EVALUATION OF THERAPEUTIC OUTCOMES

SCD is a complex disorder that requires multidisciplinary comprehensive care. All patients should be medically evaluated regularly to establish baseline, monitor changes, and provide education appropriate for age. For infants less than a year old, medical evaluations every 2 to 4 months are needed. Beyond 1 year of age, evaluation can be extended to every 6 to 12 months with modifications depending on severity of the illness.⁴¹

It is important to establish baseline laboratory values and imaging studies. Routine laboratory evaluation includes complete blood

cell counts and reticulocyte counts every 3 months up to 2 years of age, then every 6 months; HbF level should be taken every 6 months until 2 years of age, then annually. Evaluation of renal, hepatobiliary, and pulmonary function should be done annually. TCD screening is recommended to start at age 2, then annually. Ophthalmologic examination to screen for retinopathy is recommended at around age 10. In patients with recurrent ACS, pulmonary function tests should be done to establish baseline and identify declines in lung function.

It is essential to ensure that prophylactic immunizations and antibiotics are being given. When infections do occur, appropriate antibiotic therapy should be initiated and the patient should be monitored for laboratory and clinical improvement. The efficacy of hydroxyurea can best be assessed in terms of the decrease in number, severity, and duration of sickle cell pain crises. Fetal hemoglobin concentrations or MCV values may also provide some indication of the patient's response to therapy. When painful crises do occur, the evaluation of the effectiveness of analgesics depends mainly on the subjective assessments made by the patient, family, and health care practitioners. The success of poststroke blood transfusions can be measured by clinical progression or the occurrence of subsequent strokes.

CONCLUSION

The goals of the general management of SCA are to decrease the number of sickle cell crises, to decrease the complications arising from the disease, and to improve the overall quality of the patient's life. The general care of SCA patients still includes early penicillin prophylaxis and appropriate immunization. HbF inducers such as hydroxyurea may decrease the frequency and severity of painful episodes. Continued studies of other possible agents and treatment modalities that may reduce crises or reverse organ damage are warranted.

ABBREVIATIONS

ACS: acute chest syndrome
 ASPEN syndrome: association of sickle cell disease, priapism, exchange transfusion, and neurologic events
 HbAS: one normal and one sickle hemoglobin gene
 HbC: hemoglobin C
 HbF: fetal hemoglobin
 HbS β^+ -thal, HbS β^0 -thal: hemoglobin sickle β^+ -thalassemia and hemoglobin sickle β^0 -thalassemia
 HbSC: sickle-hemoglobin C
 HbSS: homozygous sickle hemoglobin
 HbS: sickle hemoglobin
 HSCT: hematopoietic stem cell transplantation
 ISC: irreversibly sickled cell
 MCHC: mean corpuscular hemoglobin concentration
 MCV: mean corpuscular volume
 MSH: Multicenter Study of Hydroxyurea in Sickle Cell Anemia
 NO: nitric oxide
 NSAID: nonsteroidal anti-inflammatory drug
 PCA: patient-controlled analgesia
 PCV 7: 7-valent pneumococcal conjugate vaccine

PPV 23: 23-valent pneumococcal polysaccharide vaccine

RBC: red blood cell

SCA: sickle cell anemia

SCD: sickle cell disease

SCT: sickle cell trait

TCD: transcranial Doppler

WBC: white blood cell

DRUG-INDUCED HEMATOLOGIC DISORDERS

S. Jay Weaver and Thomas E. Johns

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- ◀1 Drug-induced hematologic disorders are, in general, rare adverse effects associated with drug therapy.
- ◀2 The most common drug-induced hematologic disorders include aplastic anemia, agranulocytosis, megaloblastic anemia, thrombocytopenia, and hemolytic anemia.
- ◀3 Reporting during postmarketing surveillance of a drug is usually the method by which the incidence of rare adverse drug reactions is established.
- ◀4 Because drug-induced blood disorders are dangerous, rechallenging a patient with a suspected agent in an attempt to confirm a diagnosis may not be ethical.
- ◀5 The mechanisms of drug-induced hematologic disorders are thought to be the result of direct toxicity or an immune reaction.
- ◀6 The primary treatment of drug-induced hematologic disorders is removal of the drug in question and symptomatic support of the patient.
- ◀7 Frequent laboratory monitoring may be warranted for agents commonly demonstrating severe hematologic reactions.

Hematologic disorders have long been a potential risk of modern pharmacotherapy. Granulocytopenia (agranulocytosis) was reported in association with one of medicine's early therapeutic agents, sulphanilamide, in 1938.¹ Some agents cause predictable hematologic disease (e.g., antineoplastics), but others induce idiosyncratic reactions not directly related to the drugs' pharmacology. Such drug-induced hematologic disorders may include aplastic anemia, agranulocytosis, megaloblastic anemia, thrombocytopenia, and hemolytic anemia.²

◀1 By most reports, idiosyncratic drug-induced hematologic disorders are rare. Relatively few epidemiologic studies have addressed the actual incidence of these adverse reactions. A report from The Netherlands estimated the incidence of drug-associated agranulocytosis as 1.6 to 2.5 cases per million inhabitants per year.³ Similar results were found in epidemiologic studies conducted in Thailand and Brazil.^{4,5} Older data from a study conducted in Europe and Israel estimated the incidences of aplastic anemia and agranulocytosis to be 0.5 and 3.1 cases per million per year, respectively.⁶

◀2 Although rare, drug-induced hematologic disorders are important because they are associated with significant morbidity and mortality. An epidemiologic study held in the United States estimated that 4490 deaths in 1984 were attributable to blood dyscrasias from all causes. Aplastic anemia was the leading cause of death, followed by thrombocytopenia, agranulocytosis, and hemolytic anemia.⁷ Like most other adverse drug reactions, drug-induced hematologic disorders are more common in the elderly than in the young; the risk of death also appears to be greater with increasing age. The risk of agranulocytosis has been reported to be higher in women than in men.⁴

◀3 Because of the seriousness of drug-induced hematologic disorders, it is necessary to track the development of these disorders in order to predict their occurrence and to estimate their incidence.

Reporting during postmarketing surveillance of a drug is the most common method of establishing the incidence of adverse drug reactions. The MedWatch program supported by the Food and Drug Administration is one such program.⁸ Many facilities have similar drug-reporting programs to follow adverse drug reaction trends and to determine whether an association between a drug and an adverse drug reaction is causal or coincidental. In the case of drug-induced hematologic disorders, these programs can enable practitioners to confirm that an adverse event is indeed the result of drug therapy rather than one of many other potential causes; general guidelines are readily available.^{9,10}

◀4 Because drug-induced blood disorders are dangerous, rechallenging a patient with a suspected agent in an attempt to confirm a diagnosis may not be ethical. In vitro studies with the offending agent and cells or plasma from the patient's blood can be performed to determine causality.¹¹ These methods are often expensive, however, and require facilities and expertise that are not generally available. One study demonstrated that only 19% of the cases with suspected drug-induced agranulocytosis could be documented by in vitro testing.¹²

The rarity and seriousness of drug-induced hematologic disorders make it extremely important that clinicians be able to evaluate suspect drugs quickly and to interrupt therapy when necessary. Throughout the past decades, lists of drugs that have been associated with adverse events have been developed to help clinicians identify possible causes of adverse events. Unfortunately, these lists are comprehensive and include commonly used drugs, making it difficult to elicit the root cause of any abnormality. Furthermore, the absence of a drug from such a list should not discourage the investigation and reporting of an agent associated with an adverse event. It is imperative that clinicians use a rational approach to determine causality and identify the agents associated with a reaction. Focusing on the issue,

performing a high-quality investigation, developing appropriate criteria, using levels of evidence to grade the response, and having a quantifiable summary can all help to ensure the validity of the findings. A systematic approach to evaluate the information available in the literature also helps the clinician to focus and intervene in the cause of the disorder.

A common tool employed by clinicians to rate the likelihood of causality in adverse drug reaction (ADR) investigations is an ADR probability scale (algorithm). One such scale was developed and tested by Naranjo and colleagues.¹³ This tool provides a series of scored questions that lead an investigator to the likelihood that an ADR was caused by the suspected medication. Depending on the aggregate score, the causality is rated as Doubtful, Possible, Probable, or Definite. The scale gives the most weight to the temporal relationship of the reaction with relation to administration of the drug, observations following a rechallenge of the patient with the suspected medication, and alternate explanations for the ADR. As mentioned above, it is often unethical to rechallenge patients who experience severe hematologic toxicities. Thus without a rechallenge it is difficult to achieve a causality rating of “definite” using such an algorithm.

In determining the likelihood that an observed reaction is due to a particular medication, clinicians should review the medical literature for past reports supporting the observation. Using an evidence-based approach such as that proposed by Sackett,¹⁴ the investigator assigns greater weight to prospective study designs such as clinical trials or cohort studies than to case reports or expert opinion. This will provide a framework for the investigator’s confidence in published literature describing ADRs.

In this chapter, we use both methods described to review and present published information on hematologic drug toxicities. When only case reports were available, the Naranjo algorithm was applied to the cases (if not already used). This algorithm was used for two reasons. First, the algorithm has been validated for interrater reliability.¹³ The algorithm was also the most commonly applied algorithm by authors of the case reports evaluated for this chapter. Drugs rated as “Definite” and those rated as “Probable” when only a lack of rechallenge prevented a rating of “Definite” were included in the lists. An evidence-based approach was incorporated through a review of the medical literature for prospective and retrospective studies of the adverse reactions and medications of interest. Drugs significantly associated with an adverse reaction of interest through studies were also deemed to have a causal relationship to the reaction.

The understanding of drug-induced hematologic disorders requires a basic understanding of hematopoiesis (see Chap. 98 on hematopoiesis). The pluripotential hematopoietic stem cells in the bone marrow, which have the ability to self-reproduce, maintain the blood. These pluripotential hematopoietic stem cells are further differentiated to intermediate precursor cells, which are also called “progenitor cells” or “colony-forming cells.” Committed to a particular cell line, these intermediate stem cells differentiate into colonies of each type of blood cell in response to a particular colony-stimulating factor (Fig. 102–1).

Drug-induced hematologic disorders can affect any cell line, including white blood cells (WBCs), red blood cells (RBCs), and platelets. When a drug causes decreases in all three cell lines accompanied by a hypoplastic bone marrow, the result is drug-induced

FIGURE 102–1. Differentiation of the stem cell into committed cell lines, illustrating the origins of various drug-induced hematologic disorders.

aplastic anemia. The decrease in WBC count alone by a medication is drug-induced agranulocytosis. Drugs can affect RBCs by causing a number of different anemias, including drug-induced immune hemolytic anemia, drug-induced oxidative hemolytic anemia, or drug-induced megaloblastic anemia. A drug-induced decrease in platelet count is drug-induced thrombocytopenia.

DRUG-INDUCED APLASTIC ANEMIA

Ehrlich first described aplastic anemia in 1888 following an episode of failed hematopoiesis identified during the autopsy of a pregnant woman.¹⁵ Since then there have been 500 to 2500 cases reported annually, with up to 33% diagnosed in patients greater than 60 years of age.¹⁵ A number of variables can incite immune destruction of the bone marrow; the most common are drugs, chemicals, toxins, viruses, and radiation.

Drug-induced aplastic anemia is classified as an acquired form of the disorder and accounts for 7% to 86% of cases of aplastic anemia.¹⁶ It is considered the most serious drug-induced blood dyscrasia because of the associated high mortality rate, often exceeding 50% of treated cases.¹⁷ It is characterized by pancytopenia (presence of anemia, neutropenia, and thrombocytopenia) with a hypocellular or “fatty” bone marrow and no gross evidence of increased peripheral blood cell destruction.² A diagnosis of aplastic anemia can be made by the presence of two of the following criteria: a WBC count of 3500/mm³ or less, a platelet count of 55,000/mm³ or less, or a hemoglobin value of 10 g/dL or less with a reticulocyte count of 30,000/mm³ or less.¹⁶ Severe aplastic anemia is defined by at least two of the following three peripheral blood findings: neutrophil count of less than 500/mm³, platelet count of less than 20,000/mm³, and anemia with a corrected reticulocyte index of less than 1%.^{17,18} The prognosis is extremely poor if the neutrophil count declines to less than 200/mm³.¹⁹ A bone marrow aspirate and biopsy are required to exclude other causes of pancytopenia, including neoplastic infiltration or significant myelofibrosis.²⁰ There must also be no history of iatrogenic exposure to cytotoxic chemotherapy that is known to cause transient bone marrow suppression or to intensive radiation.

The onset of drug-induced aplastic anemia is variable and insidious. Symptoms appear on the average about 6.5 weeks after the initiation of the offending agent,¹⁹ sometimes after the drug has been discontinued. Clinical features of drug-induced aplastic anemia depend on the degree to which each cell line is suppressed, similarly to idiopathic disease. Symptoms of anemia include pallor, fatigue, and weakness, while fever, chills, pharyngitis, or other infection may characterize neutropenia. Thrombocytopenia, often the initial clue to diagnosis, is manifest by easy bruisability, petechiae, and bleeding.

The incidence of drug-induced aplastic anemia is estimated at 0.5 to 7.8 cases per 1 million population per year.^{6,21,22} Higher rates of occurrence have been seen in patients taking antirheumatic drugs such as indomethacin, penicillamine, and gold compounds.¹⁷ Table 102–1 lists drugs that have been associated with drug-induced aplastic anemia.

5 The cause of drug-induced aplastic anemia is damage to the pluripotential hematopoietic stem cells, before their differentiation to committed stem cells. This damage effectively reduces the normal levels of circulating erythrocytes, neutrophils, and platelets. Three mechanisms have been proposed as causes of damage to the pluripotential hematopoietic stem cells.²³ The most common proposed mechanism is direct, dose-dependent drug toxicity. This type of injury leads to transient marrow failure secondary to direct sup-

TABLE 102–1. Drugs Associated with Aplastic Anemia

| Observational study evidence | Case report evidence (“probable” or “definite” causality rating) |

| | Ticlopidine |

pression of proliferating cell lines, and hematopoietic suppression continues with dose escalation. Most often caused by chemotherapy or radiotherapy, this injury is frequently iatrogenic. The second mechanism is idiosyncratic and operates through toxic metabolites. Furthermore, individual variations in the pharmacokinetics of the suspected agent or a hypersensitivity of the stem cells to the destructive effects of the implicated drug may increase the potential for apoptosis. The third mechanism is a drug- or metabolite-induced immune reaction specific to the stem cell population. It is proposed that immunologically mediated, tissue-specific organ destruction occurs following exposure to an inciting antigen (drug) that activates cells and cytokines of the immune system, leading to the death of stem cells.²³ There is little evidence that drug-induced aplastic anemia results from the destruction of the microenvironment of the bone marrow.²⁰

The antineoplastic agents exemplify the dose-dependent mechanism for the development of aplastic anemia. Many of these agents have the ability to suppress one or more cell lines in a reversible manner. The degree of suppression and the cell line involved depend on the nature of the particular drug and its potential for inhibiting marrow proliferation. Chloramphenicol, an antimicrobial agent, also causes a bone marrow depression that is dose-dependent and reversible. In this reaction, chloramphenicol affects primarily the erythroid cell line due to an injury of the mitochondria, resulting in inhibition of protein synthesis with a subsequent reduction in reticulocytes and hematocrit.²⁴

Idiosyncratic drug-induced aplastic anemia secondary to direct toxicity may be characterized by dose independence, a latent period prior to the onset of anemia, and continuance of the marrow injury following drug discontinuation.²⁵ Drugs that cause aplastic anemia in a minority of patients suggest an abnormal metabolism or excretion. Chloramphenicol, already known to cause a dose-dependent reaction, is the prototype drug for the idiosyncratic mechanism, with an approximate incidence of 1 case per 20,000 patients treated;¹⁹ however, the overall prevalence has fallen with decreased use of this agent.²⁵ The idiosyncratic mechanism is believed to result from abnormal metabolism of chloramphenicol. The nitrobenzene ring on chloramphenicol is thought to be reduced to form a nitroso group on the chloramphenicol molecule.²⁴ The nitroso group may then interact with DNA in the stem cell, causing damage to the chromosomes, and eventually cell death. Other investigators have hypothesized that bacteria from the gastrointestinal tract may metabolize chloramphenicol to marrow-toxic metabolites.²⁶ There appears to be no relationship

between the dose-dependent and idiosyncratic reactions seen with chloramphenicol.

Other drugs thought to induce aplastic anemia through toxic metabolites include phenytoin and carbamazepine. Investigators have theorized that metabolites from phenytoin and carbamazepine bind covalently to macromolecules in the cell, and then cause cell death either by exerting a direct toxic effect on the stem cell or by causing the death of lymphocytes involved in regulating hematopoiesis.²⁷

Of the three potential mechanisms, the most common cause of drug-induced aplastic anemia is the development of an immune reaction. Early laboratory observations revealed that the removal of T lymphocytes from samples of patients with aplastic anemia improved *in vitro* colony formation.²⁸ Furthermore, overproduction of cytokines (e.g., tumor necrosis factor and interferon- γ) from activated T lymphocytes appears to be responsible for hematopoietic failure, as well as for the initiation of apoptosis.²⁹ Clinical evidence supporting this hypothesis revolves around improved hematopoiesis in patients who receive a conditioning regimen with antithymocyte globulin and cyclophosphamide prior to allogeneic bone marrow transplantation.³⁰ After the initiation of immunosuppressive therapy, bone marrow concentrations of interferon- γ decreased, while all cell lines improved.³¹ Inciting agents (i.e., drugs) are suspected to affect the function of suppressor T cells, which could inhibit stem cell production.¹⁹

Inconsistencies in the identification of antibodies to medication have made it difficult to implicate drugs as the main determinant for the

development of hematologic disease. Rather, clinical history and exposure history determine the assignment of causality. Additional supporting evidence for an immunologic basis as a mechanism of aplastic anemia comes from a prospective, randomized, placebo-controlled trial evaluating the efficacy of antilymphocyte globulin and methylprednisolone, with or without cyclosporine, in patients with severe aplastic anemia.³² The primary response variable was an improvement in blood counts (i.e., platelets, erythrocytes, and leukocytes) at 3 months. Patients receiving therapy with antilymphocyte globulin, methylprednisolone, and cyclosporine had a response rate of 65% versus a response rate of 39% in the group not receiving cyclosporine. This finding lends support to the fact that patients receiving aggressive immunotherapy are more likely to recover from a hematologic disorder and further implicates immunomodulation as a cause of disease.

Genetic predisposition may also influence the development of drug-induced aplastic anemia. Studies in animals and a case report of chloramphenicol-induced aplastic anemia in identical twins suggest a genetic predisposition to the development of drug-induced aplastic anemia.^{19,24} Furthermore, pharmacogenetic research that focuses on patients who may be slow or normal metabolizers of drugs may increase the clinician's ability to predict the development of aplastic anemia. Initial case-control studies have not had the power necessary to identify a statistical difference between controls and cases, but continued research may establish the role of altered metabolism in this population.³³

► TREATMENT: Drug-Induced Aplastic Anemia

Because of an extremely high mortality rate among patients with this disorder, it is imperative that drug-induced aplastic anemia be diagnosed quickly and therapy initiated immediately. It must be emphasized that prognosis, response to therapy, and management of drug-induced aplastic anemia are similar to that of idiopathic disease.³⁴ The goals of therapy are to improve peripheral blood counts so that patients do not require transfusions and are not at risk for opportunistic infections.

6 As with all cases of drug-induced hematologic disorders, the first step is to remove the suspected offending agent. Early withdrawal of the agent may allow for reversal of the aplastic anemia.¹⁹ The next step is to provide adequate supportive care, including symptomatic treatment of infection and transfusion support with erythrocytes and platelets. Appropriate supportive care is essential, as the major causes of mortality in patients with aplastic anemia are infections and bleeding. One study showed that 62% of deaths were due to infections, consisting mostly of bacterial and fungal pathogens.³⁵ Current treatment guidelines do not include chemoprophylaxis, except in patients undergoing hematopoietic stem cell transplantation (HSCT). Therefore, in patients receiving immunotherapy, fever of unknown origin should be aggressively managed.

The two major treatment options for patients with drug-induced aplastic anemia are HSCT and immunosuppressive therapy.

A retrospective analysis reviewing the outcomes of patients who underwent allogeneic HSCT for severe aplastic anemia between 1978 and 1991 showed an 89% response rate (including complete and partial responses).³⁶ The 15-year survival rate for complete and partial responders to HSCT was 75% and 64%, respectively. Improvement in supportive care, prevention of graft-versus-host disease, and improved engraftment have further enhanced survival benefits. Considerations in deciding to treat patients with HSCT are the availability of a donor, the age of the patient, the absolute neutrophil count, and the number of transfusions received prior to transplantation.³⁶

An alternative to HSCT is immunosuppressive therapy. Current options for this approach include antithymocyte globulin, antilymphocyte globulin, cyclosporine, and glucocorticoids. Antithymocyte globulin is a polyclonal immunoglobulin that disrupts cell-mediated immune responses and may have some immunosuppressive effects.³⁷ Antithymocyte globulin monotherapy may achieve response rates up to 50% of patients.³⁸ Recommended dosing of antithymocyte globulin has varied from 40 mg/kg per day for 4 days to 15 to 20 mg/kg per day for 8 to 14 days. Shorter, more intense regimens are preferred, as they are associated with fewer adverse events (i.e., serum sickness).³⁹ Corticosteroids (i.e., methylprednisolone) have long been used in conjunction with antithymocyte globulin for the management of drug-induced aplastic anemia, but their efficacy is questionable.¹⁸ They have minimal effects on hematopoiesis, although they benefit patients by decreasing the incidence of serum sickness. Methylprednisolone dosing is 1 mg/kg per day for 4 weeks. Cyclosporine blocks T-lymphocyte proliferation and function through alterations in interleukin-2 production. Cyclosporine dosing has varied from 4 to 6 mg/kg per day to 10 to 12 mg/kg per day with response rates equivalent to those of antithymocyte globulin monotherapy. Recommended dosing of cyclosporine is 5 mg/kg per day and titrated to a target blood concentration of 200 to 400 ng/mL. Adverse effects of cyclosporine include hypertension, renal failure, tremors, electrolyte abnormalities, and opportunistic infections.

The optimal immunosuppressive regimen is a combination of antithymocyte globulin, glucocorticoids, and cyclosporine. Three-year survival rates can approach 90%,^{32,40} which is comparable to that for HSCT, and makes immunosuppressive therapy a possible option for patients who are elderly (age >50 years), those who lack an eligible donor, and those who have less severe disease. A study comparing survival following immunosuppressive therapy or HSCT in patients with severe aplastic anemia found no significant difference between the treatment modalities at 6 years.⁴¹ These data provide

additional support for the aggressive management of all patients with aplastic anemia, regardless of age. Long-term complications of immunosuppressive therapy include relapse and conversion to other stem cell disorders (e.g., myelodysplastic syndrome, acute myelogenous leukemia, and paroxysmal nocturnal hemoglobinuria), which have occurred with relatively high incidence.^{19,36}

Granulocyte colony-stimulating factor (G-CSF),⁴² granulocyte-macrophage colony-stimulating factor (GM-CSF),⁴³ and interleukin-1⁴⁴ have also been investigated in the treatment of aplastic anemia. G-CSF, in combination with aggressive immunotherapy, may improve trilineage hematopoietic reconstitution, but it is unclear whether current data support a positive effect on outcomes (i.e., infectious complications and improved survival).⁴² Therefore prospective evaluations are required to further delineate the role of G-CSF in aplastic anemia. If long-term bone marrow suppression continues after initial treatment with optimal immunosuppression, the only viable option at present is allogeneic HSCT. Otherwise, aggressive immunosuppres-

sive therapy plays a distinct role in treating patients with drug-induced aplastic anemia and provides a viable alternative to patients ineligible for HSCT.

CLINICAL CONTROVERSY

Hematopoietic stem cell transplantation has long been the established treatment of drug-induced aplastic anemia. More recently, immunosuppressive regimens combining antithymocyte globulin, glucocorticoids, and cyclosporine are gaining favor. The utility of each treatment modality is limited by various factors. Clinical data suggest that there is no difference in survival achieved with the two treatments among patients followed for 6 years. Parity between the treatments will necessitate that clinicians individualize treatment decisions, while considering risk factors, economics, and quality of life.

DRUG-INDUCED AGRANULOCYTOSIS

It is possible to define drug-induced agranulocytosis as a drug-mediated reduction in the number of mature myeloid cells in the blood (granulocytes and immature granulocytes [bands]) to a total count of 500/mm³ or less. Symptoms of agranulocytosis include sore throat, fever, malaise, weakness, and chills. It occurs more frequently in females than in males,⁴⁵ with an overall estimated incidence of 1.6 to 3.4 million persons per year.^{3,17} The overall mortality rate in agranulocytosis is 16%; the rate increases among patients with agranulocytosis when they develop bacteremia or renal failure.⁴⁶ The symptoms can appear rapidly, within 7 to 14 days after the initiation of the offending agent. In contrast, patients with phenothiazine-induced agranulocytosis can be asymptomatic at the time of diagnosis, probably because they have a milder form of the disorder.⁴⁷ In the large majority of cases, drug-induced agranulocytosis will resolve over time.⁴⁶ Table 102–2 provides a list of medications that have been associated with drug-induced agranulocytosis.

A number of different mechanisms may lead to drug-induced agranulocytosis. Initially, it was thought that drugs affected only the mature granulocytes, causing a “maturation arrest.” More recent studies have demonstrated that drugs may have a toxic effect on the myeloid colony-forming unit in the bone marrow (either a direct toxic effect or an antibody-mediated effect);^{48,49} this may be the most frequent mechanism of drug-induced agranulocytosis.⁴⁵

Drug-induced agranulocytosis can be classified into three types (i.e., types I, II, and III).⁵⁰ The type I reaction is immune-mediated and involves the drug or drug metabolite, antibodies, and neutrophils. A type II reaction is associated with accumulated drug toxicity in hypersensitive individuals. The final type, type III, results from a combination of both immune and toxic mechanisms.

It has been postulated that drug-induced immune agranulocytosis (type I) develops by one of four different mechanisms.⁵¹ The first mechanism involves drug adsorption on the membrane of the neutrophil. The drug-membrane complex then acts as a hapten to stimulate antibody formation. The antibodies produced attach to the drug-membrane complex, causing WBC destruction through complement activation and removal by the phagocytic system (Fig. 102–2). This hapten-type reaction is often seen when drugs, such as the penicillin derivatives, are given in large doses. The dose at which this immune-mediated reaction occurs is higher than 150 mg/kg per day with the majority of penicillin derivatives, but it has occurred at lower doses.^{49,52,53}

The second mechanism of immune-mediated agranulocytosis is called the “innocent bystander phenomenon.” In this reaction, the drug combines with a drug-specific antibody. The complex is

NSAID, nonsteroidal anti-inflammatory drug.

FIGURE 102-2. Drug adsorption mechanism. The drug binds to the membrane of the blood cell. Antibodies are formed to the complex (hapten). The antibodies then attach to the complex, and cell toxicity occurs. (Reproduced with permission from Petz LD. *Drug-induced haemolytic anaemia. Ballieres Clin Haematol* 1980;91:455–482.)

nonspecifically adsorbed to the neutrophil membrane, resulting in complement activation. The activated complement then destroys the cell (Fig. 102-3). Quinidine has been associated with this type of reaction.

Functioning in a manner somewhat similar to that of the second mechanism, the third mechanism of immune response involves a protein carrier that combines with the drug and then attaches to the cell membrane. This in turn causes antibody formation. The antibodies attach to the drug protein carrier–membrane complex and activate complement. The cells are then cleared by the phagocytic system (Fig. 102-4).

The final mechanism for an immune-mediated reaction is the production of autoantibodies to a “spoiled membrane.” The offending drug alters the neutrophil membrane, which induces the formation of autoantibodies (antibodies that attach directly to the neutrophil). Their attachment to the neutrophil causes cellular destruction by the phagocytic system.

The onset of symptoms associated with immune-mediated mechanisms is rapid, occurring within 7 to 15 days of drug exposure. In the case of penicillin-induced agranulocytosis, the patient can often begin taking penicillin again, at a lower dosage, after the neutropenia has resolved without any relapse of drug-induced agranulocytosis.^{52,53} Because of the rapid onset of symptoms and the dose-related phenomenon, a second mechanism (type II) could possibly be involved with penicillin-induced agranulocytosis. This mechanism involves an accumulation of drug to toxic concentrations in hypersensitive individuals. Researchers have shown with in vitro cell cultures that

FIGURE 102-3. Innocent bystander mechanism. The drug induces antibody formation. The antibodies and drug form a complex in the serum, and the complex nonspecifically binds to the cell membrane. Complement is activated, and the cell is lysed. (Reproduced with permission from Petz LD. *Drug-induced haemolytic anaemia. Ballieres Clin Haematol* 1980;91:455–482.)

FIGURE 102-4. Protein carrier mechanism. The drug combines with a plasma protein. The complex then attaches to the cell membrane, and antibody formation is stimulated. Antibodies later attach to the complex and activate complement. The cell is then lysed by the complement. (Reproduced with permission from Young et al.⁵¹)

penicillin derivatives in high concentrations inhibit the growth of myeloid colony-forming units in patients recovering from drug-induced agranulocytosis.⁵⁴ Penicillin derivatives, therefore, may suppress WBCs by several mechanisms.

Antithyroid medications such as propylthiouracil and methimazole produce agranulocytosis in about 0.3% to 0.6% of patients.^{55,56} The mechanism by which antithyroid agents cause agranulocytosis is unknown, but antibodies to granulocytes have been demonstrated.^{57,58} In a study by Cooper and coworkers,⁵⁵ agranulocytosis occurred more frequently in older patients (>40 years old), and it appeared within 2 months after the initiation of therapy. The investigators also reported a possible dose-response relationship with methimazole.⁵⁵ For patients receiving less than 30 mg/day of methimazole, no agranulocytosis occurred, but in patients receiving higher doses, neutropenia was evident.⁵⁵ There appeared to be no dose-response relationship with conventional doses of propylthiouracil. However, another study demonstrated no relationship between age or dose and the incidence of thionamide-induced agranulocytosis.⁵⁹

Ticlopidine is an antiplatelet agent indicated for the treatment of cerebrovascular disease and the prevention of reocclusion associated with stent placement. It produces agranulocytosis in approximately 2.4% of patients,⁶⁰ reportedly by inhibiting myeloid colony growth.⁶¹ This evidence supports a potential direct toxic effect of ticlopidine on the bone marrow. In addition, ticlopidine is associated with an increase in prostaglandin E₁ concentrations, a known myelosuppressant.⁶² Other factors associated with the development of agranulocytosis include poor medullary reserve and age. Agranulocytosis occurs within 1–3 months from the initiation of therapy. Removal of the agent is the best treatment option, with counts returning to normal within 2 to 4 weeks.

The phenothiazines as a group are known to cause a type II drug-induced agranulocytosis. The onset of phenothiazine-induced agranulocytosis is approximately 2 to 15 weeks after the initiation of therapy.⁵¹ Although there is one report of acute agranulocytosis in a child who accidentally ingested a large quantity of chlorpromazine,⁴⁸ patients usually have ingested 10 to 20 g of a phenothiazine before the onset of neutropenia. Phenothiazine-induced agranulocytosis occurs most frequently in females older than 50 years of age.⁴⁷ The mechanism by which phenothiazines cause the drug-induced agranulocytosis has been studied primarily with chlorpromazine,⁴⁷ which is thought to affect cells in the cell cycle phase that manufactures enzymes needed for DNA synthesis (G₁ phase), or the phase in which cells are resting and not committed to cell division (G₀ phase).⁴⁷

The antipsychotic agents are known to precipitate proteins and may coprecipitate polynucleotides so they can no longer participate in nucleic acid synthesis. Chlorpromazine also increases the loss of macromolecules from the intracellular pools that are essential for cellular replication.⁴⁷ When the bone marrow from a patient with phenothiazine-induced agranulocytosis is examined, it initially appears to have no cellularity (aplastic), but over time it becomes hyperplastic. It is believed that toxic effects of the phenothiazines are not seen in all patients taking the medications because the majority of patients have enough bone marrow reserve to overcome the toxic effects.⁴⁷

Clozapine, an antipsychotic agent, has demonstrated an approximately 10-fold higher incidence of agranulocytosis compared with other antipsychotics.⁶³ The incidence of clozapine-induced agranulocytosis increases with age and occurs more frequently in female patients, but does not appear to be dose-related.⁶⁴ The agranulocytosis is reversible if detected early in therapy; therefore close monitoring of the WBC count is warranted. An *in vitro* study has suggested that the formation of a free radical metabolite may be responsible for clozapine-induced agranulocytosis.⁶⁵ The resulting oxidative stress caused by this metabolite may cause cytotoxicity or an immune reaction.⁶⁵

▶ TREATMENT: Drug-Induced Agranulocytosis

6 The primary treatment of drug-induced agranulocytosis is the removal of the offending drug. Following discontinuation of the drug, most cases of neutropenia resolve over time, and only symptomatic treatment (e.g., antimicrobials for infections) is necessary. Sargramostim (GM-CSF) and filgrastim (G-CSF) have been used to shorten the duration of neutropenia with varying degrees of success. A review of 118 cases of non-chemotherapy-induced agranulocytosis treated with colony-stimulating factors revealed a decrease

in the duration of neutropenia with a trend toward improved mortality, especially in patients with granulocyte counts of less than 100/mm³.⁶⁶ The time to recovery of the granulocyte count ranged from 3 to 15 days.^{67–69} A case series was published describing several schizophrenic patients who developed clozapine-induced agranulocytosis and were subsequently successfully treated with concomitant clozapine and G-CSF.⁷⁰

DRUG-INDUCED HEMOLYTIC ANEMIA

Following their release from the bone marrow, normal RBCs have 120 days before they are removed by phagocytic cells of the spleen and liver. The process of premature RBC destruction is referred to as hemolysis, which can occur either because of defective RBCs or abnormal changes in the intravascular environment. Drugs can promote hemolysis by both processes.

The causes of drug-induced hemolytic anemia can be divided into two categories: immune or metabolic. Those in the first category may operate much like the process that leads to immune-regulated agranulocytosis, or they may suppress regulator cells, which allows the production of autoantibodies. The second category involves the induction of hemolysis by metabolic abnormalities in the RBCs. Patients with drug-induced hemolytic anemia can present with signs of intravascular or extravascular hemolysis. Intravascular hemolysis, the lysis of RBCs in the circulation, can result from trauma, complement fixation to the RBC, or exogenous toxic factors. Extravascular hemolysis refers to the ingestion of RBCs by macrophages in the spleen and liver, a process that requires the existence of surface abnormalities on RBCs, such as bound immunoglobulin.⁷¹ The onset of drug-induced hemolytic anemia is variable and depends on the drug and mechanism of the hemolysis. Table 102–3 provides a list of drugs that have been associated with drug-induced immune hemolytic anemia.

DRUG-INDUCED IMMUNE HEMOLYTIC ANEMIA

A laboratory test called the direct Coombs test (or direct anti-human globulin test), which identifies foreign immunoglobulins either in the patient’s serum or on the RBCs themselves, is the best means to identify drug-induced immune hemolytic anemia. The Coombs test begins with the antiglobulin serum, which is produced by injecting rabbits with preparations of human complement, Fc fragments, or immunoglobulins. The rabbits produce antibodies that are foreign to human immunoglobulins and complement. The direct Coombs test involves combining the patient’s RBCs with the antiglobulin serum. If the patient’s RBCs are coated with antibody or complement (as a

result of a drug-induced process), the antibodies in the serum (produced by the rabbit) will attach to the Fc regions of the autoimmune globulins on two separate RBCs, creating a lattice formation called agglutination.⁷² This agglutination is considered positive for the presence of immunoglobulin G (IgG) or complement on the cell surfaces.

An indirect Coombs test can identify antibodies in a patient’s serum. This test is performed by combining the patient’s serum with normal RBCs, then subjecting them to the direct Coombs test. Antibodies that have attached to the normal RBCs will be identified. This process is important in blood bank procedures.

The mechanisms that have been proposed to explain how drugs can induce immune hemolytic anemia are similar to the mechanisms that produce drug-induced agranulocytosis. The first mechanism is the adsorption of the drug to the RBC membrane to form a hapten,

NSAID, nonsteroidal anti-inflammatory drug.

and subsequently, an antibody. The antibody attaches to the drug without direct interaction with the erythrocyte. The extravascular anemia that follows is usually caused by IgG, and generally there is no complement activation. The anemia usually develops gradually over 7 to 10 days and reverses over a couple of weeks after discontinuation of the offending drug. The direct Coombs test may remain positive for several weeks. The penicillin and cephalosporin derivatives given in high doses are mainly associated with this type of immune reaction.⁷³ Other drugs that have been reported to cause drug-induced immune hemolytic anemia by this process include minocycline, tolbutamide, and semisynthetic penicillins.⁷³ Streptomycin is also associated with this type of reaction and is associated with activation of the complement system.⁷⁴

Like drug-induced agranulocytosis, immune hemolytic anemia has been associated with the formation of immune complexes in a reaction formally known as the “innocent bystander phenomenon.” Quinidine and phenacetin are the prototype drugs of this reaction, but many other drugs have been implicated, including quinine and several sulfonamides. Drugs that induce this reaction form a “neoantigen” with a specific alloantigen on the RBC. This neoantigen, in turn, forms complexes with drug-specific antibodies (IgG or IgM) that adhere to the RBC membrane. Complement then lyses the RBC membrane.⁷³ Interestingly, the trimolecular complex is attached very loosely to the RBC.⁷³ As soon as complement is activated, the complex can detach and move on to other RBCs, and to leukocytes or platelets. Because of this low affinity, only a small amount of drug is needed to cause the reaction, and the direct Coombs test is positive for complement only. RBCs are essentially victims or “innocent bystanders” of the immunologic reaction. This type of mechanism is associated with acute intravascular hemolysis that can be severe, sometimes leading to hemoglobinuria and renal failure. Following discontinuation and clearance of the drug from the circulation, the direct Coombs test will be negative.

A third type of immune-mediated mechanism has occurred with cephalosporin derivatives. The cephalosporins can combine with non-specific proteins, including albumin, IgG, IgA, and fibrinogen, and adhere to the RBC; when this happens, a Coombs test will have a positive result. The binding is not immunologic in origin, and hemolytic anemia has not been associated with this reaction (Fig. 102–5). How-

FIGURE 102–5. Nonspecific binding of proteins mechanism. The drug combines with the cell membrane, which in turn causes a nonspecific binding of serum protein. This reaction is seen primarily with the cephalosporins, and no cell lysis or toxicity occurs. (Reproduced with permission from Petz LD. *Drug-induced haemolytic anaemia*. *Baillieres Clin Haematol* 1980;91:455–482.)

ever, the nonspecific binding of antibodies to the RBC membrane can cause difficulties in cross-matching patients for blood transfusions.⁷³

The fourth mechanism is best described. Methylodopa, like a few other drugs, is known to induce true autoantibodies to RBCs; the antibodies can be identified without the presence of the offending drug or its metabolites. About 20% of patients receiving methylodopa have a positive finding on Coombs test, but less than 1% of these patients experience hemolysis. The result of a Coombs test usually becomes positive 3 to 6 months after the beginning of therapy, but hemolysis develops from 4 to 6 months to more than 2 years after the start of therapy. After the withdrawal of the drug, results of the Coombs test can remain positive for many months.⁷⁴

The mechanism by which methylodopa induces antibody production is not completely known, but there are several hypotheses. One suggests that methylodopa inhibits suppressor T-lymphocyte function, resulting in uncontrolled autoantibody formation by B cells.⁷⁵ However, some data contradict this concept.⁷⁶ An alternative hypothesis suggests that the offending drug may bind to immature RBCs, altering the membrane antigens and inducing autoantibodies.⁷⁷

Overall, however, the reason that only some patients develop autoantibodies, and that only some of those have hemolytic disease, is not known. In an effort to explain why patients may have a positive result from a Coombs test and no hemolysis, Kelton demonstrated that methylodopa impairs the ability of these patients to remove antibody-sensitized cells.⁷⁸ In Coombs-positive patients receiving methylodopa, patients with impairment of the reticuloendothelial system could not clear the RBCs coated with autoantibodies from their bloodstream, and therefore hemolysis did not occur. Patients with hemolysis had no impairment of the reticuloendothelial system. Procainamide has also been reported to cause a positive result on the direct anti-human globulin test and hemolytic anemia.⁷⁹ Other drugs that have been reported to cause autoimmune hemolytic anemia include levodopa, mefenamic acid, and diclofenac.⁷⁷

DRUG-INDUCED OXIDATIVE HEMOLYTIC ANEMIA

A hereditary condition, drug-induced oxidative hemolytic anemia, most often accompanies a glucose-6-phosphate dehydrogenase (G6PD) enzyme deficiency, but it can occur because of other enzyme defects (reduced nicotinamide adenine dinucleotide phosphate [NADPH] methemoglobin reductase or reduced glutathione peroxidase). A G6PD deficiency is a disorder of the hexose monophosphate shunt, which is responsible for producing NADPH in erythrocytes, which in turn keeps glutathione in a reduced state. Reduced glutathione is a substrate for glutathione peroxidase, an enzyme that removes peroxide from erythrocytes, thus protecting them from oxidative stress.⁸⁰ Without reduced glutathione, oxidative drugs may oxidize the sulfhydryl groups of hemoglobin, removing them prematurely from the circulation (i.e., causing hemolysis).

A G6PD deficiency is the most common of all enzyme defects, affecting millions of people. Because the G6PD gene is located on the X chromosome, the disorder is consequently inherited via a sex-linked mode. There are many G6PD variants, but the most common types occur in American and African blacks (about 10%), people from Mediterranean areas (e.g., Greeks, Sardinians, and Khurdic and Sephardic Jews), and Asians.^{74,80} The Mediterranean variety tends to be more severe, and those with this defect also may experience hemolysis from the ingestion of fava beans (“favism”).⁸⁰

The degree of hemolysis depends on the severity of the enzyme deficiency and the amount of oxidative stress. However, the dose

required for hemolysis to occur is often less than prescribed quantities of the suspected agent.⁸⁰ Although severe hemolysis is rare, any drug that places oxidative stress on the RBC will cause drug-induced oxidative hemolytic anemia. There was one case of drug-induced oxidative hemolytic anemia that occurred in a child when dapsone (an oxidizing agent) was transferred through the breast milk of the mother, who was taking the drug.⁸¹ For a list of agents associated with drug-induced oxidative hemolytic anemia, refer to Table 102-4. An additional form of drug-induced anemia is pure red-cell aplasia. Patients with this disorder have a normochromic, normoblastic anemia and an absence of reticulocytes.⁸² Although this disorder is thought to have a directly toxic etiology, there is also evidence supporting an immune-mediated etiology. One case series described a group of 13 chronic renal failure patients who developed immune pure red-cell aplasia associated with recombinant erythropoietin injections.⁸³

▶ TREATMENT: Drug-Induced Hemolytic Anemia

The severity of drug-induced immune hemolytic anemia is usually a function of the rate of hemolysis. Hemolytic anemia caused by drugs via the hapten/adsorption and autoimmune mechanisms tend to be slower in onset and mild to moderate in severity. Conversely, hemolysis prompted via the neoantigen mechanism (innocent bystander) phenomenon may have a sudden onset, lead to severe hemolysis, and result in renal failure. The treatment of drug-induced immune hemolytic anemia includes the removal of the offending agent and supportive care. Glucocorticoids are usually unnecessary, and practitioners have questioned their efficacy.⁷⁷

A recent development in the treatment of autoimmune hemolytic anemia is the use of the chimeric, human anti-CD20 monoclonal

antibody rituximab.⁸⁴ The role of immunoglobulin treatments in drug-induced hemolytic anemia has yet to be clearly defined.

■ DRUG-INDUCED OXIDATIVE HEMOLYTIC ANEMIA

Removal of the offending drug is the primary treatment for drug-induced oxidative hemolytic anemia. No other therapy is usually necessary, as most cases of drug-induced oxidative hemolytic anemia are mild in severity. Patients with these enzyme deficiencies should be advised to avoid medications capable of inducing the hemolysis.

DRUG-INDUCED MEGALOBlastic ANEMIA

In drug-induced megaloblastic anemia, the development of RBC precursors called megaloblasts in the bone marrow is abnormal. Deficiencies in either B₁₂ or folate are responsible for the impaired proliferation and maturation of hematopoietic cells, resulting in cell arrest and subsequent sequestration. Examination of peripheral blood shows a rise in the mean corpuscular hemoglobin concentration. These megaloblastic changes are due to the direct or indirect effects of the drug on DNA synthesis. Some patients may have a normal-appearing cell line, and diagnosis must be made through alterations in B₁₂ and folate concentrations. The abnormality can be seen in any portion of the replication process, including DNA assembly, base precursor metabolism, or RNA synthesis.⁸⁶

Because of their pharmacologic action on DNA replication, the antimetabolite chemotherapeutic agents are most frequently associated with drug-induced megaloblastic anemia. Methotrexate, an irreversible inhibitor of dihydrofolate reductase, causes megaloblastic anemia in 3% to 9% of patients.⁸⁷ Dihydrofolate reductase is an enzyme responsible for generating tetrahydrofolate, an essential factor in making deoxythymidine triphosphate, which is necessary for DNA synthesis. Other drugs such as cotrimoxazole, phenytoin, or the barbiturates have also been implicated in megaloblastic anemia. Cotrimoxazole, for example, has been reported to cause drug-induced megaloblastic anemia with both low and high doses,^{88,89} particu-

larly in patients with a partial B₁₂ or folate deficiency.⁸⁶ Because the drug’s affinity for human dihydrofolate reductase is low, patients with adequate stores of these vitamins are at low risk of developing drug-induced megaloblastic anemia if they are taking cotrimoxazole. It has been postulated that phenytoin, primidone, and phenobarbital cause drug-induced megaloblastic anemia by either inhibiting folate absorption or by increasing folate catabolism. In both instances, the patient develops a relative deficiency of folate. Table 102-5 provides a list of drugs that have been suggested as causative factors in drug-induced megaloblastic anemia.

| 6-Mercaptopurine | Vinblastine |

► **TREATMENT: Drug-Induced Megaloblastic Anemia**

When drug-induced megaloblastic anemia is related to chemotherapy, no real therapeutic option is available, and the anemia becomes an accepted side effect of therapy. If drug-induced megaloblastic anemia results from cotrimoxazole, a trial course of folic acid, 5 to 10 mg up to four times a day, may correct the anemia.^{88,89}

Folic acid supplementation of 1 mg every day often corrects the drug-induced megaloblastic anemia produced by either phenytoin or phenobarbital, but some clinicians suggest that supplementation of folic acid may decrease the effectiveness of the antiepileptic medications.⁹⁰

DRUG-INDUCED THROMBOCYTOPENIA

Thrombocytopenia is defined as a platelet count below 150,000/mm³. There are three types of drug-induced thrombocytopenia: direct toxicity reactions, hapten-type immune reactions, and innocent bystander-type immune reactions. Direct toxicity reactions, resulting in suppressed thrombopoiesis, produce a decrease in the number of megakaryocytes in the bone marrow. In contrast, immune reactions result in an increased peripheral destruction of platelets and an increased number of megakaryocytes. Early symptoms of drug-induced thrombocytopenia include increased bruising, petechiae, ecchymoses, and epistaxis. Bleeding from mucous membranes and severe purpura can appear later in the disorder. A list of medications associated with drug-induced thrombocytopenia can be found in Table 102–6. Several comprehensive reviews are available.^{91,92}

Drugs that induce thrombocytopenia by their toxic effects are primarily cancer chemotherapy agents; however, organic solvents, pesticides, and inamrinone (formally named amrinone) have also been implicated. Orally administered inamrinone has been shown to cause thrombocytopenia in up to 18.6% of patients.⁹³ The only commercially available formulation of inamrinone in the United States is to be given IV, and it is associated with a 2% to 4% incidence of thrombocytopenia, possibly reflecting the short-term nature of IV administration compared to the oral route. Although investigators have demonstrated an inamrinone-dependent antibody, it is believed that because of the rapid onset, the dose-related response, and the absence of amnestic effect, a non-immune-mediated peripheral destruction of platelets may be responsible for the thrombocytopenia.⁹³ Additional data suggest that this toxic effect may be due to the inamrinone metabolite, N-acetylamrinone.⁹⁴

In the majority of patients, drug-induced thrombocytopenia develops through an immunologic mechanism. The agents most commonly implicated are quinine, quinidine, gold salts, sulfonamide antibiotics, and heparin.⁹² Study of these agents has revealed extensive information regarding the mechanism of drug-induced immune thrombocytopenia. In hapten-type reactions, the offending drug binds to certain platelet glycoproteins, most commonly Ib/IX, V, and IIb/IIIa.⁹⁵ Antibodies are generated that bind to these drug-bound glycoprotein epitopes. After the binding of drug-dependent antibodies to the platelet surface, lysis occurs through complement activation or through clearance from the circulation by macrophages.

Hapten-mediated immune thrombocytopenia usually occurs at least 7 days after the initiation of the drug, although it may occur much sooner if the exposure is actually a re-exposure to a previously administered drug. It occurs frequently in patients receiving large doses of the medication (e.g., penicillin derivatives > 150 mg/kg).^{96,97} The recovery period, once the suspected drug is discontinued, is often short in duration.⁹⁸

Rare cases of acute profound thrombocytopenia (i.e., platelet count <20,000/mm³) have been reported with the glycoprotein IIb/IIIa receptor antagonist abciximab.^{99–101} Although the mechanism is unknown, it is thought that abciximab binding to the glyco-

protein IIb/IIIa receptor may induce the expression of ligand-induced binding sites. These new binding sites may react with antibodies, leading to an increased clearance of platelets.^{101,102} In a report that does not support this immunologic hypothesis, Peter and associates describe a patient with demonstrated platelet activation and subsequent thrombocytopenia.¹⁰³ In clinical trials with abciximab plus heparin, the incidence of thrombocytopenia with platelet count less than 50,000/mm³ ranged from 1.3% to 1.6%. In comparison, in patients

| Indinavir | Vancomycin |

who received placebo plus heparin, thrombocytopenia ranged from 0.3% to 0.7%.¹⁰¹ Published case reports indicate that the incidence of acute profound thrombocytopenia with abciximab is less than 1%, and that nadir platelet counts of 1000 to 4000/mm³ occurred from 2 to 31 hours following bolus infusion.¹⁰¹ This time course contrasts with that of other hapten-type thrombocytopenias; the decrease in platelet count can occur within hours of first drug exposure.

Because abciximab is coadministered with heparin, it is important to distinguish between abciximab-induced and heparin-induced thrombocytopenia. Performing a heparin-induced platelet aggregation study is helpful in making this differentiation.

CLINICAL CONTROVERSY

Profound thrombocytopenia (i.e., platelet count less than 20,000/mm³) has been reported with the glycoprotein IIb/IIIa receptor antagonist abciximab. Before this effect was fully appreciated, clinicians were inclined to attribute this event to heparin, which was coadministered with abciximab. The current challenge for clinicians is to distinguish between abciximab-induced and heparin-induced thrombocytopenia, so that the patient's adverse event is documented properly. Thrombocytopenia associated with abciximab may present with a nadir of platelet counts of 1000 to 4000/mm³ occurring from 2 to 31 hours following bolus infusion. This is much sooner than the 5 to 10 days observed with initial heparin exposure. However, re-exposure to heparin can produce profound thrombocytopenia within hours, much like abciximab. The ubiquity of heparin use for flushing catheters renders it difficult to determine previous exposure in many cases. Clinicians can choose from several types of assays to aid in the diagnosis of heparin-induced thrombocytopenia, including platelet activation assays, platelet aggregation studies, and enzyme-linked immunosorbent assay methods, each with varying sensitivity, specificity, and availability.

Pseudothrombocytopenia, defined as *in vitro* platelet aggregation in blood anticoagulated with ethylenediaminetetraacetic acid (EDTA), is clinically insignificant, but it must also be differentiated from thrombocytopenia induced by abciximab. In this case, microscopic examination of a peripheral blood smear, along with repeated platelet counts in citrate-anticoagulated blood samples, makes the distinction possible.¹⁰⁴

Heparin can cause at least two types of thrombocytopenia.¹⁰⁵ The first is a mild, reversible, non-immune-mediated reaction that occurs 2 to 4 days after the initiation of therapy. The platelet count slowly returns to normal following an initial decline, despite continued heparin therapy. This benign condition is thought to result from weak activation of platelets, leading to sequestration.¹⁰⁵ No major sequelae develop from this type of heparin-induced thrombocytopenia.

The second type of heparin-induced thrombocytopenia is severe and may be associated with a platelet count below 100,000/mm³ and thrombosis.^{105,106} The platelet count generally begins to decline 5 to 10 days after the start of heparin therapy (sooner in patients previously treated with heparin). Thrombocytopenia and thrombosis may develop with low-dose heparin,^{105,107} heparin-coated catheters,¹⁰⁸ or even heparin flushes. Historically, the reaction was thought to be mediated by the formation of antibodies to the platelet-heparin complex. However, evidence suggests a complex interaction between heparin, platelet factor 4 (PF4), platelet membrane Fc receptors, and possibly heparin-like molecules on the surface of endothelial cells (Fig. 102-6). Circulating heparin reacts with PF4 to produce a

FIGURE 102-6. Proposed explanation for the presence of both thrombocytopenia and thrombosis in heparin-sensitive patients who are treated with heparin. Injected heparin reacts with platelet factor 4 (PF4), which is normally present on the surface of endothelial cells (ECs) or released in small quantities from circulating platelets, to form PF4-heparin complexes (1). Specific IgG antibodies react with these conjugates to form immune complexes (2) that bind to Fc receptors on circulating platelets. Fc-mediated platelet activation (3) releases PF4 from α -granules in platelets (4). Newly released PF4 binds to additional heparin, and the antibody forms more immune complexes, establishing a cycle of platelet activation. PF4 released in excess of the amount that can be neutralized by available heparin binds to heparin-like molecules (glycosaminoglycans) on the surface of ECs to provide targets for antibody binding. This process leads to immune-mediated EC injury (5) and heightens the risk of thrombosis and disseminated intravascular coagulation. (Reproduced with permission from Bell *et al.*¹¹¹)

complex that is seen as an antigen. Antibodies, predominantly IgG, react with this heparin-PF4 conjugate to form immune complexes that bind to Fc receptors on the platelet membrane. Platelet activation and aggregation occur, with subsequent release of more circulating PF4 to interact with heparin and bind to heparin-like molecules on the surface of endothelial cells. This interaction between PF4 and endothelial cells leads to antibody binding and increases the risk of thrombosis.¹⁰⁹ The incidence of heparin-induced thrombocytopenia with thrombosis has been reported to be three to four times higher with heparin from bovine sources than with heparin from porcine sources,^{110,111} but several studies have demonstrated no differences between animal sources of heparin.^{111–114} Several types of assays are available to aid in the diagnosis of heparin-induced thrombocytopenia, including platelet activation assays, platelet aggregation studies, and enzyme-linked immunosorbent assay methods, each with varying sensitivities and specificities.¹¹⁵

Low-molecular-weight heparins bind less well to PF4 than unfractionated heparin does, and would therefore seem less likely to produce thrombocytopenia.¹¹⁵ In a study designed to examine the incidence of heparin-induced thrombocytopenia in patients receiving prophylaxis for venous thromboembolism following hip surgery, it was found that thrombocytopenia occurred in 2.7% of patients treated with unfractionated heparin compared with 0% of patients treated with low-molecular-weight heparin. Interestingly, 2.2% of those who received low-molecular-weight heparin developed heparin-dependent

antibodies.¹¹⁶ Therefore, low-molecular-weight heparin should not be expected to eliminate the risk of thrombocytopenia, and should not be considered an alternative to unfractionated heparin in patients with heparin-induced thrombocytopenia because of the potential for cross-reactivity with heparin-dependent antibodies.¹¹⁷

The thrombocytopenia induced by gold salts is related to antibody formation to platelets.^{118,119} The incidence of gold-induced thrombocytopenia ranges from 1% to 3%, and the condition often has an abrupt and severe onset.¹¹⁸ The autoantibody formed to the platelets appears to be associated with the human leukocyte antigens (HLAs), which are located on the platelet membrane and on a number of other different cells in the body.^{118,119} An interaction between the gold salts and the HLAs causes the platelets to be recognized as nonself, thus inducing destruction of the platelets. The most commonly reported HLA associated with induction of the autoantibodies is DR-3, but DR-4 may also interact with the antibodies.^{118–121} The exact mechanism by which gold causes the formation of the autoantibody to regulated DR-3 and DR-4 antigens has not been elucidated. In addition to gold, autoantibodies have been identified for α -methyldopa.⁹¹

The third mechanism described for drug-induced thrombocytopenia is the innocent bystander-type immune response. The most commonly implicated drug is quinidine, and the drug-induced thrombocytopenia is frequently related to higher doses of the drug.¹²¹ Quinidine may also form a hapten with the platelet membrane to produce thrombocytopenia.¹²²

► TREATMENT: Drug-Induced Thrombocytopenia

The primary treatment of drug-induced thrombocytopenia is removal of the offending drug and symptomatic treatment of the patient. The use of corticosteroid therapy in the treatment of drug-induced thrombocytopenia is controversial, although some authors recommend it in severe symptomatic cases.¹²³ In gold salt–induced thrombocytopenia, however, some investigators believe prednisone in a dose of 60 mg daily is beneficial in correcting the thrombocytopenia.¹¹⁸

In the case of heparin-induced thrombocytopenia with thrombosis, all forms of heparin must be discontinued, including heparin flushes, and anticoagulation with argatroban or the recombinant hirudin lepirudin initiated.^{122,124} These agents should also be considered for the treatment of patients who have acute heparin-induced thrombocytopenia without thrombosis because of the increased risk

of thrombosis occurring in these patients. Because of the increased risk of venous limb gangrene, warfarin should not be used alone to treat acute heparin-induced thrombocytopenia complicated by deep vein thrombosis.¹²⁴ The relatively high risk of continued thrombocytopenia with thrombosis is a contraindication for the use of low-molecular-weight heparin in the treatment of acute heparin-induced thrombocytopenia. Abciximab-induced acute profound thrombocytopenia is effectively treated with platelet transfusion, if clinically indicated.⁹⁵

It is important for clinicians to avoid using heparin products for these patients. Several options now exist for the appropriate anticoagulation of patients prior to surgical procedures. These agents include argatroban, tirofiban, fondaparinux, and bivalirudin.

SUMMARY

7 Drug-induced hematologic disorders are rare but potentially life-threatening conditions. Clinicians should be cognizant of medications with the potential of causing hematologic disorders, and educate patients to recognize the symptoms associated with such events. Frequent laboratory monitoring of patients taking medications associated with severe hematologic events can facilitate diagnosis and treatment. Identifying the etiology of the event and documenting the causative agents may serve to prevent a recurrence secondary to the use of a related medication. Reporting such an event to national adverse event reporting services and in the peer-reviewed medical literature can serve to improve the understanding of the prevalence and risk factors for such a disorder.

ABBREVIATIONS

ADR: adverse drug reaction
 G-CSF: granulocyte colony-stimulating factor

LABORATORY TESTS TO DIRECT
ANTIMICROBIAL PHARMACOTHERAPY*Michael J. Rybak and Jeffrey R. Aeschlimann*

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Familiarity with normal host flora and typical pathogens will help to determine whether a patient is truly infected or merely colonized.
- 2 Direct examination of tissue and body fluids by Gram stain provides simple and rapid information about the potential pathogen.
- 3 Isolation of the offending organism by culture assists in the diagnosis of infection and allows for more definitive directed treatment.
- 4 The development of molecular testing systems has improved our ability to diagnose infection and determine the antimicrobial susceptibilities for numerous fastidious or slow-growing pathogens, such as mycobacteria and viruses.
- 5 Although highly standardized, *in vitro* antimicrobial susceptibility testing has limitations and often cannot truly mimic the conditions found at the site of an infection. This may have implications for discordance between *in vitro* susceptibility results and *in vivo* response to therapy.
- 6 The laboratory evaluation of antimicrobial activity is an important component of the pharmacotherapeutic management of infectious diseases.
- 7 Antimicrobial pharmacodynamics have become a crucial consideration for the clinician during the selection of both empirical and pathogen-directed therapy in the current era of antimicrobial resistance.
- 8 When used appropriately, rapid automated susceptibility test systems appear to improve therapeutic outcomes of patients with infection, especially when they are linked with other clinical information systems.
- 9 Although not performed routinely during the clinical management of patients with infections, data from certain laboratory tests (e.g., minimal bactericidal concentration tests, timed-kill tests, post-antibiotic-effect tests, and antimicrobial combination testing) are important for the clinician to understand because they help to determine an antimicrobial's pharmacodynamic properties.
- 10 Routine monitoring of serum concentrations is currently used for a select few antimicrobials (e.g., aminoglycosides, chloramphenicol, and vancomycin) in an attempt to minimize toxicity and maximize efficacy.
- 11 Appropriate timing for the collection of serum samples is crucial to ensure that proper data are generated on the pharmacokinetics of antimicrobials.
- 12 The monitoring of serum concentrations of aminoglycosides and the use of extended-interval doses of aminoglycosides can help to maximize the probability of therapeutic success and minimize the probability of aminoglycoside-related toxicity.
- 13 Vancomycin serum concentration monitoring can either be minimized or avoided entirely for many patients who are treated with this antimicrobial.
- 14 Optimization of antimicrobial pharmacodynamic parameters such as the ratio of the peak serum concentration to minimum inhibitory concentration or the time that the serum concentration remains above the minimum inhibitory concentration can improve infection treatment outcomes.

Appropriate antimicrobial pharmacotherapy for a given infectious disease requires knowledge of the infecting pathogen, host characteristics, and the drug's expected activity against the pathogen. The most fundamental aspect of therapy starts with an appropriate diagnosis.

A vast array of laboratory tests is available to assist the clinician in verifying the presence of infection and for monitoring the response to therapy. Although useful, these tests are subject to interpretation and cannot be substituted for sound clinical judgment. Organism

susceptibility to a given group of antimicrobials is key to determining the patient's therapy. Host characteristics, however, such as immune status, infection-site location, and body organ function, play a significant role in selecting the most appropriate antimicrobial for a given individual.¹ This chapter reviews the routine laboratory tests that are used to assist in the diagnosis and treatment of infection.

LABORATORY TESTS CONFIRMING THE PRESENCE OF INFECTION

NONSPECIFIC TESTS

A number of tests are used by clinicians to determine whether a patient has an infection. Although no single test can prove that a patient is infected, when used in combination with clinical findings, tests are helpful to establish the diagnosis of infection. Because many tests are nonspecific, there are often factors other than infection that can cause a test to be reported as positive when no infection exists. Therefore, the importance of careful interpretation and sound clinical judgment cannot be overemphasized. This chapter reviews the commonly employed tests and their interpretation and application for the diagnosis and management of infection.

WHITE BLOOD CELL COUNT AND DIFFERENTIAL

Understanding the role of the white blood cell (WBC) in fighting infection is important in the diagnosis of infection, the selection of drug therapy, and the monitoring of patient progress. The major role of the WBC is to defend the body against invading organisms such as bacteria, viruses, and fungi. The normal range of the WBC is 4500 to 10,000 cells/mm³. WBCs usually are elevated in response to infection. The WBC count can become elevated in response to a number of noninfectious causes, including stress, inflammatory conditions such as rheumatoid arthritis, and leukemia or in response to certain drugs (e.g., corticosteroids).

WBCs are divided into two groups: the granulocytes, which have prominent cytoplasmic granules, and the agranulocytes, which lack granules. Polymorphonuclear granulocytes (PMNs) are made up of neutrophils, basophils, and eosinophils. The two other classes of WBCs are the monocytes and lymphocytes. Neutrophils are the most common type of WBCs in the blood, comprising approximately 70% of the total WBC count. In response to infection, they leave the bloodstream and enter the tissue to interact with and phagocytize offending pathogens. Mature neutrophils sometimes are referred to as *segs* because of their segmented nucleus, which usually consists of two to five lobes. Immature neutrophils lack this segmented feature and are referred to as *bands*. During an acute infection, immature neutrophils, such as bands (single-lobed nucleus), are released from the bone marrow into the bloodstream at an increased rate, and the percentage of bands (usually 5%) may increase in relationship to mature cells. The change in the ratio of mature to immature cells is often referred to as a *shift to the left* because of the way the cells were counted by hand with a microscope and charted from immature to mature cells.

Leukocytosis is a normal host defense to infection and is an important adjunct to antimicrobial therapy. Unfortunately, bacterial infection is a common complication of neutropenia from cancer chemotherapy. These patients are incapable of increasing their WBCs in response to infection. In fact, susceptibility to infection in these patients is highly dependent on their WBC status. Patients with neutrophil counts of less than 500 cells/mm³ are at high risk for the development of bacterial or fungal infections. The absence of leukocytosis also occurs in the elderly and in severe cases of sepsis.^{2,3}

Lymphocytes comprise 15% to 40% of all WBCs and are of central importance to the immune system. Two functional types of lymphocytes are the T cell, which is involved in cell-mediated immunity, and the B cell, which produces antibodies involved in humoral immunity. Lymphocytosis frequently is associated with acute viral infections such as Epstein-Barr virus infection (mononucleosis) and cytomegalovirus infection and rarely with unusual bacterial infections (i.e., *Brucella* spp. infections).

T-lymphocytes are characterized on the basis of function (type 1 or type 2) and on the basis of surface antigen. Most type 1 and type 2 T cells carry a T4 (CD4) marker that recognizes class II major histocompatibility complex (MHC) antigens, and most cytotoxic T cells carry a T8 (CD8) marker that recognizes class I MHC antigens. A severe deficiency of CD4 cells is associated with human immunodeficiency virus (HIV) infection.⁴ Malignancies also may adversely affect cellular immunity. Patients with Hodgkin's disease and other types of lymphoma exhibit defective cell-mediated immunity that predisposes them to a variety of infections, notably fungal diseases and infections by the *Listeria* spp. Drug treatment with cytotoxic chemotherapy and corticosteroids also may have profound deleterious effects on cell-mediated immunity.⁵ Defects in cell-mediated immune function can be demonstrated by a variety of simple laboratory tests, including quantification of lymphocytes on a routine complete blood cell count and skin testing for anergy. A more detailed investigation includes quantitative measurements of CD4+ and CD8+ cells. Monocytosis is correlated less frequently with acute bacterial infection, although its presence has been associated with the response of certain infections (e.g., tuberculosis) to chemotherapy. Eosinophilia may result from parasitic infection.⁶ Figure 103-1 describes a number of cell types and their biologic function.

OTHER TESTS

There are a number of nonspecific laboratory tests that are useful to support the diagnosis of infection. The inflammatory process initiated by an infection sets up a complex of host responses. Activation of complements, such as C3a and C5a, initiates inflammation and sets off a cascade of changes and the subsequent release of mediators, all of which can be measured and monitored. Serum complement concentrations, particularly C3, usually are consumed as part of the host defense mechanism and subsequently are reduced during the early stages of an acute infectious process.⁷ Acute-phase reactants, such as the erythrocyte sedimentation rate (ESR) and the C-reactive protein concentration, are elevated in the presence of an inflammatory process but do not confirm the presence of infection because they are often elevated in noninfectious conditions, such as collagen-vascular diseases and arthritis. Large elevations in ESR are associated with infections such as endocarditis, osteomyelitis, and intraabdominal infections.⁸

Changes in endothelial membranes and the presence of a foreign pathogen and its endotoxins cause certain cytokines, such as interleukin 1 (IL-1), IL-6, and IL-8 and tumor necrosis factor α (TNF- α), to be produced by macrophages or lymphocytes. Fluctuations in cytokine levels occur during the course of an infection, which may be useful in staging and monitoring the response to therapy. Although abnormally high levels of TNF have been associated with a variety of noninfectious causes, spiked elevations in TNF are found in patients with serious infections, such as sepsis. Studies of the relationship of circulating mediators to patient outcome have determined the value of endotoxin and cytokine measurements in patients with sepsis. Although the combination of elevations in endotoxin and individual cytokines has correlated well with the mortality rate, measurement

| Cell type | Cellular function | |
|---------------------|---|---|
| Macrophage/monocyte | Antigen presenting cell Surveillance of antigens |  |
| Neutrophils | Defense against bacteria and fungus |  |
| Eosinophils | Defense against parasite Response against allergic reactions |  |
| Basophil | Allergic response |  |
| B lymphocyte | Antibody production Antigen presenting cell |  |
| T lymphocytes | Cellular immunity against virus and tumors Regulation of the immune system |  |

FIGURE 103-1. Various cell types and their biologic functions.

of IL-6 was by far the best individual cytokine that predicted patient outcome.⁹ More recent information has demonstrated a significant relationship between monocyte human leukocyte antigen (HLA) DR expression and the risk of mortality in patients with community-acquired severe infections.¹⁰ Understanding the balance between these proinflammatory and antiinflammatory processes likely will lead to interventions that may have a direct impact on the outcome of patients with sepsis.¹¹

LABORATORY IDENTIFICATION OF PATHOGENS

COLONIZATION VERSUS INFECTION

2 Pathogens are organisms that are capable of damaging host tissues and that elicit specific host responses and symptoms that are consistent with an infectious process. These organisms are transferred from patient to patient, vector to patient (animals, insects, and so on), environment to patient (e.g., hospital settings) or are derived from the patient's own flora. On the other hand, the human body contains a vast variety of microorganisms that colonize body systems and make up the so-called normal flora. These organisms occur naturally in the tissues of the host and provide some benefits, including defense by occupying space, competing for essential nutrients, stimulating cross-protective antibodies, and suppressing the growth of potentially pathogenic bacteria and fungi (Table 103-1).

Organisms that comprise the normal flora can become pathogenic when host defenses become impaired or if they are translocated to other body sites during trauma. The identification of an organism considered to be normal flora in a wound or otherwise sterile body cavity or fluid often becomes a dilemma for the clinician in deciding whether or not a patient is infected and whether or not the patient requires treatment. Such is the case with *Staphylococcus epidermidis* when it is identified in the blood of a hospitalized patient. *S. epidermidis* is considered normal skin flora and commonly colonizes intravenous catheters. In these conditions, identification of the organism must be taken in light of the patient circumstances (signs and symptoms, laboratory indices supporting infection) and the probability of the organism being responsible for the infection. Often the simple removal of the catheter may eliminate the organism from the bloodstream, thereby preventing misdiagnosis and unnecessary application of antimicrobials.¹²

DIRECT EXAMINATION

3 Direct examination of tissue or body fluids believed to be infected can provide simple, rapid information to the clinician. Microscopic examination of wet-mount specimen preparations can provide valuable information regarding potential pathogens. Applications of this procedure with or without staining preparations include direct examination of sputum, bronchial aspirates, scrapings of mucosal lesions, and urinary sediment. The Gram stain is one of the

TABLE 103-1. Examples of Normal Bacterial Flora

| | Gram-Positive | | Gram-Negative | | Other |
|------------------------|---|--|---------------|--|-------------------|
| | Cocci | Rods | Cocci | Rods | |
| Skin | <i>Staphylococcus</i> spp. (e.g., <i>S. epidermidis</i>) <i>Streptococcus</i> spp. | <i>Corynebacterium</i> spp. <i>Propionibacterium</i> spp. | | Enteric bacilli (some sites) <i>Acinetobacter</i> spp. (Coccobacilli) | |

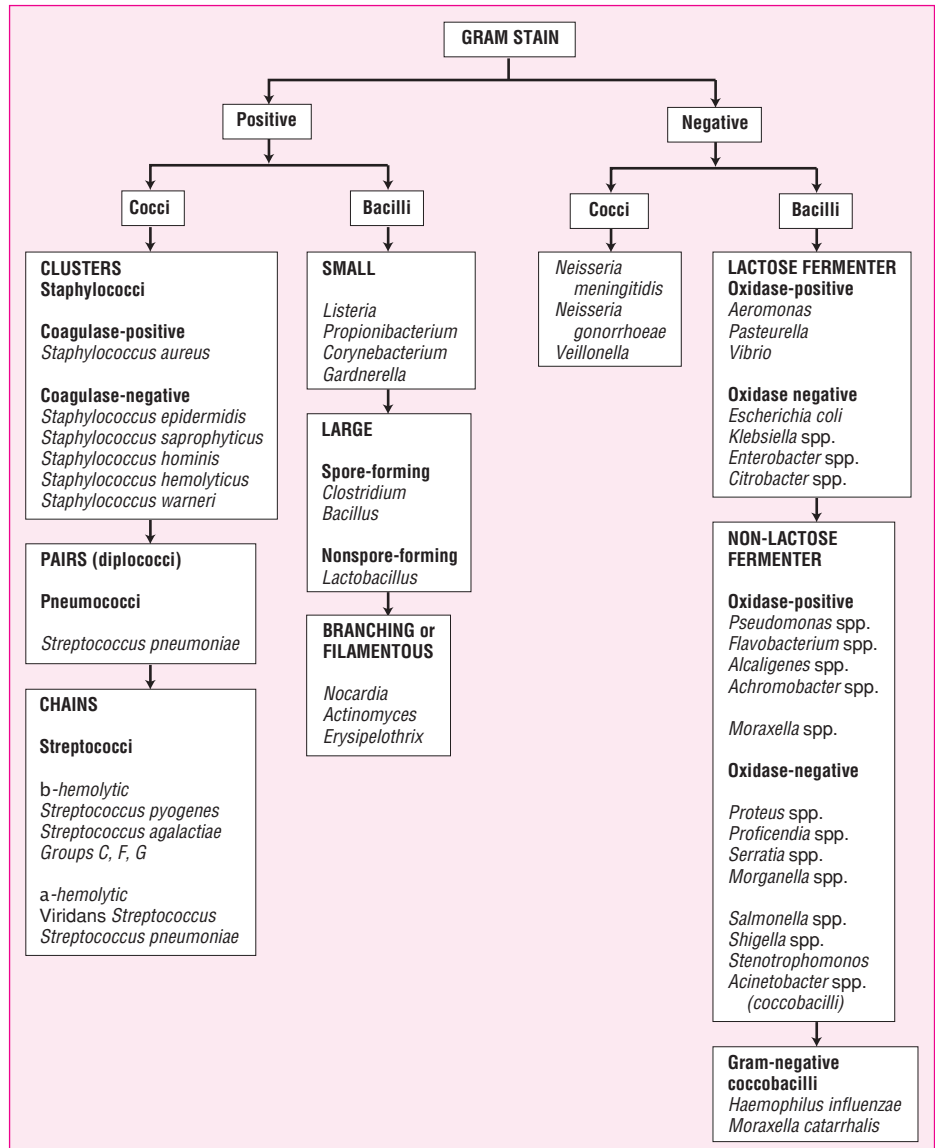

FIGURE 103–2. Important bacterial pathogens classified according to Gram stain and morphologic characteristic.

first identification tests run on a specimen brought to the laboratory. For this procedure, crystal violet is applied as the primary stain, with iodine added to enhance the staining process and to form a crystal violet–iodine complex. Alcohol decolorization is the next step in the procedure. Gram-negative cells are decolorized by the addition of alcohol, and they take in a red color when counterstained by safranin. Gram-positive cells are not decolorized by alcohol and retain the crystal violet color and appear purple. Gram staining in conjunction with microscopic examination may provide a presumptive diagnosis and some indication of the organism’s characteristics (gram-positive, gram-negative, gram-variable, bacillus, or cocci). This is extremely useful information for the selection of empirical antibiotic therapy.

Gram stains are performed routinely on cerebrospinal fluid (CSF) in cases of suspected meningitis, on urethral smears for venereal diseases, and on abscess or effusion specimens. They are helpful in identifying organisms that may not grow on culture and which otherwise would be missed. Although Gram stains of sputum are performed routinely when respiratory tract infections are suspected, there is controversy regarding the usefulness of this test because the sputum is often contaminated with mixed or normal flora. The predominance of

one particular organism, the overall number of organisms present, the amount of PMNs present, and the presence or absence of a significant amount of squamous epithelial cells (<10 per low-power field) may improve the significance of the sputum Gram stain specimen. Figure 103–2 lists some common infecting pathogens grouped according to Gram stain and other characteristics.

A number of other staining techniques are used to identify pathogens. In particular, staining procedures are used for pathogens that are best identified microscopically because of their poor growth characteristics in the laboratory setting. The best examples of these are the Ziehl-Neelsen stain for acid-fast bacilli, which is used for the identification of mycobacteria, and the india ink, potassium hydroxide (KOH), and Giemsa stains, which are useful for detecting certain fungi.¹³

CULTURES

4 Isolation of the etiologic agent by culture is the most definitive method available for the diagnosis and eventual treatment of infection. Although suspicion of a specific pathogen or group of

pathogens is helpful to the laboratory for the selection of a specific cultivating medium, the more common procedure for the laboratory is to screen for the presence of any potential pathogen. After receipt of a clinical specimen, the laboratory will inoculate the specimen in a variety of artificial media. Some culture media are designed to differentiate various organisms on the basis of biochemical characteristics or to select specific organisms on the basis of resistance to certain antimicrobials. Other media are employed commonly for the isolation of more fastidious organisms, such as *Listeria*, *Legionella*, *Mycobacterium*, or *Chlamydia*. Cultures for viruses are more difficult to perform and are undertaken primarily by larger institutions or outside laboratories because of the technical expense and time involved in processing samples.

When a culture is obtained, careful attention must be paid to ensuring that specimens are collected and transported appropriately to the laboratory. Every effort should be made to avoid contamination with normal flora and to ensure that the specimen is placed in the appropriate transport medium. Culture specimens should be transported to the laboratory as soon as possible because organisms may perish from prolonged exposure to air or drying. This is especially important for swab specimen preparations. Transport media may not be ideal for all organisms. Specimens that contain fastidious organisms or anaerobes require special transport media and should be forwarded immediately to the laboratory for processing. Finally, the source of the specimen should be clearly recorded and forwarded along with the culture to the laboratory. This process will aid the laboratory in differentiating true pathogens from the expected normal flora, and it will help in the selection of the appropriate culture media.

Detection of microorganisms in the bloodstream by standard culturing techniques is difficult because of the inherently low yield of organisms diluted by blood, humoral factors with bactericidal activity, and the potential of antimicrobial pretreatment affecting organism growth. Newer automated systems employing the use of medium-containing culture bottles and innovative organism-detection techniques have improved this situation. Most blood collection bottles dilute the blood specimen 1:10 with growth medium to neutralize the bactericidal properties of blood and antimicrobials. The addition of a polyanionic anticoagulant abolishes the effect of complement and antiphagocytic activity in the specimen. Some laboratories also add β -lactamase to their blood collection bottles. Antibiotic-binding resin bottles, such as Bactec 16 B, are also commercially available.

Rapid detection of bacteria or fungi within a few hours of specimen collection is now possible by the use of automated culturing systems, such as Bactec (Becton Dickinson Diagnostic Instruments, Sparks, MD), that use bottles of growth medium containing a fluorescent sensor to monitor culture bottles for the presence of CO₂ every 10 minutes as a by-product of microorganism growth. Computers monitoring the system alert laboratory personnel of positive culture results by both audible and visual alarms. Once detected, a battery of testing can be performed rapidly that shortens the reporting time and that enables clinicians to obtain preliminary information about the organism.^{13,14}

The initial identity of the organism can be determined by a variety of testing procedures. General schemes differentiate organisms into primary groups, such as gram-positive and gram-negative bacteria. This can be accomplished by simple Gram staining, as described previously, by evaluating organism growth patterns on selective media, and by testing for the presence or absence of specific enzymes and chemical characteristics, such as hemolytic and fermentation properties. For example, non-lactose-fermenting gram-negative bacilli that

are oxidase-positive may suggest *Pseudomonas aeruginosa* as opposed to a variety of other potential gram-negative organisms. This preliminary information, which is readily obtainable from the laboratory, may greatly assist the clinician in choosing the appropriate empirical therapy.

Definitive identification of organisms requires more complex testing procedures and devices that can further differentiate the organism on the basis of specific fermentation and biochemical reactive properties. Commercially available automated systems can inoculate the test organism into a series of panels containing a variety of test media, sugars, and other reagents. The system can then photometrically determine the results and compare the findings to a library of organism characteristics to produce a definitive identification.¹⁴

Viral agents may be detected by direct observation of inoculated culture cells for cytopathic effects or by detection of antigens after incubation by immunofluorescent methods. The culture method is most useful for organisms such as cytomegalovirus (CMV) or herpes simplex virus because these viral agents are rapidly propagated in culture cells, making them easily detected.¹⁵

DIAGNOSIS OF INFECTION USING IMMUNOLOGIC AND MOLECULAR METHODS

ANTIBODY AND ANTIGEN DETECTION

5 The use of immunologic methods for the diagnosis and monitoring of human host immune response to infection has become an indispensable laboratory tool. This is especially important in the detection of microorganisms, such as bacteria, fungi, and viruses, that otherwise would elude detection or severely delay results from conventional culturing techniques. These methods have the advantage of a rapid turnaround time and an acceptable level of sensitivity and specificity. Some tests (e.g., identification of group A streptococci) are simple to use, can be performed conveniently in the physician's office, and often may be used to decide whether antibiotics should be administered for a suspected upper respiratory infection.

The primary immunologic methods involve the detection and quantification of antibodies directed against a specific pathogen or its components (i.e., surface proteins of HIV, such as p24 antigen). The commercial availability of specific monoclonal antibodies in a variety of testing formats has led to an increased use of these methods for direct pathogen detection. Although pathogen antigenic proteins may be increased and, therefore, detected easily during acute infection, detection of past or asymptomatic infection may be difficult because of undetectable levels of antigen and, therefore, low antibody titers. Continued advancement in test sensitivity (the capability to detect a true-positive state) and specificity (the capability to detect a negative state), as well as the use of amplification techniques, likely will improve these tests in the near future.

Antibody or antigen detection may be accomplished by a variety of techniques, including immunofluorescence, which has been used routinely for the detection of cytomegalovirus, respiratory syncytial virus, varicella-zoster virus, *Treponema pallidum* (syphilis), *Borrelia burgdorferi* (Lyme's disease), and *Chlamydia trachomatis*. Latex agglutination is useful for detecting meningococcal capsular antigens in CSF of patients suspected of having bacterial meningitis and as an aid in the diagnosis of *Legionella pneumophila*. Enzyme-linked immunosorbent assay (ELISA) is a commonly employed method for detecting HIV, herpes simplex virus, respiratory syncytial virus, pneumococcal serum antibody, *Neisseria gonorrhoeae*, and *Haemophilus pylori*.¹⁵

MOLECULAR TECHNIQUES FOR THE DETECTION OF MICROORGANISMS

HYBRIDIZATION DNA PROBES

Highly sensitive and specific molecular methods are now available for the rapid detection and identification of a variety of pathogens. The two primary molecular techniques used commonly are nucleic acid hybridization, which involves the binding of a specific DNA or RNA probe to its target, and DNA amplification schemes. Probe-based methods require the extraction of DNA or RNA from a clinical specimen (i.e., body fluid, tissue, or WBC) or directly from a microorganism culture. The extract is then tested for the presence of pathogen DNA or RNA using a probe that contains a specific oligonucleic acid–based sequence for the organism. For example, a probe with a sequence of ACTGTT would bind to the complementary organism nucleic acid sequence of TGACAA. Because the probe is labeled with a signal-emitting molecule (i.e., radiolabeled, colorimetric, or chemoluminescent), a match would be detected. The primary means for detection involves the use of separation of the organism DNA into specific fragments (gel electrophoresis), transfer and fixation of the mixture to specialized paper or nylon membranes (Southern or Northern blotting), the mixing of the DNA fragments with the labeled probe (hybridization), and transfer to radiographic or photographic film for processing. These techniques have been used for many years and are fairly standardized methods for the detection of a variety of organisms. Hybridization probes are useful for a variety of diagnostic and clinical applications, including the direct examination of organisms in tissue, which enables the evaluation and documentation of organism infestation, location, distribution, and host response. The use of hybridization probes is particularly helpful for the detection of slow-growing organisms such as *Mycobacterium tuberculosis*, *N. gonorrhoeae*, and certain species of fungi. This technique is also used to document the presence or absence of antimicrobial-resistant genes in a cell culture and to track the spread of resistant microorganisms in hospital and outpatient settings.

Although employed widely, the use of hybridization probes is often limited by their lack of sensitivity. Probe amplification methods are available that improve the sensitivity of these assays. The principle of these probe-amplification schemes is to boost the probe's signal-emitting molecule to make it more easily detected. The most advanced signal-amplification system available is the branched DNA (bDNA) probe system (Chiron Corp., Emeryville, CA). This system uses multiple probes and multiple signal-emitting molecules (reporters). The target-binding probe contains two hybridization regions. One region is complementary to the target, and the other region is capable of binding with the bDNA amplification multimer. The amplification multimer binds multiple reporter molecules (as many as 3000), which provides a significant boost in the probe's signal. Branched DNA probe systems are being developed for rapid detection of hepatitis B and C, HIV-1, and CMV. Because of the system's high specificity and quantitative ability, bDNA probe assays may be useful for therapeutic monitoring, such as in the case of monitoring the response to antiretroviral therapy in acquired immunodeficiency syndrome (AIDS).^{16,17}

NUCLEIC ACID AMPLIFICATION METHODS

Nucleic acid amplification methods are now considered a standard laboratory tool. They have had a tremendous impact on the diagnosis and treatment of infectious diseases. These highly sensitive methods have the capability to detect and quantitate minute amounts of target nucleic acid in a rapid manner. The polymerase chain reaction (PCR)

is based on the capability of a DNA polymerase to copy and elongate a targeted strand of DNA. This is accomplished by the use of short oligonucleotide primers (20 to 25 nucleotides long) that correspond to the DNA targeted to be expanded. After an excess of primers and heat-stable DNA polymerases are added to the targeted DNA mixture, the targeted DNA is denatured and separated by a process of cycling hot and cool temperatures. The heat-stable DNA polymerase elongates the primers on the two separate strands of DNA, thereby generating two new strands of targeted DNA. The process of cycling typically is repeated 20 to 35 times. Each cycle doubles the amount of DNA originally present at the start of the cycle, thereby exponentially increasing the overall number of DNA copies. In theory, more than 1 million copies of the original DNA can be generated from as few as 20 cycles.

Although this amplification technique is very sensitive and has tremendous application potential, it is not without problems. The powerful amplification procedure may yield false-positive results when samples are contaminated by nucleic acid left over from previously amplified DNA. Other problems include primer artifact formation and nonspecific hybridization of primers to DNA samples. Several modifications to the original PCR technology have been made over the years to improve the sensitivity and application potential for PCR, including the use of multiple sets of amplification primers, multiplex PCR, PCR amplification of RNA by converting targeted RNA with reverse transcriptase to complementary DNA templates (which are then suitable for DNA amplification by traditional PCR techniques), and real-time quantitative PCR.

The cost-benefit ratio of PCR as compared with traditional microbiologic methods must be evaluated. Molecular amplification schemes such as PCR have become routine in situations in which rapid turnaround time is essential to improve patient diagnosis and outcome, e.g., real-time universal screening for acute HIV infection and routine testing and monitoring of patients receiving treatment for HIV infection, and the isolation and detection of fastidious or slow-growing organisms such as *M. tuberculosis*, *B. burgdorferi*, and *Helicobacter pylori*. Another potential application for this technology is the early detection of multidrug-resistant organisms. Amplification of resistant gene markers would aid in rapid selection of the most appropriate therapy in the treatment of organisms in which days or weeks traditionally are required for culturing and determining basic susceptibility. Examples fitting this description include the rapid detection of isoniazid and rifampin gene markers for *M. tuberculosis*, early detection of the *mec* gene responsible for methicillin resistance in *S. aureus*, and identification of resistant genes responsible for production of β -lactamase capable of destroying specific cephalosporins and multidrug resistant *H. pylori*.^{17–20}

EVALUATION OF ANTIMICROBIAL ACTIVITY AND DETERMINATION OF ANTIMICROBIAL PHARMACODYNAMICS

6 The laboratory evaluation of antimicrobial activity is an important component of the pharmacotherapeutic management of infectious diseases. The integration of this activity with various pharmacokinetic properties of the antimicrobial agent determines the drug's pharmacodynamic characteristics. Antimicrobial pharmacodynamics have become a crucial consideration for the clinician during the selection of both empirical and pathogen-directed therapy in the current era of antimicrobial resistance. Antimicrobial activity and pharmacodynamics also weigh heavily in contemporary formulary decision-making processes, the development of antimicrobial

streamlining programs, and for intravenous-to-oral antimicrobial switch protocols.²¹

5 Most antimicrobial susceptibility tests used in the clinical laboratory are well characterized and have been standardized by the National Committee for Clinical Laboratory Standards (NCCLS). However, controversies still exist surrounding the exact test methods, interpretation and reporting of test results, and application of the results to the treatment of patients.²² Nevertheless, there are many investigations that show that the general antimicrobial susceptibility or resistance profile of an infecting organism correlates with clinical and/or microbiologic responses to therapy.

Most of the standardized and well-accepted test methods evaluate the susceptibility of aerobic, nonfastidious bacteria. However, substantial progress has been made in the past decade toward the development of sensitive, specific, reproducible, and clinically useful susceptibility tests for anaerobic bacteria, yeasts, mycobacteria, and viruses. Continued advances in technology should further improve test methods and the rapidity with which the results can be applied to the management of patients. Although these newer systems are often very expensive, the increased quality and decreased overall costs of patient care may determine their cost-effectiveness.

QUANTITATIVE ANTIMICROBIAL SUSCEPTIBILITY TESTING

MINIMAL INHIBITORY CONCENTRATIONS

The *minimal inhibitory concentration* (MIC) is defined as the lowest antimicrobial concentration that prevents visible growth of an organism after approximately 24 hours of incubation in a specified growth medium. The MIC quantitatively determinates in vitro antibacterial activity. Classically, MICs were determined via the macrotube dilution method, which uses liquid growth medium (broth), doubling serial dilutions of antimicrobials in test tubes, and a standard inoculum of bacteria (approximately 10⁵ colony-forming units [CFU]/mL). The tubes (up to 10 mL) are incubated at approximately 35°C (95°F) for 18 to 24 hours and then examined for visible bacterial growth (Fig. 103–3). Since macrodilution MIC testing is laborious and supply-intensive, it is not used often in the contemporary clinical microbiology laboratory. However, one advantage of this method is that it tests a large inoculum of bacteria—a factor that can improve the detection of small numbers of resistant subpopulations or document the presence of inducible resistance.²³

The development and use of 96-well microtiter plates enabled the increased use of broth-dilution MIC testing in the clinical

FIGURE 103–3. Macrotube minimal inhibitory concentration (MIC) determination. The growth control (C), 0.5 mg/dL, and 1 mg/dL tubes are visibly turbid, indicating bacterial growth. The MIC is read as the first clear test tube (2 mg/dL).

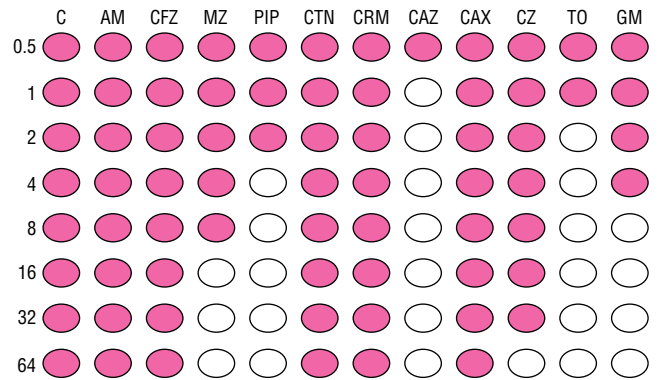

FIGURE 103–4. A prepared microtiter minimal inhibitory concentration (MIC) panel represents antibiotics tested commonly against gram-negative pathogens. This tray indicates that the organism is resistant to ampicillin (AM), ceftazidime (CFZ), cefotetan (CTN), cefuroxime (CRM), ceftriaxone (CAX), and gentamicin (GM). The isolate is sensitive to mezlocillin (MZ), piperacillin (PIP), ceftazidime (CAZ), and tobramycin (TO). The isolate would be considered intermediately susceptible to ceftioxiime (CZ).

laboratory owing to significant reductions in the amount of labor and medium needed. Volumes of 100 to 200 microliters (mcL) or less of medium are used, and multichannel pipets, automated preparation/test interpretation systems, and/or the combination of both can allow efficient preparation of numerous tests (Fig. 103–4). The microdilution MIC test method (or adaptations of this test) is the most commonly used susceptibility test method in the clinical microbiology laboratory.¹⁹ Although microdilution MIC testing is a vast improvement over macrodilution MIC testing, it still has important shortcomings. These include both limitations in the numbers and various types of antimicrobials to use in the test (especially with premade or premanufactured trays) and a decreased ability to detect some forms of antimicrobial resistance (e.g., inducible β -lactamses) as compared with the macrodilution MIC method.^{18,19}

The MIC also can be determined using solid agar. For the agar dilution MICs, the test antimicrobial is added to the molten agar at the desired concentration just prior to its solidification. After the agar has hardened, suspensions of test bacteria are applied to the agar. As with broth MICs, the agar dilution MIC is defined as the lowest concentration that prevents the visible growth of the organism after an overnight incubation period. The primary advantages of the agar dilution MICs are the ability to test many bacteria on the same agar plate and the flexibility to choose specific antimicrobials, but these advantages often are outweighed by the need to prepare agar plates manually and the instability of the antimicrobial in the agar as compared with commercially prepared microtiter MIC trays. Although agar dilution MIC once was considered the standard susceptibility test for many bacteria and for certain slow-growing organisms such as *M. tuberculosis*, its use has declined in most clinical laboratories with the advent of more rapidly performed and less cumbersome susceptibility testing methods (microtiter MICs, PCR, radiometric, and/or fluorometric tests).²⁴

LIMITATIONS AND PROBLEMS WITH MIC TESTING

Some limitations and problems of MIC testing are academic in nature, whereas others may have important implications for the clinician's everyday management of patients with serious infections. For example, because the MIC only represents the concentration of antimicrobial that is needed to inhibit visual growth of the most resistant cells within the tested bacterial population, there actually may be small numbers

of cells present contained in the total population of bacteria at the infection site that are more resistant to the antimicrobial than the MIC would indicate. This is particularly true for most β -lactam antibiotics and gram-negative bacilli, where a 100-fold increase in the size of an inoculum can increase the β -lactam's MIC so as to make a susceptible organism tested at a lower inoculum resistant at a higher inoculum. Use of the antimicrobial in vivo (where a higher inoculum of bacteria is often present) could select these more resistant subpopulations, resulting in poor clinical response. A specific example occurs with infections owing to strains of *Enterobacter* and *Citrobacter* species. These bacteria overproduce chromosomal β -lactamases that are not detected in vitro.²⁵ Treatment of a patient with a β -lactam susceptible to degradation by the β -lactamase then can result in an unacceptably high frequency of resistance development and treatment failure.

8 Many other factors also can influence the in vitro MIC value obtained and its subsequent application to the in vivo situation. The bacterial growth medium used and cation content can affect the activity of many drugs significantly. For example, aminoglycosides are less active against *P. aeruginosa* in a medium supplemented with physiologic concentrations of magnesium and calcium (NCCLS standardized method) than in a medium without these cations. MIC values of antibiotics that are highly bound to plasma proteins are significantly higher when the test medium contains human serum. Since testing of these drugs in a serum-supplemented medium has not gained widespread acceptance, their in vivo activity may be overestimated by in vitro MIC test results. Fortunately, the standardized guidelines for testing and quality assurance procedures proposed by the NCCLS attempt to minimize the impact of these problems and are followed by most clinical and research laboratories.²⁶ However, when a patient infected with an apparently susceptible organism fails therapy, it is important for the clinician to consider these potential confounding factors as possibly being related to the observed failure. In such situations, consideration of antimicrobial pharmacokinetics and pharmacodynamics also often can help to better predict therapeutic response as compared with organism susceptibility alone.

QUALITATIVE ANTIMICROBIAL SUSCEPTIBILITY TEST METHODS

DISK DIFFUSION ASSAY

The disk diffusion assay method for susceptibility testing (Bauer-Kirby method) was developed in the 1960s by Bauer and coworkers as a way to reduce the labor needed for tube dilution susceptibility testing.²⁷ It still remains one of the more common susceptibility test methods used in the clinical microbiology laboratory owing to its high degree of standardization, reliability, flexibility, low cost, and simplicity of test interpretation.²⁵ Up to 12 user-selected antibiotic-impregnated disks are placed on an agar plate previously streaked with a standard suspension of bacteria ($1\text{--}2 \times 10^8$ CFU/mL). The drug contained in the disk diffuses in a concentration gradient out into the agar. The plate is incubated (18 to 24 hours at 35°C [95°F]), and visual bacterial growth occurs only in areas in which the drug concentrations are below those required for growth inhibition. The diameters of the zones of inhibition are measured via calipers or automated scanners and are compared with standard zone size ranges that determine susceptibility, intermediate susceptibility, or resistance to the antimicrobials that were tested (Fig. 103-5). Although factors such as agar composition, incubation temperature, bacterial inoculum, and antibiotic paper disk composition can influence results, the standards for testing conditions and interpretive zone sizes are well defined by the NCCLS.

FIGURE 103-5. Disk diffusion susceptibility test. Antibiotic-impregnated disks are placed on the surface of a plate previously inoculated with the test organism. The plate is incubated for 18 hours, and the subsequent zones of inhibition are measured. The zone size correlates with the sensitivity of the organism. The larger the zone, the more sensitive is the organism to the specific antibiotic. On the basis of predetermined zone breakpoints, organisms may be classified as susceptible, resistant, or intermediately susceptible to the antibiotic. (Photograph courtesy of the Anti-Infective Research Laboratory, Wayne State University, Detroit, Michigan.)

Although a survey that was conducted of clinical microbiology laboratories in the 1990s indicated that only approximately one-quarter of laboratories performed disk diffusion as the primary susceptibility test (the remainder used primarily microdilution methods/automated testing systems), the lack of realization of substantial cost savings from automated susceptibility testing systems (discussed in more detail below), along with the emergence of more difficult-to-detect resistance mechanisms, may result in an increased use of this time-proven susceptibility testing method, especially for smaller clinical laboratories.^{23,28}

QUALITATIVE VERSUS QUANTITATIVE SUSCEPTIBILITY TESTING OF MICROORGANISMS

MIC data often are reported qualitatively by deeming an organism “susceptible,” “intermediate or indeterminate” or “moderately susceptible,” or “resistant” to the given antimicrobial agent. This simplification permits easier interpretation of susceptibility data by non-infectious-disease clinicians who might not be able to interpret the MIC value properly (or may have no need for knowing it). Many factors are considered to determine these qualitative susceptibility classifications, including pharmacokinetic properties, the distribution of MICs for the organisms, and the clinical and bacteriologic responses observed for the antimicrobial against strains of bacteria with various MIC values.¹⁹ The establishment of a susceptibility breakpoint in the range of common MIC values would be undesirable because it is quite common to observe a twofold variability during dilution MIC testing. Often the consideration of all these factors results in a susceptibility breakpoint of between one-sixteenth and one-fourth the achievable peak serum concentration.²⁸

Pathogens classified as susceptible to an antibiotic are those with the lowest MICs, and they are the most likely to be eradicated during therapy of infections using typical drug doses. Conversely, resistant

organisms are bacteria with significantly higher MICs that will result in a less-than-optimal clinical response, even at the highest doses. Responses to therapy for organisms that are moderately susceptible/intermediately susceptible/indeterminate are less clearly defined. These organisms may be less likely to be treated effectively with typical doses of the antimicrobial but may respond to treatment with maximal doses or when the drug is known to be concentrated in the site of infection (e.g., urinary tract). The indeterminate classification exists when the number of strains with MICs in the given range is too small to derive robust conclusions on susceptibility or resistance to the antimicrobial.

There are concerns that the “user friendly” susceptible/resistant classification system may oversimplify the decision-making process in the treatment of infectious diseases. For example, a critically ill patient may not respond to the antimicrobial therapy of a susceptible organism at the usual doses. If serum concentrations or concentrations at the site of infection could be assayed (not practically done), one might discover suboptimal concentrations as a result of inadequate tissue perfusion. Likewise, a patient with severe vascular insufficiency and a diabetic foot infection may fail a course of therapy with normal doses of an antimicrobial and a susceptible organism because of inadequate drug delivery. Additionally, some investigators have shown that different outcomes can be achieved for susceptible organisms with different MIC values^{29,30} and also that substantial (although not clinically acceptable) clinical and/or microbiologic cure rates can occur for infections that are caused by resistant organisms.³¹ These reports emphasize that susceptibility does not correlate unequivocally with clinical success and that resistant organisms do not always equate with impending clinical failure.

Similarities in the spectrum of activity for classes of antibiotics have led to the concept of *class testing*. Thus cephalothin susceptibility results are extrapolated to other first-generation cephalosporins, such as cephalexin or cefazolin. Likewise, susceptibility to an antibiotic that typically has minimal activity usually ensures that other more potent agents in its class will have activity as well. However, many gram-negative organisms have developed extended-spectrum β -lactamases (ESBLs) that often have different activity against members of the same drug class. These developments limit the utility of class testing to reduce susceptibility testing workload. In the setting of an inadequately responding infection with a common ESBL-producing organism (e.g., *Klebsiella pneumoniae*), the pathogen may be susceptible to a class testing antibiotic but actually may be resistant to the antimicrobial agent being administered to the patient.

CLINICAL CONTROVERSY

Some clinicians believe that the MICs of all antimicrobials for which susceptibility testing was performed should be reported in order to allow for proper selection of the best antimicrobial for a given infection in a patient. However, other clinicians argue that the additional information may be misapplied or that the nonselective reporting of all antimicrobial susceptibility data will result in the increased use of more costly broad-spectrum antimicrobials.

OTHER SUSCEPTIBILITY TESTS

EPSILOMETER TEST

8 The Epsilometer test (E-test; AB Biodisk, Solna, Sweden) combines the benefits of quantitative MIC test methods with the ease of agar diffusion testing. The E-test is a plastic strip impregnated with

FIGURE 103–6. Photograph of E-strip susceptibility test. The minimal inhibitory concentration (MIC) is determined from the point where the zone of inhibition intersects with the numerical scale. (Photograph courtesy of the Anti-Infective Research Laboratory, Wayne State University, Detroit, Michigan.)

a known, prefixed concentration gradient of antibiotic that is placed on an agar plate streaked with a suspension of known bacterial inoculum. The drug instantly diffuses from the plastic strip to form an effective concentration gradient within the agar. After overnight incubation, elliptical zones of inhibition are formed; the point where the bottom of the ellipse crosses the plastic strip is correlated with an MIC value printed on the strip (Fig. 103–6). Many investigators have analyzed the E-test’s correlation with standard susceptibility methods and assessed its potential clinical use. In general, values obtained with E-test methods are comparable with or even more consistent and accurate than standard methods. In fact, the E-test method is the recommended method for susceptibility testing of *Streptococcus pneumoniae*. In addition, good correlation with more laborious agar or broth dilution methods is documented for other fastidious or difficult-to-test organisms, such as *H. influenzae*, anaerobes, *Bartonella*, *Flavobacterium*, *Legionella*, and nutritionally variant streptococci.²⁴ However, the widespread clinical use of the E-test has been limited primarily by the excessive costs of the test strips (nearly 10 times more costly than antibiotic-impregnated disks) in relation to the benefits that may be gained from their use.

SPIRAL GRADIENT MINIMAL INHIBITORY CONCENTRATION DETERMINATIONS

The spiral gradient MIC is performed using an apparatus that applies a liquid sample of antimicrobial from the center of an agar plate to its periphery. Because of the exponential deposition of the sample, an antimicrobial gradient is formed. Bacterial inocula are streaked radially on the plate, and the distance of growth toward the center is measured after proper incubation. The distance of growth is measured and correlated with an MIC based on predetermined drug concentrations at various distances. This method has proven useful for the testing of anaerobic bacteria and for susceptibility testing in the research setting and has correlated well with agar dilution MIC test results.³²

However, as with the E-test, its use in the clinical microbiology laboratory has been limited because of the high costs of the testing apparatus and costs of operation as compared with more traditional methods.

AUTOMATED ANTIMICROBIAL SUSCEPTIBILITY TESTING

8 Various degrees of automation have been applied to susceptibility testing. Early advances included automated preparation of microtiter trays, instrument-assisted readers, and computer-assisted result databases.²⁴ Although these improvements helped to decrease preparation and interpretation times, these methods still required an 18- to 24-hour lag period for bacterial growth to evaluate susceptibility. Rapid automated susceptibility tests became available in the 1980s, and their use has increased substantially in the two subsequent decades. These systems often incorporate microprocessors, robotics, and microcomputers to produce susceptibility test results in as few as 3 hours.²⁴ These systems permit the rapid identification of organisms through the use of biochemical test batteries.

There are two rapid automated susceptibility test systems in common use in clinical microbiology laboratories. The Vitek system (bioMérieux Vitek, Hazelwood, MO) uses technology originally developed for use in spacecraft to rapidly identify and test organisms for antimicrobial susceptibility.²⁴ This system uses small plastic reagent “cards” that contain 30 or 45 wells for the testing of various antimicrobials or indicator chemicals. Bacterial test suspensions (25 mL total, providing 1×10^5 CFU/well) enter the wells by capillary diffusion, and growth is monitored automatically via photometric assessment of turbidity every hour for up to 15 hours. When the growth control reaches a specified turbidity level, growth curves for all wells are calculated and compared with the growth control curve for slope normalization. Computerized linear regression and the use of best-fit line coefficients produce an algorithm-derived MIC. The clinical laboratory can control the result output that is generated (qualitative susceptibility, quantitative susceptibility, or both).

The MicroScan WalkAway system (Dade Microscan, West Sacramento, CA) is a rapid test system that uses fluorogenic substrate hydrolysis as an indicator of bacterial growth.²⁴ This system uses standard microdilution test trays and a computer-controlled incubator and reader unit that can perform robotic manipulations, such as reagent addition and tray rotation, to allow for spectrophotometric or fluorometric growth assessments. Bacterial inocula (approximately 6×10^4 CFU/well for gram-negative organisms and approximately 10^5 CFU/well for gram-positive organisms are added to the wells), and growth is detected by the production of fluorophores from hydrolysis of amidomethylcoumarin or methyl umbelliferyl fluorogenic substrates. Although this method is a more sensitive assessment of growth as compared with turbidity, its indirect nature allows for the possibility of bacterial growth without hydrolysis of the fluorophores; this occurrence is rare, however. As with the Vitek system, growth curves are generated and algorithms applied for the determination of MICs; output is via computer or video display.

CONSIDERATIONS FOR THE USE OF RAPID AUTOMATED SUSCEPTIBILITY SYSTEMS

8 With integration and mergers being commonplace in health care systems around the country, correlation between the susceptibility results obtained from these different systems is important to enable different institutions to compare data reliably. Such correla-

tion between the Vitek and MicroScan WalkAway systems has been shown, with acceptable rates for the categories “very major” and “major discrepancies” shown between the two systems.³⁶

Both the Vitek and WalkAway systems also contain information management systems that allow for the storage and rapid retrieval of susceptibility data. Both systems are also capable of producing chartable patient data reports, antibiograms, and epidemiologic reports. Importantly, these systems can be interfaced with other clinical information systems, such as the pharmacy, infection control, or other laboratory data systems, which may help to improve clinical outcomes.^{24,34} Although the use of a rapid susceptibility testing system was associated with more rapid modification to appropriate antimicrobial therapy and also was associated with significantly lower antimicrobial and total hospitalization costs, these results also depended on aggressive result reporting strategies (which are less likely to occur in a nonstudy clinical environment).^{24,35} This factor, when coupled with disadvantages such as limitations on test drug flexibility and the need to perform confirmatory testing for certain difficult-to-detect resistance mechanisms, has resulted in lower-than-expected cost savings with these systems.²⁴

ADVANCES IN SUSCEPTIBILITY TESTING FOR MYCOBACTERIA, FUNGI, AND VIRUSES

Impressive advances have been made in the past decade in the areas of mycobacterial, fungal, and viral susceptibility testing. The use of radiometric techniques, such as the Bactec TB460 system (Becton Dickinson Biosciences, Sparks, MD), has revolutionized the analysis of antimicrobial susceptibility for *M. tuberculosis* and other slow-growing mycobacteria. Radiometric susceptibility testing involves the incubation of *M. tuberculosis* in liquid medium containing ¹⁴C-labeled growth substrate. As organisms grow, respiration causes the release of ¹⁴C, which is then detected. The growth indices for antimicrobial-containing bottles are compared with those of a control bottle with the calculation of an MIC. Use of this method, when coupled with the rapid processing of samples, can reduce the time to susceptibility result generation to approximately 1 week. A newer mycobacterial susceptibility testing method (the Bactec Mycobacteria Growth Indicator Tube [MGIT 960], Becton Dickinson Diagnostic Instruments, Sparks, MD) that is fully automated and that employs detection of fluorescence related to growth also has been developed; it produces results in a similar time frame and with similar reliability as the radiometric method. Primary advantages of this system are its automation, the elimination of radioactivity, and the elimination of needle use. Although the slower agar proportion susceptibility method (generating results in approximately 1 month) is still considered the reference standard for mycobacterial susceptibility testing by the NCCLS, the group now recommends the use of a rapid susceptibility testing method to ensure that the Centers for Disease Control and Prevention (CDC) guidelines for reporting susceptibility results for *M. tuberculosis* infections within 28 days of specimen receipt in the laboratory can be met.^{36,39}

Antimicrobial susceptibility testing for *M. avium* complex is less standardized owing to such factors as its intrinsic antimicrobial resistance and the presence of different colony variants that have differing antimicrobial susceptibilities. Nonetheless, the broth radiometric method appears to be the most consistent and reproducible method for quantitative MIC determination, and it has been advocated for use by the NCCLS and leading experts in mycobacteriology.^{35,37} In the future, the use of molecular probes for mycobacterial resistance genes most likely will become a more important component of

mycobacterial susceptibility determinations, especially in light of the increasing problems with antimicrobial resistance. Probes or PCR techniques for the *katG* gene (which is needed to cause isoniazid susceptibility) and the *rpoB* gene (which alters the β subunit of RNA polymerase causing rifampin resistance) have been evaluated in the research laboratory and hold promise for eventual clinical application.⁴⁰

There has been a substantial increase in the prevalence of fungal infections in the past two decades. An increase in the use and development of newer antifungal agents has followed.⁴⁸ Historically, antifungal susceptibility testing was imprecise and fraught with many inconsistencies. However, pioneering research in the past decade has resulted in the development of NCCLS guidelines for the antifungal susceptibility testing methods of both yeasts and filamentous fungi (molds).^{41–43} Use of these techniques can result in greater than 90% inter- and intralaboratory reproducibility. Although routine antifungal testing of every isolate is not generally necessary for most clinical microbiology laboratories, periodic batch testing for antibiograms and surveillance of resistance and/or antifungal testing of patients with such infections as cryptococcal meningitis or oropharyngeal candidiasis refractory to therapy are warranted.⁴⁴ Future research should further define the relationship between in vitro antifungal susceptibility test results and clinical outcomes of serious fungal infections.

FUTURE METHODS FOR EVALUATION OF ANTIMICROBIAL ACTIVITY

There are many innovative methods still under investigation for providing both qualitative and quantitative assessments of antimicrobial activity. Flow cytometry is a technique that has been well described as a means of assessing human cell lines for abnormalities. It has been studied increasingly in the past decade as a means of determining the antimicrobial susceptibility of bacteria, fungi, and viruses. It has the added advantages of providing quantitative information on the diversity of susceptibility to antimicrobials (commonly found in a large population of microorganisms) and also provides data on the effects of the antimicrobial on the morphology of the treated cells. It also has the potential advantages of (1) rapid determination of susceptibility (data can be obtained within one to two cell growth cycles—as quick as 10 minutes for some organisms), (2) quantification of the subinhibitory and postantibiotic effects of antimicrobials, (3) the ability to investigate cellular changes related to the mechanism of antimicrobial action, and (4) the ability to evaluate the effects of both concentration and time on cellular changes.⁴⁵ Although additional standardization and the development of cost-effective apparatus are still ongoing, it is likely that flow cytometry will become a component of antimicrobial susceptibility testing in the clinical laboratory in the future.

DETECTION OF RESISTANCE FACTORS

There are a number of methods in use that directly detect the production of antimicrobial resistance in pathogens. β -Lactamase production can be detected rapidly and easily in the clinical laboratory with the use of nitrocephin disks. Nitrocephin is a chromogenic cephalosporin derivative that changes color on hydrolysis by β -lactamase. Colonies from a growing bacterial culture can be touched to a disk, with β -lactamase production noted within a few minutes. Although rapid and reliable, this method is limited to the assessment of strains of staphylococci, enterococci, *H. influenzae*, *Moraxella catarrhalis*, and *N. gonorrhoeae*. The nitrocephin disk also cannot detect β -lactam

resistance caused by altered penicillin-binding proteins or by some of the newer ESBLs.²³ The use of PCR or DNA probes for detection of β -lactamases improves sensitivity/specificity but is still limited to the research setting. In the years to come, these molecular biologic techniques should become more refined and more prominent in the clinical microbiology laboratory.

The detection of methicillin resistance in *Staphylococcus* is particularly difficult because of the heterogeneous expression of the phenotype—it is common for only 1 in 10^{4-6} tested cells to express methicillin resistance (even though all cells may have the genetic ability to do so). Methicillin resistance is the result of the *mecA* gene, which encodes for an altered penicillin-binding protein (penicillin-binding protein 2a) that has a low binding affinity for β -lactams. Screening via oxacillin disks or by oxacillin-containing agar (6 mcg/mL) was once considered the “gold standard” for resistance detection prior to the development of PCR and DNA probes that were specific for *mecA*. The *mecA* PCR test is available for clinical use, is 99% sensitive and specific, and allows for the rapid (within 6 hours) determination of the presence of methicillin resistance. Although the *mecA* PCR test has been available for many years, many laboratories do not use it commonly because of its high costs relative to screening with oxacillin-containing agar (which still has acceptable sensitivity/specificity).

The detection of decreased vancomycin susceptibility in gram-positive organisms has become more important with the increased prevalence of both vancomycin-resistant enterococci (VRE) and vancomycin-intermediate and vancomycin-resistant *S. aureus* (VISA and VRSA). The vancomycin agar screening method (Brain-Heart Infusion agar containing 6 mcg/mL of vancomycin) is an inexpensive and reliable way to detect vancomycin resistance for both of these problem pathogens.²³ With this test, the growth of any colonies from a sample of the test organism (10^5 – 10^6 CFU) after 24 hours of incubation indicates the presence of decreased vancomycin susceptibility (VISA) or vancomycin resistance (VRE, VRSA) within the test strain. Most MIC test methods used in the clinical laboratory that incorporate at least a 16-hour incubation period also appear to reliably detect strains of VRE, VISA, and VRSA.⁴⁶

The use of PCR has now become a standard method to quantify the replication of the HIV and hepatitis viruses in infected patients (the *viral load*, described as copies per milliliter).⁴⁷ Similar methods are used to determine the presence of genetic mutations in the HIV that are associated with increased resistance to one or more of the many antiretroviral medications available for clinical use. The use of these genotyping methods as an aid to select an optimized antiretroviral regimen has been correlated with an improved clinical response to therapy, as well as with a more potent reduction in the viral load.⁴⁷ Guidelines for the use of these assays have been developed by a consensus panel of HIV therapy experts owing their the exceptionally high costs (often in excess of \$1000 per test), as well as the complexity of interpretation of the test results.⁴⁷

SPECIAL IN VITRO TESTS OF ANTIMICROBIAL ACTIVITY

MINIMAL BACTERICIDAL CONCENTRATION

9 In certain infections (e.g., meningitis and endocarditis), the bactericidal (killing) activity may be more predictive of a favorable infection outcome than the MIC. The minimal bactericidal concentration (MBC) can be performed in conjunction with the broth microtiter MIC test by taking aliquots of broth from microtiter wells that

demonstrate no visible growth and plating the samples onto antibiotic-free agar plates for subsequent incubation. The MBC is defined as the lowest concentration of drug that kills 99.9% of the total initially viable cells (representing a 3 log₁₀ CFU/mL or greater reduction in the starting inoculum).

For certain antibiotic classes such as the aminoglycosides and the quinolones, the MIC often approximates the MBC. However, for β-lactam antibiotics and glycopeptides, the MBC may exceed the MIC substantially, resulting in an overestimation of in vivo bactericidal activity. When the MBC exceeds the MIC by 32-fold or more, an organism is said to be *tolerant* to the antimicrobial's killing activity. Although the phenomenon of tolerance has been documented for β-lactams and glycopeptides against certain staphylococci, streptococci, and enterococci, its impact on the outcome of infections caused by organisms other than those just mentioned appears to be limited.

TIMED-KILL CURVE TESTS

Timed-kill curve tests are not performed routinely in the clinical laboratory but can provide important additional data on the effects of an antimicrobial on bacteria. For timed-kill curve tests, a standard inoculum of bacteria (10⁶ CFU/mL) is placed in a test tube containing liquid growth medium with or without desired test concentrations of antimicrobial. Samples are removed periodically to determine the number of living cells at the given time points. The viable cell counts are plotted versus time to construct the timed-kill profile of the antimicrobial. By standard convention, the tested concentration of antimicrobial is considered to be bactericidal if it causes at least a 3 log₁₀ CFU/mL reduction in viable inoculum.⁴⁹ Comparisons of the relative rates of bacterial killing also can be performed in timed-kill curve experiments. Additionally, the presence of concentration-dependent killing activity (where killing increases with increasing drug concentrations above the MIC) versus concentration-independent killing activity can be determined from a timed-kill curve experiment. An example of results from a timed-kill curve experiment is depicted in Fig. 103–7. These data can help to predict the best way to administer an antimicrobial to maximize activity (e.g., lower-dose continuous infusions for concentration-independent antibiotics versus higher-dose intermittent administrations for concentration-dependent antibiotics).

FIGURE 103–7. Killing curve depicting the effect of concentration on antibiotic bactericidal activity. CFU = colony-forming units; MIC = minimal inhibitory concentration. 0.25–64 times the MIC; the organism tested was *P. aeruginosa* ATCC 27853. (From ref 51.)

FIGURE 103–8. Postantibiotic effect. In this experiment, fixed inocula of *S. aureus* and *P. aeruginosa* are exposed to ticarcillin, imipenem, and ciprofloxacin at a set concentration of four times the MIC. The organism and the antibiotic are then diluted 1000-fold to a point where the antibiotic concentration is far below the MIC of the organism. Growth suppression of *S. aureus* following exposure to the three drugs (PAE) occurs for approximately 2 hours. Growth suppression of *P. aeruginosa*, however, is only demonstrated for imipenem and ciprofloxacin. The β-lactam ticarcillin has no effect on the growth of *P. aeruginosa*. (From refs, 51 and 51.)

POSTANTIBIOTIC EFFECT

The *postantibiotic effect* (PAE) is defined as the persistent suppression of an organism's growth after a brief exposure to an antibiotic.⁴⁵ A PAE experiment is performed by exposing a fixed inoculum of organism to a set concentration of antibiotic (typically some multiple of the MIC) (Fig. 103–8). The antibiotic is then removed either by inactivation (e.g., inactivation by a β-lactamase or binding the antibiotic to a resin) or by filtration/centrifugation of the mixture. The cells are resuspended in antibiotic-free growth medium, and samples are removed frequently (every 0.5 to 2 hours) to determine resumption of normal growth. The PAE is quantified as the difference in time that it takes the organism exposed to the antibiotic to demonstrate a 10-fold increase in viable cells per milliliter as compared with a separate culture of organism not subjected to the antibiotic. A PAE equal to or greater than 1 hour has been demonstrated for most antibiotics against gram-positive bacteria. As a general rule, antibiotics that inhibit DNA or protein synthesis (e.g., quinolones and aminoglycosides) demonstrate significant PAEs against gram-negative organisms. An exception to this rule are the carbapenem cell wall synthesis inhibitors (e.g., ertapenem, imipenem, and meropenem), which demonstrate PAEs against selected strains of gram-negative organisms. The primary clinical application of the PAE is to allow for less frequent administration of antimicrobials while still maintaining adequate antibacterial activity (e.g., extended-interval aminoglycoside administration).⁵⁰

ANTIMICROBIAL COMBINATION EFFECT TESTS

Antimicrobial combination therapy is used frequently to treat serious infections. Combination therapy may be used prior to knowing the pathogen or antibiotic susceptibility for the treatment of infections in neutropenic patients and in patients with enterococcal endocarditis or bacteremia, sepsis, or pneumonia caused by *P. aeruginosa*. In these cases, it is important to know whether the combination will have beneficial (or detrimental) effects on the overall antibacterial activity of the regimen. For example, the combination may result in activity that is

significantly greater than the sum of activity of either agent alone (i.e., synergy). Conversely, the combination may result in activity that is worse than either agent alone (i.e., antagonism). Combination activity that is neither synergistic nor antagonistic is said to be *indifferent* or *additive*.⁵²

Two methods are used to determine the expected effects of combination antibiotic therapy. For the most part, both methods are not used commonly in the clinical microbiology laboratory owing to the substantial labor involved with these tests and the lack of strong correlation with clinical outcome in the majority of infections. The first method is the microtiter fractional inhibitory concentration (FIC, or “checkerboard” method). The FIC is performed in a similar manner to the microtiter broth MIC except that two antibiotics are tested in the same microtiter plate. Twofold serial dilutions of one antibiotic are made in one direction on the plate (e.g., from right to left), whereas dilutions of the second antibiotic are made from the other direction on the same plate (e.g., from top to bottom). This method produces all possible combinations of twofold concentrations for the two drugs being tested. An inoculum of test bacteria is added to all wells, and the results are read in a similar manner as the MIC test. The FIC is expressed mathematically by calculation of the FIC index. The FIC index is calculated as

$$\text{FIC index} = \frac{A}{\text{MIC}_A} + \frac{B}{\text{MIC}_B}$$

where *A* or *B* is the lowest concentration of the drug that is inhibitory in the presence of the second drug, and the MIC is the minimal inhibitory concentration of each drug tested alone. Synergism is defined as an FIC index of 0.5 or less, indifference is defined as an FIC index of between 0.6 and 4.0, and antagonism is defined as an FIC index of greater than 4.0.⁵³ The microtiter FIC methods have been adapted to allow the use of E-test antibiotic-susceptibility test strips.⁵⁴ In this method, two antibiotic E-test strips are crossed at the individual MIC of each antibiotic; an extension of the zone of inhibition beyond that from either antibiotic alone is considered additive or synergistic activity, and an FIC index can be calculated in a similar manner as the microtiter method.

The second most common method to determine the effects of antibiotic combinations is an adaptation of timed-kill curve tests. Two antibiotics are added to the same test tube at fixed concentration fractions of the MIC for each drug, and killing is quantified. With this method, synergism is defined as a 100-fold decrease in viable organisms at 24 hours for the combination as compared with the most potent antibiotic tested alone. Antagonism is defined as a 100-fold or greater increase in viable organism count⁵³ (Fig. 103–9). It is

FIGURE 103–9. Timed-kill curve illustrating indifference, synergy, and antagonism.

important to note that although antagonism has been demonstrated for several combinations in vitro (e.g., penicillin plus tetracycline, chloramphenicol and an aminoglycoside, fluoroquinolones and rifampin), antagonism in vivo has been demonstrated only infrequently.

Although the methods for testing the effects of antimicrobial combinations are well described, the results from these tests have not been adequately studied in the context of infection outcome. There is little debate that the combination of a β -lactam antibiotic and an aminoglycoside is required for successful treatment of enterococcal endocarditis.⁵² For enterococci, susceptibility to high concentrations of aminoglycosides (e.g., gentamicin, 500 mg/mL) is evaluated in the clinical laboratory because it correlates closely with synergy when the drug is combined with β -lactam antibiotics.

The concept of combination therapy is not universally accepted for the treatment of other infections. There is ongoing debate as to whether the combination of a broad-spectrum β -lactam and an aminoglycoside is needed (versus the β -lactam alone) for the therapy of such infections as gram-negative bloodstream infections or infections in neutropenic patients.^{55,56} Although the data are conflicting, combination therapy usually has resulted in improved outcomes in patients with severe illness and in patients with *P. aeruginosa* bloodstream infections.^{52,56}

LABORATORY MONITORING OF ANTIMICROBIAL THERAPY

10 The clinician should have an understanding of in vivo antimicrobial agent disposition in order to select the most appropriate therapy for a given infection and to help monitor for clinical or bacteriologic efficacy. Serum concentration monitoring is the most common method used to attempt to maximize efficacy and minimize toxicity of antimicrobials. Since most antimicrobials are well tolerated at their usual doses, only a select few agents (e.g., aminoglycosides, chloramphenicol, and vancomycin) are monitored routinely in the current clinical environment. There are a number of direct and indirect methods that are used to quantify the concentration of antimicrobial in an experimental sample.

METHODS OF ANTIMICROBIAL CONCENTRATION DETERMINATION IN CLINICAL SAMPLES

FLUORESCENCE POLARIZATION IMMUNOASSAY

The fluorescence polarization immunoassay (FPIA) technique involves the application of the principles of fluorescence when molecules are exposed to light. A fluorescein-labeled drug and antibody that is directed against the drug are added in constant amounts to samples with unknown drug concentrations and to concentration standards. When the fluorescein-labeled drug complexes with the antibody, a quantifiable change in the fluorescence polarization occurs. When a sample containing non-fluorescein-labeled drug (i.e., a patient's serum sample) is mixed with the standard mixture, competition for antibody binding occurs. Comparison of the change caused by the patient's sample to the changes caused by standard concentrations determines the specific drug concentration in the patient sample.

FPIA is the most commonly used assay method for the determination of aminoglycoside and vancomycin serum concentrations in the clinical laboratory setting. Advantages of this technique include its automation through the use of the TDx system (Abbott Laboratories, North Chicago, IL). Disadvantages include the expenses for reagents and the cost for the purchase of the automated system.

RADIOIMMUNOASSAY

Radioimmunoassay (RIA) uses a radiolabeled drug and an antibody directed against the specific drug to determine the concentration contained in an unknown sample. The theory behind the assay is similar to FPIA because radiolabeled antibiotic and unlabeled antibiotic (in the patient's serum sample) are equilibrated with the antibody. The amount of free radiolabeled drug is measured and compared with the values obtained with standard concentrations of the radiolabeled drug alone to determine the concentration in the patient sample. Although RIA has good sensitivity and specificity, its main disadvantage compared with FPIA is the expense and hassle of handling and disposal of the radioactive waste generated during the test.

HIGH-PRESSURE LIQUID CHROMATOGRAPHY

High-pressure liquid chromatography (HPLC) permits the separation of different molecular species by passing a mobile solvent phase over a stationary phase. Drugs with a polarity similar to that of the stationary phase are retained for a time on the chromatographic column and then released after various retention times. Detection can be accomplished via fluorescence, electrochemical, or radiometric methods. The detector signal is proportional to the amount of molecules present. Standard curves are generated from known concentrations of the drug (usually recorded as peak area or peak height). Advantages of HPLC include a rapid turnaround time, precision, and an ability to detect the test drug in the presence of its metabolites and/or other drugs. Disadvantages include the high cost of HPLC instruments and the expertise required to perform the assays. These disadvantages usually relegate HPLC drug assay to the experimental and/or research settings.

SERUM INHIBITORY/BACTERICIDAL TITERS

Serum inhibitory titers (SITs) and serum bactericidal titers (SBTs) sometimes are used to monitor the antimicrobial therapy of certain serious infections (e.g., osteomyelitis and endocarditis). SITs and SBTs for antimicrobials are determined in a similar standardized manner as microdilution MICs and MBCs, but dilutions of the patient's serum are used instead of known concentrations of antimicrobial.⁵³ Patient serum can be collected near the expected peak, midpoint, and/or trough concentration(s) of the antimicrobial dose. The SIT is the highest twofold dilution of the serum sample that inhibits the visible growth of the patient's infecting organism, whereas the SBT is defined as the highest dilution of serum that kills 99.9% of the original bacterial inoculum is the SBT. Values for the SIT and SBT are expressed as the number of twofold serial dilutions relative to the original serum sample (e.g., SIT = 1:32, SBT = 1:8). A peak SBT of greater than 1:32 predicted successful outcome for endocarditis, whereas a trough SBT of greater than 1:2 predicted success for osteomyelitis.^{59,60}

MICROBIOLOGIC ASSAY

Microbioassay of antimicrobial agents can be performed by several methods. The most common method is a modification of the disk diffusion antimicrobial-susceptibility technique. Typically, paper disks are placed on agar that contains an inoculum of a bacterium known to be highly susceptible to the antimicrobial agent to be assayed. Fixed volumes (usually 10 mL) of a range of prepared concentration standards of the test drug are placed on the disks. The zones of growth inhibition are measured and plotted versus the drug concentration to generate a standard curve. Zone sizes from samples containing the unknown concentrations of the test drug are measured, and the

concentrations are determined from the plotted curve; the drug concentration in unknown samples is determined from the standard curve generated from the known concentrations of the drug. The advantages of this method include its relative ease of performance and the minimal cost for equipment. The disadvantages of this method include interference from other antibiotics that may be present in the unknown sample, a lack of sensitivity/specificity for certain antimicrobials, and a slow turnaround time (usually 24 to 48 hours) for generation of results.

TIMING OF COLLECTION OF SERUM SAMPLES

▶ Peak and/or trough concentrations are monitored routinely for only a select few antimicrobials (e.g., aminoglycosides and vancomycin) during the contemporary management of infections. It is crucial for the health care team to ensure that the antimicrobial's administration time and serum sample time(s) are meticulously recorded because even small errors in recording these (e.g., 1 hour) may have a substantial impact on the calculation of pharmacokinetics for antibiotics such as the aminoglycosides, which have relatively short elimination half-lives.

Samples ideally should be obtained after steady state is achieved (usually defined as the passage of at least 3 to 4 anticipated half-lives), but in certain situations, this may not be possible (e.g., critically ill patients with fluctuations in drug elimination owing to fluctuating hemodynamics, kidney function, and/or liver function). Generally, the timing of the peak serum sample collection is usually more critical than the trough concentration because adequate time must elapse to allow for completion of the distribution phase and to avoid underestimating the drug's volume of distribution. Since the distribution half-life may even vary between different dosage regimens of the same antibiotic (e.g., traditional versus extended-interval aminoglycoside dosing),⁶¹ clinicians always should plan peak serum sample collections carefully with this variability in mind.

SPECIFIC AGENTS

The aminoglycosides (i.e., amikacin, gentamicin, and tobramycin) and vancomycin remain the most common agents for which serum concentrations are monitored. A summary of the recommendations for serum concentration monitoring of these agents is shown in Table 103-2.

AMINOGLYCOSIDES

▶ There are many studies that have linked serum aminoglycoside concentrations with clinical response and with the occurrence of nephrotoxicity. One of the classic investigations into the relationship between serum aminoglycoside activity and clinical outcome revealed that peak serum concentrations of at least 5 mcg/mL for gentamicin and tobramycin and at least 20 mcg/mL for amikacin were associated with a lower prevalence of clinical failure rates during the treatment of gram-negative bacteremia.⁶² Although earlier studies suggested that trough concentrations exceeding 2–4 mcg/mL for gentamicin and tobramycin and 10 mcg/mL for amikacin predisposed patients to nephrotoxicity, more recent investigations indicate that the development of aminoglycoside-related ototoxicity and nephrotoxicity is more complex and also is associated with the total exposure to the aminoglycoside (as measured by the area under the concentration-time curve [AUC]) and/or the total duration of aminoglycoside therapy.^{58–60} The specific recommended serum peak and

TABLE 103–2. Suggested Therapeutic Serum Concentrations for Selected Antimicrobial Agents

| Drug | Time of Collection | Target Concentrations | |
|--|--|-----------------------|---|
| | | (mg/L) | Comments |
| Aminoglycosides ^{70,71} | Peak (1 h after the start of a 15- to 45-min infusion) | <5 | Urinary tract infections |
| Traditional dosage regimens | | | |
| Gentamicin | | >5 | Bacteremia |
| Tobramycin | | >6 | Bacterial pneumonia |
| | | >12 | Endocarditis caused by <i>Pseudomonas aeruginosa</i> |
| | Trough | <2–3 | High trough concentrations are most likely a result and not a cause of nephrotoxicity |
| Amikacin | Peak | >15 | Urinary tract infections |
| | | >20 | Bacteremia |
| | | >24 | Bacterial pneumonia, other serious infections |
| | Trough | >9–10 | See comments regarding trough gentamicin/tobramycin concentrations |
| Single daily dosage regimens ⁷⁶ | | | |
| Gentamicin | 8 h postdose | 1.5–6 | Concentrations above this range associated with nephrotoxicity in one study with netilmicin |
| Netilmicin | | | |
| Tobramycin | | | |
| Vancomycin ^{80,81} | Peak (1–2 h after a 30- to 60-min infusion) | 20–50 | Recommendations should be considered tentative, as definitive data are not available |
| | Trough | <10 | Therapeutic monitoring is probably not necessary for most patients |

trough concentrations for the various aminoglycosides are described in Table 103–2.

Newer regimens of once-daily or extended-interval aminoglycoside administration have gained widespread acceptance for use in the clinical setting. These regimens exploit the pharmacodynamic properties of these agents (i.e., concentration-dependent bacterial killing and a substantial PAE) to maximize activity while also attempting to minimize drug nephrotoxicity by reducing the total aminoglycoside exposure time for the patient's kidneys. The doses employed for extended-interval treatment typically range from 5–7 mg/kg of lean body weight (administered every 24 to 48 hours), with the dose and/or interval adjusted based on renal function or observed mid-dose serum concentrations.^{66,67} Although many prospective studies have been performed to evaluate the safety and efficacy of once-daily aminoglycoside dosing, substantial controversy still exists.^{66–70} Most of these studies have revealed equivalent rates of efficacy and toxicity or trends toward improved efficacy and reduced toxicity for once-daily dosage regimens as compared with traditional (thrice daily) regimens. Meta-analyses also have been performed on these study data.⁷⁹ However, since the individual studies are heterogeneous and possess many weaknesses, these meta-analyses subsequently have inherited many of these scientific study flaws.^{68,69}

CLINICAL CONTROVERSY

Although some clinicians believe that the clinical data are sufficient to support widespread use of once-daily aminoglycoside dosing without determination of individualized patient pharmacokinetics, other clinicians believe that the data from investigations on once-daily aminoglycosides are incomplete and that patients still should receive individualized pharmacokinetic assessments and dosage adjustments.

Traditional methods of aminoglycoside serum concentration monitoring (evaluating peak and trough serum concentrations) cannot be applied to extended-interval dosing

because the serum concentrations 24 hours after a dose ideally should be undetectable. If desired, pharmacokinetic assessment during extended-interval aminoglycoside regimens should be accomplished by obtaining a peak sample at least 1 hour after the end of the infusion [owing to a longer distribution phase compared with traditional (1 mg/kg) doses].⁵⁶ A midinterval serum sample can be taken approximately 6 to 12 hours after the dose to allow for use of first-order pharmacokinetic equations. A single-point nomogram-based dosing method that uses midinterval serum samples also is used frequently in the clinical setting.⁶⁶

VANCOMYCIN

13 Convincing data do not exist that definitively relate the specific recommended vancomycin peak (20–40 mcg/mL) or trough (5–15 mcg/mL) serum concentrations to efficacy and/or toxicity.^{71,72} Although intravenous vancomycin has been associated with oto- and nephrotoxicity in humans, most of these reports occurred with older, impure formulations of the drug, with extremely high concentrations uncommon with contemporary dosing regimens, or when vancomycin was combined with known nephrotoxic agents.⁸⁴ A recent investigation revealed that continuous infusions of vancomycin that resulted in constant serum vancomycin concentrations of 20–25 mcg/mL caused no substantial nephrotoxicity when compared with intermittent regimens that targeted the “accepted” serum trough concentration range.⁷³

Because vancomycin appears to possess a time-dependent killing-activity profile, it has been recommended that vancomycin concentrations remain above the organism's MIC during the entire dosing interval. Most methods of empirical vancomycin dosing result in peak concentrations of between 20 and 50 mcg/mL and trough concentrations of between 5 and 15 mcg/mL. Since the vast majority of organisms have vancomycin MICs of 2 mcg/mL or less, weight-based dosage regimens and/or nomogram-based dosage methods can

be used with minimal monitoring of serum concentrations (e.g., evaluation of vancomycin trough concentration every 5 days of therapy) for the vast majority of patients.⁷⁴

INTEGRATING ORGANISM SUSCEPTIBILITY WITH SERUM CONCENTRATION DATA TO IMPROVE ANTIMICROBIAL THERAPY

7 **4** We have advanced our understanding substantially of the importance of considering both antimicrobial pharmacokinetics and organism susceptibility when selecting therapy for the treatment of infections. Antimicrobial regimens should be selected and/or designed to maximize the probability that bacterial killing is optimized and that the probability of resistance is minimized. For example, the activity of antimicrobials such as the fluoroquinolones and the aminoglycosides can be maximized if the ratio of the peak serum concentration to the organism MIC (peak-to-MIC ratio) is greater than or equal to 10.^{77,78} Similarly, the probability of clinical and/or microbiologic infection cure can be maximized if a fluoroquinone is chosen that achieves an area under the concentration-time curve to MIC ratio (*AUC*-to-MIC ratio) of 100 to 125 or greater for gram-negative bacteria (e.g., *P. aeruginosa*) and 30 to 40 or greater for gram-positive bacteria (e.g., *S. pneumoniae*).^{79,80} The clinical application of these principles to aminoglycoside dosage regimen optimization is depicted in Fig. 103–10.

The maintenance of concentrations above the infecting organism's MIC (the time above the MIC) best predicts the clinical efficacy of the β -lactam antimicrobials and glycopeptides, although the *AUC*-to-MIC ratio also has been suggested as a predictor for treatment outcome for certain organisms and in certain clinical situations.^{75,76} In the setting of bacterial otitis media, for example, a time above the

FIGURE 103–10. Illustration of the concept of peak concentration to the minimal inhibitory concentration (MIC) ratio for aminoglycosides. The MIC for the given organism to gentamicin is 2 mg/L, whereas the tobramycin MIC is 0.5 mg/L. Administration of gentamicin would result in a suboptimal peak:MIC ratio (<10), which could increase the chances for development of resistance or an inadequate response. Administration of tobramycin would result in a peak:MIC ratio of 12, which should improve efficacy. Note that modification of the gentamicin regimen to produce peak serum concentrations of 20 mg/L or more (as commonly done with once-daily administration) also would result in a peak:MIC ratio of 10 or greater.

MIC of approximately 40% to 50% correlated with rates of response of greater than 90%.³¹

It is important to recognize that most of the data on optimization of antimicrobial pharmacodynamics have been generated in *in vitro* models of infection, in animal models of infection, within the context of controlled clinical trials, or through mathematical modeling of small data sets. However, research continues on the best ways to apply these valuable data to the everyday management of patients in the clinical setting. The recognition of the importance of antimicrobial pharmacodynamics already has resulted in the expansion of serum concentration monitoring for select antimicrobials (e.g., antiretroviral agents), the suggested revisions of breakpoint values that define antimicrobial susceptibility and/or resistance, the development of nomograms or computer programs that can suggest optimal drugs and doses for a given infection, and/or the development of newer antimicrobial agents that minimize the probability of suboptimal pharmacodynamics.^{77–82} These developments present exciting opportunities for health care providers to improve the outcomes of patients with infections in a variety of different health care settings.

ABBREVIATIONS

AIDS: acquired immunodeficiency syndrome
AUC: area under the plasma concentration versus time curve
 bDNA: branched DNA
 CDC: Centers for Disease Control and Prevention
 CFU: colony-forming unit
 CMV: cytomegalovirus
 ELISA: enzyme-linked immunosorbent assay
 ESBL: extended-spectrum β -lactamase
 ESR: erythrocyte sedimentation rate
 FIC: fractional inhibitory concentration
 FPIA: fluorescence polarization immunoassay
 HIV: human immunodeficiency virus
 HPLC: high-performance liquid chromatography
 KOH: potassium hydroxide
 MBC: minimum bactericidal concentration
 MHC: major histocompatibility complex
 MIC: minimum inhibitory concentration
 NCCLS: National Committee for Clinical Laboratory Standards
 PAE: postantibiotic effect
 PCR: polymerase chain reaction
 PMN: polymorphonuclear leukocyte
 RIA: radioimmunoassay
 SBT: serum bactericidal titer
 SIT: serum inhibitory titer
 TNF: tumor necrosis factor
 VISA: vancomycin-intermediate *Staphylococcus aureus*
 VRE: vancomycin-resistant enterococci
 VRSA: vancomycin-resistant *Staphylococcus aureus*

ANTIMICROBIAL REGIMEN SELECTION

David S. Burgess and Betty J. Abate

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Every attempt should be made to obtain specimens for culture and sensitivity testing prior to initiating antibiotics.
- 2 Empirical antibiotic therapy should be based on knowledge of likely pathogens for the site of infection, information from patient history (e.g., recent hospitalizations, work-related exposure, travel, and pets), and local susceptibility.
- 3 Patients with delayed reactions to penicillin (skin rash) generally can receive cephalosporins. Patients with type I hypersensitivity reactions to penicillins (anaphylaxis) should not receive cephalosporins or carbapenems (alternatives include aztreonam, quinolones, sulfa drugs, or vancomycin based on type of coverage indicated).
- 4 Estimated renal function should be calculated for every patient who is to receive antibiotics and the antibiotic dose interval adjusted accordingly. Hepatic function should be considered for drugs eliminated through the hepatobiliary system, such as clindamycin, erythromycin, and metronidazole.
- 5 All concomitant drugs and nutritional supplements should be reviewed when an antibiotic is added to a patient's therapy.
- 6 Combination antibiotic therapy may be indicated for polymicrobial infections (abdominal, gynecologic infections), to produce synergistic killing (β -lactam plus aminoglycoside versus *Pseudomonas aeruginosa*), or to prevent the emergence of resistance.
- 7 All patients receiving antibiotics should be monitored for resolution of infectious signs and symptoms (e.g., decreasing temperature and WBC count) and adverse drug events.
- 8 Agents with the narrowest spectrum of activity that is effective are preferred. Antibiotic route of administration should be evaluated daily, and conversion from intravenous to oral therapy should be attempted as signs of infection improve for patients with functioning gastrointestinal tracts (general exceptions are bloodstream and central nervous system infections).
- 9 Patients not responding to an appropriate antibiotic treatment in 2 to 3 days should be reevaluated to ensure (a) the correct diagnosis, (b) that therapeutic drug concentrations are being achieved, (c) that the patient is not immunosuppressed, (d) that the patient does not have isolated infection (i.e., abscess, foreign body), or (e) that resistance has not developed.

Choosing an antimicrobial agent to treat an infection is far more complicated than matching a drug to a known or suspected pathogen.¹ Most clinicians generally follow a systematic approach to select an antimicrobial regimen (Table 104–1). Problems arise when this systematic approach is replaced by prescribing broad-spectrum therapy to cover as many organisms as possible. Consequences of not using the systematic approach include the use of more expensive and potentially more toxic agents, which may, in turn, lead to widespread resistance and difficult-to-treat superinfections. Another abuse of antimicrobial agents is administration when they are not needed. An example of this is prescribing antibacterials for self-limited clinical conditions that are most likely viral in origin (i.e., the common cold).

Initial selection of antimicrobial therapy is nearly always empirical, which is the initiation of antimicrobials sometimes prior to documentation of the presence of infection and before the offending organism is identified. Infectious diseases generally are acute, and a delay in antimicrobial therapy may result in serious morbidity or even mortality. An example is the rapidly lethal nature of various forms of meningitis. Thus empirical antimicrobial therapy selection is

based on information gathered from the patient's history and physical examination and results of Gram stains or of rapidly performed tests on specimens from the infected site. This information, combined with knowledge of the most likely offending organism(s) and an institution's local susceptibility patterns, should result in a rational selection of antibiotics to treat the patient.

This chapter introduces a systematic approach to the selection of antimicrobial therapeutic regimens.

CONFIRMING THE PRESENCE OF INFECTION

FEVER

The presence of a temperature greater than the expected 98.6°F (37°C) "normal" body temperature is considered a hallmark of infectious diseases. Body temperature is controlled by the hypothalamus. In addition, the circadian rhythm, a built-in temperature cycle, is also operational. The daily temperature rhythm may vary for each individual. In a healthy person, the internal thermostat is set between the

morning low temperature and the afternoon peak as controlled by the circadian rhythm. During fever, the hypothalamus is reset at a higher temperature level.²

Fever is defined as a controlled elevation of body temperature above the normal range. The average normal body temperature range taken orally is 98.0 to 98.6°F (36.7 to 37°C). Body temperatures obtained rectally generally are 1°F (0.6°C) higher and axillary temperatures are 1°F (0.6°C) lower than oral temperatures, respectively. Skin temperatures are also less than the oral temperature but may vary depending on the specific measurement method. Fever can be a manifestation of disease states other than infection. Collagen-vascular (autoimmune) disorders and several malignancies may have fever as a manifestation. Fever of unknown or undetermined origin is a diagnostic dilemma and is reviewed extensively elsewhere.³

Many drugs have been identified as causes of fever.⁴ *Drug-induced fever* is defined as persistent fever in the absence of infection or other underlying condition. The fever must coincide temporally with the administration of the offending agent and disappear promptly on its withdrawal, after which the temperature remains normal. Possible mechanisms of drug-induced fever are either a hypersensitivity reaction or development of antigen-antibody complexes that result in the stimulation of macrophages and the release of interleukin 1 (IL-1). Although this is not a common drug effect (accounting for no more than 5% of all drug reactions), it should be suspected when obvious reasons for fever are not present. Almost any medication can produce fever, but certain ones appear to be responsible more often than others. These include β -lactam antibiotics, anticonvulsants, allopurinol, hydralazine, nitrofurantoin, sulfonamides, phenothiazines, and methyldopa.⁴

Noninfectious etiologies of fever may be referred to as “false-positives.” Although these certainly may confuse the clinician, even more troublesome are false-negatives: the absence of fever in a patient with signs and symptoms consistent with an infectious disease. Careful questioning of the patient or family is vital to assess the ingestion of any medication that can mask fever (e.g., aspirin, acetaminophen, nonsteroidal anti-inflammatory agents, and corticosteroids). The use of antipyretics should be discouraged during the treatment of infection unless absolutely necessary because they may mask a poor therapeutic response. Moreover, elevated body tempera-

ture, unless very high [$>105^{\circ}\text{F}$ (40.5°C)], is not harmful and may be beneficial.²

SIGNS AND SYMPTOMS

WHITE BLOOD CELL COUNT

Most infections result in elevated white blood cell (WBC) counts (leukocytosis) because of the increased production and mobilization of granulocytes (neutrophils, basophils, and eosinophils), lymphocytes, or both to ingest and destroy invading microbes. The generally accepted range of normal values for WBC counts is between 4000 and 10,000 cells/mm³. Values above or below this range hold important prognostic and diagnostic value.

Bacterial infections are associated with elevated granulocyte counts, often with immature forms (band neutrophils) seen in peripheral blood smears. Mature neutrophils are also referred to as *segmented neutrophils* or *polymorphonuclear leukocytes* (PMNs). The presence of immature forms (left shift) is an indication of an increased bone marrow response to the infection. With infection, peripheral WBC counts may be very high, but they are rarely higher than 30,000 to 40,000 cells/mm³. Because leukocytosis indicates the normal host response to infection, low leukocyte counts after the onset of infection indicate an abnormal response and generally are associated with a poor prognosis.

The most common granulocyte defect is neutropenia, a decrease in absolute numbers of circulating neutrophils. A thorough description of the consequences of neutropenia is given in Chap. 120. Lymphocytosis, even with normal or slightly elevated total WBC counts, generally is associated with tuberculosis and viral or fungal infections. Increases in monocytes may be associated with tuberculosis or lymphoma, and increases in eosinophils may be associated with allergic reactions to drugs or infections caused by metazoa. Many types of infections may be accompanied by a completely normal WBC count and differential.

LOCAL SIGNS

The classic signs of pain and inflammation may manifest as swelling, erythema, tenderness, and purulent drainage. Unfortunately, these are only visible if the infection is superficial or in a bone or joint. The manifestations of inflammation in deep-seated infections (e.g., meningitis, pneumonia, endocarditis, and urinary tract infection) must be ascertained by examining tissues or fluids. For example, the presence of neutrophils in spinal fluid, lung secretions (sputum), or urine is highly suggestive of a bacterial infection.

Symptoms referable to an organ system must be sought out carefully because not only do they help in establishing the presence of infection, but they also aid in narrowing the list of potential pathogens. For example, a febrile patient with complaints of flank pain and dysuria may well have pyelonephritis. In this situation, enteric gram-negative bacilli, especially *Escherichia coli*, are the predominant pathogens. If a febrile patient has no symptoms suggestive of an organ system but only constitutional complaints, the list of possible infectious diseases is lengthy.³ A febrile individual with cough and sputum production probably has a pulmonary infection. What is not so evident, however, is the etiologic organism in this situation, because it may be caused by bacteria, mycobacteria, viruses, chlamydia, or mycoplasmas.⁵ In this situation, attention to the patient's history and background disease states is important. Even more important is a

careful examination of the infected material (in this case sputum) in order to ascertain the identity of the pathogen.

IDENTIFICATION OF THE PATHOGEN

MICROBIOLOGY ISSUES

1 Infected body materials must be sampled, if at all possible or practical, before institution of any antimicrobial therapy for two reasons. First, a Gram stain of the material rapidly may reveal bacteria, or an acid-fast stain may detect mycobacteria or actinomycetes. Second, a delay in obtaining infected fluids or tissues until after antimicrobial therapy is started may result in false-negative culture results or alterations in the cellular and chemical composition of infected fluids. This is particularly true in patients with urinary tract infections, meningitis, and septic arthritis.⁶

Blood cultures usually should be performed in the acutely ill febrile patient. Blood culture collection should coincide with sharp elevations in temperature, suggesting the possibility of microorganisms or microbial antigens in the bloodstream. Ideally, blood should be obtained from peripheral sites as two sets (one set consists of an aerobic bottle and one set an anaerobic bottle) from two different sites approximately 1 hour apart. In selected infections, bacteremia is qualitatively continuous (e.g., endocarditis), so cultures may be obtained at any time.⁷

In addition to the infected materials produced by the patient (e.g., blood, sputum, urine, stool, and wound or sinus drainage), other less accessible fluids or tissues must be obtained based on localized signs or symptoms (e.g., spinal fluid in meningitis and joint fluid in arthritis). Abscesses and cellulitic areas also should be aspirated.

INTERPRETING RESULTS

After a positive Gram stain, culture results, or both are obtained, the clinician must be cautious in determining whether the organism recovered is a true pathogen, a contaminant, or a part of the normally expected flora (see Chap. 103). This latter consideration is especially problematic with cultures obtained from the skin, oropharynx, nose, ears, eyes, throat, and perineum. These surfaces are heavily colonized with a wide variety of bacteria, some of which may be pathogenic in certain settings. For example, coagulase-negative staphylococci are found in cultures of all the aforementioned sites yet are seldom regarded as pathogens unless recovered from blood, venous access catheters, or prosthetic devices.

Importantly, cultures of specimens from purportedly infected sites that are obtained by sampling from or through one of these contaminated areas may contain significant numbers of the normal flora. In the case of urine cultures, the urinalysis should be used in combination with culture results to assess the presence of WBCs, nitrite, and leukocyte esterase to help confirm infection and rule out colonization.

Particularly problematic are expectorated sputum specimens that must be evaluated carefully by determination of the presence of squamous epithelial cells and leukocytes.⁵ A predominance of epithelial cells in sputum specimens reduces the likelihood that recovered bacteria are pathogenic, especially when multiple types of organisms are seen on Gram stain. In contrast, the discovery of leukocytes in large numbers with one predominant type of organism is a more reliable indicator of a valid collection. In general, however, sputum evaluation has poor sensitivity and specificity as a diagnostic test.⁵

Caution also must be used in the evaluation of positive culture results from normally sterile sites (e.g., blood, cerebrospinal fluid, or joint fluid). The recovery of bacteria normally found on the skin in large quantities (e.g., coagulase-negative staphylococci or diphtheroids) from one of these sites may be a result of contamination of the specimen rather than a true infection. These organisms may be pathogenic in certain settings.

Gram-staining techniques, culture methods, and serologic identification, as well as susceptibility testing, are discussed in detail in Chap. 103. Emphasis must be placed on the proper collection and handling of specimens and careful assessment of Gram stain or other test results in guiding the clinician toward appropriate selection of initial antimicrobial therapy.⁸

SELECTION OF PRESUMPTIVE THERAPY

2 To select rational antimicrobial therapy for a given clinical situation, a variety of factors must be considered. These include the severity and acuity of the disease, host factors, factors related to the drugs used, and the necessity for using multiple agents. In addition, there are generally accepted drugs of choice for the treatment of most pathogens (see Appendix 104–1).

Drugs of choice are compiled from a variety of sources and are intended as guidelines rather than as specific rules for antimicrobial use. These choices are influenced by local antimicrobial susceptibility data rather than information published by other institutions or national compilations. Each institution should publish an annual summary of antibiotic susceptibilities (antibiogram) for organisms cultured from patients. Antibiograms contain both the number of nonduplicate isolates for common species and the percentage susceptible to the antibiotics tested. To further guide empirical antibiotic therapy, some hospitals publish unit-specific antibiograms in unique patient care areas, such as intensive care units or burn units.

Susceptibility of bacteria may differ substantially among hospitals within a community. For example, the prevalence of methicillin-resistant *Staphylococcus aureus* (MRSA) in some centers is quite high, whereas in other centers the problem may be nonexistent. This particular situation will influence the selection of therapy for possible *S. aureus* infection, where the clinician must choose either a β -lactam or vancomycin. The problem of differing susceptibilities is limited not only to gram-positive bacteria but also to gram-negative organisms, and all drug classes are affected.

Empirical therapy is directed at organisms that are known to cause the infection in question. These organisms for different sites of infection are discussed in Chap. 105 to 123. To define the most likely infecting organisms, a careful history and physical examination must be performed. The place where the infection was acquired should be determined, e.g., the home (community-acquired), nursing home environment, or hospital-acquired (nosocomial). Nursing home patients may be exposed to potentially more resistant organisms because they are often surrounded by ill patients who may be receiving antibiotics. Other important questions to ask infected patients regarding the history of the present illness include

1. Are any other people sick at home, especially children?
2. Are any unusual pets kept in the home such as pigeons?
3. Where are you employed (i.e., are you exposed to contaminated meat or infectious biohazards)?
4. Has there been any recent travel, for example, to endemic areas of fungal infections or developing countries?

HOST FACTORS

Several host factors should be considered when evaluating a patient for antimicrobial therapy. The most important factors are drug allergies, age, pregnancy, genetic or metabolic abnormalities, renal and hepatic function, site of infection, concomitant drug therapy, and underlying disease states.

ALLERGY

3 Allergy to an antimicrobial agent generally precludes its use. Careful assessment of allergy histories must be performed because many patients confuse common adverse drug effects (i.e., gastrointestinal disturbance) with true allergic reactions.⁹ Among the most commonly cited antimicrobial allergies are those to penicillin, penicillin-related compounds, or both. In the absence of complete penicillin skin testing capabilities, a rule of thumb for giving cephalosporins or carbapenems to patients allergic to penicillin is to avoid giving them to patients who give a good history for immediate or accelerated reactions (e.g., anaphylaxis, laryngospasm) and to give them under close supervision in patients with a history of delayed reactions, such as a rash.¹⁰ If gram-negative infection is suspected or documented, therapy with a monobactam may be appropriate because cross-reactivity with other β -lactams is virtually nil.¹¹

AGE

The patient's age is an important factor both in trying to identify the likely etiologic agent and in assessing the patient's ability to detoxify or eliminate the drug(s) to be used. The best example of an age determinant of organisms is in bacterial meningitis, where the pathogens differ as the patient grows from the neonatal period through infancy and childhood and into adulthood.¹²

In the case of the neonate, hepatic and liver functions are not well developed. The use of chloramphenicol can lead to shock and cardiovascular collapse (gray baby syndrome) caused by the inability of the newborn's liver to metabolize and detoxify the drug.¹³ Serum concentrations of chloramphenicol must be monitored to ensure that concentrations of the drug do not exceed 20–25 mcg/mL. Neonates (especially when premature) may develop kernicterus when given sulfonamides. This results from displacement of bilirubin from serum albumin.¹⁴ Additional special drug considerations for pediatric patients include low frequency of adverse effects and compliance-enhancing features (e.g., absorption not affected by food, once- to twice-daily dosing, and good taste).^{15,16}

The major physiologic change in persons older than 65 years of age is a decline in the number of functioning nephrons that, in turn, results in decreased renal function.¹⁷ This is usually manifested by an increased incidence of side effects caused by antimicrobials that are eliminated renally. For example, renal toxicity caused by aminoglycosides may be apparent much sooner during therapy than in younger patients. Oral absorption is also decreased in the elderly; in most cases, however, this has not proved to be significant clinically. Furthermore, in many cases, no identifiable cause of adverse drug effects can be determined other than "old age"; thus increased monitoring is warranted in the elderly.

PREGNANCY

During pregnancy, not only is the fetus at risk for drug teratogenicity (see Chap. 76), but also the pharmacokinetic disposition of certain drugs may be altered.¹⁸ Penicillins, cephalosporins, and aminoglyco-

sides are cleared from the peripheral circulation more rapidly during pregnancy. This is probably a result of marked increases in intravascular volume, glomerular filtration rate, and hepatic and metabolic activities. The net result is that maternal serum antimicrobial concentrations may be as much as 50% lower during this period than in the nonpregnant state. Increased dosages of certain compounds may be necessary to achieve therapeutic levels during late pregnancy.

METABOLIC ABNORMALITIES

Inherited or acquired metabolic abnormalities will influence the therapy of infectious diseases in a variety of ways. For example, patients with impaired peripheral vascular flow may not absorb drugs given by intramuscular injection. In addition, certain metabolic states may predispose patients to enhanced drug toxicity. For example, patients who are phenotypically slow acetylators of isoniazid are at greater risk for peripheral neuropathy.¹⁹ Patients with severe deficiency of glucose-6-phosphate dehydrogenase may develop significant hemolysis when exposed to such drugs as sulfonamides, nitrofurantoin, nalidixic acid, antimalarials, dapsone, and perhaps, chloramphenicol.²⁰ Although mild deficiencies are found in African-Americans, the more severe forms of the disease generally are confined to persons of eastern Mediterranean origin.

ORGAN DYSFUNCTION

4 Patients with diminished renal or hepatic function or both will accumulate certain drugs unless the dosage is adjusted.^{21,22} Recommendations for dosing antibiotics in patients with liver dysfunction are not as formalized as guidelines for patients with renal dysfunction.²² Antibiotics that should be adjusted in severe liver disease include chloramphenicol, clindamycin, erythromycin, metronidazole, and rifampin. Significant accumulation may occur when both liver dysfunction and renal dysfunction are present for these drugs: cefotaxime, nafcillin, piperacillin, and sulfamethoxazole.

CONCOMITANT DRUGS

5 Any concomitant therapy that the patient is receiving may influence the drug selection, dose, and monitoring. For example, administration of isoniazid to a patient who is also receiving phenytoin may result in phenytoin toxicity secondary to inhibition of phenytoin metabolism by isoniazid. Furthermore, drugs that possess similar adverse-effect profiles may increase the risk for effects, e.g., two drugs that cause nephrotoxicity or neutropenia. Lists of potentially severe drug-drug interactions are provided in Tables 104–2 and 104–3.

CONCOMITANT DISEASE STATES

Concomitant disease states may influence the selection of therapy. Certain diseases will predispose patients to a particular infectious disease or will alter the type of infecting organism. For example, patients with diabetes mellitus and the resulting peripheral vascular disease often develop infections of the lower extremity soft tissue. Moreover, the alterations in peripheral blood flow associated with the disease and perhaps altered immunity make such infections more difficult to treat than in nondiabetics. Patients with chronic lung disease or cystic fibrosis develop frequent pulmonary infections that may be caused by somewhat different microorganisms than are found in otherwise normal hosts.

Patients with immunosuppressive diseases, such as malignancies or acquired immunologic deficiencies, are highly predisposed to

TABLE 104–2. Major Drug Interactions with Antimicrobials

| Antimicrobial | Other Agent(s) | Mechanism of Action/Effect | Clinical Management |
|--|--|--|--|
| Aminoglycosides | Neuromuscular blocking agents Nephrotoxins (N) or ototoxins (O) (e.g., amphotericin B (N) cisplatin (N/O), cyclosporine (N), furosemide (O), NSAIDs (N), radio contrast (N), vancomycin (N)) | Additive adverse effects Additive adverse effects | Avoid Monitor aminoglycoside SDC and renal function |
| Amphotericin B | Nephrotoxins (e.g., aminoglycosides, cidofovir, cyclosporine, foscarnet, pentamidine) | Additive adverse effects | Monitor renal function |
| Azoles | See Chap. 119 | | |
| Chloramphenicol | Phenytoin, tolbutamide, ethanol | Decreased metabolism of other agents | Monitor phenytoin SDC, blood glucose |
| Foscarnet | Pentamidine IV | Increased risk of severe nephrotoxicity/hypocalcemia | Monitor renal function/serum calcium |
| Isoniazid | Carbamazepine, phenytoin | Decreased metabolism of other agents (nausea, vomiting, nystagmus, ataxia) | Monitor drug SDC |
| Macrolides/azalides | Digoxin | Decreased digoxin bioavailability and metabolism | Monitor digoxin SDC; avoid if possible |
| | Theophylline | Decreased metabolism of theophylline | Monitor theophylline SDC |
| Metronidazole (also cefamandole, cefoperazone) | Ethanol (drugs containing ethanol) | Disulfiram-like reaction | Avoid |
| Penicillins and cephalosporins | Probenecid, aspirin | Blocked excretion of β -lactams | Use if prolonged high concentration of β -lactam desirable |
| Ciprofloxacin/norfloxacin | Theophylline | Decreased metabolism of theophylline | Monitor theophylline |
| Quinolones | Class Ia and III Antiarrhythmics Multivalent cations (antacids, iron, sucralfate, zinc, vitamins, dairy, citric acid) didanosine | Increased Q-T interval Decreased absorption of quinolone | Avoid Separate by 2 hours |
| Rifampin | Azoles, cyclosporine, methadone, propranolol, protease inhibitors (PI), oral contraceptives, tacrolimus, warfarin | Increased metabolism of other agent | Avoid if possible |
| Sulfonamides | Sulfonylureas, phenytoin, warfarin | Decreased metabolism of other agent | Monitor blood glucose, SDC, PT |
| Tetracyclines | Antacids, iron, calcium, sucralfate | Decreased absorption of tetracycline | Separate by 2 hours |
| | Digoxin | Decreased digoxin bioavailability and metabolism | Monitor digoxin SDC; avoid if possible |

Azalides: azithromycin; azoles: fluconazole, itraconazole, ketoconazole, and voriconazole; macrolides: erythromycin, clarithromycin; protease inhibitors: aprenavir, indinavir, lopinavir/ritonavir, nelfinavir, ritonavir, and saquinavir; quinolones: ciprofloxacin, gatifloxacin, levofloxacin, moxifloxacin. SDC = serum drug concentrations.

infections, and the types of organisms may be vastly different from what would be expected (see Chap. 120). For example, patients undergoing chemotherapy for acute forms of leukemia often are profoundly granulocytopenic and are predisposed to infections caused by bacteria and fungi.²³ Patients with the acquired immunodeficiency syndrome (AIDS) often become infected with an enormous variety of organisms²⁴ (see Chap. 123).

Many factors predisposing to infection are related to disruption of the host's integumentary barriers. For example, trauma, burns, and iatrogenic wounds induced in surgery may lead to a substantial risk of infection depending on the severity and location of the injury or disruption. For a complete discussion of the various risks involved in surgical procedures, see Chap. 121.

DRUG FACTORS

PHARMACOKINETIC AND PHARMACODYNAMIC CONSIDERATIONS

Integration of both pharmacokinetic and pharmacodynamic properties of an agent is important when choosing antimicrobial therapy to ensure efficacy and to prevent resistance.²⁵ Early researchers relied solely on pharmacokinetic properties such as area under the drug concentration curve (*AUC*), maximum observed concentration (peak), and drug half-life to optimize therapy. Pharmacodynamics is the study of the relationship between drug concentration and the effects on the microorganism (see Chap. 103). Researchers now realize the

TABLE 104-3. Major Drug Interactions with Antiretroviral (AR) Agents

| Antiretroviral | Other Agent(s) | Mechanism of Action/Effect | Clinical Management |
|---|---|--|---|
| Groups of Antiretrovirals with Similar Drug Interactions | | | |
| PI ^a /delavirdine/ Efavirenz | Ergot alkaloids midazolam/triazolam/ alprazolam | Decreased metabolism of other agents | Avoid |
| | Phenobarbital/phenytoin/carbamazepine | Increased metabolism of AR | Monitor anticonvulsant SDC |
| PI ^a /delavirdine | Lovastatin/simvastatin | Decreased metabolism of statin drug | Avoid |
| | Rifabutin | Increased metabolism of AR | Avoid |
| | Rifampin | Decreased metabolism of rifabutin | Avoid |
| | Sildenafil | Increased metabolism of AR | Avoid |
| PI ^a /nevirapine | Sildenafil | Decreased metabolism of sildenafil | Max dose of sildenafil 25 mg/48 h |
| | Oral contraceptives (OC) | Increased metabolism of OC | Use alternative method |
| Individual Agents in Alphabetical Order by Generic Name | | | |
| Delavirdine ^b | Antacids/didanosine | Decreased absorption of delavirdine | Separate by 1 h |
| | Clarithromycin | Decreased metabolism of clarithromycin | Dose adjust in renal failure |
| | Dapsone/warfarin/quinidine | Decreased metabolism of the other agent | Monitor warfarin/avoid others |
| | Dihydropyridine Ca ⁺⁺ channel antagonists | | |
| Didanosine | H ₂ blockers/proton pump inhibitors | Decreased absorption of delavirdine | Avoid |
| | Indinavir | Increased metabolism of indinavir | Indinavir 1000 mg tid |
| | Ketoconazole | Decreased metabolism of delavirdine | Avoid |
| | Allopurinol | Decreased metabolism of didanosine | Avoid |
| Didanosine | Drugs requiring low pH; dapsone, indinavir, itra/ketoconazole | Decreased absorption of the other agent | Separate by 2 h |
| | Pyrimethamine | | |
| | Tetracycline/quinolones | | For quinolones: 6 h before or 2 h after |
| | Methadone | Decreased didanosine SDC | Increase didanosine |
| Efavirenz ^b | Ritonavir | Formulation incompatibility | Separate by 2.5 h |
| | Clarithromycin | Decreased clarithromycin SDC | Avoid: use azithromycin |
| | Indinavir | Increased metabolism of indinavir | Indinavir 1000 mg tid |
| Indinavir ^b | Rifabutin | Increased metabolism of rifabutin | Rifabutin 450 mg qd |
| | Delavirdine/efavirenz/nevirapine | Increased metabolism of indinavir | Indinavir 1000 mg tid |
| Nevirapine ^b | Itra/ketoconazole | Decreased metabolism of indinavir | Indinavir 600 mg tid |
| | Indinavir | Increased metabolism of indinavir | Indinavir 1000 mg tid |
| | Methadone/opiates/warfarin | Increased metabolism of other agents | Titrate to response/monitor warfarin |
| | Phenobarbital/phenytoin/carbamazepine | Unknown | Monitor anticonvulsant SDC |
| Ritonavir ^b | Ketoconazole/Rifampin/Tacrolimus | Increased metabolism of other agents | Avoid |
| | Amiodarone/flecainide | Decreased metabolism of other agents | Avoid |
| | propafenone/quinidine | | |
| | Ca ⁺⁺ channel antagonists | | |
| | Clarithromycin | Decreased metabolism of clarithromycin | Dose adjust in renal failure |
| | Didanosine | Formulation incompatibility | Separate by 2.5 h |
| | Desipramine | Decreased metabolism of desipramine | Reduce dose of desipramine |
| | Ketoconazole | Decreased metabolism of ketoconazole | Max dose of ketoconazole 200 mg qd |
| | Meperidine/methadone | Increased metabolism of other drug | Titrate to response |
| | Theophylline | Increased metabolism of theophylline | Monitor theophylline |
| Zidovudine | Warfarin | Increased metabolism of warfarin | Monitor warfarin |
| | Ribavirin | Ribavirin inhibits phosphorylation of zidovudine | Avoid |

^aPI: Protease inhibitors amprenavir, indinavir, lopinavir, nelfinavir, ritonavir, saquinavir

^bAlso note additional drug interactions above.

SDC = serum drug concentration.

Note: This list is meant to include major interactions and is not exhaustive. Individual package inserts along with the primary literature should be consulted because new interactions continue to be studied and reported. Avoid combinations of drugs with overlapping toxicities whenever possible.

important relationship between both pharmacokinetic and microbiologic parameters that has resulted in new measurements such as *AUC*:minimal inhibitory concentration (MIC) ratio, peak:MIC ratio, and time *T* the concentration is above MIC (*T* > MIC).

Aminoglycosides exhibit concentration-dependent bactericidal effects.²⁵ An example of the integration of pharmacokinetics and microbiological activity is the use of high-dose, once-daily aminoglycosides. For these regimens, the drug is given as a single large daily

dose to maximize the peak:MIC ratio. Aminoglycosides also possess a postantibiotic effect (persistent suppression of organism growth after concentrations fall below the MIC) that appears to contribute to the success of high-dose, once-daily administration.²⁶ Fluoroquinolones exhibit concentration-dependent killing activity, but optimal killing appears to be characterized by the *AUC*:MIC ratio.^{27,28}

β -Lactams and vancomycin display time-dependent bactericidal effects. Killing activity is enhanced only marginally if drug

concentration exceeds the MIC. Therefore, the important pharmacodynamic relationship for these antimicrobials is the duration that drug concentrations exceed the MIC ($T > \text{MIC}$). Effective dosing regimens require serum drug concentrations to exceed the MIC for at least 40% to 50% of the dosing interval.²⁵ Frequent small doses or a continuous infusion of β -lactams appears to be correlated with positive outcomes.²⁹

The ability of bacteriostatic antimicrobial agents to eradicate infections is reliant on host immune function and a postantibiotic effect. Examples include clindamycin, macrolides, and tetracyclines.²⁵

TISSUE PENETRATION

The importance of tissue penetration varies with site of infection. Some of the difficulties in interpreting data include a lack of correlation with clinical outcomes and poor understanding of whether the antimicrobial agents are present in a biologically active form.³⁰ An example of the former problem is the recognized efficacy of drugs with low biliary fluid concentrations in the treatment of cholecystitis, cholangitis, or both and the absence of the enhanced efficacy of drugs whose primary route of elimination is biliary excretion of active drug. An example of the latter difficulty is with penetration to deep infections, such as abscesses, where various factors such as acid pH, WBC products, and various enzymes may inactivate even high concentrations of certain drugs.

The central nervous system (CNS) is one body site where antimicrobial penetration is relatively well defined, and correlations with clinical outcomes are established.³¹ Cerebrospinal fluid (CSF) concentrations of antimicrobial agents necessary to cure bacterial meningitis have been defined, and drugs that do not reach significant concentrations in the CSF should either be avoided or instilled directly, if feasible.

Caution must be exercised when selecting an antimicrobial agent for clinical use on the basis of tissue or fluid penetration. Body fluids where drug concentration data are clinically relevant include CSF, urine, synovial fluid, and peritoneal fluid. Apart from these areas, more attention should be paid to clinical efficacy, antimicrobial spectrum, toxicity, and cost than to comparative data on penetration into a given body site.

The proper route of administration for an antimicrobial depends on the site of infection. Parenteral therapy is warranted when patients are being treated for febrile neutropenia or deep-seated infections such as meningitis, endocarditis, and osteomyelitis. Severe pneumonia often is treated initially with intravenous antibiotics and switched to oral therapy as clinical improvement is evident.^{5,32,33} Patients treated in the ambulatory setting for upper respiratory tract infections (e.g., pharyngitis, bronchitis, sinusitis, and otitis media), lower respiratory tract infections, skin and soft tissue infections, uncomplicated urinary tract infections, and selected sexually transmitted diseases may receive oral therapy.

DRUG TOXICITY

It is incumbent on health professionals to avoid toxic drugs whenever possible. Antibiotics associated with CNS toxicities, usually when not dose-adjusted for renal function, include penicillins, cephalosporins, quinolones, and imipenem. Hematologic toxicities generally are manifested with prolonged use of nafcillin (neutropenia), piperacillin (platelet dysfunction), cefotetan (hypoprothrombinemia), chloramphenicol (bone marrow suppression, both idiosyncratic and dose-related toxicity), and trimethoprim (megaloblastic anemia). Reversible nephrotoxicity classically is associated with aminoglycosides

and vancomycin. Reversible ototoxicity can occur with aminoglycosides or erythromycin. In the outpatient setting, patients must be counseled regarding photosensitivity with azithromycin, quinolones, tetracyclines, pyrazinamide, sulfamethoxazole, and trimethoprim. Lastly, all antibiotics have been implicated in causing diarrhea and colitis secondary to *Clostridium difficile*³⁴ (see Chap. 36).

Aside from consideration of drug toxicity, some antimicrobial use requires more intensive risk-benefit analysis. An example of this is the decision to use isoniazid prophylactically to prevent tuberculosis. Because the hepatotoxicity of isoniazid increases in frequency with age, older persons (>45 years) who are candidates for isoniazid prophylaxis (positive skin test) must have additional risk factors for tuberculosis to balance the potential toxic effects. These include evidence of recent skin-test conversion, immunosuppression, or previous gastrectomy. Older patients without additional risk factors are more likely to suffer toxicity from isoniazid than derive benefit from its use.³⁵

COST

The costs of drug therapy are increasing dramatically, especially as new products, derived from biotechnology, are introduced. Greater attention is being paid to the pharmacoeconomics of drug therapy, where patient outcomes are valued and the costs to arrive at those outcomes are estimated. With increasing numbers of patients enrolled in managed-care organizations, understanding the true cost of antimicrobial therapy is more important than ever. The total cost of antimicrobial therapy includes much more than just the acquisition cost of the drugs.³⁶

Many ancillary costs and factors affect the true cost of therapy. These include factors such as storage, preparation, distribution, and administration, as well as all the costs incurred from monitoring for adverse effects and factors such as length of hospitalization, readmissions, and all directly provided health care goods and services. More difficult to value but equally as important are indirect costs such as patient quality-of-life issues. Pharmacoeconomic and outcomes analyses are becoming more widely applied and used in order to derive values such as cost-benefit ratios and the cost-effectiveness of various products as compared with other products. A detailed review of pharmacoeconomic analyses is beyond the scope of this chapter, but excellent reviews of the subject are available.³⁷ A great deal more research in this area is needed, and multidisciplinary, collaborative efforts with the involvement of pharmacy, medicine, nursing, and microbiology are essential.³⁸

Many new oral antimicrobials have been approved, including cephalosporins, linezolid, and fluoroquinolones, that can be used in place of more expensive parenteral therapy. These agents offer extended-spectrum killing activity, increased tissue penetration, and excellent safety and pharmacokinetic profiles. Many older, less expensive oral agents also remain appropriate choices. When oral therapy is being considered, the choice between convenient once-a-day expensive agents versus multiple-dose inexpensive agents arises. It is easy to calculate the difference in acquisition cost; however, the overall cost between agents is more difficult to determine. Factors to weigh include safety, effectiveness, tolerability, patient compliance, and potential drug-drug interactions. In some instances, more expensive agents may be warranted to avoid adverse outcomes.³⁹

COMBINATION ANTIMICROBIAL THERAPY

6 In selecting a drug regimen for a given patient, consideration must be given to the necessity of using more than one drug. Combinations of antimicrobials generally are used to broaden the

spectrum of coverage for empirical therapy, achieve synergistic activity against the infecting organism, and prevent the emergence of resistance.⁴⁰

BROADENING THE SPECTRUM OF COVERAGE

Increasing the coverage of antimicrobial therapy generally is necessary in mixed infections where multiple organisms are likely to be present. This is the case in intraabdominal and female pelvic infections, in which a variety of aerobic and anaerobic bacteria may produce disease.⁴¹ Traditionally, a combination of a drug active against aerobic gram-negative bacilli, such as an aminoglycoside, and a drug active against anaerobic bacteria, such as metronidazole or clindamycin, is selected. Newer β -lactam compounds, which possess good activity against both these types of organisms, such as the cephamycins, carbapenems, or the β -lactam/ β -lactamase inhibitor combinations, may be adequate to replace the combination and thereby reduce the cost of therapy. The other clinical situation in which an increased spectrum of activity is desirable is with nosocomial infections.³²

SYNERGISM

The achievement of synergistic antimicrobial activity is advantageous for infections caused by enteric gram-negative bacilli in immunosuppressed patients. Laboratory tests to identify synergy between antibiotic combinations are described in Chap. 103. Traditionally, combinations of aminoglycosides and β -lactams have been used because these drugs together generally act synergistically against a wide variety of bacteria. The data supporting superior efficacy of synergistic over nonsynergistic combinations are weak, however. At best, it would appear that synergistic combinations produce better results in infections caused by *P. aeruginosa*, in certain infections caused by *Enterococcus* spp., and perhaps in patients with profound, persistent neutropenia.^{42,43}

The most obvious example of the use of synergy is the treatment of enterococcal endocarditis. The causative organism is usually only inhibited by penicillins, but it is killed rapidly by the addition of streptomycin or gentamicin to a penicillin.⁴² The need for bactericidal activity in the treatment of endocarditis underscores the need for these synergistic combinations.

PREVENTING RESISTANCE

The use of combinations to prevent the emergence of resistance is applied widely but not often realized. The only circumstance where this has been clearly effective is in the treatment of tuberculosis. The prevalence of resistance to a first-line drug such as isoniazid or rifampin in a population of organisms may be as high as 1 in 10^6 to 10^8 . Because the bacterial load in a patient with active tuberculosis often exceeds this, two drugs are given to reduce the likelihood of encountering resistance to less than 1 in 10^{35} . There is ample evidence from in vitro data and experimental bacterial infections that combinations of drugs with different mechanisms are effective in the prevention of the emergence of resistance. Data from clinical trials, however, are either conflicting or do not convincingly support this concept.⁴⁴

DISADVANTAGES OF COMBINATION THERAPY

Although there are potentially beneficial effects from combining drugs, there also are potential disadvantages. Examples include additive nephrotoxicity from drugs such as aminoglycosides,

amphotericin, and possibly vancomycin.⁴⁵ Inactivation of aminoglycosides by penicillins may be clinically significant when excessive doses of penicillin are given to a patient in renal failure.⁴⁶

The combination of two or more antibiotics may result in antagonistic effects. Clinically, the effect of antagonism may be evident when one drug induces β -lactamase production and another drug is β -lactamase unstable.⁴⁷ Cefoxitin and imipenem are examples of drugs capable of inducing β -lactamases and may result in more rapid inactivation of penicillins when used together.

MONITORING THERAPEUTIC RESPONSE

After antimicrobial therapy has been instituted, the patient must be monitored carefully for a therapeutic response. Culture and sensitivity reports from specimens sent to the microbiology laboratory must be reviewed and the therapy changed accordingly. Use of agents with the narrowest spectrum of activity against identified pathogens is recommended. If anaerobes are suspected, even if they are not identified, anaerobic therapy should be continued.

Patient monitoring should include many of the same parameters used to diagnose the infection. The WBC count and temperature should start to normalize. Physical complaints from the patient also should diminish (i.e., decreased pain, shortness of breath, cough, or sputum production). Appetite should improve. Radiologic improvement may lag behind clinical improvement. Determinations of serum (or other fluid) levels of antimicrobials may be useful in ensuring outcome, preventing toxicity, or both. There are only a few antimicrobials that require serum concentration monitoring and then only in selected situations. These include the aminoglycosides, flucytosine, and chloramphenicol. Achievement of adequate aminoglycoside concentrations within the first few days of therapy of gram-negative infection has been correlated with better therapeutic outcome.⁴⁸ In addition, ensuring that excessive concentrations of flucytosine or chloramphenicol (in neonates) are avoided will prevent toxicity.

Changes in the volume of distribution may have a significant impact on the efficacy, safety, or both of therapy. An unexpectedly low volume of distribution (such as in the dehydrated patient) will result in higher, potentially toxic drug concentrations, whereas a larger-than-expected volume of distribution (such as in patients with edema or ascites) will result in low, potentially subtherapeutic concentrations. The most effective methods use measured serum concentrations of the drugs rather than estimations from renal function tests to assess true drug clearance from the body.

As patients improve clinically, the route of administration should be reevaluated. Streamlining therapy from parenteral to oral (switch therapy) has become an accepted practice for many infections outside the bloodstream and CNS.^{33,49} Criteria that should be present to justify a switch to oral therapy include (1) overall clinical improvement, (2) lack of fever for 24 to 48 hours, (3) decreased WBC count, and (4) a functioning gastrointestinal tract. Drugs that exhibit excellent oral bioavailability when compared with intravenous formulations include ciprofloxacin, clindamycin, doxycycline, gatifloxacin, levofloxacin, metronidazole, moxifloxacin, linezolid, and trimethoprim-sulfamethoxazole.

FAILURE OF ANTIMICROBIAL THERAPY

A variety of factors may be responsible for an apparent lack of response to therapy.⁵⁰ Patients who fail to respond over 2 to 3 days require a thorough reevaluation. It is possible that the disease is not infectious or is nonbacterial in origin, or there is an undetected pathogen in a polymicrobial infection. Other factors include those

directly related to drug selection, the host, or the pathogen. Laboratory error in identification, susceptibility testing, or both (presence of inoculum effect or resistant subpopulations) is a rare cause of antimicrobial failure.

FAILURES CAUSED BY DRUG SELECTION

Factors related directly to the drug selection include an inappropriate drug selection or dosage or route of administration. Malabsorption of a drug product because of gastrointestinal (GI) disease, such as a short-bowel syndrome, or a drug interaction, such as complexation of fluoroquinolones with multivalent cations resulting in reduced absorption, may lead to potentially subtherapeutic serum concentrations. Accelerated drug elimination is also possible. This may occur in patients with cystic fibrosis or during pregnancy, when more rapid clearance or larger volumes of distribution may result in low serum concentrations, particularly for aminoglycosides. A common cause of failure of therapy is poor penetration into the site of infection. This is especially true for sites such as the CNS, eye, and prostate gland. Drug failure also can result from drugs that are highly protein bound or that are chemically inactivated at the site of infection.

FAILURES CAUSED BY HOST FACTORS

Host defenses must be considered when evaluating a patient who is not responding to antimicrobial therapy. Patients who are immunosuppressed (e.g., granulocytopenia from chemotherapy or AIDS) may respond poorly to therapy because their defenses are inadequate to eradicate the infection despite seemingly adequate drug regimens. A good example is the poor response of infection in granulocytopenic patients that is seen when their WBC counts remain low during therapy. This contrasts with a much better response when granulocyte counts rise during therapy.⁵¹

Other host factors are related to the need for surgical drainage of abscesses or removal of foreign bodies, necrotic tissue, or both. If these situations are not corrected, they result in persistent infection and, occasionally, bacteremia despite adequate antimicrobial therapy.

FAILURES CAUSED BY MICROORGANISMS

Factors related to the pathogen include the development of drug resistance during therapy.⁵² *Primary resistance* refers to the intrinsic resistance of the pathogens producing the infection. Several infections are more likely to result in drug resistance because of drug inaccessibility (e.g., pneumonia, endocarditis, abdominal and deep-seated skin and soft tissue infections). It has become increasingly obvious that despite the development and introduction of numerous new antimicrobial agents, bacterial resistance has continued to increase both within and across different bacterial genera.

Organisms in which resistance has increased most dramatically include enterococci, pneumococci, and *Mycobacterium tuberculosis*. Enterococci have been isolated with multiple resistance patterns. They may be resistant to β -lactams (by virtue of β -lactamase production, altered penicillin-binding proteins [PBPs], or both), vancomycin (via alterations in peptidoglycan synthesis), and high levels of aminoglycosides (via enzymatic degradation).

Pneumococci resistant to penicillins, certain cephalosporins, and macrolides are increasingly common. These organisms generally are susceptible to vancomycin, the new fluoroquinolones, and cefotaxime or ceftriaxone. *M. tuberculosis* resistant to one or more first-line antitubercular agents (e.g., isoniazid, rifampin, ethambutol, streptomycin, and pyrazinamide) have increased in frequency as well. This has been

observed principally in populations of prison inmates and patients with AIDS.

The increase in resistance among these organisms is believed to be a result of continued overuse of antimicrobials in the community, as well as in hospitals, and the increasing prevalence of immunosuppressed patients receiving long-term suppressive antimicrobials for the prevention of infections. These resistance patterns are regionally variable, and susceptibility patterns in the community (or hospital) should be monitored closely to promote rational antimicrobial selection.⁵³

Recently approved antimicrobial agents such as quinupristin-dalfopristin and linezolid have been targeted at resistant gram-positive bacteria. Numerous other drugs currently in development also have enhanced activity against these bacteria.

The emergence of resistance during antimicrobial therapy is reported most frequently in pulmonary or other deep-seated infections caused by *P. aeruginosa*. This occurs in 20% to 30% of cases and with all the available antibacterial agents, including imipenem. This organism and a group of enteric gram-negative bacilli (*Enterobacter aerogenes*, *E. cloacae*, *Citrobacter freundii*, *Serratia marcescens*, and a few others) can produce a β -lactamase that is capable of hydrolyzing broad-spectrum cephalosporins and, to a lesser extent, penicillins.⁵³ These enzymes are categorized as Bush group I, and their genetic code is found on the chromosome. Resistant mutants of these aforementioned organisms that produce large quantities of these enzymes may be present within an infection and may be responsible for the emergence of resistance during therapy. The mutants occur at a frequency of 1 in 10^6 to 1 in 10^8 bacteria, the numbers of bacteria commonly encountered in clinical infections.⁵³ Because only 10^4 to 10^5 bacteria are tested for susceptibility in the microbiology laboratory, however, this potential resistance may not be detected.

Treatment of an infection caused by *Enterobacter*, *Citrobacter*, *Serratia*, or *P. aeruginosa* with a third-generation cephalosporin or aztreonam may produce an initial clinical response by eradicating all the susceptible bacteria in the population. Within a few days, however, the highly resistant subpopulations have a selective advantage and may overgrow the infection site to produce a relapse.⁵³ These bacteria usually retain susceptibility to aminoglycosides, carbapenems, and fluoroquinolones but are resistant to all other β -lactams. Host defenses are extremely important in this scenario. Debilitated patients with pulmonary infections, abscesses, or osteomyelitis are at high risk for drug failure. In these situations, a combination regimen to prevent the emergence of resistance or the use of carbapenem or a fluoroquinolone may be warranted for empirical therapy.

ANTIMICROBIAL USE MANAGEMENT

ANTIBIOTIC FORMULARY

Institutions must decide which antibiotics to include on their formularies. The actual decision to have a formulary remains controversial; however, restricting choices does encourage familiarity with a core of antibiotics for residents and attending physicians. Open formularies allow the empirical use of any commercially available antibiotics, with recommended guidelines for changes when culture and sensitivity results are finalized. Many institutions have organized an antibiotic subcommittee to the pharmacy and therapeutics committee that meets to discuss trends in resistance and review new agents. The subcommittee is generally a multidisciplinary group including representation from microbiology, infection control, pharmacy, and physicians from several disciplines, including infectious disease. The actual

implementation of the guidelines and restrictions recommended by such groups requires the cooperation of the entire medical staff. Education is vital to the success of the antibiotic formulary.⁵⁴

ANTIMICROBIAL CYCLING

An interesting topic in formulary management that continues to gain interest despite little scientific research is *antimicrobial cycling*. Antimicrobial cycling is a predetermined change in an antimicrobial recommendation for empirical therapy of a specific infection at a predetermined time.⁵⁵ It also has been called *rotation of antimicrobials*. This strategy should not be confused with *antimicrobial switch therapy*, which involves changes in the route of administration of antimicrobial therapy (i.e., intravenous to oral).

Antimicrobial cycling is employed as a mechanism to reduce or prevent antimicrobial resistance. *Proactive cycling* is a planned switch to preempt resistance at a predetermined point or series of points with a predetermined schedule. *Reactive cycling* is a response to high or unacceptable resistance and is often a one-time switch. Most programs incorporate aspects of both types of cycling. Cycling implies returning to the original drug after other choices have been used. Rotation implies several planned changes.

Antimicrobial cycling is based on the assumptions that the resistance problem is (1) caused by the overuse of a particular agent or class of agents and (2) that discontinuation of the particular agent or class of agents will restore susceptibility. These assumptions correlate best with nosocomial gram-negative organisms that can rapidly develop resistance. Theoretically, antimicrobial agents should be sequenced in such an order that mechanisms of resistance do not overlap (i.e., changing drug classes).⁵⁵ Experts have expressed the need for further well-controlled long-term studies. The Centers for Disease Control and Prevention is currently funding several antimicrobial cycling programs.

KEEPING CURRENT

Attention must be paid to the literature on antimicrobials to assist in the selection of therapy. The results from prospective, controlled, randomized clinical trials should be evaluated whenever possible when considering appropriate antimicrobial therapy. Results from preclicensing open trials offer only limited information that may be useful in this regard because patients in these trials generally are not seriously ill and are not infected with multiple resistant bacteria and other confounding factors found in most clinical situations are excluded by virtue of the study design. Therefore, comparative data in more seriously ill patients are essential for the appropriate application of new agents.⁵⁶

Postmarketing trials are also important because results may demonstrate superiority of one regimen over another, either in efficacy, safety, or cost-effectiveness. Appropriate antimicrobial therapy may change as new organisms are discovered, susceptibility patterns change, new drugs become available, and new clinical trial results are published. Classical thinking in the treatment of infectious diseases will continue to change and evolve to maintain antimicrobial efficacy. Optimal use of modern antimicrobials is just beginning to be defined.⁵⁷

ABBREVIATIONS

AUC: area under the curve
IL: interleukin
MIC: minimal inhibitory concentration

PBP: penicillin-binding protein
PMN: polymorphonuclear leukocytes
WBC: white blood cell

APPENDIX 104-1

Drugs of Choice, First Choice, *Alternative(s)*

GRAM-POSITIVE COCCI

Enterococcus faecalis (generally not as resistant to antibiotics as *E. faecium*)

Serious infection (endocarditis, meningitis, pyelonephritis with bacteremia)

Ampicillin (or penicillin G) + (gentamicin or streptomycin)

Vancomycin + (gentamicin or streptomycin), linezolid

Urinary tract infection (UTI)

Ampicillin, amoxicillin

Doxycycline,^a fosfomicin, or nitrofurantoin

E. faecium (generally more resistant to antibiotics than *E. faecalis*)

Recommend consultation with infectious disease specialist.

Linezolid, quinupristin/dalfopristin

Staphylococcus aureus/*Staphylococcus epidermidis*

Methicillin (oxacillin)-sensitive

PRP^c

FGC,^{d,e} trimethoprim-sulfamethoxazole, clindamycin,^f
ampicillin-sulbactam, amoxicillin-clavulanate, or
fluoroquinolone

Methicillin (oxacillin)-resistant

Vancomycin + (gentamicin or rifampin)

Linezolid, quinupristin-dalfopristin, daptomycin

Per sensitivities: Trimethoprim-sulfamethoxazole,
doxycycline,^a or clindamycin

Streptococcus (groups A, B, C, G, and *S. bovis*)

Penicillin G^h or Vⁱ or ampicillin

FGC,^{d,e} erythromycin, azithromycin, clarithromycin,^j
S. pneumoniae

Penicillin-sensitive (MIC < 0.1 mcg/mL)

Penicillin G or V or ampicillin

Erythromycin, FGC,^{d,e} azithromycin, or clarithromycin^j

Penicillin intermediate (MIC 0.1–1.0 mcg/mL)

High-dose penicillin (12 million units/day for adults) or
ceftriaxone^e or cefotaxime^e

Gatifloxacin^b, levofloxacin^b, moxifloxacin^b, or vancomycin

Penicillin-resistant (MIC ≥ 1.0 mcg/mL)

Recommend consultation with infectious disease specialist.

Vancomycin ± rifampin

Per sensitivities: TGC,^{e,k} levofloxacin,^b gatifloxacin,^b or
moxifloxacin^b

Streptococcus, viridans group

Penicillin G ± gentamicin^l

TGC,^{d,e} erythromycin, azithromycin, clarithromycin,^j or
vancomycin ± gentamicin

GRAM-NEGATIVE COCCI

Moraxella (Branhamella) catarrhalis

Amoxicillin-clavulanate, ampicillin-sulbactam

Trimethoprim-sulfamethoxazole, erythromycin, azithromycin,
clarithromycin,^j doxycycline,^a SGC,^{e,m} TGC,^{e,k} or TGCpo^{e,n}

Neisseria gonorrhoeae (also give concomitant treatment for

Chlamydia trachomatis)

Disseminated gonococcal infection

Ceftriaxone^e or cefotaxime^e

Oral follow-up: Cefixime,^e cefpodoxime,^e ciprofloxacin,^b or
ofloxacin^b

Uncomplicated infection

Ceftriaxone^e or cefotaxime,^e cefixime,^e or cefpodoxime^e

Ciprofloxacin^b or ofloxacin^b

N. meningitidis

Penicillin G

TGC^{e,k}

GRAM-POSITIVE BACILLI

Clostridium perfringens

Penicillin G ± clindamycin

Metronidazole, clindamycin, doxycycline,^a ceftazolin,^e
imipenem,^o meropenem,^o or ertapenem^o

C. difficile

Oral metronidazole

Oral vancomycin

GRAM-NEGATIVE BACILLI

Acinetobacter spp.

Imipenem or meropenem either ± aminoglycoside^p (amikacin
usually most effective)

Ciprofloxacin,^b trimethoprim-sulfamethoxazole, or
ampicillin-sulbactam

Bacteroides fragilis (and others)

Metronidazole

BLIC,^g clindamycin, cephamycin,^{e,q} or carbapenem^o

Enterobacter spp.

Imipenem, meropenem, ertapenem, or cefepime ±
aminoglycoside^p

Ciprofloxacin,^b levofloxacin,^b piperacillin-tazobactam,
ticarcillin-clavulanate, or trimethoprim-sulfamethoxazole

Escherichia coli

Meningitis

TGC^{e,k} or meropenem

Systemic infection

TGC^{e,k}

Ampicillin-sulbactam, FGC,^{d,e} BL/BLI,^g

trimethoprim-sulfamethoxazole, SGC,^{e,m}

fluoroquinolone,^{b,o,r} imipenem,^o meropenem^o

Urinary tract infection

Most oral agents: Check sensitivities.

Ampicillin, amoxicillin-clavulanate,

trimethoprim-sulfamethoxazole, or cephalixin^e

Aminoglycoside, FGC,^{d,e} nitrofurantoin, fluoroquinolone^{b,o,r}

Gardnerella vaginalis

Metronidazole

Clindamycin

Hemophilus influenzae

Meningitis

Cefotaxime^e or ceftriaxone^e

Meropenem^o or chloramphenicol^o

Other infections

BLIC,^g or if β-lactamase-negative, ampicillin or amoxicillin

Trimethoprim-sulfamethoxazole, cefuroxime,^e erythromycin, azithromycin, clarithromycin,^j or fluoroquinolone^{b,o,r}

Klebsiella pneumoniae

TGC^{e,k} (if UTI only: Aminoglycoside^p)

Trimethoprim-sulfamethoxazole, cefuroxime,^e fluoroquinolone,^{b,r} BLIC,^s imipenem,^o or meropenem^o

Legionella spp.

Erythromycin ± rifampin or fluoroquinolone^{b,r}

Trimethoprim-sulfamethoxazole, clarithromycin,^j azithromycin, or doxycycline^a

Pasteurella multocida

Penicillin G, ampicillin, amoxicillin

Doxycycline,^a BLIC,^s trimethoprim-sulfamethoxazole or ceftriaxone^{e,k}

Proteus mirabilis

Ampicillin

Trimethoprim-sulfamethoxazole, most antibiotics except PRP^c

Proteus (indole-positive) (including *Providencia rettgeri*,

Morganella morganii, and *Proteus vulgaris*)

TGC^{e,k} or fluoroquinolone^{b,r}

Trimethoprim-sulfamethoxazole, BLIC,^s aztreonam,^t imipenem,^o or TGCpo^{e,n}

Providencia stuartii

TGC^{e,k} or fluoroquinolone^{b,r}

Trimethoprim-sulfamethoxazole, aztreonam,^t imipenem,^o or meropenem^o

Pseudomonas aeruginosa

Cefepime, ceftazidime, piperacillin-tazobactam, or ticarcillin-clavulanate plus aminoglycoside^p

Ciprofloxacin,^b levofloxacin,^b aztreonam,^t imipenem,^o or meropenem^o

UTI only: Aminoglycoside^p

Ciprofloxacin,^b levofloxacin,^b or gatifloxacin^b

Salmonella typhi

Ciprofloxacin,^b levofloxacin,^b ceftriaxone,^e or cefotaxime^e

Trimethoprim-sulfamethoxazole

Serratia marcescens

Piperacillin-tazobactam, ticarcillin-clavulanate, or TGC^{e,k} ± gentamicin

Trimethoprim-sulfamethoxazole, ciprofloxacin,^b levofloxacin,^b aztreonam,^t imipenem,^s meropenem,^o or ertapenem

Stenotrophomonas (Xanthomonas) maltophilia

Trimethoprim-sulfamethoxazole

Generally very resistant to all antimicrobials; check sensitivities to ceftazidime,^e ticarcillin-clavulanate, doxycycline,^a and minocycline^a

MISCELLANEOUS MICROORGANISMS

Chlamydia pneumoniae

Doxycycline^a

Erythromycin, azithromycin, clarithromycin,^j or fluoroquinolone^{b,r}

C. trachomatis

Doxycycline^a or azithromycin

Levofloxacin^b or ofloxacin^b

Mycoplasma pneumoniae

Erythromycin, azithromycin, clarithromycin^j

Doxycycline^a or fluoroquinolone^{b,r}

SPIROCHETES

Treponema pallidum

Neurosyphilis

Penicillin G

Ceftriaxone^e

Primary or secondary

Benzathine penicillin G

Doxycycline^a or ceftriaxone^e

Borrelia burgdorferi (choice depends on stage of disease)

Ceftriaxone^e or cefuroxime axetil,^e doxycycline,^a amoxicillin

High-dose penicillin, cefotaxime,^e azithromycin, or clarithromycin^j

^aNot for use in pregnant patients or children younger than 8 years old.

^bNot for use in pregnant patients or children younger than 18 years old.

^cPenicillinase-resistant penicillin: nafcillin or oxacillin.

^dFirst-generation cephalosporins—IV: cefazolin; PO: cephalexin, cephadrine, or cefadroxil.

^eSome penicillin-allergic patients may react to cephalosporins.

^fNot reliably bactericidal; should not be used for endocarditis.

^gβ-Lactamase inhibitor combination—IV: ampicillin-sulbactam,

piperacillin-tazobactam, ticarcillin-clavulanate; PO: amoxicillin-clavulanate.

^hEither aqueous penicillin G or benzathine penicillin G (pharyngitis only).

ⁱOnly for soft tissue infections or upper respiratory infections (pharyngitis, otitis media).

^jDo not use in pregnant patients.

^kThird-generation cephalosporins—IV: cefotaxime, ceftriaxone.

^lGentamicin should be added if tolerance or moderately susceptible (MIC > 0.1 g/mL) organisms are encountered; streptomycin is used but may be more toxic.

^mSecond-generation cephalosporins—IV: cefuroxime; PO: cefaclor, cefditoren, cefprozil, cefuroxime axetil, and loracarbef.

ⁿThird-generation cephalosporins—PO: cefdinir, cefixime, cefetamet, cefpodoxime proxetil, and ceftibuten.

^oReserve for serious infection.

^pAminoglycosides: gentamicin, tobramycin, and amikacin; use per sensitivities.

^qCefoxitin, cefotetan.

^rIV/PO: ciprofloxacin, ofloxacin, levofloxacin, gatifloxacin, and moxifloxacin.

^sReserve for serious infection when less toxic drugs are not effective.

^tGenerally reserved for patients with hypersensitivity reactions to penicillin.

CENTRAL NERVOUS SYSTEM INFECTIONS

Elizabeth D. Hermsen and John C. Rotschafer

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The three most likely pathogens of bacterial meningitis in the United States are *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Hemophilus influenzae*, although routine vaccination may cause a change in the epidemiology in the years to come.
- 2 In cases of meningitis, initial findings can include (a) *presenting signs and symptoms*: fever, headache, nuchal rigidity, Brudzinski's or Kernig's sign, and altered mental status, and (b) *abnormal cerebrospinal fluid (CSF) chemistries*: elevated white blood cell (WBC) count (>100 cells/mm³), elevated protein (>50 mg/dL), and decreased glucose levels (<40 mg/dL).
- 3 Two main microbiologic tests that should be obtained include a Gram stain of the CSF and CSF cultures.
- 4 Three primary goals of treatment in meningitis include (a) *amelioration* of signs and symptoms, (b) *eradication* of infection, and (c) *prevention* of the development of neurologic sequelae, such as seizures, deafness, coma, and death.
- 5 When selecting antibiotics, the clinician must consider the antibiotic concentration at the site of infection, as well as the spectrum of antibacterial activity. Empirical choices should be based on age and predisposing conditions. (a) *Ceftriaxone* or *cefotaxime* and *vancomycin* are reasonable initial choices for empirical coverage of community-acquired meningitis in adult patients. (b) *Listeria monocytogenes* is a common pathogen in infants and elderly. Therefore, *ampicillin* should be added empirically to antimicrobial coverage.
- 6 Empirical coverage with an appropriate antibiotic should be started as soon as possible when clinical suspicion of meningitis exists. If there is a delay in doing a lumbar puncture (even 30 to 60 minutes), the first dose of an antibiotic *should not* be withheld. Changes in the CSF after initiation of antibiotics usually take 12 to 24 hours.
- 7 In contrast to the treatment of other infectious diseases, antibiotic dosages in the treatment of meningitis should be maximized to optimize CNS penetration.
- 8 The duration of antibiotic treatment for meningitis has not been standardized; however, the duration of antibiotic therapy generally is based on the causative organism and the individual case and may range from 7 to 21 days.
- 9 Close contacts and relatives of the index case should be assessed for appropriate prophylaxis, particularly with *N. meningitidis* and *H. influenzae* meningitis.
- 10 Steroid treatment includes dexamethasone 0.15 mg/kg per dose to be given four times daily for 4 days in infants and children older than 2 months of age with proven or strongly suspected bacterial meningitis. Steroids should be given prior to antibiotics.

Central nervous system (CNS) infections are caused by various pathogens, including bacteria, viruses, fungi, and parasites. Infections are the result of hematogenous spread from a primary infection site, seeding from a parameningeal focus, reactivation from a latent site, trauma, or congenital defects in the CNS. Newer diagnostic techniques have enabled more rapid and definitive diagnoses, thus diminishing the number of unknown "aseptic meningitis" diagnoses and improving targeted therapy. Bacteria resistant to multiple antibiotics present new challenges in the management of meningitis. This chapter presents the etiologies, pathophysiology, therapy, and prophylaxis of these infections but will concentrate predominantly on bacterial meningitis.

EPIDEMIOLOGY

Approximately 1.2 million cases of acute bacterial meningitis, excluding epidemics, occur every year around the globe, resulting in

135,000 deaths.¹ Overall mortality rates for patients with meningitis range from 2% to 30%.² Neurologic sequelae frequently associated with meningitis include seizures, sensorineural hearing loss, and hydrocephalus. Risk for the development of neurologic sequelae depends on the infecting organism. Generally, 30% to 50% of patients who survive meningitis may develop neurologic disabilities.^{3,4} Despite the availability of antimicrobial therapy against the most common CNS pathogens, CNS infections continue to have significant morbidity and mortality.

Two recent findings have the potential for great epidemiologic impact on bacterial meningitis. First, both passive and active exposures to cigarette smoke were shown to be risk factors for bacterial meningitis, especially meningococcal disease.^{4a} Second, children with cochlear implants that include a positioner are at increased risk of bacterial meningitis, specifically pneumococcal meningitis. A recent study demonstrated an incidence of meningitis due to *Streptococcus pneumoniae* that was more than 30 times the incidence in a similar cohort of the U.S. population.⁵

ETIOLOGY

▶ CNS infections are caused by a variety of microorganisms. Historically, CNS infections were primarily community acquired; however, an increasing number are now nosocomial.⁶ Surveillance studies of bacterial meningitis in the United States were conducted in 1986 and, in a smaller study, again in 1995.^{7,8} In 1986, *Hemophilus influenzae* was the most commonly identified cause of bacterial meningitis (45%), followed by *S. pneumoniae* (18%) and *Neisseria meningitidis* (14%). In 1995, approximately 5 years after introduction of the *H. influenzae* type b conjugate (Hib) vaccine, *S. pneumoniae* was the most commonly identified cause of bacterial meningitis (47%), followed by *N. meningitidis* (25%), *Listeria monocytogenes* (8%), and *H. influenzae* (7%).

The incidence of invasive *H. influenzae* infections has decreased by more than 90% since the introduction of the Hib vaccine.⁸ Mass immunization with the Hib vaccine also has resulted in alterations in the age distribution of bacterial meningitis. While the median age was 15 months in 1986, by 1995 that age increased to 25 years. Accordingly, the proportion of cases in those 18 years of age and older increased from 20.8% to 51.5%.⁸ However, many developing countries have not adopted the Hib vaccine as part of the standard vaccines offered to children owing to cost. Thus approximately 350,000 to 700,000 children die each year worldwide owing to invasive *H. influenzae* infections.¹

Similar to the Hib vaccine, the introduction of the conjugate pneumococcal vaccine and the implementation of uniform vaccination have resulted in near-total elimination of invasive pneumococcal disease in young children in the United States.¹ To our knowledge, no studies have been published to date regarding the incidence of pneumococcal meningitis owing to *S. pneumoniae* since the introduction of the conjugate vaccine. However, the near-total elimination of pneumococcal meningitis appears to be possible with uniform vaccination. Uniform vaccination was problematic beginning in 2001, when a shortage of the conjugate vaccine resulted in interim vaccination recommendations from the Centers for Disease Control and Prevention (CDC), calling for withholding the vaccine from healthy children over the age of 2 years. Clinicians should be aware that the shortage may have caused an interruption in many vaccination schedules. As discussed for the Hib vaccine, cost will be the rate-limiting factor in developing countries.

ANATOMY AND PHYSIOLOGY OF THE CENTRAL NERVOUS SYSTEM

MENINGES

The skull and vertebrae protect the CNS from blunt or penetrating trauma (Fig. 105–1). The brain is suspended in these structures by cerebrospinal fluid (CSF) and is surrounded by the meninges. The meninges are made up of three separate membranes: dura mater, arachnoid, and pia mater.⁹ Dura mater, or pachymeninges, lies directly beneath and is adherent to the skull. The other two membranes are referred to collectively as *leptomeninges*. Pia mater lies directly over brain tissue. Arachnoid, the middle layer, lies between the dura mater and the pia mater. The subarachnoid space, located between the arachnoid and the pia mater, is the conduit for CSF. By definition, meningitis refers to inflammation of the subarachnoid space or spinal fluid, whereas encephalitis is an inflammation of the brain

FIGURE 105–1. Diagram of the central nervous system.

itself. Since infectious microorganisms frequently are an underlying cause of these inflammatory processes, the terms *meningitis* and *encephalitis* frequently are used to denote an infectious process. The decision regarding the diagnosis of meningoencephalitis depends on radiographic, laboratory, and clinical information but would refer to inflammation of both tissue and fluid.

CEREBROSPINAL FLUID

Approximately 85% of the CSF is produced within the third, fourth, and lateral ventricles by the choroid plexus (see Fig. 105–1). CSF volume in the CNS is related to patient age: Infants have approximately 40 to 60 mL of CSF, older children have 60 to 100 mL, and adults have 110 to 160 mL. Normally, CSF is produced at the rate of approximately 500 mL/day and flows unidirectionally downward through the spinal cord. The CSF is removed by the arachnoid villi and vertebral venous plexus located in the spinal cord and does not communicate with the point of production.⁹

The CSF normally is clear, with a protein content of less than 50 mg/dL, a glucose concentration of approximately 50% to 66% of the simultaneous peripheral serum glucose concentration, and a pH of approximately 7.4; also, it typically contains fewer than five white blood cells (WBCs) per cubic millimeter, all of which should be lymphocytes (Table 105–1). As meninges become inflamed, the constituency of the CSF will change, and these changes can be used diagnostically as markers of infection.

BLOOD-BRAIN BARRIER/BLOOD-CSF BARRIER

Natural barriers to the exchange of drugs and endogenous compounds among the blood, brain, and CSF are the blood-brain barrier (BBB) and the blood-CSF barrier (BCSFB) (Fig. 105–2). The BBB consists of tightly joined capillary endothelial cells. Drug entry into brain tissue is accomplished by direct passage through the capillary

TABLE 105-1. Mean Values of the Components of Normal and Abnormal Cerebrospinal Fluid

| Type | Normal | Bacterial | Viral | Fungal | Tuberculosis |
|------------------------------|---------------------------------------|---|-------------------|------------------|--------------------|

endothelial cells and further penetration of the glial cells that envelop the capillary structure.⁹

Passage of drugs into the CSF is controlled by the BCSFB. This barrier is created by ependymal cells of the choroid plexus, which function as an active transport system similar to the renal tubular epithelial cells. The inflammatory process associated with meningitis inhibits the active transport system of the choroid plexus.¹⁰ As in the active transport system in the kidney, the secretion of substances out of the choroid plexus also can be inhibited by the administration of probenecid.⁹

PATHOPHYSIOLOGY OF THE CNS INFECTION

The development of bacterial meningitis occurs following bacterial invasion of the host and CNS, bacterial multiplication with subsequent inflammation of the CNS, specifically the subarachnoid space and the ventricular space, pathophysiologic alterations owing to progressive inflammation, and the resulting neuronal damage.¹¹ The critical first

step in the acquisition of acute bacterial meningitis is nasopharyngeal colonization of the host. Immunoglobulins (Igs) such as secretory IgA are found in high concentrations within nasopharyngeal secretions and work to inhibit bacterial colonization. However, the mucus barrier is deteriorated by IgA proteases secreted by the bacteria, which then extend pili that allow adherence to the host cell surface receptors.¹² Bacterial pathogens attach themselves to nasopharyngeal epithelial cells and are phagocytized into the host’s bloodstream. After accessing the patient’s bloodstream, bacteria must overcome the host’s defense mechanisms.¹ Commonly, CNS bacterial pathogens will produce an extensive polysaccharide capsule resistant to neutrophil phagocytosis and complement opsonization. *H. influenzae*, *Escherichia coli*, and *N. meningitidis* strains lacking polysaccharide capsules are unable to cause meningitis. Capsular polysaccharides activate the alternate complement pathway, which promotes phagocytosis and clearance of infecting pathogens. Patients unable to activate the alternative complement pathway, such as asplenic and sickle cell patients, are predisposed to bacterial infections caused by encapsulated microorganisms and therefore are at risk for meningitis.

Although the exact site and mechanism of bacterial invasion into the CNS is unknown, studies suggest that invasion into the subarachnoid space occurs by continuous exposure of the CNS to large bacterial inocula. Bacteremia with inoculum densities of at least 10³ colony-forming units (CFU)/mL appears to be essential for subarachnoid space invasion.⁴ Although several sites of bacterial invasion have been theorized, the most plausible sites are the choroid plexus and/or the cerebral microvasculature. Recent studies have delineated the pathophysiology of *E. coli* meningitis, showing that successful translocation of *E. coli* across the BBB requires a high bacterial inoculum, *E. coli* binding to and invading the brain microvascular endothelial cells through specific ligand-receptor interactions, host cytoskeletal reorganization, and activation of various signaling pathways.⁴ Host defense mechanisms within the subarachnoid space are inadequate to combat bacterial pathogens; bacteria, therefore, replicate freely within the CSF until either overgrowth occurs or an effective antibiotic regimen is administered that terminates the process.

The effects of meningitis, namely, inflammation within the subarachnoid space and the ensuing neurologic damage, are not a direct result of the pathogens themselves. The neurologic sequelae occur owing to the activation of the host’s inflammatory pathways, which is induced by the pathogens or their products.² Bacterial cell death can cause the release of cell wall components, such as lipopolysaccharide (LPS), lipid A (endotoxin), lipoteichoic acid, teichoic acid, and peptidoglycan, depending on whether the pathogen is gram-positive or gram-negative (Fig. 105-3). These cell wall components cause

FIGURE 105-2. Schematic representation of a blood–cerebrospinal fluid barrier capillary, brain tissue capillary, and normal tissue capillary (below).

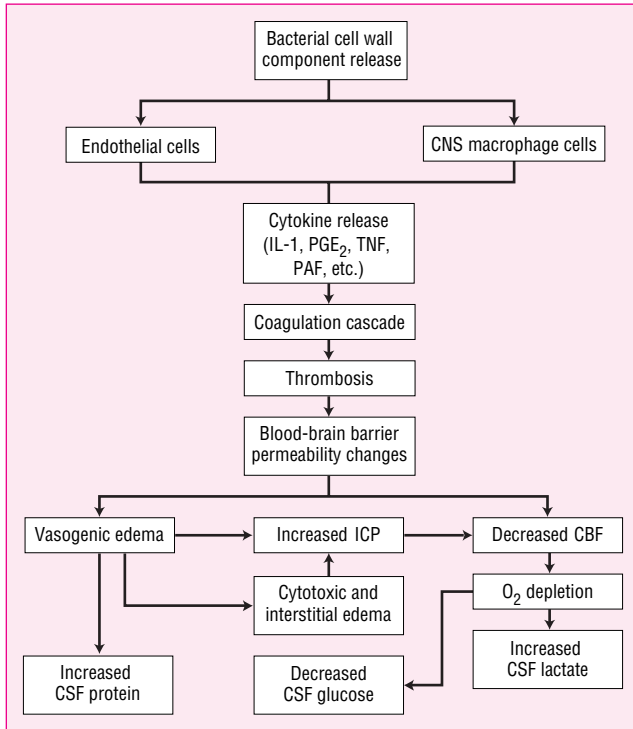

FIGURE 105-3. Hypothetical schema of pathophysiological events that occur during bacterial meningitis. IL-1 = interleukin 1; TNF = tumor necrosis factor; PAF = platelet-activating factor; CBF = cerebral blood flow; CSF = cerebrospinal fluid; PGE₂ = prostaglandin E₂; ICP = intracranial pressure.

capillary endothelial cells and CNS macrophages to release cytokines (interleukin 1 [IL-1] and tumor necrosis factor [TNF]) and other inflammatory mediators (IL-6, IL-8, platelet-activating factor [PAF], nitric oxide, arachadonic acid metabolites [e.g., prostaglandin and prostacycline], and macrophage-derived proteins). Proteolytic products and toxic oxygen radicals are released from the capillary endothelium, causing an alteration in the permeability of the BBB. PAF activates the coagulation cascade, and arachidonic acid metabolites stimulate vasodilation. These events propagate other sequential events that lead to cerebral edema, elevated intracranial pressure (ICP), CSF pleocytosis, decreased cerebral blood flow, cerebral ischemia, and death.²

FIGURE 105-5. Kernig's sign. (A) Knees are raised to form a 90-degree angle relative to the trunk, and the examiner attempts to extend the knees. (B) Once the knee reaches approximately 135 degrees, contracture or extensor spasm occurs.

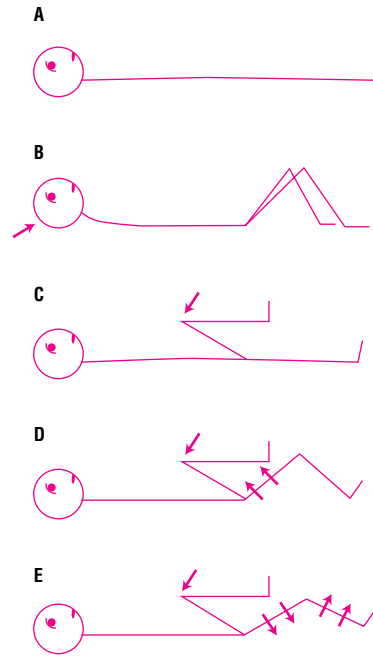

FIGURE 105-4. (A,B) Brudzinksi's neck signs. Hip and knee flexion occurs as a result of flexion of the neck (B). (C–E) Brudzinksi's leg signs. (C) Patient's leg is flexed by examiner (arrow). (D) The contralateral leg begins to flex—identical contralateral sign (arrows). (E) The contralateral leg now begins to extend spontaneously, resembling a little kick (arrows).

CLINICAL PRESENTATION AND DIAGNOSIS

CLINICAL PRESENTATION OF ACUTE MENINGITIS

GENERAL

- Clinical presentation varies with age, and generally, the younger the patient, the more atypical and the less pronounced is the clinical picture.
- Up to 50% of patients may receive antibiotics before a diagnosis of meningitis is made, delaying presentation to the hospital. Prior antibiotic therapy may cause the Gram stain and CSF culture to be negative, but the antibiotic therapy rarely affects CSF protein or glucose.¹³

SIGNS AND SYMPTOMS

- Classic signs and symptoms include fever, chills, vomiting, photophobia, severe headache, and nuchal rigidity associated with Kernig's and Brudzinksi's signs (Figs. 105-4 and 105-5). Kernig's and Brudzinksi's signs are poorly sensitive and frequently are absent in children.^{13,14}
- Other signs and symptoms include irritability, delirium, drowsiness, lethargy, and coma.
- Clinical signs and symptoms in young children may include bulging fontanelle, apneas, purpuric rash, and convulsions in addition to those just mentioned.¹³
- Seizures occur more commonly in children (20% to 30%) than in adults (0% to 12%).¹⁵

DIFFERENTIAL SIGNS AND SYMPTOMS²

- Purpuric and petechial skin lesions typically indicate meningococcal involvement, although the lesions may be present with *H. influenzae* meningitis. Rashes rarely occur with pneumococcal meningitis.
- Waterhouse-Friderichsen syndrome, a rapid eruption of multiple hemorrhagic lesions associated with a shocklike state, is associated with meningococcal meningitis.
- *H. influenzae* meningitis and meningococcal meningitis both can cause involvement of the joints during the illness.
- A history of head trauma with or without skull fracture or presence of a chronically draining ear is associated with pneumococcal involvement.

LABORATORY TESTS

- Several tubes of CSF are collected via lumbar puncture for chemistry, microbiology, and hematology tests. Theoretically, the first tube has a higher likelihood of being contaminated with both blood and bacteria during the puncture, although the total volume is more important in practice than the tube cultured. CSF should not be refrigerated or stored on ice.¹⁶
- Analysis of CSF chemistries typically includes measurement of glucose and total protein concentrations. An elevated CSF protein of 100 mg/dL or greater and a CSF glucose concentration of less than 50% of the simultaneously obtained peripheral value suggest bacterial meningitis (see Table 105–1).
- The values for CSF glucose, protein, and WBC concentrations found with bacterial meningitis overlap significantly with those for viral, tuberculous, and fungal meningitis (see Table 105–1). Therefore, CSF WBC counts and CSF glucose and protein concentrations cannot always distinguish the different etiologies of meningitis.

OTHER DIAGNOSTIC TESTS¹⁶

- Blood and other specimens should be cultured according to clinical judgment because meningitis frequently can arise via hematogenous dissemination or can be associated with infections at other sites. A minimum of

20 mL of blood in each of two to three separate cultures per each 24-hour period is necessary for the detection of most bacteremias.

- **3** Gram stain and culture of the CSF are the most important laboratory tests performed for bacterial meningitis. The Gram stain continues to be the most rapid and accurate method of presumptively diagnosing acute bacterial meningitis. When performed before antibiotic therapy is initiated, Gram stain is both rapid and sensitive and can confirm the diagnosis of bacterial meningitis in 75% to 90% of cases. The sensitivity of the Gram stain decreases to 40% to 60% in patients receiving prior antibiotic therapy. Culture is required to differentiate the various bacterial etiologies.
- Polymerase chain reaction (PCR) techniques can be used to diagnose meningitis caused by *N. meningitidis*, *S. pneumoniae*, and Hib. PCR is considered to be highly sensitive, but use of this diagnostic approach is limited owing to expense.
- Latex fixation, latex coagglutination, and enzyme immunoassay (EIA) tests provide for the rapid identification of several bacterial causes of meningitis, including *S. pneumoniae*, *N. meningitidis*, and Hib.¹³ Rapid-identification latex tests work by bringing potential capsular antigens of the pathogen causing meningitis in contact with a specific antibody, causing an antigen-antibody reaction. This capsular antigen-antibody reaction can be observed visually and quickly without waiting for culture results. The rapid antigen tests should be used in situations in which the Gram stain is negative.¹⁵ The sensitivity and specificity of latex fixation and coagglutination tests can vary with the manufacturer of the antibody, density of the antigen present in the CSF, and pathogen being tested.
- Diagnosis of tuberculosis meningitis employs acid-fast staining, culture, and PCR of the CSF.
- PCR testing of the CSF is the preferred method of diagnosing most viral meningitis infections.
- The standard diagnostic tests for fungal meningitis include culture, direct microscopic examination of stained and unstained specimens of CSF, antigen detection of cryptococcal or histoplasmal antigens, and antibody assay of serum and/or CSF.

► TREATMENT: CNS Infections**■ DESIRED OUTCOME**

The importance of supportive care, particularly early in the course of treatment, cannot be emphasized enough. Administration of fluids, electrolytes, antipyretics, analgesics, and other supportive measures is indicated for patients presenting with acute bacterial meningitis. Although supportive care is important initially, appropriate antibiotic therapy (empirical or definitive) should be started as soon as possible.

4 Understanding antibiotic selection and the issues surrounding antibiotic penetration will assist in meeting the goals of treatment, which include eradication of infection with amelioration of signs and symptoms and prevention of neurologic sequelae, such as seizures, deafness, coma, and death.

■ APPROACH TO TREATMENT

This section discusses issues surrounding the approach to treatment, such as antibiotic penetration within the CNS, duration of antibiotic therapy, and the use of adjunctive steroids. Until a pathogen is identified, prompt empirical antibiotic coverage is often needed.

5 Based on the patient's profile (i.e., allergies, age, and concurrent medical conditions), extent of antibiotic CNS penetration, and spectrum of activity, appropriate recommendations can be made, and therapy should last at least 48 to 72 hours or until the diagnosis of **6** bacterial meningitis can be ruled out (Tables 105–2 and 105–3). The first dose of antibiotics should not be withheld even if there is a delay in doing a lumbar puncture. Changes in the

TABLE 105–2. Bacterial Meningitis: Most Likely and Empirical Therapy by Age Group

| Age Commonly Affected | Most Likely Organisms | Empirical Therapy | Risk Factors for All Age Groups |
|-----------------------|--|--|---|
| Newborn–1 month | Gram-negative enterics ^a Group B <i>Streptococcus</i> <i>Listeria monocytogenes</i> | Ampicillin + cefotaxime or ceftriaxone or aminoglycoside | Respiratory tract infection Otitis media Mastoiditis Head trauma Alcoholism High-dose steroids |
| 1 month–4 years | <i>H. influenzae</i> <i>N. meningitidis</i> <i>S. pneumoniae</i> | Cefotaxime or ceftriaxone and vancomycin ^b | Splenectomy Sickle cell disease Immunoglobulin deficiency |
| 5–29 years | <i>N. meningitidis</i> <i>S. pneumoniae</i> <i>H. influenzae</i> | Cefotaxime or ceftriaxone and vancomycin ^b | Immunosuppression |
| 30–60 years | <i>S. pneumoniae</i> <i>N. meningitidis</i> | Cefotaxime or ceftriaxone and vancomycin ^b | |
| >60 years | <i>S. pneumoniae</i> Gram-negative enterics <i>L. monocytogenes</i> | Ampicillin + cefotaxime or ceftriaxone or aminoglycoside and vancomycin ^b | |

^a*Escherichia coli*, *Klebsiella* spp., *Enterobacter* spp. common.
^bVancomycin use should be based on local incidence of penicillin-resistant *S. pneumoniae* and until cefotaxime or ceftriaxone minimum inhibitory concentration results are available.

TABLE 105–3. Penetration of Antimicrobial Agents into the Cerebrospinal Fluid

| Therapeutic Levels in CSF with or without Inflammation | |
|---|---|
| Sulfonamides | Trimethoprim |
| Choramphenicol | Isoniazid |
| Rifampin | Pyrazinamide |
| Ethionamide | Cycloserine |
| Metronidazole | |
| Therapeutic Levels in CSF with Inflammation of Meninges | |
| Penicillin G | Ampicillin ± sulbactam |
| Carbenicillin | Ticarcillin ± clavulanic acid |
| Nafcillin | Mezlocillin |
| Piperacillin | Cefuroxime |
| Cefotaxime | Ceftizoxime |
| Ceftriaxone | Ceftazidime |
| Imipenem | Aztreonam |
| Meropenem | Ofloxacin |
| Vancomycin | Ciprofloxacin |
| Vidarabine | Ethambutol |
| Flucytosine | Fluconazole |
| Pyrimethamine | Ganciclovir |
| Acyclovir | Foscarnet |
| Linezolid | Quinupristin/dalfopristin |
| Colistin | |
| Nontherapeutic Levels in CSF with or without Inflammation | |
| Aminoglycosides | First-generation cephalosporins |
| Cefoperazone | Second-generation cephalosporins ^a |
| Clindamycin ^b | Ketoconazole |
| Amphotericin B | Itraconazole ^c |

^aCefuroxime is an exception.
^bAchieves therapeutic brain tissue concentrations.
^cAchieves therapeutic concentrations for *Cryptococcus neoformans* therapy. CSF = cerebrospinal fluid.

CSF after antibiotic administration usually take 12 to 24 hours. Continued therapy should be based on the assessment of clinical improvement, cultures, and susceptibility testing results. Once a pathogen is identified, antibiotic therapy should be tailored toward the specific pathogen (Tables 105–4 and 105–5). Throughout the course of treatment, various efficacy parameters, such as signs and symptoms, microbiologic findings, and CSF examination, should be followed to evaluate the success of meeting the desired outcomes.

Several factors influence the transfer of antibiotic from capillary blood into the CNS, including inflammation of the meninges, which increases antibiotic penetration through damage to tight junctions between capillary endothelial cells and decreases the activity of an energy-dependent efflux pump in the choroid plexus responsible for movement of penicillins and, to a much lesser extent, fluoroquinolones and aminoglycosides (see Table 105–3). Antibiotics having low molecular weights are passed more easily through biologic barriers than compounds of higher molecular weight. Only antibiotics that are nonionized at physiologic or pathologic pH are capable of diffusion. Highly lipid-soluble compounds penetrate more readily than water-soluble compounds. Antibiotics not extensively protein bound in the serum provide a larger free fraction of drug capable of passing into the CSF. Passage of large, polar antibiotics into the CSF may be assisted, however, by a carrier transport system. Unlike the treatment of many other infections, antibiotic dosages in the treatment of CNS infections must be maximized to optimize penetration to the site of infection.

Problems of CSF penetration may be overcome by direct instillation of antibiotics intrathecally, intracisternally, or intraventricularly (Table 105–6). Advantages of direct instillation, however, must be weighed against the risks of invasive CNS procedures. Intrathecal administration of antibiotics is unlikely to produce therapeutic concentrations in the ventricles possibly owing to the unidirectional flow of CSF.¹⁷ Although intraventricular administration from a

^eMonitor drug levels in serum.

therapeutic standpoint may be preferred over intrathecal administration, the former requires neurosurgical placement of a subcutaneous reservoir. Intraventricular delivery may be necessary when bacteria that require treatment with aminoglycosides, such as *L. monocytogenes*, *Pseudomonas aeruginosa* or enterococci, are isolated. In a review of antibiotic-induced endotoxin release, children receiving both parenteral antibiotics and intrathecal gentamicin had higher CSF endotoxin levels, higher CSF IL-1 β levels, and higher mortality than children receiving only parenteral antibiotics.¹⁸ Interestingly, the differences were attributed to direct CSF administration of gentamicin, which generally is thought to blunt the endotoxin release caused by β -lactam antibiotics.¹⁸

8 Although the length of treatment for bacterial meningitis generally is based on the causative organism, there is no universally accepted standard. Traditionally, meningitis caused by *S. pneumoniae* and *H. influenzae* has been treated successfully with 10 to 14 days of antibiotic therapy. Meningitis caused by *N. meningitidis* usually can be treated with a 7-day course of antibiotics. In contrast, a longer duration of 14 to 21 days has been recommended for patients infected with *L. monocytogenes* or group B streptococci because of a high probability of relapse. Likewise, a minimum of 3 weeks of treatment is recommended for meningitis caused by gram-negative bacilli.¹³ Therapy should be individualized, and some patients may require longer courses.

CAUSATIVE AGENTS

N. MENINGITIDIS (MENINGOCOCCUS)

N. meningitidis is the leading cause of bacterial meningitis in children and young adults in the United States, with the highest prevalence in those aged less than 2 years.¹⁹ The source of infection usually is an asymptomatic carrier. Most cases occur in the winter or spring at a time when viral meningitis is relatively uncommon. Five serogroups of *N. meningitidis* (A, B, C, Y, and W-135) are primarily responsible. Clusters of meningococcal disease, defined as two or more cases of the same serogroup that are closer in time and space than expected for the population or group under observation, generally are associated with schools.²⁰ Although some of these clusters have been due to serogroup B, the majority have been due to serogroup C. Serogroup A, although associated with meningococcal outbreaks in Africa and Asia, is a rare cause of disease in the United States.²¹ Serogroup Y, although frequently associated with pneumonia, is emerging as an important cause of invasive meningococcal disease in select areas.^{22,23} Overall, *N. meningitidis* accounts for 25% of all meningitis cases, 60% of cases in persons aged 2 to 18 years, and carries a case-fatality rate of approximately 10%.^{8,22}

Initially, patients are colonized and, at some point, develop a bacteremia, which most likely occurs prior to hospital admission.

TABLE 105–5. Antimicrobial Agents of First Choice and Alternative Choice in the Treatment of Meningitis Caused by Gram-Negative Microorganisms

^aRecommended doses for adults and pediatric patients with normal renal and/or hepatic function.
^bPediatrics.
^cDirect central nervous system administration may be added; see Table 105–6 for dosage.
^dShould be reserved for multidrug-resistant pseudomonal or *Actinobacter* infections for which all other therapeutic options have been exhausted.
^eMonitor drug levels in serum.

Meningitis occurs after the bacteria seeds into the meninges, which can occur in 50% of the cases of meningococcal disease.²⁴ After the acute phase of meningitis has resolved, there is a unique immune reaction that distinguishes meningococcal meningitis from other bacterial causes. The patient develops a characteristic immunologic reaction of fever, arthritis (usually involving large joints), and pericarditis approximately 10 to 14 days after the onset of disease and despite successful treatment.²⁵ At this time, examination of the synovial fluid will reveal a large number of polymorphonuclear cells, elevated protein concentrations, normal glucose concentrations, and sterile cultures. The reaction may last a week or longer, and no additional antibiotic therapy is required. Patients, however, may benefit from nonsteroidal anti-inflammatory agents and supportive care.²⁵

Seizures and coma are uncommon with meningococcal meningitis. Patients may behave aggressively, however, and often are manic. Patients may develop deafness and transiently impaired ocular movements. Deafness unilaterally or, more commonly, bilaterally may develop early or late in the disease course.²⁵ Hearing loss secondary to sensory nerve damage (sensorineural hearing) is usually permanent, whereas conductive hearing impairment, such as damage to the tympanic membrane, often is reversible.

The presence of petechiae may be the primary clue that the underlying pathogen is *N. meningitidis*. Approximately 50% of patients with meningococcal meningitis have purpuric lesions, petechiae, or both. Patients may have an obvious or subclinical picture of disseminated intravascular coagulation (DIC), which may progress to

TABLE 105–6. Intraventricular and Intrathecal Antibiotic Dosage Recommendation

| Antibiotic | Dose (mg) | Expected CSF Concentration ^a (mg/L) | Reference |
|---------------------------|--|--|---------------|
| Ampicillin | 10–50 | 60–300 | 104–106 |
| Methicillin | 25–100 | 160–600 | 104–106 |
| Nafcillin | 75 | 500 | 105 |
| Cephalothin | 25–100 | 160–600 | 104–106 |
| Chloramphenicol | 25–100 | 160–600 | 104, 106, 107 |
| Gentamicin | 1–10 | 6–60 | 104–108 |
| Quinupristin/dalfopristin | 1–2 | 7–13 | 109 |
| Tobramycin | 1–10 | 6–60 | 108 |
| Vancomycin | 5 | 30 | 110–112 |
| Amphotericin B | 0.05–0.25 mg/d to 0.05–1 mg 1–3 times weekly | — | 113 |

^aAssumes adult CSF volume = 150 mL. CSF = cerebrospinal fluid.

infarction of the adrenal glands and renal cortex and cause widespread thrombosis.

Aggressive, early intervention with high-dose intravenous crystalline penicillin G, 50,000 units/kg every 4 hours, is usually recommended for the treatment of *N. meningitidis* meningitis. Chloramphenicol is bactericidal for *N. meningitidis* and may be used in place of penicillin G. However, chloramphenicol has unpredictable metabolism in young infants and several drug-drug interactions and is used rarely in developed countries.² Chloramphenicol frequently is used as initial empirical therapy for meningitis in developing countries owing to the low cost. Several third-generation cephalosporins (i.e., cefotaxime, ceftazidime, ceftizoxime, ceftriaxone, and cefuroxime) have indications for the treatment of meningitis and are acceptable alternatives to penicillin G (see Table 105–5).

Cases of meningitis caused by relatively (minimum inhibitory concentration [MIC] 0.1–1 mg/L) and highly (MIC \geq 256 mg/L) penicillin-resistant meningococci have been reported. Prevalence varies geographically, ranging from 0.4% to 42.6%.²⁶ Isolated reports of treatment failure with penicillin have surfaced in recent years.^{27,28} Completely resistant strains produce β -lactamase, whereas relatively resistant strains have an alteration of penicillin-binding proteins. In 1991, strains with altered penicillin-binding proteins represented approximately 4% of meningococcal isolates in the United States.²¹ Resistance patterns of meningococci may necessitate a change away from penicillin as the antibiotic treatment of choice for meningococcal meningitis, and some authorities recommend using a third-generation cephalosporin (cefotaxime or ceftriaxone) instead of penicillin for meningococcal meningitis.²⁹

N. meningitidis is spread by direct person-to-person close contact, including respiratory droplets and pharyngeal secretions.²⁴ Close contacts of patients contracting *N. meningitidis* meningitis are at an increased risk of developing meningitis. Close contacts include day-care center contacts, members of the household, or anyone who has been exposed to respiratory or oral secretions through activities such as coughing, sneezing, or kissing.²⁴ Household contacts of people who have sporadic disease are estimated to have an incidence of meningococcal meningitis that is 500 to 800 times greater than that of the overall population.²⁴ Secondary cases of meningitis usually develop within the first week following exposure, but they may take up to 60 days after contact with the index case.³⁰ Young children are at the greatest risk of contracting *N. meningitidis*; however, all ages are at risk, especially close contacts exposed via household, day-care, or military contact.

9 Prophylaxis of close contacts should be started only after consultation with the local health department. In general, rifampin is given as prophylaxis for 2 days.²¹ The adult dose is 600 mg every 12 hours, whereas children aged 1 month and older should receive 10 mg/kg, and children younger than 1 month should receive 5 mg/kg. Intramuscular ceftriaxone (250 mg in adults, 125 mg in children younger than 12 years of age) and oral ciprofloxacin (500 mg in adults and children older than 12 years) are alternatives to rifampin.¹³ Further discussion of who should receive prophylaxis is beyond the scope of this chapter; interested readers can refer to the recommendations of the U.S. Centers for Disease Control and Prevention for that information.³¹

■ *S. PNEUMONIAE* (PNEUMOCOCCUS OR DIPLOCOCCUS)

S. pneumoniae is the leading cause of meningitis in adults. Moreover, *S. pneumoniae* is the most common cause of bacterial meningitis in children younger than 2 years of age, accounting for 45 to 145 cases

per 100,000 of this population, and the second most common cause in children older than 2 years of age.³² Case-fatality rates in children are highest with this organism and approach 20%. Approximately 50% of cases are secondary infections resulting from primary infections of parameningeal foci, such as the ear or paranasal sinuses. Pneumonia, endocarditis, CSF leak secondary to head trauma, splenectomy, alcoholism, sickle cell disease, and bone marrow transplantation may predispose the patient to the development of pneumococcal meningitis.

Neurologic complications, such as coma and seizures, are common with pneumococcal meningitis. Children with pneumococcal meningitis have lower mortality rates (4% to 17%) compared with the mortality rates in adults (20% to 30%), but children who survive suffer from a high rate of neurologic sequelae (29% to 56%).^{33,34} Risk factors for recurrent pneumococcal meningitis include traumatic tears of the dura, fracture of the cribriform plate or paranasal sinuses, nasal meningoceles, repeated episodes of otitis media, basilar skull fractures, and CSF leaks. The prognosis of pneumococcal meningitis depends on a variety of factors, including the number of WBCs in the CSF, the number of WBCs in the periphery, the CSF glucose concentration, the CSF protein concentration, the serum sodium concentration, and the presence of a comatose state and/or shock.³⁵

Treatment with intravenous crystalline penicillin G (50,000 units/kg every 4 hours) in adult patients with a penicillin-susceptible isolate and normal renal function usually results in a favorable outcome. However, the frequency of penicillin-resistant pneumococcal strains (MIC \geq 2 mg/L) in the United States increased from 14% in 1994 to 25% in 1997 and continues to rise.²⁹ Based on these resistance patterns and the fact that sufficient CSF concentrations of penicillin are difficult to achieve with standard intravenous doses, penicillin should not be used as empirical therapy if *S. pneumoniae* is a suspected pathogen. Furthermore, appropriate National Committee for Clinical Laboratory Standards (NCCLS)-approved testing of all CSF isolates for penicillin resistance is recommended. Ceftriaxone and cefotaxime have served as alternatives to penicillin in the treatment of penicillin intermediate- and high-resistant pneumococci. Of note, treatment failures with third-generation cephalosporins in the management of penicillin-resistant pneumococci have been reported.²⁹ Therapeutic approaches to cephalosporin-resistant pneumococcus include the addition of vancomycin and rifampin, which have demonstrated synergistic activity with ceftriaxone. However, no data from controlled clinical trials supporting the use of rifampin are available. Therefore, the combination of vancomycin and ceftriaxone has been suggested as empirical treatment until the results of antimicrobial susceptibility testing are available.^{2,29} Some investigators have suggested that the addition of vancomycin to the initial empirical regimen may not be necessary because the prevalence of β -lactam-resistant pneumococci has been reduced greatly as a result of the pneumococcal vaccines.²

Ceftriaxone and vancomycin are the agents of choice to treat presumed pneumococcal meningitis empirically until the susceptibility is known. Penicillin may be used for drug-susceptible isolates with MICs of 0.06 mg/L or less, but for intermediate isolates, ceftriaxone is used, and for highly drug resistant isolates, a combination of ceftriaxone and vancomycin should be used. Vancomycin should not be used as monotherapy.²⁹ In especially severe cases, therapeutic drug monitoring of the CSF and possibly even direct antibiotic instillation may be necessary.

Recent reports of the isolation of pneumococcal strains exhibiting tolerance to vancomycin are of great concern, but the clinical significance is unknown.^{36,37} Based on concern about the limited therapeutic options for penicillin- and cephalosporin-resistant pneumococcal meningitis, newer agents have been evaluated. Meropenem is approved by the Food and Drug Administration (FDA) for the treatment of bacterial meningitis in children aged 3 months and older

and has shown similar clinical and microbiologic efficacy to cefotaxime or ceftriaxone. Some concern is warranted with the use of imipenem for CNS infections because of the possibility of drug-induced seizures, especially if the dose is not adjusted for renal function. Of note, seizures may be caused by meningitis itself or by imipenem, and the cause is difficult to differentiate. The newer fluoroquinolones represent another therapeutic option owing to favorable activity against multidrug-resistant pneumococci and good penetration into the CSF.³⁸ However, clinical data to date regarding fluoroquinolone treatment of pneumococcal meningitis are limited mainly to animal models. Comparative, controlled clinical efficacy trials in patients with meningitis will be necessary before routine use of the fluoroquinolones is viable. Interestingly, some of the newer fluoroquinolones act synergistically with vancomycin and β -lactam antibiotics against penicillin-resistant pneumococcal meningitis in an animal model, but this claim has not been substantiated in humans.^{29,39} Quinupristin-dalfopristin, linezolid, and daptomycin have emerged as therapeutic options for treating multidrug-resistant gram-positive infections. However, limited data are available, and these agents cannot be recommended for use in the treatment of pneumococcal meningitis.

CLINICAL CONTROVERSY

Some investigators believe that the use of vancomycin in the empirical treatment of pneumococcal meningitis is no longer necessary owing to the great reduction in the prevalence of β -lactam-resistant pneumococci because of the widespread use of the pneumococcal vaccines. However, because the infecting organism is rarely known initially, most clinicians still use the combination of a third-generation cephalosporin and vancomycin for empirical treatment.

The available pneumococcal vaccines help in reducing the risk of invasive pneumococcal disease. Virtually all serotypes of *S. pneumoniae* exhibiting intermediate or complete resistance to penicillin are found in the 23-serotype pneumococcal polysaccharide vaccine. However, in 1997, surveillance data indicated that only 30% of people 65 years of age and older had been immunized against pneumococcal disease.⁴⁰ Therefore, the CDC issued stronger recommendations for the use of the pneumococcal polysaccharide vaccine, calling for vaccination of the following high-risk groups: persons over the age of 65 years; persons aged 2 to 64 years who have a chronic illness, who live in high-risk environments (e.g., Alaskan Natives and residents of long-term care facilities), and who lack a functioning spleen (e.g., sickle cell disease and splenectomy); and immunocompromised persons over the age of 2 years, including those with HIV infection. Additionally, the question of whether or not college students living in dormitories, a possible high-risk environment, should be vaccinated remains debatable. Unfortunately, owing to variability in the host's ability to mount an immune response to the vaccine, the efficacy of this product in children younger than 2 years of age and immunocompromised adults limits the usefulness of the vaccine as a solution to the problem of penicillin-resistant pneumococci.

In 2000, a heptavalent pneumococcal conjugate vaccine (Prevnar) was approved for use in children 2 months of age and older. Use of the vaccine has been associated with a reduction of more than 90% in invasive pneumococcal infections, including sepsis and meningitis.⁴¹ Moreover, the vaccine is safe and effective in low-birth-weight and preterm infants.^{42,43} Widespread vaccination is expected to have a significant impact on the prevalence of pneumococcal meningitis, including infection caused by antibiotic-resistant strains. A cohort study of 3.8 million healthy infants projected that vaccination would

prevent more than 12,000 cases of invasive disease for each U.S. birth cohort, resulting in substantial decreases in morbidity and mortality, as well as possible dollar savings.⁴⁴ Current recommendations are for all healthy infants younger than 2 years of age to be immunized with the heptavalent vaccine at 2, 4, 6, and 12 to 15 months. The recommendations are extended to include Alaskan Native, Native American, and African-American children between the ages of 2 and 5 years. Recently, owing to the recognition that children with cochlear implants are at increased risk for the development of pneumococcal meningitis, the CDC has issued a recommendation that all persons with cochlear implants receive age-appropriate vaccination with the pneumococcal conjugate vaccine, pneumococcal polysaccharide vaccine, or both.⁴⁵

■ H. INFLUENZAE

In the past, *H. influenzae* was the most common cause of meningitis in children 6 months to 3 years of age. Since the introduction of effective vaccines, however, the incidence of *H. influenzae* type B disease in the United States has declined dramatically. Widespread vaccination of infants and children has decreased the incidence of bacterial meningitis due to *H. influenzae* in children between the ages of 1 month and 5 years by 87%, resulting in a 55% decline in all cases of bacterial meningitis.¹² Worldwide, in countries that have adopted universal immunization, the incidence of bacterial meningitis caused by *H. influenzae* type b has decreased more than 99%.² In children older than 3 years and adults, meningitis caused by *H. influenzae* may indicate a parameningeal focus of infection such as middle ear infection, paranasal sinus infection, or CSF leakage. Spread of the organism occurs either through direct spread from infected sinuses, draining of these areas via the veins, or bacteremia originating from the local focus of infection.⁴⁶

In the past, ampicillin and chloramphenicol were the drugs of choice to treat pediatric meningitis. However, since approximately 30% to 40% of *H. influenzae* are now ampicillin-resistant, many clinicians use a third-generation cephalosporin or the combination of chloramphenicol and ampicillin for initial antimicrobial therapy. If the organism is sensitive to ampicillin, the patient then can be switched from the third-generation cephalosporin to ampicillin, and chloramphenicol, if used initially, can be discontinued. Most clinicians regard third-generation cephalosporins as the drugs of choice for meningitis caused by *H. influenzae*. Third-generation cephalosporins (cefotaxime and ceftriaxone) are active against β -lactamase-producing and non- β -lactamase-producing strains of *H. influenzae*, are relatively free of toxicity, and do not require serum concentration monitoring. Serum concentration monitoring is required for chloramphenicol to avoid toxicity and subtherapeutic levels.

Secondary cases resulting from close contact with an index case occur within 30 days of the onset of disease. Close contacts, which include household members, individuals sharing sleeping quarters, day-care attendees, nursing home residents, and crowded, confined populations, may be at 200 to 1000 times the risk of the general population for acquiring *H. influenzae* meningitis.⁴⁷ The risk of acquiring *H. influenzae* meningitis is low without intimate contact with the index patient's respiratory secretions.⁴⁷

9 Prophylaxis is to protect close contacts from the index case by eliminating nasopharyngeal and oropharyngeal carriage of *H. influenzae*. Invasive disease should be reported to the local public health department and the CDC. Prophylaxis of close contacts should be started only after consultation with the local health department. In general, children should receive rifampin 20 mg/kg per day (maximum 600 mg) and adults 600 mg/day in one dose for

4 days.¹³ Any unvaccinated children between the ages of 12 and 48 months should receive one dose of the vaccine, whereas those between the ages of 2 and 11 months should be given three doses of the vaccine.¹³ Individuals fully vaccinated are not recommended to receive prophylaxis.²¹ Further discussion of who should receive prophylaxis is beyond the scope of this chapter; interested readers can refer to the recommendations of the American Academy of Pediatrics for that information.⁴⁸

Vaccination includes a series of doses and usually is begun in children at 2 months of age. In addition to pediatric immunization, the vaccine also should be considered in patients older than 5 years of age with the following underlying conditions: sickle cell disease, asplenia, and immunocompromising diseases. Refer to the Chap. 122 for further information on dosing and administration.

■ *L. MONOCYTOGENES*

L. monocytogenes is a gram-positive diphtheroid-like organism responsible for 8% of all reported cases of meningitis.⁸ This disease primarily affects neonates, alcoholics, immunocompromised adults, and the elderly. Infections caused by *Listeria* in healthy individuals are extremely rare. *L. monocytogenes* is implicated in 20% of meningitis cases in those older than 60 years of age and carries a case-fatality rate of approximately 15%.⁸

Transmission usually involves colonization of the patient's gastrointestinal (GI) tract with the organisms, which then penetrate the gut lumen. Coleslaw, unpasteurized milk, Mexican-style soft cheese, ready-to-eat foods, and raw beef and poultry all have been identified as sources of this food-borne pathogen.²¹ If a sufficient cell-mediated immune response (T-lymphocytes, macrophages) is not produced, bacteremia, meningitis, meningoencephalitis, or cerebritis may develop.⁴⁹ Infection of the CNS may be diffuse or localized, possibly involving the cerebral hemispheres, thalamus, and brain stem. In immunocompromised hosts, approximately 75% of *L. monocytogenes* infections result in transmission into the CNS.⁴⁹

Incidence of *L. monocytogenes* meningitis tends to peak in the summer and early fall. As with gram-negative meningitis, presentation may be subtle and insidious, and clinical suspicion should prompt lumbar puncture. *L. monocytogenes* produces primarily a mononuclear CSF response.⁴⁹ One common laboratory error seen with *L. monocytogenes* is a tendency to misidentify the organism on Gram stain as a diphtheroid, streptococcus, or a poorly staining gram-negative rod.

Treatment of *L. monocytogenes* meningitis with penicillin G or ampicillin may result in only a bacteriostatic effect and possible persistence of infection. Usually the combination of penicillin G or ampicillin with an aminoglycoside results in a bactericidal effect. Patients should be treated for 2 to 3 weeks after defervescence.¹³ Combination therapy usually is employed for at least 10 days, with the remaining course of therapy completed with penicillin G or ampicillin alone. Trimethoprim-sulfamethoxazole may be an effective alternative because adequate CSF penetration is achieved. Chloramphenicol and vancomycin both possess in vitro activity against *Listeria*, but they are not recommended for use in meningitis caused by *L. monocytogenes* owing to unacceptably high failure rates.²⁹ None of the cephalosporins is effective for *L. monocytogenes*.

■ GRAM-NEGATIVE MENINGITIS

During the last several years, the incidence of gram-negative bacillary meningitis, excluding *H. influenzae*, has been increasing in both

children and adults. Enteric gram-negative organisms are the fourth leading cause of meningitis, with only *S. pneumoniae*, *H. influenzae*, and *N. meningitidis* having a higher incidence.

Several factors predispose patients to the development of gram-negative meningitis: congenital defects involving the CNS, accidental cranial trauma, neurosurgery, the use of antimicrobial agents with exclusive gram-positive activity preoperatively in neurosurgery, any form of communication between the skin and subarachnoid space (such as a dermal sinus), diabetes, malignancy, urinary tract infection in neonates, cirrhosis, parameningeal infection, spinal anesthesia, advanced age, immunosuppression, and hospitalization in general.

Elderly debilitated patients are at an increased risk of gram-negative meningitis but typically lack the classic signs and symptoms of the disease. Nuchal rigidity may be difficult to detect secondary to cervical arthritis. Presence of a low-grade fever and changes in mental status without other obvious cause should prompt consideration of meningitis and a lumbar puncture. Neonates are also at risk for gram-negative meningitis with *E. coli* and *Klebsiella pneumoniae*, which are responsible for 60% to 70% of cases.

Optimal antimicrobial therapies for gram-negative bacillary meningitis have not been fully defined. The therapy of gram-negative meningitis is complex owing to the variety of organisms that can infect the CNS. The treatment of meningitis due to *P. aeruginosa* remains a unique problem because antibiotics showing good antibacterial activity against *P. aeruginosa*, such as antipseudomonal penicillins and aminoglycosides, penetrate the CSF poorly. Furthermore, many isolates of *P. aeruginosa* are resistant to multiple, if not all, commonly used agents, and this trend in resistance is increasing. Initially, cases of *P. aeruginosa* meningitis should be treated with an extended-spectrum β -lactam such as ceftazidime, cefepime, piperacillin, or meropenem plus an aminoglycoside, usually tobramycin.² Since aminoglycosides penetrate the CSF poorly, their inclusion is predominantly to aid in the treatment of extracerebral infections. If multidrug-resistant *Pseudomonas* is suspected initially, intraventricular administration of aminoglycoside should be considered along with intravenous administration. Preservative-free forms of gentamicin and tobramycin are available and should be used for direct administration into the CSF. Intraventricular aminoglycoside dosages should be adjusted to the estimated CSF volume (0.03 mg tobramycin or gentamicin per milliliter of CSF and 0.1 mg amikacin per milliliter of CSF every 24 hours). Since CSF flows unidirectionally with gravity, intraventricular aminoglycoside administration is more likely to produce therapeutic concentrations throughout the CSF than intrathecal administration.¹⁷ While intraventricular administration of aminoglycosides is considered for treatment of *P. aeruginosa* meningitis, this method produced higher mortality in a sample of infants treated for gram-negative bacillary meningitis.¹⁷ Thus intraventricular administration of aminoglycosides to infants is not recommended routinely. Ventricular levels of aminoglycoside should be monitored every 2 or 3 days, just prior to the next intraventricular dose, and should approximate 2–10 mg/L. Interpretation of drug levels may be difficult because determinations often are contaminated with residual aminoglycoside from the preceding dose.

A recent case report exhibited favorable effects of high-dose intravenous ciprofloxacin (400 mg every 8 hours) plus intravenous ceftazidime for pseudomonal meningitis.⁵⁰ However, this information must be evaluated in a controlled clinical trial before high-dose ciprofloxacin can be recommended for use.

Multidrug-resistant *Pseudomonas* and *Acinetobacter* infections are of concern to clinicians because of the limited therapeutic options available for the treatment of such infections. This concern has led

to the reemergence of older antibiotics, such as colistin. Limited data exist suggesting that colistin can be used, both intravenously and intrathecally, in the treatment of multidrug-resistant *Pseudomonas* or *Acinetobacter* CNS infections.^{51–53} Furthermore, recent in vitro data have suggested synergistic activity with the combination of colistin and ceftazidime against multidrug-resistant *P. aeruginosa*.⁵⁴ The use of colistin should be reserved for only the most severe cases.

Other gram-negative organisms causing meningitis, excluding *P. aeruginosa* and *Acinetobacter* spp., most likely can be treated with a third-generation cephalosporin, such as cefotaxime, ceftriaxone, or ceftazidime. Ceftazidime, however, may not be the best choice of empirical antibiotic for situations where the offending organism is not known initially because CSF antibiotic concentrations greater than 10 times the minimal bactericidal concentration (MBC) may not be produced reliably for gram-positive organisms. In adults, daily doses of 8 to 12 g/day of third-generation cephalosporins (2 g twice a day of ceftriaxone) should produce CSF concentrations of 5–20 mg/L. Ceftriaxone is not recommended for use in the neonatal period because of the potential for the displacement of bilirubin from albumin-binding sites.²

Trimethoprim-sulfamethoxazole is useful in the management of the Enterobacteriaceae family and also may be useful in the management of *L. monocytogenes*.^{2,6} One advantage of trimethoprim-sulfamethoxazole is that its penetration into the CSF does not depend on meningeal inflammation. Trimethoprim-sulfamethoxazole is not, however, bactericidal. Trimethoprim-sulfamethoxazole produces CSF levels of 1.9–5.7 mg/L for the former and 20–63 mg/L for the latter when given parenterally in doses of 10 mg/kg per day (trimethoprim) and 50 mg/kg per day (sulfamethoxazole).

Fluoroquinolones are not approved for the treatment of gram-negative bacterial meningitis, and clinical experience is minimal. Animal data have shown similar effectiveness between select newer fluoroquinolones and third-generation cephalosporins. Fluoroquinolones should be considered only when multidrug-resistant gram-negative rods are suspected.²⁹ Cefepime and meropenem represent other therapeutic options for the treatment of gram-negative bacterial meningitis, as does aztreonam.^{2,29}

CSF cultures may remain positive for several days or more with a regimen that eventually will be curative. Therapeutic efficacy can be monitored through bacterial colony counts every 2 or 3 days, which should decrease progressively over the period of therapy. Therapy for gram-negative meningitis should be continued for a minimum of 21 days from the start of treatment.¹³

■ BACILLUS ANTHRACIS

B. anthracis is a large, endospore-forming, aerobic, gram-positive bacteria capable of producing infection via the cutaneous, pulmonary, or GI routes. Cases of meningitis have been reported following both cutaneous and inhalational infection. Prior to the bioterrorism-related outbreak of 11 inhalational and 12 suspected or confirmed cases of cutaneous anthrax in 2001, a total of only 18 sporadic cases had occurred in the United States in the twentieth century, with the last occurrence in 1976.⁵⁵ However, since the terrorist attack on the United States on September 11, 2001, heightened awareness of biologic warfare agents, which include *B. anthracis*, has percolated throughout the United States.

The major neurologic complication of anthrax infection is fulminant, rapidly fatal hemorrhagic meningoencephalitis. The inhalational form of anthrax seems to be a potent inducer of neurologic symptoms, and death usually occurs within a week for those with neu-

rologic complications.⁵⁵ Neurologic manifestations may be the initial symptoms leading to the diagnosis of anthrax. An index case of fatal inhalational anthrax owing to bioterrorism developed acute fever, emesis, disorientation, and confusion. A head computed tomographic (CT) scan showed no abnormalities, but a Gram stain exhibited cloudy CSF, low CSF glucose concentration, high CSF protein concentration, increased leukocytes in the CSF, and large gram-positive bacilli in chains. Shortly thereafter, the patient developed a generalized seizure and died on the third hospital day.⁵⁶

Consistent findings in the CSF of anthrax meningitis cases include a low CSF glucose level, marked infiltration of WBCs into the CSF, and the presence of gram-positive bacilli in chains. High suspicion of anthrax meningitis is warranted in the additional presence of grossly visible blood or elevated red blood cell counts with hemorrhagic changes on a CT scan.⁵⁵ Recent molecular advances can aid in the rapid diagnosis of *B. anthracis* infections. Rapid PCR techniques, such as the Light Cycler (Roche Applied Science, Indianapolis, IN.), can produce molecular confirmation for the presence of anthrax within 1 hour.⁵⁵ Extreme caution is warranted for diagnosis without the use of molecular techniques because *B. anthracis* can be confused easily with *B. cereus*, which is found commonly in soil and often considered a contaminant if identified.

B. anthracis typically is susceptible to penicillin, amoxicillin, erythromycin, doxycycline, ciprofloxacin, and chloramphenicol. The bioterrorism-related strain was susceptible to the fluoroquinolones, rifampin, tetracycline, vancomycin, imipenem, meropenem, chloramphenicol, clindamycin, and the aminoglycosides. However, the strain was resistant to third-generation cephalosporins and trimethoprim-sulfamethoxazole.⁵⁵ Ciprofloxacin or doxycycline plus one or two of the aforementioned antibiotics is the currently recommended regimen for the treatment of inhalational anthrax, but doxycycline is not recommended for the treatment of anthrax meningitis owing to poor CNS penetration and recent in vitro resistance.⁵⁵

Clinicians must be aware that what we know now about biologic weapons may be helpful, but knowledge of natural disease may not reflect what could happen in biologic attacks. First, antibiotic susceptibility is a function of how the organism may or may not have been altered genetically. For example, anthrax could be manipulated genetically to be resistant to the commonly used agents. Second, the antibiotics used for biologic attacks may not have FDA indications for such uses, and many physicians may be placed under pressure to prescribe. Additionally, security issues may emerge for pharmacists and pharmacies and their antibiotic supply. Third, patient compliance will be important to ensure proper treatment and the prevention of resistance. Fourth, most metropolitan areas have a response plan, and clinicians should be aware of their role, if any. Lastly, be watchful, because many health care workers will be the first line of defense. Of note, the Web site of the Center for Infectious Disease Research and Policy (www.cidrap.umn.edu) provides a wealth of information regarding bioterrorism and is an up-to-date resource for clinicians.

■ Dexamethasone as an Adjuvant Treatment for Meningitis

In addition to antibiotics, dexamethasone has become a commonly used therapy for the treatment of pediatric meningitis.¹² Corticosteroids inhibit the production of both TNF and IL-1. A series of clinical studies assessing the efficacy of corticosteroid therapy for the initial treatment of bacterial meningitis has reported conflicting results.^{57–61} The majority of trials were conducted on small sample populations, each with different pathogenic bacterial causes and treatment modalities. The findings of several studies have shown significant

improvement in markers of active infection, such as CSF levels of proinflammatory cytokines, as well as CSF protein, glucose, and lactate concentrations, after corticosteroid administration as adjunctive treatment.¹²

Trials consistently detected a significantly lower incidence of neurologic sequelae commonly associated with bacterial meningitis with corticosteroid use. In trials that measured inflammatory mediators, lower levels of TNF, PAF, or IL-1 were detected in patients treated with dexamethasone.^{57,58,61} No study, however, has detected a significant difference in time to bacterial eradication. Only one study has detected a significant difference in mortality between patients treated with dexamethasone plus antibiotics and antibiotic therapy alone, favoring use of the corticosteroid.⁵⁹ Based on these investigations, some authors advocate all infants (>2 months of age) and children with suspected bacterial meningitis receive dexamethasone.^{57,58,60–62}

Data suggesting the use of corticosteroids in adults with meningitis is scarce. A recent prospective, randomized, double-blind multicenter study evaluated the use of adjuvant therapy plus dexamethasone compared with adjuvant therapy plus placebo in adults with acute bacterial meningitis.⁶³ The results showed that early treatment with dexamethasone improved clinical outcome in adults with bacterial meningitis, reducing the risk of both unfavorable outcome and death. However, the study did not show a beneficial effect of dexamethasone on neurologic sequelae, including hearing loss.

Routine use of dexamethasone in meningitis is not without controversy. A potential concern is that adjunctive dexamethasone therapy might reduce the penetration of antibiotics into the CSF by inhibiting meningeal inflammation. In experimental models of meningitis, steroids decreased the CSF concentrations of ampicillin, rifampin, vancomycin, and gentamicin.^{61,64} Ceftriaxone penetration into CSF was unaffected by concurrent dexamethasone administration in pediatric patients.⁶⁵

A fundamental problem with corticosteroid investigations to date is that the majority of patients in the trials had *H. influenzae* meningitis. While *H. influenzae* was the most commonly identified causative pathogen responsible for bacterial meningitis in the United States in 1986, the incidence of *H. influenzae* meningitis has decreased dramatically because of the introduction of polysaccharide conjugate vaccines. Additionally, the majority of studies examining dexamethasone use for pneumococcal meningitis were conducted before the widespread problem of penicillin-resistant pneumococcus had emerged. Whether or not steroids are beneficial in meningitis caused by penicillin-resistant *S. pneumoniae*, *N. meningitidis*, and group B streptococci is unclear at this time. A retrospective analysis of pediatric patients with pneumococcal meningitis and one unblinded, noncontrolled trial suggested that adjunctive steroids may decrease the neurologic sequelae and mortality associated with *S. pneumoniae* meningitis.^{57,66} A meta-analysis suggests that with the possible exception of hearing loss, dexamethasone does not protect against neurologic sequelae.⁶⁷ The protective effect of dexamethasone was observed to be strongest in those with meningitis due to *H. influenzae*.

The use of dexamethasone interferes with the interpretation of clinical response to treatment. For example, corticosteroid use interferes with the resolution of fever. Thus all infants and children are recommended to undergo a repeat lumbar puncture after 24 to 48 hours of treatment to verify CSF sterilization.¹²

◀ The American Academy of Pediatrics suggests that dexamethasone be considered for infants and children 2 months of age or older with pneumococcal meningitis and be given to those with *H. influenzae* meningitis.^{48,68} The commonly used intravenous dose is 0.15 mg/kg every 6 hours for 4 days. Alternatively, prospective, randomized, double-blind studies have found dexamethasone 0.15 mg/kg

every 6 hours for 2 days or dexamethasone 0.4 mg/kg every 12 hours for 2 days to be equally effective and potentially less toxic.^{61,69} Dexamethasone should be administered prior to or with the first antibiotic dose and not after antibiotics already have been started.¹² Additionally, serum hemoglobin and stool guaiac should be monitored for evidence of GI bleeding.^{58,60,66,69} Dexamethasone should not be used in neonates or any infant younger than 6 weeks of age.^{12,17} The dose used for adults in the recent multicenter trial was 10 mg every 6 hours for 4 days.⁶³

CLINICAL CONTROVERSY

Some clinicians believe that corticosteroids should be administered to all patients over the age of 2 months with bacterial meningitis, whereas others believe that corticosteroids not only have limited proven benefits but also have negative effects on the treatment of meningitis. Most clinicians recognize the beneficial effects of corticosteroids in meningitis caused by *H. influenzae*, but the effects of corticosteroid use in *S. pneumoniae* and *N. meningitidis* meningitis remain unclear.

MYCOBACTERIUM TUBERCULOSIS

M. tuberculosis is the primary cause of tuberculous meningitis. Tuberculous meningitis is associated with significant morbidity and mortality and is difficult to diagnose in a timely manner. The most life-threatening form of extrapulmonary tuberculosis is tuberculous meningitis.⁷⁰ The epidemiology of tuberculous meningitis as a cause of extrapulmonary tuberculosis has changed. Between the years 1997 and 1990, an average of 193 cases of tuberculous meningitis were reported to the CDC, representing 4.7% of extrapulmonary cases.⁷¹ The number of cases reported in 1990 was 284, or 6.2% of extrapulmonary cases.⁷¹ This change is most likely secondary to HIV/AIDS and rising rates among minority adults leading to increased tuberculosis in their children.⁷¹ The incidence of tuberculosis in general has increased 15% since 1985, and the increase is more substantial in children than in adults.⁷⁰

The most useful clue to diagnose tuberculous meningitis is the presence of inflammation of the CSF in an individual who is at epidemiologic risk for tuberculosis. Although up to 40% of patients may present with evidence of pulmonary involvement with hilar adenopathy, tuberculous meningitis still may exist in the absence of disease in the lung or extrapulmonary sites. The tuberculin skin test (purified protein derivative [PPD]) is also negative in 5% to 50% of cases.⁷²

On initial examination, CSF usually contains from 100 to 1000 WBCs/mm³, which may be 75% to 80% polymorphonuclear cells.^{72,73} Over time, the pattern of WBCs in the CSF will shift to lymphocytes and monocytes (see Table 105–1). CSF glucose concentration may be normal initially but gradually decreases as the disease progresses.^{72,73} Protein concentration within the CSF may be normal or elevated, with high protein levels shown to correlate with advanced disease.^{72–74} CSF cultures often are positive for *M. tuberculosis* even if the patient is asymptomatic.

One potentially useful diagnostic sign unique to tuberculous meningitis is paralysis of the VI cranial nerve, which initially is unilateral and then progresses to bilateral.²⁵ Initial acid-fast bacilli (AFB) smears are approximately 37% sensitive and as high as 87% sensitive following subsequent smears. Sensitivity of the AFB smear is enhanced by the examination of multiple CSF specimens collected on consecutive days. Cultures of CSF are positive in 45% to 90% of cases depending on the quantity of CSF used in the culture, pathogen density, and experience of the laboratory in culturing *M. tuberculosis*.

Some clinicians will obtain fluid from the base of the brain or the ventricles in an attempt to increase the yield. Positive culture results may take up to 8 weeks, providing little help with the initial diagnosis.^{72,73} Several systems employing rapid broth culture (Organon Teknika MB/BacT, Organon Teknika, Durham, NC; ESP system, Trek Diagnostic Systems, Inc., Westlake, OH; and Bactec 9000 TB series or Bactec 460, Becton Dickinson Diagnostic Instruments, Sparks, MD) have considerably shortened the time to detection and are able to detect organisms in less than 3 weeks.¹⁶ Nucleic acid amplification products, such as Amplicor (Roche) and MTD (Genprobe), allow for the direct identification of *M. tuberculosis* within 48 hours and yield higher sensitivity than a smear.

Unfortunately, the incidence of multidrug-resistant strains of *M. tuberculosis* has increased, necessitating the use of at least three antitubercular agents to treat active pulmonary disease. The CDC recommends an initial regimen of four drugs for empirical treatment of *M. tuberculosis*.⁷⁵ This regimen consists of isoniazid, rifampin, pyrazinamide, and ethambutol 15 to 20 mg/kg per day (maximum 1.6 g/day) for the first 2 months, generally followed by isoniazid plus rifampin for the remaining duration of therapy. The recommended therapy for HIV-positive individuals is the same as for immunocompetent patients, although rifabutin may be considered in place of other rifamycins in an effort to minimize drug interactions with protease inhibitors and nonnucleoside reverse-transcriptase inhibitors. Therapy in HIV-negative and HIV-positive patients should be individualized based on susceptibility patterns and guidelines from the CDC and the American Thoracic Society, which are updated frequently and available on the Internet (www.cdc.gov/nchstp/tb/pubs/mmwrhtml/maj_guide.htm). Patients with *M. tuberculosis* meningitis should be treated for a duration of 9 months or longer with multiple-drug therapy, and patients with rifampin-resistant strains should receive 18 to 24 months of therapy.

Isoniazid, the mainstay in virtually any regimen to treat *M. tuberculosis*, penetrates the CSF with or without meningeal inflammation and achieves concentrations of more than 30 times the MIC of *M. tuberculosis* (MICs of 0.05 to 0.2 mg/L).^{49,72,73} Rifampin's penetration of CSF approximates only 20% of serum concentrations in the presence of meningeal inflammation. *M. tuberculosis* typically is so exquisitely sensitive to rifampin, however, that the low penetration ratio is of little clinical significance.^{72,73,76} However, the incidence of *M. tuberculosis* resistance to rifampin has increased, necessitating empirical multiple-antibiotic regimens.

Pyrazinamide is a small molecule that penetrates the CSF well in the presence or absence of meningeal inflammation. Streptomycin, an aminoglycoside, penetrates the CSF poorly, even in the presence of meningeal inflammation. The incidence of resistance to streptomycin is increasing, and this drug should not be recommended unless susceptibility is known. Ethambutol is a weak antitubercular agent that reaches the CSF in moderate concentrations. Ethambutol's use is also limited by a high incidence of dose-related optic neuritis. Ethionamide and cycloserine are two other agents that sometimes are used to treat tuberculous meningitis. These agents both penetrate the CSF well in the absence of meningeal inflammation.^{72,73}

The usual dose of isoniazid in children is 10 to 15 mg/kg per day (maximum 300 mg/day), and adults usually receive 5 mg/kg per day or a daily dose of 300 mg.⁷⁵ Supplemental doses of pyridoxine hydrochloride (vitamin B₆) 50 mg/day are recommended to prevent the peripheral neuropathy associated with isoniazid administration.^{72,73} Concurrent administration of rifampin is recommended at doses of 10 to 20 mg/kg per day (maximum 600 mg/day) for children and 600 mg/day for adults.⁷⁵ The addition of pyrazinamide (children and adults 15 to 30 mg/kg per day; maximum in both 2 g/day) to the regimen of isoniazid and rifampin is recommended.⁷⁵ Duration

of concomitant pyrazinamide therapy generally should be limited to 2 months to avoid hepatotoxicity.

The role of steroids in the management of tuberculous meningitis remains unclear. The administration of oral prednisone 60 to 80 mg/day or 0.2 mg/kg per day of intravenous dexamethasone for adults and prednisone 1 to 2 mg/kg per day for children, tapered over 4 to 8 weeks, has been used in clinical practice. Corticosteroids improve neurologic sequelae and survival in adults and decrease mortality, long-term neurologic complications, and permanent sequelae in children.^{77,78} Concerns regarding the use of steroids include a possible interference with CSF chemistry studies and decreased penetration of antitubercular agents because of a decrease in inflammation. Despite the controversy, the trend toward an improved outcome generally supports their use for tuberculous meningitis.^{77,78}

Tuberculous meningitis has a mortality rate of 10% to 50% despite early diagnosis and treatment.^{72,73,79} The level of patient consciousness at the start of therapy is the most useful prognostic indicator. Patients who are comatose at the beginning of therapy have a mortality rate of approximately 75%.⁷³ Other negative prognostic factors include old age, poor nutrition, evidence of miliary disease, high initial CSF protein concentrations, presence of hydrocephalus, and evidence of elevated ICP.⁷³ Between 10% and 30% of patients surviving the disease have physical or mental sequelae, including deafness, vertigo, and short-term memory loss.^{72,73}

■ CRYPTOCOCCUS NEOFORMANS

Cryptococcal meningitis is the most common form of fungal CNS infection in the United States and is a major cause of morbidity and mortality in immunosuppressed patients. In the United States, 85% of cases occur in HIV-infected patients. *C. neoformans* is a soil fungus acquired by inhalation of spores from the environment leading to a pneumonia, which is usually asymptomatic. Most patients present initially with disseminated disease, especially meningoencephalitis. The incubation period in AIDS patients may be very short, as opposed to a relatively normal host, in whom it may be very long.

Symptoms of cryptococcal meningitis are insidious and may be present for varying periods, depending on the host involved, before the definitive diagnosis is made. Fever and a history of headaches are the most common symptoms, although altered mentation and evidence of focal neurologic deficits may be present. Examination of the CSF usually reveals small numbers of WBCs (<150/mm³), which are primarily lymphocytes (see Table 105-1). Diagnosis is based on the presence of a positive CSF, blood, sputum, or urine culture for *C. neoformans*. The CSF cultures are positive in more than 90% of cases. Organisms may be seen by microscope when stained with India ink and are more likely to be seen in AIDS patients compared with other hosts. An additional rapid test helpful in diagnosis is latex agglutination, which detects the presence of cryptococcal antigens.⁸⁰ Latex agglutination is positive in more than 90% of culture-positive cases. A cryptococcal antigen test can be used to follow the prognosis of non-AIDS patients, but cryptococcal antigen titers do not correlate well with treatment efficacy in AIDS patients.⁸¹ A cryptococcal antigen detection test needs to be considered in any patient presenting initially with meningitis. Risk factors predictive of a poor outcome include lethargy at presentation, high CSF cryptococcal antigen titer, and low CSF WBC count.⁸²

Despite poor penetration into the CSF, amphotericin B has long been the drug of choice for the treatment of acute *C. neoformans* meningitis. Amphotericin B 0.5 to 1 mg/kg per day combined with flucytosine 100 mg/kg per day is more effective than amphotericin alone, with successful outcomes in 75% of non-AIDS patients and

50% in AIDS patients.⁸³ Unfortunately, in the AIDS population, flucytosine is often poorly tolerated, causing bone marrow suppression and GI distress. Amphotericin B alone, although less effective, has been used in AIDS patients with preexisting granulocytopenia.^{83,84} Because of the high acute mortality rate of up to 40% and a relapse rate of 50% in AIDS patients receiving therapy, many new agents and regimens are being investigated in this population.⁸² A small, noncomparative open study evaluating the safety and efficacy of liposomal amphotericin B (AmBisome) found the product to be well tolerated and moderately effective.⁸⁵ A second study found high-dose liposomal amphotericin B (4 mg/kg) to clear CSF cultures more rapidly relative to standard amphotericin B, although clinical efficacy was not significantly different.⁸⁶

Azole therapy is the most studied alternative regimen for the treatment of *C. neoformans* meningitis in AIDS patients. Fluconazole at doses of 200 mg/day was compared with amphotericin B alone (0.4 mg/kg per day) with no significant difference in overall mortality between groups.⁸⁷ However, patients receiving fluconazole had a higher 2-week mortality rate and time to CSF conversion.⁸⁷ High-dose fluconazole therapy (800 mg/day) was tried as salvage therapy in eight AIDS patients who failed previous antifungal therapy, but success was limited.⁸⁸ Itraconazole 200 mg orally twice daily was less effective than amphotericin B plus flucytosine in a small nonblinded study.⁸⁹

Patients with AIDS often require lifelong maintenance or suppressive therapy because of high relapse rates following acute therapy for *C. neoformans*. A large multicenter, controlled trial compared fluconazole (200 mg/day) and amphotericin B (1 mg/kg per week) in the prevention of relapse.⁹⁰ Two percent of patients receiving fluconazole versus 18% of patients on amphotericin B relapsed. In addition, the amphotericin B group had significantly more frequent bacterial infections, bacteremias, and drug-related toxicity.⁹⁰ Fluconazole is superior to itraconazole in the prevention of relapse.⁹¹ Therefore, patients with AIDS-associated cryptococcal meningitis should receive primary therapy generally using amphotericin B, with or without flucytosine, followed by maintenance therapy with fluconazole for the life of the patient unless a sustained (>6 months) immune reconstitution occurs as a result of highly active antiretroviral therapy. However, treatment recommendations are controversial, and treatment needs to be individualized. Guidelines for the prevention of opportunistic infections in HIV-infected persons are updated frequently and can be found at www.aidsinfo.nih.gov.

■ VIRAL ENCEPHALITIS

The epidemiology of viral encephalitis in the United States has changed dramatically since the mid-1960s because of the introduction of large-scale polio and mumps immunization programs. In the United States, the incidence of mumps has decreased 98% between 1967 and 1985. Worldwide, mumps remains a causative agent of viral encephalitis in countries with low vaccination rates. Poliomyelitis, once a significant cause of encephalitis, is now confined to only a few less developed countries and likely soon will be eradicated as an infectious agent.

Nonpolio enteroviruses such as coxsackieviruses A and B, echoviruses, and enteroviruses 70 and 71 cause approximately 85% of all viral encephalitis cases.^{92,93} The remaining 10% to 15% of viral encephalitis cases are caused by a variety of pathogens, such as arboviruses, adenoviruses, influenzae virus A and B, rotavirus, corona virus, cytomegalovirus, varicella-zoster, herpes simplex virus, Epstein-Barr virus, and lymphocytic choriomeningitis.^{16,92} In the past, the St. Louis and LaCrosse viruses have been the most common cause

of arbovirus encephalitis.¹⁶ However, in 2002, the largest arboviral meningoencephalitis epidemic in the western hemisphere was caused by the West Nile Virus, accounting for 4156 human cases of West Nile disease in 44 states and the District of Columbia.⁹⁴

Viral encephalitis is acquired primarily by hematogenous spread or, alternatively, by neuronal spread of the causative pathogen.⁹⁵ After entry into the host, viral replication occurs, resulting in dissemination through the reticuloendothelial system or vasculature. Infection of the capillary endothelial cells and choroid plexus may provide a conduit for CNS infections.⁹⁵ Viruses such as polio, herpes, and varicella-zoster virus also may gain access to the CNS by axonal retrograde transmission from peripheral nerve endings.⁹⁵ Once a virus gains access to the CNS, the course of infection depends on the virulence of the particular virus and the host immune response. Host response to aseptic CNS infections is mediated by a complex cascade of inflammatory cytokines in a manner similar to purulent meningitis. In contrast with purulent meningitis, host response to viral encephalitis is mediated primarily through cytotoxic T-lymphocytes. Although TNF is a prominent mediator in purulent bacterial meningitis, TNF concentrations are not increased in viral encephalitis, whereas increases in concentrations of IL-1 and interferon (INF) α and γ occur.⁹⁶ TNF concentrations have been suggested as a diagnostic tool for differentiating between bacterial meningitis and viral encephalitis.⁹⁶ While cytokine assays are available for investigational use, they are not used routinely in the clinical diagnosis of viral encephalitis.

The clinical syndrome associated with viral encephalitis generally is independent of viral etiology and may vary depending on the patient's age. Common signs in adults include headache, mild fever (<40°C), nuchal rigidity, malaise, drowsiness, nausea, vomiting, and photophobia. Only fever and irritability may be evident in the infant, and meningitis must be ruled out as a cause of fever when no other localized findings are observed in a child. Duration of symptoms generally is 1 to 2 weeks, and specific manifestations outside the meninges also can occur depending on the viral etiology.

Laboratory examination of the CSF usually reveals a pleocytosis with 100 to 1000 WBCs/mm³, which are primarily lymphocytic; however, 20% to 75% of patients with viral encephalitis may have a predominance of polymorphonuclear cells on initial examination of the CSF, especially in enteroviral meningitis.⁹² On repeat lumbar puncture, 90% of patients presenting initially with a predominance of neutrophils experience a shift to a predominance of mononuclear cells. Other laboratory findings include normal to mildly elevated protein concentrations and normal or mildly reduced glucose concentrations⁹² (see Table 105-1).

Historically, pathogens responsible for viral encephalitis were not identified.⁹⁷ Poor laboratory recovery of viral pathogens and limited treatment options for viral encephalitis made the need for specific identification of pathogens of questionable value. Advances in diagnostic laboratory techniques and the potential for decreased costs associated with longer duration of hospitalization for patients with unconfirmed viral encephalitis have led to a reevaluation of the need for confirmatory pathogen diagnosis.⁹⁸ When clinical signs warrant pathogen identification, appropriate laboratory diagnostic techniques, including PCR, should be undertaken. Molecular methods are preferred to conventional laboratory tests in the diagnosis of viral encephalitis owing to the ability to detect a specific virus in 30% to 70% of cases as compared with the 14% to 24% sensitivity of viral culture.¹⁶

Although there are numerous pathogenic causes of viral encephalitis, much of the clinical presentation, diagnosis, and treatment are similar. The most commonly isolated viral etiologies are described next.

Nonpolio enteroviruses are unenveloped single-strand RNA viruses. Commonly, the incidence of enteroviral encephalitis peaks

in late summer and continues into early fall. Enteroviruses are transmitted in the host via the fecal-oral route. Clinical presentation of enteroviral infection frequently is nonspecific and characterized by fever, nausea, vomiting, and malaise; however, GI symptoms may not be present. Following a prodrome of 1 to 2 days, headache, photophobia, and neck stiffness develop. Diagnosis can be confirmed by cell culture from the CSF, where the incidence of successful isolation has ranged from 40% to 80%.⁹⁶ In addition, enterovirus can be isolated from throat swabs (60%) and stool cultures (80%), but they are not necessarily diagnostic because the virus is shed in the stool for 1 to 2 weeks following infection.⁹⁷ Conversely, an enterovirus-specific reverse-transcriptase polymerase chain reaction (EV-PCR) test can provide prompt results within 24 hours with a sensitivity and a specificity of 100%.⁹⁹ Treatment for enteroviral encephalitis consists of supportive care, fluids, antipyretics, and analgesics. Generally, disease progression is self-limiting, and the patient recovers fully without long-term neurologic complications.

Both herpes simplex virus types 1 and 2 have been associated with infections of the CNS. Herpes simplex type 1 (HSV1) is associated with encephalitis in adults, whereas herpes simplex type 2 (HSV2) is associated predominantly with encephalitis in newborns.⁹³ An HSV infection of the CNS most likely is spread via retrograde movement from the dorsal root ganglion. Sexually active adults acquire herpes simplex meningitis during or after an attack of genital or rectal herpes. Although HSV2 frequently can be cultured from CSF, HSV1 cannot. As such, PCR may be more useful than culture in detecting infection with HSV; diagnosis is usually made by PCR, culture, or a fourfold rise in complement-fixing antibody to the virus. Establishing the correct diagnosis as early as possible is paramount because mortality rates are between 50% and 85% without treatment, and unlike other viral encephalitides, specific and effective therapy is available. As a result, empirical therapy of suspected HSV encephalitis while laboratory results are pending is necessary. Additionally, a clinical decision to treat may need to be made regardless of test results.

Acyclovir is the drug of choice for herpes simplex encephalitis. In patients with normal renal function, acyclovir is usually administered as 10 mg/kg intravenously every 8 hours for 2 to 3 weeks.⁹³ Herpes virus resistance to acyclovir has been reported with increasing incidence, particularly from immunocompromised patients with prior or chronic exposures to acyclovir.¹⁰⁰ The alternative treatment for acyclovir-resistant herpes simplex virus is foscarnet.⁹³ The major toxicity of foscarnet is renal impairment, and doses must be individualized for renal function.¹⁰¹ The dose for patients with normal renal function is 40 mg/kg infused over 1 hour every 8 to 12 hours for 2 to 3 weeks. Ensuring adequate hydration is imperative. In addition, patients receiving foscarnet should be monitored for seizures related to alterations in plasma electrolyte levels.

Historically, the four most important arboviral pathogens in the United States were the St. Louis virus, the La Crosse virus, and the eastern and western equine viruses. However, the West Nile virus has been recognized as an emerging pathogen and has been implicated in an epidemic occurring in the United States since 1999. Transmission of these viruses occurs through the bites of mosquitoes. Typically, an incubation period of 2 to 14 days precedes the onset of clinical

symptoms. Infection of the brain tissue results in fever, headache, paralysis, and coma. While many patients have a benign presentation, symptomatic cases are associated with a higher degree of mortality. Mortality rates of 50% to 75% have been reported for eastern equine virus, whereas mortality rates for western equine and St. Louis viruses are 3% to 4% and 10% to 20%, respectively.^{93,95} Treatment is supportive, including treatment for seizures and increased ICP, and in the majority of cases, the disease is self-limiting.⁹⁵

Because of the recent epidemic in the United States, a separate discussion of the West Nile virus is warranted. Although West Nile virus is transmitted primarily by mosquitoes, transmission of the virus via blood products, organ transplantation, transplacental transfer, and breast milk has been documented recently.⁹⁴ Similar to the other arboviruses, the incubation period for West Nile virus ranges from 3 days to 2 weeks. West Nile virus infection is asymptomatic in most adults or causes a mild flulike syndrome characterized by fever, malaise, myalgia, and lymphadenopathy. Typically, less than 1% of patients develop neurologic disease, and approximately two-thirds have encephalitis, with the remainder having meningitis without encephalitis.¹² Many patients develop a maculopapular, erythematous rash, which is more common in children than in adults and is uncommon in other forms of viral encephalitis.¹² The other neurologic manifestations include fever, nausea, vomiting, headache, altered mental status, movement disorders, and/or a syndrome much like poliomyelitis.^{12,102,103} The primary risk factor for this manifestation seems to be advanced age. The poliomyelitis syndrome is characterized by an early prodromic phase of fevers and weakness followed by the sudden onset of flaccid paralysis. Among patients hospitalized with West Nile virus, the mortality rate is approximately 10% to 15%, whereas patients with encephalitis and weakness have a mortality rate of 30%.¹² CSF examination of West Nile virus encephalitis typically shows pleocytosis and a slightly elevated CSF protein concentration.¹² Several diagnostic methods have been developed for West Nile virus, including a PCR assay and ELISA tests. However, serologic tests (ELISA) can cross-react with other flaviviruses causing a false-positive result. Moreover, the IgM antibodies for West Nile virus can persist for up to 1 year, leading to confusion regarding whether the infection is an acute or previous infection.¹² Ribavirin has shown inhibitory effects on the West Nile virus in neural tissue cultures, but this has not been studied in controlled trials.

HIV encephalitis is the most common CNS complication associated with AIDS. Frequently, patients may complain of headache, photophobia, or stiff neck at the time of presumed seroconversion. As the disease progresses, however, neurologic symptoms are reported frequently secondary to other opportunistic infections. Diagnosis of viral encephalitis is difficult because mental status and neurologic examinations are not sensitive enough to detect early changes. Direct evidence of HIV encephalitis can be obtained through CSF culture, p24 antigen testing, or qualitative or quantitative PCR for HIV RNA. Diagnostic workup of other potential copathogens, such as herpes simplex virus (HSV), *Toxoplasma gondii*, *M. tuberculosis*, *Aspergillus* spp., and *Cryptococcus* also should be performed. Refer to Chap. 123 for a complete discussion of infectious complications in HIV-positive individuals.

EVALUATION OF THERAPEUTIC OUTCOMES

SIGNS AND SYMPTOMS

Because of the potential for rapid deterioration associated with meningitis, signs and symptoms of fever, headache, meningismus (e.g.,

nuchal rigidity, Brudzinski's sign, or Kernig's sign), vital signs, and signs of cerebral dysfunction should be evaluated every 4 hours for the initial 3 days and then daily thereafter. The Glasgow Coma Scale should be used in severely ill patients. Trends in improvement and resolution rather than single evaluations in time are more important in monitoring the signs and symptoms of meningitis.

MICROBIOLOGIC FINDINGS

CSF and blood samples for Gram stain, cultures, and sensitivity testing should be taken prior to starting antibiotic therapy. If lumbar puncture is delayed, however, antibiotics should be started. Although the CSF cultures may be negative, antibiotic therapy rarely interferes with the protein and/or glucose concentrations in the CSF.¹³ Furthermore, if the laboratory is made aware of the antibiotic therapy, steps can be taken to diminish the effects of the antibiotic during the detection process.¹⁶ Gram stain results can be obtained immediately and can guide empirical antibiotic treatment. Identification of the organism can be made within 24 hours, and sensitivities should be available within 48 hours. Repeat cultures should be performed to help determine if sterilization is achieved. A second tube of blood should be taken to allow for latex agglutination tests of antigens to common meningeal pathogens (*H. influenzae*, *S. pneumoniae*, *N. meningitidis*, *E. coli*, and group B streptococcus) if the Gram stain has not been helpful.

CSF EXAMINATION

In bacterial meningitis, the CSF WBC count usually is greater than 1000 cells/mm³, the CSF protein concentration is elevated, and the CSF glucose concentration (hypoglycorachia) is often low (<50 mcg/dL or 50% to 60% of a simultaneous blood glucose value). Viral encephalitis, in contrast, results in relatively normal CSF protein and glucose levels and typically does not result in greater than 90% polymorphonuclear neutrophils (PMNs) in the CSF (see Table 105-1).

ABBREVIATIONS

AFB: acid-fast bacilli
 AIDS: acquired immunodeficiency syndrome
 BBB: blood-brain barrier
 BCSFB: blood-cerebrospinal fluid barrier
 CBF: cerebral blood flow
 CDC: Centers for Disease Control and Prevention
 CFU: colony forming unit
 CNS: central nervous system
 CSF: cerebrospinal fluid
 CT: computed tomographic
 DIC: disseminated intravascular coagulation
 EV-PCR: enterovirus-specific reverse-transcriptase polymerase chain reaction
 FDA: Food and Drug Administration
 GI: gastrointestinal
 Hib: *H. influenzae* type b
 HIV: human immunodeficiency virus
 ICP: intracranial pressure
 IL-1: interleukin 1
 INF: interferon
 LPS: lipopolysaccharide
 MBC: minimum bactericidal concentration
 MIC: minimum inhibitory concentration
 NCCLS: National Committee for Clinical Laboratory Standards
 PAF: platelet-activating factor
 PCR: polymerase chain reaction
 PGE₂: prostaglandin E₂
 PPD: purified protein derivative
 TNF: tumor necrosis factor
 WBC: white blood cell

LOWER RESPIRATORY TRACT INFECTIONS

Mark L. Glover and Michael D. Reed

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Respiratory infections remain the major cause of morbidity from acute illness in the United States and likely represent the most common reasons why patients seek medical attention.
- 2 The majority of pulmonary infections follow colonization of the upper respiratory tract with potential pathogens, whereas microbes less commonly gain access to the lungs via the blood from an extrapulmonary source or by inhalation of infected aerosol particles. The competency of a patient's immune status is an important factor influencing the susceptibility to infection, etiologic cause, and disease severity.
- 3 An appropriate treatment regimen for the patient with uncomplicated lower respiratory tract infection usually can be established by patient history, physical examination, chest radiograph, and properly collected sputum for culture interpreted in light of current knowledge of the most common lung pathogens and their antibiotic susceptibility patterns within one's community.
- 4 Acute bronchitis is caused most commonly by respiratory viruses and almost always is self-limiting with therapy targeting associated symptoms, such as lethargy, malaise, or fever (ibuprofen or acetaminophen), fluids for rehydration, and in some patients cough suppressants. The routine use of antibiotics should be avoided.
- 5 Chronic bronchitis is a result of several contributing factors; the most prominent of these are cigarette smoking and exposure to occupational dusts, fumes, environmental pollution, and bacterial (and possibly viral) infection. The hallmark of this disease is a chronic cough with resulting sputum production and the persistent presence of microorganisms in the patient's sputum.
- 6 The treatment of acute exacerbations of chronic bronchitis includes attempts to mobilize and enhance sputum expectoration (chest physiotherapy, humidification of inspired air), oxygen if needed, aerosolized bronchodilators (albuterol) in select patients with demonstrated benefit, and antibiotics.
- 7 Respiratory syncytial virus is the most common cause of acute bronchiolitis, an infection that mostly affects infants during their first year of life. In the well infant, bronchiolitis is usually a self-limiting viral illness, whereas in the child with underlying respiratory or cardiac disease or both, the child may develop severe respiratory compromise (failure) necessitating in-hospital treatment, such as rehydration, oxygen, and in select patients, bronchodilators, ribavirin aerosol, or both.
- 8 The most prominent pathogens causing community-acquired pneumonia in otherwise healthy adults are *Streptococcus pneumoniae* (70%) and *Mycoplasma pneumoniae* (10% to 20%), whereas the most common pathogens causing hospital-acquired pneumonia (including in nursing home residents) are *Staphylococcus aureus* and gram-negative aerobic bacilli. Anaerobic bacteria are the most common etiologic agents in pneumonia that follows aspiration of gastric or oropharyngeal contents.
- 9 The treatment of community-acquired pneumonia may consist of humidified oxygen for hypoxemia, bronchodilators (albuterol) when bronchospasm is present, rehydration fluids, and chest physiotherapy for marked accumulation of retained respiratory secretions. Antibiotic regimens should be selected based on presumed causative pathogens and pulmonary distribution characteristics and should be adjusted to provide optimal activity against pathogens identified by culture (sputum or blood).
- 10 The treatment of nosocomial pneumonia requires aggressive therapy with careful consideration of the dominance and susceptibility patterns of the pathogens present within the institution. The epidemiology of these common pathogens should be evaluated on a regular basis to identify changing resistance patterns and subsequent alternation of treatment guidelines.
- 1 Respiratory tract infections remain the major cause of morbidity from acute illness in the United States and most likely represent the single most common reason patients seek medical attention. This chapter focuses on bacterial and viral infections involving the lower respiratory tract, which includes the tracheobronchial tree and lung parenchyma.
- 2 The respiratory tract has an elaborate system of host defenses, including humoral immunity, cellular immunity, and anatomic mechanisms.¹⁻⁴ When functioning properly, the host defenses of the respiratory tract are markedly effective in protecting against pathogen invasion and removing potentially infectious agents from the lungs.²⁻⁴ For the most part, infections in the lower respiratory

tract occur only when these defense mechanisms are impaired, such as with dysgammaglobulinemia or compromised ciliary function caused by the chronic inflammation that accompanies cigarette smoking. In addition, local defenses may be overwhelmed when a particularly virulent microorganism or excessive inoculum invades lung parenchyma. The majority of pulmonary infections follow colonization of the upper respiratory tract with potential pathogens, which, after achieving sufficiently high concentrations, gain access to the lung via aspiration of oropharyngeal secretions. Less commonly, microbes enter the lung via the blood from an extrapulmonary source or by the inhalation of infected aerosolized particles. The specific type of pulmonary infection caused by an invading microorganism is determined by a variety of host factors, including age, anatomic features of the airway, and specific characteristics of the infecting agent.

The most common infections involving the lower respiratory tract include bronchitis, bronchiolitis, and pneumonia. Lower respiratory tract infections in children and adults are most commonly a result of either viral or bacterial invasion of lung parenchyma. The diagnosis of viral infections rests primarily on the recognition of a characteristic constellation of clinical signs and symptoms. Because treatment is largely supportive, only occasionally does the diagnosis require laboratory confirmation; this is achieved through serologic tests or identification of the organism by culture or antigen detection in respiratory secretions. New laboratory techniques employing

polymerase chain reaction (PCR) technology have emerged as a means to identify specific pathogens rapidly and accurately.

In contrast, because bacterial pneumonia usually necessitates expedient, effective, and specific antibiotic therapy, its management depends, in large part, on isolation of the etiologic agent by culture from lung tissue or secretions. The pharynx is colonized with many organisms that potentially can cause pneumonia; therefore, culture of expectorated sputum can be misleading unless the specimen is examined to ensure that it has originated from the lower respiratory tract.⁵ The Gram stain provides the easiest method to distinguish lower from upper respiratory tract secretions; moreover, through determination of the shape and color of the bacteria, the Gram stain frequently narrows the microbiologic differential diagnosis sufficiently to allow accurate initial therapy. Scanned under low-power microscopy, Gram-stained expectorated upper respiratory tract secretions contain many irregularly shaped epithelial cells with little evidence of inflammation. Microorganisms of a variety of morphologies are present (Fig. 106-1). In contrast, a lower-tract specimen from a patient with bacterial pneumonia usually contains multiple neutrophils per high-powered field and a single or predominant bacterial species. Culture of specimens confirmed to originate from the lower tract by Gram stain provides valuable diagnostic information in the majority of patients with bacterial pneumonia.^{6,7}

3 An appropriate treatment regimen for the patient with an uncomplicated lower respiratory tract infection usually can be

FIGURE 106-1. Gram stain of sputum. (*Left panel*) Scanned under low power (10 \times), this sample contains many irregularly shaped epithelial cells (*arrow 1*) and no inflammatory cells, indicating that the specimen was derived from the upper respiratory tract. (*Right panel*) Under oil immersion (100 \times), this specimen contains a predominance of gram-negative rods (*arrow 2*) and many polymorphonuclear cells (*arrow 3*) per high-power field, confirming that this specimen was derived from the lower respiratory tract. The sample grew *Klebsiella pneumoniae*.

established by history, physical examination, chest radiograph, and properly collected sputum cultures interpreted in light of the most common lung pathogens and their antibiotic susceptibility patterns within one's community. More sophisticated or invasive diagnostic methods (such as computed tomography, bronchoscopy, and lung biopsy)^{8–11} should be reserved for very ill patients who are unable to expectorate sputum or who are not responding to empirical therapy or for pulmonary infections occurring in immunocompromised patients.

BRONCHITIS

Bronchitis and bronchiolitis are inflammatory conditions of the large and small elements, respectively, of the tracheobronchial tree. The inflammatory process does not extend to the alveoli. Bronchitis frequently is classified as acute or chronic. Acute bronchitis occurs in all ages, whereas chronic bronchitis primarily affects adults. Bronchiolitis is a disease of infancy.

ACUTE BRONCHITIS

EPIDEMIOLOGY AND ETIOLOGY

Acute bronchitis occurs most commonly during the winter months, following a pattern similar to those of other acute respiratory tract infections. Cold, damp climates, the presence of high concentrations of irritating substances, such as air pollution or cigarette smoke, or both may precipitate attacks.^{12,13}

4 Respiratory viruses are by far the most common infectious agents associated with acute bronchitis. The common cold viruses, rhinovirus and coronavirus, and lower respiratory tract pathogens, including influenza virus and adenovirus, account for the majority of cases. In children, similar pathogens are observed with the addition of the parainfluenza viruses. While the true incidence remains to be defined, *Mycoplasma pneumoniae* also appears to be a frequent cause of acute bronchitis. Additionally, *Chlamydia pneumoniae*¹⁴ and *Bordetella pertussis* (the agent responsible for whooping cough) have been associated with acute respiratory tract infections. Although a variety of bacteria, including *Streptococcus pneumoniae*, *Streptococcus* spp., *Staphylococcus* spp., and *Hemophilus* spp., may be isolated from throat or sputum culture, it is probable that these organisms represent contamination by normal flora of the upper respiratory tract rather than true pathogens. Although a primary bacterial etiology for acute bronchitis appears rare, secondary bacterial infection may be involved.

PATHOGENESIS

4 Because acute bronchitis is primarily a self-limiting illness and rarely a cause of death, few data are available to describe the pathology. In general, infection of the trachea and bronchi yields

Fever rarely exceeds 39°C

Physical Examination

Rhonchi or coarse, moist, bilateral rales

Chest Radiograph

Normal

hyperemic and edematous mucous membranes with an increase in bronchial secretions. Destruction of respiratory epithelium can range from mild to extensive and may affect bronchial mucociliary function. In addition, the increase in bronchial secretions, which can become thick and tenacious, further impairs mucociliary activity. The probability of permanent damage to the airways as a result of acute bronchitis remains unclear; however, epidemiologic evaluations support the belief that recurrent acute respiratory infections may be associated with increased airway hyperreactivity and possibly the pathogenesis of asthma or chronic obstructive pulmonary disease (COPD).^{13,15}

CLINICAL PRESENTATION

Acute bronchitis usually begins as an upper respiratory infection with nonspecific complaints (Table 106–1). Cough is the hallmark of acute bronchitis and occurs early. The onset of cough may be insidious or abrupt, and the symptoms persist despite resolution of nasal or nasopharyngeal complaints. Frequently, the cough is initially non-productive, but progresses, yielding mucopurulent sputum. In older children and adults, the sputum is raised and expectorated; in the young child, sputum is often swallowed and can result in gagging and vomiting. Substantial discomfort may result from the coughing. Dyspnea, cyanosis, or signs of airway obstruction are observed rarely unless the patient has underlying pulmonary disease, such as emphysema or COPD. Fever, when present, rarely exceeds 39°C (102.2°F) and appears most commonly with adenovirus, influenza virus, and *M. pneumoniae* infections. The diagnosis typically is made on the basis of a characteristic history and physical examination. Bacterial cultures of expectorated sputum generally are of limited use because of the inability to avoid normal nasopharyngeal flora by the sampling technique. In routine cases, viral cultures are unnecessary and frequently unavailable. Viral antigen-detection tests, developed to identify respiratory viral antigens from nasal secretions rapidly, can be obtained in many hospital laboratories and in some practice settings when a specific diagnosis is necessary for clinical or epidemiologic reasons.¹⁶ Cultures or serologic diagnosis of *M. pneumoniae* and culture or direct fluorescent antibody detection for *B. pertussis* should be obtained in prolonged or severe cases when epidemiologic considerations would suggest their involvement.¹⁷

▶ TREATMENT: Acute Bronchitis

■ DESIRED OUTCOME

In the absence of a complicating bacterial superinfection, acute bronchitis is almost always self-limiting. The goals of therapy, therefore, are to provide comfort to the patient and, in the unusually severe case, to treat associated dehydration and respiratory compromise.

■ GENERAL APPROACH TO TREATMENT

4 The treatment of acute bronchitis is symptomatic and supportive in nature. Reassurance and antipyretics frequently are all that are needed. Bed rest for comfort may be instituted as desired. Patients should be encouraged to drink fluids to prevent dehydration and

possibly to decrease the viscosity of respiratory secretions. Mist therapy, the use of a vaporizer, or both may further promote the thinning and loosening of respiratory secretions.

PHARMACOLOGIC THERAPY

Mild analgesic-antipyretic therapy is often helpful in relieving the associated lethargy, malaise, and fever. Aspirin or acetaminophen (650 mg in adults or 10–15 mg/kg per dose in children; maximum daily pediatric dose 60 mg/kg; maximum daily adult dose 4 g) or ibuprofen (200–800 mg in adults or 10 mg/kg per dose in children; maximum daily pediatric dose 40 mg/kg; maximum daily adult dose 3.2 g) should be administered every 4 to 6 hours. In children, aspirin should be avoided and acetaminophen used as the preferred agent because of the possible association between aspirin use and the development of Reye's syndrome.¹⁸

The use of ibuprofen as an antipyretic has increased. The drug's antipyretic efficacy appears identical to that of aspirin or acetaminophen, although its duration of antipyretic effect may be slightly longer (e.g., 3 to 4 hours for aspirin and acetaminophen versus 5 to 6 hours for ibuprofen). Caution should be exercised in the administration of ibuprofen in those younger than 3 months of age and elderly patients and individuals with poor renal function. Aspirin and ibuprofen inhibit prostaglandin synthesis and may adversely influence renal function in these predisposed patient populations.

Patients suffering from acute bronchitis frequently medicate themselves with over-the-counter (OTC) cough and cold remedies containing various combinations of antihistamines, sympathomimet-

ics, and antitussives despite the lack of definitive evidence supporting their effectiveness.¹⁹ In fact, the tendency of these agents to dehydrate bronchial secretions potentially could aggravate and prolong the recovery process. Persistent, mild cough, which may be bothersome, can be treated with dextromethorphan; more severe coughs may require intermittent codeine or other similar agents. In severe cases, cough may be persistent enough to disrupt sleep, and the use of a mild sedative-hypnotic, concomitantly with a cough suppressant, may be desirable; however, antitussives should be used cautiously when the cough is productive. The primary or supplemental use of expectorants is questionable because their clinical effectiveness has not been well established.

Routine use of antibiotics in the treatment of acute bronchitis should be discouraged^{20,21}; however, in patients who exhibit persistent fever or respiratory symptoms for more than 4 to 6 days, the possibility of a concurrent bacterial infection should be suspected. When possible, antibiotic therapy should be directed toward anticipated respiratory pathogen(s) (*S. pneumoniae*, *H. influenzae*). *M. pneumoniae*, if suspected by history or positive cold agglutinins (titers > 1:32) or if confirmed by culture or serology, may be treated with erythromycin or its analogues (clarithromycin, azithromycin). Alternatively and empirically, a fluoroquinolone with activity against these pathogens (e.g., gatifloxacin or levofloxacin) may be used. During known epidemics involving the influenza A virus, amantadine or rimantadine may be effective in minimizing associated symptoms if administered early in the course of the disease.²² The recently marketed neuraminidase inhibitors (zanamivir and oseltamivir) are active against both influenza A and B viral infections and may reduce the severity and duration of the influenza episode if administered promptly during the onset of the viral infection.^{23,24}

CHRONIC BRONCHITIS

EPIDEMIOLOGY AND ETIOLOGY

Chronic bronchitis is a nonspecific disease that primarily affects adults. Between 10% and 25% of the adult population 40 years of age or older suffer from chronic bronchitis, resulting in substantial health care dollar expenditures and lost wages.^{25–27} This disease is so common that acute bronchitis and acute exacerbations of chronic bronchitis result in approximately 14 million physician visits per year in the United States. Similar to acute bronchitis, cold, damp climates and the presence of elevated airborne concentrations of irritating substances may favor this disease.^{25–27} Chronic bronchitis occurs more commonly in men than in women.

5 Chronic bronchitis is a result of several contributing factors; the most prominent of these include cigarette smoking; exposure to occupational dusts, fumes, and environmental pollution; and bacterial (and possibly viral) infection. The influence that each of these factors and others, either alone or in combination, contributes to chronic bronchitis is unknown. Cigarette smoke is a well-known airway irritant and is believed to be the predominant factor in the etiology of chronic bronchitis. Studies of lungs from smoking and nonsmoking individuals clearly have demonstrated a substantial increase in the number of alveolar macrophages, as well as the presence of bronchial inflammation, in individuals who smoke cigarettes. Although the majority of patients who suffer from chronic bronchitis have a positive smoking history, no history of smoking can be identified in as many as 10% of patients. These findings suggest that additional airway irritants, either alone or more probably in combination, are responsible for the pathogenesis of chronic bronchitis. The only known genetic abnormality

leading to COPD is α_1 -antitrypsin deficiency, which occurs in less than 1% of COPD patients in the United States.

In addition, the influence of recurrent respiratory tract infections during childhood or young adult life on the later development of chronic bronchitis remains obscure. Recurrent respiratory infections at a young age may predispose individuals to the development of chronic bronchitis^{15,28}; however, it is unclear whether these recurrent respiratory tract infections are a result of unrecognized anatomic abnormalities of the airways or impaired pulmonary defense mechanisms.

PATHOGENESIS

The chronic inhalation of an irritating noxious substance compromises the normal secretory and mucociliary function of bronchial mucosa. In chronic bronchitis, the bronchial wall is thickened, and the number of mucus-secreting goblet cells in the surface epithelium of both larger and smaller bronchi is increased markedly.²⁹ In contrast, goblet cells generally are absent from the smaller bronchi of normal individuals. In addition to the increased number of goblet cells, hypertrophy of the mucous glands and dilation of the mucous gland ducts are also observed. As a result of these changes, chronic bronchitics have substantially more mucus in their peripheral airways, further impairing normal lung defenses. This increased quantity of tenacious secretions within the bronchial tree frequently causes mucous plugging of the smaller airways. Accompanying these changes are squamous cell metaplasia of the surface epithelium, edema and increased vascularity of the basement membrane of larger airways, and variable chronic inflammatory cell infiltration. Continued progression of this pathology

can result in residual scarring of small bronchi, augmenting airway obstruction and weakening of bronchial walls.

CLINICAL PRESENTATION

5 The hallmark of chronic bronchitis is a cough that may range from a mild “smoker’s cough” to severe, incessant coughing productive of purulent sputum. Coughing may be precipitated by multiple stimuli, including simple, normal conversation. Expectoration of the largest quantity of sputum usually occurs on arising in the morning, although many patients expectorate sputum throughout the day. The expectorated sputum usually is tenacious and can vary in color from white to yellow-green. As a result, many patients complain of a frequent bad taste in their mouth and of halitosis.

The diagnosis of chronic bronchitis is based primarily on clinical assessment and history. Any patient who reports the coughing up of sputum on most days for at least 3 consecutive months each year for 2 consecutive years presumptively has chronic bronchitis.^{26,27} The diagnosis of chronic bronchitis is made only when the possibilities of bronchiectasis, cardiac failure, cystic fibrosis, and lung carcinoma have been effectively excluded. In an attempt to be more specific in the diagnosis, some investigators have added lost wages for 3 or more weeks to the criteria. In addition, many clinicians attempt to subdivide their patients into one of three subgroups: (1) those with simple chronic bronchitis, (2) those with chronic or recurrent mucopurulent bronchitis (based on the presence of mucopurulent sputum confirmed by microscopic analysis), and (3) those with chronic obstructive bronchitis (based on the clinical history and presence of airway obstruction documented by pulmonary function testing). More recently, an ad hoc international committee comprised of pulmonary and infectious disease physicians developed a classification system that can serve as a practical guide for initial patient assessment and management (Table 106–2) for patients with chronic bronchitis.²⁷

TABLE 106–3. Clinical Presentation of Chronic Bronchitis

| |
|--|
| Signs and Symptoms |
| Cyanosis (advanced disease) |
| Obesity |
| Physical Examination |
| Chest auscultation usually reveals inspiratory and expiratory rales, rhonchi, and mild wheezing with an expiratory phase that is frequently prolonged. There is hyperresonance on percussion with obliteration of the area of cardiac dullness |
| Normal vesicular breathing sounds are diminished |
| Clubbing of digits (advanced disease) |
| Chest Radiograph |
| Increase in the anteroposterior diameter of the thoracic cage (observed as a barrel chest) |
| Depressed diaphragm with limited mobility |
| Laboratory Tests |
| Erythrocytosis (advanced disease) |
| Pulmonary Function Tests |
| Decreased vital capacity |
| Prolonged expiratory flow |

Typical clinical presentation of chronic bronchitis is found in Table 106–3.

In more progressed stages of chronic bronchitis, physical findings associated with cor pulmonale, including cardiac enlargement, hepatomegaly, and edema of the lower extremities, are observed. In general, chronic bronchitics tend to maintain at least normal body weight and are commonly obese. Radiographic studies are of limited value either in the diagnosis or as a means of sequentially following a patient. The microscopic and laboratory assessment of sputum is considered an important component in the overall evaluation of patients with chronic bronchitis. A fresh sputum specimen obtained

TABLE 106–2. Classification System for Patients with Chronic Bronchitis and Initial Treatment Options²⁷

| Baseline Status | Criteria or Risk Factors | Usual Pathogens | Initial Treatment Options |
|---------------------------------------|--|---|---|
| Class I | | | |
| Acute tracheobronchitis | No underlying structural disease | Usually a virus | 1. None unless symptoms persist 2. Amoxicillin; amoxicillin-clavulanate; or a macrolide/azalide |
| Class II | | | |
| Chronic bronchitis | FEV ₁ > 50% predicted value, increased sputum volume and purulence | <i>Hemophilus influenzae</i> , <i>Hemophilus</i> spp., <i>Moraxella catarrhalis</i> , <i>Streptococcus pneumoniae</i> (β-lactam resistance possible) | 1. Amoxicillin, or fluoroquinolone if prevalence of <i>H. influenzae</i> resistance to amoxicillin is >20% 2. Fluoroquinolone, amoxicillin-clavulanate, azithromycin, tetracycline, or trimethoprim-sulfamethoxazole |
| Class III | | | |
| Chronic bronchitis with complications | FEV ₁ < 50% predicted value, increased sputum volume and purulence, advanced age, at least four flares per year, or significant comorbidity | Same as class II; also <i>Klebsiella pneumoniae</i> , <i>Pseudomonas aeruginosa</i> , <i>K. pneumoniae</i> , and other gram-negative organisms (β-lactam resistance common) | 1. Fluoroquinolone 2. Expanded spectrum cephalosporin, amoxicillin-clavulanate, or azithromycin |
| Class IV | | | |
| Chronic bronchial infection | Same as for class III plus yearlong production of purulent sputum | Same as class III | 1. Oral or parenteral fluoroquinolone, carbapenem or expanded spectrum cephalosporin |

1 = preferred therapy; 2 = alternative treatment options. Fluoroquinolone: ciprofloxacin, gatifloxacin, levofloxacin; tetracycline: tetracycline HCL, doxycycline; carbapenem: imipenem-cilastatin, meropenem; expanded-spectrum cephalosporin: ceftazidime, cefepime.

as an early-morning sample is preferred. Comparison of the cellular constituents of chronic bronchitic sputum with those of normal sputum can provide insight into the degree of activity of the disease processes.²⁵ An increased number of polymorphonuclear granulocytes often suggests continual bronchial irritation, whereas an increased number of eosinophils suggests an allergic component that should be further investigated. Gram staining of the sputum often reveals a mixture of both gram-positive and gram-negative bacteria, reflecting normal oropharyngeal flora and tracheal colonization by *S. pneumoniae*, *H. influenzae*, and *Moraxella catarrhalis*. Table 106–4 outlines the most common bacterial isolates identified from sputum culture in patients experiencing an acute exacerbation of chronic bronchitis.

TABLE 106–4. Common Bacterial Pathogens Isolated from the Sputum of Patients with an Acute Exacerbation of Chronic Bronchitis

| Pathogen | Percent of Cultures |
|--|---------------------|
| <i>Hemophilus influenzae</i> ^a | 24–26 |
| <i>Hemophilus parainfluenzae</i> | 20 |
| <i>Streptococcus pneumoniae</i> ^b | 15 |
| <i>Moraxella catarrhalis</i> ^a | 15 |
| <i>Klebsiella pneumoniae</i> | 4 |
| <i>Serratia marcescens</i> | 2 |
| <i>Neisseria meningitidis</i> ^a | 2 |
| <i>Pseudomonas aeruginosa</i> | 2 |

^aOften β -lactamase-positive.

^bAs many as 25% of strains may be intermediate or highly resistant to penicillin.

► TREATMENT: Chronic Bronchitis

■ DESIRED OUTCOME

The goals of therapy for chronic bronchitis are twofold: to reduce the severity of the chronic symptoms and to ameliorate acute exacerbations and achieve prolonged infection-free intervals.

■ GENERAL APPROACH TO TREATMENT

The approach to the treatment of chronic bronchitis is multifactorial. First and foremost, attempts must be made to reduce the patient's exposure to known bronchial irritants (e.g., smoking). A complete occupational and environmental history for the determination of exposure to noxious, irritating gases, as well as preference toward cigarette smoking, must be assessed. Often easier discussed than accomplished, honest, yet reasonable attempts should be made with the patient to reduce or eliminate completely the number of cigarettes smoked daily and to reduce exposure to secondhand smoke. In an organized, coordinated smoking-cessation program, which includes counseling and hypnotherapy, the adjunctive use of nicotine substitutes, such as a nicotine gum or patch, may promote the reduction or complete withdrawal from cigarette smoking. Often just as difficult is the modification of exposure to irritating substances within the home and workplace.

6 Additionally, measures to provide pulmonary toilet can be instituted. During acute pulmonary exacerbations of the disease, a patient's ability to mobilize and expectorate sputum may be reduced dramatically. In these instances, attempts at postural drainage techniques, with instruction, active participation, or both from a respiratory therapist, may assist in promoting clearance of pulmonary secretions. In addition, humidification of inspired air may promote the hydration (liquefaction) of tenacious secretions, allowing for more productive removal. The use of mucolytic aerosols, such as *N*-acetylcysteine and DNase, is of questionable therapeutic value, particularly considering their propensity to induce bronchospasm (*N*-acetylcysteine) and their excessive cost. Oral or aerosolized bronchodilators may benefit some patients during acute pulmonary exacerbations. Finally, in the face of an acute exacerbation, a trial of antibiotics directed against the most likely underlying pathogens may be initiated.

■ PHARMACOLOGIC THERAPY

For patients who consistently demonstrate clinical limitation in airflow, a therapeutic challenge of bronchodilators (such as albuterol aerosol) should be considered. Pulmonary function tests can be performed before and after β_2 -agonist aerosol administration to determine more objectively a patient's propensity to benefit from supplemental aerosol therapy. However, this laboratory assessment, often performed at times of better health, may not accurately predict a patient's potential benefit from β_2 aerosols during an acute exacerbation of chronic bronchitis.

Although chronic theophylline administration has been used extensively in the past, this therapy is being employed with decreasing frequency in favor of aerosolized β_2 -receptor agonists. Albuterol is used most commonly, one to two puffs of the metered-dose inhaler three to four times daily.²⁶ The role of aerosolized surfactant also has been assessed in patients with stable chronic bronchitis and has demonstrated encouraging results with respect to improvement in pulmonary function and sputum transport by cilia (i.e., clearance).³⁰ The role of surfactant as a carrier vehicle for other aerosol medications also appears promising and most likely will continue to be evaluated.

The use of antimicrobials for chronic bronchitis is controversial. Numerous comparative evaluations, including placebo-controlled studies of antibiotic administration with acute and chronic treatment of chronic bronchitis, have suggested definite clinical benefit, whereas other similar studies have not.^{26,27,31–33} The antibiotics selected most frequently possess variable in vitro activity against the common sputum isolates *H. influenzae*, *S. pneumoniae*, *M. catarrhalis*, and *M. pneumoniae*.

In general, these conflicting results appear independent of which antibiotic was used or regimen compared. The wide disparity that exists in the results from these studies, combined with the difficulties in recognition and lack of standardized diagnostic criteria for acute exacerbation of chronic bronchitis,³¹ serves as the basis for the enormous controversy surrounding the use of antibiotics in this condition.^{34,35}

Further complicating antibiotic selection is the increasing resistance of the common bacterial pathogens to first-line agents. As many as 30% to 40% of *H. influenzae* and 95% of *M. catarrhalis* produce β -lactamase. Moreover, up to 30% of *S. pneumoniae* isolates demonstrate resistance to penicillin (minimum inhibitory concentration [MIC] = 0.1–2 mg/L), with approximately 14% of isolates being highly resistant (MIC > 2 mg/L).^{36,37} In addition, concern for

S. pneumoniae resistance is increasing because the incidence of macrolide resistance is approximately 20%.^{33,38} Despite these changes in bacterial susceptibility, it is recommended to initiate therapy with first-line agents in less severely affected patients. The scheme outlined in Table 106–2 can be used as an initial guide in the selection of antibiotics based on disease severity (classes I through IV). These guidelines are quite consistent with those recently published by the Canadian Thoracic and Infectious Disease Societies.³⁹

Regardless of which antibiotic is selected, careful attention to predetermined outcome measures should be monitored closely in each patient to determine the success or failure of the therapeutic intervention.³⁵ Oral antibiotics with broader antibacterial spectra (e.g., cefixime, amoxicillin-clavulanate, fluoroquinolones, or azalides) that possess more potent *in vitro* activity against sputum isolates generally are not needed as initial therapy because clinical response often appears independent of the pathogen's *in vitro* susceptibility for many patients.^{26,27,32,33}

An important clinical outcome variable directing drug selection and criteria for beginning antibiotics in individual patients is the infection-free period when chronic bronchitics are off antibiotics. The actual length of the infection-free time period, as well as the change in the number of physician office visits and hospital admissions with a particular antibiotic regimen, are extremely important to identify, whenever possible, for each patient. The antibiotic regimen that results in the longest infection-free period defines the “regimen of choice” for specific patients for future acute exacerbations of their disease.

Antibiotics should be selected that are effective against responsible pathogens, that demonstrate the least risk of drug interactions, and that can be administered in a manner that promotes compliance. Antibiotics commonly used in the treatment of these patients and their respective adult starting doses are outlined in Table 106–5. Doses of antibiotics should be adjusted as needed to the desired clinical effect and the lowest incidence of acceptable side effects. A frequently used clinical strategy to enhance the duration of symptom-free periods incorporates higher-dose antibiotic regimens using the upper limit of the recommended daily antibiotic dose for a period of 10 to 14 days.³³

Traditionally, ampicillin has been considered the drug of choice for the treatment of acute exacerbations of chronic bronchitis. Unfortunately, the need for multiple repeat daily doses (four times daily), increased incidence of gastrointestinal side effects, and the increasing incidence of penicillin-resistant β -lactamase-producing strains of bacteria (see Tables 106–2 and 106–4) have limited the usefulness of this safe and very cost-effective antibiotic. As stated earlier, the proposed classification system outlined in Table 106–2 offers first- and second-line treatment options for acute exacerbations of chronic bronchitis that are directed by the baseline clinical status of the patient. These treatment recommendations can be used to initiate therapy in patients with class I through IV disease.

The value of the erythromycins when *Mycoplasma* is involved is unquestionable, whereas the value, if any, of the newer erythromycin analogues azithromycin or clarithromycin as first-line agents in the

TABLE 106–5. Oral Antibiotics Commonly Used for the Treatment of Acute Respiratory Exacerbations in Chronic Bronchitis

| Antibiotic | Usual Adult Dose (g) | Dose Schedule (doses/day) |
|-------------------------------|----------------------|---------------------------|
| Preferred Drugs | | |
| Ampicillin | 0.25–0.5 | 4 |
| Amoxicillin | 0.5 | 3 |
| Cefprozil | 0.5 | 2 |
| Cefuroxime | 0.5 | 2 |
| Ciprofloxacin | 0.5–0.75 | 2 |
| Gatifloxacin | 0.4 | 1 |
| Levofloxacin | 0.5–0.75 | 1 |
| Doxycycline | 0.1 | 2 |
| Minocycline | 0.1 | 2 |
| Tetracycline HCl | 0.5 | 4 |
| Amoxicillin-clavulanate | 0.5 | 3 |
| Trimethoprim-sulfamethoxazole | 1 DS ^a | 2 |
| Supplemental Drugs | | |
| Azithromycin | 0.25–0.5 | 1 |
| Erythromycin | 0.5 | 4 |
| Clarithromycin | 0.25–0.5 | 2 |
| Cefixime | 0.4 | 1 |
| Cephalexin | 0.5 | 4 |
| Cefaclor | 0.25–0.5 | 3 |

^aDS = double-strength tablet (160 mg trimethoprim/800 mg sulfamethoxazole).

treatment of these patients is unknown. Azithromycin should be considered as the macrolide/azalide of choice when considering the drug's *in vitro* antibacterial spectrum of activity, tissue distribution characteristics, and lack of metabolic-based drug-drug interactions.⁴⁰ In contrast, the fluoroquinolones have emerged as effective alternative agents, particularly when gram-negative pathogens are involved or in more clinically or severely ill patients (see Table 106–2). The increasing resistance of selected pathogens to ciprofloxacin may necessitate the use of newer analogues with greater *in vitro* antibacterial activity, including penicillin-tolerant or -resistant *S. pneumoniae* (e.g., gatifloxacin). The increased cost of fluoroquinolones may be outweighed by the possible superiority of fluoroquinolones in their apparent initial success rate and more prolonged infection-free time period.^{26,27}

In the patient whose history suggests recurrent exacerbations of disease that might be attributable to specific events (i.e., it is seasonal or related to the winter months), a trial of prophylactic antibiotics might be beneficial. If no clinical improvement is noted over an appropriate time period (2 to 3 months per year for 2 to 3 years), further attempts at prophylactic therapy could be discontinued. Similarly, patient-specific antibiotic trials could be performed in individuals experiencing acute exacerbations, focusing on defining the infection-free period. Although less than desirable, this method of clinical assessment may distinguish patients who will benefit from prophylactic antibiotic therapy from those who will not.

BRONCHIOLITIS

EPIDEMIOLOGY AND ETIOLOGY

7 Bronchiolitis is an acute viral infection of the lower respiratory tract most commonly affecting infants during the first year of life, with peak attack rates occurring in infants between the ages of 2 and 10 months. Infectious bronchiolitis is unusual in children older than 2 years of age. The occurrence of bronchiolitis peaks during

the winter months and persists through early spring. Bronchiolitis remains a major reason why infants younger than 6 months of age require hospitalization. The hospitalization rate for infants younger than 6 months of age for bronchiolitis approximates 6 per 1000 children per year. The incidence of bronchiolitis appears to be more common in males than in females.^{12,13,41}

Respiratory syncytial virus (RSV) is the most common cause of bronchiolitis, accounting for 45% to 60% of all cases. During epidemic periods, the incidence of RSV-induced bronchiolitis can

exceed 80% of cases. Parainfluenza viruses type 3 (10% to 15%), type 1 (5% to 10%), and type 2 (1% to 5%) are the second most common pathogens, constituting as a group nearly 25% of cases. Bacteria serve as secondary pathogens in a minority of cases.

CLINICAL PRESENTATION

A prodrome suggesting an upper respiratory tract infection, usually lasting from 2 to 7 days, precedes the onset of clinical symptoms (Table 106–6). As a result of limited oral intake because of coughing combined with fever, vomiting, and diarrhea, infants frequently are dehydrated. The increased work of breathing and tachypnea most likely further increases fluid loss. In most cases, this clinical picture persists between 3 and 7 days. Although the hospital course of bronchiolitic children is often variable, substantial clinical improvement usually is observed within the first 2 days, with gradual improvement and resolution over the next 7 to 21 days.

The diagnosis of bronchiolitis is based primarily on history and clinical findings. It is important for the clinician to attempt to differentiate between bronchiolitis and a host of other clinical entities affecting infants, which may produce a similar picture of dyspnea and wheezing. Asthma, congestive heart failure, anatomic airway abnormalities, cystic fibrosis, foreign bodies, and gastroesophageal reflux are the primary disease entities that may present with wheezing on physical examination in children. The isolation of a viral pathogen in the respiratory secretions of a wheezing child establishes a presumptive diagnosis of infectious bronchiolitis. The ability to identify specific viral pathogens is, however, often hindered by the limited availability of special virology laboratories. The proliferation of commercial enzyme-linked immunosorbent assays (ELISA) and fluorescent antibody staining techniques of nasopharyngeal secretions has increased the ability to identify viral antigens within several hours.¹⁶

TABLE 106–6. Clinical Presentation of Bronchiolitis

Signs and Symptoms

Prodrome with irritability, restlessness, and mild fever
Cough and coryza
Vomiting, diarrhea, noisy breathing, and an increase in respiratory rate as symptoms progress
Labored breathing with retractions of the chest wall, nasal flaring, and grunting

Physical Examination

Tachycardia and respiratory rate of 40–80 per minute in hospitalized infants
Wheezing and inspiratory rales
Mild conjunctivitis in one third of patients
Otitis media in 5–10% of patients

Laboratory Examinations

Peripheral white blood cell count normal or slightly elevated
Abnormal arterial blood gases (hypoxemia and, rarely, hypercarbia)

Identification of RSV by PCR should be available routinely from most clinical laboratories, but its relevance to the clinical management of bronchiolitis remains obscure.

Multiple clinical laboratory determinations have been used to assist in the management of cases of bronchiolitis. Roentgenographic evaluation of the chest in children with bronchiolitis yields variable findings, but may help to distinguish this illness from other entities characterized by wheezing.²⁸ In children requiring hospitalization, abnormalities in blood gas tensions are frequent and appear to relate to disease severity. Hypoxemia is common and increases the respiratory drive, whereas hypercarbia is seen only in the most severe cases. Despite the presence of moderate degrees of hypoxemia, clinical cyanosis is unusual.

► TREATMENT: Bronchiolitis

■ DESIRED OUTCOME

◀ In the well infant, bronchiolitis is usually a self-limiting illness, and reassurance and antipyretics are usually all that are necessary while waiting for resolution of the underlying viral infection. In-hospital support is necessary for the child suffering from respiratory failure or dehydration; underlying cardiac and pulmonary diseases potentiate these conditions.

■ GENERAL APPROACH TO TREATMENT

◀ Almost all otherwise healthy babies with bronchiolitis can be followed as outpatients. Such infants are treated for fever, provided generous amounts of oral fluids, and observed closely for evidence of respiratory deterioration. In severely affected children, the mainstays of therapy for bronchiolitis are oxygen therapy and intravenous fluids. In a subset of patients, aerosolized bronchodilators may have a role. In selected infants, particularly those with underlying pulmonary or cardiac disease or both, with severe acute infection, therapy with the antiviral agent ribavirin may be considered.

■ PHARMACOLOGIC THERAPY

◀ Aerosolized β_2 -adrenergic therapy appears to offer little benefit for the majority of patients and may even be detrimental.^{13,41,42} However, this therapy may offer some benefit to the child with a predisposition toward bronchospasm. In hospitalized patients, bronchodilator therapy may be offered initially, but should not be pursued in the absence of a clearcut clinical benefit. Similarly, controlled trials of corticosteroids have failed to reveal any therapeutic benefit (or harmful effect) when administered to bronchiolitic infants.^{41,42} As a result, the routine use of systemically administered corticosteroids is discouraged. Although it has been common practice to place children with bronchiolitis in mist tents, there are no data to document the effectiveness of this practice.

CLINICAL CONTROVERSY

Because bacteria do not represent primary pathogens in the etiology of bronchiolitis, antibiotics should not be administered routinely. Despite this, many clinicians frequently administer antibiotics initially while awaiting culture results because the clinical and radiographic findings in bronchiolitis are often suggestive of a possible bacterial pneumonia.⁴³

Ribavirin may offer benefit to a subset of infants with bronchiolitis. Although ribavirin, a synthetic nucleoside, possesses *in vitro* antiviral properties against a variety of RNA and DNA viruses, including influenza A, influenza B, parainfluenza, and adenovirus,⁴⁴ it is approved only in aerosolized form against RSV.⁴⁵ Use of the drug requires special equipment (small-particle aerosol generator) and specially trained personnel for administration via oxygen hood or mist tent.¹³ Special care must be taken to avoid drug particle deposition and the resulting clogging of respiratory tubing and valves in mechanical ventilators.⁴⁶

Among hospital admissions for RSV infection, ribavirin therapy failed to decrease length of hospital stay, number of days in the intensive care unit, or number of days receiving mechanical ventilation.⁴⁷ Consequently, the American Academy of Pediatrics has modified its recommendation for the use of ribavirin from “should be used” to “may be considered.”⁴⁸ In light of this and because of the requirement

for special aerosolization equipment and the cost of the drug itself, most experts recommend reserving use of ribavirin for severely ill patients, especially those with chronic lung disease (particularly bronchopulmonary dysplasia), congenital heart disease, prematurity, and immunodeficiency (especially severe combined immunodeficiency and human immunodeficiency virus [HIV] infection).^{49,50} Ribavirin also may be considered in otherwise healthy patients with severe distress because of RSV infection.

In infants with underlying pulmonary or cardiovascular disease, prophylaxis against RSV may be warranted. When administered monthly during the RSV season, both respiratory syncytial virus immune globulin (RSVIG)⁵¹ and palivizumab⁵² (a monoclonal antibody for RSV) may decrease the number of RSV episodes and the need for hospitalization. Among the two, palivizumab appears to be preferred, given its ease of administration, lack of administration-related adverse effects, and noninterference with select immunizations.

PNEUMONIA

EPIDEMIOLOGY

Pneumonia is the most common infectious cause of death in the United States, where approximately 4 million cases are diagnosed annually at a cost of \$23 billion redundant to the health care system. Pneumonia occurs throughout the year, with the relative prevalence of disease resulting from different etiologic agents varying with the seasons. It occurs in persons of all ages, although the clinical manifestations are most severe in the very young, the elderly, and the chronically ill.

PATHOGENESIS

Microorganisms gain access to the lower respiratory tract by three routes. They may be inhaled as aerosolized particles, or they may enter the lung via the bloodstream from an extrapulmonary site of infection; however, aspiration of oropharyngeal contents, a common occurrence in both healthy and ill persons during sleep, is the major mechanism by which pulmonary pathogens gain access to the normally sterile lower airways and alveoli. When pulmonary defense mechanisms are functioning optimally, aspirated microorganisms are cleared from the region before infection can become established^{1–4}; however, aspiration of potential pathogens from the oropharynx can result in pneumonia if lung defenses are impaired. Factors that promote aspiration, such as altered sensorium and neuromuscular disease, may result in an increase in the size of the inoculum delivered to the lower respiratory tract, thereby overwhelming local defense mechanisms. Lung infections with viruses suppress the antibacterial activity of the lung by impairing alveolar macrophage function and mucociliary clearance, thus setting the stage for secondary bacterial pneumonia. Mucociliary transport is also depressed by ethanol and narcotics and by obstruction of a bronchus by mucus, tumor, or extrinsic compression. All these factors can severely impair the pulmonary clearance of aspirated bacteria.^{1–4}

8 The most prominent pathogens causing community-acquired pneumonia in otherwise healthy adults are *S. pneumoniae* (pneumococcus) and *M. pneumoniae*. Pneumococcus is the most common cause of bacterial pneumonia in all age groups and accounts for up to 70% of all acute bacterial pneumonias in the United States. *M. pneumoniae* is believed to account for 10% to 20% of cases. *Legionella*, *C. pneumoniae*, and a variety of viruses also cause pneumonia among otherwise healthy persons.⁵³ Community-acquired

pneumonias caused by *S. aureus* and gram-negative rods are observed primarily in the elderly, especially those residing in nursing homes, and in association with alcoholism and other debilitating conditions.⁵⁴ The term *atypical* may be applied to pneumonia to indicate that the pneumonia may be caused by an atypical pathogen. Although this is older terminology that is slowly fading, a reference to atypical pneumonia or atypical pathogens refers to pneumonia (i.e., bilateral lobar pneumonia with a negative Gram stain) caused by *M. pneumoniae*, *C. pneumoniae*, or *Legionella*.

Gram-negative aerobic bacilli and *S. aureus* are the leading causative agents in hospital-acquired pneumonia.⁵⁵ Anaerobic bacteria are the most common etiologic agents in pneumonia that follows the gross aspiration of gastric or oropharyngeal contents.

Pneumonia in infants and children is caused by a wider range of microorganisms, and unlike in adults, nonbacterial pathogens predominate. Most pneumonias in the pediatric age group are caused by viruses, especially RSV, parainfluenza, and adenovirus. *M. pneumoniae* is an important pathogen in older children. Beyond the neonatal period, pneumococcus is the major bacterial pathogen in childhood pneumonia, followed by group A *Streptococcus* and *S. aureus*. *H. influenzae* type b, once a major childhood pathogen, has become an infrequent cause of pneumonia since the introduction of active vaccination against this organism in the late 1980s.

CLINICAL PRESENTATION

BACTERIAL PNEUMONIA

Bacterial pneumonia is caused most commonly by gram-positive streptococci and staphylococci and gram-negative organisms that normally inhabit the gastrointestinal tract (enterics) and soil and water (nonenterics). In addition, *Legionella pneumophila*, itself a weakly staining gram-negative nonenteric organism, accounts for a small percentage of community- and hospital-acquired bacterial pneumonia. Finally, *Mycobacterium tuberculosis*, an acid-fast staining bacillus, has reemerged as an important cause of pneumonia in urban centers throughout the United States.

Although a wide array of gram-positive and gram-negative organisms can cause pneumonia, they usually present a similar clinical appearance (Table 106–7). Pneumococcus, *Staphylococcus*, the enteric gram-negative rods, and occasionally other organisms may produce local irritation or destruction of blood vessels leading to rust-colored sputum or hemoptysis. Pleural effusions, both sterile

TABLE 106–7. Clinical Presentation of Pneumonia**Signs and Symptoms**

Abrupt onset of fever, chills, dyspnea, and productive cough
Rust-colored sputum or hemoptysis
Pleuritic chest pain

Physical Examination

Tachypnea and tachycardia
Dullness to percussion
Increased tactile fremitus, whisper pectoriloquy, and egophony
Chest wall retractions and grunting respirations
Diminished breath sounds over the affected area
Inspiratory crackles during lung expansion

Chest Radiograph

Dense lobar or segmental infiltrate

Laboratory Examination

Leukocytosis with a predominance of polymorphonuclear cells
Low oxygen saturation on arterial blood gas or plus oximetry

and empyematous, may be associated with many of these entities, evidenced by distant breath sounds and a wide area of dulled percussion. The chest radiograph and sputum examination and culture are the most useful diagnostic tests in gram-positive and gram-negative bacterial pneumonia. Typically, the chest radiograph reveals a dense lobar or segmental infiltrate. Patchy consolidation may be seen occasionally, however, with virtually all these pathogens. Occasionally, pneumonia resulting from hematogenous spread of the organisms results in a diffuse, alveolar pattern on chest radiograph. Gram stain of the expectorated sputum demonstrates many polymorphonuclear cells per high-powered field in the presence of a predominant organism (see Fig. 106–1), which is reflected in heavy growth of a single species on culture. Other laboratory tests are less sensitive or specific. Blood cultures may be helpful in identifying the offending organism, but are positive in only a minority of patients. The complete blood count usually reflects a leukocytosis with a predominance of polymorphonuclear cells; in some instances, particularly with pneumococcus, the elevation of the white blood cell (WBC) count may be pronounced. Normal or mildly elevated WBC counts, however, do not exclude bacterial pneumonic disease. The patient also may be hypoxic, as reflected by low oxygen saturation on arterial blood gas or pulse oximetry.

Although the clinical appearance of the gram-positive and gram-negative pneumonias is similar, there are epidemiologic and clinical clues that render one more likely than the other.

Gram-Positive Bacteria

8 Pneumococcus is the most common community-acquired bacterial pneumonia, accounting for 25% to 70% of cases. It is particularly prevalent and severe in patients with splenic dysfunction, diabetes mellitus, chronic cardiopulmonary or renal disease, or HIV infection. *S. aureus* pneumonia occurs in both the community and hospital settings.⁵⁵ Community-acquired disease with *S. aureus* is identified most frequently in young infants, patients with early cystic fibrosis, and those recovering from an antecedent respiratory viral infection. *S. aureus* is a prominent cause of nosocomial pneumonia and may result from hematogenous spread from a distant source. In both settings, it is characteristically severe and accompanied by the formation of pneumatoceles (air-containing cavities within the lung). Group B *Streptococcus*, although rare in adults, is the most common cause of bacterial pneumonia among neonates, where it typically causes a clinical and radiographic picture nearly indistinguishable from hya-

line membrane disease.⁵⁶ Group A *Streptococcus* is an uncommon cause of community-acquired pneumonia and frequently occurs after a viral respiratory tract infection. Only occasionally is it associated with streptococcal pharyngitis. The organism is pyogenic and the presentation can be severe.

Enteric Gram-Negative Bacteria

Community-acquired enteric gram-negative pneumonia is identified most frequently among patients with chronic illness, especially alcoholism and diabetes mellitus. The enteric gram-negative bacteria are also leading causes of nosocomial pneumonia because the upper respiratory tract becomes rapidly colonized with gram-negative organisms after hospitalization, particularly among critically ill patients and those receiving antibiotics. Outbreaks of nosocomial disease may be caused occasionally by contaminated respiratory therapy equipment. *Klebsiella pneumoniae* is the most frequently encountered pathogen among the gram-negative enteric bacteria, although the relative prominence of these organisms varies from hospital to hospital. The gram-negative bacilli are associated with high mortality, sometimes exceeding 50%; their potential to produce significant morbidity and mortality also has been enhanced by the emergence of highly antibiotic-resistant organisms in some hospital settings.⁵⁷

Nonenteric Gram-Negative Bacteria

The most prominent nonenteric gram-negative rods associated with pneumonia include *Pseudomonas*, *Hemophilus*, and *Moraxella*. Like the enteric gram-negative organisms, *Pseudomonas aeruginosa* is a frequent cause of hospital-acquired pneumonia and is particularly prominent among neutropenic and burn patients.⁵⁷ In addition, cystic fibrosis patients suffer from chronic, multilobar infections with *P. aeruginosa*, as well as other *Pseudomonas* spp.; these infections are punctuated with acute exacerbations.⁵⁸ *H. influenzae* type b historically has been a prominent pathogen in childhood pneumonia. Since the introduction of the conjugated *Hemophilus* vaccines in the late 1980s, however, there has been a dramatic drop in the incidence of all invasive disease owing to this organism in the pediatric age group. Two different clinical presentations of *H. influenzae* pneumonia are still seen in adults, however. The most common by far is the bronchopneumonia form, which develops most frequently in patients with underlying chronic lung disease and is believed to represent, in most patients, an exacerbation of chronic bronchitis. In the second form of *H. influenzae* pneumonia, segmental or lobar involvement predominates. The course of this illness is more acute, with sudden onset of cough, fever, and pleuritic chest pain. Finally, *M. catarrhalis*, an important cause of otitis media and sinusitis, has been found to be an increasingly important cause of lower respiratory tract infections in immunoincompetent and hospitalized patients.

Legionella pneumophila

Of the several *Legionella* spp. known to cause pneumonia in humans, *L. pneumophila* is by far the most important and accounts for 2% to 15% of all community-acquired pneumonias in North America and Europe.⁵⁹ *Legionella* is a water and soil organism and most probably is transmitted by the inhalation of aerosols containing the organism or by microaspiration of contaminated water. Outbreaks of illness caused by *L. pneumophila* have been linked to excavation sites and to contaminated water from air conditioners and showers. Person-to-person transmission has not been demonstrated. In addition to epidemics, *L. pneumophila* causes sporadic illness that peaks in summer and fall. Individuals who are male, middle-aged or older, immunocompromised, chronic bronchitics, or cigarette smokers are at increased risk.

Infection with *L. pneumophila* is characterized by multisystem involvement, including rapidly progressive pneumonia. It has a gradual onset, with prominent constitutional symptoms, such as malaise, lethargy, weakness, and anorexia, occurring early in the course of the illness. A dry, nonproductive cough is present initially that becomes productive of mucoid or purulent sputum over several days. Fevers exceeding 40°C (104°F) develop in more than half of patients and typically are unremitting and associated with a relative bradycardia. Pleuritic chest pain and progressive dyspnea may be seen. Extrapulmonary symptoms remain evident throughout the course of the illness, particularly diarrhea, nausea, and vomiting. Myalgias and arthralgias also occur. Substantial changes in a patient's mental status, often out of proportion to the degree of fever, are seen in approximately one-fourth of patients. Obtundation, hallucinations, grand mal seizures, and focal neurologic findings are also associated with this illness. Chest roentgenograms initially reveal patchy alveolar infiltrates that may be bilateral. Progression to lobar or multilobar consolidation is frequent, as are small pleural effusions.

Laboratory findings include leukocytosis with a predominance of mature and immature granulocytes in 50% to 75% of patients. Urinalysis may reveal proteinuria, hematuria, and casts; liver function tests may be abnormal. Hyponatremia and hypophosphatemia also have been reported frequently. Because *L. pneumophila* stains poorly with commonly used stains, routine microscopic examination of sputum is of little diagnostic value. While it exhibits slow growth and has highly selective growth requirements, *L. pneumophila* has been isolated successfully from tissue using a specialized medium. Direct fluorescent antibody examination of respiratory tract secretions, lung tissue, or pleural fluid is the most rapid means of establishing the diagnosis. The sensitivity of this method approaches 70% for sputum and 90% for lung tissue, and diagnostic specificity is high for both.⁵⁹ Commercially available urine antigen tests have been developed for *L. pneumophila*; these tests are 70% sensitive and remain positive for weeks, even after effective antibiotics have been started. Because these diagnostic tests are unavailable in many clinical laboratories, the diagnosis of Legionnaire's disease often is presumptive and based on a suggestive clinical presentation.

Anaerobic Pneumonia

8 Anaerobic pneumonitis is most likely to occur in individuals predisposed to aspiration by impaired consciousness and may be more prevalent in those with periodontal disease or dysphagia. In addition, bronchogenic carcinoma is an associated underlying condition. A variety of gram-positive and gram-negative anaerobic bacteria indigenous to the upper airway may cause pneumonitis when large quantities of oropharyngeal secretions are aspirated into the lower airways. The organisms most frequently implicated are *Peptostreptococcus* spp., *Fusobacteria*, *Bacteroides melaninogenicus*, *Bacteroides fragilis*, and *Peptococcus* spp.; polymicrobial infections with anaerobes and aerobes, such as *S. aureus*, *S. pneumoniae*, and gram-negative bacilli, are common.⁶⁰

The course of illness typically is indolent, with cough, low-grade fever, and weight loss, although an acute presentation may occur. Rigors are notably absent and bacteremia is rare. Putrid sputum, when present, is highly suggestive of the diagnosis. Chest radiographs reveal infiltrates typically located in dependent lung segments, and lung abscesses develop in 20% of patients 1 to 2 weeks into the course of the illness.⁶⁰

Tuberculosis

The acid-fast bacillus *M. tuberculosis* causes tuberculosis. After years of steady decline, the number of cases of pneumonia caused by

M. tuberculosis in the United States began to increase in the middle to late 1980s. The new epidemic was a consequence of an increased incidence in prison inmates, intravenous drug abusers, immigrants, and most prominently, HIV-infected patients⁶¹ and is most prominent in urban neighborhoods afflicted with crowded conditions and poor access to health care. Unlike previous eras in which tuberculosis was seen most frequently in elderly men, infection currently is identified in increasing numbers of young minority adults.⁶² As mentioned, the resurgence of tuberculosis is at least partially related to coinfection with HIV; HIV-infected patients are more likely to develop symptomatic disease with its associated fits of coughing than their immunocompetent counterparts, and this enables further spread of infection.⁶³ Other groups prone to tuberculosis include the homeless and patients in chronic care facilities and homes for the elderly. Fortunately, since 1992, the incidence of tuberculosis in the United States has declined, reaching a record low. However, worldwide, the incidence continues to increase. Both this sustained worldwide increase in tuberculosis and the past reemergence of tuberculosis in the United States are important reasons for the development of multiple-drug resistance, that is, mycobacteria that are resistant to two or more of the first-line antituberculosis drugs. Infection caused by these organisms is poorly responsive to alternative therapy and is associated with mortality rates exceeding 50% (see Chap. 110).

Tuberculosis is spread person-to-person through the inhalation of droplet nuclei generated by vigorous coughing. Most patients who become infected with *M. tuberculosis* remain asymptomatic despite lifelong infection and have a normal chest radiograph. Infection in these patients is detected only through routine skin testing. Less frequently, particularly in those with poor immunity, the infection cannot be contained by local macrophages, and the tuberculous burden grows sufficiently to cause clinical manifestations.

Adult disease (from adolescence onward) begins with constitutional complaints, followed by a prominent chronic, troublesome cough productive of mucopurulent material. The infection appears initially in the lung apices with little or no hilar adenopathy and, in advanced disease, results in lung necrosis, producing a cavity containing enormous numbers of organisms. With sufficient cough, the cavity contents are mobilized and aspirated into other areas of the lung, where additional cavities may be formed.

In contrast, pediatric tuberculosis commonly is associated with little cough even in the presence of extensive pulmonary infection. Instead, the child presents with a subacute course of poor appetite, weight loss, lethargy, fever, and sweats. The chest radiograph reveals a widened mediastinum representing enlarged hilar lymph nodes reacting to the tuberculin inoculum. In progressive cases, the nodes impinge on or erode through a large bronchus, resulting in a dense consolidation of the segment distal to the lesion. Cavitary disease is uncommon.

Nonbacterial Pneumonia

Viruses, *Mycoplasma* spp., *Chlamydia* spp., and fungi are recognized causes of pneumonia syndromes in all age groups. The designation *atypical pneumonia*, distinct from the typical bacterial pneumonia seen most commonly in adults, has been used to describe the illness caused by many of these agents.⁶⁴

Mycoplasma Pneumonia

Taxonomically, the mycoplasmas are included in their own class labeled Mollicutes. Although their small size and filterability are similar to viruses, the structure of their ribosomal RNA indicates that they have evolved from bacteria, and unlike any virus, they contain cytoplasm and can replicate in an extracellular environment. They are

distinguished from eubacteria by their low genetic content; in addition, the mycoplasmas lack a cell wall and are surrounded instead by a lipid membrane.⁶⁴

M. pneumoniae causes human disease throughout the year, with a slightly increased incidence in fall and early winter. During the summer months when other causes of pneumonia are less common, *M. pneumoniae* is responsible for a greater proportion of cases. Both infection and disease from *M. pneumoniae* are common, with two-thirds of children ages 2 to 5 years and 97% of persons older than 17 years of age having detectable serum antibody to the organism. Overall, *M. pneumoniae* is responsible for approximately 20% of pneumonia cases, although in enclosed populations, such as military recruits and college dormitory residents, it may cause more than 50%. Infection is spread by close person-to-person contact, and the incubation period is 2 to 3 weeks. *M. pneumoniae* infections are unusual in children younger than 5 years of age and show a peak incidence in older children and young adults. Only 3% to 10% of persons infected with *M. pneumoniae* develop pneumonia, with the majority of respiratory tract involvement being manifested as pharyngitis and tracheobronchitis. Asymptomatic infection is common.

M. pneumoniae presents with a gradual onset of fever, headache, and malaise, with the appearance 3 to 5 days after the onset of illness of a persistent, hacking cough that initially is nonproductive. Sore throat, ear pain, and rhinorrhea often are present. Chills are seen only occasionally, and pleuritic pain is uncommon. Lung findings generally are limited to rales and rhonchi; findings of consolidation are present rarely. Nonpulmonary manifestations are extremely common and include nausea, vomiting, diarrhea, myalgias, arthralgias, polyarticular arthritis, skin rashes, myocarditis and pericarditis, hemolytic anemia, meningoencephalitis, cranial neuropathies, and Guillain-Barré syndrome. Systemic symptoms generally clear in 1 to 2 weeks, whereas respiratory symptoms may persist for up to 4 weeks. Although the course of mycoplasmal pneumonia usually is benign and self-limited, severe respiratory disease may develop in patients with sickle cell disease, agammaglobulinemia, and COPD.⁶⁴

Radiographic findings generally are more impressive than the patient's physical findings and include patchy or interstitial infiltrates, which are seen most commonly in the lower lobes. Small unilateral, transient pleural effusions are common, but large effusions and empyema are rare. Roentgenographic abnormalities resolve slowly, and 4 to 6 weeks may be required for complete resolution.

Sputum Gram stain may reveal mononuclear or polymorphonuclear leukocytes, with no predominant organism. Although *M. pneumoniae* can be cultured from respiratory secretions using specialized medium, its growth is slow, and 2 to 3 weeks may be necessary for culture identification. Indirect evidence of infection by *M. pneumoniae* is the presence of elevated levels of serum cold hemagglutinins. These immunoglobulin M (IgM) antibodies develop in approximately half of patients with mycoplasmal pneumonia and can be elevated in other illnesses, especially viral infection. A definitive diagnosis also can be made by demonstrating a fourfold or greater rise in serum antibodies to *M. pneumoniae*; however, because this test also requires 2 to 4 weeks for results, the diagnosis of mycoplasmal pneumonia during the acute phase of the illness must be based on the characteristic history, appropriate clinical setting, and typical physical findings.

Chlamydia Pneumonia

C. pneumoniae, formally designated the *TWAR agent*, after the laboratory designations for the first two isolates, is a relatively recently identified pathogen antigenically similar to *C. psittaci*. *C. pneumoniae* infection is ubiquitous worldwide, but only a small percentage of

infections result in clinically apparent pneumonia.⁶⁵ Conversely, approximately 5% to 15% of pneumonia is associated with this pathogen. Primary-infection *Chlamydia pneumoniae* typically occurs in young adults and is characterized by mild respiratory symptoms with a gradual onset. Constitutional manifestations, particularly fever and headache, are common. The radiographic findings are nonspecific and usually consist of multilobular interstitial infiltrates. Immunity is incomplete and reinfection with *C. pneumoniae* is common, particularly among the elderly. The definitive diagnosis of *C. pneumoniae*-associated pneumonia depends on identification of the organism in sputum. Culture of this organism is difficult, and antigen-detection systems, though available commercially, are insensitive.

Viral Pneumonia

Viruses are an uncommon cause of pneumonia in adults except in the immunosuppressed. Influenza virus, usually type A, is the most common cause of pneumonia in the adult civilian population, whereas adenoviruses cause most cases in military trainees. In contrast, viruses are by far the most common agents producing pneumonia in infants and young children, with RSV, parainfluenza, and adenovirus producing most cases.

All viral respiratory tract infections occur more commonly in the winter, and rapid person-to-person spread through susceptible populations is typical. Underlying cardiac or pulmonary disease predisposes to an increased incidence and severity of viral lower respiratory tract infection, especially with influenza virus in adults and RSV in children. Radiographic findings are nonspecific and include bronchial wall thickening and perihilar and diffuse interstitial infiltrates. Pleural effusions may be seen, especially in adenovirus and parainfluenza pneumonia.

The clinical pictures produced by respiratory viruses are sufficiently variable and overlap to such a degree that an etiologic diagnosis cannot be made confidently on clinical grounds alone. Although virus isolation in tissue culture is possible, 7 or more days are often required for virus identification; thus this method usually cannot be relied on for definitive diagnosis during the acute phase of illness. Serologic tests for virus-specific antibodies are used often in the diagnosis of viral infections. The diagnostic fourfold rise in titer between acute and convalescent phase sera may require 2 to 3 weeks to develop. Same-day diagnosis of viral infections is now possible through the use of indirect immunofluorescence tests on exfoliated cells from the respiratory tract. The immunofluorescence technique frequently employs a battery of monoclonal antibodies, including those against influenza A and B, RSV, parainfluenza, and adenovirus, to provide rapid diagnosis of a range of viral infections.¹⁶

PNEUMONIA IN SPECIAL CLINICAL CIRCUMSTANCES

Pneumonia in the HIV-Infected Patient

HIV infects and destroys helper T-lymphocytes bearing the CD4 surface molecule; these cells are critical for orchestrating a wide variety of immunologic responses. Their depletion consequently results in the dysfunction of both cell-mediated and humoral immunity. As a result, a broad range of pathogens can cause pneumonia in HIV infection⁶⁶⁻⁶⁸ (Table 106-8). The HIV-infected patient may be afflicted with pneumonia multiple times in his or her lifetime, particularly in the advanced stages of the disease, and a given episode may be caused by more than one species.

The clinical presentation of pneumonia in HIV-infected persons is frequently not helpful in distinguishing one pathogen from another.

From ref. 61.

The pneumonia usually is subacute in onset and consists of fever, nonproductive cough, and dyspnea. Radiographically, most of these entities produce a multilobular or diffuse pattern. Some practitioners initially treat the HIV-infected patient with pneumonia empirically, covering the most common entities (bacteria and *Pneumocystis carinii*). More frequently, however, given the wide array of possible pathogens, a specific microbiologic diagnosis is aggressively pursued early in the patient's course through sputum induction or bronchoalveolar lavage to allow a rational choice of an antimicrobial regimen.^{66–68} The diagnosis and treatment of HIV-infected patients with pulmonary disease is discussed in detail in Chap. 123.

Pneumonia in the Neutropenic Host

Neutropenia in the cancer patient is a common complication of aggressive chemotherapy, but occasionally can result from the cancer itself. The risk of infection in the cytopenic patient is increased significantly when the absolute neutrophil count falls below 500 cells/mm³ and the neutropenia persists for longer than 7 days.^{69–71} In many patients, the duration of chemotherapy-induced cytopenia can be reduced by the judicious application of colony-stimulating factors.⁷²

The organisms that cause pneumonia in the cytopenic cancer patient include a broad range of bacteria and fungi. Prominent among these are enteric and nonenteric (particularly *Pseudomonas*) gram-negative rods, streptococci, and staphylococci, as well as the fungi *Candida*, *Aspergillus*, and *Mucor*.^{69–71} The chest radiograph may re-

veal the lobar pattern typical of bacterial infection in the normal host, or it may exhibit a diffuse pattern; sometimes the pneumonia remains invisible by chest radiograph until the neutropenia resolves. Noninfectious entities also may cause pulmonary symptoms; these include toxicity from radiation or chemotherapy or infiltration of the lung parenchyma by the tumor itself.

Nosocomial Pneumonia

After the urinary tract and the bloodstream, the lungs are the most frequent site of infection acquired in the hospital.^{57,73} Nosocomial pneumonia is seen most commonly in critically ill patients. Several factors that predispose to the development of nosocomial pneumonia include the severity of illness, duration of hospitalization, and prior antibiotic exposure. The strongest predisposing factor, however, is mechanical ventilation (intubation), which bypasses the natural airway defenses against the migration of upper respiratory tract organisms into the lower tract. This situation is exacerbated by the wide use of H₂-receptor blocking agents in the intensive care unit.^{57,74} Such use increases the pH of gastric secretions and may promote the proliferation of microorganisms in the upper gastrointestinal tract. Subclinical microaspirations are events that occur routinely in intubated patients resulting in the inoculation of bacteria-contaminated gastric contents into the lung and a higher incidence of nosocomial pneumonia. Ventilator-associated pneumonia can be diagnosed accurately by any one of multiple standard criteria, including histopathologic examination of lung tissue obtained by open-lung biopsy, rapid cavitation of a pulmonary infiltrate in the absence of cancer or tuberculosis, positive pleural fluid culture, and same species with an identical antibiogram for a pathogen(s) isolated from blood and respiratory secretions without another identifiable source of bacteremia.⁷⁵

The organisms most commonly associated with nosocomial pneumonia are *S. aureus* and enteric (e.g., *Klebsiella* or *Escherichia coli*) and nonenteric (e.g., *Pseudomonas*) gram-negative bacilli, organisms that colonize the pharynx of the hospitalized, critically ill patient. The diagnosis of nosocomial pneumonia usually is established by the presence of a new infiltrate on chest radiograph, fever, worsening respiratory status, and the appearance of thick, neutrophil-laden respiratory secretions. In actuality, the diagnosis is often difficult to make in the intensively ill patient with underlying lung pathology that can itself be associated with an abnormal, changing radiograph, such as congestive heart failure or chronic lung disease. Broad-spectrum antibiotics frequently are started empirically even in equivocal circumstances, with bronchoscopy reserved for poorly responsive patients.^{74,76}

Severe Acute Respiratory Syndrome

In November 2002, an extremely contagious atypical pneumonia manifested in China that since has been termed *severe acute respiratory syndrome* (SARS).⁷⁷ The etiology of SARS is an enveloped RNA virus, a coronavirus, referred to as SARS-CoV. The virus is transmitted primarily via large-droplet spread; however, surface contamination and airborne and fecal spread are also possible. Signs and symptoms associated with SARS include high fever, myalgias, headache, diarrhea, and a dry, nonproductive cough. The respiratory symptoms may progress to shortness of breath and hypoxemia, necessitating the need for intubation and mechanical ventilation. Diagnostic tests for patients suspected of contracting SARS should include chest x-ray, blood cultures, sputum cultures and Gram stain, pulse oximetry, and identification of other potential pathogens, including influenza A and B, *Legionella*, and RSV. For unclear reasons, SARS appears to be less severe in pediatric patients.

► TREATMENT: Pneumonia

■ DESIRED OUTCOME

Eradication of the offending organism through the selection of the appropriate antibiotic and complete clinical cure are the goals of therapy for bacterial pneumonia. Therapy should minimize associated morbidity, including either one or both of these: reversible or irreversible disease and drug-induced organ toxicity (e.g., renal, lung, or hepatic dysfunction). Most cases of viral pneumonia are self-limiting, although therapy of influenza pneumonia with specific antiviral agents (amantadine or rimantadine) may hasten recovery. All efforts should focus on the design of the most cost-effective approach to therapy. Whenever possible, the oral (versus parenteral) route for drug administration should be selected, encouraging outpatient management rather than hospitalization.

■ GENERAL APPROACH TO TREATMENT

9 The first priority in assessing the patient with pneumonia is to evaluate the adequacy of respiratory function and to determine whether there are signs of systemic illness, specifically dehydration or sepsis with resulting circulatory collapse. Oxygen or, in severe cases, mechanical ventilation and fluid resuscitation should be provided as necessary. Further supportive care of the patient with pneumonia includes humidified oxygen for hypoxemia, administration of bronchodilators (albuterol) when bronchospasm is present, and chest physiotherapy with postural drainage if there is evidence of retained secretions. Additional therapeutic adjuncts include adequate hydration (intravenously if necessary), optimal nutritional support, and control of fever. Appropriate sputum samples may be obtained to determine the microbiologic etiology. Rehydration should be provided to replace losses that may have occurred because of fever, poor intake, associated vomiting, or all these. Finally, selection of an appropriate antimicrobial must be made based on the patient's probable or documented microbiology, distribution in the respiratory tract, side effects, and cost.

■ PHARMACOLOGIC THERAPY

■ ANTIBIOTIC CONCENTRATIONS

Antibiotic concentrations in respiratory secretions in excess of the pathogen MIC are necessary for successful treatment of pulmonary infections.^{78,79} The concept of a blood-bronchus barrier, analogous but dissimilar to the blood-brain barrier, has been used to assess the characteristics of drug penetration into pulmonary secretions. The ability of a drug to penetrate respiratory secretions depends on multiple physicochemical factors, including molecular size, lipid solubility, and degree of ionization at serum and biologic fluid pH and extent of protein binding. Studies performed in animals and cystic fibrosis patients suggest that larger molecular size favors the accumulation of drugs in bronchial secretions. This finding contrasts with data on drug penetration of other physiologic compartments, such as the cerebrospinal fluid, and may be a result of the trapping of lower-molecular-weight compounds in mucin pores. Nevertheless, the rate at which a drug may accumulate in certain respiratory secretions would

appear to remain an important factor relative to the drug's clinical efficacy in treating pulmonary infections. The un-ionized form of a drug and lipid solubility also appear to favor drug penetration. It should be noted that the pH of the infected bronchi is often more acidic than that of normal tissue and blood.^{79–81}

Fewer data are available for assessing the influence of drug protein binding on the rate and amount of respiratory secretion penetration. Clearly, it is the free antibiotic fraction reaching the infected site capable of binding to the bacterial cell target that is responsible for antibacterial activity. Since the degree of protein binding influences a drug's ability to traverse membranes, a similar relationship would be expected within the lung. However, focusing on the absolute amount for which an antibiotic is bound to plasma/tissue proteins without accounting for the drug's overall antibacterial potency is errant. To completely assess an antibiotic's therapeutic potential in the treatment of pneumonia, or any infectious process, it is prudent to assess the antibiotic's integrated pharmacokinetic-pharmacodynamic characteristics (i.e., bacterial killing may be concentration-dependent or time-dependent) that account for the drug's degree of binding to serum proteins, tissue distribution, and *in vitro* potency. Thus, simply focusing on a drug's degree of protein binding is an errant, overly simplistic approach that does not account for the drug's inherent antibacterial activity or distribution characteristics.

The concepts relating to antibiotic activity and overall drug penetration of respiratory secretions just outlined have supported the clinical practice of administering certain antibiotics (aminoglycosides) to achieve high peak serum concentrations on the assumption that higher (and possibly more effective) biologic fluid concentrations of the drug will be achieved. The aminoglycosides are large, polar molecules that diffuse poorly into tissue and respiratory secretions; however, with increasing concentrations as obtained with once-daily dosing, increased target-tissue concentrations would be expected with increasing individual doses. Substantial clinical experience supports this practice for treating pulmonary infections with certain antibiotics (i.e., concentration-dependent antimicrobials), although more data are needed to describe the relationships between these variables and clinical response (see Chap. 103).

CLINICAL CONTROVERSY

Prior to the availability of newer β -lactam and fluoroquinolone antibiotics possessing consistently potent activity against multiple gram-negative pathogens, the administration of antibiotics by direct endotracheal instillation was promoted by some investigators.^{79,81} This method of drug administration is an attempt to provide increased topical concentrations of antibiotics that do not appear to penetrate respiratory secretions effectively while reducing the likelihood of systemic toxicity. In addition, greater local concentrations of antibiotics, particularly for the polymyxins and aminoglycosides, are believed to overcome partially the substantial decrease in antibiotic bioactivity observed when these agents interact with the purulent material present in infectious foci.^{79–81} Despite these potential theoretical advantages, the role of antibiotic aerosols or direct endotracheal instillation in clinical practice remains controversial.

Sputum is frequently assessed as possibly representing the pharmacodynamic interface for pulmonary infections. However, sputum

represents only one of many pulmonary fluids and secretions, although sputum may serve as a reservoir for pathogen growth. These beliefs have led many investigators to assess antibiotic concentrations in sputum, frequently describing sputum drug concentrations as a ratio of serum to sputum drug concentration. Although sputum drug concentrations provide us with some insight into the characteristics of drug penetration of respiratory secretions, caution should be exercised in the interpretation of these data. Data describing sputum drug concentrations are often difficult to interpret because of differences in analytic techniques, method of sputum sampling, and random nature of sampling times relative to drug dose. Moreover, representation of sputum drug concentrations as a ratio of serum drug concentration can be misleading and most probably should be described relative to absolute drug concentration or apparent area under the drug concentration versus time curve in sputum. To more accurately describe the distribution characteristics of antimicrobial agents in sputum, research studies should be designed to allow sequential repeated sputum sampling over a dosage interval under both first-dose and steady-state conditions. Thus, until greater sophistication is realized in our understanding of the relationships between antibiotic concentrations in specific anatomic sites, plasma (blood)-based integrated pharmacokinetic-pharmacodynamic correlates should be used for antibiotic and dose selection.

■ SELECTION OF ANTIMICROBIAL AGENTS

The treatment of bacterial pneumonia, like the treatment of most infectious diseases, initially involves the empirical use of a relatively broad-spectrum antibiotic that is effective against probable pathogens after appropriate cultures and specimens for laboratory evaluation have been obtained.⁸² Therapy should be narrowed to cover specific

pathogens after the results of cultures are known. Multiple factors that help to define the potential pathogens involved include patient age, previous and current medication history, underlying disease(s), major organ function, and present clinical status. These factors must be evaluated to select an appropriate and effective empirical antibiotic regimen, as well as the most appropriate route for drug administration (oral or parenteral). For a more detailed discussion on the principles of antibiotic selection, see Chap. 104.

Numerous antibiotics are available, and the majority are effective in the treatment of bacterial pneumonia. Superiority of one antibiotic over another when both demonstrate similar *in vitro* activity and tissue distribution characteristics is difficult to define. Our opinions on appropriate empirical choices for the treatment of bacterial pneumonias relative to a patient's underlying disease are shown in Table 106–9 for adults and Table 106–10 for children. A complete listing of antimicrobial agents for specific pathogens is beyond the scope of this chapter and is presented in Chap. 104.

Table 106–11 lists dosages for the treatment of bacterial pneumonia. The list of commercially available antimicrobial agents with documented bacterial and clinical effectiveness in the treatment of pneumonia appears endless. The large number of expensive drugs mandates critical evaluation for formulary selection and clinical use. Similarities of *in vitro* activity, resistance to bacterial-inactivating enzymes, and overall effectiveness often make rational therapeutic decisions difficult and even appear random. Some general principles, however, may be applied to guide rational antibiotic choice, including direct comparison of the antibiotic's likely attainment of the defined pharmacokinetic-pharmacodynamic target correlate for specific bacterial species within the infected site. For the treatment of bacterial pneumonia with concentration-independent antimicrobials (e.g., β -lactams and carbapenems), a plasma drug concentration exceeding the pathogen MIC for more than 50% of the dosing interval correlates with

TABLE 106–9. Empirical Antimicrobial Therapy for Pneumonia in Adults^a

| Clinical Setting | Usual Pathogen(s) | Presumptive Therapy |
|--|--|---|
| Previously healthy, ambulatory patient | <i>Pneumococcus</i> , <i>Mycoplasma pneumoniae</i> | Macrolide/azalide, ^b tetracycline ^c |
| Elderly | <i>Pneumococcus</i> , gram-negative bacilli (such as <i>Klebsiella pneumoniae</i>); <i>Staphylococcus aureus</i> , <i>Hemophilus influenzae</i> | Piperacillin/tazobactam, cephalosporin ^d ; carbapenem ^e |
| Chronic bronchitis | <i>Pneumococcus</i> , <i>H. influenzae</i> , <i>M. catarrhalis</i> | Amoxicillin, tetracycline, ^c TMP-SMZ, ^f cefuroxime, amoxicillin/clavulanate, macrolide-azalide, ^b fluoroquinolone |
| Alcoholism | <i>Pneumococcus</i> , <i>K. pneumoniae</i> , <i>S. aureus</i> , <i>H. influenzae</i> , possibly mouth anaerobes | Ticarcillin-clavulanate, piperacillin-tazobactam, plus aminoglycoside; carbapenem, ^e fluoroquinolone ^g |
| Aspiration | | |
| Community | Mouth anaerobes | Penicillin or clindamycin |
| Hospital/residential care | Mouth anaerobes, <i>S. aureus</i> , gram-negative enterics | Clindamycin, ticarcillin-clavulanate, piperacillin-tazobactam, plus aminoglycoside |
| Nosocomial pneumonia | Gram-negative bacilli (such as <i>K. pneumoniae</i> , <i>Enterobacter</i> spp., <i>Pseudomonas aeruginosa</i>), <i>S. aureus</i> | Piperacillin-tazobactam, carbapenem, ^e or expanded spectrum cephalosporin ^h plus aminoglycoside, fluoroquinolone ^g |

^aSee section on treatment of bacterial pneumonia.

^bMacrolide/azalide: erythromycin, clarithromycin-azithromycin.

^cTetracycline: tetracycline HCl, doxycycline.

^dCephalosporin: cefuroxime, ceftriaxone, cefotaxime.

^eCarbapenem: imipenem-cilastatin, meropenem.

^fTMP-SMZ: trimethoprim-sulfamethoxazole.

^gFluoroquinolone: ciprofloxacin, gatifloxacin, or levofloxacin.

^hExpanded-spectrum cephalosporin: ceftazidime, cefepime.

TABLE 106–10. Empirical Antimicrobial Therapy for Pneumonia in Pediatric Patients^a

| Age | Usual Pathogen(s) | Presumptive Therapy |
|------------------|---|--|
| 1 month | Group B streptococcus, <i>Hemophilus influenzae</i> (nontypable), <i>Escherichia coli</i> , <i>Staphylococcus aureus</i> , <i>Listeria</i> , CMV, RSV, adenovirus | Ampicillin-sulbactam, cephalosporin ^b carbapenem ^c Ribavirin for RSV |
| 1–3 months | <i>Chlamydia</i> , possibly <i>Ureaplasma</i> , CMV, <i>Pneumocystis carinii</i> (afebrile pneumonia syndrome) RSV | Macrolide-azalide, ^d trimethoprim-sulfamethoxazole Ribavirin |
| 3 months–6 years | Pneumococcus, <i>S. aureus</i> Pneumococcus, <i>H. influenzae</i> , RSV, adenovirus, Parainfluenza | Semisynthetic penicillin ^e or cephalosporin ^f Amoxicillin or cephalosporin ^f Ampicillin-sulbactam, amoxicillin-clavulanate Ribavirin for RSV |
| >6 years | Pneumococcus, <i>Mycoplasma pneumoniae</i> , adenovirus | Macrolide/azalide ^d cephalosporin, ^f amoxicillin-clavulanate |

CMV = cytomegalovirus; RSV = respiratory syncytial virus.

^aSee section on treatment of bacterial pneumonia.

^bThird-generation cephalosporin: ceftriaxone, cefotaxime, cefepime. Note that cephalosporins are not active against *Listeria*.

^cCarbapenem: imipenem-cilastatin, meropenem.

^dMacrolide/azalide: erythromycin, clarithromycin-azithromycin.

^eSemisynthetic penicillin: nafcillin, oxacillin.

^fSecond-generation cephalosporin: cefuroxime, cefprozil.

See text for details regarding ribavirin treatment for RSV infection.

bacteriologic cure. For concentration-dependent antimicrobials (e.g., aminoglycosides and fluoroquinolones), a peak drug concentration to pathogen MIC ratio of greater than 8 to 10 or the ratio of the pathogen MIC to antibiotic area under the curve (AUC) of greater than 25 to 40 for gram-positive pathogens and greater than 100 for gram-negative pathogens correlates with bacteriologic cure. An understanding and application of these inherent drug characteristics would appear to be of the utmost importance for the selection of an optimal therapeutic regimen. Thus, whenever possible, identification of the causative pathogen and expected/defined antibiotic activity

(i.e., MIC) is of paramount importance to the selection/design of the optimal antibiotic regimen.

■ **COMMUNITY-ACQUIRED PNEUMONIA**

For community-acquired pneumonia, the bacterial causes are relatively constant, even across geographic areas and patient populations. Unfortunately, pathogen resistance to standard antimicrobials is increasing (e.g., penicillin-resistant pneumococci), necessitating

TABLE 106–11. Antibiotic Doses for the Treatment of Bacterial Pneumonia

| Antibiotic Class | Antibiotic | Daily Antibiotic dose | |
|----------------------------------|--|--|---|
| | | Pediatric (mg/kg/day) | Adult (total dose/day) |
| Macrolide | Clarithromycin | 15 | 0.5–1 g |
| | Erythromycin | 30–50 | 1–2 g |
| Azalide | Azithromycin | 10 mg/kg × 1 day, then 5 mg/kg/day × 4 days | 500 mg day 1, then 250 mg/day × 4 days |
| Tetracycline ^a | Tetracycline HCL | 25–50 | 1–2 g |
| | Oxytetracycline | 15–25 | 0.25–0.3 g |
| Penicillin | Ampicillin | 100–200 | 2–6 g |
| | Amoxicillin/amoxicillin-clavulanate ^b | 40–90 | 0.75–1 g |
| | Piperacillin-tazobactam | 200–300 | 12 g |
| Extended-spectrum cephalosporins | Ampicillin-sulbactam | 100–200 | 4–8 g |
| | Ceftriaxone | 50–75 | 1–2 g |
| | Ceftazidime | 150 | 2–6 g |
| Fluoroquinolones | Cefepime | 100–150 | 2–4 g |
| | Gatifloxacin ^c | 10–20 | 0.4 g |
| | Levofloxacin | 10–15 | 0.5–0.75 g |
| Aminoglycosides | Ciprofloxacin | 20–30 | 0.5–1.5 g |
| | Gentamicin | 7.5 | 3–6 mg/kg |
| | Tobramycin | 7.5 | 3–6 mg/kg |

Note: Doses may be increased for more severe disease and may require modification in patients with organ dysfunction.

^aTetracyclines are rarely used in pediatric patients, particularly in those younger than 8 years of age because of tetracycline-induced permanent tooth discoloration.

^bHigher dose amoxicillin, amoxicillin-clavulanate (e.g., 90 mg/kg/day) is used for penicillin resistant *S. pneumoniae*.

^cFluoroquinolones are avoided in pediatric patients because of the potential for cartilage damage; however, their use in pediatrics is emerging. Doses shown are extrapolated from adults and will require further study.

TABLE 106–12. Guidelines for the Empirical Treatment of Community-Acquired Pneumonia

| Clinical Setting | Empirical Therapy |
|----------------------------------|---|
| Outpatients | Macrolide/azalide, doxycycline, or fluoroquinolone |
| Inpatients, general medical ward | Extended-spectrum cephalosporin + macrolide/azalide or β -lactam/ β -lactamase inhibitor + macrolide/azalide or fluoroquinolone |
| Inpatients, intensive care unit | Extended-spectrum cephalosporin or β -lactam/ β -lactamase inhibitor + fluoroquinolone or macrolide/azalide |

careful attention by the clinician to local and regional bacterial susceptibility patterns.⁸³ Thus, whenever possible, initial therapy should be based on presumed antibacterial susceptibility and consist of older, less-expensive agents, with newer and more expensive antibiotics reserved for unresponsive illness or special circumstances. The indiscriminate use of recently introduced agents increases health care costs and, in some instances (such as with the widespread use of fluoroquinolones), induces resistance among a significant percentage of community-acquired organisms.^{84,85} It must be emphasized, however, that the rapidly evolving epidemiology of bacterial resistance, including the increasing emergence of penicillin-resistant pneumococcus in many areas of the United States and Europe,⁸⁶ forces the clinician to be vigilant and knowledgeable about antibiotic sensitivity patterns in each community. The indiscriminate use of antimicrobials for the treatment of pneumonia has contributed to the problem of antimicrobial resistance, underscoring the need for defining the optimal antibiotic regimen for each patient.^{82,83}

9 Recommended empirical therapy differs among outpatients, hospitalized patients, and hospitalized patients admitted to an intensive care unit⁸² (Table 106–12). Additionally, antimicrobial therapy should be initiated in hospitalized patients with acute pneumonia within 8 hours of admission because an increase in mortality has been demonstrated when therapy was delayed beyond 8 hours of admission.

NOSOCOMIAL PNEUMONIA

10 Antibiotic selection within the hospital environment demands greater care because of constant changes in antibiotic resistance patterns in vitro and in vivo. Ironically, some β -lactam antibiotics, which were developed to treat multiple-antibiotic-resistant hospital-acquired organisms, can themselves induce broad-spectrum bacterial β -lactamases and thereby lead to even greater problems with resistance.⁸⁶ These facts underscore the importance of regularly documenting the epidemiology of pathogens and infectious diseases within a specific practice or institution. As a result, an antimicrobial agent for a specific infectious disease favored in one practice site may not be the most desirable selection in another despite similarities in size and patient profile. Strict and careful control and, possibly, rotation of empirical antibiotics in the hospital environment may help to limit the emergence of resistant organisms. Newer antibiotics developed to treat resistant, hospital-acquired pathogens are, however, costly; therefore, their use must be moderated to some extent in an era where capitated hospital costs and mandated budget cuts will not tolerate careless antibiotic use.

SEVERE ACUTE RESPIRATORY SYNDROME

The treatment of SARS involves primarily supportive care and procedures to prevent transmission to others.⁷⁷ Owing to the uncertainty associated with the diagnosis of SARS, empirical therapy with broad-spectrum antibiotics should be employed. To date, fluoroquinolones or macrolides typically have been used. Although its efficacy is unproven, patients also have been treated with ribavirin. Owing to the potential benefit of corticosteroids in the presence of progressive pulmonary disease, methylprednisolone also has been used in doses ranging from 80 to 500 mg/day.

FLUOROQUINOLONE ANTIBIOTICS

The in vitro spectrum of antibacterial activity of systemically absorbed fluoroquinolone antibiotics, such as ciprofloxacin, levofloxacin, moxifloxacin, and gatifloxacin, suggests that these drugs have an important role in the treatment of bacterial infections of the lower respiratory tract. Numerous clinical studies describe the efficacy of these drugs for the treatment of purulent bronchitis, acute exacerbations of chronic bronchitis, pneumonia, and cystic fibrosis.⁸⁷ The widespread use of earlier analogues (ciprofloxacin) by primary care physicians has led, however, to pathogen resistance and treatment failures, including, perhaps most important, isolates of *S. pneumoniae*. Although newer fluoroquinolones are more active against common respiratory tract pathogens than older agents, this experience renders it difficult to recommend their indiscriminate use for routine community-acquired pneumonia. Nevertheless, these drugs may be effective alternative agents for the treatment of community-acquired pneumonia or in the initial treatment of nosocomial pneumonia for hospitalized patients and patients residing in extended-care facilities. The availability of newer analogues with broad spectra of antibacterial activity, including *S. pneumoniae* (e.g., gatifloxacin), further enhances the desirability of a fluoroquinolone as a first-line agent, expanding the therapeutic armamentarium for both community-acquired and nosocomially acquired pneumonia.

At present, fluoroquinolone use in pediatrics remains restricted and limited because of possible fluoroquinolone-induced destructive lesions of growing cartilage primarily of the weight-bearing joints. These fluoroquinolone-associated arthritic lesions were determined in animals following large doses, but have not been reflected in the human experience. The need for fluoroquinolones for the treatment of selected infections arising in pediatric patients continues, and their continued safety in these patients has served as the foundation for ongoing controlled clinical efficacy and safety trials in pediatric patients.

MACROLIDE-AZALIDE ANTIBIOTICS

Among the more recently introduced classes of oral antibiotics, the newer macrolide-azalide antibiotics (clarithromycin-azithromycin) possess excellent activity against most *S. pneumoniae* and *Mycoplasma* and appear to offer viable alternatives to erythromycin, particularly in patients who are intolerant of erythromycin analogues (e.g., gastrointestinal upset) and, with azithromycin, in patients who are taking medications that may result in a clinically significant drug-drug interaction (e.g., erythromycin with carbamazepine or theophylline).⁴⁰ Azithromycin offers the added advantage of once-daily dosing and short-course therapy because of the drug's extensive tissue distribution characteristics and prolonged elimination half-life.⁴⁰

PREVENTION

Prevention of some cases of pneumonia is possible through the use of vaccines and medications against selected infectious agents. Polyvalent polysaccharide vaccines are available for two of the leading causes of bacterial pneumonia, pneumococcus and *H. influenzae* type b. Inactivated influenza virus vaccines formulated annually to contain antigens representative of expected prevalent strains are widely available and generally well tolerated. Recently, a newly developed cold-adapted live influenza virus vaccine available as a nasal spray (Flumist) was approved.⁸⁸ Immunization is recommended for individuals likely to experience serious complications from influenza infection, such as patients with underlying heart or lung disease or chronic renal disease and the elderly. For a detailed description of the use of these vaccines, see Chap. 122. Although they should not replace active immunization, the tricyclic amines amantadine hydrochloride and rimantadine hydrochloride may be administered for prevention and treatment of influenza A infection.⁸⁹ When therapy is initiated to healthy individuals within 48 hours of the onset of symptoms, both drugs have been proved to decrease the severity and shorten the course of illness by approximately 1 day. The recommended dose for each drug is 5 mg/kg per day in one or two doses not to exceed 150 mg/day in children 1 to 9 years of age and 200 mg/day in two divided doses in patients 9 years of age or older. Additionally, the discovery of the importance of neuraminidase to the viability of the influenza A and B virus has led to the development of the most effective drugs available for the prevention and treatment of influenza disease. Oseltamivir and zanamivir are the first of a new class of neuraminidase inhibitors. Zanamivir is available for aerosol administration, leading to some concern over aerosolization in patients with disease-induced hyperactive airways, whereas oseltamivir is available for oral administration. Both agents are effective in preventing disease, particularly if therapy is begun within 30 hours of symptom onset or exposure (e.g., epidemics) and for treatment in febrile individuals.^{90,91}

EVALUATION OF THERAPEUTIC OUTCOMES

After therapy has been instituted, appropriate clinical parameters should be monitored to ensure efficacy and safety of the therapeutic regimen. In patients with bacterial infections of the upper or lower respiratory tract, the time to resolution of initial presenting symptoms and the lack of appearance of new associated symptomatology is important to determine. In patients with community-acquired pneumonia or pneumonia from any source of mild to moderate clinical severity, the time to resolution of cough, decreasing sputum production, and fever, as well as other constitutional symptoms of malaise, nausea, vomiting, and lethargy, should be noted. If the patient requires supplemental oxygen therapy, the amount and need also should be assessed regularly. A gradual and persistent improvement in the resolution of these symptoms and therapies should be observed. Initial resolution should be observed within the first 2 days, progressing to complete resolution within 5 to 7 days, but usually in no more than 10 days. In patients with nosocomial pneumonia or substantial underlying diseases or both, additional parameters can be followed, including the magnitude and character of the peripheral blood WBC count, chest radiograph, and blood gas determinations. Similar to patients with less severe disease, some resolution of symptoms should be observed within 2 days of instituting antibiotic therapy. If within 2 days of starting seemingly appropriate antibiotic therapy no resolution of symptoms is observed, or if the patient's clinical status is

deteriorating, the appropriateness of initial antibiotic therapy should be critically reassessed. The patient should be evaluated carefully for deterioration in underlying concurrent disease(s). Additionally, the caregiver should consider the possibility of changing the initial antibiotic therapy to expand antimicrobial coverage not included in the original regimen (e.g., *Mycoplasma*, *Legionella*, and anaerobes). Furthermore, the possible need for antifungal therapy (amphotericin B) should be considered. Some resolution of symptoms should be observed within 2 days of starting proper antibiotic therapy, with complete resolution expected within 10 to 14 days.

ABBREVIATIONS

AUC: area under the curve
 COPD: chronic obstructive pulmonary disease
 ELISA: enzyme-linked immunosorbent assay
 MIC: minimum inhibitory concentration
 PCR: polymerase chain reaction
 RSV: respiratory syncytial virus
 RSVIG: respiratory syncytial virus immune globulin
 SARS: severe acute respiratory syndrome

UPPER RESPIRATORY TRACT INFECTIONS

Yasmin Khaliq, Sarah Forgie, and George Zhanel

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Most nonspecific upper respiratory tract infections have a viral, not bacterial, etiology and tend to resolve spontaneously.
- 2 Each time antibiotics are administered for an upper respiratory tract infection, the recipient is at increased risk of selection and carriage of resistant organisms that can be passed to others. This can lead to future antibiotic failure.
- 3 Amoxicillin is the drug of choice for acute otitis media. For patients who are suspected of having infection or who are at high risk for infection with drug-resistant *Streptococcus pneumoniae*, high-dose amoxicillin should be administered.
- 4 Vaccination against influenza and pneumococcus may decrease the risk of acute otitis media, especially in those with recurrent episodes.
- 5 Viral and bacterial sinusitis are difficult to differentiate because their clinical presentations are similar. Viral infections, however, tend to resolve by 7 to 10 days. Persistence of symptoms beyond this time likely indicates a bacterial infection.
- 6 Amoxicillin is first-line treatment for acute bacterial sinusitis. Since there is no difference in clinical outcome among antibiotics, the advantages of amoxicillin include proven efficacy and safety, a relatively narrow spectrum that minimizes emergence of resistance, good tolerability, and low cost.
- 7 Group A β -hemolytic *Streptococcus* (*S. pyogenes*) is the most common bacterial cause of pharyngitis, and despite representing a small percentage of causes of pharyngitis, it is the only commonly occurring form of acute pharyngitis for which antimicrobial therapy is indicated.
- 8 Antimicrobial treatment of pharyngitis should be limited to those who have clinical and epidemiologic features of group A streptococcal pharyngitis with a positive laboratory test. Penicillin is first-line treatment. Amoxicillin can be used for children because of its better taste.
- 9 The evidence that treatment of group A streptococcal pharyngitis prevents rheumatic fever comes solely from studies using depot intramuscular penicillin. Penicillin administered by other routes has been assumed to be equally efficacious. The ability of other antibiotics to eradicate group A *Streptococcus* has led to extrapolation that these agents also will prevent rheumatic fever.

Upper respiratory tract infections include otitis media, sinusitis, pharyngitis, laryngitis (croup), rhinitis, and epiglottitis. These infections are responsible for the majority of antibiotics prescribed in ambulatory practice in the United States.¹ In 1998, the estimated cost of otitis media was \$3 to \$4 billion in the United States and \$600 million in Canada.²

1 Most nonspecific upper respiratory tract infections have a viral, not bacterial, etiology and tend to resolve spontaneously.^{3,4} Strategies for limiting unnecessary antibiotic use have been developed^{1,3,5} in an effort to address the problem of increased bacterial resistance that is associated with antibiotic use. This is particularly important for *Streptococcus pneumoniae*, the leading bacterial cause of meningitis, pneumonia, otitis media, and sinusitis.¹ In Canada, an average of 15 deaths per year due to *S. pneumoniae* are reported in children younger than 5 years of age.⁶

This chapter will focus primarily on otitis media, pharyngitis, and sinusitis because these infectious entities are frequently bacterial in origin, and appropriate antibiotic treatment can minimize morbidity and potentially prevent complications.

OTITIS MEDIA

Otitis media is inflammation of the middle ear. The diagnosis of acute otitis media includes signs and symptoms of infection of the middle ear, such as otalgia, fever, and irritability, as well as the presence of fluid in the middle ear.^{7–11} In otitis media with effusion, middle ear fluid is present, but signs and symptoms of infection are absent. Otitis media is most common in infants and children, 75% of whom have had at least one episode by the age of 1 year.¹² About 20% of otitis cases occur in adults, particularly in those with a history of these infections as a child.¹³ Table 107–1 lists the risk factors for otitis media. Risk factors for otitis media owing to resistant pathogens include (1) day-care attendance, (2) prior antibiotic exposure, and (3) age younger than 2 years.¹⁴

PATHOPHYSIOLOGY

Acute otitis media usually follows a viral upper respiratory tract infection that causes Eustachian tube dysfunction and mucosal swelling in

the middle ear.^{12,14} Bacteria and viruses that colonize the nasopharynx thus enter the middle ear and are not cleared properly by the mucociliary system.⁷ In the presence of effusion, the bacteria proliferate and cause infection.^{7,14} Children tend to be more susceptible to otitis media than adults because the anatomy of their Eustachian tube is shorter and more horizontal, facilitating bacterial entry into the middle ear.¹⁴

MICROBIOLOGY

S. pneumoniae is the most common bacterial cause of acute otitis media, with an incidence of 20% to 35%.^{6,8,15} Nontypeable *Haemophilus influenzae* and *Moraxella catarrhalis* are each responsible for 20% to 30% and 20% of cases, respectively. Bacterial organisms that have been associated less frequently with otitis media include *Staphylococcus aureus*, *S. pyogenes*, and gram-negative bacilli such as *Pseudomonas aeruginosa*.¹⁴ In 20% to 30% of cases, no bacterial pathogen is found, and in up to 44%, a viral etiology is found with or without concomitant bacteria.⁷

BACTERIAL RESISTANCE

Bacterial resistance to antimicrobial therapy for acute otitis media is of growing concern, particularly in view of the increasing levels of drug resistant *S. pneumoniae*. Data from the United States (1999–2000) indicate that 8.3% to 34.2% of all *S. pneumoniae* isolates are penicillin-nonsusceptible (minimum inhibitory concentration [MIC] = 0.12–1 mcg/mL), that 12.2% to 21.5% are highly penicillin-resistant (MIC \geq 2 mcg/mL), and that these rates are highly variable based on regional differences.^{16,17} Canadian data from isolates collected between 1997 and 2002 indicate that 20.2% of *S. pneumoniae* isolates are penicillin-nonsusceptible.¹⁸ High-level penicillin resistance increased from 2.4% to 13.8% from 1999 to 2002, and multidrug resistance was reported at 8.8% in 2002. Multidrug resistance in the United States is reported as 12.2% to 22.4% of *S. pneumoniae* isolates.^{16,17} *Multidrug resistance* is defined as concomitant resistance to at least three different antibiotic classes. Antibiotic resistance rates with other β -lactams (penicillins other than penicillin, as well as cephalosporins), macrolides (azithromycin and clarithromycin), clindamycin, trimethoprim-sulfamethoxazole, tetracyclines, and fluoroquinolones also must be considered. In oti-

tis media, non- β -lactam antibiotic treatment is mostly considered when penicillin-allergic patients are treated or when treatment failure occurs.

S. pneumoniae resistance to amoxicillin with or without clavulanate is reported to range from 1% to 14%.^{17,18} The second-generation cephalosporins that were most active were cefuroxime and cefprozil, followed by cefixime and cefaclor, with resistance rates of 6% to 12% in Canada and about 25% to 50% in the United States. The approximate rates of resistance for individual classes are clarithromycin (8% to 26%), trimethoprim-sulfamethoxazole (16% to 30%), doxycycline (4%), and levofloxacin (1%).

β -Lactamase-producing *H. influenzae* and *M. catarrhalis* are found in 23% to 35% and up to 100% of infected patients, respectively.^{17,19} It is important to note that susceptibilities vary by geographic region, particularly for *H. influenzae*.²⁰ While these organisms tend to cause infection that is more likely to resolve spontaneously as compared with *S. pneumoniae*, they are still pathogens that must be accounted for, particularly in treatment failures.

❖ Bacterial resistance increases with antibiotic usage such that it is difficult to achieve an appropriate balance between antibiotic prescribing and minimizing resistance. Each time antibiotics are administered, the recipient is at increased risk of selection and carriage of resistant organisms that can be passed to others. This can lead to future antibiotic failure. Without antibiotic therapy, however, acute otitis media secondary to *S. pneumoniae* is less likely to resolve spontaneously than that from other causes. *S. pneumoniae* is increasingly resistant to penicillin, and penicillin-resistant *S. pneumoniae* is more likely to be resistant to multiple antibiotics.^{15,16,18}

CLINICAL PRESENTATION AND DIAGNOSIS

Acute otitis media presents as an acute onset of signs and symptoms of middle ear infection such as otalgia, irritability, and tugging on the ear, following cold symptoms of runny nose, nasal congestion, or cough (Table 107–2).

Resolution of the symptoms of acute otitis media occurs over 1 week. Pain and fever tend to resolve after 2 to 3 days, with most children becoming asymptomatic at 7 days. Over a period of 1 week, changes in the eardrum normalize, and the pus becomes serous

TABLE 107–2. Clinical Presentation of Acute Otitis Media

General

The acute onset of signs and symptoms of middle ear infection following cold symptoms of runny nose, nasal congestion, or cough

Signs and Symptoms

Pain that can be severe (more than 75% of patients)

Children may be irritable, tug on the involved ear, and have difficulty sleeping

Fever is present in less than 25% of patients and, when present, is more often in younger children

Examination shows a discolored, thickened, bulging eardrum

Pneumatic otoscopy or tympanometry demonstrates an immobile eardrum; 50% of cases are bilateral

Draining middle ear fluid occurs (less than 3% of patients) that usually reveals a bacterial etiology

Laboratory Tests

Gram stain, culture, and sensitivities of draining fluid or aspirated fluid if tympanocentesis is performed

From ref. 7.

fluid. Air-fluid levels are apparent behind the eardrum, at which the stage is now referred to as *otitis media with effusion*. This does not represent ongoing infection, nor are additional antibiotics required.¹² Otitis media with effusion also can occur *de novo* and is thought to be a result of respiratory viruses. Otitis media with effusion usually occurs in spring or autumn, not winter, and may be a result of allergens or viruses common at these times. It also differs from acute otitis media in that pain is not present, nor a bulging eardrum. Effusions resolve slowly. At 3 months, 90% have disappeared.^{10,12} Younger children or those with a history of recurrent infections have

a further delay in resolution.^{7,12,21} Because of symptoms of viral upper respiratory tract infection (the “common cold”), antibiotics frequently are prescribed for otitis media with effusion but are not needed if duration is less than 3 months.⁸ Limiting antibiotic use to documented acute otitis media would save up to \$8 million annually in the United States.^{8,20} Unfortunately the longer the time spent with otitis media with effusion, the higher is the likelihood of poor linguistic performance.^{22,23} Complications of otitis media are infrequent but include mastoiditis, bacteremia, meningitis, and auditory sequelae.

▶ TREATMENT: Acute Otitis Media

■ DESIRED OUTCOME

The goals of treatment of acute otitis media are the reduction in signs and symptoms, eradication of the infection, and prevention of complications. Avoidance of unnecessary antibiotic prescribing is another goal in view of the increasing problem of *S. pneumoniae* resistance.

■ GENERAL APPROACH TO TREATMENT⁸

The management of acute otitis media is not without controversy. For example, a systematic review of studies demonstrated that antimicrobial therapy provides resolution of symptoms in about 95% of patients, whereas about 80% of placebo-treated patients also have a resolution of symptoms.^{21,24} Although only a small benefit has been found, antimicrobial treatment is still considered an appropriate management strategy.¹⁵ However, the choices of which patient should receive antimicrobials, which antimicrobial regimen, and at what point antibiotics should be given after diagnosis require further evaluation. Generally, otitis media is treated empirically without laboratory tests.

■ NONPHARMACOLOGIC THERAPY

Acetaminophen or a nonsteroidal anti-inflammatory agent such as ibuprofen can be used to relieve pain and malaise in acute otitis media. Decongestants, antihistamines, topical corticosteroids, and expectorants have not been proved effective for acute otitis media.^{10,26} Side effects associated with these treatments also may be unpleasant.

Surgical insertion of tympanostomy tubes (T-tubes) is an effective method for the prevention of recurrent otitis media. These small tubes are placed through the inferior portion of the tympanic membrane under general anesthesia and aerate the middle ear. Children with recurrent otitis who have more than three episodes in 6 months or four or more episodes (one of which is recent) in a year should be considered for T-tube placement. If these children have moderate to severe nasal obstruction in addition to recurrent otitis, adenoidectomy may be of benefit. Tonsillectomy, however, is not indicated for the treatment of otitis media. Although T-tube insertion is effective for many, some children may require subsequent surgeries. Repeat T-tube placement with adenoidectomy (regardless of adenoid size) should be considered if the child continues to have episodes of acute otitis media after extrusion of the original T-tubes.

■ PHARMACOLOGIC THERAPY

■ ANTIMICROBIAL THERAPY

Acute otitis media must be distinguished from otitis media with effusion. Antimicrobials are indicated only in the former unless the effusion persists beyond 3 months in otitis media with effusion. Middle ear effusion in acute otitis media tends to continue after antimicrobial therapy is completed but does not require retreatment.

Studies have not demonstrated any one antimicrobial agent to be superior in the treatment of acute uncomplicated otitis media.²¹ Amoxicillin is considered the drug of choice regardless of the prevalence of drug-resistant *S. pneumoniae*.^{6,15} Amoxicillin has the best pharmacodynamic profile (time above the minimum inhibitory concentration [MIC₉₀] in the middle ear fluid for more than 40% of the dosing interval) against drug-resistant *S. pneumoniae* of all available oral agents, it has a long record of safety, it possesses a narrow spectrum, and it is inexpensive.²⁰ Its excellent efficacy against *S. pneumoniae* outweighs the issue of β -lactamase-producing *H. influenzae* and *M. catarrhalis*, against which amoxicillin may not be effective. This is so because *H. influenzae* and *M. catarrhalis* are both more likely to lead to a spontaneous resolution of the infection compared with *S. pneumoniae*.

▶³ Amoxicillin is the drug of choice for acute otitis media. High-dose amoxicillin (80–90 mg/kg per day) is recommended if drug-resistant *S. pneumoniae* is suspected or a patient is at high risk for a resistant infection. Treatment recommendations for acute otitis media are found in Table 107–3. Patients who have received a course of antibiotics within the last 3 months are considered high risk. Higher middle ear fluid concentrations of amoxicillin as a result of higher dosing should overcome drug-resistant *S. pneumoniae* even with its increased MIC.²⁷ Some clinicians have expressed concerns, however, about the increased risk of adverse effects and patient noncompliance associated with high-dose amoxicillin.

If treatment failure occurs with amoxicillin, an agent should be chosen with activity against β -lactamase-producing *H. influenzae* and *M. catarrhalis*, as well as drug-resistant *S. pneumoniae*.^{14,20} Examples include amoxicillin-clavulanate, cefuroxime, and intramuscular ceftriaxone. Second-generation cephalosporins, while β -lactamase-stable, are expensive, have an increased incidence of side effects, and may increase selective pressure for resistant bacteria. They also are less effective against drug-resistant *S. pneumoniae*. Consideration also must be given to the fact that most cephalosporins do not achieve adequate middle ear fluid concentrations against drug-resistant *S. pneumoniae* for the desired duration over the dosing interval. Oral cephalosporins that may be tried include cefuroxime (as advocated by the Centers for Disease Control and Prevention [CDC]

TABLE 107–3. Acute Otitis Media Treatment Recommendations^{a,b}

| Antibiotic Therapy in Prior Month | Day 0 | Clinically Defined Treatment Failure Day 3 | Clinically Defined Treatment Failure Days 10 to 28 |
|-----------------------------------|--|---|--|
| No | Amoxicillin usual dose 40–45 mg/kg/day | Amoxicillin-clavulanate high dose ^d Amoxicillin component 80–90 mg/kg/day clavulanate component 6.4 mg/kg/day | Same as day 3 |
| | Amoxicillin high dose 80–90 mg/kg/day (high-risk patients) | Cefuroxime axetil Suspension: 30 mg/kg/day divided twice daily (max: 1 g) Tablets: 250 mg twice daily Intramuscular ceftriaxone 1 g (50 mg/kg) daily for 3 days | |
| Yes | Amoxicillin high dose 80–90 mg/kg/day | Intramuscular ceftriaxone 1 g (50 mg/kg) daily for 3 days | Amoxicillin-clavulanate high dose ^d Amoxicillin component 80–90 mg/kg/day Clavulanate component 6.4 mg/kg/day |
| | Amoxicillin-clavulanate high dose ^d Amoxicillin component 80–90 mg/kg/day Clavulanate component 6.4 mg/kg/day | Clindamycin ^c 10–30 mg/kg/day divided every 6–8 hours (max: 1.8 g/day) | Cefuroxime axetil Suspension: 30 mg/kg/day divided twice daily (max: 1 g) Tablets: 250 mg twice daily |
| | Cefuroxime axetil Suspension: 30 mg/kg/day divided twice daily (max: 1 g) Tablets: 250 mg twice daily | Tympanocentesis | Intramuscular ceftriaxone 1 g (50 mg/kg) daily for 3 days Tympanocentesis |

^aThese recommendations are made by a group convened by the Centers for Disease Control.

^bThe recommended duration of treatment for oral therapy is 7 to 10 days.

^cClindamycin is only recommended in cases of documented *S. pneumoniae*. It is not effective against *H. influenzae* or *M. catarrhalis*.

^dHigher doses of clavulanate produce a significant increase in diarrhea.

From refs. 8 and 15.

guidelines), as well as cefprozil or cefpodoxime.^{11,15} Intramuscular ceftriaxone is the only agent other than amoxicillin that achieves middle ear fluid concentrations above the MIC for more than 40% of the dosing interval.²⁰ While single doses have been used, daily doses for 3 days are recommended to optimize clinical outcomes.^{14,15} Ceftriaxone should be reserved for severe and unresponsive infections or for patients in whom oral medication is inappropriate because of vomiting, diarrhea, or possible nonadherence. Ceftriaxone is an expensive agent, and the intramuscular injections generally are not appealing to young patients. Tympanocentesis also can be considered for treatment failure. It has a therapeutic effect of relieving pain and pressure and can be used to collect fluid to identify the causative agent. This procedure, however, is not frequently performed in practice.^{9,14}

CLINICAL CONTROVERSY

It is not clear when antibiotics should be prescribed for acute otitis media—at the onset of signs and symptoms or after 48 to 72 hours to allow assessment for a spontaneous resolution. In general, the North American approach is to institute empirical treatment immediately. In some European countries such as the Netherlands, the practice is not to initiate treatment initially, but rather to treat a child 6 months to 2 years of age only if he or she does not improve by 24 hours or an older child by 72 hours.

Patients with penicillin allergy can be treated with several alternative antibiotics. Some clinicians feel that the incidence of

cross-reaction is sufficiently low that use of a cephalosporin is warranted in patients who have not experienced immediate penicillin hypersensitivity reactions. Others prefer to use a macrolide such as azithromycin or clarithromycin, erythromycin-sulfisoxazole, trimethoprim-sulfamethoxazole, or if *S. pneumoniae* is documented, clindamycin as alternative agents. However, the incidence of resistance is much higher with these agents,^{9,14} and of these agents, only clindamycin is recommended by the CDC guidelines.¹⁵

■ DELAYED ANTIMICROBIAL THERAPY

It is difficult to identify who will benefit from antimicrobial therapy. With or without treatment, about 60% of children who have acute otitis media are symptom-free within 24 hours. In almost 40% of the remaining children, antibiotic use reduces the duration of symptoms by about 1 day.^{28,29} A trial of 315 children (6 months to 10 years of age) compared immediate antibiotic treatment with a 72-hour delay in treatment that was to be given only if the child had not improved. Symptoms continued for 1 extra day in 10% to 20% of the delayed-therapy group, but 10% fewer also experienced diarrhea. At 3 days, there was no difference in symptoms. In the delayed-therapy group, only 24% of children eventually received antibiotics, and 77% of parents reported being satisfied with this approach.³⁰

Delayed treatment decreases antibiotic use by 31% (and associated side effects) and minimizes bacterial resistance to rates as low as 30% to 50% of that in countries that do not delay antimicrobial therapy.^{31,32} Some clinicians feel that delayed treatment is not

advisable in children younger than 2 years of age, those with recent antimicrobial exposure, or when underlying conditions exist because these patients are at increased risk of susceptibility to invasive disease and resistant bacterial infections.¹¹

If delayed therapy is tried, use of appropriate pain medication, such as oral ibuprofen or acetaminophen, should be advised. If a child 6 months to 2 years of age does not improve by 24 hours or an older child by 72 hours, antibiotic treatment should be initiated.³¹

In addition to the desire for immediate symptom improvement, prevention of mastoiditis and meningitis has been suggested as a reason to prescribe immediate antibiotic treatment for acute otitis media. The rates of mastoiditis in the Netherlands, Norway, and Denmark (all countries in which delayed therapy has been adopted) and those in Canada, the United States, Australia, and the United Kingdom were compared.³² The delay of antibiotic use resulted in an increase from about 2 to 4 cases of mastoiditis per 100,000 children per year, accompanied by about 1600 fewer children per 100,000 experiencing antibiotic side effects. Of note, in the Netherlands, only 1.1% of infections caused by *S. pneumoniae* are penicillin-resistant.

SHORT COURSES OF THERAPY

4 A meta-analysis of 32 trials³³ reported no difference in effect (cure rates) after short (<7 days) and usual durations (≥7 days) of antibiotic therapy in children. The authors suggest that 5 days of therapy is effective in acute uncomplicated otitis media. The advantages of short-term therapy are an increased likelihood the patient will adhere to the full course of treatment and decreased bacterial selective pressure for both the individual and the community. The disadvantages are that the data are not well established for complicated or recurrent acute otitis media, and there are inadequate data to support short treatment courses in children younger than 2 years of age.³⁴

CLINICAL CONTROVERSY

The optimal duration of antimicrobial therapy for otitis media has not been established. Some studies have demonstrated efficacy with 3 to 5 days of therapy in acute uncomplicated otitis media. However, high-risk populations, e.g., children younger than 3 years of age and those with resistant or recurrent infections, were not studied.

EVALUATION OF THERAPEUTIC OUTCOMES

Treatment failure is a lack of clinical improvement after 3 days in the signs and symptoms of infection, including pain, fever, and redness/bulging of the tympanic membrane. Early reevaluation of the eardrum when signs and symptoms are improving can be misleading because effusions persist. A concern that requires evaluation after otitis infections is hearing loss resulting from persistent middle ear effusions. Examination of an asymptomatic child may be delayed until 3 months after the infection began, at which time the continued presence of fluid should prompt a hearing evaluation.¹⁰

ANTIBIOTIC PROPHYLAXIS OF RECURRENT INFECTIONS

Recurrent otitis media is defined as at least three episodes in 6 months or at least four episodes in 12 months. Recurrent infections are of concern because patients younger than 3 years of age are at high risk for hearing loss and language and learning disabilities.¹¹ Data from studies generally do not favor prophylaxis. A meta-analysis demonstrated that prophylaxis against these infections leads to a reduction of 0.11 episodes per month.³⁵ This translates into one infection prevented each time one child is treated for 9 months. Prophylaxis is even less effective in those with effusion. Amoxicillin 20 mg/kg per day and sulfisoxazole 75 mg/kg per day have been evaluated. Success with sulfisoxazole generally is thought to be better because it results in less carriage of resistant organisms; however, side effects are much worse (i.e., rash, mouth sores, and potential for blood dyscrasias). Of further concern is antibiotic resistance as a result of continued use of these antibiotics. For this reason, treatment can be delayed until the onset of symptoms of an upper respiratory tract infection (viral symptoms). Another approach is to limit antibiotic prophylaxis duration to 6 months and during the winter months.¹¹ T-tube placement, adenoidectomy, and tonsillectomy may be of value in children with recurrent treatment failure.

VACCINATION

4 Vaccination against influenza and pneumococcus may decrease the risk of acute otitis media, especially in those with recurrent episodes. Immunization with the influenza vaccine has been associated with up to a 36% reduction in the incidence of acute otitis media infection.³⁶ Others have described a benefit during the influenza season.^{12,37} The influenza vaccine can be administered to any healthy person without contraindications, especially individuals with chronic disease who are at least 6 months of age.^{6,15} Some clinicians feel that the data do not justify universal influenza vaccination but that it is warranted for high-risk patients, including those younger than 2 years of age.²⁵

A conjugate pneumococcal vaccine that is indicated in infants and children has become available and provides a 6% reduction in the frequency of acute otitis media and a 20% reduction in the need for placement of a T-tube.³⁸ Also, vaccine use has demonstrated an 8% decrease in office visits, as well as a 10% to 26% decrease in otitis media episodes in children who experienced 3 to 10 infections per year.³⁹ Pneumococcal conjugate vaccine is recommended for all children aged 2 to 23 months; it is also recommended for those 24 to 59 months of age who are at high risk of invasive disease.^{6,40} Previously unvaccinated children older than age 1 who have had recurrent otitis media infections do not benefit from later vaccination.⁴¹

SINUSITIS

Sinusitis is an inflammation and/or infection of the paranasal sinus mucosa.^{42–44} The term *rhinosinusitis* is used by some specialists because sinusitis typically also involves the nasal mucosa.^{42,44–46} The majority of these infections are viral in origin; nevertheless, antimicrobials are prescribed frequently. It is thus important to differentiate between viral and bacterial sinusitis to aid in optimizing treatment decisions.

5 Viral sinusitis and bacterial sinusitis are difficult to differentiate because their clinical presentations are similar. Viral

TABLE 107–4. Clinical Presentation and Diagnosis of Bacterial Sinusitis^{42–44,46–49}**General**

A nonspecific upper respiratory tract infection that persists beyond 7 to 14 days

Signs and Symptoms**Acute***Adults:*

Nasal discharge/congestion

Maxillary tooth pain, facial or sinus pain that may radiate (unilateral in particular) as well as deterioration after initial improvement

Severe or persistent (beyond 7 days) signs and symptoms are most likely bacterial and should be treated with antimicrobials

Children:

Nasal discharge and cough for greater than 10 to 14 days or severe signs and symptoms such as temperature above 39°C or facial swelling or pain are indications for antimicrobial therapy

Chronic

Symptoms are similar to acute sinusitis but more nonspecific

Rhinorrhea is associated with acute exacerbations

Chronic unproductive cough, laryngitis, and headache may occur

Chronic/recurrent infections occur 3 to 4 times a year and are unresponsive to steam and decongestants

From refs. 42–44 and 46–49.

infections, however, tend to resolve by 7 to 10 days. Persistence of symptoms beyond this time likely indicates a bacterial infection. Bacterial sinusitis can be categorized into acute and chronic disease. Acute disease lasts less than 30 days with complete resolution of symptoms.^{42–44,47} Chronic sinusitis is defined as episodes of inflammation lasting more than 3 months with persistence of respiratory symptoms.^{42,43,48}

Sinusitis is diagnosed more frequently in children than in adults. Typical clinical presentation and diagnosis of bacterial sinusitis are illustrated in Table 107–4. Between 5% and 13% of viral upper respiratory tract infections in children are complicated by bacte-

rial sinusitis,^{46,47} whereas only 0.5% to 2% of viral upper respiratory tract infections in adults are complicated by sinusitis.^{42–44,46} Factors associated with the development of bacterial sinusitis include viral respiratory tract infections and, less commonly, allergic inflammation.⁴⁶ Other factors that can be associated with sinus disease include systemic diseases, trauma, environmental exposures, and anatomic abnormalities.^{44,46,49}

PATHOPHYSIOLOGY

Similar to acute otitis media, acute sinusitis usually is preceded by a viral respiratory tract infection that causes mucosal inflammation.^{43,45} This can lead to obstruction of the sinus ostia—the pathways that drain the sinuses. Mucosal secretions become trapped, local defenses are impaired, and bacteria from adjacent surfaces begin to proliferate.^{42,44} The pathogenesis of chronic sinusitis has not been well studied. Whether it is caused by more persistent pathogens or there is a subtle defect in the host's immune function, some patients develop chronic symptoms after their acute infection.^{44,46,51,52}

MICROBIOLOGY

Viruses are responsible for most cases of acute sinusitis; however, when symptoms are persistent (≥ 7 days) or severe, bacteria may be a primary cause or the cause of secondary infection.⁴² Acute sinusitis that is bacterial in origin is caused most often by the same bacteria implicated in acute otitis media: *S. pneumoniae* and *H. influenzae*.^{1,43–46,50} These organisms are responsible for about 70% of bacterial causes of acute sinusitis in both adults and children.^{45,48} *M. catarrhalis* is also frequently implicated in children (25%).^{44–46} *Streptococcus pyogenes*, *Staphylococcus aureus*, fungi, and anaerobes have been associated less frequently with acute sinusitis.^{42,47} Chronic sinusitis can be polymicrobial with an increased prevalence of anaerobes, as well as less common pathogens, including gram-negative bacilli and fungi.⁴⁴ Issues of bacterial resistance are similar to those found with otitis media and are further addressed in that section of this chapter.

► TREATMENT: Sinusitis**■ DESIRED OUTCOME**

The goals of treatment of acute sinusitis are the reduction in signs and symptoms, achieving and maintaining patency of the ostia, limiting antimicrobial treatment to those who may benefit, eradication of bacterial infection with appropriate antimicrobial therapy, minimizing the duration of illness, prevention of complications, and prevention of progression from acute disease to chronic disease.^{43–45,47,51}

■ GENERAL APPROACH TO TREATMENT

Approximately 40% to 60% of patients with acute sinusitis will recover spontaneously (these are likely patients with viral sinusitis).^{45,48} When the decision to treat with antimicrobials thus is made, the choice must be effective and safe, and cost must be considered.

CLINICAL CONTROVERSY

Is antimicrobial treatment warranted in bacterial sinusitis? Since most studies have not used sinus aspiration to diagnose bacterial sinusitis, many patients with viral infections likely have diluted the results of studies of antimicrobial therapy. It is recommended that patients with mild acute sinusitis can be given decongestants and reassurance, whereas those with moderate to severe disease for 7 days or more and those with severe disease should be given antimicrobial therapy.

■ NONPHARMACOLOGIC THERAPY

Data regarding supportive therapy are limited, but such therapy may be useful. Nasal decongestant sprays such as phenylephrine and oxymetazoline that reduce inflammation by vasoconstriction are used often in sinusitis.^{42,44,46} Use should be limited to the recommended

duration of the product to prevent rebound congestion. Oral decongestants also may aid in nasal/sinus patency.⁴⁸ To reduce mucociliary function, irrigation of the nasal cavity with saline and steam inhalation may be used to increase mucosal moisture, and mucolytics (e.g., guaifenesin) may be used to decrease the viscosity of nasal secretions.^{42,46}

Antihistamines should not be used for acute bacterial sinusitis in view of their anticholinergic effects that can dry mucosa and disturb clearance of mucosal secretions.⁴⁸ Second-generation antihistamines may play a role in chronic sinusitis where allergy is a component.⁴⁹ Glucocorticoids intranasally decrease tissue inflammation and edema⁴⁴; however, delayed onset limits their usefulness in acute sinusitis.

■ PHARMACOLOGIC THERAPY

■ ANTIMICROBIAL THERAPY

Two meta-analyses have demonstrated that antimicrobial therapy is superior to placebo in reducing or eliminating symptoms, although the benefit is small.^{46,54} Two randomized, controlled, double-blind studies reported conflicting results as to the value of antimicrobial therapy.^{30,55} Neither used sinus aspiration for diagnosis. The study that showed no benefit with antibiotic treatment had two major flaws.⁵⁵ Radiography was used for diagnosis of sinusitis, and duration of illness was not specified. Viral infection thus was likely present in a number of patients, complicating evaluation of antimicrobial usefulness. The second study⁵⁰ demonstrated the effectiveness of penicillin and amoxicillin in patients with at least 7 days of illness and findings of sinusitis on computed tomography. Because of more rigorous inclusion criteria and better diagnostic tools, patients with bacterial sinusitis were included, and those with viral sinusitis were more likely excluded.

6 Amoxicillin is first-line treatment for acute bacterial sinusitis. Since there is no difference in clinical outcome among antibiotics, the advantages of amoxicillin include proven efficacy and safety, a relatively narrow antibacterial spectrum that minimizes emergence of resistance, good tolerability, and low cost. Most consensus reports and reviews consider amoxicillin as first-line treatment for acute bac-

TABLE 107-5. Approach to Treatment of Acute Bacterial Sinusitis

| Uncomplicated Sinusitis | Amoxicillin |
|--|---|
| Uncomplicated sinusitis, penicillin-allergic patient | Immediate-type hypersensitivity: Clarithromycin or azithromycin or trimethoprim-sulfamethoxazole Nonimmediate-type hypersensitivity: β -Lactamase-stable cephalosporin |
| Treatment failure or prior antibiotic therapy in past 4 to 6 weeks | High-dose amoxicillin with clavulanate or β -lactamase-stable cephalosporin |
| High suspicion of penicillin-resistant <i>S. pneumoniae</i> | High-dose amoxicillin or clindamycin |

From refs. 43–48.

terial sinusitis (Table 107-5). It is cost-effective in acute uncomplicated disease, and initial use of newer broad-spectrum agents is not justified.^{43,46–48,56,57} If a patient is penicillin-allergic, azithromycin or clarithromycin may be used. In adults, a quinolone such as levofloxacin is an alternative in the penicillin-allergic patient. If the penicillin allergy is not a true IgE-mediated reaction (e.g., hives or anaphylaxis), a second-generation cephalosporin may be used (e.g., cefprozil, cefuroxime, or cefpodoxime).^{47,58}

If drug-resistant *S. pneumoniae* is highly suspected (day-care attendance, recent antibiotic use, age younger than 2 years), high-dose amoxicillin should be given. Some recommend clindamycin, but it is important to note that this drug is not active against *H. influenzae* and *M. catarrhalis*.^{43,47}

In the case of treatment failure with amoxicillin (i.e., no improvement in symptoms 72 hours after starting therapy) or in patients who have received antimicrobial therapy in the prior 4 to 6 weeks, improved coverage of *H. influenzae* and *M. catarrhalis* with either high-dose amoxicillin plus clavulanate or a β -lactamase-stable cephalosporin that covers *S. pneumoniae* (e.g., cefprozil, cefuroxime, or cefpodoxime[IS1]) is suggested.^{45,47} Other alternatives include[IS2][IS3] cefdinir, azithromycin, clarithromycin, and trimethoprim-sulfamethoxazole.^{44,47} Clinical cure rates are similar among antimicrobial agents,^{56,57} although local-area resistance rates also must be considered. Increasing resistance of *S. pneumoniae*,

TABLE 107-6. Dosing Guidelines for Acute Bacterial Sinusitis

| Drug | Adult Dosage | Pediatric Dosage |
|-------------------------------|---|--|
| Amoxicillin | 500 mg three times daily High dose = 1 g three times daily | Low dose: 40–50 mg/kg/day divided in 3 doses High dose: 80–100 mg/kg/day divided in 3 doses |
| Amoxicillin-clavulanate | 500/125 mg three times daily | 40–50 mg/kg/day divided in 3 doses High dose: Can add 40–50 mg/kg/day amoxicillin |
| Cefuroxime | 250–500 mg twice daily | 15 mg/kg/day divided in 2 doses |
| Cefaclor | 250–500 mg three times daily | 20 mg/kg/day divided in 3 doses |
| Cefixime | 200–400 mg twice daily | 8 mg/kg/day in 1 dose or divided in 2 doses |
| Cefdinir | 600 mg daily or divided in 2 doses | 14 mg/kg/day in 1 dose or divided in 2 doses |
| Cefpodoxime | 200 mg twice daily | 10 mg/kg/day in 2 divided doses (max: 400 mg daily) |
| Cefprozil | 250–500 mg twice daily | 15–30 mg/kg/day divided in 2 doses |
| Trimethoprim-sulfamethoxazole | 160/800 mg every 12 hours | 6–8 mg/kg/day trimethoprim, 30–40 mg/kg/day sulfamethoxazole divided in 2 doses |
| Clindamycin | 150–450 mg every 6 hours | 30–40 mg/kg/day divided in 3 doses |
| Clarithromycin | 250–500 mg twice daily | 15 mg/kg/day divided in 2 doses |
| Azithromycin | 500 mg day 1, then 250 mg/day \times 4 days | 10 mg/kg day 1, then 5 mg/kg/day \times 4 days |
| Levofloxacin | 500 mg daily | N/A |

N/A = not applicable.
From refs. 44, 47, 48, 58, and 59.

H. influenzae, and *M. catarrhalis* to trimethoprim-sulfamethoxazole and resistance of *S. pneumoniae* to macrolides must be taken into consideration. See Table 107–6 for dosing guidelines.

Duration of therapy for treatment of sinusitis is not well established. Most trials have used 10- to 14-day antimicrobial courses, although some trials also have investigated courses as short as 3 days.⁶⁰ In one placebo-controlled comparison of 3- versus 10-day treatment with trimethoprim-sulfamethoxazole and decongestant, a

similar number in each group were cured or improved at 14 days. Since the publication of this study, however, rates of resistant *S. pneumoniae* have increased dramatically, and trimethoprim-sulfamethoxazole is not an effective agent against resistant *S. pneumoniae*. Furthermore, extrapolation of these results to other antimicrobials is not appropriate. Therefore, the current recommendations are 10 to 14 days of antimicrobial therapy or at least 7 days after signs and symptoms are under control.^{43–45,48}

EVALUATION OF THERAPEUTIC OUTCOMES

Antimicrobial therapy reduces the median duration of illness from 17 to 9 to 11 days.⁵⁰ A patient with persistence or worsening of symptoms 72 hours after initiating antimicrobial therapy may be considered a treatment failure.⁴⁵ Referral to a specialist should be considered in patients who have not responded to first- or second-line therapy, those with recurrent and chronic disease, and patients at risk for complications. Surgery may be considered in more complicated patients.

PHARYNGITIS

Pharyngitis is an acute infection of the oropharynx or nasopharynx.⁶¹ It results in 1% to 2% of all outpatient visits.⁶² While viral causes are most common, group A β -hemolytic *Streptococcus*, or *S. pyogenes*, is the primary bacterial cause and is the focus of this section.^{61,63} In the pediatric population, group A *Streptococcus*, or “strep throat,” causes 15% to 30% of cases of pharyngitis. In adults, it is the cause of 5% to 15% of all symptomatic episodes of pharyngitis.^{61–64}

MICROBIOLOGY

6 Viruses cause most of the cases of acute pharyngitis. Specific etiologic agents include rhinovirus (20%), coronavirus ($\geq 5\%$), adenovirus (5%), influenza virus (2%), parainfluenza virus (2%), and Epstein-Barr virus ($>1\%$).^{61,63} A bacterial etiology for acute pharyngitis is far less likely. Out of all the bacterial causes, group A *Streptococcus* is the most common (15% to 30% of persons of all ages with pharyngitis⁵²), and it is the only commonly occurring form of acute pharyngitis for which antimicrobial therapy is indicated.^{52,61}

Other less common causes of acute pharyngitis include groups C and G *Streptococcus*, *Corynebacterium diphtheriae*, *Neisseria gonorrhoeae*, *M. pneumoniae*, *Arcanobacterium haemolyticum*, *Yersinia enterocolitica*, and *Chlamydia pneumoniae*. Treatment options for these organisms will not be addressed in this chapter.^{61,63}

PATHOPHYSIOLOGY

The mechanism by which group A *Streptococcus* causes pharyngitis is not well defined.⁵² Asymptomatic pharyngeal carriers of the organism may have an alteration in host immunity (e.g., a breach in the pharyngeal mucosa) and the bacteria of the oropharynx, allowing colonization to become infection. Pathogenic factors associated with the organism itself also may play a role. These include the antiphagocytic M protein, erythrogenic toxins, hemolysins, streptokinase, and proteinase.

Group A streptococcal pharyngitis is difficult to differentiate from viral pharyngitis based on history and clinical findings. However,

although all age groups are susceptible, epidemiologic data show that certain groups are at higher risk for group A streptococcal pharyngitis. Children aged 5 to 15 years old are most susceptible, and parents of school-age children and those who work with children are also at increased risk. Pharyngitis in a child younger than 3 years of age is rarely due to group A *Streptococcus*.⁵²

Seasonal outbreaks occur, and the occurrence of group A streptococcal pharyngitis is highest in winter and early spring.^{61,65} The incubation period is 2 to 5 days, and the illness often occurs in clusters.^{62,65} Spread occurs via direct contact with droplets of saliva or nasal secretions, and transmission is thus worse in institutions, schools, families, and areas of crowding.^{64,66} See Table 107–7 for clinical presentation and diagnosis of pharyngitis.

Nonsuppurative complications such as acute rheumatic fever, acute glomerulonephritis, and reactive arthritis may occur, as well as suppurative complications, such as peritonsillar abscess, retropharyngeal abscess, cervical lymphadenitis, mastoiditis, otitis media, sinusitis, and necrotizing fasciitis.

Acute rheumatic fever is seen rarely in developed countries. Acute rheumatic fever secondary to group A streptococcal infection was a cause of concern in the 1950s and was the major reason for penicillin therapy, but the incidence of this disease today is extremely rare (>1 in 1 million). However, the risk remains. Outbreaks have been reported in the United States as recently as the late 1980s and early 1990s. Furthermore, acute rheumatic fever is widespread in developing countries (e.g., it is estimated that there are 50,000 cases of acute rheumatic fever per year in India).

TABLE 107–7. Clinical Presentation and Diagnosis of Group A Streptococcal Pharyngitis

General

A sore throat of sudden onset that is mostly self-limited
Fever and constitutional symptoms resolving in about 3 to 5 days
Clinical signs and symptoms are similar for viral causes as well as nonstreptococcal bacterial causes

Signs and Symptoms

Sore throat
Pain on swallowing
Fever
Headache, nausea, vomiting, and abdominal pain (especially children)
Erythema/inflammation of the tonsils and pharynx with or without patchy exudates
Enlarged, tender lymph nodes
Red swollen uvula, petechiae on the soft palate, and a scarlatiniform rash
Several symptoms that are not suggestive of group A *Streptococcus* are cough, conjunctivitis, coryza, and diarrhea

Laboratory Tests

Throat swab and culture or rapid antigen detection testing

From refs. 52, 61–65, 67, and 68.

DIAGNOSIS

For a patient presenting with pharyngitis, the most important clinical decision that needs to be made is whether the pharyngitis is caused by group A *Streptococcus*. Diagnosis is essential because it directs management.

Clinical scoring systems such as the Centor criteria⁶⁹ have been advocated for diagnosis in adults to overcome the lack of sensitivity and specificity of clinician judgment and to avoid laboratory testing of all patients.^{62,64} These criteria include history of fever, tonsillar exudates, absence of cough, and presence of enlarged lymph nodes. However, there is concern that use of these criteria will lead to over-prescribing because they give physicians the option of a “no test” strategy, where prescriptions can be written based purely on the clinical criteria.^{61,63} Guidelines from the Infectious Disease Society of America, the American Academy of Pediatrics, and the American Heart Association suggest that testing be done in all patients with signs and symptoms. Only those with a positive test for group A *Streptococcus* require antibiotic treatment.^{61,65,70}

A combined approach would take into account the prevalence of group A streptococcal disease (which differs by age group and geography) and history of a close contact of a well-documented case, along with clinical criteria, to aid in assessing a patient’s risk of the disease. If the diagnosis cannot be excluded at this point,

laboratory testing is recommended to confirm or exclude group A *Streptococcus* as the cause of pharyngitis. It is important to note that laboratory testing should not be used without consideration of clinical criteria. This is so because a positive test does not necessarily indicate disease. A positive test may indicate carriage (but not active infection) with group A *Streptococcus*. The incidence of carriage in children is 5% to 20% and is considerably lower in adults.^{52,65}

There are several options to test for group A streptococcal pharyngitis. A throat swab can be sent for culture or used for rapid antigen-detection testing (RADT). RADT is more practical in that it gives results quickly, it can be done at the bedside, and it is less expensive than culture. Cultures are the “gold standard” and have a 90% sensitivity but require 24 to 48 hours for results.⁶³ Cultures are recommended for children, adolescents, parents, and schoolteachers with negative RADT tests (which have a sensitivity below 80%), as well as in situations of outbreak or to monitor resistance.^{64,65,67} Delaying therapy while awaiting test results does not affect the risk of complications (although some argue that symptomatic benefit is postponed), and patients must be educated as to the value of waiting. Newer RADT tests use optical immunoassay and chemiluminescent DNA probes, but the cost of such tests may be prohibitive, and results of individual tests should be compared with cultures to validate their sensitivity in practice.⁶⁵

▶ TREATMENT: Pharyngitis

■ DESIRED OUTCOME

The goals of treatment of pharyngitis are to improve clinical signs and symptoms, minimize adverse drug reactions, prevent transmission to close contacts, and prevent acute rheumatic fever and suppurative complications, such as peritonsillar abscess, cervical lymphadenitis, and mastoiditis.^{61,62}

■ GENERAL APPROACH TO TREATMENT

Antimicrobial therapy should be limited to those who have clinical and epidemiologic features of group A streptococcal pharyngitis with a positive laboratory test.

■ NONPHARMACOLOGIC THERAPY

Since pain is often the primary reason for visiting a physician, emphasis on analgesics such as acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs) to aid in pain relief is strongly recommended.⁷¹ However, acetaminophen is a better option because there is some concern that NSAIDs may increase the risk for necrotizing fasciitis/toxic shock syndrome. Toxic shock syndrome has been linked to GAS pharyngitis. Either systemic or topical analgesics can be used, as well as antipyretics and other supportive care, including rest, fluids, lozenges, and saltwater gargles. Symptoms may resolve 1 to 2 days sooner with such interventions.^{62–64}

■ PHARMACOLOGIC THERAPY

■ ANTIMICROBIAL THERAPY

Antimicrobial therapy decreases the duration of signs and symptoms by 1 to 2 days.^{62,72} Therapy also decreases the severity of symptoms when initiated within 2 to 3 days of onset in patients with proven group A *Streptococcus*. Microbiological eradication will occur in 48 to 72 hours, which aids in decreasing transmission.⁶²

7 Antimicrobial treatment should be limited to those who have clinical and epidemiologic features of group A streptococcal pharyngitis with a positive laboratory test. Penicillin is the drug of choice in the treatment of group A streptococcal pharyngitis^{61,62} (Table 107–8). It has the narrowest spectrum of activity, and it is effective, safe, and inexpensive. The only controlled studies that have demonstrated that antimicrobial therapy prevents rheumatic fever were done with procaine penicillin, which was later replaced with benzathine penicillin.^{73,74}

8 The evidence that treatment of group A streptococcal pharyngitis prevents rheumatic fever comes solely from studies using depot intramuscular penicillin. Penicillin given by other routes has been assumed to be equally efficacious. The ability of other antibiotics to eradicate group A *Streptococcus* has led to extrapolation that these agents also will prevent rheumatic fever.⁶⁴ Amoxicillin can be used in children because the suspension has a better taste than that of penicillin.^{61,66} Gastrointestinal side effects and rash, however, are more common. In patients allergic to penicillin, a macrolide such as erythromycin or a first-generation cephalosporin such as cephalexin (if the reaction is non-IgE-mediated hypersensitivity with hives or anaphylaxis) can be used.⁶¹ Newer macrolides such as azithromycin and clarithromycin are equally effective as erythromycin and cause fewer gastrointestinal adverse effects.

TABLE 107–8. Dosing Guidelines for Pharyngitis

| Drug | Adult Dosage | Pediatric Dosage | Duration |
|--|---|--|----------|
| Penicillin VK | 250 three times daily or four times daily or 500 mg twice daily | 50 mg/kg/day divided in 3 doses | 10 days |
| Penicillin benzathine | 1.2 million units intramuscularly | 0.6 million units for under 27 kg (50,000 units/kg) | One dose |
| Penicillin G procaine and benzathine mixture | Not recommended in adolescents and adults | 1.2 million units (benzathine 0.9 million units, procaine 0.3 million units) | One dose |
| Amoxicillin | 500 mg three times daily | 40–50 mg/kg/day divided in 3 doses | 10 days |
| Erythromycin | | | 10 days |
| Estate | 20–40 mg/kg/day divided two to four times daily (max: 1 g/day) | Same as adults | |
| Stearate | 1 g daily divided two to four times daily (adolescents, adults) | — | |
| Ethylsuccinate | 40 mg/kg/day divided two to four times daily (max: 1 g/day) | Same as adults | |
| Cephalexin | 250–500 mg PO four times daily | 25–50 mg/kg/day divided in 4 doses | 10 days |

From refs. 61, 63, 65, and 79.

Second-generation cephalosporins, such as cefuroxime and cefprozil, or third-generation cephalosporins, such as cefpodoxime and cefdinir, which are β -lactamase–stable, have been advocated for clinical failures with penicillin. In cases of documented macrolide resistance (owing to low-level macrolide resistance—erythromycin MIC 1–8 mcg/mL—caused by expression of the *mefA/E* gene leading to efflux of macrolide out of the bacterial cell), clindamycin is an alternative. The new ketolides such as telithromycin also may have a role to play, especially in regions with a high prevalence of macrolide-resistant strains. If patients are unable to take oral medications, intramuscular benzathine penicillin can be given, although it is painful and is no longer available in Canada.⁶¹ Amoxicillin-clavulanate or clindamycin may be considered for recurrent episodes to maximize bacterial eradication in potential carriers and to counter copathogens that produce β -lactamases.^{61,65,67} Tables 107–8 and 107–9 outline dosing for acute and recurrent episodes of pharyngitis.

To date, no resistance of group A *Streptococcus* to penicillin has been reported in clinical isolates.^{61,62,65,75} Macrolide resistance is low (>5%) and is not widespread.^{75,76} However, there have been reports of an outbreak of macrolide-resistant group A streptococcal pharyngitis in the United States. The concern is that if macrolide use continues to increase, macrolide resistance rates also will increase.^{77,78} Therefore, use of newer macrolides as first-line therapy is discouraged in febrile patients with upper respiratory tract infections. Group A *Streptococcus* resistance rates to tetracyclines and sulfonamides are high; therefore, use of these agents is no longer recommended.⁶¹

CLINICAL CONTROVERSY

The duration of therapy for group A streptococcal pharyngitis is 10 days to maximize bacterial eradication.⁶¹ Short-course therapy has been advocated to help overcome compliance issues that lead to bacteriologic failure.⁸⁰ A 6-day course of amoxicillin shows promising results, as well as other recent studies with newer broad-spectrum agents (e.g., azithromycin, cefuroxime, cefprozil, cefdinir, cefixime, cefpodoxime, and telithromycin) that have demonstrated durations of 5 days to be effective. However, confounding factors from these studies, such as lack of strict entry criteria or differentiation between new or failed infections, limit the widespread application of short antibiotic courses at this time.⁶¹ Furthermore, newer agents are more expensive and may be more likely to lead to resistance in light of their broad spectra of activity.⁶³

CLINICAL CONTROVERSY

Once-daily amoxicillin given at a dose of 750 mg is as effective as penicillin 250 mg three times daily (duration 10 days each) in children aged 4 to 18 years with group A streptococcal pharyngitis.⁸¹ This dosing regimen has not yet been endorsed by expert panels but may gain support in the future if the results are reproducible.^{61,62,64}

TABLE 107–9. Antibiotics and Dosing for Recurrent Episodes of Pharyngitis

| Drug | Adult Dosage | Pediatric Dosage |
|-------------------------------------|---|---|
| Clindamycin | 600 mg orally divided in 2–4 doses | 20 mg/kg/day in 3 divided doses (max: 1.8 g/day) |
| Amoxicillin-clavulanate | 500 mg twice daily | 40 mg/kg/day in 3 divided doses |
| Penicillin benzathine | 1.2 million units intramuscularly for one dose | 0.6 million units for under 27 kg (50,000 units/kg) |
| Penicillin benzathine with rifampin | As above 20 mg/kg/day orally in 2 divided doses × last 4 days of treatment with penicillin | As above Rifampin dose same as adults |

From refs. 61, 63, 65, and 79.

Overprescribing is a large concern that requires consideration. Antibiotics are prescribed in 73% of patients who visit their physician with a complaint of sore throat.⁸² This is well above the incidence of group A *Streptococcus*. For those who receive antibiotics, 68% of prescriptions are described as being nonrecommended treat-

ments, e.g., extended-spectrum macrolides (e.g., azithromycin and clarithromycin) or fluoroquinolones (e.g., ciprofloxacin, gatifloxacin, levofloxacin, and moxifloxacin). Cost and resistance are factors that should discourage this practice.

EVALUATION OF THERAPEUTIC OUTCOMES/CONTACT CASES

Most cases of pharyngitis are self-limited; however, antimicrobial therapy will hasten resolution when given early to proven cases of group A *Streptococcus*.^{52,61} Fever generally resolves by 3 to 5 days and most other acute symptoms by 1 week.⁵² Tonsils and lymph nodes may take a few weeks to return to baseline. Children should be kept home from day care or school until afebrile and for the first 24 hours after antimicrobial treatment is initiated, after which time transmission is unlikely.^{64–66}

Follow-up testing generally is not necessary for index cases or in asymptomatic contacts of the index patient.^{61,63,65} Symptomatic contacts may be treated without cultures.⁶⁶ In epidemics or in cases of severe infection, follow-up testing may be prudent. The incidence of invasive group A streptococcal infection in household contacts is rare, and routine chemoprophylaxis is not recommended by the CDC,⁸³ although testing is advocated and guides management.^{61,65} Twenty-five percent of household contacts are carriers, but treatment would only be required in persons with signs and symptoms of disease or contacts of severe or resistant disease.⁶¹

ABBREVIATIONS

MIC: minimal inhibitory concentration
 MIC₉₀: minimal inhibitory concentration for 90% of isolates
 RADT: rapid antigen-detection testing

SKIN AND SOFT TISSUE INFECTIONS

Susan L. Pendland, Douglas N. Fish, and Larry H. Danziger

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Folliculitis, furuncles (boils), and carbuncles begin around hair follicles and are caused most often by *Staphylococcus aureus*. Folliculitis generally can be treated with local measures such as warm, moist compresses or topical antibiotics. Small furuncles usually are treated with warm, moist heat to promote drainage; large furuncles and carbuncles are treated most often with an antistaphylococcal antibiotic such as dicloxacillin. Lesions often drain spontaneously; if not, surgical incision may be necessary.
- 2 Erysipelas is a superficial skin infection with extensive lymphatic involvement that is caused by *Streptococcus pyogenes* and is treated with penicillin. Serious infections should be treated with intravenous antibiotics.
- 3 Impetigo, a superficial skin infection characterized by fluid-filled vesicles that develop rapidly into pus-filled blisters that rupture to form golden-yellow crusts, is caused by *S. aureus* and/or *S. pyogenes* and occurs most commonly in children. Dicloxacillin is used commonly for treatment, although topical antibiotics such as mupirocin are also effective.
- 4 Lymphangitis is an infection of the subcutaneous lymphatic channels generally caused by *S. pyogenes*. Acute lymphangitis is characterized by the rapid development of fine red linear streaks extending from the initial infection site toward the regional lymph nodes, which are usually enlarged and tender. Penicillin is the drug of choice.
- 5 Cellulitis is an infection of the epidermis, dermis, and superficial fascia. Lesions generally are hot, painful, and erythematous, with nonelevated, poorly defined margins. The most common causes of cellulitis are *S. pyogenes* and *S. aureus*. Treatment generally consists of a penicillinase-resistant penicillin for 7 to 10 days.
- 6 Necrotizing fasciitis is a rare but life-threatening infection of subcutaneous tissue that results in progressive destruction of superficial fascia and subcutaneous fat. Early and aggressive surgical débridement is an essential part of therapy for treatment of necrotizing fasciitis.
- 7 Diabetic foot infections are managed with a comprehensive treatment approach that includes both proper wound care and antimicrobial therapy. Antimicrobial regimens for diabetic foot infections should include broad-spectrum coverage of staphylococci, streptococci, enteric gram-negative bacilli, and anaerobes. Outpatient therapy with oral antimicrobials should be used whenever possible.
- 8 Prevention is the single most important aspect in the management of pressure sores. After a sore develops, successful local care includes a comprehensive approach consisting of relief of pressure, proper cleaning (débridement), disinfection, and appropriate antimicrobial therapy if an infection is present. Good wound care is crucial to successful management.
- 9 All bite wounds (either animal or human) should be irrigated thoroughly with large volumes of sterile normal saline, and the injured area should be immobilized and elevated. Infections developing within the first 24 hours after a dog or cat bite are caused most often by *Pasteurella multocida* and should be treated with penicillin or amoxicillin for 10 to 14 days. Infections developing more than 36 to 48 hours after an animal bite are most likely caused by staphylococci or streptococci and should be treated with an antistaphylococcal penicillin or cephalosporin.
- 10 While antimicrobial prophylaxis of dog or cat bites is not recommended routinely, patients with noninfected human bite injuries of the hand should be given prophylactic antimicrobial therapy with penicillin plus dicloxacillin for 3 to 5 days. Infected wounds of the hand, particularly clenched-fist injuries, should be treated with penicillin plus dicloxacillin or amoxicillin-clavulanate for 7 to 14 days.

The skin serves as a barrier between humans and their environment and therefore functions as a primary defense mechanism against infections. The skin consists of the epidermis, the dermis, and subcutaneous fat. The epidermis is the outermost, nonvascular layer of the skin. It varies in thickness from approximately 0.1 mm on most areas of the body to a maximum of 1.5 mm on the soles of the feet.

Although extremely thin, the epidermis is composed of several layers. The innermost layer consists of continuously dividing cells. The outer layers are renewed as cells are gradually pushed outward. As the cells approach the surface, they become flattened, lose their nuclei, and are filled with keratin. The outermost layer, the stratum corneum, is composed of flattened, cornified, nonnucleated cells. The

dermis is the layer of skin directly beneath the epidermis. It consists of connective tissue and contains blood vessels and lymphatics, sensory nerve endings, sweat and sebaceous glands, hair follicles, and smooth muscle fibers. Beneath the dermis is a layer of loose connective tissue containing primarily fat cells. This subcutaneous fat layer is of variable thickness over the body. Beneath the subcutaneous fat lies the fascia, which separates the skin from underlying muscle. It is generally divided into superficial fascia, which is located immediately beneath the skin, and deep fascia, which forms sheaths for muscles.

Skin and soft tissue infections (SSTIs) may involve any or all layers of the skin, fascia, and muscle. They also may spread far from the initial site of infection and lead to more severe complications, such as endocarditis, Gram-negative sepsis, or streptococcal glomerulonephritis. The treatment of SSTIs at times may necessitate both medical and surgical management. This chapter presents details of the pathogenesis and management of some of the most common infections involving the skin and soft tissues. The first part of the chapter discusses a variety of SSTIs that range in severity from superficial to life-threatening. The remainder of the chapter discusses diabetic foot infections, pressure sores, and human and animal bites.

EPIDEMIOLOGY

A number of classification schemes have been developed to describe SSTIs. Bacterial infections of the skin can be classified as primary or secondary (Table 108–1). Primary bacterial infections usually involve areas of previously healthy skin and typically are caused by a single pathogen. In contrast, secondary infections occur in areas of previously damaged skin and are frequently polymicrobial. SSTIs are also classified as complicated or uncomplicated. Infections are considered complicated when they involve deeper skin structures (e.g., fascia, muscle layers, etc), require significant surgical intervention, or occur in patients with compromised immune function (e.g., diabetes mellitus, human immunodeficiency virus [HIV] infection, etc).¹

The classification system recently developed by Eron divides SSTIs into four classes based on severity of signs and symptoms, as well as the presence and stability of any comorbidities.² The classification was used to develop an algorithm to help with admission and treatment decisions. Class 1 includes patients who are afebrile and otherwise healthy. These patients generally can be managed on an outpatient basis with topical or oral antimicrobials. Class 2 includes patients who are febrile and ill-appearing but have no unstable comorbid conditions. Some class 2 patients may be treated with oral antimicrobials, but most likely will require some parenteral therapy, either as an outpatient or with short-term hospitalization. Patients having a toxic appearance, at least one unstable comorbidity, or a limb-threatening infection are grouped into class 3. Class 4 includes patients with sepsis syndrome or other life-threatening infection, such as necrotizing fasciitis. Patients in classes 3 and 4 require hospitalization and parenteral antimicrobial therapy initially but may be candidates for oral or outpatient parenteral therapy once their condition has stabilized. Patients in class 4 also generally require some type of surgical intervention.

SSTIs are among the most common infections seen in both community and hospital settings. However, data on the exact incidence of SSTIs are lacking. Most infections are believed to be mild and therefore treated in an outpatient setting, making it difficult to quantify community-acquired SSTIs. One description of office visits among health plan members listed cellulitis and impetigo as the primary diagnosis for 2.2% and 0.3% of patients, respectively.³ According to the most recent Healthcare Cost and Utilization Project Nationwide Inpatient Sample, SSTIs are the twenty-eighth most common diagnosis of patients in community hospitals.⁴ Approximately 0.1% of the adult population in the United States required hospitalization for SSTIs in 1995.²

While the exact incidence of SSTIs is unknown, the frequency of infection caused by invasive group A streptococci and drug-resistant gram-positive cocci have been increasing.¹ Group A streptococci (*Streptococcus pyogenes*) are among the most common etiologic agents of SSTIs. While they may be found in many mild, superficial skin infections, they are also responsible for life-threatening cases of necrotizing fasciitis.¹ A dramatic increase in necrotizing fasciitis due

TABLE 108–1. Bacterial Classification of Important Skin and Soft Tissue Infections

| | |
|-----------------------------|--|
| Primary Infections | |
| Erysipelas | Group A streptococci |
| Impetigo | <i>Staphylococcus aureus</i> , group A streptococci |
| Lymphangitis | Group A streptococci; occasionally <i>S. aureus</i> |
| Cellulitis | Group A streptococci, <i>S. aureus</i> ; occasionally other gram-positive cocci, gram-negative bacilli, and/or anaerobes |
| Necrotizing fasciitis | |
| Type I | Anaerobes (<i>Bacteroides</i> spp., <i>Peptostreptococcus</i> spp.) and facultative bacteria (streptococci, Enterobacteriaceae) |
| Type II | Group A streptococci |
| Secondary Infections | |
| Diabetic foot infections | <i>S. aureus</i> , streptococci, Enterobacteriaceae, <i>Bacteroides</i> spp., <i>Peptostreptococcus</i> spp., <i>Pseudomonas aeruginosa</i> |
| Pressure sores | <i>S. aureus</i> , streptococci, Enterobacteriaceae, <i>Bacteroides</i> spp., <i>Peptostreptococcus</i> spp., <i>Pseudomonas aeruginosa</i> |
| Bite wounds | |
| Animal | <i>Pasteurella multocida</i> , <i>S. aureus</i> , streptococci, <i>Bacteroides</i> spp. |
| Human | <i>Eikenella corrodens</i> , <i>S. aureus</i> , streptococci, <i>Corynebacterium</i> spp., <i>Bacteroides</i> spp., <i>Peptostreptococcus</i> spp. |
| Burn wounds | <i>Pseudomonas aeruginosa</i> , Enterobacteriaceae, <i>S. aureus</i> , streptococci |

TABLE 108–2. Predominant Microorganisms of Normal Skin**Bacteria**

Gram-positive

- Coagulase-negative staphylococci
- Micrococci (*Micrococcus luteus*)
- Corynebacterium* species (diphtheroids)
- Propionibacterium* species

Gram-negative

- Actinobacter* species

Fungi

- Malassezia* species
- Candida* species

to *S. pyogenes* is a major concern because of the high morbidity and mortality associated with these infections.

Another worrisome trend is the increased in vitro resistance reported for many gram-positive bacteria.¹ Of greatest concern is the increasing incidence of methicillin-resistant *Staphylococcus aureus* (MRSA).⁵ Treatment choices for SSTIs have been further complicated by the increased incidence of macrolide-resistant strains of *S. aureus* and *S. pyogenes*.¹

ETIOLOGY

The majority of SSTIs are caused by gram-positive organisms and, less commonly, gram-negative bacteria present on the skin surface.¹ Gram-positive bacteria (coagulase-negative staphylococci, diphtheroids) are the predominant flora of the skin, with gram-negative organisms (*Escherichia coli* and other Enterobacteriaceae) being relatively uncommon⁶ (Table 108–2). *S. aureus*, as well as a variety of gram-negative bacteria, can be found in moist intertriginous areas (e.g., axilla, groin, and toe webs) of the body. *Acinetobacter* species have been cultured from these moister areas in 25% of the population.^{6,7} *S. aureus* also inhabits the anterior nares of approximately 30% of healthy individuals.⁶ Colonization, whether transient or permanent, provides a nidus for infection should the integrity of the epidermis be compromised.

S. aureus and *S. pyogenes* account for the majority of community-acquired SSTIs.¹ Data from the most recent SENTRY Antimicrobial Surveillance Program showed *S. aureus* to also be the most common cause (45.9%) of nosocomial SSTIs.⁵ Also of note in this study was the 30% incidence of methicillin resistance among strains of *S. aureus*. Other common nosocomial pathogens included *Pseudomonas aeruginosa* (11%), enterococci (8%), and *E. coli* (7%).⁵

PATHOPHYSIOLOGY

The skin and subcutaneous tissues normally are extremely resistant to infection but may become susceptible under certain conditions. Even when high concentrations of bacteria are applied topically or injected into the soft tissue, resulting infections are rare.⁸ Several host factors act together to confer protection against skin infections. The surface of the skin is relatively dry, has a pH of approximately 5.6, and therefore is not conducive to bacterial growth.⁶ Continuous renewal of the epidermal layer results in the shedding of keratocytes, as well as skin bacteria. In addition, sebaceous secretions are

hydrolyzed to form free fatty acids that strongly inhibit the growth of many bacteria and fungi.⁸ The conditions that may predispose a patient to the development of skin infections include (1) a high concentration of bacteria ($>10^5$ microorganisms), (2) excessive moisture of the skin, (3) inadequate blood supply, (4) availability of bacterial nutrients, and (5) damage to the corneal layer allowing for bacterial penetration.^{7,8}

The majority of SSTIs result from the disruption of normal host defenses by processes such as skin puncture, abrasion, or underlying diseases (e.g., diabetes). The nature and severity of the infection depends on both the type of microorganism present and the site of inoculation.

FOLLICULITIS, FURUNCLES, AND CARBUNCLES

1 Folliculitis is inflammation of the hair follicle and can be caused by physical injury, chemical irritation, or infection.³ Infection occurring at the base of the eyelid is referred to as a stye. Furuncles and carbuncles occur when a follicular infection extends from around the hair shaft to involve the deeper areas of the skin. A furuncle, commonly known as an *abscess* or *boil*, is a walled-off mass of purulent material arising from a hair follicle.³ The lesions are called *carbuncles* when they coalesce and extend to the subcutaneous tissue. This aggregate of infected hair follicles forms deep masses that generally open and drain through multiple sinus tracts.³ *S. aureus* is the most common cause of folliculitis, furuncles, and carbuncles. Inadequate chlorine levels in whirlpools, hot tubs, and swimming pools have been responsible for outbreaks of folliculitis caused by *P. aeruginosa*.⁹

CLINICAL PRESENTATION**FOLLICULITIS**

- Pruritic, erythematous papules typically appear within 48 hours (range 6–72 hours) of exposure to large numbers of organisms.
- Papules evolve into pustules that generally heal in several days.
- Systemic signs such as fever and malaise are uncommon, although they have been reported in cases caused by *P. aeruginosa*.

FURUNCLES

- Furuncles can occur anywhere on hairy skin but generally develop in areas subject to friction and perspiration.
- Furuncles are discrete lesions, whether occurring as singular or multiple nodules.
- The lesion starts as a firm, tender, red nodule that becomes painful and fluctuant.
- Lesions often drain spontaneously.

CARBUNCLES

- Carbuncles are broad, swollen, erythematous, deep, and painful follicular masses.
- Unlike folliculitis and furuncles, carbuncles are commonly associated with fever, chills, and malaise.
- Bacteremia with secondary spread to other tissues is common.

► TREATMENT: Folliculitis, Furuncles, and Carbuncles

Treatment of folliculitis generally requires only local measures, such as warm saline compresses or topical therapy (e.g., clindamycin, erythromycin, mupirocin, or benzoyl peroxide).¹⁰ Topical agents generally are applied two to four times daily for 7 days. Small furuncles generally can be treated with moist heat, which promotes localization and drainage of pus.¹⁰ Large and/or multiple

furuncles and carbuncles generally are treated with a penicillinase-resistant penicillin (dicloxacillin 250 mg orally every 6 hours for 7 to 10 days). An alternative agent for penicillin-allergic patients is clindamycin (150–300 mg orally every 6 hours). Surgical incision is indicated for large and fluctuant lesions that do not drain spontaneously.¹⁰

EVALUATION OF THERAPEUTIC OUTCOMES

Many follicular infections resolve spontaneously without medical or surgical intervention. Lesions may need to be incised if they do not respond to a few days of moist heat and over-the-counter topical agents. Following drainage, most lesions begin to heal within several days.

ERYSIPELAS

2 Erysipelas is an infection of the more superficial layers of the skin and cutaneous lymphatics.¹¹ The intense red color and burning pain associated with this skin infection led to the common name of St. Anthony's fire. The infection is almost always caused by β -hemolytic streptococci, with the organisms gaining access via small breaks in the skin. While group A streptococci (*S. pyogenes*) are responsible for most infections, group G streptococci also have been implicated in a considerable number of infections.^{12,13} Infections are more common in infants, young children, the elderly, and patients with nephrotic syndrome.¹⁰ Erysipelas also commonly occurs in areas of preexisting lymphatic obstruction or edema.¹⁰ Diagnosis is made on the basis of the characteristic lesion.

CLINICAL PRESENTATION

GENERAL

- The lower extremities are the most common sites for erysipelas.

SYMPTOMS

- Patients often experience flulike symptoms (fever, malaise) prior to the appearance of the lesion.
- The infected area is described as painful or as a burning pain.

SIGNS

- The lesion is bright red and edematous, often with lymphatic streaking.
- Temperature is often mildly elevated.
- The clinical presentation differs from cellulitis in that the lesion has clearly demarcated raised margins.

LABORATORY TESTS

- Cultures should be considered.
- The causative organism usually cannot be cultured from the surface skin but sometimes may be aspirated from the edge of the advancing lesion.

OTHER DIAGNOSTIC TESTS

- A complete blood count is often performed because leukocytosis is common.
- C-reactive protein is also generally elevated.

► TREATMENT: Erysipelas

The goal of treatment of erysipelas is rapid eradication of the infection. Mild to moderate cases of erysipelas are treated with procaine penicillin G 600,000 units intramuscularly twice daily or penicillin VK 250–500 mg orally four times daily (in children 1–18 years of age, 25,000–90,000 units/kg per day divided into four doses) for 7 to 10 days.^{10,14,15} Penicillin-allergic patients can be treated with clindamycin 150–300 mg orally every 6 to 8 hours (in children, 10–30 mg/kg per day in three to four divided doses). For more serious infections, the patient should be hospitalized, and aqueous penicillin G

2–8 million units daily should be administered intravenously.^{10,11} Marked improvement usually is seen within 48 hours, and the patient often may be switched to oral penicillin to complete the course of therapy. One randomized, double-blind, placebo-controlled study showed that the median time for cure, intravenous antibiotics, and hospital stay was reduced in patients receiving prednisolone in addition to antibiotics. Further studies are needed, however, before corticosteroids can be recommended for routine use.¹³

EVALUATION OF THERAPEUTIC OUTCOMES

Erysipelas generally responds quickly to appropriate antimicrobial therapy. Temperature and white blood count should return to normal within 48 to 72 hours. Erythema, edema, and pain also should resolve gradually.

IMPETIGO

3 Impetigo is a superficial skin infection that is seen most commonly in children and is transmitted easily from person to person.¹⁶ The infection generally is classified as bullous or nonbullous

based on clinical presentation.³ Impetigo is most common during hot, humid weather, which facilitates microbial colonization of the skin.¹⁰ Minor trauma, such as scratches or insect bites, then allows entry of organisms into the superficial layers of skin, and infection ensues.¹⁰ Impetigo is highly communicable and readily spreads through close contact, especially among siblings and children in day-care centers and schools.^{10,11}

Most cases of impetigo were caused by *S. pyogenes*, but *S. aureus* either alone or in combination with *S. pyogenes* has emerged more recently as the principal cause of impetigo.¹⁶ The bullous form is caused by strains of *S. aureus* capable of producing exfoliative toxins.¹⁶ The bullous form most frequently affects neonates and accounts for approximately 10% of all cases of impetigo.^{10,16}

CLINICAL PRESENTATION

GENERAL

- Exposed skin, especially the face, is the most common site for impetigo.

SYMPTOMS

- Pruritus is common, and scratching of the lesions may further spread infection through excoriation of the skin.
- Other systemic signs of infection are minimal.
- Weakness, fever, and diarrhea sometimes are seen with bullous impetigo.

SIGNS

- Nonbullous impetigo manifests initially as small, fluid-filled vesicles.
- These lesions rapidly develop into pus-filled blisters that rupture readily.
- Purulent discharge from the lesions dries to form golden-yellow crusts that are characteristic of impetigo.
- In the bullous form of impetigo, the lesions begin as vesicles and turn into bullae containing clear yellow fluid.
- Bullae soon rupture, forming thin, light brown crusts.
- Regional lymph nodes may be enlarged.

LABORATORY TESTS

- Cultures should be collected.
- Crusted tops of lesions should be raised so that purulent material at the base of the lesion can be cultured.
- Cultures should not be collected from open, draining skin pustules because they may be colonized with staphylococci and other normal skin flora.

OTHER DIAGNOSTIC TESTS

- A complete blood count is often performed because leukocytosis is common.

► TREATMENT: Impetigo

Although impetigo may resolve spontaneously, antimicrobial treatment is indicated to relieve symptoms, prevent formation of new lesions, and prevent complications, such as cellulitis. Penicillinase-resistant penicillins (dicloxacillin 12.5 mg/kg orally daily in four divided doses for children) are preferred for treatment because of the increased incidence of infections caused by *S. aureus*. First-generation cephalosporins are also effective, although they are generally more expensive. Cephalexin (25–50 mg/kg orally daily in two divided doses for children) and cefadroxil (30 mg/kg orally daily in two divided doses for children) are used commonly. Penicillin, administered as either a single intramuscular dose of benzathine penicillin G (300,000–

600,000 units in children, 1.2 million units in adults) or as oral penicillin VK, is effective for infections caused by *S. pyogenes*. Penicillin-allergic patients can be treated with clindamycin (adults 150–300 mg orally every 6 to 8 hours; children 10–30 mg/kg per day in three to four divided doses). The duration of therapy is 7 to 10 days. Topical antibiotics, such as mupirocin and bacitracin, have been used to treat nonbullous impetigo. Mupirocin ointment (applied three times daily for 7 days) is as effective as erythromycin.¹⁷ With proper treatment, healing of skin lesions generally is rapid and occurs without residual scarring. Removal of crusts by soaking in soap and warm water also may be helpful in providing symptomatic relief.^{10,14}

EVALUATION OF THERAPEUTIC OUTCOMES

Clinical response should be seen within 7 days of initiating antimicrobial therapy for impetigo. Treatment failures could be due to noncompliance or antimicrobial resistance. A follow-up culture of exudates should be collected for culture and sensitivity, with treatment modified accordingly.¹⁶

LYMPHANGITIS

4 Acute lymphangitis is an inflammation involving the subcutaneous lymphatic channels. Lymphangitis usually occurs secondary to puncture wounds, infected blisters, or other skin lesions. Most infections are caused by *S. pyogenes*.^{14,18}

CLINICAL PRESENTATION

GENERAL

- Lymphadenitis (acute or chronic inflammation of the lymph nodes) also may occur when microorganisms reach the lymph nodes and elicit an inflammatory response.

SYMPTOMS

- Systemic manifestations of infection (i.e., fever, chills, malaise, and headache) often develop rapidly before any sign of infection is evident at the initial site of inoculation or even after the initial lesion has subsided.
- Systemic symptoms often are more profound than would be expected based on examination of the cutaneous lesion.

SIGNS

- Identification of a peripheral lesion associated with proximal red linear streaks directed toward the regional lymph nodes is diagnostic of acute lymphangitis.
- Lymph nodes usually are enlarged and tender.
- Peripheral edema of the involved extremity often is present.
- Thrombophlebitis and acute lymphangitis in the lower extremities may be confused because both are associated with red linear streaking and tender areas; however, in thrombophlebitis, no portal of entry is identifiable.

LABORATORY TESTS

- Cultures of the affected lesions often yield negative results because the infection resides within the lymphatic channels.
- Offending pathogens often can be identified by Gram stain of the initial lesion if done early in the course of the disease.

OTHER DIAGNOSTIC TESTS

- A complete blood count frequently is performed because leukocytosis is common.

▶ TREATMENT: Lymphangitis

The goal of therapy for lymphangitis is rapid eradication of infection and prevention of further systemic complications. Penicillin is the antibiotic of choice. Because these infections are potentially serious and rapidly progressive, initial treatment should be with intravenous penicillin G. Parenteral treatment should be continued for 48 to 72 hours,

followed by oral penicillin VK for a total of 10 days.^{14,18,19} Nondrug therapy includes immobilization and elevation of the affected extremity and warm-water soaks every 2 to 4 hours.¹⁴ For penicillin-allergic patients, clindamycin may be used.

EVALUATION OF THERAPEUTIC OUTCOMES

Lymphangitis usually responds rapidly to appropriate therapy; signs and symptoms often are decreased markedly or absent within 24 hours of starting antibiotics.

CELLULITIS

5 Cellulitis is an acute, infectious process that represents a more serious type of SSTI. Cellulitis initially affects the epidermis and dermis and may spread subsequently within the superficial fascia. Cellulitis is considered a serious disease because of the propensity of the infection to spread through lymphatic tissue and to the bloodstream. *S. pyogenes* and *S. aureus* are the most frequent etiologic agents. However, a number of bacteria have been implicated in various types of cellulitis (see Table 108–1). The rising incidence of infections due to MRSA is a major concern in both the community and hospital settings.

Injection drug users are predisposed to a number of infectious complications, including abscess formation and cellulitis at the site of injection.²⁰ These SSTIs are located most frequently on the upper extremities and often are polymicrobial in nature.²¹ Infecting organisms are believed to originate from the skin and/or oropharynx, as well as from contaminated needles, syringes, and diluents.²¹ *S. aureus* and streptococci are the most common pathogenic organisms isolated from these infections. Anaerobic bacteria, especially oropharyngeal anaerobes, are also found commonly, particularly in polymicrobial infections.²¹

Acute cellulitis with mixed aerobic and anaerobic flora generally occurs in diabetics, where the skin is adjacent to some site of trauma, at sites of surgical incisions to the abdomen or perineum, or where host defenses have been otherwise compromised (vascular insufficiency). In older patients, cellulitis of the lower extremities also may be complicated by thrombophlebitis. Other complications of cellulitis include local abscess, osteomyelitis, and septic arthritis.^{14,15}

CLINICAL PRESENTATION**GENERAL**

- There is usually a history of an antecedent wound from a minor trauma, abrasion, ulcer, or surgery.
- Because these infections occur often in patients with alterations in host defense mechanisms, poor nutrition, or both, systemic findings such as hypotension, dehydration, and altered mental status are common.

SYMPTOMS

- Patients often experience fever, chills, or malaise and complain that the affected area feels hot and painful.

SIGNS

- Cellulitis is characterized by erythema and edema of the skin.
- Lesions, which may be extensive, are nonelevated and have poorly defined margins.
- Affected areas generally are warm to touch.
- Inflammation generally is present with little or no necrosis or suppuration of soft tissue.
- Tender lymphadenopathy associated with lymphatic involvement is common.

LABORATORY TESTS

- Cultures should be collected when possible.
- A Gram stain of fluid obtained by injection and aspiration of 0.5 mL of saline (using a small 22-gauge needle) into the advancing edge of the lesion may aid the microbiologic diagnosis but often yields negative results.
- Diagnosis usually is made on clinical grounds, i.e., the appearance of the lesion.

OTHER DIAGNOSTIC TESTS

- A complete blood count frequently is performed because leukocytosis is common.

Bacteremia may be present in as many as 30% therefore, blood cultures may be useful for diagnosis in some patients.

► TREATMENT: Cellulitis

The goal of therapy of acute bacterial cellulitis is rapid eradication of the infection and prevention of further complications. Antimicrobial therapy of bacterial cellulitis is directed against the type of bacteria either documented or suspected to be present based on the clinical presentation. Local care of cellulitis includes elevation and immobilization of the involved area to decrease swelling. Cool sterile saline dressings can decrease pain and can be followed later with moist heat to aid in localization of the cellulitis. Surgical intervention (incision and drainage) as a mode of therapy is rarely indicated in the treatment of cellulitis.

Since staphylococcal and streptococcal cellulitis are indistinguishable clinically,¹¹ administration of a semisynthetic penicillin (nafcillin or oxacillin) is recommended until a definitive diagnosis, by skin or blood cultures, can be made^{10,14,15} (Table 108–3). Mild to moderate infections not associated with systemic symptoms may be treated orally with dicloxacillin. If documented to be a mild cellulitis secondary to streptococci, oral penicillin VK or intramuscular procaine penicillin may be administered. More severe infections, either staphylococcal or streptococcal, should be treated initially with intravenous antibiotic regimens. Ceftriaxone 50–100 mg/kg as a single daily dose is efficacious in the treatment of cellulitis in pediatric patients.²² The usual duration of therapy for cellulitis is 7 to 10 days.^{10,14,15}

In penicillin-allergic patients, oral or parenteral clindamycin may be used.^{1,2} Alternatively, a first-generation cephalosporin, such as cefazolin (1–2 g intravenously every 8 hours), may be used cautiously for patients who have not experienced immediate or anaphylactic penicillin reactions and are negative for a penicillin skin test. In mild cases in which an oral cephalosporin can be used, cefadroxil 500 mg twice daily or cephalexin 250–500 mg four times daily is recommended. Other oral cephalosporins, such as cefaclor, cefprozil, and cefpodoxime proxetil, are also effective in the treatment of cellulitis but are considerably more expensive.¹⁴ In severe cases in which cephalosporins cannot be used because of documented methicillin-resistant staphylococci or severe β -lactam allergies, vancomycin should be administered.

Alternative agents for documented infections with resistant gram-positive bacteria such as MRSA and vancomycin-resistant enterococci (VRE) include linezolid, quinupristin-dalfopristin, and daptomycin.^{1,2,23–26} The excellent activity of these drugs against resistant gram-positive pathogens and significantly higher cost make them most appropriate for treatment of complicated or refractory infections or those caused by multidrug-resistant pathogens.

The carbapenems (i.e., imipenem, meropenem, and ertapenem) and the β -lactamase inhibitor combination antibiotics (ampicillin-sulbactam, ticarcillin-lavulanic acid, and piperacillin-tazobactam) also appear to be equivalent to standard therapies in adults.^{1,27–30} The greater cost of these newer agents without increased efficacy compared with other reliable regimens, however, makes them less desirable.

CLINICAL CONTROVERSY

Oral fluoroquinolones have demonstrated efficacy similar to parenteral cephalosporins in the treatment of soft tissue infections caused by gram-positive organisms.^{1,31,32} Caution is warranted when treating SSTIs with ciprofloxacin owing to the unreliable activity of this agent against streptococci.¹ Lower eradication rates of streptococci also have been reported with moxifloxacin when compared with cephalexin in the treatment of uncomplicated SSTIs.³³ The newer fluoroquinolones (i.e., levofloxacin, gatifloxacin, and moxifloxacin) are all effective treatment for uncomplicated SSTIs, but their role in complicated infections has not been elucidated.^{1,33–35} The use of fluoroquinolones is of concern, however, because of increasing reports of resistance among both gram-positive and gram-negative bacteria.³⁶ Sensitivity testing is recommended when a fluoroquinolone is to be used. Also, fluoroquinolones are not approved for use in children because of toxicity concerns.

For cellulitis caused by gram-negative bacilli or a mixture of microorganisms, immediate antimicrobial chemotherapy, as determined by Gram stain, is essential (see Table 108–3). Surgical excision of necrotic tissue and drainage also may be appropriate. Gram-negative cellulitis may be treated appropriately with an aminoglycoside or first- or second-generation cephalosporin. If gram-positive aerobic bacteria are also present, penicillin G or a semisynthetic penicillin should be added to the regimen. Ceftazidime and the fluoroquinolones are effective in the treatment of cellulitis caused by both gram-negative and gram-positive bacteria.^{1,31}

Since some infections may be polymicrobial in nature, antibiotic therapy may need to be broadened to include agents with good activity against anaerobic bacteria. Many different treatment regimens are possible depending on the bacteriology of the lesion (see Table 108–3). Usually an aminoglycoside combined with an antianaerobic cephalosporin, extended-spectrum penicillin, or clindamycin is used. Second- or third-generation cephalosporins have been suggested as single-agent therapy in certain instances.^{37,38} Monotherapy with a β -lactam plus β -lactamase inhibitor combination antibiotic or a carbapenem also may be appropriate in seriously ill patients. Therapy should be 10 to 14 days in duration.

Because gram-negative and mixed aerobic-anaerobic cellulitis can progress quickly to serious tissue invasion, therapeutic intervention should be immediate. If treated early, a quick response can be seen. Unfortunately, because these infections often occur in patients with compromised immune defenses, they may still progress, even with therapeutic intervention. If the infectious process is secondary to a systemic cause (e.g., diabetes), the treatment course often is prolonged and may be associated with high morbidity and mortality.

Infections in injection drug users generally are treated similarly to those in other types of patients.²¹ It is important that

TABLE 108–3. Initial Treatment Regimens for Cellulitis Caused by Various Pathogens

| Antibiotic | Adult Dose and Route | Pediatric Dose and Route |
|--|--|--|
| Staphylococcal or Unknown Gram-Positive Infection | | |
| Mild infection | Dicloxacillin 0.25–0.5 g PO every 6 h ^{a,b} | Dicloxacillin 25–50 mg/kg/day PO in four divided doses ^{a,b} |
| Moderate-severe infection | Nafcillin or oxacillin 1–2 g IV every 4–6 h ^{a,b} | Nafcillin or oxacillin 150–200 mg/kg/day (not to exceed 12 g/24 h) IV in four to six equally divided doses ^{a,b} |
| Streptococcal (Documented) | | |
| Mild infection | Penicillin VK 0.5 g PO every 6 h ^a or procaine penicillin G 600,000 units IM every 8–12 h ^a | Penicillin VK 125–250 mg PO every 6–8 h, or procaine penicillin G 25,000–50,000 units/kg (not to exceed 600,000 units) IM every 8–12 h ^a |
| Moderate-severe infection | Aqueous penicillin G 1–2 million units IV every 4–6 h ^{a,c} | Aqueous penicillin G 100,000–200,000 units/kg/day IV in four divided doses ^a |
| Gram-Negative Bacilli | | |
| Mild infection | Cefaclor 0.5 g PO every 8 h ^d or cefuroxime axetil 0.5 g PO every 12 h ^d | Cefaclor 20–40 mg/kg/day (not to exceed 1 g) PO in three divided doses or cefuroxime axetil 0.125–0.25 g (tablets) PO every 12 h |
| Moderate-severe infection | Aminoglycoside ^e or IV cephalosporin (first- or second-generation depending on severity of infection or susceptibility pattern) ^d | Aminoglycoside ^e or intravenous cephalosporin (first- or second-generation depending on severity of infection or susceptibility pattern) |
| Polymicrobial Infection without Anaerobes | | |
| | Aminoglycoside ^e + penicillin G 1–2 million units every 4–6 h or a semisynthetic penicillin (nafcillin 1–2 g every 4–6 h) depending on isolation of staphylococci or streptococci ^b | Aminoglycoside ^e + penicillin G 100,000 to 200,000 units/kg/day IV in four divided doses or a semisynthetic penicillin (nafcillin 150–200 mg/kg/day [not to exceed 12 g/24 h] IV in four to six equally divided doses) depending on isolation of staphylococci or streptococci ^b |
| Polymicrobial Infection with Anaerobes | | |
| Mild infection | Amoxicillin/clavulanate 0.875 g PO every 12 h <i>or</i> A fluoroquinolone (ciprofloxacin 0.4 g PO every 12 h or levofloxacin 0.5–0.75 g PO every 24 h) plus clindamycin 0.3–0.6 g PO every 8 h or metronidazole 0.5 g PO every 8 h | Amoxicillin/clavulanic acid 20 mg/kg/day PO in three divided doses |
| Moderate-severe infection | Aminoglycoside ^{e,f} + clindamycin 0.6–0.9 g IV every 8 h or metronidazole 0.5 g IV every 8 h <i>or</i> Monotherapy with second- or third-generation cephalosporin (cefoxitin 1–2 g IV every 6 h or ceftizoxime 1–2 g IV every 8 h) <i>or</i> Monotherapy with imipenem 0.5 g IV every 6–8 h, meropenem 1 g IV every 8 h, or extended-spectrum penicillins with a β -lactamase inhibitor (piperacillin/tazobactam 4.5 g IV every 6 h) | Aminoglycoside ^e plus clindamycin 15 mg/kg/day IV in three divided doses or metronidazole 30–50 mg/kg/day IV in three divided doses |

^aFor penicillin-allergic patients, use clindamycin 150–300 mg orally every 6–8 h (pediatric dosing: 10–30 mg/kg/day in 3–4 divided doses).
^bFor methicillin-resistant staphylococci, use vancomycin 0.5–1 g every 6–12 h (pediatric dosing 40 mg/kg/day in divided doses) with dosage adjustments made for renal dysfunction.
^cFor type II necrotizing fasciitis, use clindamycin 0.6–0.9 g IV every 8 h (in children, clindamycin 15 mg/kg/day IV in 3 divided doses) should be added.
^dFor penicillin-allergic adults, use a fluoroquinolone (ciprofloxacin 0.5–0.75 g PO every 12 h or 0.4 g IV every 12 h; levofloxacin 0.5–0.75 g PO or IV every 24 h; gatifloxacin 0.4 g PO or IV every 24 h; or moxifloxacin 0.4 g PO or IV every 24 h).
^eGentamicin or tobramycin, 2 mg/kg loading dose, then maintenance dose determined by serum concentrations.
^fA fluoroquinolone or aztreonam 1 g IV every 6 h may be used in place of the aminoglycoside in patients with severe renal dysfunction or other relative contraindications to aminoglycoside use.

blood cultures be obtained because 25% to 35% of patients may be bacteremic.^{21,39} Also, patients should be assessed for the presence of abscesses; incision, drainage, and culture of these lesions are of extreme importance.¹⁰ Initial antimicrobial therapy while awaiting

culture results of abscesses should include coverage for anaerobic organisms, in addition to *S. aureus* and streptococci.²¹ In areas where MRSA is prevalent, treatment with vancomycin plus metronidazole is preferred.²¹

EVALUATION OF THERAPEUTIC OUTCOMES

If treated promptly with appropriate antibiotics, the majority of patients with cellulitis are cured rapidly. Culture and sensitivity results

should be evaluated carefully both for the adequacy of culture material and the presence of resistant organisms. Additional high-quality samples for culture may be needed for microbiologic analysis. Failure

to respond to therapy also may be indicative of an underlying local or systemic problem or a misdiagnosis.

NECROTIZING SOFT TISSUE INFECTIONS

Necrotizing soft tissue infections consist of a group of highly lethal infections that require early and aggressive surgical débridement in addition to appropriate antibiotics and intensive supportive care.⁴⁰ A number of different descriptive terms have been used to classify necrotizing infections. These have been based on factors such as predisposing conditions, onset of symptoms, pain, skin appearance, etiologic agent, gas production, muscle involvement, and systemic toxicity. While many of the necrotizing soft tissue infections have been designated as unique infectious processes, they all share similar pathophysiologies, clinical features, and treatment approaches.⁴⁰ The major clinical entities of necrotizing infections are *necrotizing fasciitis* and *clostridial myonecrosis* (gas gangrene).⁴⁰

6 Necrotizing fasciitis is a rare but very severe infection of the subcutaneous tissue that may be caused by aerobic and/or anaerobic bacteria and results in progressive destruction of the superficial fascia and subcutaneous fat. It is generally characterized as one of two different types based on bacterial etiology. Type I necrotizing fasciitis generally occurs after trauma and surgery and involves a mixture of anaerobes (*Bacteroides*, *Peptostreptococcus*) and facultative bacteria (streptococci and members of Enterobacteriaceae) that act synergistically to cause destruction of fat and fascia. In type I infections, the skin may be spared, and the speed at which the infection spreads is somewhat slower than type II. Necrotizing fasciitis affecting the male genitalia has been termed *Fournier's gangrene*. Type II necrotizing fasciitis is caused by virulent strains of *S. pyogenes* and is more commonly referred to as *streptococcal gangrene*. This type of infection has received considerable attention in recent years because of reports of “flesh-eating bacteria” by the lay press. Unlike previous reports of streptococcal gangrene that affected older individuals with underlying diseases, recent reports have occurred primarily in young, previously healthy adults following some type of minor trauma. It differs from the polymicrobial type I infections in its clinical presentation. Type II infections have rapidly extending necrosis of subcutaneous tissues and skin, gangrene, severe local pain, and systemic toxicity.¹¹ Type II infections are also highly associated with an early onset of shock and organ failure and are present in approximately half the cases of streptococcal toxic shock-like syndrome.¹¹

Clostridial myonecrosis is a necrotizing infection that involves the skeletal muscle. Gas production and muscle necrosis are prominent features of this infection, which readily explains why this infection is commonly referred to as *gas gangrene*.⁴⁰ The infection advances rapidly, often over a matter of a few hours.⁴⁰ Most infections occur after surgery or trauma, with *Clostridium perfringens* identified as the most common etiologic agent.

► TREATMENT: Necrotizing Soft Tissue Infections

After the diagnosis is made, immediate and aggressive surgical débridement of all necrotic tissue is essential.⁴⁰ Broad-spectrum antibiotics should be administered, with coverage against streptococci, Enterobacteriaceae, and anaerobes. A number of antibiotic regimens have been used successfully to treat necrotizing soft tissue infections; these are generally similar to those used for severe polymicrobial cellulitis involving anaerobes (see Table 108–3). Other combina-

CLINICAL PRESENTATION

GENERAL

- These infections may occur in almost any anatomic location but most frequently involve the abdomen, the perineum, and the lower extremities.
- Patients often have predisposing factors such as diabetes mellitus, local trauma or infection, or recent surgery.

SYMPTOMS

- Systemic symptoms generally are marked (e.g., fever, chills, and leukocytosis) and may include shock and organ failure, especially in patients with type II infections.
- In general, pain in the affected area and systemic toxicity are more pronounced than would be expected with cellulitis.

SIGNS

- At the beginning of an infection, it may be difficult to differentiate between necrotizing fasciitis and cellulitis.
- Like cellulitis, the affected area is initially hot, swollen, and erythematous without sharp margins.
- The affected area is often shiny, exquisitely tender, and painful.
- Diffuse swelling of the area is followed by the appearance of bullae filled with clear fluid.
- The infectious process progresses rapidly, with the skin taking on a maroon or violaceous color after several days.
- Without appropriate intervention, the infection will evolve rapidly into a frank cutaneous gangrene, sometimes with myonecrosis (involvement of skin and muscle).
- Because of the aggressive nature and high mortality (20% to 50%) associated with these infections, a rapid diagnosis is critical.

LABORATORY TESTS

- Although computed tomography and magnetic resonance imaging studies can distinguish these infections, the best and most rapid diagnosis of necrotizing infections is obtained via surgical exploration.
- Intraoperative samples should be collected for culture and sensitivity, as well as for histologic examination.
- Unlike necrotizing fasciitis, clostridial myonecrosis shows little inflammation on histologic examination.

OTHER DIAGNOSTIC TESTS

- Because marked systemic symptoms are seen commonly in necrotizing infections, blood samples should be collected for complete blood count and chemistry profile, as well as for bacterial culture.

tion antibiotic regimens that may be used prior to obtaining bacteriologic data include ampicillin, gentamicin, and clindamycin (or metronidazole); ampicillin-sulbactam and gentamicin; or imipenem and metronidazole.¹⁰

Antibiotic therapy can be modified after Gram stain and culture reports are available. If a diagnosis of type II necrotizing fasciitis is established, the broad-spectrum empirical therapy should be

replaced with the combination of penicillin and clindamycin.¹¹ While *S. pyogenes* remains susceptible to penicillin, clindamycin has been shown experimentally to be more effective.¹¹ A number of factors have been postulated to explain the higher efficacy of clindamycin. These include the mechanism of action (inhibition of protein synthesis), which is not affected by the size of the inoculum or the stage of

bacterial growth.¹¹ In addition, clindamycin has immunomodulatory properties that may account for the higher efficacy.¹¹ The combination of penicillin and clindamycin is also recommended for treatment of clostridial myonecrosis.⁴⁰ In addition, hyperbaric oxygen is of some benefit for clostridial myonecrosis.⁴⁰

EVALUATION OF THERAPEUTIC OUTCOMES

Because of the high mortality associated with necrotizing infections, rapid and complete débridement of all devitalized and necrotic tissue is essential. Surgical débridement, coupled with appropriate antimicrobial therapy and typical supportive measures for management of shock and organ failure, should stabilize the patient. Vital signs and laboratory tests should be monitored carefully for signs of resolution of the infection. Change in antimicrobial therapy or additional surgical débridement may be needed in patients who do not show signs of improvement.

DIABETIC FOOT INFECTIONS

Three major types of foot infections are seen in diabetic patients: deep abscesses, cellulitis of the dorsum, and mal perforans ulcers.⁴¹ Most deep abscesses involve the central plantar space (arch) and are caused by minor penetrating trauma or by an extension of infection of a nail or web space of the toes. Skin infections of the dorsal area generally arise from infections in the toes that are related to routine care of the nails, nailbeds, and calluses of the toes. Mal perforans ulcer is a chronic ulcer of the sole of the foot. The ulcer develops on thickened, hardened calluses over the first or fifth metatarsal. Mal perforans ulcers are associated with neuropathy, which is responsible for the misalignment of the weight-bearing bones of the foot.⁴¹ Osteomyelitis is one of the most serious complications of foot problems in diabetic patients and may occur in 30% to 40% of infections.^{42–44}

EPIDEMIOLOGY

Disorders of the foot are among the most common complications of diabetes, accounting for as many as 20% of all hospitalizations in diabetic patients at an annual cost of \$200 to \$350 million.^{42,45} Approximately 25% of diabetic patients experience significant soft tissue infection at some time during the course of their lifetime. Approximately 55,000 lower extremity amputations, often sequelae of uncontrolled infection, are performed each year on diabetic patients; this represents 50% of all nontraumatic amputations in the United States.⁴⁵ Between 10% and 20% of diabetics will undergo additional surgery or amputation of a second limb within 12 months of the initial amputation.⁴⁶ By 5 years, this increases to 25% to 50%, with death reported in as much as two-thirds of patients.⁴⁶

ETIOLOGY

Diabetic foot infections begin with local bacterial invasion and typically involve a number of different bacterial pathogens.⁴⁶ The infections are polymicrobial in nature, with an average of 4.1 to 5.8 isolates per culture⁴⁷ (Table 108–4). Staphylococci (especially *S. aureus*) and streptococci are the most common pathogens, although gram-negative bacilli and/or anaerobes occur in approximately 50% of cases.⁴⁸ Common gram-negative bacilli isolated include *E. coli*, *Klebsiella* spp., *Proteus* spp., and *P. aeruginosa*. *Bacteroides fragilis* and *Peptostreptococcus* spp. are among the most common anaerobes isolated.

The optimum technique for obtaining culture material from ulcerated lesions is still debated.⁴¹ Routine swab cultures of ulcerative lesions are difficult to interpret because of organisms that colonize the surface of the wounds. Cultures of material from sinus tracts are also unreliable. The correlation between these superficial cultures and true deep cultures (via biopsy or needle aspiration of drainage or abscess fluid) is poor.^{43,47,48} Therefore, cultures and sensitivity tests should be done with specimens obtained from a deep culture whenever possible. Before the wound is cultured, it should be scrubbed vigorously with saline-moistened sterile gauze to remove any overlying necrotic debris.⁴⁹ Cultures then can be obtained from the wound base, preferably from expressed pus.⁴⁹ Specimens obtained from curettage of the base of the ulcer correlate best with results from deep-tissue or bone biopsies.⁴⁹

PATHOPHYSIOLOGY

Three key factors are involved in the development of diabetic foot problems: (1) neuropathy, (2) angiopathy and ischemia, and (3) immunologic defects. Any of these disorders can occur in isolation; however, they frequently occur together.

Neuropathic changes to the autonomic nervous system as a consequence of diabetes may affect the motor nerve supply of small intrinsic muscles of the foot, resulting in muscular imbalance, abnormal stresses on tissues and bone, and repetitive injuries.⁵⁰ Diminished sensory perception causes an absence of pain and unawareness of minor injuries and ulceration. Also, the sympathetic nerve supply may be damaged and can result in an absence of sweating; this leads to dry cracked skin, which can become secondarily infected.⁴²

TABLE 108–4. Bacterial Isolates from Foot Infections in Diabetic Patients

| Organisms | Percentage of Isolates |
|-----------------------------------|------------------------|
| Aerobes | 69% |
| Gram-positive | 45% |
| <i>Staphylococcus aureus</i> | 13% |
| <i>Streptococcus</i> spp. | 11% |
| <i>Enterococcus</i> spp. | 8% |
| Coagulase-negative staphylococci | 7% |
| Gram-negative | 24% |
| <i>Proteus</i> spp. | 5% |
| <i>Enterobacter</i> spp. | 3% |
| <i>Escherichia coli</i> | 3% |
| <i>Klebsiella</i> spp. | 2% |
| <i>Pseudomonas aeruginosa</i> | 2% |
| Other gram-negative bacilli | 7% |
| Anaerobes | 31% |
| <i>Peptostreptococcus</i> spp. | 13% |
| <i>Bacteroides fragilis</i> group | 5% |
| Other <i>Bacteroides</i> spp. | 4% |
| <i>Clostridium</i> spp. | 2% |
| Other anaerobes | 7% |

From Ref. 34 with permission.

Atherosclerosis is more common, appears at a younger age, and progresses more rapidly in the diabetic than in the nondiabetic. Diabetics may have problems with both small vessels (microangiopathy) and large vessels (macroangiopathy) that can result in varying degrees of ischemia, ultimately leading to skin breakdown and infection.

Diabetic patients typically have normal humoral immunity, normal levels of immunoglobulins, and normal antibody responses. Patients with diabetes, however, have impaired phagocytosis and intracellular microbicidal function as compared with nondiabetics; this may be related to angiopathy and low tissue levels of oxygen.⁴² These defects in cell-mediated immunity make patients with diabetes more susceptible to certain types of infection and impair the patients' ability to heal wounds adequately.⁵⁰

CLINICAL PRESENTATION

GENERAL

- Infections are often much more extensive than they appear initially.

SYMPTOMS

- Patients with peripheral neuropathy often do not experience pain but seek medical care for swelling or erythema in the foot.

SIGNS

- Clinical signs of infection in the diabetic foot may not be present secondary to the angiopathy and neuropathy.
- When present, lesions vary in size and clinical features (e.g., erythema, edema, warmth, presence of pus, draining sinuses, pain, and tenderness).
- A foul-smelling odor suggests the presence of anaerobic organisms.
- Temperature may be mildly elevated or normal.

LABORATORY TESTS

- Specimens for culture and sensitivities should be collected.
- If possible, deep intraoperative samples should be obtained during surgical débridement.
- Because of the complex microbiology of these infections, wounds must be cultured for both aerobic and anaerobic organisms.

OTHER DIAGNOSTIC TESTS

- The presence of osteomyelitis also must be assessed via radiograph, bone scan, or both, as appropriate.

► TREATMENT: Diabetic Foot Infections

7 The goal of therapy of diabetic foot infections is preservation of as much normal limb function as possible while preventing additional infectious complications. Up to 90% of these infections can be treated successfully with a comprehensive treatment approach that includes both wound care and antimicrobial therapy.⁴³ After carefully assessing the extent of the lesion and obtaining necessary cultures, necrotic tissue must be thoroughly débrided, with wound drainage and amputation as required. Wounds must be kept clean and dressings changed frequently (two to three times daily). Because of the relationship between hyperglycemia and immune system defects, glycemic control must be maximized to ensure optimal wound healing. In addition, the patient's activities should be restricted initially to bed rest for leg elevation and control of edema, if present. Finally, appropriate antimicrobials must be initiated.^{42–45} However, the optimal antimicrobial therapy for diabetic foot infections has yet to be defined.

The majority of mild, uncomplicated infections can be managed successfully on an outpatient basis with oral antimicrobials and good wound care. Many different agents have been studied, including cefaclor, cephalixin, fluoroquinolones, clindamycin, and amoxicillin-clavulanic acid; these agents provide clinical cure rates of 60% to 85% in published studies.^{44,48,50,51} However, significant failure rates and/or relapse rates have been reported with the use of oral agents. In addition, the development of resistance was problematic in some infections involving *P. aeruginosa* and staphylococci.⁵² Many clinicians consider amoxicillin-clavulanic acid to be the preferred agent because of its broad spectrum of activity, which includes staphylococci, streptococci, enterococci, and many Enterobacteriaceae and anaerobes.⁴⁸ However, this agent does not have activity against *P. aeruginosa*. Fluoroquinolones, which provide coverage against *P. aeruginosa*, have been studied extensively as monotherapy, but they are perhaps most appropriately used in combination with metronidazole or clindamycin

to provide anaerobic activity.² Oral antimicrobials should be used cautiously in serious infections, especially those complicated by osteomyelitis, extensive ulceration, areas of necrosis, or a combination of these.

Initial therapy for patients requiring hospitalization for moderate to severe infections is similar to that for polymicrobial cellulitis with anaerobes (see Table 109–3). Monotherapy with broad-spectrum parenteral antimicrobials, along with appropriate medical or surgical management, or both, is often effective in treating these infections, including those in which osteomyelitis is present.^{53,54} Monotherapy is particularly attractive because of the potential advantages of convenience, cost, and avoidance of toxicities. Microbiologic and clinical cure rates ranging from 60% to 90% may be expected from any of these agents; selection of a specific regimen is determined primarily by cost. In penicillin-allergic patients, metronidazole or clindamycin plus either a fluoroquinolone, aztreonam, or possibly a third-generation cephalosporin is appropriate.^{2,44,48,50} Vancomycin also is used frequently in severe infections because of its excellent activity against gram-positive pathogens. With the increased incidence of MRSA, linezolid, quinupristin-dalfopristin, and daptomycin are alternatives for treatment of these resistant organisms.^{1,2} Because these patients already may have some degree of diabetic nephropathy that may place them at higher risk of nephrotoxicity, strong recommendations have been made for the avoidance of aminoglycoside antibiotics unless no alternative agents are available.⁴² When an aminoglycoside is used, care must be taken to avoid further compromising renal function. All antibiotic regimens should be adjusted as necessary for renal dysfunction.

Empirical therapy that is totally comprehensive in its coverage of all possible pathogens may not be necessary unless the infection is life-threatening.^{48,53,54} No differences were reported in the efficacy of ampicillin-sulbactam versus imipenem-cilastatin for

treatment of limb-threatening diabetic foot infections despite the higher incidence of potential pathogens resistant to the ampicillin-sulbactam regimen.⁵³

Mild infections can be treated with oral agents and generally should be treated for at least 10 to 14 days, whereas more severe

infections dictate initial parenteral therapy and often require up to 21 days or more of antibiotic therapy. In cases of underlying osteomyelitis, treatment should continue for 6 to 12 weeks.^{42,44,48,50} After healing of the infection has occurred, a well-designed program for prevention of further infections should be instituted.

EVALUATION OF THERAPEUTIC OUTCOMES

Therapy should be reevaluated carefully after 48 to 72 hours to assess favorable response. Change in therapy (or route of administration, if oral) should be considered if clinical improvement is not observed at this time. For optimal results, drug therapy should be appropriately modified according to information from deep tissue culture and the clinical condition of the patient. Infections in diabetic patients often require extended courses of therapy because of impaired host immunity and poor wound healing.

PRESSURE SORES

The terms *decubitus ulcer*, *bed sore*, and *pressure sore* are used interchangeably. The decubitus ulcer and the bed sore are types of pressure sores. The term *decubitus ulcer* is derived from the Latin word *decumbere*, meaning “lying down.” Pressure sores, however, can develop regardless of a patient’s position.

Numerous systems for classification of pressure sores have been described. The two most frequently used systems are those of Shea⁵⁵ and the 1989 National Pressure Ulcer Advisory Panel.⁵⁶ These classification systems define the various stages of progression through which a pressure sore may pass (Table 108–5).

Complications of pressure sores are not uncommon and may be life-threatening. Infection is one of the most serious and most frequently encountered complications of pressure ulcers. Bacterial colonization must be differentiated from true bacterial infection. While most pressure sore wounds are colonized, the majority of these eventually heal.⁵⁷ When the tissue is infected, there is bacterial invasion of previously healthy tissue. Without treatment, an initial small, localized area of ulceration can progress rapidly to 5 to 6 cm within days. The visible ulcer is just a small portion of the actual wound; up to 70% of the total wound is below the skin. A pressure-gradient phenomenon is created by which the wound takes on a conical nature; the smallest point is at the skin surface, and the largest portion of the defect is at the base of the ulcer (Fig. 108–1).

TABLE 108–5. Pressure Sore Classification⁴⁸

| | |
|----------|---|
| Stage 1 | Pressure sore is generally reversible, is limited to the epidermis, and resembles an abrasion. It is best described as an irregularly shaped area of soft tissue swelling with induration and heat. |
| Stage 2 | A stage 2 sore may also, be reversible; it extends through the dermis to the subcutaneous fat along with extensive undermining. |
| Stage 3* | In this instance, the sore or ulcer extends further into subcutaneous fat along with extensive undermining. |
| Stage 4* | The sore or ulcer is characterized by penetration into deep fascia involving both muscle and bone. |

*Stage 3 and 4 lesions are unlikely to resolve on their own and often require surgical intervention.

EPIDEMIOLOGY

Pressure sores are seen most frequently in chronically debilitated persons, the elderly, and persons with serious spinal cord injury. Generally, patients who are at risk for pressure sores are elderly or chronically ill young patients who are immobilized either in bed or a wheelchair and who may have altered mental status and/or incontinence.

ETIOLOGY

Similar to diabetic foot infections, a large variety of aerobic gram-positive and gram-negative organisms, as well as anaerobes, frequently are isolated from wound cultures.⁵⁸ Curettage of the ulcer base after débridement provides more reliable culture information than does needle aspiration.⁵⁷ Biopsy specimens give the most reliable data but may not be practical to obtain. Deep-tissue cultures from different sites may give different results. Cultures collected from pressure ulcers reveal polymicrobial growth. A culture collected by swab is likely to identify surface bacteria colonizing the wound rather than to diagnose the infection.⁵⁹

PATHOPHYSIOLOGY

Many factors are thought to predispose patients to the formation of pressure sores: paralysis, paresis, immobilization, malnutrition, anemia, infection, and advanced age. Four factors thought to be most critical to their formation are pressure, shearing forces, friction, and moisture; however, there is still debate as to the exact pathophysiology of pressure sore formation.

Pressure is the essential element in the formation of pressure sores. The areas of highest pressure are generated most often over the bony prominences. Studies show that when the pressure is relieved intermittently within a 2-hour period, only minimal changes

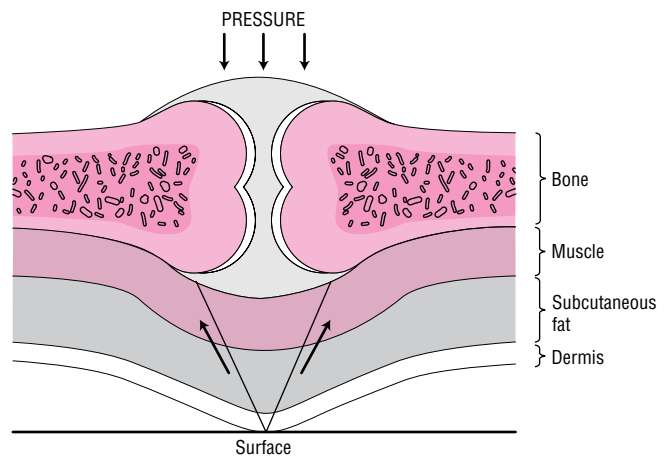

FIGURE 108–1. Distribution of forces involved with sore formation in a conical fashion.

occur in soft tissue and skin structures.⁶⁰ Therefore, both the degree of pressure and the length of time that the pressure is applied are important.

Shearing forces are caused by the sliding of adjacent parallel surfaces of soft tissues in an unequal fashion. This situation can occur when the head of a bed is raised, causing the upper torso to slide downward, transmitting pressure to the sacrum and other areas. This effect results in occlusion or distortion of vessels, leading to compromise of the dermis. At the same time, sitting and gravity create shearing forces; the posterior sacral skin area can become fixed secondary to friction with the bed. The effects of friction and shearing forces combine, resulting in transmission of force to the deep portion of the superficial fascia and leading to further damage of soft tissue structures.

Compounding the problems of shearing and friction forces are the macerating effects of excessive moisture in the local environment, resulting from incontinence and perspiration. This factor is of critical importance because when combined with the other forces, it increases the risk of pressure sore formation fivefold.⁶¹

CLINICAL PRESENTATION

GENERAL

- Pressure sores can occur anywhere on the body.
- However, more than 95% of all pressure sores are located on the lower part of the body (65% in the region of the pelvis and 3.4% on the lower extremities) (Fig. 108–2).
- The most common sites on the lower portion of the body are the sacral and coccygeal areas, ischial tuberosities, and greater trochanter.

SYMPTOMS

- Patients with pressure sores commonly have other medical problems that may mask the typical signs and symptoms of infection.

SIGNS

- Clinical infection is recognized by the presence of surrounding redness, heat, and pain.
- Purulent discharge, foul odor, and systemic signs (e.g., fever and leukocytosis) of infection may be present.

FIGURE 108–2. Supine view of areas where pressure sore formation tends to occur.

LABORATORY TESTS

- Cultures should be collected from either a biopsy or fluid obtained by needle aspiration.

OTHER DIAGNOSTIC TESTS

- Clinicians also must be aware of the possibility of underlying osteomyelitis; therefore, magnetic resonance imaging or other radiographic procedures should be considered.

► TREATMENT: Pressure Sores

8 Prevention is the single most important aspect in the management of pressure sores. Prevention is far easier and less costly than the intensive care necessary for the healing and eventual closure of pressure sores. Of primary importance, then, is the ability to identify patients who are at high risk so that preventive measures may be instituted.

The medical approach to the treatment of pressure sores depends on the stage of the disease. Medical management generally is indicated for lesions that are of moderate size and relatively shallow depth (stage 1 or 2 lesions) and are not located over a bony prominence. Depending on their location and severity, from 30% to 80% of these ulcers will heal without an operation. Surgical intervention is almost always necessary for ulcers that extend through superficial fascia or into bone (stage 3 and 4 lesions).

The goal of therapy is to clean and decontaminate the ulcer to promote wound healing by permitting the formation of healthy granulation tissue or to prepare the wound for an operative procedure. The main factors to be considered for successful topical therapy (local care) are (1) relief of pressure, (2) débridement of necrotic tissue as needed, (3) wound cleansing, (4) dressing selection, and (5) prevention, diagnosis, and treatment of infection.⁶²

Friction and shearing forces can be minimized with proper positioning. Skin care and prevention of soilage are important, with the intent being to keep the surface relatively free of moisture. Patients with problems of incontinence should be cleaned frequently, and efforts should be made to keep the involved areas dry. Natural sheepskin is believed to be useful in minimizing the effects of moisture, shearing forces, and friction. Relief of pressure is probably the

single most important factor in preventing pressure sore formation. Relief for a period of only 5 minutes once every 2 hours is believed to give protection against pressure sore formation.⁶⁰

The goals of débridement and cleansing measures are removal of devitalized tissue and reduction of bacterial contamination, which can slow granulation time and, therefore, impede healing. Débridement can be accomplished by surgical, mechanical, or chemical means. Surgical débridement rapidly removes necrotic material from the wound and is recommended for urgent situations (e.g., cellulitis and sepsis).⁶² Mechanical débridement generally involves wet-to-dry dressing changes. Saline-soaked gauze is applied to the wound; after drying, the gauze is removed and with it any adherent necrotic tissue. Other effective mechanical therapies include hydrotherapy (use of the whirlpool [Hubbard tank] to remove necrotic tissue and debris), wound irrigation, and dextranomers (beads placed in the wound to absorb exudate and bacteria). Chemical débridement includes enzymatic and autolytic agents. Enzymatic débridement involves application of topical débriding agents to remove devitalized tissue. This method is recommended for patients who cannot tolerate surgery or are in a long-term care or home setting. Autolytic débridement involves the use of synthetic dressings that allow devitalized tissue to self-digest via enzymes present in wound fluids. Autolytic débridement is contraindicated in the treatment of infected pressure sores.

Pressure sore wounds should be cleaned with normal saline. Cleansing agents that are cytotoxic, such as povidone-iodine, iodophor, sodium hypochlorite solution, hydrogen peroxide, and acetic acid, should be avoided.⁶² Many of these agents impair healing. Many different types of dressings are available for pressure sores. Wound dressing materials should keep the wound moist, allow free exchange of air, act as a physical barrier to bacteria, and prevent physical damage. Controlled studies of the various types of wound dressings have shown no significant differences in healing outcomes.⁶² Occlusive dressings should be avoided if infection is present.⁵⁹ If occlusive dressings are used, any infection should be controlled or the dressing frequency increased.

Systemic treatment (see Table 108–3) of an infected pressure ulcer should be guided by results from appropriately collected cultures. Systemic antibiotics generally are reserved for treatment of bacteremia, sepsis, cellulitis, or osteomyelitis.⁵⁹ However, a 2-week trial of topical antibiotics (silver sulfadiazine or triple antibiotic) is recommended for a clean ulcer that is not healing or is producing a moderate amount of exudate despite appropriate care.⁵⁹

Other nonpharmacologic approaches to shortening the healing time have included the use of hyperbaric oxygenation, hydrotherapy, high-frequency/high-intensity sound waves, and electrotherapy.^{57,63} Electrical stimulation is the only adjunctive therapy that has been shown to be effective.^{57,63}

EVALUATION OF THERAPEUTIC OUTCOMES

With appropriate wound care and antimicrobial therapy, infected pressure sores can heal. A reduction in erythema, warmth, pain, and other signs and symptoms should be seen in 48 to 72 hours.

BITE WOUNDS

Bite wounds have a substantial potential for infectious complications. If left untreated, complications such as soft tissue infection and osteomyelitis may occur, possibly requiring extensive débridement or amputation. Approximately half the population in the United States will be bitten by either an animal or another human sometime during their lifetimes.⁶⁴

ANIMAL BITES

EPIDEMIOLOGY

Dog bites account for approximately 80% of all animal bite wounds requiring medical attention. A survey of U.S. emergency departments reported an annual adjusted total of 333,687 visits from 1992 to 1994 for new dog bite–related injuries.⁶⁵ Based on the data gathered in this study, approximately 914 new dog bite injuries are seen in emergency departments every day. Dog bites commonly occur in individuals younger than 20 years of age (52.2% of reported cases) who are most often male (57.8%). More than 70% of bites are to the extremities.⁶⁴ Occasionally, facial bites may occur, and these are seen most often in children younger than 15 years of age and can be a lethal event via exsanguination. From 1979 through 1994, 279 deaths were the result of attacks by dogs.⁶⁶

Patients at greatest risk of acquiring an infection after a bite have had a puncture wound (usually the hand), have not sought medical attention within 12 hours of the injury, and are older than 50 years of age.^{67,68}

Cat bites, with an estimated incidence of 5% to 15% of all animal bites, are the second most common cause of animal bite wounds in the United States.⁶⁹ Bites and scratches occur most commonly on the upper extremities, with most injuries reported in women.⁶⁴ Infection rates, estimated at 30% to 50%, are more than double those seen with dog bites.^{64,69}

ETIOLOGY

Infections from dog bite wounds are caused predominantly by organisms documented to be from the dog's oral flora.^{68,70} Most infections are polymicrobial, with approximately five bacterial isolates per culture.⁷¹ *Pasteurella* species are the most frequent isolates. Other common aerobes include streptococci, staphylococci, *Moraxella*, and *Neisseria*. The most common anaerobes are *Fusobacterium*, *Bacteroides*, *Porphyromonas*, and *Prevotella*.⁷¹ Wound-site cultures in both infected and noninfected patients have similar bacteria present, with aerobic organisms isolated from 74% to 90% and anaerobic organisms isolated from 41% to 49%.^{71–73}

Infections arising from cat bites or scratches are frequently (75%) caused by *P. multocida*, which has been isolated in the oropharynx of 50% to 70% of healthy cats.⁶⁷ Mixed aerobic and anaerobic infections have been reported in 63% of cat bite wounds, whereas approximately one-third of cultures grow aerobes only.⁷¹ Both tularemia (*Pasteurella tularensis*) and rabies also have been transmitted by cat bites.⁶⁷

PATHOPHYSIOLOGY

The potential for infection from an animal bite is great owing to the pressure that can be exerted during the bite and the vast number of potential pathogens that make up the normal oral flora.⁷⁰ Cats' teeth are slender and extremely sharp. Their teeth easily penetrate into bones and joints, resulting in a higher incidence of septic arthritis

and osteomyelitis.⁶⁴ While a dog's teeth may not be as sharp, they can exert a pressure of 200 to 450 lb/in² and therefore result in a serious crush injury with much devitalized tissue.⁷⁰ Known human pathogens such as *S. aureus*, *P. multocida*, and anaerobes are among the more than 64 species of bacteria that are harbored in the average dog mouth.⁷⁰ In addition, the polymicrobial (aerobic and anaerobic) nature of animal bites provides a synergistic relationship, thus making an infection harder to eradicate.⁷⁰

CLINICAL PRESENTATION

GENERAL

- Health care providers see two distinct groups of patients seeking medical attention for dog bites.
- The first group presents within 12 hours of the injury; these patients require general wound care, repair of tear wounds, or rabies and/or tetanus treatment.
- The second group of patients presents more than 12 hours after the injury has occurred; these patients usually have clinical signs of infection and seek medical attention for infection-related complaints.

SYMPTOMS

- Patients seek medical care for infection-related complaints (i.e., pain, purulent discharge, and swelling).

SIGNS

- Patients with infected dog bite wounds generally present with a localized cellulitis and pain at the site of injury.
- Cellulitis usually spreads proximally from the initial site of injury, and a gray malodorous discharge may be encountered.
- If *P. multocida* is present, a rapidly progressing cellulitis is observed, with pain and swelling developing within 24 (70%) to 48 (90%) hours of initial injury.
- Fever is uncommon.
- Fewer than 20% of patients have a concomitant adenopathy or lymphangitis.

LABORATORY TESTS

- Samples for bacterial cultures (aerobic and anaerobic) should be obtained.
- Wounds seen less than 8 hours or more than 24 hours after injury that show no signs of infection may not need to be cultured.

OTHER DIAGNOSTIC TESTS

- A roentgenogram of the affected part should be considered when infection is documented in proximity to a bone or joint.

► TREATMENT: Dog and Cat Bites (see Table 108–3)

Cultures obtained from early, noninfected bite wounds are not of great value in predicting the subsequent development of infection. Documentation of the mechanism of injury is important; if possible, an immunization history of the animal should be obtained. It is also important for the patient's tetanus immune status to be determined.

Wounds should be irrigated thoroughly with a copious volume (>150 mL) of sterile normal saline. Proper irrigation will reduce the bacterial count in the wound. Antibiotic or iodine solutions do not offer any advantage over saline and actually may increase tissue irritation. Several management techniques used in the treatment of bite wounds remain controversial; these include the extent and type of débridement,⁷⁴ the use of primary closure within 24 hours of the injury,⁷³ and indications for the use of antibiotics.

The role of prophylactic antimicrobial therapy for the early, noninfected bite wound remains controversial.^{64,75} Unfortunately, suggestions concerning the use of prophylactic antibiotics are based on minimal data because few clinical trials have been performed. Most reports are of retrospective studies or observations of complicated cases. A meta-analysis of eight randomized trials of dog-bite wounds evaluated the use of antibiotics for prophylaxis for the prevention of infectious complications.⁷⁶ The overall occurrence of infectious complications ranged from 3.2% to 45.8%. All studies used oral antibiotics, with six of the eight using either penicillin or a penicillinase-resistant penicillin. Five of the eight studies documented a reduced risk of infection in patients receiving antimicrobial prophylaxis.

Controlled studies have not shown benefits definitively with prophylactic antibiotics for noninfected bites. Because up to 20% of bite wounds may become infected, a 3- to 5-day course of antimicrobial therapy generally is recommended.⁶⁴ This is especially important for patients at greater risk for infection (patients older than 50 years of age and those with puncture wounds and wounds to the hands, and

those who are immunocompromised).^{77,78} Treatment should be directed at the typical aerobic and anaerobic oral flora of dogs, as well as at potential pathogens from the skin flora of the bite victim.

CLINICAL CONTROVERSY

To date, there is no single, universally agreed on treatment regimen for bite wounds. Penicillin provides excellent coverage for *P. multocida* but not for *S. aureus* and most of the other staphylococci that are commonly isolated from bite wounds. Although penicillinase-resistant penicillins, first-generation cephalosporins, erythromycin, and clindamycin have excellent activity against staphylococci, these agents are not active against most strains of *P. multocida*.

Antibiotic regimens suggested for empirical therapy of dog bite wounds include (1) a combination of a β -lactam antibiotic and a β -lactamase inhibitor, (2) a second-generation cephalosporin with anaerobic activity, or (3) penicillin in combination with a first-generation cephalosporin or clindamycin. Tetracyclines (e.g., doxycycline) and trimethoprim-sulfamethoxazole have activity against *P. multocida* and often are recommended as an alternative form of therapy for patients who are allergic to penicillins. However, tetracyclines should not be used in children and/or pregnant women; trimethoprim-sulfamethoxazole also should be avoided during pregnancy. Erythromycin may be considered an alternative in growing children or pregnant women. If erythromycin is selected, bacterial sensitivities should be obtained and clinical response monitored carefully because most strains of *P. multocida* are resistant.

In addition to irrigation and antibiotics, when indicated, the injured area should be immobilized and elevated. Clinical

failures due to edema have occurred despite appropriate antibiotic therapy.⁶⁴ Therefore, it is important to stress to patients that the affected area should be elevated for several days or until edema has resolved.

Infections developing within the first 24 hours of a bite are caused most often by *P. multocida* and should be treated with penicillin VK 500 mg orally four times daily (in children, 80,000–90,000 units/kg per day orally divided into four doses) or amoxicillin 500 mg orally three times daily (in children, 40 mg/kg per day orally divided into three doses). Tetracycline is an alternative for penicillin-allergic children and nonpregnant adults (500 mg orally four times daily; in children, 50 mg/kg per day orally divided into four doses).⁷⁷ For severe infections, IV penicillin (1.2 million units every 4 to 6 hours) therapy should be started and followed by oral therapy when the signs of cellulitis have subsided. Treatment should be given for 10 to 14 days.

For infections developing more than 36 to 48 hours after the bite, the risk of *P. multocida* being involved decreases dramatically. In these patients, staphylococci or streptococci are the most likely causative pathogens. Therapy in this instance includes a penicillinase-resistant penicillin (dicloxacillin 250–500 mg orally four times daily; in children, 25–50 mg/kg per day orally divided into four doses) or a cephalosporin (cefuroxime axetil 500 mg orally twice daily; in children, 20–30 mg/kg per day orally divided into two doses) and should be given for a full 10 to 14 days.⁷⁷

The fluoroquinolones are highly active in vitro against *Pasteurella* and other common aerobic isolates found in these bite wounds. Some of the newer fluoroquinolones also have activity against anaerobes commonly isolated in these infections. However, clinical data on the use of fluoroquinolones with enhanced anaerobic

activity are lacking, and the role of these agents in the therapy of bite wounds has yet to be defined.⁷⁹

Tetanus does not occur commonly after dog bites; however, it is a theoretical possibility. If the immunization history of a patient with anything other than a clean, minor wound is unknown, tetanus-diphtheria (TD) toxoids and tetanus immune globulin (TIG) should be administered.⁸⁰ Patients with wounds that do not require immunization with TD toxoids are those who have had three or more immunization doses of TIG within the past 5 years. Patients who have received three or more doses of TIG within the last 10 years or patients who received two doses of TIG within the first 24 hours of injury do not require additional TIG therapy.⁸⁰

Because the rabies virus can be transmitted via saliva, rabies may be a potential complication of a bite. When the symptoms of rabies develop after a bite, the prognosis for survival is poor. Roughly 3% of rabies cases documented in animals were in dogs (the most frequent vectors are skunks, raccoons, and bats).

After a patient has been exposed to rabies, the treatment objectives consist of thorough irrigation of the wound, tetanus prophylaxis, antibiotic prophylaxis, if indicated, and immunization. Prompt, thorough irrigation of the wound with soap or iodine solution may reduce the development of rabies.⁶⁹ Postexposure prophylaxis immunization consists of the administration of both passive antibody and vaccine. The only exceptions to antibody administration are patients who have been immunized previously and have the appropriate degree of documented rabies antibody titers.

The management of cat bites is similar to that discussed for dog bites. Cat scratches typically involve the same organisms as bites and should be treated accordingly. Antibiotic therapy with penicillin is the mainstay, and therapy is as described for dog bites.

EVALUATION OF THERAPEUTIC OUTCOMES

Results of a Gram stain should be used to confirm the appropriateness of therapy. If signs and symptoms are not reduced within 24 hours, then surgical débridement may be needed.

HUMAN BITES

EPIDEMIOLOGY

Human bites are the third most frequent type of bite. Infected human bites can occur as bites from the teeth or from blows to the mouth (clenched-fist injuries). Human bites generally are more serious than animal bites and carry a higher likelihood of infection than do most animal bites. Infectious complications occur in 10% to 50% of patients with human bites.^{69,81,82}

Self-inflicted bites most commonly occur on the lips or around the fingernails (from sucking or biting the nails). Bites by others can occur to any part of the body, but most often involve the hands. Bites to the hand are most serious and become infected more frequently. The clenched-fist injury is a traumatic laceration caused by one person hitting another in the mouth and is a very serious bite wound. The areas most commonly affected by this injury are the third and fourth metacarpophalangeal joints.

ETIOLOGY

Infections caused by these injuries are similar and are caused most often by the normal oral flora, which include both aerobic and anaerobic microorganisms. *Streptococcus* spp. (especially *S. anginosus*) are the

most common isolates, followed by *Staphylococcus* spp. (predominantly *S. aureus*).⁷⁹ *Eikenella corrodens* is isolated from human bite wounds approximately 30% of the time.^{69,79} Anaerobic microorganisms have been isolated in approximately 40% of human bites and 55% of clenched-fist injuries.⁶⁰ Common anaerobes recovered from human bite infections include *Prevotella*, *Fusobacterium*, *Veillonella*, and *Peptostreptococcus* species.⁷⁹

PATHOPHYSIOLOGY

Human bites generally are more serious and more prone to infection than animal bites, particularly clenched-fist injuries.⁷⁰ While the force of a punch may sever a tendon or nerve or break a bone, it most often causes a breach in the capsule of the metacarpophalangeal joint, leading to direct inoculation of bacteria into the joint or bone.⁶⁴ When the hand is relaxed, the tendons carry bacteria into deeper spaces of the hand, resulting in more extensive infection.⁶⁴

CLINICAL PRESENTATION

GENERAL

- Most clenched-fist injuries are already infected by the time patients seek medical care, and most require hospitalization.

SYMPTOMS

- Patients with infected bites to the hand may develop a painful, throbbing, swollen extremity.

- Wounds often have a purulent discharge, and the patient complains of a decreased range of motion.

SIGNS

- Signs of infection include erythema, swelling, and clear or pussy discharge.
- Adjacent lymph nodes may be enlarged.
- In clenched-fist injuries, edema may limit the ability of tendons to glide in their sheaths, thereby limiting a joint's range of motion.

LABORATORY TESTS

- Samples for bacterial cultures (aerobic and anaerobic) should be collected as per animal bites.
- In severe infections, a peripheral leukocytosis of 15,000 to 30,000 cells/mm³ may be seen; therefore, the white blood count should be monitored for resolution of infection.

OTHER DIAGNOSTIC TESTS

- If damage to a bone or joint is suspected, radiographic evaluation should be undertaken.

► TREATMENT: Human Bites (see Table 108–4)

9 Management of bite wounds consists of aggressive irrigation, surgical débridement, and immobilization of the affected area. Primary closure for human bites generally is not recommended. Tetanus toxoid and antitoxin may be indicated. Transmission of viruses has been documented through human bites; therefore, information about the biter is important. Although the possibility of acquiring the human immunodeficiency virus (HIV) through bites is believed to be unlikely, the presence of the virus in the saliva makes disease transmission possible. If the biter is HIV-positive, the victim should have a baseline blood specimen drawn to determine preexposure HIV status and then be retested in 3 months and 6 months.⁸² The bite wound should be irrigated thoroughly and vigorously with a virucidal agent such as povidone-iodine.⁶⁹ Bite victims exposed to blood-tainted saliva should be offered antiretroviral chemoprophylaxis.

10 Patients with noninfected hand bite injuries should be given prophylactic antibiotic therapy. Initial therapy should consist of a penicillinase-resistant penicillin (dicloxacillin 250–500 mg orally four times daily; in children, 25–50 mg/kg per day orally divided into four doses) in combination with penicillin VK 250–500 mg orally four times daily (in children, 40,000–90,000 units/kg per day orally divided into four doses). Prophylactic therapy should be given for

3 to 5 days as for dog bites.⁸³ A first-generation cephalosporin or macrolide is not recommended because the sensitivity of these agents to *E. corrodens* is variable.⁸⁴

For infected bite wounds, penicillin and a penicillinase-resistant penicillin or amoxicillin–clavulanic acid 875 mg/125 mg orally twice daily (40 mg/kg per day orally of the amoxicillin component divided into two doses) should be started empirically pending the culture results. Tetracyclines or a combination of clindamycin plus a fluoroquinolone or trimethoprim-sulfamethoxazole may be used as an alternative therapy for the penicillin-allergic patient. Hospitalization for minor wounds is not necessary if surgical repair of vital structures has not been performed. Patients suffering serious injuries or clenched-fist injuries should be started on intravenous antibiotics. Duration of therapy for infected bite injuries should be 7 to 14 days.

Antibiotic therapy always should be used in clenched-fist injuries. Therapy should include penicillin (or ampicillin) plus a penicillinase-resistant penicillin until the final cultures are available. Therapeutic failures have been documented when either first-generation cephalosporins or penicillinase-resistant penicillins have been used alone, most likely because of their poor and variable activity against *E. corrodens*.^{85,86} Therapy should be continued from 7 to 14 days.⁸³

EVALUATION OF THERAPEUTIC OUTCOMES

Results of a Gram stain should be used to confirm the appropriateness of therapy. Surgical débridement may be necessary if signs and symptoms are not reduced within 24 hours.

ABBREVIATIONS

HIV: human immunodeficiency virus
 MRSA: methicillin-resistant *Staphylococcus aureus*
 SSTI: skin and soft tissue infection
 TD: tetanus-diphtheria
 TIg: tetanus immune globulin
 VRE: vancomycin-resistant enterococci

INFECTIVE ENDOCARDITIS

Michael A. Crouch and Angie Veverka

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Infective endocarditis (IE) is an uncommon infection usually occurring in persons with preexisting cardiac valvular abnormalities (e.g., prosthetic heart valves) or with other specific risk factors (e.g., intravenous drug abuse).
- 2 Three groups of organisms cause a majority of IE cases: streptococci (55% to 62% of cases), staphylococci (25% to 35%), and enterococci (5% to 18%).
- 3 The clinical presentation of IE is highly variable and non-specific, although a fever and murmur usually are present. Classic peripheral manifestations (Osler nodes) may or may not occur.
- 4 The diagnosis of IE requires the integration of clinical, laboratory, and echocardiographic findings. The two major diagnostic criteria are bacteremia and echocardiographic changes (e.g., valvular vegetation).
- 5 Treatment of IE involves isolation of the infecting pathogen and determination of antimicrobial susceptibilities, followed by high-dose, parenteral, bactericidal antibiotics for an extended period.
- 6 Surgical replacement of the infected heart valve is an important adjunct to endocarditis treatment in certain situations (e.g., patients with acute heart failure).
- 7 β -Lactam antibiotics, such as penicillin G, nafcillin, and ampicillin, remain the drugs of choice for streptococcal, staphylococcal, and enterococcal endocarditis, respectively.
- 8 Aminoglycosides are essential to obtain a synergistic bactericidal effect in the treatment of enterococcal endocarditis. Adjunctive aminoglycosides also may decrease the emergence of resistant organisms (e.g., prosthetic valve endocarditis caused by coagulase-negative staphylococci) and hasten the pace of clinical and microbiologic response (e.g., some streptococcal and staphylococcal infections).
- 9 Vancomycin is reserved for patients with immediate β -lactam allergies and the treatment of resistant organisms.
- 10 Antimicrobial prophylaxis is used as an attempt to prevent IE in patients at high risk (such as persons with prosthetic heart valves) before a bacteremia-causing procedure (e.g., dental extraction).

Endocarditis is an inflammation of the endocardium, the membrane lining the chambers of the heart and covering the cusps of the heart valves.^{1,2} More commonly, *endocarditis* refers to infection of the heart valves by various microorganisms. Although it typically affects native valves, it also may involve nonvalvular areas or implanted mechanical devices (e.g., mechanical heart valves). Bacteria primarily cause endocarditis, but fungi and other atypical microorganisms can lead to the disease; thus the more encompassing term *infective endocarditis* (IE) is preferred.

Endocarditis is often referred to as acute or subacute depending on the pace and severity of the clinical presentation. The acute, fulminating form is associated with high fevers and systemic toxicity. Virulent bacteria, such as *Staphylococcus aureus*, frequently cause this syndrome, and if untreated, death occurs within a few days to weeks. On the other hand, subacute IE is more indolent and is caused by less invasive organisms, such as viridans streptococci, usually occurring in preexisting valvular heart disease. IE is best classified based on the etiologic organism, the anatomic site of infection, and pathogenic risk factors.² Infection also may follow surgical insertion of a prosthetic heart valve, resulting in prosthetic valve endocarditis (PVE).³

EPIDEMIOLOGY AND ETIOLOGY

IE is an uncommon but not rare infection affecting about 10,000 to 20,000 persons annually in the United States. The infection accounts for approximately 1 in every 1000 hospital admissions.¹ Yet the incidence of IE may be increasing, and it is now the fourth leading cause of infectious disease syndromes that are life threatening, after urosepsis, pneumonia, and intraabdominal sepsis.⁴ The male-to-female ratio is 1.7:1. Overall, most cases occur in individuals older than 50 years of age, and it is uncommon in children.^{1,2} PVE accounts for 7% to 25% of cases of IE.⁵ As the population ages, and as valve replacement surgery becomes more common, the mean age of patients with IE increases. However, those with a history of intravenous drug abuse (IVDA), who tend to be younger males, are also at high risk of IE. Other conditions associated with a higher incidence of IE include diabetes, long-term hemodialysis, and poor dental hygiene.

- 1 Most persons with IE have risk factors, such as preexisting cardiac valvular abnormalities. Many types of structural heart disease result in turbulence of blood flow that increases the risk for IE.

TABLE 109–1. Etiologic Organisms in Infective Endocarditis

| Agent | Percentage of Cases |
|-------------------------------|---------------------|
| Streptococci | 55–62 |
| Viridans streptococci | 30–40 |
| Other streptococci | 15–25 |
| Staphylococci | 20–35 |
| Coagulase-positive | 10–27 |
| Coagulase-negative | 1–3 |
| Enterococci | 5–18 |
| Gram-negative aerobic bacilli | 1.5–13 |
| Fungi | 2–4 |
| Miscellaneous bacteria | <5 |
| Mixed infections | 1–2 |
| “Culture negative” | <5–24 |

Adapted from ref. 1.

A predisposing factor, however, may be absent in up to 25% of cases. Some of the more important risk factors include⁵

- Presence of a prosthetic valve (400-fold increased risk)
- Previous endocarditis (400-fold increased risk)
- Complex cyanotic congenital heart disease (e.g., single-ventricle states)
- Surgically constructed systemic pulmonary shunts or conduits
- Acquired valvular dysfunction (e.g., rheumatic heart disease)
- Hypertrophic cardiomyopathy
- Mitral valve prolapse with regurgitation
- Intravenous drug abuse

In the past, rheumatic heart disease was a prevalent risk factor for IE, but the incidence of this disease continues to decline. The risk of IE in persons with mitral valve prolapse and regurgitation is small; however, because the condition is prevalent, it is an important contributor to the overall number of IE cases.⁵ Prosthetic valve endocarditis occurs in 1% to 4% of patients undergoing valve replacement surgery.³

2 Nearly every organism causing human disease has been reported to cause IE (Table 109–1), but three groups of organisms result in a majority of cases: streptococci (55% to 62% of cases), staphylococci (25% to 35%), and enterococci (5% to 18%).¹ The incidence of staphylococci, particularly *S. aureus*, has increased, and staphylococci have surpassed viridans streptococci as the leading cause of IE.⁵ In general, streptococci cause IE in patients with underlying cardiac abnormalities, such as mitral valve prolapse or rheumatic heart disease. Staphylococci (*S. aureus* and coagulase-negative staphylococci) are the most common cause of PVE within the first year after valve surgery, and *S. aureus* is common in those with a history of IVDA. Although polymicrobial IE is uncommon, it is encountered most often in association with IVDA.⁵ Enterococcal endocarditis tends to follow genitourinary manipulations (older men) or obstetric procedures (younger women). There are many exceptions to the preceding generalizations; thus isolation of the causative pathogen and determination of its antimicrobial susceptibilities offer the best chance for successful therapy.

The mitral and aortic valves are affected most commonly in cases involving a single valve. Subacute endocarditis tends to involve the mitral valve, whereas acute disease often involves the aortic valve. Up to 35% of cases involve concomitant infections of both the aortic and the mitral valves. Infection of the tricuspid valve is less common, with a majority of these cases occurring in patients with a history of IVDA. It is rare for the pulmonary valve to be infected.^{1,2}

PATHOPHYSIOLOGY

The development of IE via hematogenous spread, the most common route, requires the sequential occurrence of several factors. These components are complex and not fully elucidated^{1,2}:

- *The endothelial surface of the heart is damaged.* This injury occurs with turbulent blood flow associated with the valvular lesions previously described.
- *Platelet and fibrin deposition occurs on the abnormal epithelial surface.* These platelet-fibrin deposits are referred to as *nonbacterial thrombotic endocarditis* (NBTE).
- *Bacteremia gives organisms access to and results in colonization of the endocardial surface.* Bacteremia is the result of trauma to a mucosal surface with a high concentration of resident bacteria, such as the oral cavity and gastrointestinal tract. Transient bacteremia commonly follows certain dental, gastrointestinal, urologic, and gynecologic procedures. Staphylococci, viridans streptococci, and enterococci are most likely to adhere to NBTE, probably because of production of specific adherence factors, such as dextran by some oral streptococci and glycocalyx for staphylococci.^{2,8} Gram-negative bacteria rarely adhere to heart valves and are uncommon causes of IE.
- *After colonization of the endothelial surface, a “vegetation” of fibrin, platelets, and bacteria forms.* The protective cover of fibrin and platelets allows unimpeded bacterial growth to concentrations as high as 10^9 to 10^{10} organisms per gram of tissue.

The pathogenesis of early PVE differs from the IE acquired by the hematogenous route in that surgery may directly inoculate the valve with bacteria from the patient’s skin or operating room personnel. The recently placed nonendothelialized valve is more susceptible to bacterial colonization than native valves. Bacteria also may colonize the new valve from contaminated bypass pumps, cannulas, and pacemakers or from a nosocomial bacteremia subsequent to an intravascular catheter.^{3,6,7} The mechanism of bacterial colonization and pathogenesis in late PVE is similar to native-valve endocarditis.³

The vegetations seen in IE may be single or multiple and vary in size from a few millimeters to centimeters. Bacteria within the vegetation grow slowly and are protected from antibiotics and host defenses. The adverse effects of IE and the resulting lesions can be far-reaching and include (1) local perivalvular damage, (2) embolization of septic fragments with potential hematogenous seeding of remote sites, and (3) formation of antibody complexes.

Formation of vegetations may destroy valvular tissue, and continued destruction can lead to acute heart failure via perforation of the valve leaflet, rupture of the chordae tendineae or papillary muscle, or in the patient with PVE, valve dehiscence. Occasionally, valvular stenosis may occur. Abscesses can develop in the valve ring or in myocardial tissue itself. Even with resolution of the process, fibrosis of tissue with some residual dysfunction is possible.

Vegetations may be friable, and fragments may be released downstream. These infected particles, termed *septic emboli*, can result in organ abscess or infarction. Septic emboli from right-sided endocarditis commonly lodge in the lungs, causing pulmonary abscesses. Emboli from left-sided vegetations commonly affect organs with high blood flow, such as the kidneys, spleen, and brain.

Circulating immune complexes consisting of antigen, antibody, and complement may deposit in organs, producing local inflammation and damage (e.g., glomerulonephritis in the kidneys). Other potential

pathologic changes that result from immune-complex deposition or septic emboli include the development of “mycotic” aneurysms (although the aneurysm is usually bacterial in origin, not fungal), cerebral infarction, splenic infarction and abscess, and skin manifestations such as petechiae, Osler nodes, and Janeway lesions.

CLINICAL PRESENTATION

3 The clinical presentation of IE is highly variable and nonspecific. Fever is the most common finding and is often accompanied by other vague symptoms (Table 109–2). The fever may be relatively low grade, particularly in subacute cases. Heart murmurs are found in a majority of patients, most often preexisting, with some documented as new or changing. Infective endocarditis usually begins insidiously and worsens gradually. Patients may present with nonspecific findings, such as fever, chills, weakness, dyspnea, night sweats, weight loss, or malaise. In contrast, patients with acute disease, such as those with a history of IVDA with *S. aureus* IE, may appear with classic signs of sepsis.

Splenomegaly is a frequent finding in patients with prolonged endocarditis. Other important clinical signs especially prevalent in subacute illness may include the following peripheral manifestations (“stigmata”) of endocarditis^{1,2}:

- **Osler nodes.** Purplish or erythematous subcutaneous papules or nodules on the pads of the fingers and toes. These lesions are 2 to 15 mm in size and are painful and tender. These nodes are not specific for IE and may be the result of embolism, immunologic phenomena, or both.
- **Janeway lesions.** Hemorrhagic, painless plaques on the palms of the hands or soles of the feet. These lesions are believed to be embolic in origin.
- **Splinter hemorrhages.** Thin, linear hemorrhages found under the nailbeds of the fingers or toes. These lesions are not specific for IE and more commonly are the result of traumatic injuries.

TABLE 109–2. Clinical Presentation of Infective Endocarditis

General

The clinical presentation of IE is highly variable and nonspecific.

Symptoms

The patient may complain of fever, chills, weakness, dyspnea, night sweats, weight loss, and/or malaise.

Signs

Fever is common as well as a heart murmur (sometimes new or changing). The patient may or may not have embolic phenomenon, splenomegaly, or skin manifestations (e.g., Osler nodes, Janeway lesions).

Laboratory Tests

The patient’s WBC count may be normal or only slightly elevated. Nonspecific findings include anemia (normocytic, normochromic), thrombocytopenia, an elevated erythrocyte sedimentation rate or C-reactive protein, and altered urinary analysis (proteinuria/microscopic hematuria).

The hallmark laboratory finding is continuous bacteremia; three sets of blood cultures should be collected over 24 hours.

Other Diagnostic Tests

An electrocardiogram, chest radiograph, and echocardiogram are commonly performed. Echocardiography to determine the presence of valvular vegetations plays a key role in the diagnosis of IE; it should be performed in all suspected cases.

Distal lesions are more likely the result of trauma, whereas proximal lesions tend to be associated with IE.

- **Petechiae.** Small (usually 1 to 2 mm in diameter), erythematous, painless, hemorrhagic lesions. These lesions appear anywhere on the skin but more frequently on the anterior trunk, buccal mucosa and palate, and conjunctivae. Petechiae are nonblanching and resolve after a few days.
- **Clubbing of the fingers.** Proliferative change in the soft tissues about the terminal phalanges observed in long-standing endocarditis.
- **Roth spots.** Retinal infarct with central pallor and surrounding hemorrhage.
- **Emboli.** Embolic phenomena occur in up to one-third of cases and may result in significant complications. Left-sided endocarditis can result in renal artery emboli causing flank pain with hematuria, splenic artery emboli causing abdominal pain, and cerebral emboli, which may result in hemiplegia or alteration in mental status. Right-sided endocarditis may result in pulmonary emboli, causing pleuritic pain with hemoptysis.

Patients with IE typically have laboratory abnormalities; however, none of these changes is specific for the disease.⁷ Anemia (normocytic, normochromic), leukocytosis, and thrombocytopenia may be present. The white blood cell (WBC) count is often normal or only slightly elevated, sometimes with a mild left shift. Acute bacterial endocarditis, however, may present with an elevated WBC count, consistent with a fulminant infection. The erythrocyte sedimentation rate (ESR) is elevated in 90% to 100% of patients, and the level of C-reactive protein also may be elevated.¹ Often the urinary analysis is abnormal, with proteinuria and microscopic hematuria occurring in approximately 50% of individuals.

The hallmark of IE is a continuous bacteremia caused by bacteria shedding from the vegetation into the bloodstream; more than 95% of patients with IE have positive blood cultures.^{1,2} Three sets of blood cultures, each from separate venipuncture sites, should be collected over 24 hours, and antibiotics should be withheld until adequate blood cultures are obtained. On the other hand, if a patient has a toxic appearance, several blood cultures should be collected promptly, followed by immediate empirical antimicrobial treatment. The blood cultures in patients who have received previous antibiotics should be monitored more closely because pathogen growth may be suppressed. “Culture negative” endocarditis describes a patient in whom a clinical diagnosis of IE is likely but blood cultures do not yield a pathogen.⁸ This condition is often the consequence of previous antibiotic therapy, improperly collected blood cultures, or unusual organisms.⁴ When blood cultures from patients suspected of having IE show no growth after 48 to 72 hours, the laboratory should be advised and cultures held for up to a month to detect growth of fastidious organisms.

An electrocardiogram (ECG), chest radiograph, and echocardiogram are performed commonly in patients suspected of endocarditis. The ECG rarely shows important diagnostic findings but may reveal heart block suggesting extension of the infection. The chest radiograph may provide more diagnostic information, especially in a patient with right-sided endocarditis. Septic pulmonary emboli may occur, leading to multiple lung foci. The echocardiogram is the most important test and should be performed in all patients suspected of this infection.

Echocardiography using the transthoracic (TTE) or transesophageal (TEE) technique plays an important role in the diagnosis and management of IE.⁴ The TEE technique is more sensitive for detecting vegetations (90% to 100%) as compared with TTE (58%

to 63%), and TEE maintains good specificity (85% to 95%).² TEE is preferred in high-risk patients such as those with a prosthetic heart valve, congenital heart disease, previous endocarditis, a new murmur, or stigmata of endocarditis.^{4,9,10} TTE appears reasonable in the evaluation of those with native valves who are good candidates for imaging.^{5,11} The lack of vegetation on echocardiogram does not exclude infection even if the transesophageal approach is used. Conversely, the test may reveal an unsuspected large vegetation, extension of the disease into surrounding tissue, valvular defects, abscess formation, cordial rupture, or an intracardiac fistula. Thus, in addition to helping in the diagnosis of IE, the echocardiogram allows the physician to evaluate hemodynamic stability and the need for urgent surgical intervention; it also provides a rough estimate of the likelihood of embolism.^{12,13}

CLINICAL CONTROVERSY

Some clinicians argue that the cost and invasiveness of TEE warrant performing a TTE first and obtaining a TEE only if TTE images are inconclusive. There are currently no prospective, randomized, controlled trials comparing the cost-effectiveness of either strategy.

DIAGNOSIS

4 The signs and symptoms of IE are not specific, and the diagnosis is often unclear. The diagnosis of IE requires the integration of clinical, laboratory, and echocardiographic findings. The most

TABLE 109–3. Diagnosis of Infective Endocarditis According to the Modified Duke Criteria

| Criteria | Comments |
|---|--|
| Major Criteria | |
| <i>Microbiologic</i> | |
| Typical microorganism isolated from two separate blood cultures: <i>Streptococcus viridans</i> , <i>Streptococcus bovis</i> , HACEK group, <i>Staphylococcus aureus</i> , or community-acquired enterococcal bacteremia without a primary focus | In patients with possible IE, at least two sets of cultures of blood collected by separate venipunctures should be obtained within the first 1–2 hours of presentation. Patients with cardiovascular collapse should have three cultures of blood obtained at 5–10-minute intervals and thereafter receive empirical antibiotic therapy. |
| or | |
| Microorganism consistent with IE isolated from persistently positive blood cultures | |
| or | |
| Single positive blood culture for <i>Coxiella burnetii</i> or phase IIgG antibody titer to <i>C. burnetii</i> > 1:800 | <i>C. burnetii</i> is not readily cultivated in most clinical microbiology laboratories. |
| <i>Evidence of endocardial involvement</i> | |
| New valvular regurgitation (increase or change in preexisting murmur not sufficient) | Three echocardiographic findings qualify as major criteria: a discrete, echogenic, oscillating intracardiac mass located at a site of endocardial injury; a periannular abscess; and a new dehiscence of a prosthetic valve |
| or | |
| Positive echocardiogram (transesophageal echocardiography recommended in patients who have a prosthetic valve, who are rated as having at least possible IE by clinical criteria, or who have complicated IE) | |
| Minor Criteria | |
| <i>Predisposition to IE that includes certain cardiac conditions and IV drug use</i> | |
| | Cardiac abnormalities that are associated with IE are classified into three groups: <i>High-risk conditions:</i> Previous IE, aortic valve disease, rheumatic heart disease, prosthetic heart valve, coarctation of the aorta, and complex cyanotic congenital heart diseases <i>Moderate-risk conditions:</i> Mitral valve prolapse with valvular regurgitation or leaflet thickening, isolated mitral stenosis, tricuspid-valve disease, pulmonary stenosis, and hypertrophic cardiomyopathy <i>Low- or no-risk conditions:</i> Secundum atrial septal defect, ischemic heart disease, previous coronary artery bypass graft surgery, and mitral valve prolapse with thin leaflets in the absence of regurgitations |
| <i>Fever</i> | Temperature >38°C (100.4°F) |
| <i>Vascular phenomena</i> | Petechiae and splinter hemorrhages are excluded. None of the peripheral lesions are pathognomonic for IE |
| <i>Immunologic phenomena</i> | Presence of rheumatoid factor, glomerulonephritis, Osler's nodes, or Roth spots |
| <i>Microbiologic findings</i> | Positive blood cultures that do not meet the major criteria Serologic evidence of active infection; single isolates of coagulase-negative staphylococci, and organisms that very rarely cause IE are excluded from this category |

Note: Cases are defined clinically as definite if they fulfill two major criteria, one major criterion plus three minor criteria, or five minor criteria; they are defined as possible if they fulfill one major and one minor criterion or three minor criteria. HACEK denotes *Haemophilus* species (*H. parainfluenzae*, *H. aphrophilus*, *H. paraphrophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*).

Adapted from ref. 15.

recent diagnostic criteria (the Duke criteria) include major and minor variables^{14,15} (Table 109–3). Based on the number of major and minor criteria that are fulfilled, patients suspected of IE are divided into three separate categories: definite IE, possible IE, or IE rejected¹⁵ (see Table 109–3).

PROGNOSIS

The outcome for endocarditis is improved with rapid diagnosis, appropriate treatment (i.e., antimicrobial therapy, surgery, or both), and prompt recognition of complications should they arise. Factors associated with increased mortality include (1) heart failure, (2) culture-negative endocarditis, (3) endocarditis caused by resistant organisms such as fungi or gram-negative bacteria, (4) left-sided endocarditis caused by *S. aureus*, and (5) prosthetic-valve endocarditis.^{1,16} The presence of heart failure has the greatest negative impact on the short-

term prognosis.⁴ For native-valve IE, mortality rates range from 16% to 27%; lower rates occur with viridans streptococci (4% to 9%), and higher rates occur with left-sided IE caused by enterococci (15% to 20%) and staphylococci (25% to 47%). Even higher rates of mortality are seen with unusually encountered organisms (e.g., mortality greater than 50% for *Pseudomonas aeruginosa*). The mortality rate for right-side IE associated with IVDA is generally low (e.g., 10%).⁴ For those who relapse after treatment for IE, most will do so within the first 2 months after discontinuation of antimicrobials. Relapse rates for viridans streptococcus are generally low (2%), whereas relapse is more likely in those with enterococcal infection (8% to 20%) and PVE (10% to 15%).⁵ After appropriate treatment and recovery, the risk of morbidity and mortality following IE persist for years, although it declines gradually annually. Morbidity remains elevated because of a greater likelihood of recurrent IE, heart failure, and embolism or, if a valve is replaced, the risk of anticoagulation, valve thrombosis, or additional valve surgery.¹⁷

▶ TREATMENT: Infective Endocarditis

■ DESIRED OUTCOMES

The desired outcomes for treatment and prophylaxis of IE are to

- Relieve the signs and symptoms of the disease.
- Decrease morbidity and mortality associated with the infection.
- Eradicate the causative organism with minimal drug exposure.
- Provide cost-effective antimicrobial therapy determined by the likely or identified pathogen, drug susceptibilities, hepatic and renal function, drug allergies, and anticipated drug toxicities.
- Prevent IE from occurring or recurring in high-risk patients with appropriate prophylactic antimicrobials.

■ GENERAL APPROACH TO TREATMENT

5 The most important approach in the treatment of IE is isolation of the infecting pathogen and determination of antimicrobial susceptibilities, followed by high-dose, parenteral, bactericidal antibiotics for an extended period.^{1,2} Treatment usually is started in the hospital, but in selected patients it is often completed in the outpatient setting so long as defervescence has occurred and follow-up blood cultures show no growth. Large doses of parenteral antimicrobials usually are necessary to achieve bactericidal concentrations within vegetations. An extended duration of therapy is required, even for susceptible pathogens, because microorganisms are enclosed within valvular vegetations and fibrin deposits. These barriers impair host defenses and protect microbes from phagocytic cells. In addition, the high bacterial concentrations within vegetations may result in an inoculum effect that further resists killing (see Chap. 103 for additional discussion). Many bacteria are not actively dividing, further limiting the rate of bacterial death. For most patients, 4 to 6 weeks of therapy is required.

Pharmacodynamic investigations in the IE animal model allow quantitation of bacterial densities within vegetations over time as a function of antibiotic concentration. These models empirically confirm many of the observed IE treatment principles.^{18,19} The antibiotic concentration in serum that is needed to kill bacteria within vegetations may be many times the minimal bactericidal concentration

(MBC) of the infecting pathogen depending on additional characteristics. The most effective antibiotics have a rapid and homogeneous distribution into the vegetation, kill bacteria rapidly, and are least susceptible to a large inoculum. Aminoglycosides have the most favorable characteristics, followed by β -lactams, and then glycopeptides.¹⁹

■ NONPHARMACOLOGIC THERAPY

6 Surgery is an important adjunct in the management of endocarditis. In most surgical cases, valvectomy and valve replacement are performed to remove infected tissue and to restore hemodynamic function. Echocardiographic features that suggest the need for surgery include persistent vegetation or an increase in vegetation size after prolonged antibiotic treatment, valve dysfunction, or perivalvular extension (e.g., abscess).⁴ Surgery also may be considered in cases of PVE endocarditis caused by resistant organisms (e.g., fungi or gram-negative bacteria), or if there is persistent bacteremia or other evidence of failure despite appropriate antimicrobial therapy.^{3,21} The major indications for surgical intervention in the past have been heart failure in left-sided IE and persistent infection in right-sided IE.¹

■ PHARMACOLOGIC THERAPY

7 Specific treatment recommendations from the American Heart Association (AHA) provide guidance for the management of the more common causes of IE.²² These guidelines were last updated in 1995, with expected revision to be initiated in 2005. β -Lactam antibiotics, such as penicillin G, nafcillin, and ampicillin, remain the drugs of choice for streptococcal, staphylococcal, and enterococcal endocarditis, respectively. These recommendations are summarized in Tables 109–4 through 109–9 and are discussed in more detail in the following sections. Because these guidelines address only common causes of endocarditis, readers are referred to other references for more in-depth discussion of unusually encountered organisms.⁴

TABLE 109–4. Suggested Regimens for Therapy of Native-Valve Endocarditis Due to Penicillin-Susceptible Viridans Streptococci and *Streptococcus bovis* (Minimum Inhibitory Concentration ≤ 0.1 mcg/mL)^a

| Antibiotic | Dosage and Route | Duration (wks) | Comments |
|---|---|----------------|---|
| Aqueous crystalline penicillin G sodium | 12–18 million units/24 h IV either continuously or in six equally divided doses | 4 | Preferred in most patients older than 65 years and in those with impairment of the eighth nerve or renal function |
| or | | | |
| Ceftriaxone sodium | 2 g once daily IV or IM ^b | 4 | |
| Aqueous crystalline penicillin G sodium | 12–18 million units/24 h IV either continuously or in six equally divided doses | 2 | |
| With gentamicin sulfate ^c | 1 mg/kg IM or IV every 8 h | 2 | When obtained 1 h after a 20–30 min IV infusion or IM injection, serum concentration of gentamicin of approximately 3 mcg/mL is desirable; trough concentration should be <1 mcg/mL. |
| Vancomycin hydrochloride ^d | 30 mg/kg per 24 h IV in two equally divided doses, not to exceed 2 g/24 h unless serum levels are monitored | 4 | Vancomycin therapy is recommended for patients allergic to β -lactams (see text regarding drug levels); according to the guidelines, serum concentrations of vancomycin should be obtained 1 h after completion of the infusion and should be in the range of 30–45 mcg/mL for twice-daily dosing |

^aDosages recommended are for patients with normal renal function. For nutritionally variant streptococci, see Table 109–8.

^bPatients should be informed that IM injection of ceftriaxone is painful.

^cDosing of gentamicin on a mg/kg basis will produce higher serum concentrations in obese patients than in lean patients. Therefore, in obese patients, dosing should be based on ideal body weight. (Ideal body weight for men is 50 kg + 2.3 kg per inch over 5 feet, and ideal body weight for women is 45.5 kg + 2.3 kg per inch over 5 feet.) Relative contraindications to the use of gentamicin are age > 65 years, renal impairment, or impairment of the eighth nerve. Other potentially nephrotoxic agents (e.g., nonsteroidal anti-inflammatory drugs) should be used cautiously in patients receiving gentamicin.

^dVancomycin dosage should be reduced in patients with impaired renal function. Each dose of vancomycin should be infused over at least 1 h to reduce the risk of the histamine-release “red man” syndrome.

IV = intravenous; IM = intramuscular.

From Wilson WR, Karchmer AW, Dajani AS, et al. Antibiotic treatment of adults with infective endocarditis due to streptococci, enterococci, and staphylococci, and HACEK microorganisms. *JAMA* 1995;274:1706–1713, with permission. Copyright 1995–1997, American Medical Association.

8 For some pathogens, such as enterococci, the use of synergistic antimicrobial combinations (including an aminoglycoside) is essential to obtain a bactericidal effect. Combination antibiotics also may decrease the emergence of resistant organisms during treatment (e.g., PVE caused by coagulase-negative staphylococci) and hasten the pace of clinical and microbiologic response (e.g., some streptococcal and staphylococcal infections). Occasionally, combination treatment will result in a shorter treatment course.

CLINICAL CONTROVERSY

The AHA guidelines recommend traditional aminoglycoside dosing whenever clinicians use these antibiotics. Extended-interval dosing (once-daily administration) is an intriguing dosing strategy, but data only support this approach for the treatment of streptococcal IE, and it is not recommended routinely.

TABLE 109–5. Therapy for Native-Valve Endocarditis Due to Strains of Viridans Streptococci and *Streptococcus bovis* Relatively Resistant to Penicillin G (Minimum Inhibitory Concentration > 0.1 mcg/mL and < 0.5 mcg/mL)^a

| Antibiotic | Dosage and Route | Duration (wks) | Comments |
|---|---|----------------|---|
| Aqueous crystalline penicillin G sodium | 18 million units/24 h IV either continuously or in six equally divided doses | 4 | Cefazolin or other first-generation cephalosporins may be substituted for penicillin in patients whose penicillin hypersensitivity is not of the immediate type |
| With gentamicin sulfate ^b | 1 mg/kg IM or IV every 8 h | 2 | |
| Vancomycin hydrochloride ^c | 30 mg/kg per 24 h IV in two equally divided doses, not to exceed 2 g/24 h unless serum levels are monitored | 4 | Vancomycin therapy is recommended for patients allergic to β -lactams |

^aDosages recommended are for patients with normal renal function.

^bFor specific dosing adjustment and issues concerning gentamicin, see Table 109–4 footnotes.

^cFor specific dosing adjustment and issues concerning vancomycin, see Table 109–4 footnotes.

IV = intravenous; IM = intramuscular.

From Wilson WR, Karchmer AW, Dajani AS, et al. Antibiotic treatment of adults with infective endocarditis due to streptococci, enterococci, and staphylococci, and HACEK microorganisms. *JAMA* 1995;274:1706–1713, with permission. Copyright 1995–1997, American Medical Association.

TABLE 109–6. Therapy for Endocarditis Due to *Staphylococcus* in the Absence of Prosthetic Material^a

| Antibiotic | Dosage and Route | Duration (wks) | Comments |
|--|---|----------------|---|
| Methicillin-Susceptible Staphylococci | | | |
| Regimens for non- β -lactam-allergic patients | | | |
| Nafcillin sodium or oxacillin sodium | 2 g IV every 4 h | 4–6 | Benefit of additional aminoglycosides has not been established |
| With optional addition of gentamicin sulfate [†] | 1 mg/kg IM or IV every 8 h | 3–5 days | |
| Regimens for β -lactam-allergic patients | | | |
| Cefazolin (or other first-generation cephalosporins in equivalent dosages) | 2 g IV every 8 h | 4–6 | Cephalosporins should be avoided in patients with immediate type hypersensitivity to penicillin |
| With optional addition of gentamicin ^b | 1 mg/kg IM or IV every 8 h | 3–5 days | |
| Vancomycin hydrochloride ^c | 30 mg/kg per 24 h IV in two equally divided doses, not to exceed 2g/24 h unless serum levels are monitored | 4–6 | Recommended for patients allergic to penicillin |
| Methicillin-Resistant Staphylococci | | | |
| Vancomycin hydrochloride ^c | 30 mg/kg per 24 h IV in two equally divided doses, not to exceed 2 g/24 h unless serum levels are monitored | 4–6 | |

^aFor treatment of endocarditis due to penicillin-susceptible staphylococci (minimum inhibitory concentration ≤ 0.1 mcg/mL), aqueous crystalline penicillin G sodium (Table 109-4, first regimen) can be used for 4 to 6 wk instead of nafcillin or oxacillin. Shorter antibiotic courses have been effective in some drug addicts with right-sided endocarditis due to *Staphylococcus aureus* (see text). See text for comments on use of rifampin.

^bFor specific dosing adjustment and issues concerning gentamicin, see Table 109-4 footnotes.

^cFor specific dosing adjustment and issues concerning vancomycin, see Table 109-4 footnotes.

IV = intravenous; IM = intramuscular.

From Wilson WR, Karchmer AW, Dajani AS, et al. Antibiotic treatment of adults with infective endocarditis due to streptococci, enterococci, and staphylococci, and HACEK microorganisms. JAMA 1995;274:1706–1713, with permission. Copyright 1995–1997, American Medical Association.

Subsequent to the most recent publication of the AHA guidelines (1995), the British Society for Antimicrobial Chemotherapy (BSAC) has published treatment recommendations.²³ Although derived separately, these recommendations are quite similar to those of the AHA with regard to organism-specific treatment. The only major difference in these two guidelines pertains to empirical treatment of endocarditis. After appropriate blood cultures are obtained, the BSAC guidelines suggest empirical therapy with penicillin plus gentamicin for most patients, but when staphylococcal infection is suspected, they

recommend vancomycin plus gentamicin. Although community-acquired staphylococcal infections rarely are methicillin-resistant, the BSAC guidelines recommend vancomycin for all suspected staphylococcal infections in an attempt to simplify recommendations, at least during the initial phase of treatment. While not specifically mentioned in the BSAC guidelines, a penicillinase-resistant penicillin (e.g., nafcillin) is a reasonable alternative to vancomycin during the short-term empirical treatment of community-acquired infection suspected to be staphylococci while identification and susceptibilities are obtained.

TABLE 109–7. Treatment of Staphylococcal Endocarditis in the Presence of a Prosthetic Valve or Other Prosthetic Material^a

| Antibiotic | Dosage and Route | Duration (wks) | Comments |
|--|--|----------------|--|
| Regimen for Methicillin-Resistant Staphylococci | | | |
| Vancomycin hydrochloride ^b | 30 mg/kg per 24 h IV in 2 or 4 equally divided doses, not to exceed 2 g/24 h unless serum levels are monitored | ≥ 6 | Rifampin increases the amount of warfarin sodium required for antithrombotic therapy. |
| With rifampin ^c | 300 mg orally every 8 h | ≥ 6 | |
| And with gentamicin sulfate ^{d,e} | 1 mg/kg IM or IV every 8 h | 2 | |
| Regimen for Methicillin-Susceptible Staphylococci | | | |
| Nafcillin sodium or oxacillin sodium | 2 g IV every 4 h | ≥ 6 | First-generation cephalosporins or vancomycin should be used in patients allergic to β -lactam. |
| With rifampin ^c | 300 mg orally every 8 h | ≥ 6 | |
| And with gentamicin sulfate ^{d,e} | 1 mg/kg IM or IV every 8 h | 2 | Cephalosporins should be avoided in patients with immediate-type hypersensitivity to penicillin or with methicillin-resistant staphylococci. |

^aDosages recommended are for patients with normal renal function.

^bFor specific dosing adjustment and issues concerning vancomycin, see Table 109-4 footnotes.

^cRifampin plays a unique role in the eradication of staphylococcal infection involving prosthetic material (see text); combination therapy is essential to prevent emergence of rifampin resistance.

^dFor specific dosing adjustment and issues concerning gentamicin, see Table 109-4 footnotes.

^eUse during initial 2 weeks.

IV = intravenous; IM = intramuscular.

TABLE 109–8. Standard Therapy for Endocarditis Due to Enterococci^a

| Antibiotic | Dosage and Route | Duration (wks) | Comments |
|---|---|----------------|---|
| Aqueous crystalline penicillin G sodium | 18–30 million units/24 h IV either continuously or in six equally divided doses | 4–6 | Four-week therapy recommended for patients with symptoms <3 months in duration; 6-week therapy recommended for patients with symptoms >3 months in duration |
| With gentamicin sulfate ^b | 1 mg/kg IM or IV every 8 h | 4–6 | |
| Ampicillin sodium | 12 g/24 h IV either continuously or in six equally divided doses | 4–6 | |
| With gentamicin sulfate ^b | 1 mg/kg IM or IV every 8 h | 4–6 | Vancomycin therapy is recommended for patients allergic to β -lactams; cephalosporins are not acceptable alternatives for patients allergic to penicillin |
| Vancomycin hydrochloride ^c | 30 mg/kg per 24 h IV in two equally divided doses, not to exceed 2 g/24 h unless serum levels are monitored | 4–6 | |
| With gentamicin sulfate ^b | 1 mg/kg IM or IV every 8 h | 4–6 | |

^aAll enterococci causing endocarditis must be tested for antimicrobial susceptibility in order to select optimal therapy (see text). This table is for endocarditis due to gentamicin- or vancomycin-susceptible enterococci, viridans streptococci with a minimum inhibitory concentration of >0.5 mcg/mL, nutritionally variant viridans streptococci, or prosthetic valve endocarditis caused by viridans streptococci or *Streptococcus bovis*. Antibiotic dosages are for patients with normal renal function.

^bFor specific dosing adjustment and issues concerning gentamicin, see Table 109–4 footnotes.

^cFor specific dosing adjustment and issues concerning vancomycin, see Table 109–4 footnotes.

IV = intravenous; IM = intramuscular.

■ STREPTOCOCCAL ENDOCARDITIS

Streptococci cause a majority of IE cases, with most isolates being viridans streptococci. *Viridans streptococci* refer to a large number of different species, such as *S. mutans*, *S. sanguis*, and *S. mitis*. These bacteria are common inhabitants of the human mouth and gingiva, and they are especially common causes of endocarditis involving native valves.^{1,24} During dental surgery and even when brushing the teeth, these organisms can cause a transient bacteremia. In susceptible individuals, this potentially can result in IE. Streptococcal endocarditis is usually subacute, and the response to medical treatment is good. *S. bovis* is not a viridans streptococcus, but it is included in this group because it is penicillin sensitive and requires the same treatment as viridans streptococci. *S. bovis* is a group D *Streptococcus* that resides in the gastrointestinal tract. IE caused by this organism is often associated with a gastrointestinal pathology, especially colon carcinoma. Endocarditis caused by *S. pneumoniae*, *S. pyogenes*, and groups B, C, and G streptococci are relatively uncommon, and their treatment is not well defined.¹

Antimicrobial regimens for viridans streptococci are well studied, and in uncomplicated cases, response rates as high as 98% can be

expected. Viridans streptococci are penicillin-susceptible, although some are more susceptible than others. Most are exquisitely sensitive to penicillin G and have minimal inhibitory concentrations (MICs) of less than 0.1 mcg/mL.^{22,24} Approximately 10% to 20% are moderately susceptible (MIC 0.1–0.5 mcg/mL). This difference in in vitro susceptibility led to recommendations that the MIC be determined for all viridans streptococci and that the results be used to guide therapy. Some streptococci are deemed tolerant to the killing effects of penicillin, where the MBC exceeds the MIC by 32 times. A tolerant organism is inhibited but not killed by an antibiotic normally considered bactericidal.²⁵ Bactericidal activity is required for successful treatment of IE; therefore, infections with a tolerant organism may relapse after treatment. Despite some animal studies of endocarditis suggesting that tolerant strains do not respond as readily to β -lactam therapy as nontolerant ones, this phenomenon is primarily a laboratory finding with little clinical significance.²⁶ Treatment for tolerant strains is identical to that for nontolerant organisms, and measurement of the MBC is not recommended.^{22,23}

An assortment of regimens can be used to treat uncomplicated endocarditis caused by fully susceptible viridans streptococci (see Table 109–4). Two single-drug regimens consist of either

TABLE 109–9. Therapy for Endocarditis Due to HACEK Microorganisms (*Haemophilus parainfluenzae*, *Haemophilus aphrophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*)^a

| Antibiotic | Dosage and Route | Duration (wks) | Comments |
|--------------------------------------|--|----------------|---|
| Ceftriaxone sodium | 2 g once daily IV or IM ^b | 4 | Cefotaxime sodium or other third-generation cephalosporins may be substituted |
| Ampicillin sodium ^c | 12 g/24 h IV either continuously or in six equally divided doses | 4 | |
| With gentamicin sulfate ^d | 1 mg/kg IM or IV every 8 h | 4 | |

^aAntibiotic dosages are for patients with normal renal function.

^bPatients should be informed that IM injection of ceftriaxone is painful.

^cAmpicillin should not be used if laboratory tests show β -lactamase production.

^dFor specific dosing adjustment and issues concerning gentamicin, see Table 109–4 footnotes.

IV = intravenous; IM = intramuscular.

From Wilson WR, Karchmer AW, Dajani AS, et al. Antibiotic treatment of adults with infective endocarditis due to streptococci, enterococci, and staphylococci, and HACEK microorganisms. *JAMA* 1995; 274:1706–1713, with permission. Copyright 1995–1997, American Medical Association.

high-dose parenteral penicillin G or ceftriaxone for 4 weeks. If a shorter course of therapy is desired, the guidelines suggest high-dose parenteral penicillin G plus an aminoglycoside.²² When used in select patients, this combination is equally effective to 4 weeks of penicillin alone. Although streptomycin was listed in previous guidelines, gentamicin is the preferred aminoglycoside because serum drug concentrations are obtained easily, clinicians are more familiar with its use, and the few strains of streptococci resistant to the effects of streptomycin-penicillin remain susceptible to gentamicin-penicillin. Other aminoglycosides are not recommended.

The decision of which regimen to use depends on the perceived risk versus benefit. For example, a 2-week course of gentamicin in an elderly patient with renal impairment may be associated with ototoxicity, worsening renal function, or both. Furthermore, the 2-week regimen is not recommended for patients with complications such as extracardiac foci. On the other hand, a 4-week course of penicillin alone generally entails greater expense, especially if the patient remains in the hospital. Monotherapy with once-daily ceftriaxone offers ease of administration, facilitates home health care treatment, and may be cost-effective.²⁷

The BSAC guidelines suggest that all the following conditions be present to consider a 2-week treatment regimen for penicillin-sensitive streptococcal endocarditis^{23,28}:

- Penicillin-sensitive viridans streptococcus or *S. bovis* (penicillin MIC < 0.1 mcg/mL)
- No cardiovascular risk factors such as heart failure, aortic insufficiency, or conduction abnormalities
- No evidence of thromboembolic disease
- Native-valve infection
- No vegetation of greater than 5 mm diameter on echocardiogram
- Clinical response within 7 days (The temperature should return to normal, the patient should feel well, and the patient's appetite should return to normal.)

9 When a patient has a history of an immediate-type hypersensitivity to penicillin, vancomycin is the drug of choice for IE caused by viridans streptococci. When vancomycin is chosen, the addition of gentamicin is not recommended.²² First-generation and some third-generation cephalosporins (ceftriaxone) are alternatives in patients with a history of delayed penicillin reactions. Most patients who report a penicillin allergy have a negative penicillin skin test and consequently are at low risk of anaphylaxis.²⁹ The published experience with penicillin is more extensive than with alternative regimens; therefore, a thorough allergy history must be obtained before a second-line therapy is administered.

In patients with complicated infections (e.g., extracardiac foci) or when the streptococcus has an MIC of 0.1–0.5 mcg/mL, combination therapy with an aminoglycoside and penicillin (higher dose preferred) for the first 2 weeks, followed by penicillin alone for an additional 2 weeks, is recommended²² (see Table 109–5). Some viridans streptococci have biologic characteristics that complicate diagnosis and treatment. For example, a few bacteria have nutritional deficiencies that hinder growth in routine culture media.² These organisms require special broth supplemented with pyridoxal hydrochloride or cysteine. For patients infected with nutritionally variant streptococci or when the *Streptococcus* has an MIC of more than 0.5 mcg/mL, treatment should follow the enterococcal endocarditis treatment guidelines²² (see Table 109–8).

The rationale for combination therapy of penicillin-susceptible viridans streptococci is that enhanced activity against these organisms

usually is observed when cell wall active agents are combined with aminoglycosides in vitro.^{22,26} Combined treatment results in quicker sterilization of vegetations in animal models of endocarditis and probably explains the high response rates observed in patients treated for a total of 2 weeks.²² The combined treatment, however, is not superior to penicillin alone. For IE caused by streptococci relatively resistant to penicillin (MIC of 0.1–0.5 mcg/mL), combination therapy for 2 weeks is recommended, followed by penicillin alone for 2 additional weeks.^{22,24} Some authors question the need for combination therapy for such relatively resistant streptococci, emphasizing that few human data suggest that patients with endocarditis caused by these organisms respond less well to penicillin alone.³⁰

Whether or not extended-interval aminoglycoside dosing has a role in IE is controversial. This dosing approach, as compared with thrice-daily dosing, appears to have an equal and possibly greater efficacy in streptococcal endocarditis.^{31–34} One study specifically evaluated the combination of ceftriaxone (2 g daily) with gentamicin (3 mg/kg daily) for 2 weeks compared with ceftriaxone (2 g daily) alone for 4 weeks for penicillin-sensitive streptococci. Both regimens were safe and effective with similar clinical cure rates at 3 months following treatment.³⁵

■ STAPHYLOCOCCAL ENDOCARDITIS

Endocarditis caused by staphylococci is becoming more prevalent, mainly because of increased IVDA, more frequent use of peripheral and central venous catheters, and increased frequency of valve replacement surgery.^{36,37} *Staphylococcus aureus* is the most common organism causing IE among those with IVDA and persons with venous catheters. Coagulase-negative staphylococci (usually *S. epidermidis*) are prominent causes of PVE.

Staphylococcal endocarditis is not a homogeneous disease; appropriate management requires consideration of several questions, such as, Is the organism methicillin resistant? Should combination therapy be used? Is the infection on a native or prosthetic valve? Does the patient have a history of IVDA? Is the infection on the left or right side of the heart? Another consideration in staphylococcal endocarditis is that some organisms may exhibit tolerance to antibiotics. However, similar to streptococci, the concern for tolerance among staphylococci should not affect antibiotic selection.²²

Any patient who develops staphylococcal bacteremia is at risk for endocarditis. Many investigators have attempted to develop criteria that identify the bacteremic patient likely to have IE.³⁷ In hospitalized patients with *S. aureus* bacteremia and an identified focus of infection, such as a vascular catheter, the risk of concomitant IE is low, and treatment of the bacteremia can be reduced to 2 weeks. This approach applies only if the patient does not have a prosthetic valve or additional clinical evidence for endocarditis.^{36,37} On the other hand, the following parameters predict higher risk of IE in patients with *S. aureus* bacteremia: (1) the absence of a primary site of infection, (2) community acquisition of infection, (3) metastatic signs of infection, and (4) valvular vegetations detected by echocardiography.^{1,4}

The recommended therapy for patients with left-sided IE caused by methicillin-sensitive *S. aureus* (MSSA) is 4 to 6 weeks of nafcillin or oxacillin, often combined with a short course of gentamicin (see Table 109–6). From in vitro studies, the combination of an aminoglycoside and penicillinase-resistant penicillin or vancomycin enhances the activity of these drugs toward MSSA. In animal models of endocarditis, combinations of penicillin with an aminoglycoside eradicate organisms from vegetations more rapidly than penicillins

alone.³⁶ In human studies, the addition of an aminoglycoside to nafcillin for the first week of therapy hastens the resolution of fever and bacteremia, but it does not affect survival or relapse rates.³⁸ Traditional thrice-daily dosing of aminoglycosides is recommended when administered for staphylococcal IE, albeit initial data have evaluated gentamicin given once a day.³⁹

If a patient has a mild, delayed allergy to penicillin, first-generation cephalosporins (such as cefazolin) are effective alternatives, but they should be avoided in patients with a history of immediate-type hypersensitivity reactions to penicillins (see Table 109–6). The potential for a true immediate-type allergy should be assessed carefully, and a penicillin skin test should be conducted before giving antibiotic treatment to any patient claiming an allergy.⁴⁰

9 In a patient with a positive skin test or a history of immediate hypersensitivity to penicillin, vancomycin is the agent of choice. Vancomycin, however, kills *S. aureus* slowly and is regarded as inferior to penicillinase-resistant penicillins for MSSA.³⁷ Rifampin as an adjunctive therapy is controversial; however, this agent, added to vancomycin in refractory or complicated infections in patients with left-sided IE may result in dramatic patient improvement.^{36,37} Generally, antibiotic therapy should be continued for 4 to 6 weeks. Unfortunately, left-sided IE caused by *S. aureus* continues to have a poor prognosis, with a mortality rate of 25% to 47%.^{16,22} For reasons discussed in the following section, those with IE associated with IVDA have a more favorable response to therapy.

During the past decade, greater numbers of staphylococci became resistant to penicillinase-resistant penicillins (e.g., methicillin).

9 Vancomycin is the drug of choice for these resistant organisms because most MRSA and coagulase-negative staphylococci are susceptible to it (see Table 109–6). The presence or lack of a prosthetic heart valve in patients with a methicillin-resistant organism guides therapy and determines whether vancomycin should be used alone or, if a prosthetic valve is present, whether combination therapy is necessary.^{3,22} (see Table 109–7).

■ Staphylococcus Endocarditis: Intravenous Drug Abuser

Infective endocarditis in those with IVDA is frequently (60% to 70%) caused by *S. aureus*, although other organisms may be common in certain geographic locations.⁴¹ In this setting, the tricuspid valve is frequently infected, resulting in right-sided IE. Most patients have no history of valve abnormalities, are usually otherwise healthy, and have a good response to medical treatment. Nonetheless, surgery may be required.

Standard treatment for MSSA endocarditis is 4 weeks of monotherapy with a penicillinase-resistant penicillin (see Table 109–6). In the intravenous drug abuser, however, the clinical response with right-sided MSSA endocarditis is usually excellent. Emerging data suggest that these patients may be treated effectively (clinical and microbiologic cure exceeding 90%) with a 2-week course of nafcillin or oxacillin plus an aminoglycoside.^{41–47} Short-course vancomycin, in place of nafcillin or oxacillin, appears to be ineffective.⁴⁵ Another trial suggested that a 2-week regimen of a penicillinase-resistant penicillin alone, without the addition of an aminoglycoside, is as effective as combined therapy in MSSA tricuspid valve endocarditis.⁴⁸ Although these data suggest that an aminoglycoside is unnecessary for short-course treatment in the intravenous drug abuser with right-sided IE, most clinicians are uncomfortable with monotherapy and choose combination treatment in this situation so long as there are

no reasons to avoid an aminoglycoside. Short-course therapy should not be used in left-sided endocarditis, and it is inappropriate in patients with underlying acquired immunodeficiency syndrome (AIDS) or substantial pulmonary complications, such as lung abscess from right-sided IE.²²

An intriguing therapeutic approach for staphylococcal endocarditis in those with IVDA is oral treatment. Preliminary data have suggested that short-course intravenous treatment (primarily nafcillin, mean 16 days) followed by oral treatment (dicloxacillin or oxacillin, mean 26 days) might be effective for tricuspid valve MSSA endocarditis.⁴⁹ The positive results of this trial can be explained by the duration of intravenous antibiotics (>2 weeks), which may be a sufficient treatment course in this patient population. Yet two other studies that predominantly used oral therapy (ciprofloxacin and rifampin) found this approach to be effective (cure rates exceeding 90%) in addicts with uncomplicated right-sided endocarditis caused by MSSA.^{50,51} At this time, concerns with resistance (e.g., ciprofloxacin) and limited published data preclude routine use of oral antibacterial regimens for the treatment of IE in the intravenous drug abuser.

CLINICAL CONTROVERSY

Oral antibiotics for the treatment of IE have been assessed primarily in those with IVDA. Although treating IE with oral antibiotics would decrease adverse events associated with prolonged use of intravenous catheters (e.g., infection, septic thrombus), the paucity of data preclude this being a routine treatment.

■ Staphylococcal Endocarditis: Prosthetic Valves

PVE accounts for approximately 15% of all IE cases.⁵² An episode of PVE occurring within 2 months of surgery strongly suggests that the cause is staphylococci implanted during the procedure.³ Yet the risk of staphylococcal endocarditis remains elevated for up to 12 months after

9 valve replacement. Because this type of IE is typically a nosocomial infection, methicillin-resistant organisms are common, and vancomycin is the cornerstone of therapy. Combination antimicrobials are recommended because of the high morbidity and mortality associated with PVE and its refractoriness to therapy.^{3,22} Although the addition of rifampin to a penicillinase-resistant penicillin or vancomycin does not result in predictable bacterial synergism, rifampin may have unique activity against staphylococcal infection that involves prosthetic material, where its addition results in a higher microbiologic cure rate.² Combination therapy also decreases the emergence of resistance to rifampin, which frequently occurs when it is used alone. For methicillin-resistant staphylococci (both MRSA and coagulase-negative staphylococci), vancomycin is recommended with rifampin for 6 weeks or more (see Table 109–7). An aminoglycoside is added for the first 2 weeks if the organism is aminoglycoside-susceptible. For MSSA, a penicillinase-resistant penicillin is administered in place of vancomycin. PVE responds poorly to medical treatment and has a higher mortality compared with native-valve endocarditis. Valve dehiscence and incompetence can result in acute heart failure, and surgery is often a component of treatment.³

After 12 months, the likely organism for PVE parallels that of native-valve endocarditis. As with native-valve endocarditis, antimicrobial therapy should be based on the identified organism and

in vitro susceptibility. If an organism is identified other than staphylococci, the treatment regimen should be guided by susceptibilities and should be at least 6 weeks in duration.^{3,23} Additionally, a concomitant aminoglycoside is recommended if streptococci or enterococci are identified. Once-daily aminoglycoside regimens have not been evaluated in PVE and are not recommended.³

The use of anticoagulation is controversial in PVE. Those who require anticoagulation for prosthetic valves should continue the anticoagulant cautiously during endocarditis therapy, unless a contraindication to therapy exists.

■ ENTEROCOCCAL ENDOCARDITIS

Enterococci are normal inhabitants of the human gastrointestinal tract and, occasionally, of the anterior urethra. These organisms are usually of low virulence but can become a pathogen in predisposed patients following genitourinary manipulations (older men) or obstetric procedures (younger women).² Historically, enterococci were considered group D streptococci, but they have been reclassified into the genus *Enterococcus* (*E. faecalis* and *E. faecium*). *E. faecalis* is the most common clinical isolate (approximately 90%) of the two species. Enterococci cause 5% to 18% of endocarditis cases, but they are more resistant to therapy than staphylococci and streptococci. Enterococci are noteworthy for these reasons: (1) no single antibiotic is bactericidal, (2) MICs to penicillin are relatively high (1–25 mcg/mL), (3) intrinsic resistance occurs to all cephalosporins and relative resistance occurs to aminoglycosides (e.g., “low level” aminoglycoside resistance), (4) combinations of a cell wall active agent such as a penicillin or vancomycin and an aminoglycoside are necessary for killing, and (5) resistance to all available drugs is increasing.^{1,22,53}

Monotherapy with penicillin for IE caused by enterococci results in relapse rates of 50% to 80%. When used alone, penicillins are only bacteriostatic against enterococci, and combination therapy is always recommended for susceptible strains.⁵³ The relapse rate following penicillin-gentamicin therapy for susceptible strains is less than 15%.¹³ The killing of enterococci by the bactericidal combination of an aminoglycoside and a penicillin is the best clinical example of antibiotic synergy. Because the aminoglycoside cannot penetrate the bacterial cell in the absence of the penicillin, enterococci usually will appear to be resistant to aminoglycosides by routine susceptibility testing (low-level resistance). However, in the presence of an agent that disrupts the cell wall such as penicillin, the aminoglycoside can gain entry, attach to bacterial ribosomes, and cause rapid cell death. An aminoglycoside-vancomycin combination is also synergistic against enterococci and is appropriate therapy for the penicillin-allergic patient.⁵⁴

Enterococcal endocarditis ordinarily requires 4 to 6 weeks of high-dose penicillin G or ampicillin plus an aminoglycoside for cure (see Table 109–8). Ampicillin has greater in vitro activity than penicillin G, although there are no clinical data to document differences in efficacy. A 6-week course is recommended for patients with symptoms lasting longer than 3 months, recurrent cases, and those with mitral valve involvement. Streptomycin has been the most extensively studied aminoglycoside, but gentamicin is presently favored. Other aminoglycosides cannot be substituted routinely. In the treatment of enterococcal endocarditis, relatively low serum concentrations of aminoglycosides appear adequate for successful therapy, such as a gentamicin peak concentration of approximately 3 mcg/mL.⁵⁵ Even though the most recent treatment guidelines advocate this

low-peak-concentration approach, it is debated as to whether this is suitable because it has not been well documented to be equally or more efficacious than higher-serum-concentration approaches.⁵⁶ Treatment of enterococcal endocarditis does not have the high success rate seen with IE caused by viridans streptococci presumably because the organism is more resistant to killing.

Although some data support the use of extended-interval aminoglycoside dosing for other types of endocarditis (i.e., streptococci), the data are more vague regarding this strategy in enterococcal IE.⁵⁷ While some studies suggest that extended-interval aminoglycoside dosing and short-interval (traditional) dosing are clinically equivalent,^{58–60} discordant studies imply otherwise.^{61,62} The paucity of human data precludes routine use of extended-interval aminoglycoside dosing in this setting.

Resistance among enterococci to penicillins and aminoglycosides is increasing.⁵³ Enterococci that exhibit high-level resistance to streptomycin (MIC > 2000 mcg/mL) are not synergistically killed by penicillin and streptomycin because the aminoglycoside either no longer binds to the ribosome or is inactivated by an aminoglycoside-modifying enzyme, streptomycin adenylase. Because enterococci will appear resistant to aminoglycosides on routine susceptibility testing, the only way to distinguish high-level from low-level resistance is by performing special susceptibility tests using 500–2000 mcg/mL of the aminoglycoside. High-level streptomycin-resistant enterococci occur with a frequency of 40% to 50%, and high-level resistance to gentamicin is now found in 10% to 50% of isolates. Although most gentamicin-resistant enterococci are resistant to all aminoglycosides (including amikacin), 30% to 50% remain susceptible to streptomycin.⁵³ High-level gentamicin resistance is mediated by a bifunctional aminoglycoside-modifying enzyme, 6'-acetyltransferase/2'-phosphotransferase, and most strains also possess streptomycin adenylase. These organisms do not commonly cause IE; data on appropriate therapy are sparse, and therapeutic options are few. Case reports indicate that some patients will respond to high doses of ampicillin, as observed in the early trials of penicillin monotherapy.⁶³

In addition to isolates with high-level aminoglycoside resistance, β -lactamase-producing enterococci (especially *E. faecium*) have been reported.⁶⁴ If these organisms are discovered, use of vancomycin or ampicillin-sulbactam should be considered. VRE are reported increasingly, primarily with *E. faecium*. Vancomycin resistance occurs when the bacterium replaces the normal vancomycin target with a peptidoglycan precursor that does not bind vancomycin.⁶⁵ Combination therapies including teicoplanin, quinupristin-dalfopristin, or linezolid appear to be the most promising treatments.

■ LESS COMMON TYPES OF INFECTIVE ENDOCARDITIS

■ HACEK Group

Gram-negative bacteria from the HACEK group (*Hemophilus parainfluenzae*, *H. aphrophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*) are unusual causes of IE. Frequently, these types of IE present as subacute illnesses with large vegetations and emboli.⁶⁶ These oropharyngeal organisms typically are slow growing and should be considered as possible causes of “culture negative” endocarditis. Ceftriaxone or high-dose ampicillin with gentamicin for 4 weeks is the recommended therapy, although ceftriaxone may be preferred²² (see Table 109–9). Valve replacement is required occasionally.

■ Culture-Negative Endocarditis

Sterile blood cultures are reported in up to 5% of patients with IE if strict diagnostic criteria are used.^{1,5,67} This type of IE may occur as a result of unidentified subacute right-sided IE, previous antibiotic therapy, slow-growing fastidious organisms, nonbacterial etiologies (e.g., fungi), and improperly collected blood cultures. When blood cultures from patients suspected of IE show no growth after 48 to 72 hours, the laboratory should be advised and cultures held for up to a month to detect growth of fastidious organisms.

Clinicians should individualize therapy for culture-negative IE. In patients without a history of IVDA, culture-negative IE treatment usually will follow an approach that encompasses treatment for enterococci, the HACEK group, and nutritionally variant streptococci. Although controversial, one source recommends penicillin or ampicillin, an aminoglycoside (e.g., gentamicin), and ceftriaxone. In the intravenous drug abuser in whom staphylococci are suspected, a penicillinase-resistant penicillin or a cephalosporin with activity against staphylococci could be added to the preceding regimen.¹ Therapy for PVE often includes at least vancomycin and gentamicin.⁵ Irrespective of the treatment chosen, extended antimicrobial therapy is required (e.g., 6 weeks), although the aminoglycoside may be removed after 2 weeks if clinical improvement is observed. The preceding empirical approaches to culture-negative IE highlight the need for proper collection and monitoring of blood cultures and an extensive medication history.

■ Other Atypical Microorganisms

Endocarditis caused by organisms such as *Coxiella burnetii*; *Brucella*, *Candida*, and *Aspergillus* spp.; *Legionella*; and gram-negative bacilli (e.g., *Pseudomonas*) is relatively uncommon. Medical therapy for IE caused by these organisms is usually unsuccessful.⁵ Readers are referred elsewhere for an in-depth discussion regarding the management of unusually encountered organisms.⁴ Consultation with an infectious disease expert is warranted when these microorganisms are identified.

Patients at higher risk of gram-negative bacilli IE include intravenous drug abusers and those with prosthetic heart valves. In addition to *Pseudomonas* spp., other gram-negative bacilli that have been implicated include *Salmonella* spp., *Escherichia coli*, *Citrobacter* spp., *Klebsiella-Enterobacter* spp., *S. marcescens*, *Proteus* spp., and *Providencia* spp.¹ Generally, these infections have a poor prognosis, with mortality rates as high as 60% to 80%.¹⁶ Valve replacement is considered mandatory for left-sided pseudomonal IE.⁴ If medical management is implemented, large doses of a penicillin with activity

toward *Pseudomonas* (e.g., piperacillin 18 g/day) with an aminoglycoside are necessary for an extended period (e.g., 6 weeks).^{1,4} Higher doses of the aminoglycoside (e.g., 8 mg/kg per day) may improve the survival rates of *Pseudomonas* IE, especially when combined with surgery.^{66,68}

All cases of *Legionella* IE have had an extended febrile course over months and high anti-*Legionella* antibody titers and have occurred in patients with prosthetic valves.⁴ When special media are used, blood cultures will reveal this organism. Prolonged parenteral therapy with either doxycycline or erythromycin, with prolonged oral therapy (e.g., 6 to 17 months), has elicited cure in some patients.⁴ Most patients require concomitant valve replacement.

Fungi cause between 2% and 4% of endocarditis cases; most patients with fungal endocarditis have undergone recent cardiovascular surgery, are intravenous drug abusers, have received prolonged treatment with intravenous catheters or antibiotics, or are immunocompromised.^{1,2,69} *Candida* spp. and *Aspergillus* spp. are most commonly involved, and the mortality rate is high for these reasons: (1) large, bulky vegetations that often form, (2) systemic septic embolization that may occur, (3) the tendency for fungi to invade the myocardium, (4) poor penetration of vegetations by antifungals, (5) the low toxic:therapeutic ratio of agents such as amphotericin B, and (6) the lack of consistent fungicidal activity of available antifungal agents.^{1,70} When fungal IE is identified, the combined medical-surgical approach is recommended. Because these infections occur infrequently, scant clinical data are available to make solid treatment recommendations; however, the use of antifungal agents alone has been globally unsuccessful. Amphotericin B is the mainstay pharmacologic approach with the possible addition of flucytosine. The usefulness of fluconazole and itraconazole remains unknown at this time, although high-dose itraconazole may be of worth in *Aspergillus* endocarditis, and fluconazole has had limited success in *Candida* IE.

Coxiella burnetii (Q fever) just recently has been recovered from blood cultures, but infection is more likely to be identified via serologic tests. It is a common cause of IE in certain areas of the world where goat, cattle, and sheep farming are widespread. The most favorable therapy for Q fever is unknown but may include doxycycline with trimethoprim-sulfamethoxazole, rifampin, or fluoroquinolones.⁴

Brucella are facultative intracellular gram-negative bacilli. Humans are infected by this organism after ingesting infected unpasteurized milk or undercooked meat, inhalation of infectious aerosols, or contact with infected tissues. This type of IE is more common in veterinarians and livestock handlers. Cure requires valve replacement and antimicrobial agents including doxycycline with streptomycin or gentamicin or doxycycline with trimethoprim-sulfamethoxazole or rifampin for an extended period (8 weeks to months).⁴

PHARMACOECONOMIC CONSIDERATIONS

IE remains an uncommon disease, but the cost of treatment can be substantial. In the past, the long duration of hospitalization required to administer intravenous antimicrobials was the major expense. In selected cases, abbreviated, outpatient, and possibly in the future oral antimicrobial therapy may appreciably reduce the cost of care.

Shorter-course antimicrobial regimens are advocated when possible. For instance, in exquisitely sensitive streptococcal endocarditis (MICs < 0.1 mcg/mL), a 2-week regimen of high-dose parenteral penicillin G in combination with an aminoglycoside is as effective as 4 weeks of penicillin alone.^{22,23} Uncomplicated right-sided MSSA endocarditis in the intravenous drug abuser also may be treated with

a 2-week course. Treatment with nafcillin or oxacillin in combination with an aminoglycoside appears to be cost-effective.

The initiation of outpatient parenteral antibiotics should be considered early in the treatment of IE, after the patient is stable clinically and responds favorably to initial antibiotics. Outpatient treatment has been demonstrated to be safe and effective in select situations.⁷¹ Patients considered for home therapy must be hemodynamically stable, compliant with therapy, have careful medical monitoring, understand the potential complications of the disease, and have immediate access to medical care. Advances in technology allow for the outpatient administration of complex antibiotic regimens that significantly reduce the cost of therapy. Simple regimens, such as single daily doses of ceftriaxone for streptococcal IE, are particularly attractive. Although

endocarditis is common in those with a history of IVDA, and home health care would substantially reduce the cost of treatment, many clinicians are uncomfortable with outpatient intravenous therapy because central venous access is required. Sudden cardiac decompensation in an outpatient setting is also of concern.

EVALUATION OF THERAPEUTIC OUTCOMES

The evaluation of patients treated for IE includes assessment of disease signs and symptoms, blood cultures, microbiologic tests, serum drug concentrations, and other tests that evaluate organ function.

SIGNS AND SYMPTOMS

Fever usually subsides within 1 week of initiating therapy.^{1,2} Persistence of fever may indicate ineffective antimicrobial therapy, emboli, infections of intravascular catheters, or drug reactions. In some patients, low-grade fever may persist even with appropriate antimicrobial therapy. With defervescence, the patient should begin to feel better, and other symptoms, such as lethargy or weakness, should subside.

BLOOD CULTURES

Blood cultures should be negative within a few days, although microbiologic response to vancomycin may be slower.^{1,2} If bacteria continue to be isolated from blood beyond the first few days of therapy, it may indicate that the antimicrobials are inactive against the pathogen or that the doses are not producing adequate concentrations at the site of infection. After the initiation of therapy, blood cultures should be rechecked until negative. During the remainder of therapy, frequent blood culturing is not necessary. Additional blood cultures should be rechecked after successful treatment (e.g., once or twice within the 8 weeks after treatment) to ensure cure.

MICROBIOLOGIC TESTS

For all isolates from blood cultures, MICs should be determined; MBCs are no longer recommended.^{22,23} The agent currently being used should be tested, as well as alternatives that may be required if intolerance, allergy, or resistance occurs. Occasionally, it is useful to determine whether synergy exists for antimicrobial combinations, although synergistic regimens usually can be predicted from the literature. Methods for in vitro determinations of synergy are summarized in Chap. 103.

Serum bactericidal titers (SBTs; also called *Schlichter tests*) have been used in the past in association with a number of infectious diseases.^{72,73} The SBT is the greatest dilution of a patient's serum sample that is obtained while receiving antimicrobial treatment that kills greater than 99.9% of an inoculum of the infecting pathogen in vitro over 18 to 24 hours. In animal models of endocarditis, studies suggest that an SBT of 1:8 is predictive of response.¹⁸ In humans with endocarditis, however, the correlation with SBTs and outcome is not clear. One investigation found peak and trough SBT ratio of 1:64 or greater and 1:32 predicted cure, although a lower titer did not predict failure.⁷⁴ Serum bactericidal titers of 1:32 are achieved easily for most streptococci causing endocarditis because the MBC is low relative to achievable concentrations of penicillin; however, for enterococci, methicillin-resistant staphylococci, and gram-negative bacilli, high SBTs may be difficult to achieve.

At present, SBTs have little value in monitoring treatment of common types of IE and should not be recommended routinely.^{22,23}

This test may be useful when the causative organisms are only moderately susceptible to antimicrobials, when less well-established regimens are used, or when response to therapy is suboptimal and dosage escalation is being considered.

SERUM DRUG CONCENTRATIONS

Of the agents used commonly for IE, measurement of serum drug concentrations is routinely available for aminoglycosides (except streptomycin) and vancomycin. Few data, however, support attaining any specific serum concentrations in patients with IE. In general, serum concentrations of the antimicrobial should exceed the MBC of the organisms, but in practice, this principle is usually not helpful in monitoring patients with endocarditis. Aminoglycoside concentrations rarely exceed the MBC for certain organisms, such as streptococci and enterococci, and concentrations have not been correlated with response, such as aminoglycosides and vancomycin for staphylococci.^{74,75}

When aminoglycosides are administered for IE caused by gram-positive cocci with a traditional thrice-daily regimen, peak serum concentrations are recommended to be on the low side of the traditional ranges (3 mcg/mL for gentamicin). If extended-interval dosing is used, which is not a standard practice at this time, the most appropriate method of monitoring has not been determined. When vancomycin is administered, the most recent treatment guidelines (1995) recommend serum drug monitoring.²² Although the guidelines recommend to obtain peak serum concentrations when using vancomycin, measuring peak concentrations has limited applicability. The primary goal of serum vancomycin monitoring clinically is to ensure that there are adequate trough concentrations when treating resistant organisms.

TABLE 109–10. Cardiac Conditions Associated with Endocarditis

Endocarditis Prophylaxis Recommended

| |
|---|
| High-risk category |
| Prosthetic cardiac valves, including bioprosthetic and homograft valves |
| Previous bacterial endocarditis |
| Complex cyanotic congenital heart disease (e.g., single ventricle states, transposition of the great arteries, tetralogy of Fallot) |
| Surgically constructed systemic pulmonary shunts or conduits |
| Moderate-risk category |
| Most other congenital cardiac malformations (other than above and below) |
| Acquired valvular dysfunction (e.g., rheumatic heart disease) |
| Hypertrophic cardiomyopathy |
| Mitral valve prolapse with valvar regurgitation and/or thickened leaflets |

Endocarditis Prophylaxis Not Recommended

| |
|---|
| Negligible-risk category (no greater risk than the general population) |
| Isolated secundum atrial septal defect |
| Surgical repair of atrial septal defect, ventricular septal defect, or patent ductus arteriosus (without residua beyond 6 mo) |
| Previous coronary artery bypass graft surgery |
| Mitral valve prolapse without valvar regurgitation |
| Physiologic, functional, or innocent heart murmurs |
| Previous Kawasaki disease without valvar dysfunction |
| Previous rheumatic fever without valvar dysfunction |
| Cardiac pacemakers (intravascular and epicardial) and implanted defibrillators |

TABLE 109–11. Dental Procedures and Endocarditis Prophylaxis**Endocarditis Prophylaxis Recommended^a**

- Dental extractions
- Periodontal procedures including surgery, scaling and root planing, probing, and recall maintenance
- Dental implant placement and reimplantation of avulsed teeth
- Endodontic (root canal) instrumentation or surgery only beyond the apex
- Subgingival placement of antibiotic fibers or strips
- Initial placement of orthodontic bands but not brackets
- Intraligamentary local anesthetic injections
- Prophylactic cleaning of teeth or implants where bleeding is anticipated

Endocarditis Prophylaxis Not Recommended

- Restorative dentistry^b (operative and prosthodontic) with or without retraction cord^c
- Local anesthetic injections (nonintraaligamentary)
- Intracanal endodontic treatment; after placement and buildup
- Placement of rubber dams
- Postoperative suture removal
- Placement of removable prosthodontic or orthodontic appliances
- Taking of oral impressions
- Fluoride treatments
- Taking of oral radiographs
- Orthodontic appliance adjustment
- Shedding of primary teeth

^aProphylaxis is recommended for patients with high- and moderate-risk cardiac conditions.

^bThis includes restoration of decayed teeth (filling cavities) and replacement of missing teeth.

^cClinical judgment may indicate antibiotic use in selected circumstances that may create significant bleeding.

PREVENTION

10 Antimicrobial prophylaxis is used as an attempt to prevent IE in patients at high risk.^{76,77} The use of antimicrobials for this purpose requires consideration of (1) cardiac conditions associated with endocarditis, (2) procedures causing bacteremia, (3) organisms likely to cause endocarditis, and (4) pharmacokinetics, spectrum, cost, adverse effects, and ease of administration of available antimicrobial agents. The objective of prophylaxis is to diminish the likelihood of IE in high-risk individuals (Table 109–10) who are undergoing procedures that cause transient bacteremia (Tables 109–11 and 109–12). Although there are no prospective, controlled human trials demonstrating that prophylaxis in high-risk individuals protects against the development of endocarditis during bacteremia-induced procedures, animal studies suggest possible benefit.⁷⁸ Most causes of IE, however, appear not to be secondary to an invasive procedure. Bacteremia as a consequence of daily activities in fact may be the major culprit, and the value of antibiotic prophylaxis before bacteremia-causing procedures has been questioned.⁷⁹ Retrospective human studies, though, support that a reduction of endocarditis occurs in selected patients following dental surgery where prophylaxis is employed.⁸⁰ The common practice of using antimicrobial therapy in this setting remains controversial. The mechanism of a beneficial effect in humans is unclear, but antibiotics may decrease the number of bacteria at the surgical site, kill bacteria after they are introduced into the blood, and prevent adhesion of bacteria to the valve. Studies have found that prophylaxis

TABLE 109–12. Other Procedures and Endocarditis Prophylaxis**Endocarditis Prophylaxis Recommended**

- Respiratory tract
 - Tonsillectomy and/or adenoidectomy
 - Surgical operations that involve respiratory mucosa
 - Bronchoscopy with a rigid bronchoscope
- Gastrointestinal tract^a
 - Sclerotherapy for esophageal varices
 - Esophageal stricture dilation
 - Endoscopic retrograde cholangiography with biliary obstruction
 - Biliary tract surgery
 - Surgical operations that involve intestinal mucosa
- Genitourinary tract
 - Prostatic surgery
 - Cystoscopy
 - Urethral dilation

Endocarditis Prophylaxis Not Recommended

- Respiratory tract
 - Endotracheal intubation
 - Bronchoscopy with a flexible bronchoscope, with or without biopsy^b
 - Tympanostomy tube insertion
- Gastrointestinal tract
 - Transesophageal echocardiography^b
 - Endoscopy with or without gastrointestinal biopsy^b
- Genitourinary tract
 - Vaginal hysterectomy^b
 - Vaginal delivery^b
 - Cesarean section
 - In uninfected tissue
 - Urethral catheterization
 - Uterine dilation and curettage
 - Therapeutic abortion
 - Sterilization procedures
 - Insertion or removal of intrauterine devices
- Other
 - Cardiac catheterization, including balloon angioplasty
 - Implanted cardiac pacemakers, implanted defibrillators, and coronary stents
 - Incision or biopsy of surgically scrubbed skin
 - Circumcision

^aProphylaxis is recommended for high-risk patients; optional for medium-risk patients.

^bProphylaxis is optional for high-risk patients.

From Dajani AS, Taubert KA, Wilson W, et al. *Prevention of bacterial endocarditis: Recommendations by the American Heart Association. JAMA 1997;277:1794–1801, with permission. Copyright 1995–1997, American Medical Association.*

does not reduce the frequency of bacteremia immediately following tooth extraction as compared with a control group, suggesting that a reduction in adhesion or effects after the bacteria adhere to the endocardium are more likely mechanisms.^{81,82} Other studies have further questioned the benefit of antibiotic prophylaxis.⁸³

CLINICAL CONTROVERSY

The common practice of administering antibiotics to high-risk individuals before a bacteremia-causing procedure is controversial. Despite limited data supporting this approach and the fact that 100% compliance with AHA preventative guidelines would have only a modest benefit, the use of single-dose antibiotics for the prevention of endocarditis remains a standard of care.

TABLE 109–13. Prophylactic Regimens for Dental, Oral, Respiratory Tract, or Esophageal Procedures

| Situation | Agent | Regimen ^a |
|---|---|--|
| Standard general prophylaxis Unable to take oral medications | Amoxicillin | Adults: 2 g; children: 50 mg/kg orally 1 h before procedure |
| | Ampicillin | Adults: 2 g intramuscularly (IM) or intravenously (IV); children: 50 mg/kg IM or IV within 30 min before procedure |
| Allergic to penicillin | Clindamycin | Adults: 600 mg; children: 20 mg/kg orally 1 h before procedure |
| | Cephalexin ^b or cefadroxil ^b | Adults: 2 g; children: 50 mg/kg orally 1 h before procedure |
| | Azithromycin or clarithromycin | Adults: 500 mg; children: 15 mg/kg orally 1 h before procedure |
| Allergic to penicillin and unable to take oral medications | Clindamycin | Adults: 600 mg; children: 20 mg/kg IV within 30 min before procedure |
| | Cefazolin ^b | Adults 1 g; children: 25 mg/kg IM or IV within 30 min before procedure |

^aTotal children's dose should not exceed adult dose.

^bCephalosporins should not be used in individuals with immediate-type hypersensitivity reaction (urticaria, angioedema, or anaphylaxis) to penicillins.

From Dajani AS, Taubert KA, Wilson W, et al. Prevention of bacterial endocarditis: Recommendations by the American Heart Association. *JAMA* 1997;277:1794–1801, with permission. Copyright 1995–1997, American Medical Association.

PATIENTS AT RISK

Patients with certain cardiac lesions, particularly those with prosthetic heart valves or a history of bacterial endocarditis, are at high risk for developing IE (see Table 109–10). Nevertheless, only 15% to 25% of patients who develop IE are in a definable high-risk category.⁷⁶ Few cases of IE are preventable with antibiotic prophylaxis, even with 100% effectiveness.⁸⁴ The concern of antibiotic resistance also questions the routine use of antimicrobials in this setting. Despite the low probability that IE will develop, prophylaxis is recommended for some dental, respiratory, gastrointestinal, and genitourinary pro-

cedures (see Tables 109–11 and Tables 109–12) because of the significant morbidity associated with the disease. Patients undergoing valve implant surgery are at a much greater risk for IE than are those patients undergoing dental surgery.

PROCEDURES CAUSING BACTEREMIA

Bacteremia accompanies many everyday events, such as brushing the teeth and chewing, although certain medical and surgical procedures are more likely to cause a transient bacteremia (see Tables 109–11 and

TABLE 109–14. Prophylactic Regimens for Genitourinary Gastrointestinal (Excluding Esophageal) Procedures

| Situation | Agent ^a | Regimen ^b |
|--|-------------------------------|--|
| High-risk patients | Ampicillin plus gentamicin | Adults: Ampicillin 2 g intramuscularly (IM) or intravenously (IV) plus gentamicin 1.5 mg/kg (not to exceed 120 mg) within 30 min of starting the procedure; 6 h later, ampicillin 1 g IM/IV or amoxicillin 1 g orally. Children: Ampicillin 50 mg/kg IM or IV (not to exceed 2 g) plus gentamicin 1.5 mg/kg within 30 min of starting the procedure; 6 h later, ampicillin 25 mg/kg IM/IV or amoxicillin 25 mg/kg orally. |
| High-risk patients allergic to ampicillin/amoxicillin | Vancomycin plus gentamicin | Adults: Vancomycin 1 g IV over 1–2 h plus gentamicin 1.5 mg/kg IV/IM (not to exceed 120 mg); complete injection/infusion within 30 min of starting the procedure. Children: Vancomycin 20 mg/kg IV over 1–2 h plus gentamicin 1.5 mg/kg IV/IM; complete injection/infusion within 30 min of starting the procedure. |
| Moderate-risk patients | Amoxicillin or ampicillin | Adults: Amoxicillin 2 g orally 1 h before procedure, or ampicillin 2 g IM/IV within 30 min of starting the procedure. Children: Amoxicillin 50 mg/kg orally 1 h before procedure, or ampicillin 50 mg/kg IM/IV within 30 min of starting the procedure. |
| Moderate-risk patients allergic to ampicillin/amoxicillin | Vancomycin | Adults: Vancomycin 1 g IV over 1–2 h; complete infusion within 30 min of starting the procedure. Children: Vancomycin 20 mg/kg IV over 1–2 h; complete infusion within 30 min of starting the procedure. |

^aTotal children's dose should not exceed adult dose.

^bNo second dose of vancomycin or gentamicin is recommended.

From Dajani AS, Taubert KA, Wilson W, et al. Prevention of bacterial endocarditis: Recommendations by the American Heart Association. *JAMA* 1997;277:1794–1801, with permission. Copyright 1995–1997, American Medical Association.

109–12). Antibiotic prophylaxis is recommended in patients at risk undergoing a bacteremia-causing procedure. For dental procedures of the gums and oral structures that cause bleeding, viridans streptococci frequently cause bacteremia, whereas instrumentation and surgery of the gastrointestinal and genitourinary tracts more often result in enterococcal bacteremia.¹

ANTIBIOTIC REGIMENS

The AHA routinely publishes guidelines regarding the prevention of IE, with the most recent revision occurring in 1997.⁷⁸ A single 2-g dose of amoxicillin is recommended for adult patients at risk, given 1 hour before undergoing procedures associated with bacteremia (see Table 109–13). Because the duration of antimicrobial prophylaxis appears to be relatively short, these guidelines do not advocate a second oral dose of amoxicillin, which was recommended previously. Alternative prophylaxis regimens for patients allergic to penicillins or those unable to take oral medications and regimens for genitourinary and gastrointestinal procedures are provided (Tables 109–13 and 109–14). One report highlights the need to educate physicians and patients regarding these guidelines because overuse of IE prophylaxis occurs in low-risk patients, and underuse is common in moderate-risk patients.⁸⁵

TUBERCULOSIS

Charles A. Peloquin

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Tuberculosis (TB) is the most prevalent communicable infectious disease on earth and remains out of control in many developing nations. These nations require medical and financial assistance from developed nations in order to control the spread of TB globally.
- 2 In the United States, TB disproportionately affects ethnic minorities as compared with whites, reflecting greater ongoing transmission in ethnic minority communities. Additional TB surveillance and preventive treatment are required within these communities.
- 3 Coinfection with human immunodeficiency virus (HIV) and TB accelerates the progression of both diseases, thus requiring rapid diagnosis and treatment of both diseases.
- 4 Mycobacteria are slow growing organisms; in the laboratory, they require special stains, special growth media, and long periods of incubation to isolate and identify.
- 5 TB can produce atypical signs and symptoms in infants, the elderly, and immunocompromised hosts, and it can progress rapidly in these patients.
- 6 Latent TB infection (LTBI) can lead to reactivation disease years after the primary infection occurred.
- 7 The patient suspected of having active TB disease must be isolated until the diagnosis is confirmed and he or she is no longer contagious. Often, isolation takes place in specialized “negative pressure” hospital rooms to prevent the spread of TB.
- 8 Isoniazid and rifampin are the two most important TB drugs; organisms resistant to both these drugs (multidrug-resistant TB [MDR-TB]) are much more difficult to treat.
- 9 *Never add a single drug to a failing regimen!*
- 10 Directly observed treatment (DOT) should be used whenever possible to reduce treatment failures and the selection of drug-resistant isolates.

1 Tuberculosis (TB) remains a leading infectious killer globally. TB is caused by *Mycobacterium tuberculosis*, which can produce either a silent, latent infection or a progressive, active disease.¹ Left untreated or improperly treated, TB causes progressive tissue destruction and eventually death. Because of renewed public health efforts, TB rates in the United States continue to decline. In contrast, TB remains out of control in many developing countries—to the point that one-third of the world’s population currently is infected.¹ Estimates suggest that 1 person dies of TB in India each minute (*Times of India*, August 29, 2003). Given increasing drug resistance, it is critical that a major effort be made to control TB before the most effective drugs are lost permanently.

M. tuberculosis preferentially infects humans, and the closely related *M. bovis* causes a similar disease in cattle and other livestock. Although uncommon today, humans frequently developed TB by drinking milk contaminated with *M. bovis*—a threat that spurred the development of pasteurization. Today, airborne *M. tuberculosis* is the main threat to humans.

Evidence of TB has been found in ancient human remains, and ancient texts describe it.^{1–3} TB commonly was known as “consumption” because of the pronounced weight loss that it caused.¹ Other common names included “wasting disease” and the “white plague.” As the term *plague* implies, TB had a profound impact on human

history, most notably in Europe. (*Note:* The “black plague,” or bubonic plague, is a separate disease caused by *Yersinia pestis*.)

TB rates generally have risen with increasing urbanization and overcrowding because it is easier for an airborne disease to spread when people are packed closely together.³ Hence TB became a significant pathogen in Europe during the Middle Ages and peaked during the Industrial Revolution, when it caused about 25% of all deaths in Europe and in the United States.^{1–3} This dire threat led to the rise of public health departments and to procedures such as the isolation of infected patients. Thus TB was directly responsible for many of the health care practices that we take for granted today. Unfortunately, in developing nations, some of these practices are not widely available, and TB continues to rage unabated.

EPIDEMIOLOGY

Globally, roughly 2 billion people are infected by *M. tuberculosis*, and roughly 2 to 3 million people die from active TB each year despite the fact that it is curable.^{1,2,4} In the United States, about 13 million people are latently infected with *M. tuberculosis*, meaning that they are not currently sick but that they could fall ill with TB at any time. The United States had over 15,000 new cases of active

FIGURE 110-1. Reported TB cases in the United States, 1982–2003.

TB in 2002 and about 1500 deaths.⁵ (For detailed data analysis, visit the Centers for Disease Control and Prevention (CDC) Web site at www.cdc.gov/nchstp/tb.)

The annual incidence of TB in the United States declined by about 5% per year from 1953 to 1983⁶ (Fig. 110-1). In 1984, this decline slowed, and then the incidence of TB rose from 1988 to 1992, reaching 10.5 cases per 100,000 population. Since 1992, more effective infection control practices and treatment protocols have reduced TB rates to 5.2 per 100,000 population as of 2002.⁵ Despite this good news, the eradication of TB from the United States will remain very difficult. One reason is that we continue to import new cases from countries where TB remains out of control.^{4,5}

RISK FACTORS FOR INFECTION

LOCATION AND PLACE OF BIRTH

TB can infect anyone, but the risk is not evenly distributed across the U.S. population. The major points of entry into the United States have the most TB cases. California, Florida, Illinois, New York, and Texas accounted for over 50% of all TB cases in 2002.⁵ Within these states, TB is most prevalent in large urban areas.⁴

The percentage of foreign-born TB patients in the United States has increased annually since 1986, reaching 51% in 2002.⁵ Nearly two-thirds of these patients came from only seven countries, in order of highest to lowest: Mexico, the Philippines, Vietnam, India, China, Haiti, and South Korea.⁵ Therefore, health care workers must “think TB” when caring for patients from these countries who experience symptoms such as cough, fever, and weight loss.

Close contacts of pulmonary TB patients are most likely to become infected.²⁻⁴ These include family members, coworkers, or coresidents in places such as prisons, shelters, or nursing homes. The more prolonged the contact, the greater is the risk, with infection rates as high as 30%.^{5,6} Although many circumstances exist, TB patients frequently have limited access to health care, live in crowded conditions, or are homeless.^{2,4} Many patients have histories of alcohol abuse or illicit drug use, and many are coinfecting with hepatitis B or human immunodeficiency virus (HIV). These concurrent social and health problems make treating some TB patients particularly difficult.

RACE, ETHNICITY, AGE, AND GENDER

2 In the United States, TB disproportionately affects ethnic minorities. In 2002, non-Hispanic blacks accounted for 30% of all TB cases, followed by Hispanics at 27%.⁶ Asians and Pacific Islanders accounted for 22%, whereas non-Hispanic whites accounted for only 20% of the new TB cases.⁶

TB is most common among people 25 to 44 years of age (35% of all U.S. cases in 2002).⁶ They are followed by those 45 to 64 years of age (28%) and 65+ years of age (21%). TB is more common in older

whites and Asians compared with younger people from these groups. This reflects reactivation of latent infection acquired many years earlier when TB was very common. Older blacks and Hispanics also have more TB than younger folks, but the differences by age are not as pronounced.⁶ This reflects a greater amount of recent transmission among younger blacks and Hispanics compared with younger whites and Asians. Until the age of 15, TB rates are similar for males and females, but after that, the male predominance increases with each decade of life.⁶

COINFECTION WITH HUMAN IMMUNODEFICIENCY VIRUS (HIV)

3 HIV is the most important risk factor for active TB, especially among people 25 to 44 years of age.^{2,4,6,7} TB and HIV seem to act synergistically within patients and across populations, making each disease worse than it might otherwise be. Roughly 10% of U.S. TB patients are coinfecting with HIV, and roughly 20% of TB patients ages 25 to 44 years are coinfecting.^{5,6} HIV coinfection may not increase the risk of acquiring *M. tuberculosis* infection, but it does increase the likelihood of progression to active disease.^{1,7} Further, TB and HIV patients share a number of behavioral risk factors that contribute to the high rates of coinfection.^{2,8,9}

RISK FACTORS FOR DISEASE

Once infected with *M. tuberculosis*, a person’s lifetime risk of active TB is about 10%.^{2,4,7} The greatest risk for active disease occurs during the first 2 years after infection. Children younger than 2 years and adults over 65 years of age have 2 to 5 times greater risk for active disease compared with other age groups. Patients with underlying immune suppression (e.g., renal failure, cancer, and immunosuppressive drug treatment) have 4 to 16 times greater risk than other patients. Finally, HIV-infected patients with *M. tuberculosis* infection are 100 times more likely to develop active TB than normal hosts.^{4,10} HIV-infected patients have an annual risk of active TB of about 10% rather than a lifetime risk at that rate. Therefore, all patients with HIV infection should be screened for tuberculous infection, and those known to be infected with *M. tuberculosis* should be tested for HIV infection.

ETIOLOGY

M. tuberculosis is a slender bacillus with a very waxy outer layer.^{2,7} It is 1 to 4 microns in length, and under the microscope, it is either straight or slightly curved in shape.^{1,11,12} It does not stain well with Gram’s stain, so the Ziehl-Neelsen stain (ZN) or the fluorochrome stain must be used instead.^{1,2,7} After ZN staining with carbol-fuchsin, mycobacteria retain the red color despite acid-alcohol washes. Hence they are called *acid-fast bacilli* (AFB).¹¹ After staining, microscopic examination (“smear”) detects about 8000 to 10,000 organisms per milliliter of specimen, so a patient can be “smear negative” but still grow *M. tuberculosis* on culture. Microscopic examination also cannot determine which of the 80+ mycobacterial species is present or whether the organisms in the original samples were alive or dead.^{1,11,12} On smear, they are all dead. On culture, *M. tuberculosis* grows slowly, doubling about every 20 hours. This is very slow compared with gram-positive and gram-negative bacteria, which double about every 30 minutes.

Among the mycobacteria, only *M. tuberculosis* is a frequent human pathogen. Some nontuberculous mycobacteria (NTM) such as *M. kansasii*, *M. fortuitum*, and *M. avium* complex (MAC) cause

infections in patients with other medical problems, especially the acquired immunodeficiency syndrome (AIDS). The treatment of these infections is discussed in Chap. 123.

CULTURE AND SUSCEPTIBILITY TESTING

4 Direct susceptibility testing involves inoculating specialized media with organisms taken directly from a concentrated, smear-positive specimen.^{1,11,12} This approach produces susceptibility results in 2 to 3 weeks. Indirect susceptibility testing involves inoculating the test media with organisms obtained from a pure culture of the organisms, which can take several more weeks. The most common agar method, known as the *proportion method*, uses the ratio of colony counts on drug-containing agar to that on drug-free agar.^{1,12} In the United States, the critical proportion for resistance is 1%. That means that if a drug-containing plate shows only 2% of the growth seen on a drug-free plate, some of the organisms from the specimen were resistant to that drug. Therefore, it is likely that many of the organisms in the patient also are resistant to that drug, and it should not be used to treat that patient.

The proportion method's limitations include many weeks to obtain results, drug degradation during the incubation, and a qualitative result (susceptible or resistant). The Bactec system (Becton-Dickinson, Sparks, MD) uses liquid medium (7H12 broth) and detects live mycobacteria based on the release of radiolabeled CO₂.¹¹ Advantages of the Bactec system include reduced incubation time (as few as 9 to 14 days), reduced drug loss in the medium, and when multiple concentrations are tested, a truly quantitative end point (minimal inhibitory concentration [MIC]).^{1,11,12} Newer, nonradiometric rapid methods such as the MIGIT system are now being marketed.¹³

Rapid-identification tests are now available.¹³ Nucleic acid probes such as the AccuProbe (Gen-Probe, San Diego) use DNA probes to identify the presence of complementary rRNA for several mycobacterial species.^{7,11,14} DNA fingerprinting using restriction-fragment-length polymorphism (RFLP) analysis has been used to identify clusters of cases.^{1,11,14} Amplification of the genetic material can be achieved through polymerase chain reaction (PCR; Roche Molecular Systems, Branchburg, NJ), the amplified *M. tuberculosis* direct test (MTD; Gen-Probe), and strand-displacement amplification (SDA; Becton-Dickinson, Sparks, MD).^{11,15} Thin-layer chromatography (TLC), high-performance liquid chromatography (HPLC) for mycolic acid identification, and gas chromatography (GC) for short-chain fatty acids (methyl esters) have been used to speciate mycobacterial isolates.^{1,11,14} Other tests are designed to detect common genetic changes associated with drug resistance, such as changes in the *katG* gene associated with isoniazid resistance and the *rpoB* gene associated with rifampin resistance.^{7,16–18} These tests offer clinicians a chance to know rapidly what organism they are treating and what drugs might be good initial choices.

TRANSMISSION

M. tuberculosis is transmitted from person-to-person by coughing or sneezing.^{2,7,13} This produces “droplet nuclei” that are dispersed in the air. Each droplet nuclei contains one to three organisms. Riley and colleagues¹⁹ showed that air circulated from a hospital TB ward could cause disease in guinea pigs. When this air was filtered or treated with ultraviolet radiation, the animals were not infected. About 30% of individuals who experience prolonged contact with an infectious TB patient will become infected.

A person with cavitary, pulmonary TB and a cough may infect roughly one person per month until he or she is treated effectively,

although this number can vary significantly. A person with the uncommon laryngeal form of TB can spread organisms even when talking, so the transmission rates can be very high. HIV-infected patients acquire the organisms through the lungs just like normal hosts, but their weakened immune system puts them at very high risk for active disease.^{2,4,7,13}

PATHOPHYSIOLOGY

IMMUNE RESPONSE

Good T-lymphocyte responses are essential to controlling *M. tuberculosis* infections.^{2,7,20,21} In the mouse model, two different T-cell responses—the type 1 T-helper (TH₁) response and the type 2 T-helper (TH₂) response—have been described. The TH₁ response is the preferred response to TB, and the TH₂ response, including the potentially subversive influence of interleukin 4 (IL-4), is undesirable.^{2,20,21} Some workers have argued that this dichotomy is clearer in the mouse model, and in many humans, the T-cell response may be classified as TH₀ (elements of both TH₁ and TH₂).²⁰ In either case, T-lymphocytes activate macrophages that, in turn, engulf and kill mycobacteria. T-lymphocytes also destroy immature macrophages that harbor *M. tuberculosis* but are unable to kill the invaders.^{20,21} CD4+ cells are the primary T cells involved, with contributions by gamma-delta T cells and CD8+ T cells.²⁰ CD4+ T cells produce interferon- γ (IFN- γ) and other cytokines, including IL-2 and IL-10, that coordinate the immune response to TB.²⁰ Because CD4+ cells are depleted in HIV-infected patients, these patients are unable to mount an adequate defense to TB.^{20,21}

Although B-cell responses and antibody production can be demonstrated in TB-infected mammals, these humoral responses do not appear to contribute much to the control of TB within the host.^{2,7,20} T cells are responding to certain mycobacterial antigens, but the key antigen(s) invoking the immune response have not been identified.²⁰ Tumor necrosis factor (TNF- α) and IFN- γ important cytokines involved in coordinating the host's cell-mediated response. Rheumatoid arthritis patients treated with TNF- α inhibitors (infliximab) have high rates of reactivation TB.²² Therefore, patients known to be deficient in the activity of TNF- α or IFN- γ should be screened for TB infection and offered appropriate treatment.

M. tuberculosis has several ways of evading or resisting the host immune response.^{20,21} In particular, *M. tuberculosis* can inhibit the fusion of lysosomes to phagosomes inside macrophages. This prevents the destructive enzymes found in the lysosomes from getting to the bacilli captured in the phagosomes. This stay of execution allows time for *M. tuberculosis* to escape into the cytoplasm. Virulent *M. tuberculosis* are able to multiply in the macrophage cytoplasm, thus perpetuating their spread. Finally, lipoarabinomannan (LAM), the principal structural polysaccharide of the mycobacterial cell wall, inhibits the host immune response.^{20,21} LAM induces immunosuppressive cytokines, thus blocking macrophage activation, and LAM scavenges O₂, thus preventing attack by superoxide anions, hydrogen peroxide, singlet oxygen, and hydroxyl radicals.^{20,21} These survival mechanisms make *M. tuberculosis* a particularly difficult organism to control. Any defects in the host immune system make it likely that *M. tuberculosis* will not be controlled and that active disease will ensue.

PRIMARY INFECTION

Primary infection usually results from inhaling airborne particles that contain *M. tuberculosis*.^{2,7,21} These particles, called *droplet nuclei*,

contain one to three bacilli and are small enough (1 to 5 mm) to reach the alveolar surface. Ingestion (swallowing) and inoculation (puncture wound) are other rare pathways to acquire *M. tuberculosis* infection.²¹

The progression to clinical disease depends on three factors: (1) the number of *M. tuberculosis* organisms inhaled (infecting dose), (2) the virulence of these organisms, and (3) the host's cell-mediated immune response.^{2,5,7,13,21,23} At the alveolar surface, the bacilli that were delivered by the droplet nuclei are ingested by pulmonary macrophages.²¹ If these macrophages inhibit or kill the bacilli, infection is aborted.²¹ If the macrophages cannot do this, the organisms continue to multiply. The macrophages eventually rupture, releasing many bacilli, and these mycobacteria are then phagocytized by other macrophages. This cycle continues over several weeks until the host is able to mount a more coordinated response.²¹ During this early phase of infection, *M. tuberculosis* multiplies logarithmically.²¹

Some of the intracellular organisms are transported by the macrophages to regional lymph nodes in the hilar, mediastinal, and retroperitoneal areas. The cycle of phagocytosis and cell rupture continues. During lymph node involvement, the mycobacteria may be held in check. More frequently, *M. tuberculosis* spreads throughout the body through the bloodstream.^{2,7,21} When this intravascular dissemination occurs, *M. tuberculosis* can infect any tissue or organ in the body. Most commonly, *M. tuberculosis* infects the posterior apical region of the lungs. This may be so because of the high oxygen content, and it may be due to a less-vigorous immune response in this area.

After about 3 weeks of infection, T-lymphocytes are presented with *M. tuberculosis* antigens. These T cells become activated and begin to secrete IFN- γ and the other cytokines noted earlier. The processes described in the immune response section earlier then begin to occur. First, T-lymphocytes stimulate macrophages to become bactericidal.²¹ Large numbers of activated microbicidal macrophages surround the solid caseous (cheeselike) tuberculous foci (the necrotic area of infection).²¹ This process of creating activated microbicidal macrophages is known as *cell-mediated immunity* (CMI).²¹

At the same time that CMI occurs, delayed-type hypersensitivity (DTH) also develops through the activation and multiplication of T-lymphocytes. DTH refers to the cytotoxic immune process that kills nonactivated immature macrophages that are permitting intracellular bacillary replication.²¹ These immature macrophages are killed when the T-lymphocytes initiate Fas-mediated apoptosis (programmed cell death).²¹ The bacilli released from the immature macrophages then are killed by the activated macrophages.²¹

By this time (>3 weeks), macrophages have begun to form granulomas to contain the organisms. In a typical tuberculous granuloma, activated macrophages accumulate around a caseous lesion and prevent its further extension.²¹ At this point, the infection is largely under control, and bacillary replication falls off dramatically. Depending on the inflammatory response, tissue necrosis and calcification of the infection site plus the regional lymph nodes may occur.

Over 1 to 3 months, activated lymphocytes reach an adequate number, and tissue hypersensitivity results. This is shown by a positive tuberculin skin test. Any remaining mycobacteria are believed to reside primarily within granulomas or within macrophages that have avoided detection and lysis, although some residual bacilli have been found in various types of cells.^{2,7,20}

Approximately 90% of infected patients have no further clinical manifestations. Most patients only show a positive skin test (70%), whereas some also have radiographic evidence of stable granulomas (about 20%). This radiodense area on chest x-ray is called a *Ghon complex*. About 5% of patients (usually children, the elderly, or the immunocompromised) experience "progressive primary" disease that

occurs before skin test conversion.^{24,25} This presents as a progressive pneumonia, usually in the lower lobes. Disease frequently spreads, leading to meningitis and other severe forms of TB.^{24,25} Because of this risk of severe disease, very young, elderly, and immunocompromised patients, including those with HIV, should be evaluated and treated for latent or active TB.

REACTIVATION DISEASE

6 Roughly 10% of infected patients develop reactivation disease at some point in their lives. Nearly half of these cases occur within 2 years of infection.^{2,7,13} In the United States, most cases of TB are believed to result from reactivation. Reinfection is uncommon in the United States because of the low rate of exposure and because previously sensitized individuals possess some degree of immunity to reinfection.^{2,21} Exceptions include patients coinfecting with HIV who live in areas of higher exposure to *M. tuberculosis*.

The apices of the lungs are the most common sites for reactivation (85% of cases).² This reflects the fact that *M. tuberculosis* prefers areas with high oxygen content and possibly because the immune response may not be as effective in this region.^{2,21} For reasons that are not entirely known (waning cellular immunity, loss of specific T-cell clones, blocking antibody), organisms within granulomas emerge and begin multiplying extracellularly.²⁴ The inflammatory response produces caseating granulomas, which eventually will liquefy and spread locally, leading to the formation of a hole (cavity) in the lungs.

The immune response contributes to the severity of the lung damage. There is targeted killing of immature macrophages that are allowing mycobacterial multiplication (DTH).^{20,21} In addition, there is "innocent bystander" killing of host cells and locally thrombosed blood vessels.²¹ The killing of mycobacteria, macrophages, and neutrophils that have entered the battle releases cytokines and lysozymes into the infectious foci. This toxic mixture can be too much for the surrounding alveoli and airway cells, causing regional necrosis and structural collapse.^{2,21} These unstable foci liquefy, spreading the infection to neighboring areas of the lung, creating a cavity. Some of this necrotic material is coughed out, producing droplet nuclei. Bacterial counts in the cavities can be as high as 10⁸ per milliliter of cavitary fluid. Partial healing may result from fibrosis, but these lesions remain unstable and may continue to expand.^{2,21} If left untreated, pulmonary TB continues to destroy the lungs, resulting in hypoxia, respiratory acidosis, and eventually death.

EXTRAPULMONARY AND MILIARY TUBERCULOSIS

Caseating granulomas at extrapulmonary sites can undergo liquefaction, releasing tubercle bacilli and causing symptomatic disease.^{2,7} Extrapulmonary TB without concurrent pulmonary disease is uncommon in normal hosts but more common in HIV-infected patients. Because of these unusual presentations, the diagnosis of TB is difficult and often delayed in immunocompromised hosts.^{2,4,7} Lymphatic and pleural diseases are the most common forms of extrapulmonary TB, followed by bone, joint, genitourinary, meningeal, and other forms.^{2,7} Left untreated, these forms will spread to other organs and may result in death.

Occasionally, a massive inoculum of organisms enters the bloodstream, causing a widely disseminated form of the disease known as *miliary TB*. It is named for the millet seed appearance of the small granulomas seen on chest radiographs, and it can be rapidly fatal.²⁰ Miliary TB is a medical emergency requiring immediate treatment.

INFLUENCE OF HIV INFECTION ON PATHOGENESIS

3 HIV infection is the largest risk factor for active TB.^{2,7,20} As CD4+ lymphocytes multiply in response to the mycobacterial infection, HIV multiplies within these cells and selectively destroys them. In turn, the TB-fighting lymphocytes are depleted.²⁰ This vicious cycle puts HIV-infected patients at 100 times the risk of active TB compared with HIV-negative people.²⁵ In addition, the combination of HIV infection and certain social behaviors increases the risk of newly acquired TB. In selected areas of the United States, up to 50% of new TB cases are the result of recent infection, particularly among HIV-infected individuals.^{26–28}

While mycobacteria are spreading throughout the body, HIV replication accelerates in lymphocytes and macrophages. This leads to progression of HIV disease.^{20,29} HIV-infected patients infected with TB deteriorate more rapidly unless they receive antimycobacterial chemotherapy.^{30,31} Most clinicians elect to begin TB treatment first, and once this is under control, begin HIV treatment as well. Starting both treatments at the same time can lead to paradoxical worsening of the TB.^{13,32} This appears to result from a reinvigorated inflammatory response to TB. Because TB can be very dangerous in HIV-positive patients, they should be screened for tuberculous infection or disease soon after they are shown to be HIV-positive.^{2,4,7,20}

CLINICAL PRESENTATION

The classical presentation of TB is shown below. The onset of TB may be gradual, and the diagnosis may not be considered until a chest radiograph is performed. Unfortunately, many patients do not seek medical attention until more dramatic symptoms, such as frank hemoptysis, occur. At this point, patients typically have large cavitory lesions in the lungs. These cavities are loaded with *M. tuberculosis*. Expectoration or swallowing of infected sputum may spread the disease to other areas of the body.^{1,2,7,23} Physical examination is nonspecific but suggestive of progressive pulmonary disease.

CLINICAL PRESENTATION OF TUBERCULOSIS

SIGNS AND SYMPTOMS

- Patients typically present with weight loss, fatigue, a productive cough, fever, and night sweats^{1,2,7,23}
- Frank hemoptysis

PHYSICAL EXAMINATION

- Dullness to chest percussion, rales, and increased vocal fremitus are observed frequently on auscultation

LABORATORY TESTS

- Moderate elevations in the white blood cell (WBC) count with a lymphocyte predominance

CHEST RADIOGRAPH

- Patchy or nodular infiltrates in the apical areas of the upper lobes or the superior segment of the lower lobes^{2,7,23}
- Cavitation that may show air-fluid levels as the infection progresses

5 Patients coinfecting with HIV may have atypical presentations.^{1,2,7,23,33} As their CD4+ counts decline, HIV-positive patients are less likely to have positive skin tests, cavitory lesions, or fever. Pulmonary radiographic findings may be minimal or absent. HIV-positive patients have a higher incidence of extrapulmonary TB and are more likely to present with progressive primary disease. Because their symptoms are not specific to TB, a thorough work-up for TB is essential.^{2,7,20,23}

Extrapulmonary TB typically presents as a slowly progressive decline in organ function.^{2,7,23} Patients may have low-grade fever and other constitutional symptoms. Patients with genitourinary TB may present with sterile pyuria and hematuria. Lymphadenitis often involves the cervical and supraclavicular nodes and may appear as a neck mass with spontaneous drainage. Tuberculous arthritis and osteomyelitis occur most commonly in the elderly and usually affect the lower spine and weight-bearing joints. TB of the spine is known as *Pott's disease*.² Abnormal behavior, headaches, or convulsions suggest tuberculous meningitis. Involvement of the peritoneum, pericardium, larynx, and adrenal glands also occurs.^{2,7,23}

THE ELDERLY

5 TB in the elderly is easily confused with other respiratory diseases. Many clinical findings are muted or absent altogether. Compared with younger patients, TB in the elderly is far less likely to present with positive skin tests, fevers, night sweats, sputum production, or hemoptysis.^{2,23,34,35} Weight loss may occur but is nonspecific. In contrast, mental status changes are twice as common in the elderly, and mortality is six times higher.^{2,23,34} TB is a preventable cause of death in the elderly that should not be overlooked.

CHILDREN

5 TB in children, especially those younger than 12 years of age, may present as a typical bacterial pneumonia and is called *progressive primary TB*.^{23–25} Clinical disease often begins 1 to 2 months after exposure and precedes skin-test positivity. Unlike adults, pulmonary TB in children often involves the lower and middle lobes.^{23–25} Dissemination to the lymph nodes, gastrointestinal and genitourinary tracts, bone marrow, and meninges is fairly common. Because of delays in recruitment of cellular immunity, cavitory disease is infrequent, and the number of organisms present typically is smaller than in an adult. Because cavitory lesions are uncommon, children do not spread TB readily. However, TB can be rapidly fatal in a child, and it requires prompt chemotherapy.

DIAGNOSIS

SKIN TESTING

The key to stopping the spread of TB is early identification of infected individuals.^{1,2,7,23} Populations most likely to benefit from skin testing are listed in Table 110–1 (column 1 patients are at highest risk for TB, followed by those in column 2). Members of these high-risk groups should be tested for TB infection and educated about the disease.

The Mantoux test is the preferred TB skin test. It uses tuberculin purified protein derivative (PPD), and unlike the Heaf or tine test, the Mantoux test is quantitative. The standard 5 tuberculin unit PPD dose is placed intracutaneously on the volar aspect of the forearm with a 26- or 27-gauge needle.^{2,23,30} This injection should produce a small, raised, blanched wheal. An experienced professional should

TABLE 110–1. Criteria for Tuberculin Positivity, by Risk Group

| Reaction ≥ 5 mm of Induration | Reaction ≥ 10 mm of Induration | Reaction ≥ 15 mm of Induration |
|--|--|-------------------------------------|
| Human immunodeficiency virus (HIV)-positive persons | Recent immigrants (i.e., within the last 5 yr) from high prevalence countries | Persons with no risk factors for TB |
| Recent contacts of tuberculosis (TB) case patients | Injection drug users | |
| Fibrotic changes on chest radiograph consistent with prior TB | Residents and employees ^b of the following high-risk congregate settings: prisons and jails, nursing homes and other long-term facilities for the elderly, hospitals and other health care facilities, residential facilities for patients with acquired immunodeficiency syndrome (AIDS), and homeless shelters | |
| Patients with organ transplants and other immunosuppressed patients (receiving the equivalent of ≥ 15 mg/d of prednisone for 1 mo or more) ^a | Mycobacteriology laboratory personnel Persons with the following clinical conditions that place them at high risk: silicosis, diabetes mellitus, chronic renal failure, some hematologic disorders (e.g., leukemias and lymphomas), other specific malignancies (e.g., carcinoma of the head or neck and lung), weight loss of $\geq 10\%$ of ideal body weight, gastrectomy, and jejunioileal bypass Children younger than 4 yr of age or infants, children, and adolescents exposed to adults at high-risk | |

^aRisk of TB in patients treated with corticosteroids increases with higher dose and longer duration.

^bFor persons who are otherwise at low risk and are tested at the start of employment, a reaction of ≥ 15 mm induration is considered positive.

Adapted from Centers for Disease Control and Prevention. Screening for tuberculosis and tuberculosis infection in high-risk populations: recommendations of the Advisory Council for the Elimination of Tuberculosis. *MMWR* 1995;44(No. RR-11):19–34.

read the test in 48 to 72 hours. The area of induration (the “bump”) is the important end point, not the area of redness. Criteria for interpretation are listed in Table 110–1.^{1,2,7,23,30} The CDC does not recommend the routine use of anergy panels.^{30,36} Aplisol and Tubersol 5 tuberculin unit products are available commercially, but because of more predictable results, Tubersol appears to be the preferred product.

The “booster effect” occurs in patients who do not respond to an initial skin test but show a positive reaction if retested about a week later.^{23,36} Patients with past *M. tuberculosis* infection and some patients with past immunization with bacillus Calmette-Guérin (BCG) vaccine or past infection with other mycobacteria may “boost” with a second skin test. Individuals who require periodic skin testing, such as health care workers, should receive a two-stage test initially.^{23,36,37} Once they are shown to be skin-test–negative, any positive skin test later shows recent infection, and this requires treatment.

The PPD skin test is an imperfect diagnostic tool. Up to 20% of patients with active TB are falsely skin-test–negative presumably because their immune systems are overwhelmed.^{20,36} False-positive

results are more common in low-risk patients and those recently vaccinated with BCG. Despite BCG vaccination, one should not ignore a positive PPD result. These patients require careful evaluation for active disease, and they may be offered preventive treatment because many come from areas where TB infection is common.

ADDITIONAL TESTS

When active TB is suspected, attempts should be made to isolate *M. tuberculosis* from the site of infection.^{2,7,23,36} Sputum collected in the morning usually has the highest yield.^{2,11,23} Daily sputum collections over three consecutive days is recommended.

For patients unable to expectorate, sputum induction with aerosolized hypertonic saline may produce a diagnostic sample. Bronchoscopy, or aspiration of gastric fluid via a nasogastric tube, may be attempted in selected patients.²³ For patients with suspected extrapulmonary TB, samples of draining fluid, biopsies of the infected site, or both may be attempted. Blood cultures are positive occasionally, especially in AIDS patients.^{23,33,38}

► TREATMENT: Tuberculosis

The desired outcomes for the treatment of tuberculosis are

1. Rapid identification of a new TB case
2. Isolation of the patient with active disease to prevent spread of the disease
3. Collection of appropriate samples for smears and cultures
4. Initiation of specific antituberculosis treatment
5. Prompt resolution of the signs and symptoms of disease

6. Achievement of a noninfectious state in the patient, thus ending isolation
7. Adherence to the treatment regimen by the patient
8. Cure of the patient as quickly as possible (generally at least 6 months of treatment)

Secondary goals are identification of the index case that infected the patient, identification of all persons infected by both the index case and the new case of TB, and completion of appropriate treatments for those individuals.

GENERAL APPROACHES TO TREATMENT

Drug treatment is the cornerstone of TB management.^{2,7,13,39} Monotherapy can be used only for infected patients who do not have active TB (latent infection, as shown by a positive skin test). Once active disease is present, a minimum of two drugs and generally three or four drugs must be used simultaneously.^{2,7,13,39} The duration of treatment depends on the condition of the host, extent of disease, presence of drug resistance, and tolerance of medications. The shortest duration of treatment generally is 6 months, and 2 to 3 years of treatment may be necessary for cases of multidrug-resistant TB (MDR-TB).^{2,7,13,39} Because the duration of treatment is so long, and because many patients feel better after a few weeks of treatment, careful follow-up is required. Directly observed therapy (DOT) by a health care worker is a cost-effective way to ensure completion of treatment.^{2,7,13,39–41}

PRINCIPLES FOR TREATING INFECTION AND TREATING DISEASE

Asymptomatic patients with tuberculous infection have a bacillary load of about 10^3 organisms, compared with 10^{11} organisms in a patient with cavitary pulmonary TB.^{2,7,42} As the number of organisms increases, the likelihood of naturally occurring drug-resistant mutants also increases. Naturally occurring mutants are found at rates of 1 in 10^6 to 1 in 10^8 organisms for the antituberculosis drugs.^{2,39,42} When treating asymptomatic latent infection with isoniazid monotherapy, the risk of selecting out isoniazid-resistant organisms is low. The isoniazid mutation rate is about 1 in 10^6 , but only about 10^3 organisms are present in the body. In contrast, the risk of selecting out isoniazid-resistant organisms is unacceptably high in patients with cavitary TB. One can prevent selection of these resistant mutants by adding more drugs because the rates for resistance mutations to multiple drugs are additive functions of the individual rates. For example, only 1 in 10^{13} organisms would be naturally resistant to both isoniazid (1 in 10^6) and rifampin (1 in 10^7).^{2,39,42} It is unlikely that such rare organisms are present in a previously untreated patient.

Combination chemotherapy is required for treating active TB disease. The patient should receive at least two drugs to which the isolate is susceptible, and generally four drugs are given at the outset of treatment. Rifampin and isoniazid are the best drugs for preventing drug resistance, followed by ethambutol, streptomycin, and pyrazinamide.^{2,7,39,42,43}

Three subpopulations of mycobacteria are proposed to exist within the body, and each appears to respond to certain drugs.^{2,39,42} Most numerous are the extracellular, rapidly dividing bacteria, often found within cavities (about 10^7 to 10^9 organisms). These are killed most readily by isoniazid, followed by rifampin, streptomycin, and the other drugs. A second group resides within caseating granulomas (possibly 10^5 to 10^7 organisms). These organisms appear to be in a semidormant state, with occasional bursts of metabolic activity. Pyrazinamide, through its conversion within *M. tuberculosis* to pyrazinoic acid, appears most active against these organisms. Rifampin and isoniazid also may be active against this subpopulation. The third subset is the intracellular mycobacteria present within macrophages (10^4 to 10^6). Rifampin, isoniazid, and the quinolones appear to be most active against intracellular *M. tuberculosis*. While these theories appear to

explain what happens during the treatment of TB, there is no practical way to quantitate these populations within a given patient.

NONPHARMACOLOGIC THERAPY

Nonpharmacologic interventions aim to (1) prevent the spread of TB, (2) find where TB has already spread using contact investigation, and (3) replenish the weakened (consumptive) patient to a state of normal weight and well-being. Items 1 and 2 are performed by public health departments. Clinicians involved in the treatment of TB should verify that the local health department has been notified of all new cases of TB.

Workers in hospitals and other institutions must prevent the spread of TB within their facilities.^{2,4,13,30} All such workers should learn and follow each institution's infection control guidelines. This includes using personal protective equipment, including properly fitted respirators, and closing doors to "negative pressure" rooms. These hospital isolation rooms draw air in from surrounding areas rather than blowing air (and *M. tuberculosis*) into these other areas. The air from the isolation room may be treated with ultraviolet lights and then vented safely outside. However, these isolation rooms work properly only if the door is closed.

Debilitated TB patients may require therapy for other medical problems, including substance abuse and HIV infection, and some may need nutritional support. Therefore, clinicians involved in substance abuse rehabilitation and nutritional support services should be familiar with the needs of TB patients.

Surgery may be needed to remove destroyed lung tissue, space-occupying infected lesions (*tuberculomas*), and certain extrapulmonary lesions.^{2,13,39} Vaccines against TB include BCG and *M. vaccae*.³⁹ However, these vaccines are of limited value, and neither can prevent infection by *M. tuberculosis*. BCG (discussed below) may prevent extreme forms of TB in infants, whereas *M. vaccae* cannot be recommended.^{39,44}

PHARMACOLOGIC THERAPY

TREATING LATENT INFECTION

Isoniazid is the preferred drug for treating latent TB infection.^{2,7,13,39} Generally, isoniazid alone is given for 9 months. The treatment of latent TB infection (LTBI) reduces a person's lifetime risk of active TB from about 10% to about 1%. Because TB is spread easily through the air, each case prevented also prevents a second wave of cases that each prevented case would have produced. Historically, the treatment of LTBI has been called *prophylaxis*, *chemoprophylaxis*, or *preventive treatment*. By any name, it is one of the primary mechanisms for reducing TB in the United States. The LTBI treatment options are listed in Table 110–2.

Because young children, the elderly, and HIV-positive patients are at greater risk of active disease once infected with *M. tuberculosis*, they require careful evaluation. Once active TB is ruled out, they should receive treatment for latent infection.^{2,22,23,39}

The keys to successful treatment of LTBI are (1) infection by an isoniazid-susceptible isolate, (2) adherence to the 9-month regimen, and (3) no exogenous reinfection.² Isoniazid adult doses are usually 300 mg daily (5–10 mg/kg of body weight)⁵² (see Table 110–2). Lower doses are less effective.^{2,49} Isoniazid should be

TABLE 110–2. Recommended Drug Regimens for Treatment of Latent Tuberculosis (TB) Infection in Adults

| Drug | Interval and Duration | Comments | Rating ^a (Evidence) ^b | |
|-----------|--------------------------------------|--|---|------------------|
| | | | HIV ⁻ | HIV ⁺ |
| Isoniazid | Daily for 9 mo ^{c,d} | In human immunodeficiency virus (HIV)-infected patients, isoniazid may be administered concurrently with nucleoside reverse transcriptase inhibitors (NRTIs), protease inhibitors, or non-nucleoside reverse transcriptase inhibitors (NNRTIs) | A (II) | A (II) |
| | Twice weekly for 9 mo ^{c,d} | Directly observed therapy (DOT) must be used with twice-weekly dosing | B (II) | B (II) |
| Isoniazid | Daily for 6 mo ^d | Not indicated for HIV-infected persons, those with fibrotic lesions on chest radiographs, or children | B (I) | C (I) |
| | Twice weekly for 6 mo ^d | DOT must be used with twice-weekly dosing | B (II) | C (I) |
| Rifampin | Daily for 4 mo | For persons who cannot tolerate pyrazinamide For persons who are contacts of patients with isoniazid-resistant, rifampin-susceptible TB who cannot tolerate pyrazinamide | B (II) | B (III) |

^aStrength of recommendation: A = preferred; B = acceptable alternative; C = offer when A and B cannot be given.

^bQuality of evidence: I = randomized clinical trial data; II = data from clinical trials that are not randomized or were conducted in other populations; III = expert opinion.

^cRecommended regimen for children younger than 18 yr of age.

^dRecommended regimens for pregnant women. Some experts would use rifampin and pyrazinamide for 2 mo as an alternative regimen in HIV-infected pregnant women, although pyrazinamide should be avoided during the first trimester.

Adapted from Centers for Disease Control and Prevention. Targeted tuberculin testing and treatment of latent tuberculosis infection. *MMWR* 2000;49(RR-6):31.

given on an empty stomach, and antacids should be avoided within 2 hours of dosing. When adherence is an issue, twice-weekly isoniazid (900 mg in an adult) can be given using DOT. Nine months of treatment is recommended, but 6 months still provides considerable benefit.

Rifampin 600 mg daily for 4 months can be used when isoniazid resistance is suspected or when the patient cannot tolerate isoniazid.^{2,25,48,49} Rifabutin 300 mg daily might be substituted for rifampin for patients at high risk of drug interactions. The combination of pyrazinamide plus rifampin is no longer recommended because of higher than expected rates of hepatotoxicity. When resistance to isoniazid and rifampin is suspected in the isolate causing infection, there is no regimen proved to be effective.^{2,39} Regimens that *might* be effective include ethambutol plus levofloxacin, but data regarding efficacy are lacking.

For recent skin-test converters of all ages, the risk of active TB outweighs the risk for drug toxicity.^{30,39} Pregnant women, alcoholics, and patients with poor diets who are treated with isoniazid should receive pyridoxine (vitamin B₆) 10–50 mg daily to reduce the incidence of central nervous system (CNS) effects or peripheral neuropathies. All patients who receive treatment of LTBI should be monitored monthly for adverse drug reactions and for possible progression to active TB.

■ TREATING ACTIVE DISEASE

8 The treatment of active TB requires the use of multiple drugs. There are two primary antituberculosis drugs, isoniazid and rifampin, with the rest of the drugs having specific roles.^{39,42,43} Isoniazid and rifampin should be used together whenever possible. Typically, *M. tuberculosis* is either very susceptible or very resistant to a given drug. This contrasts with *M. avium*, where moderately resistant organisms are a frequent occurrence. Theoretically, minimal inhibitory concentration (MIC) results could be used to guide dosing in the treatment of moderately resistant *M. tuberculosis*, but this remains to be studied prospectively.^{2,13,39}

Drug-susceptibility testing should be done on the initial isolate for all patients with active TB. These data should guide the selection

of drugs over the course of treatment.^{2,7,13,39} However, some patients are unable to provide a suitable specimen for laboratory testing. If susceptibility data are not available for a given patient, the drug-susceptibility data for the suspected source case or regional susceptibility data should be used.^{2,39}

Drug resistance should be expected in patients presenting for the retreatment of TB. These patients require retesting of drug susceptibility using freshly collected specimens. It is imperative to learn what drugs the patient received and for how long the patient received them.^{2,13,39} A treatment history, often called a “drug-o-gram,” shows the start and stop dates of all antimycobacterial drugs on a horizontal bar graph.^{2,39} A “drug-o-gram” should be constructed for all retreatment patients.

10 The standard TB treatment regimen is isoniazid, rifampin, pyrazinamide, and ethambutol for 2 months, followed by isoniazid and rifampin for 4 months, for a total of 6 months of treatment.^{2,13,39} If susceptibility to isoniazid, rifampin, and pyrazinamide is shown, ethambutol can be stopped at any time. Without pyrazinamide, a total of 9 months of isoniazid and rifampin treatment is required. Table 110–3 shows the recommended treatment regimens. When intermittent therapy is used, DOT is essential. Doses missed during an intermittent TB regimen decrease its efficacy and increase the relapse rate. Note that Table 110–3 shows recommendations that differ for HIV-negative and HIV-positive patients. HIV-positive patients should not receive highly intermittent regimens. In general, regimens given daily five times each week or three times weekly can be used for HIV-positive patients. Less frequent dosing has been associated with higher failure and relapse rates and the selection of rifampin-resistant organisms.³⁹

CLINICAL CONTROVERSY

The recommended duration of treatment often is the same for HIV-negative and HIV-positive patients. However, some clinicians believe that therapy should be extended for patients with weakened immune systems. These clinicians treat HIV-positive patients with drug-susceptible TB for 9 months rather than the usual 6 months.

TABLE 110–3. Drug Regimens for Culture-Positive Pulmonary Tuberculosis Caused by Drug-Susceptible Organisms

| Initial Phase | | | Continuation Phase | | | Range of Total Doses (Minimal Duration) | Rating ^a (Evidence) ^b | | | | | | | |
|---------------|---|--|--------------------|---------|--|---|---|---------------------|-------------------------------|---------|-----------------------------------|-----------------|-------|--------|
| Regimen | Drugs | Interval and Doses ^c (Minimal Duration) | Regimen | Drugs | Interval and Doses ^{c,d} (Minimal Duration) | | HIV ⁻ | HIV ⁺ | | | | | | |
| 1 | INH | Seven days per week for | 1a | INH/RIF | Seven days per week for 126 | 182–130 (26 wk) | A (I) | A (II) | | | | | | |

| | RIF | 56 doses (8 wk) or 5 d/wk | | | | | | | | | | | | |
| EMB | for 40 doses (8 wk) ^c | | | | | | | | | | | | | |

Definition of abbreviations: EMB = Ethambutol; INH = isoniazid; PZA = pyrazinamide; RIF = rifampin; RPT = rifapentine.

^aDefinitions of evidence ratings: A = preferred; B = acceptable alternative; C = offer when A and B cannot be given; E = should never be given.

^bDefinition of evidence ratings: I = randomized clinical trial; II = data from clinical trials that were not randomized or were conducted in other populations; III = expert opinion.

^cWhen DOT is used, drugs may be given 5 days/week and the necessary number of doses adjusted accordingly. Although there are no studies that compare five with seven daily doses, extensive experience indicates this would be an effective practice.

^dPatients with cavitation on initial chest radiograph and positive cultures at completion of 2 months of therapy should receive a 7-month (31 week; either 217 doses [daily] or 62 doses [twice weekly]) continuation phase.

^eFive-day-a-week administration is always given by DOT. Rating for 5 day/week regimens is AIII.

^fNot recommended for HIV-infected patients with CD4⁺ cell counts <100 cells/ μ L.

^gOptions 1c and 2b should be used only in HIV-negative patients who have negative sputum smears at the time of completion of 2 months of therapy and who do not have cavitation on initial chest radiograph (see text). For patients started on this regimen and found to have a positive culture from the 2-month specimen, treatment should be extended an extra 3 months.

From Centers for Disease Control and Prevention. *Treatment of tuberculosis*. MMWR 2003;52 (RR-11).

When the patients' sputum smears convert to a negative, the risk of them infecting others is greatly reduced, but it is not zero.^{2,21,39} Such patients can be removed from respiratory isolation, but they must be careful not to cough on others and should meet only in well-ventilated places. Smear-negative patients still may be culture-positive, so they still can transmit TB to others.

Patients who are slow to respond clinically, those who remain culture-positive at 2 months of treatment, those with cavitory lesions on chest radiograph, and perhaps HIV-positive patients should be treated for a total of 9 months and for at least 6 months from the time that they convert to smear and culture negativity.^{2,7,13,39} Some authors recommend therapeutic drug monitoring for such patients.^{2,39,43,45} When isoniazid and rifampin cannot be used, treatment durations become 2 years or more regardless of immune status.^{2,13,39,43}

Adjustments to the regimen should be made once the susceptibility data are available.^{2,13,39} If the organism is drug-resistant, careful consideration of the remaining therapeutic options must be made. Two or more drugs with in vitro activity against the patient's isolate and that the patient has not received previously should be added to the regimen, as needed.^{2,13,39} TB specialists should be consulted regarding cases of drug-resistant TB.^{2,13,39}

9 There is no standard regimen for MDR-TB.^{2,13,39} Each patient's exposure history, previous treatment history (including toxicity and adherence issues), and current susceptibility data must be considered simultaneously. *It is critical to avoid monotherapy, and it is critical to avoid adding a single drug to a failing regimen.*^{2,13,39} Adding one drug at a time leads to the sequential selection of drug resistance until there are no drugs left. The treatment of MDR-TB

should be managed by TB specialists. It may take several months for a patient with MDR-TB to become culture-negative because the drugs used lack the potency of isoniazid and rifampin.^{2,42,43} Therefore, prolonged respiratory isolation may be required.

Drug resistance should be suspected in the following situations:

- Patients who have received prior therapy for TB
- Patients from areas with a high prevalence of resistance (New York City, Mexico, Southeast Asia, the Baltic countries, and the former Soviet states)
- Patients who are homeless, institutionalized, intravenous drug abusers, or infected with HIV
- Patients who still have AFB-positive sputum smears after 1 to 2 months of therapy
- Patients who still have positive cultures after 2 to 4 months of therapy
- Patients who fail treatment or relapse after treatment
- Patients known to be exposed to MDR-TB cases

The patients just listed should be considered infected with drug-resistant TB until proved otherwise. Empirical therapy with four or more drugs may be needed for acutely ill patients.^{2,13,39} These regimens may be altered when the susceptibility pattern becomes known. If the index case is known, then the same effective regimen should be employed for the new case. Again, MDR-TB cases should be referred to specialists.

TABLE 110-4. Evidence-Based^a Guidelines for the Treatment of Extrapulmonary Tuberculosis and Adjunctive Use of Corticosteroids^b

| Site | Length of Therapy (mo) | Rating (Duration) | Corticosteroids ^c | Rating (Corticosteroids) |
|---------------------------------------|------------------------|-------------------|------------------------------|--------------------------|
| Lymph node | 6 | AI | Not recommended | DIII |
| Bone and joint | 6–9 | AI | Not recommended | DIII |
| Pleural disease | 6 | AI | Not recommended | DI |
| Pericarditis | 6 | AI | Strongly recommended | AI |
| CNS tuberculosis including meningitis | 9–12 | BII | Strongly recommended | AI |
| Disseminated disease | 6 | AI | Not recommended | DIII |
| Genitourinary | 6 | AI | Not recommended | DIII |
| Peritoneal | 6 | AI | Not recommended | DIII |

^aFor rating system, see Table 110-3.

^bDuration of therapy for extrapulmonary tuberculosis caused by drug-resistant organisms is not known.

^cCorticosteroid preparations vary among studies.

See Table 110-3.

■ SPECIAL POPULATIONS

■ Tuberculous Meningitis and Extrapulmonary Disease

Patients with CNS tuberculosis usually are treated for longer periods (9 to 12 months instead of 6 months)^{2,13,39} (Table 110-4). In general, isoniazid, pyrazinamide, ethionamide, and cycloserine penetrate the cerebrospinal fluid (CSF) readily, but rifampin, ethambutol, and streptomycin have variable CNS penetration.⁴⁶ Of the quinolones, levofloxacin may be preferred based on current data. Extrapulmonary TB of the soft tissues can be treated with conventional regimens.^{2,13,39} TB of the bone typically is treated for 9 months, occasionally with surgical débridement.^{2,13,39}

■ Children

TB in children may be treated with regimens similar to those used in adults, although some physicians still prefer to extend treatment to 9 months.^{2,13,23,24,39,47,48} Pediatric doses of isoniazid and rifampin on a milligram per kilogram basis are higher than those used in adults³⁹ (Table 110-5).

■ Pregnancy

Women with TB should be cautioned against becoming pregnant because the disease poses a risk to the fetus and to the mother. If already pregnant, the usual treatment is isoniazid, rifampin, and ethambutol for 9 months.³⁹ Isoniazid or ethambutol are relatively safe for use in pregnant women.^{2,39,46–48} B vitamins are particularly important during pregnancy and should be provided to women being treated for TB. Rifampin has been associated rarely with birth defects, including limb reduction and CNS lesions.⁴⁶ In general, rifampin is used in pregnant women with TB. Pyrazinamide has not been studied in large numbers of pregnant women, but anecdotal data suggest that it may be safe.³⁹

Streptomycin use during pregnancy may lead to hearing loss in the newborn, including complete deafness. Streptomycin and the other aminoglycosides must be reserved for critical situations where alternatives do not exist.^{2,39} Although the polypeptide capreomycin has not been studied, it probably carries the same risks.

Ethionamide may cause premature delivery and congenital deformities when used during pregnancy.^{39,46} Mongolism also has been reported, so it cannot be recommended in this setting. *p*-Aminosalicylic acid has been used safely in pregnancy, but specific data are lacking.^{39,46} Cycloserine is known to cross the placenta, but the effects on the developing fetus are not known. Therefore, cycloserine generally cannot be recommended during pregnancy.⁴⁶

Ciprofloxacin, levofloxacin, moxifloxacin, and the other quinolones have been associated with permanent damage to cartilage in the weight-bearing joints of immature animals, especially dogs and rabbits.^{39,46} While these drugs have not been shown to cause joint problems frequently in humans, other antituberculosis agents should be used during pregnancy.

Pregnant women with LTBI are not at the same level of risk compared with those with active disease. Therapy with isoniazid for LTBI may be delayed until after pregnancy or, if recent skin-test conversion has occurred, started during the second trimester of pregnancy.^{39,46–48} Although most antituberculosis drugs are excreted in breast milk, the amount of drug received by the infant through nursing is insufficient to cause toxicity. Quinolones should be avoided in nursing mothers, if possible.

■ HIV Infection

Patients with AIDS and other immunocompromised hosts may be managed with chemotherapeutic regimens similar to those used in immunocompetent individuals, although treatment is often extended to 9 months^{2,13,39} (see Table 110-3). The precise duration to recommend remains a matter of debate. Highly intermittent regimens (twice or once weekly) are not recommended for HIV-positive TB patients. Prognosis has been particularly poor for HIV-infected patients infected with MDR-TB. Differentiation must be made between infection with *M. tuberculosis* and NTM, such as MAC, because the drugs used are different. While awaiting laboratory results, the patient can be treated empirically for TB if there is any doubt about the causative organism. Some patients with AIDS malabsorb their oral medications; this is discussed under therapeutic drug monitoring later.^{2,39,43,45} The major issue of drug interactions is discussed further below under rifampin.

■ Renal Failure

In nearly all patients, isoniazid and rifampin do not require dose modification in renal failure. They are eliminated primarily by the liver.^{43,46,49} In the unlikely event that peripheral neuropathies develop, the frequency of isoniazid dosing may be reduced. Pyrazinamide and ethambutol typically require a reduction in dosing frequency from daily to three times weekly^{39,49} (Table 110-6).

Renally cleared TB drugs include the aminoglycosides (amikacin, kanamycin, and streptomycin), capreomycin, ethambutol, cycloserine, and levofloxacin.^{39,46,49,50} Dosing intervals need to

^aDose per weight is based on ideal body weight. Children weighing more than 40 kg should be dosed as adults.

^bFor purposes of this document adult dosing begins at age 15 years.

^cDose may need to be adjusted when there is concomitant use of protease inhibitors or nonnucleoside reverse transcriptase inhibitors.

^dThe drug can likely be used safely in older children but should be used with caution in children less than 5 years of age, in whom visual acuity cannot be monitored. In younger children EMB at the dose of 15 mg/kg per day can be used if there is suspected or proven resistance to INH or RIF.

^eIt should be noted that, although this is the dose recommended generally, most clinicians with experience using cycloserine indicate that it is unusual for patients to be able to tolerate this amount. Serum concentration measurements are often useful in determining the optimal dose for a given patient.

^fThe single daily dose can be given at bedtime or with the main meal.

^gDose: 15 mg/kg per day (1 g), and 10 mg/kg in persons more than 59 years of age (750 mg). Usual dose: 750–1000 mg administered intramuscularly or intravenously, given as a single dose 5–7 days/week and reduced to two or three times per week after the first 2–4 months or after culture conversion, depending on the efficacy of the other drugs in the regimen.

^hThe long-term (more than several weeks) use of levofloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. However, most experts agree that the drug should be considered for children with tuberculosis caused by organisms resistant to both INH and RIF. The optimal dose is not known.

ⁱThe long-term (more than several weeks) use of moxifloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. The optimal dose is not known.

^jThe long-term (more than several weeks) use of gatifloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. The optimal dose is not known.

^kMaximum dose regardless of weight.

be extended for these drugs (see Table 110–6). Ciprofloxacin is about 50% cleared by the kidneys but may not require a change in dose from once daily, as it is used for TB. The metabolites of isoniazid, pyrazinamide, and *p*-aminosalicylic acid are cleared primarily by the kidneys. The role of these metabolites in causing toxicity is unknown, so their accumulation in renal failure may carry some risk.

Ethionamide and its sulfoxide metabolite are cleared hepatically, so dosing is unchanged.^{39,50} *p*-Aminosalicylic acid is converted largely to metabolites prior to renal elimination; these metabolites may accumulate in renal failure.⁵⁰ For patients on hemodialysis, the usual 12-hour dosing interval for *p*-aminosalicylic acid granules seems to be safe. Dialysis will remove the metabolites. Serum concentration monitoring must be performed for cycloserine to avoid dose-related toxicities in renal failure patients.^{43,45,50}

■ Hepatic Failure

Antituberculosis drugs that rely on hepatic clearance for most of their elimination include isoniazid, rifampin, pyrazinamide, ethionamide,

and *p*-aminosalicylic acid.⁴⁶ Ciprofloxacin is about 50% cleared by the liver. Elevations of serum transaminase concentrations generally are not correlated with the residual capacity of the liver to metabolize drugs, so these markers cannot be used as guides for drug dosing. Further, isoniazid, rifampin, pyrazinamide, and to a lesser degree, ethionamide, *p*-aminosalicylic acid, and rarely, ethambutol may cause hepatotoxicity.^{39,43,46} For some patients with drug-susceptible TB, a “liver sparing” regimen may be used, at least temporarily. It consists of streptomycin, levofloxacin, and ethambutol.^{39,43,46} Note that this regimen would require 18 or more months of treatment to be successful. Therefore, patients usually are switched to isoniazid- and rifampin-containing regimens as soon as they are able.

■ Morbid Obesity

Data are not available for dosing the TB drugs in patients with morbid obesity.⁴⁶ Relatively hydrophilic drugs (isoniazid, pyrazinamide, the aminoglycosides, capreomycin, ethambutol, *p*-aminosalicylic acid, and cycloserine) can be dosed initially based on ideal body weight

TABLE 110–6. Dosing Recommendations for Adult Patients with Reduced Renal Function and for Adult Patients Receiving Hemodialysis

| Drug | Change in Frequency? | Recommended Dose and Frequency for Patients with Creatinine Clearance <30 mL/min or for Patients Receiving Hemodialysis |
|-------------------------------|----------------------|---|
| Isoniazid | No change | 300 mg once daily, or 900 mg three times per week |
| Rifampin | No change | 600 mg once daily, or 600 mg three times per week |
| Pyrazinamide | Yes | 25–35 mg/kg per dose three times per week (not daily) |
| Ethambutol | Yes | 15–25 mg/kg per dose three times per week (not daily) |
| Levofloxacin | Yes | 750–1000 mg per dose three times per week (not daily) |
| Cycloserine | Yes | 250 mg once daily, or 500 mg/dose three times per week ^a |
| Ethionamide | No change | 250–500 mg/dose daily |
| <i>p</i> -Aminosalicylic acid | No change | 4 g/dose, twice daily |
| Streptomycin | Yes | 12–15 mg/kg per dose two or three times per week (not daily) |
| Capreomycin | Yes | 12–15 mg/kg per dose two or three times per week (not daily) |
| Kanamycin | Yes | 12–15 mg/kg per dose two or three times per week (not daily) |
| Amikacin | Yes | 12–15 mg/kg per dose two or three times per week (not daily) |

Standard doses are given unless there is intolerance.

The medications should be given after hemodialysis on the day of hemodialysis. Monitoring of serum drug concentrations should be considered to ensure adequate drug absorption, without excessive accumulation, and to assist in avoiding toxicity. Data currently are not available for patients receiving peritoneal dialysis. Until data become available, begin with doses recommended for patients receiving hemodialysis and verify adequacy of dosing, using serum concentration monitoring.

^aThe appropriateness of 250-mg daily doses has not been established. There should be careful monitoring for evidence of neurotoxicity.

(IBW). Very low or very high serum concentrations can be avoided by checking the serum concentrations.

THE TB DRUGS

The interested reader is referred to several other publications for more detailed information regarding these drugs.^{2,12,39,42,43,45,46,51–53} Note that although the ATS/CDC guidelines recommend “maximum” doses, I disagree with this approach to therapy³⁹ (see Table 110–5). In my view, the “maximum” dose for a given patient is the dose that produces the desired response with an acceptable level of toxicity.^{43,45} This can only be determined on a case-by-case basis. Artificially capping doses may deprive patients of needed drug.

Primary Antituberculosis Drugs

Isoniazid. Isoniazid is one of the two most important TB drugs. It is highly specific for mycobacteria, with an MIC against *M. tuberculosis* of 0.01 to 0.25 mcg/mL. Most NTM such as *M. avium* are resistant to isoniazid, although *M. kansasii* and *M. xenopi* are susceptible. The

most common mechanism of resistance results from mutations in the *katG* gene leading to the loss of catalase-peroxidase activity and the failure to produce the toxic isoniazid derivatives.

Isoniazid is readily absorbed from the gastrointestinal tract and from intramuscular injection sites. It also can be given as a short intravenous infusion over 5 minutes if diluted in about 20 mL of normal saline.⁵⁴ Isoniazid should be given on an empty stomach whenever possible.⁵⁵ *N*-acetyltransferase 2 (NAT2) forms the principal metabolite, acetylisoniazid, which lacks antimycobacterial activity. The rate at which humans acetylate isoniazid is determined genetically; slow acetylation is an autosomal recessive trait and reflects a relative lack of NAT2. Fast acetylators have isoniazid half-lives of less than 2 hours. Approximately 50% of whites and blacks and 80% to 90% of Asians and Eskimos are rapid acetylators. Slow acetylators have isoniazid half-lives of 3 to 4 hours and may be at an increased risk of neurotoxicity. The association of acetylator status and risk of hepatotoxicity, however, appears to be weak.⁵⁶ Poor absorption and rapid clearance of isoniazid in patients receiving highly intermittent therapy have been associated with poor clinical outcomes.⁵⁷

Transient elevations of the serum transaminases occur in 12% to 15% of patients receiving isoniazid and usually occur within the first 8 to 12 weeks of therapy.³⁹ Overt hepatotoxicity, however, occurs in only 1% of cases. Risk factors for hepatotoxicity include patient age, preexisting liver disease, excessive alcohol intake, pregnancy, and the postpartum state. Isoniazid also may result in neurotoxicity, most frequently presenting as peripheral neuropathy or, in overdose, as seizures and coma. Patients with pyridoxine deficiency, such as pregnant women, alcoholics, children, and the malnourished, are at increased risk. Isoniazid may inhibit the metabolism of phenytoin, carbamazepine, primidone, and warfarin.⁴³ Patients who are being treated with these agents should be monitored closely, and appropriate dose adjustments should be made when necessary.

Rifampin. The introduction of rifampin into routine use during the 1970s allowed for true short-course treatment of TB (6 to 9 months).^{2,13,39} Without rifampin, treatment is generally 18 months or longer. Drug resistance to rifampin is an ominous prognostic factor because it is frequently associated with isoniazid resistance and leaves the patient with few good therapeutic options. Clinicians *must* take care to protect susceptibility to rifampin by carefully treating their patients.

Rifampin shows bactericidal activity against *M. tuberculosis* and several other mycobacterial species, including *M. bovis* and *M. kansasii*.⁵⁸ Other NTM, including MAC, show variable susceptibility to rifampin. Rifampin also is active against a broad array of other bacteria. Alteration of the target site on RNA polymerase, primarily through changes in the *rpoB* gene, leads to most forms of rifampin resistance.^{39,58}

Rifampin usually is given orally, but it also can be given as a 30-minute intravenous infusion.^{51,58} Oral doses are best given on an empty stomach.⁵⁹ Patients with AIDS, diabetes, and other gastrointestinal problems appear to have difficulty absorbing rifampin after oral doses, and this has been associated with therapeutic failures in some cases.^{43,45} Rifampin is metabolized to 25-desacetyl-rifampin, which retains most of rifampin’s activity; most of rifampin and its metabolite are cleared in the bile. Rifampin generally is given at 600 mg daily or intermittently, although this dose does not take full advantage of rifampin’s concentration-dependent killing.^{43,45} Higher doses should be tested in humans within the context of clinical trials.

CLINICAL CONTROVERSY

Rifampin shows concentration-dependent killing. Larger doses produce higher concentrations that more effectively kill bacteria and mycobacteria. High-dose rifampin fell out of favor because high doses given one to two times per week caused flulike symptoms. However, high doses (900–1200 mg and possibly higher) can be given safely daily. Studies should be performed in humans with TB to take full advantage of rifampin's potent activity.

Elevations in hepatic enzymes have been attributed to rifampin in 10% to 15% of patients, with overt hepatotoxicity occurring in less than 1%.^{39,58} More frequent adverse effects of rifampin include rash, fever, and gastrointestinal distress. Allergic reactions to rifampin have been reported and occur more frequently with intermittent rifampin doses 900 mg or more twice weekly. These reactions may take the form of a flulike syndrome with development of fever, chills, headache, arthralgias, and rarely, hypotension and shock.^{39,52} Alternatively, hemolytic anemia or acute renal failure may occur, requiring permanent discontinuation.

Rifampin's potent induction of hepatic enzymes, especially cytochrome P450 (CYP) 3A4, may enhance the elimination of many other drugs, most notably the protease inhibitors used to treat HIV (Table 110–7). HIV-positive patients may benefit from the use of rifabutin instead of rifampin (see below).^{39,60–63} Also, women who use oral contraceptives must use another form of contraception during therapy because increased clearance of the hormones may lead to unexpected pregnancies. Patient records should be reviewed for potential drug interactions before dispensing rifampin.⁵¹ Rifampin may turn urine and other secretions orange-red and may permanently stain some types of contact lenses.

■ **Other Rifamycins.** Rifabutin is used for disseminated *M. avium* infection in AIDS patients and is quite active against *M. tuberculosis*. Most rifampin-resistant organisms are resistant to rifabutin. Because rifabutin is a less potent enzyme inducer than rifampin, it may be used in patients receiving protease inhibitors.^{39,60–63} For HIV-positive patients, the American Thoracic Society (ATS)/CDC recommends regimens with three or more doses of the TB drugs per week (see Table 110–3). Rifapentine is a long-acting rifamycin that can be used once weekly in the continuation phase of treatment (after the first 2 months) in carefully selected HIV-negative patients. Rifapentine is about 85% as potent an enzyme inducer as rifampin, so similar drug interactions are likely.^{39,60–63}

■ **Pyrazinamide.** Adding pyrazinamide to the first 2 months of treatment with isoniazid and rifampin shortens the duration to 6 months for most patients.^{2,39} It is usually well absorbed and displays a fairly long half-life.^{64,65} The most common toxicities of pyrazinamide are gastrointestinal distress, arthralgias, and elevations in the serum uric acid concentrations.^{39,52} Most patients do not experience true gout. Hepatotoxicity is the major limiting adverse effect and is dose-related when pyrazinamide is given daily.

A fixed-combination product (Rifater, Aventis) of rifampin 120 mg, isoniazid 50 mg, and pyrazinamide 300 mg is designed to prevent drug resistance by keeping the self-medicating patient from using only one drug at a time. If the patient is receiving DOT, there is no particular advantage to this product. The typical dose of Rifater will be five to six tablets daily. When pyrazinamide is discontinued after

2 months of treatment, the combination product Rifamate (isoniazid 150 mg and rifampin 300 mg) can be substituted.

■ **Ethambutol.** Ethambutol replaced *p*-aminosalicylic acid as a first-line agent in the 1960s because it was better tolerated by patients.^{2,39} Ethambutol is used as a fourth drug for TB while awaiting susceptibility data.³⁹ If the organism is susceptible to isoniazid, rifampin, and pyrazinamide, ethambutol can be stopped. Ethambutol is active against most mycobacteria, including *M. tuberculosis* and *M. avium*, but it is generally bacteriostatic.

Ethambutol should not be given with antacids.⁶⁶ The ethambutol dose should be reduced to three times per week in patients with renal failure.^{49,67} Retrobulbar neuritis is the major adverse effect. Patients may complain of a change in visual acuity, the inability to see the color green, or both. They should be monitored monthly while on the drug using Snellen wall charts for visual acuity and Ishihara red-green color discrimination cards.^{39,51,52}

■ Second-Line Antituberculosis Drugs

■ **Streptomycin.** Streptomycin is one of three aminoglycoside antibiotics (along with amikacin and kanamycin) that are active against mycobacteria. Streptomycin is quite active against MAC and several other mycobacteria, *Enterococci*, *Brucella*, *Yersinia*, and various other bacteria. Although labeled only for intramuscular dosing, streptomycin can be given safely as intravenous infusions (100 mL of dextrose 5% water or normal saline) over 30 minutes, similar to the other aminoglycosides.⁶⁸ Streptomycin, like other aminoglycosides, is cleared renally by glomerular filtration and must be given less often in patients with renal dysfunction.^{39,43,51}

Streptomycin occasionally causes nephrotoxicity, although it tends to be mild and reversible. It also is capable of causing ototoxicity (vestibular and cochlear), which may become permanent with continued use.^{39,52} Older patients and those receiving long durations of treatment are most likely to experience hearing loss, whereas vestibular toxicity is highly unpredictable.

Resistance to amikacin and kanamycin is frequently linked but independent of resistance to streptomycin and independent of resistance to capreomycin. Therefore, susceptibility tests should guide the selection of these injectable drugs.

■ ***p*-Aminosalicylic Acid.** In the United States, only the enteric-coated, sustained-release granule form (Paser) is available.^{69–71} Gastrointestinal disturbances are the most common adverse effects from *p*-aminosalicylic acid. Diarrhea is usually self-limited, with symptoms improving after the first 1 to 2 weeks of therapy. Occasionally, a few doses of an opiod will resolve the problem. It is also important to tell the patient that the empty granules will appear in the stool. Although FDA approved for three daily doses, pharmacokinetic data support twice-daily dosing.⁷⁰

Various types of malabsorption, including steatorrhea, were reported with previous dosage forms of *p*-aminosalicylic acid. Hypersensitivity may occur and, rarely, severe hepatitis. *p*-Aminosalicylic acid is known to produce goiter, with or without myxedema, that seems to occur more frequently with concomitant ethionamide therapy.

■ **Cycloserine.** Cycloserine is only used to treat MDR-TB. It is well absorbed orally and is best taken on an empty stomach.⁷² It is cleared primarily through the kidneys by glomerular filtration and requires dosage reduction in renal failure. Cycloserine can produce

TABLE 110–7. Clinically Significant Drug-Drug Interactions Involving the Rifamycins

| Drug Class | Drugs Whose Concentrations Are Substantially Decreased by Rifamycins (References) | Comments | |
|----------------------------|--|--|--|
| Antiinfectives | HIV-1 protease inhibitors (saquinavir, indinavir, nelfinavir, amprenavir, ritonavir, lopinavir/ritonavir) | Can be used with rifabutin. Ritonavir, 400–600 mg twice daily, probably can be used with rifampin. The combination of saquinavir and ritonavir can also be used with rifampin. | |
| | Nonnucleoside reverse transcriptase inhibitors Delavirdine Nevirapine Efavirenz | Delavirdine should not be used with any rifamycin. Doses of nevirapine and efavirenz need to be increased if given with rifampin, no dose increase needed if given with rifabutin. | |
| | Macrolide antibiotics (clarithromycin, erythromycin) | Azithromycin has no significant interaction with rifamycins. | |
| | Doxycycline | May require use of a drug other than doxycycline. | |
| | Azole antifungal agents (ketoconazole, itraconazole, voriconazole) | Itraconazole, ketoconazole, and voriconazole concentrations may be subtherapeutic with any of the rifamycins. Fluconazole can be used with rifamycins, but the dose of fluconazole may have to be increased. | |
| | Atovaquone | Consider alternate form of <i>Pneumocystis carinii</i> treatment or prophylaxis. | |
| | Chloramphenicol | Consider an alternative antibiotic. | |
| | Mefloquine | Consider alternate form of malaria prophylaxis. | |
| | Hormone therapy | Ethinylestradiol, norethindrone | Women of reproductive potential on oral contraceptives should be advised to add a barrier method of contraception when taking a rifamycin. |
| | | Tamoxifen | May require alternate therapy or use of a nonrifamycin-containing regimen. |
| Levothyroxine | | Monitoring of serum TSH recommended; may require increased dose of levothyroxine. | |
| Narcotics | Methadone | Rifampin and rifapentine use may require methadone dose increase; rifabutin infrequently causes methadone withdrawal. | |
| Anticoagulants | Warfarin | Monitor prothrombin time; may require two- to threefold dose increase. | |
| Immunosuppressive agents | Cyclosporine, tacrolimus | Rifabutin may allow concomitant use of cyclosporine and a rifamycin; monitoring of cyclosporine serum concentrations may assist with dosing. | |
| | Corticosteroids | Monitor clinically; may require two- to threefold increase in corticosteroid dose. | |
| Anticonvulsants | Phenytoin, lamotrigine | Therapeutic drug monitoring recommended; may require anticonvulsant dose increase. | |
| Cardiovascular agents | Verapamil, nifedipine, diltiazem (a similar interaction is also predicted for felodipine and nisoldipine) | Clinical monitoring recommended; may require change to an alternate cardiovascular agent. | |
| | Propranolol, metoprolol | Clinical monitoring recommended; may require dose increase or change to an alternate cardiovascular drug. | |
| | Enalapril, losartan | Monitor clinically; may require a dose increase or use of an alternate cardiovascular drug. | |
| | Digoxin (among patients with renal insufficiency), digitoxin | Therapeutic drug monitoring recommended; may require digoxin or digitoxin dose increase. | |
| | Quinidine | Therapeutic drug monitoring recommended; may require quinidine dose increase. | |
| | Mexilitine, tocainide, propafenone | Clinical monitoring recommended; may require change to an alternate cardiovascular drug. | |
| | Bronchodilators | Theophylline | Therapeutic drug monitoring recommended; may require theophylline dose increase. |
| Sulfonylurea hypoglycemics | Tolbutamide, chlorpropamide, glyburide, glimepiride, repaglinide | Monitor blood glucose; may require dose increase or change to an alternate hypoglycemic drug. | |
| Hypolipidemics | Simvastatin, fluvastatin | Monitor hypolipidemic effect; may require use of an alternate hypolipidemic drug. | |
| Psychotropic drugs | Nortriptyline | Therapeutic drug monitoring recommended; may require dose increase or change to alternate psychotropic drug. | |
| | Haloperidol, quetiapine | Monitor clinically; may require a dose increase or use of an alternate psychotropic drug. | |
| | Benzodiazepines (e.g., diazepam, triazolam), zolpidem, buspirone | Monitor clinically; may require a dose increase or use of an alternate psychotropic drug. | |

dose-related CNS toxicity, including lethargy, confusion, or unusual behavior. Seizures, although reported, are exceedingly rare.^{2,39,51} Therapy is vastly improved by maintaining 2-hour postdose serum concentrations between 20 and 35 mcg/mL.^{43,45} Most patients reach a maximum dose of 750 mg daily, divided unevenly into two doses. This can be achieved by starting with 250 mg daily for 2 days, followed by 250-mg increments over 2-day intervals. This dose of cycloserine can be maintained if the patient complains of only occasional mild CNS effects, such as difficulty concentrating. Serum concentrations can be checked 1 to 2 weeks into therapy. The addition of pyridoxine 50 mg daily may improve patient tolerance of cycloserine.

■ **Ethionamide.** Ethionamide shares structural features with two other antimycobacterial agents, isoniazid and, more distantly, thiacetazone, a drug not used in the United States. Prothionamide, the *n*-propyl derivative of ethionamide, is used in Europe. Ethionamide is only active against organisms of the genus *Mycobacterium*, and it should be considered primarily bacteriostatic because it is difficult to achieve serum concentrations that would be bactericidal.^{39,43,45}

Gastrointestinal toxicity is the dose-limiting adverse effect. The drug should be introduced gradually in 250-mg increments, as described earlier for cycloserine. Rarely will a patient tolerate more than 1000 mg daily in divided oral doses. Ethionamide may be administered with a light snack or prior to bedtime to minimize gastrointestinal intolerance. Food does not affect absorption significantly.⁷³ Little ethionamide is recovered in the urine, so doses remain the same in renal failure. Ethionamide may cause goiter, with or without hypothyroidism (especially when given with *p*-aminosalicylic acid), gynecomastia, alopecia, impotence, menorrhagia, photodermatitis, and acne. The management of diabetes also may be more difficult in patients receiving ethionamide. Because of these problems, ethionamide is only used when absolutely necessary.

■ **Clofazimine.** Clofazimine is a drug with good activity against *M. leprae* and weak activity against *M. tuberculosis* and *M. avium*. It is used in doses of 100 to 200 mg daily in advanced cases of MDR-TB or MAC, especially when therapeutic options are limited.^{39,43} The drug has a terminal elimination half-life that is weeks long. Gastrointestinal distress and skin discoloration are the most important adverse reactions. Although uncommon, severe gastrointestinal pain may occur because of deposition of clofazimine crystals within the intestines; this may require surgical correction.

■ **Thiacetazone.** Thiacetazone is a weak agent used rarely in parts of the developing world because of its low cost. Skin reactions, including rash and Stevens-Johnson syndrome, may occur. Thiacetazone must be discontinued permanently as soon as a rash appears. Similar to trimethoprim-sulfamethoxazole, the incidence of skin reactions is much higher in AIDS patients.⁷⁴

■ **Quinolones.** Levofloxacin, ciprofloxacin, and moxifloxacin are sometimes used to treat MDR-TB. Moxifloxacin also is being studied as a possible replacement for certain first line agents, but data are not available at this time.^{2,13,39,43} Quinolones are useful because most are available in oral and intravenous dosage forms, so they can be used in critically ill patients.

■ **β -Lactam and β -Lactamase Inhibitor Combinations.** The β -lactams have limited activity against mycobacteria because of β -lactamases and because β -lactams fail to enter macrophages.^{39,43,75} Cefoxitin, a β -lactamase-stable cephalosporin, has useful activity against rapidly growing mycobacteria, such as *M. fortuitum* and

M. chelonae. Combinations of β -lactams with β -lactamase inhibitors have been used in salvage regimens for TB patients with no other options but are not used routinely to treat TB.

■ **Macrolides/Azalides.** The macrolide clarithromycin and azalide azithromycin represent substantial advances in the treatment of MAC but demonstrate limited activity against *M. tuberculosis* and are not used frequently for TB.^{2,13,39,43}

■ **New Drugs and Delivery Systems.** The nitroimidazopyran PA 824, which is chemically related to metronidazole and tinidazole, has activity against *M. tuberculosis* in vitro.⁷⁶ This class, along with the oxazolidinones, may produce useful agents for TB. Linezolid has been used in a few patients with TB.⁹⁶ Long-term use of linezolid requires careful monitoring of hematologic indices for potential anemia and thrombocytopenia. Although not proved conclusively, it may be possible to reduce the incidences of these toxicities by giving linezolid 600 mg daily for the slow-growing *M. tuberculosis* rather than the usual twice-daily dose used for gram-positive organisms. Chemical modification of existing compounds, such as pyrazinamide, may produce new TB drugs. Finally, continuing research on the construction of the mycobacterial cell wall and intracellular pathways may lead to agents with unique activity against this genus.

Liposomes have been investigated as delivery systems for various agents against mycobacteria, including isoniazid, rifampin, and the aminoglycosides. Liposomes also could be used to deliver β -lactams or other agents that generally are excluded from macrophages. By changing the pharmacokinetic profile of such agents, their use in the treatment of mycobacterial infections could be enhanced greatly. Currently, no such product is licensed for use against TB.

■ **Corticosteroids.** Adjunctive therapy with corticosteroids may be of benefit in some patients with tuberculous meningitis or pericarditis to relieve inflammation and pressure^{2,39} (see Table 110-4). They should be avoided in most other circumstances because they detract from the immune response to TB.

■ **Bacille Calmette-Guérin Vaccine (BCG).** The BCG vaccine is an attenuated, hybridized strain of *M. bovis*. It was developed in 1921 and is used as a prophylactic vaccine against TB. Administration of BCG vaccine is compulsory in many developing countries and is officially recommended in many others. Vaccination with BCG produces a subclinical infection resulting in sensitization of T-lymphocytes and cross-immunity to *M. tuberculosis*, as well as cutaneous hypersensitivity and, in many cases, a positive tuberculin skin test.

In the published clinical trials, several different BCG preparations were used, and the efficacy of these vaccinations ranged from negative 56% (some patients did worse with the vaccine) to positive 80%.^{2,39} Trials within the United States and Puerto Rico have shown efficacy rates of 6% to 29%. The primary benefit of BCG vaccination appears to be the prevention of severe forms of TB in children. Data from the BCG trials show that the incidence of tuberculous meningitis and miliary TB is 52% to 100% lower and that the incidence of pulmonary TB is 2% to 80% lower in vaccinated children younger than 15 years of age than it was in unvaccinated controls.

Unfortunately, BCG does not appear to be very reliable in preventing disease by *M. tuberculosis* in other segments of the population. Side effects occur in 1% to 10% of vaccinated persons and

usually include severe or prolonged ulceration at the vaccination site, lymphadenitis, and lupus vulgaris. It is recommended that pregnant women and patients with impaired immune systems, including those with HIV infection, avoid vaccination. The World Health Organization (WHO) has recommended, however, that in populations where the risk of TB is high, HIV-infected infants who are asymptomatic should receive BCG vaccine at birth or as soon as possible there-

after. Because BCG infection has occurred in AIDS patients given the vaccine, individuals with symptomatic HIV infection should not be vaccinated.^{2,39}

In the United States, BCG vaccination is recommended only for uninfected children who are at unavoidable risk of exposure to TB and for whom other methods of prevention and control have failed or are not feasible.^{2,39} Its use is very limited.

PHARMACOECONOMIC CONSIDERATIONS

The WHO and the World Bank agree that the control of TB is one of the most cost-effective health interventions any nation can pursue. Early identification of TB cases and the effective use of isoniazid, rifampin, and pyrazinamide (plus ethambutol) while the isolate is still drug-susceptible always should be the primary goals of public health departments. Contact investigation and treatment of those infected but without disease are important secondary goals to reduce the number of future cases.

Patients who complete all their treatment for drug-susceptible TB have cure rates approaching 100%. Noncompliance (nonadherence), drug resistance, extrapulmonary disease, and concomitant disease states reduce the overall effectiveness of chemotherapy of TB to about 75%.

The treatment of TB is not particularly expensive, especially if hospitalization is not required.⁷⁷ Further, TB is quite curable. Because the various TB drugs each have a role to play in the treatment of TB or MDR-TB, all the antituberculosis drugs approved by the Food and Drug Administration should be on institutional formularies. Centers that see little MDR-TB need not keep stocks of the second-line drugs, provided that they are readily available should the need arise. Because the treatment of MDR-TB is difficult, and because missteps are potentially disastrous, such patients should be referred to centers experienced in the management of MDR-TB.^{2,39,78,79}

EVALUATION OF THERAPEUTIC OUTCOMES

MONITORING OF THE PHARMACEUTICAL CARE PLAN

The most serious problem with TB therapy is patient nonadherence to the prescribed regimens.^{80,81} Unfortunately, there is no reliable way to identify such patients a priori. In the study by Brudney and Dobkin,⁸⁰ 89% of the patients were noncompliant with therapy. It is critical to the control of TB that such adherence rates be improved dramatically. The most effective way to achieve this end is with DOT.^{2,13,39} Despite criticisms that it will cost more money, it is far cheaper in the long run to prevent the further spread of disease with DOT than to track down and treat additional cases of TB continuously.

The homeless and other underprivileged individuals are assumed to constitute the group of patients considered “unreliable,” and DOT should be reserved for them; it is also assumed that “responsible” patients cared for by private physicians may be treated with daily, unsupervised therapy. A study conducted in Baltimore, however, compared outcomes (sputum culture conversion to negative at 3 months) in patients with pulmonary TB who were treated by private physicians with outcomes in patients treated via DOT in a city-run clinic. Surprisingly, 3-month culture conversion occurred in only 40% of the private-care patients compared with 90% in the city clinic-care

patients.⁸² Clearly, expansion of the use of DOT to nearly all patients with TB may be of benefit.

For patients who are AFB smear positive, they should have sputum samples sent for AFB stains every 1 to 2 weeks until two consecutive smears are negative. This provides early evidence of a response to treatment.³⁹ Once on maintenance therapy, sputum cultures can be performed monthly until two consecutive cultures are negative, which generally occurs over 2 to 3 months. If sputum cultures continue to be positive after 2 months, drug susceptibility testing should be repeated, and serum concentrations of the drugs should be checked.

Serum chemistries, including blood urea nitrogen, creatinine, aspartate transaminase (AST), and alanine transaminase (ALT) and a complete blood count with platelets should be performed at baseline and periodically thereafter, depending on the presence of other factors that may increase the likelihood of toxicity (e.g., advanced age, alcohol abuse, pregnancy).^{2,39} Hepatotoxicity should be suspected in patients whose transaminases exceed five times the upper limit of normal or whose total bilirubin concentration exceeds 3 mg/dL and in patients with symptoms such as nausea, vomiting, or jaundice. At this point, the offending agent(s) should be discontinued. Sequential reintroduction of the drugs with frequent testing of liver enzymes is often successful in identifying the offending agent; other agents may be continued. Alternative agents should be selected as needed. Audiometric testing should be performed at baseline and monthly in patients who must receive streptomycin for more than 1 to 2 months. Vision testing (Snellen visual acuity charts and Ishihara color discrimination plates) should be performed on all patients who receive ethambutol. All patients diagnosed with TB should be tested for HIV infection.

THERAPEUTIC DRUG MONITORING

Therapeutic drug monitoring (TDM) or applied pharmacokinetics is the use of serum drug concentrations to optimize therapy.^{39,43,45} Non-AIDS patients with drug-susceptible TB generally do well, and TDM generally should be used if they are failing appropriate DOT (no clinical improvement after 2 to 4 weeks or smear-positive after 4 to 6 weeks). On the other hand, patients with AIDS, diabetes, cystic fibrosis, and various gastrointestinal disorders often fail to absorb these drugs properly and are candidates for TDM. Also, patients with hepatic or renal disease should be monitored, given their potential for overdoses.

In the treatment of MDR-TB, the differences between the maximum serum concentration (C_{max}) and the minimal inhibitory concentration (MIC) for the second-line agents are much smaller than with isoniazid and rifampin. Therefore, alterations in the absorption of these drugs can have significant impact on the outcome of therapy.^{43,45} Although the optimal serum concentrations for TB are not known, target serum peak concentrations have been proposed.^{43,45} Blood samples collected at 2 and 6 hours after a dose have been used with some success, although they may not be the optimal sampling times for all the drugs. Long-half-life drugs (e.g., pyrazinamide and cycloserine) can be sampled at 2 and 10 hours if an estimate of the

half-life is desired. Finally, TDM of the TB and HIV drugs is perhaps the most logical way to untangle the complex drug interactions that take place⁸³ (see Table 110–7).

CLINICAL CONTROVERSY

Some TB centers employ TDM for many of their patients at the outset of treatment in order to identify drug-delivery problems early. Other centers wait to see how the patient responds and perform TDM only if problems arise. An argument can be made for either approach. The latter can save money, but delays in effective treatment can affect the patient's outcome adversely. Most otherwise healthy TB patients will absorb their drugs adequately. Patients who are critically ill or who have MDR-TB can benefit from early TDM.

CONCLUSIONS

Good patient adherence to treatment regimens is the cornerstone to effective antimycobacterial chemotherapy. Pharmacists should monitor TB therapy with particular interest in drug-drug interactions, drug malabsorption, and avoiding the error of adding a single drug to a failing regimen. They should educate patients on the importance of continuing their chemotherapy despite symptomatic improvement. Pharmacists should become part of a multidisciplinary team (with nurses, physicians, social workers) devoted to successful chemotherapy of TB patients and their families.

ABBREVIATIONS

AFB: acid-fast bacillus
 ALT: alanine transaminase
 AST: aspartate transaminase
 ATS: American Thoracic Society
 BCG: bacillus Calmette-Guérin
 CDC: Centers for Disease Control and Prevention
 CMI: cell-mediated immunity
 CYP: cytochrome P450
 DOT: directly observed treatment
 DTH: delayed-type hypersensitivity
 GC: gas chromatography
 HPLC: high-pressure liquid chromatography
 IBW: ideal body weight
 IFN: interferon
 LTBI: latent tuberculosis infection
 MAC: *Mycobacterium avium* complex
 MDR: multidrug resistance
 MIC: minimal inhibitory concentration
 NTM: nontuberculosis mycobacterium
 PPD: purified protein derivative
 RFLP: restriction-fragment-length polymorphism
 TB: tuberculosis
 TDM: therapeutic drug monitoring
 TLC: thin-layer chromatography
 TNF: tumor necrosis factor
 WHO: World Health Organization
 ZN: Ziehl-Neelsen strain

GASTROINTESTINAL INFECTIONS AND ENTEROTOXIGENIC POISONINGS

Steven Martin and Rose Jung

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The etiology of infectious diarrhea includes bacteria, viruses, and protozoans. Viral infections are the leading cause of diarrhea in the world.
- 2 Fluid and electrolyte replacement is the cornerstone of therapy. Oral rehydration therapy is preferred in most cases of mild and moderate diarrhea. The necessary components of oral replacement therapy are glucose, sodium, potassium, chloride, and water.
- 3 Antimicrobial therapy often is not indicated for enteritis because many cases are mild and self-limited or are viral in nature.
- 4 When antimicrobials are used for enteritis, they should be active against the most likely pathogen based on clinical symptoms, epidemiologic patterns, and resistance patterns in the area.
- 5 The most common pathogens for traveler's diarrhea include enterotoxigenic *Escherichia coli*, *Shigella*, *Campylobacter*, *Salmonella*, and viruses.
- 6 Patient education and prevention strategies are important in preventing and treating traveler's diarrhea. Prophylaxis with antibiotics is appropriate in certain situations.
- 7 Common pathogens responsible for food poisoning include *Staphylococcus*, *Salmonella*, *Shigella*, and *Clostridium*.

Gastrointestinal (GI) infections encompass a wide variety of syndromes from mild gastroenteritis to life-threatening systemic infections. Dehydration from GI infections is the second leading cause of morbidity and mortality worldwide, especially in infants and children younger than 5 years of age. From 1992 to 2000, the median incidence of diarrhea for all children younger than 5 years of age was 3.2 episodes per child-year. The incidence of diarrhea was higher in younger children, with 4.8 episodes per child per year among children aged 6 to 11 months in comparison with 1.4 episodes per child per year for 4-year-olds. Younger children also had a higher risk for death from acute dehydrating diarrhea. For children younger than 1 year of age and those aged 1 to 4 years, the median mortality rates were 8.5 and 3.8 per 1000 children per year, respectively. Overall, the median mortality for children younger than 5 years of age was 4.9 per 1000 per year.¹ Although this was a decrease from 13.6 per 1000 per year during 1955–1979 and 5.6 per 1000 per year during 1980–1989, diarrhea remains a severe disease in children, especially in those younger than 1 year of age.^{2,3}

In the developing world, the risk of death is highest among young children, but in developed countries such as the United States, most of those who die of diarrheal illness are elderly. According to data from the National Center for Health Statistics, for the 9-year period from 1979 to 1987, there were an average of 3171 deaths per year from diarrheal disease, of which 51% were among patients over 74 years of age, 27% were 55 to 74 years old, and 11% were younger than 5 years of age.⁴ Similarly, a study of the McDonnell-Douglas Health Information System database revealed that 25% of all hospitalizations and 85% of all mortality associated with diarrhea involved

the elderly (≥ 60 years old).⁵ Other groups at risk for GI infections include travelers and campers, immunocompromised patients such as those with the acquired immunodeficiency syndrome (AIDS), patients in chronic care facilities, and military personnel assigned overseas.

1 A variety of pathogens can be responsible for acute infectious diarrhea. Viruses are the most common cause of gastroenteritis in children. Bacterial species that are commonly associated with infectious diarrhea in the United States are *Shigella* spp., *Salmonella* spp., *Campylobacter* spp., *Yersinia* spp., *Escherichia* spp., *Clostridium* spp., and *Staphylococcus* spp. Although not a major cause in North America, *Vibrio* spp. is a leading cause of bacterial gastroenteritis on a global scale. This chapter focuses on the bacterial and viral etiologies of GI infections such as *Vibrio cholerae*, *Escherichia coli*, *Salmonella*, *Shigella*, *Campylobacter jejuni*, rotaviruses, Norwalk-like viruses, astrovirus, and enteric adenovirus.

EPIDEMIOLOGY

Several U.S. population-based studies have estimated the prevalence of acute GI infections and the burden of illness resulting from acute diarrhea. Based on these studies, the estimates by the Centers for Disease Control and Prevention (CDC) suggest that 211 million episodes of acute gastroenteritis occur each year in the United States, resulting in over 900,000 hospitalizations and over 6000 deaths.⁶ Although infectious diarrhea in the United States is often self-limited, the economic burden of GI infections still remains enormous.

Diarrheal illness accounts for 2 to 3.7 million doctor visits and 200,000 hospitalizations per year in children younger than 5 years of age in the United States.⁷ The cost per diarrhea episode resulting in a physician visit in children younger than 5 years of age is estimated to be approximately \$290. This extrapolates to a cost of over \$2 billion per year for children younger than 5 years of age. In a study of claims data from a large insurance database from 1993 to 1996 for children younger than 5 years of age with diarrhea, an annual average rate of 35 hospitalizations and 943 outpatient visits per 10,000 children occurred.⁸ Six deaths (0.08%) occurred during this period. The median payments (in constant 1998 dollars) for hospitalization decreased from \$2528 in 1993 to \$2101 in 1996. The median payment for outpatient visits was \$47. The total payments for combined diarrhea-associated hospitalizations and outpatient visits averaged \$7.1 million (in 1998 dollars) per year, with hospitalizations accounting for three-fourths of these payments. In addition, 50% of diarrheal illnesses lead to at least one full day of lost activity by patients or the parents of patients. This results in a total projected cost of diarrheal disease of \$23 billion per year in the United States based on estimated medical costs and lost productivity.⁹

In addition, traveler's diarrhea interferes with planned activities or work in 30% of those affected, accounting for unknown but substantial direct and indirect lost dollars because of decreased productivity.¹⁰

CLINICAL PRESENTATION

In patients with GI illnesses, a careful history and physical examination are crucial in providing clues to the likely etiology. An organism-specific diagnosis is necessary for the appropriate management and treatment in moderate to severe cases. Unfortunately, the methods for diagnosis of diarrheal disease vary widely in clinical practice. One practice guideline recommends selective approaches to improving cost-effectiveness of stool cultures.¹¹ Fecal testing is recommended

in patients with community-acquired diarrheal illnesses lasting for more than 1 day in patients with a recent use of antibiotics, day-care center attendance, hospitalization, or illness accompanied by fever, bloody stools, systemic illness, or dehydration. In hospitalized patients, fecal testing for standard bacterial pathogens (*Campylobacter*, *Salmonella*, *Shigella*, etc.) or ova and parasites is not recommended for diarrhea that occurs 3 days after the start of hospitalization owing to low yield, except in persons 65 years of age and older with comorbid disease, neutropenia, or human immunodeficiency virus (HIV) infection. Microscopic examination for fecal polymorphonuclear cells or a simple immunoassay for the neutrophil marker lactoferrin can further provide evidence of an inflammatory process and increase the yield of culture for invasive pathogens in patients presenting with fever or bloody stool.

For community-acquired or traveler's diarrhea, stool samples should be sent for culture of *Salmonella*, *Shigella*, *Campylobacter*, and *Escherichia coli* O157:H7.¹¹ A careful history may further point to specific etiologic agents. Bloody diarrhea may indicate enterohemorrhagic *E. coli*. Outbreaks should prompt consideration of *Staphylococcus aureus*, *Bacillus cereus*, *Clostridium perfringens*, *Vibrio*, *Salmonella*, *Campylobacter*, *Shigella*, or *E. coli* infection. Ingestion of inadequately cooked seafood should increase suspicions for infections with *Vibrio* or Norwalk-like viruses. Antibiotics predispose patients to cytotoxicigenic *Clostridium difficile*. Travel to tropical areas increases the chances of developing enterotoxigenic *E. coli*, viral (Norwalk-like or rotaviral), and parasitic infections (*Giardia*, *Entamoeba*, *Strongyloides*, and *Cryptosporidium*).

For patients who develop diarrhea after 3 days of hospitalization, 15% to 20% of cases are due to *C. difficile*.¹¹ This suggests that in hospitalized patients, especially in those who are exposed to antimicrobial therapy or chemotherapy, the stool specimen should be tested for *C. difficile* toxin(s). In immunocompromised hosts, a wide range of viral, bacterial, and parasitic agents should be tested.

► TREATMENT: Diarrhea

■ GENERAL APPROACHES TO TREATMENT

■ REHYDRATION THERAPY

2 Fluid replacement is the cornerstone of therapy for diarrhea regardless of etiology. Initial assessment of fluid loss is essential for rehydration, but an accurate baseline weight may not be available. Acute weight loss is the most reliable means of determining the extent of water loss. Clinical signs can be helpful in determining approximate deficits¹² (Table 111–1). Serum electrolyte concentrations should be measured. Physical assessment generally is more reliable in young children and infants than in adults.

Glucose-based oral rehydration therapy (ORT) reverses dehydration in nearly all patients with mild to moderate diarrhea.¹² Treatment failure is infrequent (3% to 6%).¹³ Oral rehydration therapy offers the advantages of being inexpensive and noninvasive and does not require hospitalization for administration. In those who are able to take oral fluids, ORT is superior to administration of intravenous (IV) fluids. In addition, thirst drives ORT and provides a safeguard against overhydration. Glucose-based ORT generally does not decrease the duration of diarrhea or stool volume, but it does prevent dehydration, which is responsible for most diarrheal deaths. Weight loss of 9% to 10% is considered severe and requires IV fluid replacement with Ringer's lactate or normal saline. Intravenous therapy is also indicated in patients with

uncontrolled vomiting, the presence of a paralytic ileus, stool output greater than 10 mL/kg per hour, shock, or loss of consciousness. Rapid IV rehydration is preferred over more prolonged deficit-replacement regimens for restoring extracellular fluids and electrolytes because it more effectively reestablishes gastrointestinal and renal perfusion.¹⁴ Table 111–1 summarizes fluid-replacement guidelines for each dehydration category.

The necessary components of ORT solutions include glucose, sodium, potassium, chloride, and water^{13,15} (Table 111–2). Oral rehydration therapy takes advantage of glucose-coupled sodium transport in the small bowel. Glucose enhances sodium and subsequently water transport across intestinal walls. Glucose concentrations greater than 5% may produce an osmotic diarrhea. Low-osmolarity ORT solutions (rice- or cereal-based) reduce the diarrhea stool number, volume, and frequency, as well as the duration of diarrhea and the ORT solution volume requirements when compared with isotonic high-glucose ORT solutions similar to the World Health Organization (WHO) formulation.¹⁶ The efficacy of rice-based ORT solutions may be a result in part of their hypotonicity, which promotes intestinal water absorption.¹⁷ Also, slow rice hydrolysis allows some rice (glucose) absorption to take place before hydrolysis occurs. Starch and simple proteins provide more cotransport molecules with a lower intraluminal osmotic load, thus increasing fluid and electrolyte uptake by enterocytes and reducing stool losses.¹⁵ Therefore, a larger

TABLE 111–1. Clinical Assessment of Degree of Dehydration in Children Based on Percentage of Body Weight Loss*

| Variable | Mild, 3%–5% | Moderate, 6%–9% | Severe, ≥10% |
|-------------------|---|---|--|
| Blood pressure | Normal | Normal | Normal to reduced |
| Quality of pulses | Normal | Normal or slightly decreased | Moderately decreased |
| Heart rate | Normal | Increased | Increased (bradycardia in severe cases) |
| Skin turgor | Normal | Decreased | Decreased |
| Fontanelle | Normal | Sunken | Sunken |
| Mucous membranes | Slightly dry | Dry | Dry |
| Eyes | Normal | Sunken orbits/decreased tears | Deeply sunken orbits/decreased tears |
| Extremities | Warm, normal capillary refill | Delayed capillary refill | Cool, mottled |
| Mental status | Normal | Normal to listless | Normal to lethargic or comatose |
| Urine output | Slightly decreased | <1 mL/kg/h | <1 mL/kg/h |
| Thirst | Slightly increased | Moderately increased | Very thirsty or too lethargic to indicate |
| Fluid replacement | ORT 50 mL/kg over 2–4 h | ORT 100 mL/kg over 2–4 h | Ringer lactate 40 mL/kg in 15–30 min, then 20–40 mL/kg if skin turgor, alertness, and pulse have not returned to normal <i>or</i> Ringer lactate or NS 20 mL/kg, repeat if necessary, and then replace water and electrolyte deficits over 1–2 days Followed by ORT 100 mL/kg over 4 hours. Replace ongoing losses with low-sodium ORT (40–60 mEq/L Na ⁺) at 10 mL/kg per stool or emesis |
| | Replace ongoing losses with low-sodium ORT (40–60 mEq/L Na ⁺) at 10 mL/kg per stool or emesis | Replace ongoing losses with low-sodium ORT (40–60 mEq/L Na ⁺) at 10 mL/kg per stool or emesis | |

*Percentages vary among authors for each dehydration category; hemodynamic and perfusion status is most important; when unsure of category, therapy for more severe category is recommended.

ORT, oral rehydration therapy

Adapted from refs. 10 and 15.

carbohydrate load can be given with rice solutions, resulting in a greater nutritional advantage. Amylase-resistant starch added to standard ORT solutions shortened the duration of diarrhea in cholera patients as compared with standard ORT solutions and rice-based ORT solutions.¹⁸ Human breast milk, cow's milk, glycine, soy fiber formulas, and cereal preparations have been used successfully as rehydration substrates.^{19,20}

Sodium content for oral replacement solutions should be between 50 and 90 mEq/L for initial rehydration. The American Academy of Pediatrics (AAP) recommends rehydration with a more electrolyte-concentrated rehydration phase and a subsequent maintenance phase using the more dilute solutions and larger volume²¹ (see Table 111–1). In children with vomiting and diarrhea, ORT may be given as 5 mL

every 2 to 3 minutes in a teaspoon or oral syringe. Nasogastric administration of ORT is an alternative method of administration in a child with persistent vomiting.¹² Maintenance rehydration requires sodium concentrations between 40 and 60 mEq/L. ORT solutions with high sodium content may be alternated with water if a low-sodium fluid is not available. The maintenance phase should provide 100–150 mL/kg per day plus additional replacement for stool losses. Clear fluids, such as soda, apple juice, broth, and Gatorade, are hyperosmolar solutions that may draw free water into the gut lumen and cause hypernatremia. Use of these solutions should be avoided.

Early refeeding as tolerated is recommended.²² The AAP guidelines recommend age-appropriate diet resumption as soon as dehydration is corrected.²¹ Breast milk, lactose-free soy formula, and cow's

| Sports beverage | 20 | 3 | 3 | 255 | 330 |

Adapted from ref. 15.

milk-based formulas often can be continued.^{12,22} Early initiation of feeding has shortened the course of diarrhea. In a study of severely malnourished children younger than 5 years of age with diarrhea, using a standardized protocol of slower oral rehydration, immediate feeding, and intensive management of complications resulted in a significant reduction of mortality as compared with standard therapy. Initially, easily digested foods, such as bananas, applesauce, and cereal, may be added. Foods high in fiber, sodium, and sugar should be avoided. Lactase deficiency may be exacerbated among known lactase-deficient patients and may persist up to 10 days.

After starting rehydration therapy, parents should be instructed to observe the child for a reversal of the signs of dehydration, increased stool consistency, and decreased stool frequency. If ORT is not improving the fluid status and the patient continues to produce frequent, large-volume watery stools, close supervision with medical support is justified.²²

■ ANTIMICROBIAL THERAPY

The indiscriminate use of antimicrobial therapy in GI infections produces increases in antimicrobial resistance, side effects of antimicrobial agents, and the threat of superinfections owing to eradication of normal flora. Increasing fluoroquinolone resistance in *Campylobacter* and multidrug resistance in *Salmonella* species worldwide reinforce the importance of local resistance patterns in making decisions about antimicrobial therapy.^{23,24} Knowledge of the local patterns of susceptibility can guide the initial choice of antibiotic, but the appropriate choice ultimately depends on isolation of pathogens from recent clinical specimens. To decrease resistance, antibiotics should be prescribed judiciously in addition to adoption of prudent infection control measures.

3 Antibiotics are not essential in the treatment of most mild diarrheas, and empirical therapy for acute GI infections may result in courses of unnecessary antibiotics. However, appropriate antibiotic

TABLE 111-3. Recommendations for Antibiotic Therapy

| Pathogen | First-Line Agents | Alternative Agents |
|--|--|--|
| Enterotoxigenic (Cholera-Like) Diarrhea | | |
| <i>Vibrio cholerae</i> O1 or O139 | Doxycycline 300 mg oral single dose; tetracycline 500 mg orally four times daily × 3 days; or trimethoprim-sulfamethoxazole DS tablet twice daily × 3 days; norfloxacin 400 mg orally twice daily × 3 days; or ciprofloxacin 500 mg orally twice daily × 3 days or 1 g orally single dose | Chloramphenicol 50 mg/kg IV every 6 hours, erythromycin 250–500 mg PO every 6–8 hours, and furazolidone |
| Enterotoxigenic <i>E. coli</i> | Norfloxacin 400 mg or ciprofloxacin 500 mg orally twice daily × 3 days | Trimethoprim-sulfamethoxazole DS tablet every 12 hours |
| <i>C. difficile</i> | Metronidazole 250 mg four times daily to 500 mg three times daily × 10 days | Vancomycin 125 mg orally four times daily × 10 days; bacitracin 20,000–25,000 units four times daily × 7–10 days |
| Invasive (Dysentery-Like) Diarrhea | | |
| <i>Shigella</i> species ^a | Trimethoprim-sulfamethoxazole DS twice daily × 3–5 days | Ofloxacin 300 mg, norfloxacin 400 mg, or ciprofloxacin 500 mg twice daily × 3 days, or nalidixic acid 1 g/day × 5 days; azithromycin 500 mg orally × 1, then 250 mg orally daily × 4 days. |
| <i>Salmonella</i> Nontyphoidal ^a | Trimethoprim-sulfamethoxazole DS twice daily; ofloxacin 300 mg, norfloxacin 400 mg, or ciprofloxacin 500 mg twice daily × 5 days; or ceftriaxone 2 g IV daily or cefotaxime 2 g IV three times daily × 5 days | Azithromycin 1000 mg orally × 1 day, followed by 500 mg orally once daily × 6 days |
| Enteric fever | Ciprofloxacin 500 mg orally twice daily × 3–14 days (ofloxacin and perfloxacin equally efficacious) | Azithromycin 1000 mg orally × 1 day, followed by 500 mg daily × 5 days; or cefixime, cefotaxime, and cefuroxime; or chloramphenicol 500 mg four times daily orally or IV × 14 days |
| <i>Campylobacter</i> ^a | Erythromycin 500 mg orally twice daily × 5 days; azithromycin 1000 mg orally × 1 day, followed by 500 mg daily or clarithromycin 500 mg orally twice daily | Ciprofloxacin 500 mg or norfloxacin 400 mg orally twice daily × 5 days |
| <i>Yersinia</i> species ^a | A combination therapy with doxycycline, aminoglycosides, trimethoprim-sulfamethoxazole, or fluoroquinolones | |
| Traveler's Diarrhea | | |
| Prophylaxis ^a | Norfloxacin 400 mg or ciprofloxacin 500 mg orally daily (in Asia, Africa, and South America); trimethoprim-sulfamethoxazole DS tablet orally daily (in Mexico) | |
| Treatment | Norfloxacin 400 mg or ciprofloxacin 500 mg orally twice daily × 3 days, or trimethoprim-sulfamethoxazole DS tablet orally twice daily × 3 days (in Mexico), or azithromycin 500 mg orally once daily × 3 days (only in areas of high prevalence of quinolone-resistant <i>Campylobacter</i> species, such as Thailand) | |

^aFor high-risk patients only. See the preceding text for the high-risk patients in each infection.

therapy has been shown to shorten illness and reduce morbidity in some bacterial (cholera, enterotoxigenic *E. coli*, shigellosis, campylobacteriosis, yersiniosis) infections and can be lifesaving in invasive infections (*C. difficile*, salmonellosis). Antibiotic treatment also reduces the duration and shedding of organisms in infections with susceptible *Shigella* spp. and possibly in infection with susceptible *Campylobacter* spp.^{25,26}

It is also important to note that outcomes of some bacterial diarrheal illnesses may be worsened by the use of antibiotics. Antibiotic treatment may prolong asymptomatic carriage of *Salmonella*.²⁷ In patients infected with *E. coli* O157, use of an antimicrobial agent may worsen the risk of hemolytic-uremic syndrome (HUS), which is defined by the triad of acute renal failure, thrombocytopenia, and microangiopathic hemolytic anemia, by increasing the production of shiga-like toxin.²⁸

4 Table 111–3 summarizes antibiotic recommendations, and further details in the treatment of specific infections are discussed in appropriate sections.

ANTIMOTILITY AGENTS

Agents that inhibit peristalsis such as diphenoxylate and loperamide are contraindicated in most toxin-mediated diarrheal illnesses (enterohemorrhagic *E. coli*, pseudomembranous colitis, shigellosis). Slowing of fecal transit time is thought to result in extended toxin-associated damage. On the other hand, in traveler's diarrhea, a combination of appropriate antibiotics and loperamide controls symptoms within 10 hours.²⁹

PREVENTION OF GASTROINTESTINAL INFECTIONS

Many diarrheal diseases can be prevented by following simple rules of personal hygiene and safe food preparation. Handwashing with soap is instrumental in preventing the spread of illness and should be emphasized for caregivers and persons with diarrheal illnesses. Safe food handling and preparation practices can decrease the incidence of certain types of enteric infections significantly. The public health measures of improved water supply and sanitation facilities and the quality control of commercial products are very important for the control of the majority of enteric infections.

Reporting suspected outbreaks and cases of notifiable illness to local health authorities is vital to allow measures to be taken to investigate threats of enteric infection arising from increasingly global and industrialized food supplies. The reporting of specific infectious diseases to the appropriate public health authorities is the cornerstone of public health surveillance, outbreak detection, and prevention and control efforts.

Vaccines also may be used to boost specific immune processes directed against the bacteria themselves or against adherence appendages, cytotoxins, or enterotoxins. Currently available vaccines for typhoid fever in the United States are the parenteral Vi capsular polysaccharide vaccine, the oral live-attenuated Ty21a vaccine, and the older heat-phenol-inactivated parenteral vaccine.³⁰ Only the older parenteral cholera vaccine is licensed for use in the United States, but it is not recommended owing to the low risk of cholera to the traveler and the limited efficacy of the vaccine.³¹ New oral live and killed vaccines are licensed outside the United States and are used by some travelers. The rotavirus vaccine, although effective, has presented complications in the form of rare cases of intussusceptions; it is no longer marketed and thus is not recommended.³²

PATIENT ASSESSMENT

Appropriate follow-up care of patients with acute diarrhea is based on successful restoration of fluid losses. The clinical signs and symptoms (see Table 111–1) that led to the diagnosis also can indicate adequate rehydration and should be assessed frequently. Because oral rehydration therapy is now preferred, routine laboratory testing often is unnecessary. Electrolytes should be measured in those receiving parenteral fluids, when oral replacement fails, or when signs of hypernatremia or hypokalemia are present. Follow-up stool samples to ensure complete evacuation of the infecting pathogen may be necessary only

in patients at high risk to initiate or contribute to a community outbreak. All patients should be monitored for complications associated with the infecting pathogen, resolution of the diarrhea, and adverse reactions to the pharmacologic agents used. One panel suggests prompt discharge of hospitalized children when rehydration is achieved, IV fluids have not been required, oral intake equals or exceeds losses, or adequate family education and medical follow-up are ensured. For most patients, discharge can occur in 16 to 24 hours.

BACTERIAL INFECTIONS

Bacterial agents are important causes of GI infections, and syndromes caused by these pathogens are better understood than viral gastroenteritis. For a simple generalization, the bacterial pathogens presented in this section are divided into either those which cause watery (enterotoxigenic) diarrhea or those which cause dysentery (invasive diarrhea). Watery diarrhea is usually self-limiting, whereas those who present with dysenteric symptoms, such as fever, tenesmus, and blood and/or pus in the stool, require close monitoring and intensive follow-up. Clinical signs and symptoms of these two broad categories are presented in the Table 111–4.

ENTEROTOXIGENIC (CHOLERA-LIKE) DIARRHEA

CHOLERA (*VIBRIO CHOLERAE*)

Epidemiology

Cholera has been endemic in the Ganges delta, West Bengal, Bangladesh, and southern Asia (including Southeast Asia) since at least 1817.³³ A 1994 outbreak of a multidrug-resistant strain of cholera among Rwandan refugees resulted in more than 20,000 deaths. Cholera epidemics in 1991 and 1998 caused more than 1 million deaths in Latin America. As international travel has increased, the occurrence of cholera in the United States also has increased. Cholera has been reported in all major regions of the United States. However, the incidence, 1 case per 1 million persons, is extremely low.³⁴

Vibrio cholerae O1 is the most common serogroup associated with epidemics and pandemics. Within this serogroup, there are two biotypes, classic and El Tor.³³ The six pandemics since 1817 presumably were caused by the classic biotype, and the seventh pandemic introduced the El Tor biotype. In 1992, a new serogroup, *V. cholerae* O139 Bengal, appeared in India and spread rapidly through Southeast

Adapted from Ref. 7.

Asia. *V. cholerae* O139 also has been isolated from food-production animals in the Netherlands. Four mechanisms for transmission have been proposed, including animal reservoirs, chronic carriers, asymptomatic or mild disease victims, and water reservoirs. A relatively large inoculum of 10^3 to 10^6 is required for infection if water is the vehicle and 10^2 to 10^4 if the vehicle is food. Approximately half the people infected with *V. cholerae* O1 are symptomatic, whereas only 1% to 5% of those infected with *V. cholerae* O139 manifest symptoms. The hallmark of cholera is the production of watery diarrhea, and severe dehydration may develop within a few hours, causing death within 24 hours. An estimated 25% to 50% of cases are fatal if left untreated. The prevention of cholera transmission depends on the provision of clean drinking water and public sanitation, which is difficult in impoverished developing countries.³³

► TREATMENT: Cholera

Regardless of the serotypes, the primary goal of therapy is restoration of fluid and electrolyte losses caused by watery diarrhea. ORT is the preferred method of rehydration, and several studies showed reduction in fluid requirements by 32% to 35% when rice-based instead of glucose-based ORT solutions are used (50–80 g rice instead of 20 g glucose per liter).³⁶ In patients who cannot tolerate ORT, IV Ringer's lactate solution can be used.³⁷ Normal saline is not recommended because it does not correct metabolic acidosis. After rehydration, maintenance fluid is given based on accurate recording of intake and output volumes.

Antibiotics shorten the duration of diarrhea, decrease fluid loss, and shorten the duration of the carrier state.³⁷ Table 111–3 provides recommendations on antibiotic selection. There appears to be substantial mobility in genetic elements encoding antibiotic resistance in *V. cholerae*, and the drug resistance patterns may change between outbreaks. For example, O139 strains isolated during 1992 and

Pathogenesis

V. cholerae is a gram-negative bacillus sharing similar characteristics with the family Enterobacteriaceae. Most pathology of cholera results from an enterotoxin (cholera toxin) produced by the bacteria.³³ Conditions that reduce gastric acidity, such as the use of antacids, histamine-receptor blockers, or proton pump inhibitors or infections with *Helicobacter pylori*, increase the risk for clinical disease. Cholera toxin stimulates adenylate cyclase, which increases intracellular cAMP and results in inhibition of sodium and chloride absorption by microvilli and promotes the secretion of chloride and water by crypt cells. The toxin likely acts along the entire intestinal tract, but most fluid loss occurs in the duodenum.³⁵ The net effect of the cholera toxin is isotonic fluid secretion (primarily in the small intestine) that exceeds the absorptive capacity of the intestinal tract (primarily the colon). This results in the production of watery diarrhea with electrolyte concentrations similar to that of plasma.

Clinical Presentation

The average incubation period for *V. cholerae* infection is 1 to 3 days.³⁵ The clinical presentation can vary from asymptomatic to life-threatening dehydration owing to watery diarrhea. The onset of diarrhea is abrupt and is followed rapidly or sometimes preceded by vomiting. Initial stools generally do not have the “rice water” appearance that is classically noted with cholera. Fever occurs in less than 5% of patients, and the physical examination correlates well with the severity of dehydration. In the most severe state, this disease can progress to death in 2 to 4 hours if not treated. In some cases, fluid accumulates within the intestinal lumen causing abdominal distension and ileus and may cause intravascular depletion without diarrhea. Patients may lose up to 1 liter of isotonic fluid every hour.

Laboratory abnormalities such as increased packed red blood cell volume and total protein, magnesium, and calcium levels are a result of hemoconcentration. Hypoglycemia, seizures, fever, and mental alterations are seen more often in children, perhaps as a reflection of the greater degree of dehydration and electrolyte losses observed with diarrhea in children.^{33,35} Other complications include metabolic acidosis, prerenal azotemia, iatrogenic water intoxication from overhydration, and aspiration pneumonia. Children, the elderly, and pregnant women are at an increased risk of complications due to cholera.

1993 showed a trend toward increased resistance to trimethoprim-sulfamethoxazole, but those isolated in India during 1996 and 1997 showed susceptibility to the same agent.³⁵ A single dose of doxycycline is the preferred agent, especially in endemic areas, although it has been associated with prolonged fecal excretion of bacteria. In children younger than 7 years of age, trimethoprim-sulfamethoxazole, erythromycin, and fuazolidone are preferred. In pregnant women, erythromycin or furazolidone can be used. In areas of high tetracycline resistance, fluoroquinolones such as ciprofloxacin are effective. Ciprofloxacin has been studied more extensively than other fluoroquinolones.³⁸

The manufacture of the only licensed whole-cell cholera vaccine in the United States has been discontinued. Two vaccines are available in other countries.³⁵ These are oral vaccines; Dukoral consists of killed *V. cholerae* organisms and the cholera B subunit, and Orochol is an avirulent mutant of *V. cholerae* strain CVD103HgR.

Both vaccines are effective in field trials and volunteer studies, but their cost-effectiveness in endemic settings is uncertain. The WHO does not require vaccination for international travel to or from en-

demic areas because the series of two injections is effective in only 50% of people and immunity wanes in 6 months or less. It is more cost-effective to provide counseling about avoiding risks.

ESCHERICHIA COLI

Epidemiology

E. coli is a gram-negative bacillus commonly found in the human GI tract. It is divided into five groups based on pathogenic features of diarrheal disease and toxin production: enterotoxigenic *E. coli* (ETEC), enteroinvasive *E. coli* (EIEC), enteropathogenic *E. coli* (EPEC), enteroadhesive *E. coli* (EAEC), and enterohemorrhagic *E. coli* (EHEC).³⁹ The most common group is ETEC; it accounts for about half of all cases of *E. coli* diarrhea and for more than 79,000 cases in the United States each year.^{39,40} Enterotoxigenic *E. coli* is incriminated as being the most common cause of traveler's diarrhea and a common cause of food- and water-associated outbreaks.⁴¹ EAEC strains are also important causes of traveler's diarrhea in Mexico and North Africa. However, unlike ETEC, EAEC produces diarrhea more commonly in developing populations in association with persistent diarrhea (≥ 14 days). EPEC infection is primarily a disease of children younger than 2 years of age in the developing world. The reason for the relative resistance of adults and older children is not known.

Recognized as a common and potentially deadly cause of infectious diarrhea, EHEC is believed to be the major etiologic factor responsible for the development of hemorrhagic colitis and HUS.²⁸ The CDC estimates the annual disease burden of *E. coli* O157:H7 in the United States to be more than 20,000 infections and as many as 250 deaths, but the failure of many clinical laboratories to screen for this organism greatly complicates any estimates. In the United States, serotype O157:H7 causes 50% to 80% of all EHEC infections, but in the southern hemisphere, such as Argentina, Australia, Chile, and South Africa, non-O157:H7 serotypes are often more important.³⁹ Transmission usually occurs via food and water, and outbreaks have been associated with undercooked ground beef.²⁸ Reports of EHEC enteritis continue to increase. EIEC strains are biochemically, genetically, and pathogenetically related closely to *Shigella* spp. and cause a disease similar to *Shigella*-like dysentery.

Pathogenesis

Enterotoxigenic *E. coli* are capable of producing two plasmid-mediated enterotoxins: heat-labile toxin (HLT) and heat-stable toxin (HST).⁴² A cholera-like toxin, HLT has two subunits (A and B) that

have similar antigenic properties and action on the gut mucosa. The net effect of this toxin on the mucosa is production of a cholera-like secretory diarrhea. HST is nonantigenic and has a low molecular weight. HST has a rapid onset of action and probably acts only on the small intestine.⁴³

The mode of pathogenesis of the non-ETEC varieties is less well understood. The hallmark histopathologic lesion of EPEC infection is the effacing of microvilli and intimate adherence between the bacterium and the epithelial cell membrane. EAEC adheres to intestinal mucosal Hep-2 cells, eliciting mucus production and bacterial biofilm layering. The final step in the pathogenesis of EAEC is cytotoxin elaboration from the organism causing damage to intestinal cells. This can result in persistent diarrhea (≥ 14 days). The pathogenicity of EHEC is related to the production of cytotoxins, commonly called *shiga-like toxins* because of their resemblance to the shiga toxin of *Shigella dysenteriae*.⁴⁴ EIEC invades the colonic epithelium.

Clinical Presentation

Nausea and watery stools, with or without abdominal cramping, are characteristic of the disease caused by ETEC.³⁹ Usually there is no blood or pus in the stool. Signs and symptoms are dependent directly on the extent of fluid loss, which in most cases is subclinical. Most ETEC diarrhea is typically abrupt in onset and resolves within 24 to 48 hours without complication. The clinical features of EAEC diarrhea are characterized as watery, mucoid, secretory diarrhea with low-grade fever and little or no vomiting. Common symptoms of EPEC infection include profuse watery diarrhea, vomiting, and low-grade fever.

Symptoms from EHEC infection can be severe, with as many as 11 to 12 bloody stools per day.^{44,45} Cramping and severe abdominal pain are common. Nausea occurs in about two-thirds of patients, and vomiting occurs in less than a third. Symptoms usually last 1 week. The white blood cell (WBC) count is elevated and accompanied by a left shift, but patients often remain afebrile. Stool cultures should be performed when EHEC is suspected.²⁸ Death may occur rarely, usually as a result of HUS.³⁷ EIEC infection presents most commonly as watery diarrhea, which can be indistinguishable from the secretory diarrhea seen with ETEC, but in a minority of cases, patients experience the dysentery syndrome, manifested as blood, mucus, and leukocytes in the stool with tenesmus and fever.

► TREATMENT: *E. coli* Diarrhea

The cornerstone of management of diarrheogenic *E. coli* infection is to prevent dehydration by correcting fluid and electrolyte imbalances. ORT is often lifesaving in infants and children.³⁹ Treatment of EHEC infection is primarily limited to supportive care, which may include dialysis, hemofiltration, transfusion of packed erythrocytes, platelet infusions, and other interventions as indicated clinically.⁴⁶ Severe disease may require renal transplant. Bismuth subsalicylate and loperamide are effective in decreasing the severity of ETEC diarrhea.

the management of diarrhea due to EHEC. There is evidence that the use of such agents can increase the risk for development of HUS, possibly by delaying intestinal clearance of the organism and thereby increasing toxin absorption.

Although antimicrobial prophylaxis with doxycycline, trimethoprim-sulfamethoxazole, or a fluoroquinolone is effective in preventing ETEC diarrhea, the growing problem of antibiotic resistance and the possibility of adverse effects from antimicrobial agents deter recommendations of prophylaxis. Instead, experts recommend avoiding risk factors while traveling. In addition, if significant disease occurs, bismuth subsalicylate given four times

CLINICAL CONTROVERSY

Loperamide should not be used in patients with fever or dysentery because antimotility agents are contraindicated in

daily may alleviate symptoms, and empirical antibiotics may shorten the duration of the disease.⁴⁷ Fluoroquinolones (e.g., ciprofloxacin, norfloxacin, and ofloxacin) are the most commonly recommended agents owing to increasing antimicrobial resistance among other drug classes. Vaccines that target colonization factor antigens are under development for ETEC infection.⁴⁸

A number of antibiotics have been used to treat EPEC, but multiple-antibiotic resistance is common. The use of antibiotics remains controversial in EHEC infection.⁴⁹ Their use may be harmful owing to lysis of bacteria leading to increased release of toxin and alteration of normal intracolonic bacterial flora thereby increasing the systemic absorption of the toxin.

PSEUDOMEMBRANOUS COLITIS (*CLOSTRIDIUM DIFFICILE*)

Epidemiology

Pseudomembranous colitis (PMC) was first reported in 1893 and was associated with antibiotic therapy in 1955. Although described in the preantibiotic era, the incidence increasingly has been associated with antibiotic administration. *C. difficile* is thought to be the cause in 10% to 20% of patients experiencing antibiotic-associated diarrhea, 50% to 75% of those with antibiotic-associated colitis, and greater than 90% of those with antibiotic-associated pseudomembranous colitis.⁵⁰ It is also the most common cause of nosocomial diarrhea, infecting 16% to 20% of inpatients, one-third of whom are symptomatic.⁵¹

The incidence of intestinal colonization is variable, ranging from 30% to 70% in infants to 3% to 5% in healthy adults.⁵⁰ The relationship between the colonized state and active disease is poorly understood. Many people are colonized with the bacteria yet do not go on to develop PMC. It occurs most often in high-risk groups, such as the elderly, debilitated patients, cancer patients, surgical patients, any patient receiving antibiotics, patients with nasogastric tubes, and patients who frequently use laxatives. PMC has been associated with use of broad-spectrum antimicrobials, including clindamycin, ampicillin, or third-generation cephalosporins.⁵⁰ Other agents that have been implicated, albeit at a lower incidence rate, include aminoglycosides, erythromycin, fluoroquinolones, trimethoprim-sulfamethoxazole, and surprisingly, vancomycin and metronidazole, two of the most commonly used antimicrobials for treatment of *C. difficile*.⁵²

Pathogenesis

C. difficile is a gram-positive spore-forming anaerobic bacillus and causes a toxin-mediated disease. Once antibiotics disrupt normal

colonic flora and colonization of *C. difficile* occurs, two toxins (A and B) are released to mediate diarrhea and colitis. Toxin A is the major pathogenic factor and has been characterized as an enterotoxin that causes intestinal fluid secretion, mucosal injury, and inflammation through actin disaggregation, intracellular calcium release, and damage to neurons. Toxin B is a nonenterotoxic cytotoxin that causes depolymerization of filamentous actin and mediates more potent damage to human colonic mucosa than toxin A. Initially, raised white and yellowish plaques form, and the surrounding mucosa may be inflamed. With progression of disease, these pseudomembranous plaques become enlarged and scattered over the colorectal mucosa.⁵³

Clinical Presentation

C. difficile infection may cause a spectrum of disease from mild antibiotic-associated diarrhea to pseudomembranous enterocolitis.⁵⁰ In colitis without pseudomembrane formation, patients present with malaise, abdominal pain, nausea, anorexia, watery diarrhea, low-grade fever, and leukocytosis. PMC is characterized by more severe illness, with severe abdominal pain, profuse diarrhea, high fever, marked leukocytosis, and classic pseudomembrane formation evident with sigmoidoscopic examination. Symptoms can start a few days after the start of antibiotic therapy or several weeks after antibiotics have been discontinued. The onset of illness is often abrupt.

C. difficile infection should be suspected in patients experiencing diarrhea with a recent history of antibiotic use (within the previous 2 months) or in those whose diarrhea began 72 hours after hospitalization. Diagnosis can be established by detection of toxin A or B, stool culture for *C. difficile*, or endoscopy. If the stool sample is negative, a second analysis is recommended because the testing sensitivity may be increased with repeat testing. Endoscopy should be reserved for situations where rapid diagnosis is needed, ileus is present, a stool is not available, or other colonic diseases are in the differential diagnosis.⁵⁴

► TREATMENT: Pseudomembranous Colitis

Initial therapy should include discontinuation of the offending agent with a change to an alternative antibiotic if possible.⁵⁰ Fluid and electrolyte replacement therapy is necessary. Although diarrhea will resolve in 15% to 23% of patients without therapy, most patients will require antibiotics. Both vancomycin and metronidazole are effective, but metronidazole 250 mg orally four times daily is the drug of choice.⁵⁰ It is similar to vancomycin in time to resolution of diarrhea, incidence of side effects, and relapse rates. However, it is less expensive than vancomycin, and the concern for vancomycin resistance promotes metronidazole use.

Oral vancomycin 125 mg four times daily is second-line therapy. Its use is appropriate in the following situations: The patient has not responded to oral metronidazole; the organism is resistant to metronidazole; the patient is allergic or intolerant to metronidazole; treatment includes ethanol-containing solutions; the patient is either pregnant or younger than 10 years of age; the patient is critically ill because of *C. difficile* diarrhea or colitis (the duration of diarrhea is reduced

to 3 versus 4.6 days with metronidazole); and there is evidence suggesting that the diarrhea is caused by *S. aureus*.⁵⁰ Vancomycin must be administered orally because IV vancomycin does not achieve gut lumen concentrations high enough for effective bacterial elimination.

Bacitracin is third-line treatment. In resolving symptoms, 80,000 units of bacitracin orally daily is as effective as vancomycin but is not as effective in eradicating the organism. Bacitracin's poor taste, which reduces patient adherence, limits its use.⁵⁴ Teicoplanin and fusidic acid have been effective in resolving symptoms and eradicating the organism.⁵⁴

Relapse after antibiotic treatment occurs in about 20% to 25% of patients and does not appear to be influenced by the choice of initial therapy, dose of drug used, or duration of treatment.⁵⁰ Recurrences occur because of the persistence of the spore forms of *C. difficile* that are not killed by antibiotic therapy or reinfection by a new strain. Recurrences usually occur 3 to 21 days after antibiotics are stopped. Retreatment with metronidazole or vancomycin at the previous dose

for 10 to 14 days generally is successful. The addition of rifampin to vancomycin also has been effective.⁵⁰

CLINICAL CONTROVERSY

Some investigators have found prophylaxis with competing, nonpathogenic organisms such as *Lactobacillus* spp. or *Saccharomyces* spp. to be helpful in preventing relapse in small numbers of patients.^{55,56} It is thought that these organisms help to restore the natural flora in the gut and make patients more resistant to colonization by *C. difficile*.

Vancomycin has been used in combination with anion-exchange resins dosed to avoid drug-resin binding, and this has been used successfully in a small number of cases.⁵⁴ Cholestyramine 4 g orally three to four times daily and colestipol 5 g orally twice daily have been used as alternatives to antibiotics in mild cases.

Drugs that inhibit peristalsis, such as diphenoxylate, are contraindicated in PMC.⁵⁰ Slowing of fecal transit time is thought to result in extended toxin-associated damage. Strict handwashing and contact precautions are imperative measures in preventing the spread of the organism. *C. difficile* can be cultured in rooms of infected individuals up to 40 days of after discharge.⁵¹

INVASIVE (DYSENTERY-LIKE) DIARRHEA

BACILLARY DYSENTERY (SHIGELLOSIS)

Epidemiology

The shigellae are gram-negative bacilli belonging to the family Enterobacteriaceae. Four species most often associated with disease are *Shigella dysenteriae* type I, *S. flexneri*, *S. boydii*, and *S. sonnei*.⁵⁷ The shigellae have worldwide distribution, with regional differences in prevalence of subgroups responsible for disease. For example, in the United States, the common causes of shigellosis are *S. sonnei* and *S. flexneri*. Cases caused by other shigellae are successfully acquired during travel to developing countries. Because of overuse of antibiotics in human and animal feed, Southeast Asia and India have higher levels of resistance. Poor sanitation, poor personal hygiene, inadequate water supply, malnutrition, and increased population density are associated with an increased risk of *Shigella* gastroenteritis epidemics, even in developed countries.

Most cases result from fecal-oral transmission. A few well-documented food- and water-associated outbreaks have been reported. Peak incidence in the United States is in late summer. Estimates indicate that 450,000 cases of shigellosis occur in the United States and that 165 million cases occur in the world annually, resulting in over 1 million deaths worldwide each year.⁵⁷

Shigellosis is primarily a disease of children, with the highest incidence between the ages of 6 months and 5 years. Infection among infants is uncommon, and only a third of all cases occur in adults.

Pathogenesis

Ingestion of as few as 10 to 200 viable organisms of the *Shigella* species causes disease in healthy adults, explaining the ease with which the disease is transmitted from person to person.⁵⁸ The bacteria multiply and spread within the submucosa of the small bowel, but they rarely extend beyond the mucosa. Penetration of the mucosa

is conferred genetically by large “invasion plasmids” and results in distortion of the crypts, death to intestinal epithelium causing focal ulceration, sloughing of mucosal cells, bloody mucoid exudate into the gut lumen, and submucosal accumulation of inflammatory cells with microabscess formation.⁵⁹ Microabscesses eventually may coalesce, forming larger abscesses. Infection frequently involves the entire colon. In addition to the virulence characteristics of invasiveness, *S. dysenteriae* type I and, to lesser degree, *S. flexneri* and *S. sonnei* produce a cytotoxin, or shiga toxin, the pathogenic role of which is unclear, although it is thought to damage endothelial cells of the lamina propria, resulting in microangiopathic changes that can progress to HUS.⁶⁰ Watery diarrhea commonly precedes the dysentery and may be a result of these toxins.

Clinical Presentation

Initial signs and symptoms include abdominal pain, cramping, and fever followed by frequent watery stools.⁶¹ Within a few days, patients experience a decrease in fever, severe abdominal pain, and tenderness prior to the development of bloody diarrhea and other signs of dysentery (see Table 111-4). Stools are often greenish in color and contain leukocytes. Fluid and electrolyte losses may be significant, particularly in infants and elderly patients. In the early stages of the disease, stool cultures are positive. A rapid diagnostic test kit that uses DNA amplification by the polymerase chain reaction (PCR) is also available.

If left untreated, bacillary dysentery usually lasts about 1 week (range 1–30 days). Complications are unusual but may include severe dehydration, generalized seizures, septicemia, toxic megacolon, perforated colon, arthritis, protein-losing enteropathy, and HUS. Mortality is rare, but it may be more likely with *S. dysenteriae* type I. Less than 3% of persons who are infected with *S. flexneri* will later develop Reiter's syndrome, characterized by pains in the joints, irritation of the eyes, and painful urination. This can lead to chronic arthritis.⁶²

► TREATMENT: Bacillary Dysentery (Shigellosis)

Shigellosis is usually a self-limiting disease. Most patients recover in 4 to 7 days, although 10% may experience a recurrence. Oral fluid and electrolyte replacement is the foundation of treatment (dysentery is not generally associated with significant fluid loss). However, intravenous fluid replacement therapy may be necessary, especially in children and the elderly.

Owing to the self-limiting nature of the illness and rapid development of antimicrobial resistance on completion of therapy, antibiotic treatment is reserved for the elderly and infirmed, those who are immunocompromised, children in day-care centers, malnourished children, and health care workers. Antibiotics shorten

the period of fecal shedding and attenuate the clinical illness. The choice of agent depends on location (see Table 111-3). For infections acquired in the United States, the agent of choice is trimethoprim-sulfamethoxazole (only 4% resistance). For infections acquired outside the United States, the agents of choice are ciprofloxacin, norfloxacin, and azithromycin.²⁶

Antimotility agents such as diphenoxylate are not recommended because they can worsen bacillary dysentery and could be involved in the development of toxic dilatation of the colon. Oral vaccines currently in development contain attenuated strains of *Shigella* and provide protection against shigellosis in human challenges.⁶³

SALMONELLOSIS

Epidemiology

Salmonella species are gram-negative bacilli belonging to the family Enterobacteriaceae. As a result of DNA hybridization experiments, the classification and nomenclature of *Salmonella* spp. have been changing, causing much confusion.⁶⁴ Owing to a high degree of DNA similarity, all important *Salmonella* isolates have been classified into a single species, *S. choleraesuis*, with approximately 2500 different serotypes. Because various serotypes were known formally as species, it has been acceptable to refer to serotypes as species. For example *S. enterica* serotype Typhi is commonly referred to as *S. typhi*. Unfortunately, there is also a serotype Choleraesuis within *S. choleraesuis*. To decrease misunderstanding, a new name, *S. enterica*, was proposed to replace *S. choleraesuis*, and thus much of the current literature uses this name.

Specific *Salmonella* serotypes produce characteristic human disease. For example *S. enterica* serotypes Typhimurium or Enteritidis causes gastroenteritis, whereas serotypes Typhi or Paratyphi causes enteric fever. Clinical manifestations produced by *Salmonella* serotypes commonly include acute gastroenteritis (enterocolitis), bacteremia, extraintestinal localized infection, enteric fever (typhoid and paratyphoid fever), and a chronic carrier state.

In the United States, approximately 1.4 million cases of salmonellosis, 16,000 hospitalizations, and 600 deaths occur annually.⁶ Salmonellosis is a disease primarily of infants, children, and adolescents. Children younger than 5 years of age account for about 25% of all diagnosed cases.²⁷ Conditions that may predispose to infection include those which decrease gastric acidity, antibiotic use, malnutrition, and immunodeficiency states. Contaminated food or water has been implicated in the majority of cases. Direct fecal-oral transmission occurs less frequently but is particularly important in children. Foods most often implicated in human salmonellosis are poultry, poultry products, beef, pork, and dairy products. Pets, particularly reptiles, are a common source of infection.

There is decreasing incidence in rates of salmonellosis in the United States. Foodborne outbreaks of enteric fever are rare, and a small number of cases often are associated with international travel, especially to developing countries. The most common *Salmonella* serotypes are Typhimurium and Enteritidis, accounting for approximately 50% of isolates from patients.⁶⁵ The overall downward trend in rates of salmonellosis is believed to be due to the improved food-handling practices and water treatment.

Pathogenesis

The incubation period, symptoms, and disease severity depend on the amount of organism ingested. The inoculum necessary for infection is estimated to less than 1000 organisms, and this infectious dose is lowered in patients with achlorhydria (gastric pH > 4.0). If the organisms survive the gastric acid barrier, mucosal invasion of the small intestine begins.⁶⁶ After penetration, microorganisms translocate to the intestinal lymphoid follicles and the draining mesenteric lymph nodes, in addition to the reticuloendothelial cells of the liver and spleen. Thereafter, the ability of organisms to survive and multiply within the mononuclear phagocytic cells of the lymphoid follicles, liver, and spleen plays an instrumental role in the pathogenesis. In the asymptomatic phase, the organisms are sequestered intracellularly. Once the critical number of organisms has been reached, bacteria are released into the bloodstream, and the symptoms of enteric fever are manifested. This dissemination of organisms via bloodstream also causes secondary infection in the liver, spleen, bone marrow, gallblad-

der, and Peyer's patches of the terminal ileum. After several weeks of infection, recruitment of mononuclear cells and lymphocytes induced by *Salmonella* is thought to be responsible for necrosis of Peyer patches and the abdominal pain observed in enteric fever.⁶⁶

The mechanism by which nontyphoidal salmonellae cause enterocolitis is less well understood. Although a number of enterotoxins have been described in salmonellae, their role remains illusive.⁶⁷ Some salmonellae, such as *S. enterica* serotype Choleraesuis, which is the most invasive, are frequently associated with bacteremia and metastatic localization, whereas others seldom cause disease. Enterocolitis often is characterized by massive neutrophil infiltration into both the large and small bowel mucosa. The serotypes that are responsible for human illness cause intestinal epithelial cells to secrete interleukin 8 (IL-8), a potent neutrophil chemotactic factor. Degranulation and release of toxic substances by neutrophils may contribute to inflammation and result in tissue damage, fluid secretion, or leakage across the intestinal mucosa.

Clinical Presentation

Enterocolitis. Most patients experience symptoms within 72 hours of ingestion of contaminated food or water.⁶⁷ Patients often complain of nausea and vomiting followed by abdominal cramps, headache, fever, and diarrhea, although the actual presentation is quite variable. Some patients do not have increased stool frequency, whereas others have more than one stool per hour. Stools generally are loose and may be mucoid or bloody (dysentery-like) or both. Febrile episodes usually range between 100 and 102°F (37.7 and 38.8°C) but may be higher. Some evidence suggests that fever of 104°F (40°C) or higher is associated with shorter bacterial excretion.⁶⁸ Diarrhea and fever usually resolve spontaneously within 1 to 5 days but may last 2 weeks.

Stool cultures inevitably yield the causative organism if obtained early (i.e., in patients hospitalized less than 3 days).⁵² Recovery of organisms continues to decrease with time so that by 3 to 4 weeks, only 5% to 15% of adult patients are passing *Salmonella*. Infants and children tend to pass bacteria for longer periods than adults. Some patients may continue to shed *Salmonella* for a year or longer. These "chronic carrier" states are rare for serotypes other than Typhi.⁶⁶

Bacteremia. Salmonellae can produce bacteremia without classic enterocolitis or enteric fever. Bacteremia rarely occurs in older adults, but it can occur in up to 40% of infants.⁶⁹ It is also reported more frequently in persons with severe underlying illness or immunosuppression, including AIDS. The clinical syndrome is characterized by persistent bacteremia and prolonged intermittent fever with chills. Stool cultures frequently are negative. This clinical syndrome is most frequent with serotype Choleraesuis infections (50%). Leukocyte counts are often within the normal range.

Localized Infections. Localized infections develop in 5% to 10% patients with bacteremia.⁶⁷ Extraluminal infection or abscess formation or both can occur at any site. They may follow any of the other syndromes, or they may be the primary presentation. Metastatic infections involve bone, cysts, heart, kidney, liver, lungs, pericardium, spleen, and tumors. The clinical presentation usually is determined by the organ systems involved. Polymorphonuclear leukocyte counts often are elevated.

Enteric Fever (Typhoid and Paratyphoid). Enteric fever caused by serotype Typhi is called *typhoid fever*.⁶⁶ If caused by any other serotype, it is referred to as *paratyphoid fever*. The clinical

presentations of typhoid fever and paratyphoid fever generally are indistinguishable, although paratyphoid fever tends to be less severe than typhoid fever. The incubation period can range from 10 to 14 days. The onset of symptoms is gradual. Nonspecific symptoms of fever, dull headache, malaise, anorexia, and myalgias are most common. Initially, fever tends to be remittent, but it progresses gradually over the first week to temperatures that are often sustained over 104°F (40°C). Other frequently encountered symptoms include chills, nausea, vomiting, cough, weakness, and sore throat. Symptoms subside slowly within 4 weeks.

Physical examination generally reveals an acutely ill patient. An erythematous maculopapular rash known as *rose spots* appears primarily on the abdomen in 15% to 50% of patients. The abdomen also may be tender, particularly in the lower quadrants. Hepatomegaly,

splenomegaly, or both also may be present in 50% of the cases, and cervical lymph nodes may be enlarged.

A normochromic anemia may develop rapidly without evidence of GI blood loss, although intestinal bleeding may be contributory. Leukopenia may be reflective of a relative decrease in polymorphonuclear leukocytes. WBC counts may range from 1200 to 20,000 cells/mm³. As many as one-third of the patients have elevated levels of the liver enzymes glutamic-oxaloacetic transaminase and alkaline phosphatase in serum. About 80% of patients have positive blood cultures. Bacteremia persists in about a third of cases for several weeks if not treated. Intestinal perforation, intestinal hemorrhage, thrombophlebitis, toxemia with circulatory collapse, encephalopathy, and pneumonia all contribute to a fatality rate of 1% to 2%. Without treatment, mortality may be 10%.⁶⁶

▶ TREATMENT: Salmonellosis

■ ENTEROCOLITIS

Fluid and electrolyte replacement is the primary mode of treatment. Most patients respond well to ORT (self-limited illness).⁶⁷ Antimotility drugs should be avoided because they increase the risk of mucosal invasion and complications. Antibiotic therapy is *not* indicated in healthy adults. Antibiotics have no effect on the duration of fever or diarrhea, and their frequent use increases the likelihood of resistance and the duration of fecal shedding. Antibiotics should be used in: (1) neonates or infants younger than 6 months of age because young children have an increased risk of complicated infection, (2) patients with primary or secondary immunodeficiency, such as AIDS or chemotherapy patients, (3) severely symptomatic patients with fever and bloody diarrhea, and (4) patients after splenectomy.⁶⁷ Susceptibility testing is recommended because many drug-resistant strains of *Salmonella* have emerged. Recommended antibiotics include the fluoroquinolones, trimethoprim-sulfamethoxazole, ampicillin, and third-generation cephalosporins. If susceptibility results are not available, a fluoroquinolone or third-generation cephalosporin should be instituted owing to resistance with trimethoprim-sulfamethoxazole and ampicillin. Azithromycin and aztreonam also have been studied and may be used as alternative agents.

■ BACTEREMIA AND LOCALIZED INFECTIONS

Owing to increasing resistance, empirical therapy for life-threatening bacteremia or focal infections following nontyphoidal *Salmonella* infection should include both a third-generation cephalosporin (such as ceftriaxone 2 g IV daily) and a fluoroquinolone (ciprofloxacin 500 mg orally twice daily) until the susceptibilities are known.⁶⁹ The duration of antibiotic therapy is dictated by the site of infection. Bacteremia without endovascular infection should be treated for 7 to 14 days. In documented or suspected endovascular infection, 6 weeks of intravenous therapy with ampicillin or ceftriaxone is recommended. Chloramphenicol is no longer recommended in patients with endovascular infection owing to high rates of failure.

■ ENTERIC FEVER (TYPHOID AND PARATYPHOID)

Antibiotic choice is dictated by susceptibility testing.⁶⁶ Fluoroquinolones are the drugs of choice for the treatment of enteric fever.⁷⁰

A short course of 3 to 5 days is effective in uncomplicated enteric fever, but a minimum of 10 days is recommended in severe cases. In patients who are infected with fluoroquinolone-susceptible *S. enterica* serotype Typhi, the average time for defervescence is less than 4 days, and the cure rates exceed 96%, with fewer than 2% of treated patients having persistent fecal carriage or relapse. Unfortunately, fluoroquinolone resistance is increasing in some areas, and these strains are also often multidrug-resistant, limiting the choice of antibiotics. Among patients with fluoroquinolone-resistant *S. enterica* serotype Typhi infection, fluoroquinolones still can be used but at the maximal possible dose for a minimum of 10 to 14 days. These patients should be monitored carefully to determine whether they are excreting the organism in their feces. High-dose fluoroquinolone regimens have been successful in 90% to 95% of patients with multidrug-resistant infection.⁷¹ However, the average time to defervescence is 7 days, and the rate of fecal carriage during convalescence can be as high as 20%.

The third-generation cephalosporins (e.g., ceftriaxone, cefixime, cefotaxime, and cefoperazone) and azithromycin are also effective drugs for typhoid. Chloramphenicol, amoxicillin, and trimethoprim-sulfamethoxazole remain appropriate for the treatment of typhoid fever in areas of the world where the bacterium is still fully susceptible to these drugs and where the fluoroquinolones are not available or affordable.⁶⁶ Although fluoroquinolones are not recommended in children, the pediatric use of ciprofloxacin in areas where multidrug-resistant *S. typhi* occurs is acceptable. In pregnant women, the β -lactam antibiotics are safe, and there are some case reports to support fluoroquinolone use.

Adults and children with severe enteric fever characterized by delirium, obtundation, stupor, coma, or shock benefit from prompt administration of dexamethasone 1 mg/kg every 6 hours for 24 to 48 hours.⁷² Three vaccines against *S. typhi* are licensed in the United States: a heat-phenol-inactivated parenteral vaccine (Typhoid Vaccine, USP), an orally administered vaccine (Ty21a, Vivotif Berna), and a parenteral polysaccharide vaccine (ViCPS, Typhim Vi).³⁰ The efficacy of these vaccines ranges from 42% to 77%, and immunity persists for 3 to 5 years. The parenteral inactivated vaccine causes substantially more adverse reactions than the other two but provides more prolonged protection. The Ty21a and Vi vaccines are recommended for travelers to areas of endemic disease and those in high-risk groups, including household contacts of *S. typhi* carriers, laboratory technicians with repeated exposure, and sanitation workers in endemic areas. Since the Ty21a vaccine is a live, attenuated vaccine, it should not be administered to immunocompromised persons, patients taking antibiotics, or patients with gastroenteritis.

■ “CHRONIC CARRIERS” OF *SALMONELLA*

“Chronic carriers” of *Salmonella* usually have negative stool cultures at 12 weeks after the onset of illness, but some may have continued positive stool cultures at 6 to 12 months. Chronic fecal shedding of *Salmonella* has been associated with chronic biliary infection

and cholelithiasis. To alleviate the chronic carrier state, the drug of choice is norfloxacin 400 mg orally twice daily for 28 days. In addition, amoxicillin and trimethoprim-sulfamethoxazole are effective in eradicating the bacteria in greater than 80% of cases after 6 weeks of therapy.²⁷ Chronic carriers should take preventative measures (i.e., antibiotics and hygiene) so that they do not serve as reservoirs of infection to the community.

CAMPYLOBACTERIOSIS

Epidemiology

The *Campylobacter* spp. are flagellated, curved, gram-negative rods that are thought to be one of the most common bacterial causes of diarrheal illnesses worldwide. Although there are 14 different species, *C. jejuni* is the species responsible for more than 99% of *Campylobacter*-associated gastroenteritis.⁷³ In the United States, the incidence of *Campylobacter* infection decreased 26% from 1996 to 1999. However, surveillance studies indicate that *Campylobacter* spp. remain the most commonly isolated enteric pathogen, detected two to seven times more frequently than *Salmonella* or *Shigella*.⁷⁴ Currently, the CDC estimates that 2.4 million persons are affected each year in the United States, involving almost 1% of the entire population.

In developed countries, the peak incidence of *Campylobacter* infections occurs in children younger than 1 year of age and young adults of 15 to 44 years of age. The incidence is also higher in males than in females, although the reason for this is unknown. Patients with AIDS are particularly susceptible; the incidence in AIDS patients is 40 times that of the general population.⁷³ Most reported cases occur during the summer months, beginning in May and peaking in August. In tropical developing countries, *Campylobacter* infections are common among children younger than 2 years of age, and asymptomatic infections of children and adults are more common than those seen in industrialized nations. This decrease in the case-to-infection ratio suggests that previous exposure confers immunity to the infecting strain.

The transmission of infection occurs primarily by ingestion of contaminated food or water. Although *Campylobacter* spp. have varied reservoirs, such as livestock, dogs, cats, and birds, the consumption of chicken has been shown to be the major vector of infections in industrialized nations.⁷⁵ Poultry products are nearly always contaminated with *Campylobacter* spp. during the slaughtering process, and it is estimated that 1 drop of chicken juice may contain 500 infectious organisms. Although public education emphasizes safe handling and cooking of chicken, it is easy to see how simple errors may result in human illness.

Pathogenesis

Campylobacter spp. are labile in acidic environments, much like *Salmonella*. Therefore, an inoculum of approximately 800 organisms is required to initiate infection. Conditions in the upper small intestine are favorable for multiplication. Flagella-mediated adherence and tissue invasion by bacteria have been demonstrated in the jejunum, ileum, and colon. Infection results in an acute inflammatory enteritis. *C. jejuni* can produce an enterotoxin or cytotoxin.⁷⁶ Both cytotoxins and enterotoxins may be produced in many strains. Symptom manifestation depends on immunity. Patients infected with *Campylobacter* develop specific IgG, IgM, and IgA antibodies in serum and IgA antibodies in intestinal secretions. Volunteer studies indicate that immunity does protect against illness.

Clinical Presentation

The average incubation period of *Campylobacter* is 2 to 4 days.⁷⁴ The most common presenting symptoms include diarrhea, abdominal pain, and fever. Nausea, vomiting, headache, myalgias, and malaise also may occur. Bowel movements may be numerous, bloody (dysentery-like), and foul smelling and range from loose to watery. Cramping and abdominal pain usually are relieved by defecation. In 75% of cases, leukocytes and red blood cells are detected in the stool samples. Peripheral leukocytosis also may be present. The disease usually is self-limited to about 1 week, but it may persist for several weeks in 10% to 20% of patients. The case-fatality rate is 0.05 per 1000 infections.

Complications, including pseudoappendicitis, pancreatitis, gastrointestinal hemorrhage, thrombophlebitis, abscess, septicemia, peritonitis, empyema, urinary tract infection, and cholecystitis, are uncommon but occur more frequently in those who are immunocompromised. *C. jejuni* has been associated with Guillain-Barré syndrome (GBS), but the relationship is not well understood.⁷⁷ *C. jejuni* infections are a common trigger of GBS, accounting for approximately 30% of GBS cases, but the risk of developing GBS after *C. jejuni* infection appears to be low (<1 case of GBS per 1000 *C. jejuni* infections). A reactive arthritis may develop several weeks after infection in persons with the HLA-B27 histocompatibility antigens.⁶² Diagnosis is made by stool culture, but the bacteria sometimes are identifiable with Gram stain or carbol-fuchsin stain.

► TREATMENT: *Campylobacteriosis*

The primary treatment of campylobacteriosis is oral fluid and electrolyte replacement.⁷⁴ Most people recover from this self-limiting disease in 4 to 7 days. Antibiotics are *not* useful unless started within 4 days of the start of the illness because they do not shorten the duration or severity of diarrhea but only shorten the duration of bacterial excretion. However, antibiotics are warranted in patients who present with high fevers, severe bloody diarrhea, prolonged illnesses (>1 week), pregnancy, and immunocompromised states, including HIV infection (see Table 111–3).

C. jejuni is susceptible to a wide variety of antimicrobial agents. Fluoroquinolone resistance has increased to 10% to 13%

in the United States (41% to 88% in Europe and Asia) in recent years and may be a result of the use of quinolone antibiotics in poultry feed and their frequent use overseas in treating enteric infections. Erythromycin is considered the drug of choice owing to its low cost, high efficacy, safety profile, and ease of administration. Newer macrolides such as clarithromycin and azithromycin are equally effective. Tetracycline, chloramphenicol, clindamycin, and aminoglycosides may be effective.⁷³ Antimotility agents such as loperamide are contraindicated because slowing fecal transit time may extend the duration of infection and increase toxin mucosal invasion.

YERSINIOSIS

Yersinia spp. are non-lactose-fermenting gram-negative coccobacilli that are widely distributed in nature. The genus *Yersinia* includes six species known to cause disease in humans. The best known species is *Y. pestis*, the causative agent of plague, which is usually spread by bites from infected animals, such as fleas, rodents, or cats. *Y. enterocolitica* and, to lesser extent, *Y. pseudotuberculosis* are most likely associated with intestinal infection, but overall, both are a relatively infrequent cause of diarrhea and abdominal pain. More than 50 serotypes of *Y. enterocolitica* exist; of these, serotypes 0:3, 0:8, and 0:9 are associated most frequently with enterocolitis.⁷⁸ Infections are reported commonly from northern Europe, and the peak incidence occurs during the winter months.

Children are most likely to experience illness with *Y. enterocolitica* infection.⁷⁹ Transmission of infection occurs frequently by ingestion of contaminated food or water. The organisms have been isolated from a variety of food sources, including pigs and raw goat and cow milk. Refrigeration does not deter the development of adherence and invasive virulence factors.

Y. enterocolitica invade the intestinal epithelium and penetrate the intestinal mucosa.⁸⁰ An inoculum of 10⁹ organisms may be required for infection. Most strains produce an enterotoxin, but the role of toxin production in causing diarrhea is not well established. However, this infection causes mucosal ulcerations in the terminal ileum, necrotic lesions in Peyer's patches, and enlargement of mesenteric lymph nodes.

Clinical Presentation

These bacteria cause a wide spectrum of clinical syndromes.⁷⁹ Most patients with *Y. enterocolitica* infection present with enterocolitis that is mild and self-limiting. Symptoms include vomiting, abdominal pain, diarrhea, and fever; up to 60% of patients will have blood-streaked stools. Diarrhea resolves after 1 to 3 weeks, but bacteria excretion may continue for up to 3 months after diarrhea subsides. Most patients with this type of infection are younger than 5 years of age. In older children and adolescents, mesenteric adenitis and/or terminal ileitis with fever, right lower quadrant pain, and leukocytosis are common. Mesenteric adenitis, which is difficult to distinguish from acute appendicitis, is also seen in patients infected with *Y. pseudotuberculosis*.

Approximately 10% to 30% of adult patients develop a reactive arthritis 1 to 2 weeks after recovery from enteritis. This arthritis, involving the knees, ankles, toes, fingers, and wrists, usually resolves in 1 to 4 months but may persist in about 10% of patients.⁷⁹ This complication is more common in persons with the HLA-B27 antigen.⁶² Other postinfection complications include erythema nodosum, exudative pharyngitis, pneumonia, empyema, and lung abscess. Although rare, *Y. enterocolitica* bacteremia has been reported in patients with diabetes mellitus, severe anemia, hemochromatosis, cirrhosis, and malignancy. Other groups at risk include the elderly and those who received frequent red blood cell transfusions (iron overload).⁸¹ These patients are at increased risk for hepatic or splenic abscesses, peritonitis, septic arthritis, osteomyelitis, wound infections, meningitis, and endocarditis.

► TREATMENT: Yersiniosis

Oral fluid and electrolyte replacement is an important initial approach. Owing to the self-limiting nature of the illness, antibiotics may not alter the time to resolution of the diarrhea or the rate of bacteriologic cure. Antibiotics should be used in high-risk patients who develop bacteremia (i.e., infants younger than 3 months of age and patients with cirrhosis or iron overload) or in patients with bone and joint infections.⁷⁹

Drugs of choice are not yet identified. Fluoroquinolones alone or in combination with third-generation cephalosporins or aminoglycosides may be effective for *Yersinia* bacteremia or for those with bone and joint infections.⁷⁹ Other antibiotics effective in vitro are chloramphenicol, tetracyclines, and trimethoprim-sulfamethoxazole. Agents frequently resistant to *Yersinia* are penicillin G, ampicillin, and first-generation cephalosporins.

ACUTE VIRAL GASTROENTERITIS

Acute viral gastroenteritis was unknown until the 1970s. Viruses are now recognized as the leading cause of diarrhea in the world, although in many cases an exact pathogen cannot be determined. In Asia, Africa, and Latin America, viral gastroenteritis accounts for an estimated 3 to 5 billion cases and is associated with 5 to 10 million deaths.⁸² Viruses that cause gastroenteritis include rotavirus, calicivirus, enteric adenovirus, and astrovirus. Other viruses, such as toroviruses, coronaviruses, picobirnaviruses, and pestiviruses, are being identified increasingly as causative agents of diarrhea.

fecal-oral route is thought to be the most common mode of transmission. Although infection is seen most often in children aged 3 to 24 months, adults can be infected and may act as a reservoir for transmission. Serologic surveys show that nearly all children are infected by age 4 years. Rotavirus infection rates peak from November to May each year. In the first 5 years of life, four of five children in the United States will develop diarrhea from a rotavirus infection.

PATHOGENESIS

Rotaviruses are double-stranded wheel-shaped RNA viruses. These strains cause diarrhea by infecting the enterocytes of the villi in the small intestine. Changes to the villi include shortening of villus height, crypt hyperplasia, and mononuclear cell infiltration of the lamina propria. Diarrhea results from decreased absorption across intestinal mucosal surface.⁸⁴

ROTAVIRUSES

EPIDEMIOLOGY

Rotavirus is the most important cause of diarrhea worldwide, and 1 million people die annually from the infection. In the United States, approximately 3.5 million cases of diarrhea, 500,000 physician visits, 50,000 hospitalizations, and 20 deaths occur each year in children younger than 5 years of age. In developing countries, almost all children younger than 5 years of age are infected with rotaviruses.⁸³ The

CLINICAL PRESENTATION

The rotavirus incubation period is less than 48 hours.⁸⁵ Clinical manifestations of rotavirus infections vary from asymptomatic (which is common in adults) to severe nausea, vomiting, and diarrhea with dehydration. The first infection tends to be the most severe. Symptoms are

characterized initially by nausea and vomiting (67% to 90%). Fever occurs in about two-thirds of children. Diarrhea occurs in most patients and lasts from 1 to 9 days. Other signs and symptoms include respiratory symptoms, irritability, lethargy, pharyngeal erythema, rhinitis, red tympanic membranes, and palpable cervical lymph nodes. Dehydration and electrolyte disturbances occur more frequently in children.

► TREATMENT: Rotavirus Infection

Oral fluid and electrolyte replacement is the cornerstone of treatment.⁸⁶ Oral *Lactobacillus* therapy may reduce the duration of diarrhea and of viral excretion. There is no role for antibiotics in acute infection. Bismuth subsalicylate, although shown to decrease the duration of diarrhea and stool output, is not recommended for routine use because of the self-limiting nature of the disease and the risk of bismuth subsalicylate overdose. Antimotility agents are not recommended because they have not been shown to decrease the duration or volume of diarrhea.

Laboratory findings reflect the degree of vomiting, diarrhea, or both. Transient rises in liver enzymes may be seen in 60% of children hospitalized for rotavirus diarrhea. The WBC count is usually normal. Stools rarely contain blood or leukocytes. Rotavirus detection in stool samples is possible with an enzyme immunoassay and a latex agglutination assay, both of which are available commercially.

The first vaccine (RotaShield) to prevent rotavirus infection was licensed for use in the United States in 1998, but it was withdrawn from the market after 1.5 million doses were administered owing to an increased rate of idiopathic intussusception.³² A number of rotavirus vaccines are under development, but the one that shows early promise is the rotavirus oral vaccine (Rotateq, Merck). This is a reassortant pentavalent vaccine with a backbone of bovine rotavirus and surface proteins of virus strains representing G types (G1–G4) and P1A. The preliminary results from the trial of 1946 healthy infants (aged 2 to 8 months) showed a level of protection of approximately 75%.⁸⁷

NORWALK AND NORWALK-LIKE AGENTS

The human caliciviruses are assigned to two genera, Norwalk-like virus and Sapporo-like viruses, responsible for gastroenteritis. The Norwalk-like viruses cause illness in all age groups, whereas Sapporo-like viruses cause illness mainly in children.⁸⁸ Although the relative importance of these viruses as causes of GI infections is unknown, Norwalk-like viruses are important causes of outbreaks. The Norwalk virus was the first of these agents to be described in 1972 in Norwalk, Ohio. Other viruses that are morphologically indistinguishable from Norwalk virus and thus belong in this family were named according to the location of the outbreak of illness or contaminated source, such as Norwalk, Hawaii, Montgomery County, Ditchling, Cockle, Paramatta, Snow Mountain, and Marin County.

As with most viruses, the epidemiology of the Norwalk-like organism is not well understood. The disease commonly affects children and adults, but it is not often associated with disease in neonates and preschool children.⁸⁹ Outbreaks occur throughout the year and have been documented in families, health care systems, cruise ships, and college dormitories. Norwalk-like viruses are often spread from person to person. Other vectors of transmission include contaminated water supplies, fecal-oral spread, and food-borne outbreaks. Almost any food that has come in contact with contaminated water can serve as a vehicle for an outbreak. A major source of food-borne gastroenteritis is contamination of shellfish beds from raw sewage dumped into the water supply.

The pathophysiology of this disease is similar to that caused by the rotavirus. Human volunteer studies show histopathologic changes in the jejunum within 24 hours of viral challenge, and clinical manifestations appear within 48 hours.⁸⁸ Brush-border enzyme activity may be decreased, resulting in lactose intolerance, but it generally returns to preinfection levels within 2 weeks. The exact mechanisms of virus-induced vomiting or diarrhea are unknown. Virus shedding in the stool can occur over the first 24 to 48 hours after illness.

Norwalk-like viral gastroenteritis is characterized by sudden onset of abdominal cramps with nausea, vomiting, or both.⁸⁹ Although adults frequently experience nonbloody diarrhea, and children experience vomiting more often than diarrhea. Other complaints are myalgias, headache, and malaise, which are accompanied by fever

in about 50% of patients. Signs and symptoms generally last 12 to 48 hours.⁷²

The disease is generally self-limiting. Oral fluid and electrolyte replacement should be used, if necessary.⁸⁹ An oral Norwalk virus vaccine produced via expression of viral antigens in plants is under investigation, but the clinical availability of such a product is several years in the future.

ASTROVIRUSES

Astroviruses are being recognized increasingly as important causes of gastroenteritis. Astroviral illness is often reported in children younger than 3 years of age, but it also been described in adults and elderly.⁹⁰ Astroviruses have been detected in the stools of children, as well as in patients with immunodeficiency conditions such as HIV infection or bone marrow transplantation. Transmission is suspected to occur via the fecal-oral route. Outbreaks have been reported in schools, day-care settings, and pediatric wards. The pathogenesis of astroviral infection is believed to be similar to that noted for rotavirus. The clinical presentation consists of diarrhea, headache, malaise, nausea, and to lesser extent, vomiting. These symptoms appear to be similar to those observed with rotavirus but milder. The incubation period is estimated to be 3 to 4 days, and the disease is usually self-limiting within 5 days. Maintenance of adequate hydration and electrolyte balance is the only therapeutic issue. The duration of viral shedding may be as long as 35 days.⁹¹

ENTERIC ADENOVIRUS

Adenovirus is an icosahedral virus previously associated with respiratory, ocular, and genitourinary infections; however, serotypes 40 and 41 have been identified as GI pathogens. The peak incidence is in children younger than 2 years of age, and infections occur year-round. Transmission is primarily person to person and fecal-oral, and viral shedding from the gut may occur for extended periods. The incubation time is 8 to 10 days. Diarrhea and vomiting often last 1 to 2 weeks. Low-grade fever and respiratory symptoms are also common.⁹² The diagnosis can be made by enzyme immunoassay that identifies serotypes.

TABLE 111-5. Agents Responsible for Acute Viral Gastroenteritis and Diarrhea

| Virus | Peak Age of Onset | Time of Year | Duration | Mode of Transmission | Symptoms |
|----------------------------|-------------------|-----------------------|----------|------------------------------|---|
| Rotavirus | 6 mo–2 yr | October to April | 3–8 days | Fecal-oral, water, food | Vomiting, diarrhea, fever, abdominal pain, lactose intolerance |
| Enteric adenovirus | <2 yr | Year-round | 7–9 days | Fecal-oral | Diarrhea, respiratory symptoms, vomiting, fever |
| <i>Calicivirus</i> | 3 mo–6 yr | Peak in winter | 4 days | Fecal-oral, water, shellfish | Vomiting, diarrhea |
| Astrovirus | <7 yr | Winter | 1–4 days | Fecal-oral, water, shellfish | Vomiting, diarrhea, fever, abdominal pain |
| Pestivirus | <2 yr | NR | 3 days | NR | Mild |
| Coronavirus-like particles | <2 yr | Fall and early winter | 7 days | NR | Respiratory disease |
| Enterovirus | NR | NR | NR | NR | Mild diarrhea, secondary organ damage |
| Norwalk | >5 yr | Variable | 12–24 h | Fecal-oral, food, aerosol | Nausea, vomiting, diarrhea, abdominal cramps, headache, fever, chills, myalgias |

NR = not reported.

Compiled from refs. 85, 91, and 92.

OTHER POTENTIAL VIRAL PATHOGENS

Although less commonly associated with severe GI disease, pestivirus, torovirus, and coronavirus-like particles have been recovered from diarrheal stools. In HIV-infected patients, the presence of diarrhea is associated with virus in 35% of stool specimens. Astrovirus, picobirnavirus, calicivirus, and adenovirus appear to be the most commonly isolated viral pathogens.^{92,93} Table 111-5 presents specific characteristics of these agents.

TRAVELER'S DIARRHEA

Traveler's diarrhea is identified by multiple names depending on where the disease occurs, but all describes the clinical syndrome manifested by malaise, anorexia, and abdominal cramps followed by the sudden onset of diarrhea that incapacitates many travelers.²⁵ In particular, an increased risk lies with North Americans and northern Europeans traveling to Latin America, southern Europe, Africa, and Asia. The highest risk is observed with patients with immunocompromised conditions, achlorhydria, or inflammatory bowel disease and people taking diuretics, digoxin, lithium, or insulin (because of the need for appropriate hydration). Overall, an estimated 20% to 50% of people traveling to high-risk areas will develop the illness.

5 The onset of symptoms usually occurs during the first 2 weeks of travel but can occur anytime during the visit or after returning home.¹⁰ The severity of the syndrome is determined by the number of stools per day and the presence or absence of cramping, nausea, and

vomiting. Traveler's diarrhea is rarely life-threatening and is caused by contaminated food or water. Foods at high risk for contamination include raw or undercooked meat and seafood and raw fruits and vegetables. Tap water, ice, and unpasteurized milk and dairy products may be associated with increased risk. The most common pathogens include ETEC (20% to 72%), *Shigella* (3% to 25%), *Campylobacter* (3% to 17%), *Salmonella* (3% to 7%), and viruses (0% to 30%).¹⁰

PROPHYLAXIS

6 Patient education in avoiding high-risk food and beverages may reduce the risk to less than 15%, even in endemic areas. Slogans such as "Peel it, boil it, cook it, or forget it" remind travelers to avoid contaminated food and to use water purification or reliable bottled beverages.⁹⁴ Bismuth subsalicylate 525 mg orally once to four times daily for up to 3 weeks is a commonly recommended prophylactic regimen. Bismuth subsalicylate may inhibit enterotoxin activity and prevent diarrhea. Although efficacy of prophylactic antibiotics have been documented, their uses are discouraged owing to the increased risk of selection of drug-resistant organisms, side effects of antibiotics (e.g., photosensitivity), and possible acquisition of more severe infections. Prophylactic antibiotics (see Table 111-3) are recommended only in high-risk individuals or in situations in which short-term illness could ruin the purpose of the trip.²⁵ Travelers to high-risk areas should pack a kit that includes a thermometer, loperamide, 3 days of antibiotics (see below), oral rehydration solution salts, and a water purification method.⁹⁴ No vaccines are currently marketed in United States, and those which are available and in development are ineffective.

TREATMENT: Traveler's Diarrhea

Fluid and electrolyte replacement should be initiated at the onset of diarrhea. (ORT generally is not required in healthy individuals; flavored mineral water offers a good source of sodium and glucose.^{10,25}) For symptom relief, loperamide (preferred because of its quicker onset and longer duration of relief relative to bismuth) should be taken (4 mg orally initially and then 2 mg with each subsequent loose stool to a maximum of 16 mg/day in patients without bloody diarrhea and discontinued if symptoms persist for over 48 hours). Other symptomatic

therapy includes bismuth subsalicylate 525 mg every 30 minutes up to 8 doses. Antibiotics (see Table 111-3) are recommended in addition to loperamide in moderate or severe diarrhea with systemic symptoms. Currently, the drug of choice is a fluoroquinolone. In pregnant women and children younger than 16 years of age, a combination of trimethoprim-sulfamethoxazole and erythromycin has been suggested. Macrolides are the drugs of choices only in areas of high prevalence of *Campylobacter* species resistant to quinolones, such as Thailand.

FOOD POISONING

7 Food poisoning results from the ingestion of food containing pathogenic microorganisms, preformed toxins that were produced by microorganisms, or other toxic compounds. In the United States, food-borne disease causes approximately 76 million illnesses, 325,000 hospitalizations, and 5200 deaths each year.⁶ Food-borne transmission may account for up to 35% of acute gastroenteritis cases caused by unknown agents. A number of bacteria can cause food poisoning (Table 111–6). Common bacterial (*Campylobacter*, *Salmonella*, *Shigella*, *E. coli*, *Yersinia*, *Vibrio*) and viral (Norwalk-like virus) causes of GI infections have been discussed in the preceding sections. Other common food-borne pathogens that cause gastroenteritis include *S. aureus*, *Bacillus cereus*, *C. perfringens*, and *C. botulinum*. Unfortunately, sporadic illness caused by these pathogens is not reportable through passive or active systems, and thus it is difficult to determine their disease burden.

Since food-borne disease can appear as sporadic cases or outbreaks, the diagnosis should be suspected whenever two or more people present with acute gastrointestinal or neurologic manifestations after sharing a meal within the previous 72 hours. Important clues about etiologic agents can be gathered from demographic information (age, gender, etc.), the clinical syndrome, incubation period, medical history, type of foods consumed, seasonality, and geographic location of the outbreak.

Staphylococcal food poisoning results from the ingestion of food contaminated by an enterotoxin produced by certain strains of *S. au-*

reus growing within the food.⁹⁵ Enterotoxin production generally results from leaving foods at room temperature, allowing the staphylococci to grow. Symptoms are rapid in onset, generally occurring within 1 to 6 hours of ingestion of preformed toxin-containing foods. The condition is characterized by nausea and vomiting (75%), although abdominal cramps and diarrhea also may be present. Symptoms resolve in less than 12 hours. ORT should be provided in severe cases, but antibiotics are not indicated.

B. cereus causes two different types of clinical syndromes.⁹⁶ The first one is characterized by a short incubation period with vomiting, abdominal cramps, and to a lesser extent, diarrhea within 1 to 6 hours of ingestion of contaminated food. This syndrome is caused by a preformed heat-stable toxin. Similar to staphylococcal food poisoning, illnesses caused by *B. cereus* usually last less than 12 hours. The second syndrome has a longer incubation period (8–16 hours) and is caused by toxins produced *in vivo* after the ingestion of contaminated food. In this syndrome, patients experience diarrhea, abdominal cramps, and less frequently, vomiting. The heat-labile enterotoxin produced in this syndrome activates intestinal adenylate cyclase and causes intestinal fluid secretion. This illness usually resolves within 24 hours, but symptom durations of several days to weeks also have been observed.

Food-borne *C. perfringens* infection may present as two distinct syndromes.⁹⁷ Type A organisms are seen in Western nations and result in a 24-hour illness characterized by watery diarrhea and epigastric pain. Symptoms generally resolve within 24 hours. This enterotoxin-related syndrome damages the brush borders of epithelial cells at the

TABLE 111–6. Food Poisonings

| Organism | Time to Symptoms (h) | Principal Foods | Peak Incidence (U.S.A) | Principal Mechanism of Pathophysiology | Duration | Treatment |
|---|----------------------|--|------------------------|--|----------|---|
| <i>Staphylococcus aureus</i> | 1–6 | Salad, pastries, ham, poultry | Summer | Preformed toxins A–E (heat stable) | 12 h | Supportive |
| <i>Bacillus cereus</i> | 1–6 | Meats, vegetables, fried rice | None | Preformed toxin | 12 h | Supportive |
| | 8–16 | | | Toxin production (<i>in vivo</i>) | 24 h | Supportive |
| <i>Clostridium perfringens</i> (type A) | 6–24 | Meats, poultry | Fall, winter, spring | Toxin production (<i>in vivo</i>) | 24 h | Supportive |
| <i>Vibrio parahaemolyticus</i> | 16–72 | Shellfish | Spring, summer, fall | Toxin production and tissue invasion | 2–7 day | Supportive |
| <i>Salmonella</i> spp. | 16–48 | Beef, poultry, water, eggs, dairy products | Summer | Tissue invasion | 2–7 day | Supportive |
| <i>Shigella</i> spp. | 16–48 | Salad, water | Summer | Tissue invasion | 2–7 day | Supportive |
| EPEC | 16–48 | Water | None | Tissue invasion | 2–7 day | Supportive |
| <i>Campylobacter</i> | 16–48 | Poultry, dairy products, clams, water | Spring, summer | Tissue invasion | 2–7 day | Supportive |
| ETEC | 16–72 | Water | None | Toxin production (<i>in vivo</i>) | 1–7 day | Supportive |
| <i>Vibrio cholerae</i> | 16–72 | Water | | Toxin production (<i>in vivo</i>) | 2–12 day | Supportive, antibiotics |
| <i>Yersinia enterocolitica</i> | 16–48 | Dairy products | | Toxin production and/or tissue invasion | 1–30 day | Supportive |
| <i>Clostridium botulinum</i> | 12–72 | Canned fruits, vegetables, meats, honey | None | Preformed toxins A, B, and E (children and adults) | | Supportive (including mechanically assisted ventilation) Trivalent antitoxin |
| | | | | Toxin production (<i>in vivo</i>) (infants) | | |

EPEC = enteropathogenic *E. coli*; ETEC = enterotoxigenic *E. coli*.

villus tips to cause a noninflammatory diarrhea. Type C organisms can be found in undercooked pork and occur in underdeveloped tropical regions. Type C organisms can produce a toxin-related syndrome called *enteritis necroticans*, which is a coagulative transmural necrosis of the intestinal wall. This syndrome can result in intestinal perforation leading to sepsis and mortality in approximately 40% of victims.

Food-borne botulism results from the ingestion of food contaminated with preformed toxins or toxin-producing spores from *C. botulinum*. *C. botulinum* poisoning is relatively rare; only 110 cases are reported per year in the United States. Botulism is almost always associated with improper preparation or storage of food. Seven distinct toxins (A to G) have been described. The toxins, which are produced by the bacteria and released on lysis, are the most potent biologic or chemical toxins known to humans. The toxin prevents the release of acetylcholine at the peripheral cholinergic nerve terminal. Toxin activity has prompted the use of minute locally injected doses to treat select spastic disorders, such as blepharospasm, hemifacial spasm, and certain dystonias.⁹⁸

Food-borne botulism is suspected when patients present with acute GI symptoms concurrently or just prior to the onset of a symmetric descending paralysis without sensory or central nervous system involvement. Symptoms usually begin 18 to 24 hours after ingestion and progress over days to weeks. Other symptoms can include blurred vision, photophobia (90%), dysphagia (76%), generalized weakness (58%), nausea and vomiting (56%), and dysphonia (55%). Diagnosis is made by culturing *C. botulinum* from the stool. Guillain-Barré syndrome associated with *C. jejuni* infection has been a common differential diagnosis in patients who present with these symptoms. The difference lies in the onset of neurologic symptoms, which typically occur 1 to 3 weeks after the onset of *C. jejuni* infection, and the condition usually is manifested by an ascending paralysis in *C. jejuni*-associated Guillain-Barré syndrome.⁷⁷

Treatment consists primarily of respiratory support and use of botulinum antitoxin.⁹⁹ Respiratory failure may occur prior to involvement of other upper muscle groups. If evaluation is performed within several hours of ingestion, gastric lavage or induction of vomiting is suggested. Cathartics and enemas also can be used to remove residual toxin from the bowel, but they are contraindicated in cases of ileus. Although the effectiveness of antitoxins is unknown, patients diagnosed with botulism should receive botulinum antitoxin. Botulinum antitoxin is a concentrated preparation of equine globulins obtained from horses immunized with toxins A, B, and E. Because trivalent antitoxin is equine in origin, patients should be tested for hypersensitivity before receiving the product intravenously. Other agents used experimentally as adjunctive therapy are guanidine, which antagonizes the effect of botulinum toxin at the neuromuscular junction, and 4-aminopyridine, which increases acetylcholine release.¹⁰⁰ Newer and more effective methods of treatment and prevention are under development, including a botulinum toxin vaccine consisting of nontoxic botulinum fragments. Prevention always should be stressed. Botulinum toxins are heat labile and readily destroyed by 10 minutes of boiling. All home-canned foods should be processed according to directions and boiled, not just warmed, prior to consumption.

In food-borne illnesses, the cornerstone of therapy remains supportive care. ORT is preferred in replenishing and maintaining fluid and electrolyte balance, and intravenous fluid therapy should be reserved for those who are severely ill and cannot tolerate oral therapy. Antiemetics and antiperistaltic agents offer symptomatic relief, but the latter should not be given in patients who present with high fever, bloody diarrhea, or fecal leukocytes. Antimicrobial therapy is not effective in the management of *S. aureus*, *C. perfringens*, or *B. cereus* food poisonings. In developed countries, many of the food-borne ill-

ness can be prevented with proper food selection, preparation, and storage. However, in developing countries, sanitation and clean water supply are larger concerns.

INTRAABDOMINAL INFECTIONS

Joseph T. DiPiro and Thomas R. Howdieshell

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Most intraabdominal infections are “secondary” infections that are caused by a defect in the gastrointestinal tract that must be treated by surgical drainage, resection, and/or repair.
- 2 Primary peritonitis generally is caused by a single organism (*Staphylococcus aureus* in patients undergoing chronic ambulatory peritoneal dialysis [CAPD] or *Escherichia coli* in patients with cirrhosis).
- 3 Secondary intraabdominal infections usually are caused by a mixture of enteric gram-negative bacilli and anaerobes. This mix of organisms enhances the pathogenic potential of the bacteria.
- 4 For peritonitis, early and aggressive intravenous fluid resuscitation and electrolyte replacement therapy are essential. A common cause of early death is hypovolemic shock caused by inadequate intravascular volume and tissue perfusion.
- 5 Cultures of secondary intraabdominal infection sites generally are not useful for directing antimicrobial therapy. Treatment generally is initiated on a “presumptive” or empirical basis.
- 6 Antimicrobial regimens for secondary intraabdominal infections should include coverage for enteric gram-negative bacilli and anaerobes. Antimicrobials that may be used for the treatment of secondary intraabdominal infections include (a) a β -lactam/ β -lactamase inhibitor combination, (b) a carbapenem, (c) quinolone plus metronidazole, or an aminoglycoside plus clindamycin (or metronidazole).
- 7 Treatment of primary peritonitis for CAPD patients should include an antistaphylococcal antimicrobial such as a first-generation cephalosporin or vancomycin (usually given by the intraperitoneal route).
- 8 The duration of antimicrobial treatment should be for a total of 5 to 7 days for most intraabdominal infections.
- 9 Patients treated for intraabdominal infections should be assessed for the occurrence of drug-related adverse effects, particularly hypersensitivity reactions (β -lactam antimicrobials), diarrhea (most agents), fungal infections (most agents), and nephrotoxicity (aminoglycosides).

Intraabdominal infections are those contained within the peritoneal cavity or retroperitoneal space. The peritoneal cavity extends from the undersurface of the diaphragm to the floor of the pelvis and contains the stomach, small bowel, large bowel, liver, gallbladder, and spleen. The duodenum, pancreas, kidneys, adrenal glands, great vessels (aorta and vena cava), and most mesenteric vascular structures reside in the retroperitoneum. Intraabdominal infections may be generalized or localized. They may be contained within visceral structures, such as the liver, gallbladder, spleen, pancreas, kidney, or female reproductive organs. Two general types of intraabdominal infection are discussed throughout this chapter: peritonitis and abscess. *Peritonitis* is defined as the acute inflammatory response of the peritoneal lining to microorganisms, chemicals, irradiation, or foreign-body injury. This chapter deals only with peritonitis of infectious origin.

An *abscess* is a purulent collection of fluid separated from surrounding tissue by a wall consisting of inflammatory cells and adjacent organs. It usually contains necrotic debris, bacteria, and inflammatory cells. These processes differ considerably in presentation and approach to treatment.

EPIDEMIOLOGY

Peritonitis may be classified as primary, secondary, or tertiary. Primary peritonitis, also called *spontaneous bacterial peritonitis*, is an infection of the peritoneal cavity without an evident source in the abdomen.^{1,2} Bacteria may be transported from the bloodstream to the peritoneal cavity, where the inflammatory process begins. In secondary peritonitis, a focal disease process is evident within the abdomen. Secondary peritonitis may involve perforation of the gastrointestinal (GI) tract (possibly because of ulceration, ischemia, or obstruction), postoperative peritonitis, or posttraumatic peritonitis (blunt or penetrating trauma). Tertiary peritonitis occurs in critically ill patients and is infection that persists or recurs at least 48 hours after apparently adequate management of primary or secondary peritonitis.

1 Primary peritonitis develops in up to 25% of patients with alcoholic cirrhosis.³ Patients undergoing chronic ambulatory peritoneal dialysis (CAPD) average one episode of peritonitis every 2 years.⁴ Epidemiologic data for secondary and tertiary intraabdominal infections are limited. Secondary peritonitis may be caused by

perforation of a peptic ulcer; traumatic perforation of the stomach, small or large bowel, uterus, or urinary bladder; appendicitis; pancreatitis; diverticulitis; bowel infarction; inflammatory bowel disease, cholecystitis; operative contamination of the peritoneum; or diseases of the female genital tract such as septic abortion, postoperative uterine infection, endometritis, or salpingitis. Appendicitis is one of the most common causes of intraabdominal infection. In 1998, 278,000 appendectomies were performed in the United States for suspected appendicitis.⁵

ETIOLOGY

Primary peritonitis in adults occurs most commonly in association with alcoholic cirrhosis, especially in its end stage, or with ascites caused by postnecrotic cirrhosis, chronic active hepatitis, acute viral hepatitis, congestive heart failure, malignancy, systemic lupus erythematosus, or nephritic syndrome. It also may result from the use of a peritoneal catheter for dialysis or central nervous system ventriculoperitoneal shunting for hydrocephalus. Rarely, primary peritonitis occurs without apparent underlying disease.

Table 112–1 summarizes many of the potential causes of bacterial peritonitis. These include inflammatory processes of the GI tract or abdominal organs, bowel obstruction, vascular occlusions that may lead to gangrene of the intestines, and neoplasia that may cause intestinal perforation or obstruction. Other possible causes include those resulting from traumatic injuries or postoperative infections.

Abscesses are the result of chronic inflammation and may occur without preceding generalized peritonitis. They may be located within one of the spaces of the peritoneal cavity or within one of the visceral organs and may range from a few milliliters to a liter or more in volume. These collections often have a fibrinous capsule and may take from a few weeks to years to form.

The causes of intraabdominal abscess overlap those of peritonitis and, in fact, may occur sequentially or simultaneously. Appendicitis is the most frequent cause of abscess. Other potential causes of intraabdominal abscess include pancreatitis, diverticulitis, lesions of the biliary tract, genitourinary tract infections, perforating tumors in the abdomen, trauma, and leaking intestinal anastomoses. In addition, pelvic inflammatory disease in women may lead to tuboovarian abscess. For certain diseases, such as appendicitis and diverticulitis, abscesses occur more frequently than generalized peritonitis.

TABLE 112–1. Causes of Bacterial Peritonitis

| | |
|---|--|
| Primary Bacterial Peritonitis | |
| Peritoneal dialysis | |
| Cirrhosis with ascites | |
| Nephrotic syndrome | |
| Secondary Bacterial Peritonitis | |
| Miscellaneous causes | |
| Diverticulitis | |
| Appendicitis | |
| Inflammatory bowel diseases | |
| Salpingitis | |
| Biliary tract infections | |
| Necrotizing pancreatitis | |
| Neoplasms | |
| Intestinal obstruction | |
| Perforation | |
| Mechanical gastrointestinal problems | |
| Any cause of small bowel obstruction (adhesions, hernia) | |
| Vascular causes | |
| Mesenteric arterial or venous occlusion (atrial fibrillation) | |
| Mesenteric ischemia without occlusion | |
| Trauma | |
| Blunt abdominal trauma with rupture of intestine | |
| Penetrating abdominal trauma | |
| Iatrogenic intestinal perforation (endoscopy) | |
| Intraoperative events | |
| Peritoneal contamination during abdominal operation | |
| Leakage from gastrointestinal anastomosis | |

MICROFLORA OF THE GASTROINTESTINAL TRACT AND FEMALE GENITAL TRACT

A full appreciation of intraabdominal infection requires an understanding of the normal microflora within the GI tract. There are striking differences in bacterial species and concentrations of flora within the various segments of the GI tract (Table 112–2), and this bacterial environment usually determines the severity of infectious processes in the abdomen. Generally, the low gastric pH eradicates bacteria that enter the stomach. With achlorhydria, bacterial counts may rise to 10⁵ to 10⁷ organisms per milliliter. The normally low bacterial count also may increase by 1000- or 10,000-fold with gastric outlet obstruction, hemorrhage, gastric cancer, and in patients receiving histamine 2 (H₂)-receptor antagonists, proton pump inhibitors, or antacids.

TABLE 112–2. Usual Microflora of the Gastrointestinal Tract

| Site | Commonly Found Bacteria | Approximate Concentration (Log No. Organisms/mL) | |
|----------------------|--|--|-----------------------------------|
| | | Aerobes | Anaerobes |
| Stomach ^a | <i>Streptococcus</i> , <i>Lactobacillus</i> | 10–100 | Rare |
| Biliary tract | Normally sterile (<i>Escherichia coli</i> , <i>Klebsiella</i> , or enterococci in some patients) | 0 | 0 |
| Proximal small bowel | <i>Streptococcus</i> (including enterococci), <i>E. coli</i> , <i>Klebsiella</i> , <i>Lactobacillus</i> , diphtheroids | 100 | Few |
| Distal ileum | <i>E. coli</i> , <i>Klebsiella</i> , <i>Enterobacter</i> , enterococci, <i>Bacteroides fragilis</i> , <i>Clostridium</i> , peptostreptococci | 10 ⁴ –10 ⁶ | 10 ⁵ –10 ⁷ |
| Colon | <i>Bacteroides</i> spp., peptostreptococci, <i>Clostridium</i> , <i>E. coli</i> , <i>Klebsiella</i> , enterococci, <i>Enterobacter</i> , and many others | 10 ⁵ –10 ⁸ | 10 ⁹ –10 ¹¹ |

^aWith achlorhydria, H₂-antagonist therapy, gastric cancer, or gastric outlet obstruction, bacterial counts may rise to 10⁵/mL.

The biliary tract (gallbladder and bile ducts) is sterile in most healthy individuals, but in certain groups (age greater than 70 years, acute cholecystitis, jaundice, or common bile duct stones), it is likely to be colonized by aerobic gram-negative bacilli (particularly *Escherichia coli* and *Klebsiella* spp.) and enterococci.⁶ Patients with biliary tract bacterial colonization are at greater risk of intraabdominal infection.

In the distal ileum, bacterial counts of aerobes and anaerobes are quite high. In the colon, there may be 400 to 500 different types of bacteria, with concentrations often reaching 10^{11} organisms per milliliter and anaerobic bacteria outnumbering aerobic bacteria by more than 1000 to 1. In fact, up to 50% of the dry mass of stool is bacteria. Fortunately, most colonic bacteria are not pathogens because they cannot survive in environments outside the colon. Perforation of the colon results in the release of large numbers of anaerobic and aerobic bacteria into the peritoneum. The colonic flora generally are consistent unless broad-spectrum antimicrobials have been used, in which case there are increases in *Candida* or gram-negative bacteria.

The lower female genital tract generally is colonized by a large number of aerobic and anaerobic bacteria. Anaerobes may number 10^9 organisms per milliliter and often include lactobacilli, eubacteria, clostridia, anaerobic streptococci, and less frequently, *Bacteroides fragilis*. Aerobic bacteria most often are streptococci and *Staphylococcus epidermidis*, and these may number 10^8 organisms per milliliter.

PATHOPHYSIOLOGY

Intraabdominal infection results from bacterial entry into the peritoneal or retroperitoneal spaces or from bacterial collections within intraabdominal organs. In primary peritonitis, bacteria may enter the abdomen via the bloodstream or the lymphatic system by transmigration through the bowel wall, through an indwelling peritoneal dialysis catheter, or via the fallopian tubes in females. Hematogenous bacterial spread (through the bloodstream) occurs more frequently with tuberculosis peritonitis or peritonitis associated with cirrhotic ascites. When peritonitis results from peritoneal dialysis, skin surface flora are introduced via the peritoneal catheter.⁷ In secondary peritonitis, bacteria most often enter the peritoneum or retroperitoneum as a result of perforation of the GI or female genital tracts caused by diseases or traumatic injuries. Also, peritonitis or abscess may result from contamination of the peritoneum during a surgical procedure or following anastomotic leak.

The physiologic characteristics of the peritoneal cavity determine the nature of the response to infection or inflammation within it. The peritoneum is lined by a highly permeable serous membrane with a surface area approximately that of skin. The peritoneal cavity is lubricated with less than 100 mL of sterile, clear yellow fluid, normally with fewer than 300 cells/mm³, a specific gravity below 1.016, and protein content below 3 g/dL. These conditions change drastically with peritoneal infection or inflammation, as described below.

After bacteria are introduced into the peritoneal cavity, there is an immediate response to contain the insult. Humoral and cellular defenses respond first; then the omentum adheres to the affected area. A limited bacterial inoculum is handled rapidly by defense mechanisms, including complement activation. Under certain conditions, the bacterial insult is not contained, and bacteria disseminate throughout the peritoneal cavity, resulting in peritonitis. This is more likely to occur in the presence of a foreign body, hematoma, dead tissue, a large bacterial inoculum, continuing bacterial contamination, and contamination involving a mixture of synergistic organisms. Protein-calorie

malnutrition, antecedent steroid therapy, and diabetes mellitus also may contribute to the formation of an intraabdominal abscess.

When bacteria become dispersed throughout the peritoneum, the inflammatory process involves most of the peritoneal lining. There is an outpouring into the peritoneum of fluid containing leukocytes, fibrin, and other proteins that form exudates on the inflamed peritoneal surfaces and begin to form adhesions between peritoneal structures. This process, combined with a paralysis of the intestines (ileus), may result in confinement of the contamination to one or more locations within the peritoneum. Fluid also begins to collect in the bowel lumen and wall, and distension may result.

The fluid and protein shift into the abdomen (called *third-spacing*) may be so dramatic that circulating blood volume is decreased, which causes decreased cardiac output and hypovolemic shock. Accompanying fever, vomiting, or diarrhea may worsen the fluid imbalance. A reflex sympathetic response, manifested by sweating, tachycardia, and vasoconstriction, may be evident. With an inflamed peritoneum, bacteria and endotoxins are absorbed easily into the bloodstream (translocation), and this may result in septic shock. Other foreign substances present in the peritoneal cavity potentiate peritonitis. These adjuvants, notably feces, dead tissues, barium, mucus, bile, and blood, have detrimental effects on host defense mechanisms, particularly on bacterial phagocytosis.

Many of the manifestations of intraabdominal infections, particularly peritonitis, result from cytokine activity. Inflammatory cytokines, such as tumor necrosis factor α (TNF- α), interleukin 1 (IL-1), IL-6, IL-8, and interferon- γ (INF- γ), are produced by macrophages and neutrophils in response to bacteria and bacterial products or in response to tissue injury resulting from the surgical incision.⁸ These cytokines produce wide-ranging effects on the endothelium of organs, particularly the liver, lungs, kidneys, and heart. With uncontrolled activation of these mediators, sepsis may result⁹ (see Chap. 117).

Peritonitis may result in death because of the effects on major organ systems. Fluid shifts and endotoxin may result in hypovolemic and septic shock. Hypoalbuminemia may result from protein loss into the peritoneum exacerbating intravascular volume loss. Pulmonary function may be compromised by the inflamed peritoneum producing splinting (muscle rigidity caused by pain) that inhibits adequate diaphragmatic movement leading to atelectasis and pneumonia. Increased kung vascular permeability and resulting shunting of blood may induce onset of the respiratory distress syndrome and associated hypoxemia and hypercarbia. With fluid loss, hypotension, endotoxemia, and renal and hepatic perfusion may be compromised, and acute renal and hepatic failure are potential threats.

If peritoneal contamination is localized but bacterial elimination is incomplete, an abscess results. This collection of necrotic tissue, bacteria, and white blood cells (WBCs) may be at single or multiple sites and may be within one of the spaces of the peritoneal cavity or in one of the visceral organs. The location of the abscess often is related to the site of primary disease. For example, abscesses resulting from appendicitis tend to appear in the right lower quadrant or the pelvis; those resulting from diverticulitis tend to appear in the left lower quadrant or pelvis.

An abscess begins by the combined action of inflammatory cells (such as neutrophils), bacteria, fibrin, and other inflammatory mediators. Bacteria may release heparinases that cause local thrombosis and tissue necrosis or fibrinolysins, collagenases, or other enzymes that allow extension of the process into surrounding tissues. Neutrophils gathered in the abscess cavity die in 3 to 5 days, releasing lysosomal enzymes that liquefy the core of the abscess. A mature abscess may have a fibrinous capsule that isolates bacteria and the liquid core from antimicrobials and immunologic defenses.

Within the abscess, the oxygen tension is low, and anaerobic bacteria thrive, and thus the size of the abscess may increase because it is hypertonic, resulting in an additional influx of fluid. Hypertonicity promotes the formation of bacterial L forms, which are resistant to antimicrobial agents that disrupt cell walls. Abscess formation may continue and mature for long periods of time and may not be readily evident to either patient or physician. In some instances, the abscess may resolve spontaneously, and infrequently, it may erode into adjacent organs or rupture and cause diffuse peritonitis. If the abscess erodes through the skin, it may result in an enterocutaneous fistula, connecting bowel to skin, or in a draining sinus tract.

MICROBIOLOGY OF INTRAABDOMINAL INFECTION

Primary bacterial peritonitis often is caused by a single organism. In children, the pathogen is usually *Streptococcus pneumoniae* or a group A *Streptococcus*.⁴ When peritonitis occurs in association with cirrhotic ascites, *Escherichia coli* is isolated most frequently. Other potential pathogens are: *Hemophilus pneumoniae*, *Klebsiella*, *Pseudomonas*, anaerobes, and *S. pneumoniae*.¹⁰ Occasionally, primary peritonitis may be caused by *Mycobacterium tuberculosis*. Peritonitis in patients undergoing peritoneal dialysis is caused most often by common skin organisms, such as *S. epidermidis*, *Staphylococcus aureus*, streptococci, and diphtheroids. Occasionally, aerobic gram-negative bacilli may cause infections, particularly in patients undergoing dialysis during hospitalization. Mortality from primary peritonitis caused by gram-negative bacteria is much greater than that from gram-positive bacteria.¹¹

Because of the diverse bacteria present in the GI tract, secondary intraabdominal infections often are polymicrobial.¹³ The mean number of different bacterial species isolated from infected intraabdominal sites ranged from 2.9 to 3.7, including an average of 1.3 to 1.6 aerobes and 1.7 to 2.1 anaerobes.^{14,15} With proper anaerobic specimen collection, anaerobic organisms are isolated in most patients. In one report of patients with gangrenous and perforated appendicitis, an average of 10.2 different organisms was isolated from each patient, including 2.7 aerobes and 7.5 anaerobes.¹⁶ Purely aerobic or anaerobic infections are uncommon, as are infections caused by fungi. The frequencies with which specific bacteria were isolated from patients with peritonitis are given in Table 112–3.¹⁷ *E. coli*, *Streptococcus* spp., and *Bacteroides* spp. were isolated most often from the infection site, as well as from blood cultures. In patients diagnosed with severe infections, the pattern of bacterial isolates may change and

TABLE 112–3. Pathogens Isolated from Patients with Secondary Peritonitis

| | |
|-------------------------------|--------|
| Gram-Negative Bacteria | |
| <i>E. coli</i> | 32–61% |
| <i>Enterobacter</i> | 8–26% |
| <i>Klebsiella</i> | 6–26% |
| <i>Proteus</i> | 4–23% |
| Gram-Positive Bacteria | |
| Enterococci | 18–24% |
| Streptococci | 6–55% |
| Staphylococci | 6–16% |
| Anaerobic Bacteria | |
| <i>Bacteroides</i> | 25–80% |
| <i>Clostridium</i> | 5–18% |
| Fungi | 2–5% |

Adapted from ref. 2.

commonly includes *Candida*, enterococci, Enterobacteriaceae, and *S. epidermidis*.

Visceral abscesses differ in character from the typical intraabdominal abscess. Hepatic abscesses may be polymicrobial (involving *E. coli* and anaerobes) or occasionally may be caused by amoeba. Pancreatic abscesses are often polymicrobial, involving enteric bacteria that ascend through the biliary system. Splenic abscesses usually result from hematogenous dissemination of bacteria, such as *S. aureus*, streptococci, and occasionally, *Salmonella* or anaerobic organisms. Pelvic inflammatory disease is associated initially with *Neisseria gonorrhoeae* or *Chlamydia trachomatis*. However, tuboovarian abscesses usually are polymicrobial, having a mix of gram-positive and gram-negative aerobes and anaerobes.

BACTERIAL SYNERGISM

The size of the bacterial inoculum and the number and types of bacterial species present in intraabdominal infections influence patient outcome. The combination of aerobic and anaerobic organisms appears to increase the severity of infection greatly. In animal studies, combinations of aerobic and anaerobic bacteria were much more lethal than infections caused by aerobes or anaerobes alone.

Facultative bacteria may provide an environment conducive to the growth of anaerobic bacteria.¹³ Although many bacteria isolated in mixed infections are nonpathogenic by themselves, their presence may be essential for the pathogenicity of the bacterial mixture.³ The role of facultative bacteria in mixed infections can include (1) promotion of an appropriate environment for anaerobic growth through oxygen consumption, (2) production of nutrients necessary for anaerobes, and (3) production of extracellular enzymes that promote tissue invasion by anaerobes.

Rat models of intraabdominal infection demonstrate that uncontrolled infection with an implanted mix of aerobes and anaerobes leads to a two-stage infectious process. There is an early peritonitis phase with a high mortality rate and isolation of *E. coli* from blood and a late abscess formation phase in all survivors with isolation of anaerobes such as *B. fragilis* and *Fusobacterium varium*. These experiments and others support the concept that aerobic enteric organisms and anaerobes are pathogens in intraabdominal infection. Aerobic bacteria, particularly *E. coli*, appear responsible for the early mortality from peritonitis, whereas anaerobic bacteria are major pathogens in abscesses, with *B. fragilis* predominating.¹⁸

Enterococcus can be isolated from many intraabdominal infections in humans, but its role as a pathogen is not clear.¹⁹ Enterococcal infection occurs more commonly in postoperative peritonitis, in the presence of specific risk factors indicating failure of the host's defenses (immunocompromised patients), or with the use of broad-spectrum antibiotics.^{20,21}

CLINICAL PRESENTATION

Intraabdominal infections have a wide spectrum of clinical features often depending on the specific disease process, the location and magnitude of bacterial contamination, and concurrent host factors. Peritonitis usually is recognized easily, but intraabdominal abscess often may continue for considerable periods of time, either going unrecognized or being attributed to an unrelated disease process. Patients with primary and secondary peritonitis present quite differently (Table 112–4).

Primary peritonitis can develop over a period of days to weeks and usually is a more indolent process than secondary peritonitis. The

TABLE 112-4. Clinical Presentation of Peritonitis

| <i>Primary Peritonitis</i> |
|---|
| General |
| The patient may not be in acute distress, particularly with peritoneal dialysis. |
| Signs and Symptoms |
| The patient may complain of nausea, vomiting (sometimes with diarrhea), and abdominal tenderness. |
| Temperature may be only mildly elevated or not elevated in patients undergoing peritoneal dialysis. |
| Bowel sounds are hypoactive. |
| The cirrhotic patient may have worsening encephalopathy. |
| Cloudy dialysate fluid with peritoneal dialysis. |
| Laboratory Tests |
| The patient's WBC count may be only mildly elevated. |
| Ascitic fluid usually contains greater than 300 leukocytes/mm ³ , and bacteria may be evident on Gram stain of a centrifuged specimen. |
| In 60% to 80% of patients with cirrhotic ascites, the Gram stain is negative. |
| Other Diagnostic Tests |
| Culture of peritoneal dialysate or ascitic fluid should be positive. |
| <i>Secondary Peritonitis</i> |
| Signs and Symptoms |
| Generalized abdominal pain. |
| Tachypnea. |
| Tachycardia. |
| Nausea and vomiting. |
| Temperature normal initially then increasing to 100 to 102°F (37.7 to 38.8°C) within the first few hours and may continue to rise for the next several hours. |
| Hypotension and shock if volume is not restored. |
| Decreased urine output due to dehydration. |
| Physical Examination |
| Voluntary abdominal guarding changing to involuntary guarding and a "board-like abdomen." |
| Abdominal tenderness and distension. |
| Faint bowel sounds that cease over time. |
| Laboratory Tests |
| Leukocytosis (15,000–20,000 WBC/mm ³ , with neutrophils predominating and an elevated percentage of immature neutrophils (bands). |
| Elevated hematocrit and blood urea nitrogen because of dehydration. |
| Patient progresses from early alkalosis because of hyperventilation and vomiting to acidosis and lactic acidemia. |
| Other Diagnostic Tests |
| Abdominal radiographs may be useful because free air in the abdomen (indicating intestinal perforation) or distension of the small or large bowel is often evident. |

first sign of peritonitis may be a cloudy dialysate in patients undergoing peritoneal dialysis or worsening encephalopathy in a cirrhotic patient.

The patient with generalized bacterial peritonitis presents most often in acute distress. The patient lies still, usually on his or her back, possibly with hips slightly flexed. Any movement of the patient, including rocking the bed or breathing, worsens the generalized abdominal pain.

If peritonitis continues untreated, the patient may experience hypovolemic shock from third-space fluid loss into the peritoneum, bowel wall, and lumen. This may be accompanied by sepsis because the inflamed peritoneum absorbs bacteria and toxins into mesenteric blood vessels and lymph nodes, initiating production of inflammatory

cytokines. Hypovolemic shock is the major factor contributing to mortality in the early stage of peritonitis.

Intraabdominal abscess may pose a difficult diagnostic challenge because the symptoms are neither specific nor dramatic. The patient may complain of abdominal pain or discomfort, but these symptoms are not reliable. Fever usually is present; often it is low grade, but it may be high, with a spiking pattern. The patient may have a paralytic ileus and abdominal distension. The abdominal examination is unreliable; tenderness and pain may be present, and a mass may be palpated.

Peritonitis may result from an abscess that ruptures, spreading bacteria and toxins throughout the peritoneum. In other patients, the entry of bacterial toxins into the systemic circulation from the abscess may lead to sepsis and progressive multisystem organ failure (e.g., renal, hepatic, pulmonary, or cardiovascular).

Laboratory studies generally are not helpful in the diagnosis of intraabdominal abscess, although most patients will have leukocytosis. Some patients may have positive blood cultures, whereas others, particularly diabetics, may have hyperglycemia. The finding of *Bacteroides* or any two enteric bacteria in the bloodstream is often indicative of an intraabdominal infectious process.

Radiographic methods are used to make the diagnosis of an intraabdominal abscess. Plain radiographs may show air-fluid levels or a shift of normal intraabdominal contents by the abscess mass. GI contrast studies also may demonstrate this displacement of abdominal structures. Both these modalities provide indirect evidence of abscess presence but are not generally helpful in precisely locating the abscess.

Ultrasound is a frequent first diagnostic method used when an intraabdominal abscess is suspected. The procedure may be done at the bedside, which is particularly helpful in the patient in the intensive care unit. In some patients, particularly the obese, it is technically difficult to perform and interpret the examination.²²

Computed tomographic (CT) scan is used frequently to evaluate the abdomen for the presence of an abscess and is the imaging modality of greatest value. An oral radiocontrast agent should be given to allow differentiation of the abscess from the bowel. Intravenous radiocontrast material will be taken up preferentially in the wall of the abscess, creating a unique radiographic appearance, so-called rim enhancement.

Magnetic resonance imaging (MRI) is used infrequently to locate an intraabdominal abscess, particularly in the retroperitoneum, but this modality offers no significant advantage when compared with CT scan.

Radioactive isotope imaging with ⁶⁷Ga citrate-, ^{99m}Tc-, or ¹¹¹In-labeled leukocytes also may be used.²³ These studies require long preparation and image acquisition and are not used routinely unless CT scanning fails to demonstrate a suspected abscess.

Intraabdominal infection caused by disease processes at specific sites often produces characteristic manifestations that are helpful in diagnosis. For example, a patient with diverticulitis may exhibit stabbing left lower quadrant abdominal pain and constipation. Fever and leukocytosis frequently are present, and a tender mass sometimes is palpable. With appendicitis, the findings may be inconsistent, but many patients have a sudden onset of periumbilical or epigastric pain that usually is colicky and later shifts to the right lower quadrant. The location of pain may vary because the appendix can be in many locations (e.g., retrocecal or pelvic) in the abdomen. A mass may be palpable on abdominal, pelvic, or rectal examination. The patient's temperature generally is mildly elevated early and then increases. If perforation and peritonitis occur, findings would include diffuse abdominal pain, rigidity, and sustained fever. More frequently, however, appendiceal perforation results in a local abscess.

► TREATMENT: Intraabdominal Infections

■ DESIRED OUTCOME

The primary goals of treatment are correction of the intraabdominal disease processes or injuries that have caused infection and the drainage of collections of purulent material (abscesses). A secondary objective is to achieve a resolution of infection without major organ system complications (pulmonary, hepatic, cardiovascular, or renal failure) or adverse drug effects. Ideally, the patient should be discharged from the hospital with full function for self-care and routine daily activities.

■ GENERAL APPROACH TO TREATMENT

The treatment of intraabdominal infection most often requires the coordinated use of three major modalities: (1) prompt drainage, (2) support of vital functions, and (3) appropriate antimicrobial therapy to treat infection not eradicated by surgery.

Antimicrobials are an important adjunct to drainage procedures in the treatment of secondary intraabdominal infections; however, the use of antimicrobial agents without surgical intervention usually is inadequate. For most cases of primary peritonitis, drainage procedures may not be required, and antimicrobial agents become the mainstay of therapy.

4 In the early phase of serious intraabdominal infections, attention should be given to the maintenance of organ system functions. With generalized peritonitis, large volumes of intravenous (IV) fluids are required to restore vascular volume, to improve cardiovascular function, and to maintain adequate tissue perfusion and oxygenation. Adequate urine output should be maintained to ensure adequate resuscitation and proper renal function. Respiratory function can be assisted by a variety of methods, including oxygen therapy, pulmonary physiotherapy, and ventilatory support in severely ill patients. Often the critically ill patient with intraabdominal infection will require intensive care management, particularly if there is cardiovascular or respiratory instability. Also, isolation procedures may be required if the infectious process poses a threat to other hospitalized patients.

An additional important component of therapy is nutrition. Intraabdominal infections often directly involve the GI tract or disrupt its function (paralytic ileus). The return of GI motility may take days, weeks, and occasionally, months. In the interim, enteral or parenteral nutrition as indicated facilitates improved immune function and wound healing to ensure recovery.

■ NONPHARMACOLOGIC TREATMENT

■ DRAINAGE PROCEDURES

Primary peritonitis is treated with antimicrobials and rarely requires drainage. Secondary peritonitis requires surgical correction of the underlying pathology. The drainage of the purulent material is the critical component of management of an intraabdominal abscess. Without adequate drainage of the abscess, antimicrobial therapy and fluid resuscitation can be expected to fail.

Secondary peritonitis is treated surgically. At the time of laparotomy, attempts are made to correct the cause of the peritonitis. This

may include patching a perforated ulcer with omentum, resection of a segment of perforated colon, or excision of a portion of gangrenous small intestine. The goal of all these procedures is to repair or remove the inflamed or gangrenous viscus and to prevent further bacterial contamination. The presence of active inflammation increases the difficulty of the surgical procedure. This results in a higher morbidity and mortality rate than if the same procedures were performed in an elective setting without inflammation.

The presence of active inflammation may make it technically impossible to perform the ultimate surgical procedure. In this situation, attempts are made to provide drainage of the infected or gangrenous structures. If an intraabdominal abscess, separate from any intraabdominal organ, is discovered during an exploratory laparotomy, it may be débrided, excised, or drained. If the intraabdominal abscess involves an abdominal structure, then a resection of part or all of that organ may be required. An example of this situation is an abscess associated with diverticular disease of the colon. Management may include drainage of the abscess and resection of the involved colon. All foreign material, necrotic tissue, feces, blood, or pus should be removed from the operative field, and the peritoneum should be copiously irrigated with 0.9% sodium chloride to decrease the concentrations of bacteria or other noxious substances.

After an abscess is located, it must be drained. This may be performed surgically or using percutaneous, image-guided techniques.^{24,25} Typically, image-guided techniques are done using ultrasound or CT scanning. The management of an intraabdominal abscess with percutaneous catheter drainage may be sufficient to resolve the infection. Some patients may require a subsequent procedure to treat the underlying gastrointestinal conditions; however, a significant advantage is obtained by first draining the abscess percutaneously. This allows the surgical procedure to be performed on a patient who is no longer suffering the systemic manifestations of uncontrolled infection.

A number of drainage techniques have been described using endoscopy and laparoscopy.^{26,27} These minimal-access techniques may offer advantages when compared with traditional surgery but probably will be used less often than radiologically assisted percutaneous drainage techniques.

The most valuable microbiologic information may be obtained at the time of percutaneous or operative abscess drainage. If pus or fluid is found that is believed to be infected, it is best to aspirate 2 to 3 mL into a syringe, remove any air, and tightly cap the syringe. The specimen should be taken promptly to the microbiology laboratory, where a Gram stain should be performed immediately and cultures prepared for identification of aerobic and anaerobic bacteria. If no fluid is available for collection, culture swab devices may be applied to the infected area; however, anaerobic organisms often are not isolated from swabs.

■ FLUID THERAPY

4 Aggressive fluid repletion and management are required for successful treatment of intraabdominal infections. Fluid therapy is instituted for the purposes of achieving or maintaining proper intravascular volume to ensure adequate cardiac output, tissue perfusion, and correction of acidosis. Loss of fluid through vomiting, diarrhea, or a nasogastric suction contributes to dehydration. Intravascular volume can be assessed by blood pressure and heart rate but more accurately

TABLE 112–5. Likely Intraabdominal Pathogens

| Type of Infection | Aerobes | Anaerobes |
|--|---|---|
| Primary Bacterial Peritonitis | | |
| Children (spontaneous) | Pneumococci, group A <i>Streptococcus</i> | — |
| Cirrhosis | <i>E. coli</i> , <i>Klebsiella</i> , pneumococci (many others) | — |
| Peritoneal dialysis | <i>Staphylococcus</i> , <i>Streptococcus</i> | — |
| Secondary Bacterial Peritonitis | | |
| Gastroduodenal | <i>Streptococcus</i> , <i>E. coli</i> | — |
| Biliary tract | <i>E. coli</i> , <i>Klebsiella</i> , enterococci | <i>Clostridium</i> or <i>Bacteroides</i> (infrequent) |
| Small or large bowel | <i>E. coli</i> , <i>Klebsiella</i> spp., <i>Proteus</i> spp. | <i>Bacteroides fragilis</i> and other <i>Bacteroides</i> , <i>Clostridium</i> |
| Appendicitis | <i>E. coli</i> , <i>Pseudomonas</i> | <i>Bacteroides</i> spp. |
| Abscesses | <i>E. coli</i> , <i>Klebsiella</i> , enterococci | <i>B. fragilis</i> and other <i>Bacteroides</i> , <i>Clostridium</i> , anaerobic cocci |
| Liver | <i>E. coli</i> , <i>Klebsiella</i> , enterococci staphylococci, amoeba | <i>Bacteroides</i> (infrequent) |
| Spleen | <i>Staphylococcus</i> , <i>Streptococcus</i> | |

by measurement of central venous pressure, pulmonary capillary wedge pressure, or urinary output. When a contracted vascular volume is accompanied by hemorrhage, the initial hematocrit may be normal, but if there is no associated hemorrhage, the hematocrit usually is elevated as an indication of hemoconcentration. Urine output should be monitored continuously in severely ill patients by use of a urinary bladder catheter, quantitated hourly, and should equal or exceed 0.5 mL/kg of body weight per hour.

In patients with peritonitis, hypovolemia often is accompanied by acidosis, so a reasonable IV fluid would be lactated Ringer's solution, which contains the bicarbonate precursor lactate, as well as sodium, chloride, potassium, and calcium. In the initial hour of treatment, large volumes of solution may be required to restore intravascular volume. Hours thereafter, fluids may be required at a rate of 1 L/h. Maintenance fluids should be instituted (after intravascular volume is restored) with 0.9% sodium chloride and potassium chloride (20 mEq/L) or 5% dextrose and 0.45% sodium chloride with potassium chloride (20 mEq/L). The administration rate should be based on estimated daily fluid loss through urine and nasogastric suction, including 0.5 to 1.0 L for insensible fluid loss. Potassium would not be included routinely if the patient is hyperkalemic or has renal insufficiency.

In patients with significant blood loss, blood transfusion may be indicated. This is generally in the form of packed red blood cells. The criteria for blood transfusion are controversial, but a hematocrit of 25% generally is accepted. In the individual patient, the decision is often determined by the overall clinical status and the ability of the patient to compensate for the reduction in oxygen-carrying capacity associated with an acute anemia. Additional blood component therapy with fresh frozen plasma or platelets is also based on the needs of the individual patient. Aggressive fluid therapy often must be continued in the postoperative period because fluid will continue to sequester in the peritoneal cavity, bowel wall, and lumen.

■ PHARMACOLOGIC TREATMENT

■ ANTIMICROBIAL THERAPY

The goals of antimicrobial therapy are (1) to control bacteremia and prevent the establishment of metastatic foci of infection, (2) to reduce

suppurative complications after bacterial contamination, and (3) to prevent local spread of existing infection. After suppuration has occurred (e.g., an abscess has formed), a cure by antibiotic therapy alone is very difficult to achieve; antimicrobials may serve to improve the results with surgery.

5 An empirical antimicrobial regimen should be started as soon as the presence of intraabdominal infection is suspected. Therefore, antibiotics usually are initiated before identification of the infecting organisms is complete. Therapy must be initiated based on the likely pathogens. Predominant pathogens, as discussed in the preceding section, vary depending on the site of intraabdominal infection and the underlying disease process. Table 112–5 lists the likely pathogens against which antimicrobial agents should be directed.

■ Antimicrobial Experience

Many studies have been conducted evaluating or comparing the effectiveness of antimicrobials for the treatment of intraabdominal infections. Substantial differences in patient outcomes from treatment with a variety of agents generally have not been demonstrated.

Important findings from the last 20 years of clinical trials regarding selection of antimicrobials for intraabdominal infections are

- Antimicrobial regimens should cover a broad spectrum of aerobic and anaerobic bacteria from the gastrointestinal tract.
- Single-agent regimens (such as antianaerobic cephalosporins, extended-spectrum penicillins with β -lactamase inhibitors, or carbapenems) are as effective as combinations of aminoglycosides with antianaerobic agents. This is also true for antimicrobial treatment of acute bacterial contamination from penetrating abdominal trauma.^{28,29}
- Clindamycin and metronidazole appear to be equivalent in efficacy when combined with agents effective against aerobic gram-negative bacilli (gentamicin or aztreonam).
- For most patients, antimicrobial treatment can be completed orally with amoxicillin-clavulanate or the combination of ciprofloxacin and metronidazole.
- Five to seven days of antimicrobial treatment is sufficient for most intraabdominal infections of mild to moderate severity.

Intraabdominal infection presents in many different ways and with a wide spectrum of severity. The regimen employed and duration of treatment depend on the specific clinical circumstances (i.e., the nature of the underlying disease process and the condition of the patient). Compromised patients require more aggressive therapies than do otherwise healthy patients who experience the same intraabdominal infection.

Recommendations

6 For most intraabdominal infections, the antimicrobial regimen should be effective against both aerobic and anaerobic bacteria.³⁰ Although it is impossible to provide antimicrobial activity against every possible pathogen, agents with activity against enteric gram-negative bacilli such as *E. coli* and *Klebsiella* and anaerobes such as *B. fragilis* and *Clostridia* spp. should be administered. If most of the organisms can be eliminated through drainage or antimicrobials, the synergistic effect may be removed, and the patient's defenses may be able to eradicate the remaining infection.

Table 112-6 presents the recommended agents for treatment of community-acquired and complicated intraabdominal infections from the Infectious Diseases Society of America and the Surgical Infection Society.³⁰⁻³² These recommendations were formulated using an evidence-based approach. Most community-acquired infections are "mild to moderate," whereas health care-associated infections tend to be more severe and difficult to treat. Table 112-7 presents guidelines for treatment and alternative regimens for specific situations. These are general guidelines; there are many factors that cannot be incorporated into such a table.

Most patients with severe intraabdominal infection, generalized peritonitis, or sepsis should be placed on a β -lactam/ β -lactamase inhibitor combination or carbapenem such as imipenem, ertapenem, or meropenem. Combinations of an aminoglycoside with an antianaerobic agent, such as clindamycin or metronidazole, may be used, but some authorities consider such combinations to be obsolete.^{1,30} Gentamicin is the aminoglycoside of choice based on its lower cost. Other aminoglycosides, such as tobramycin, amikacin, and netilmicin, have

no advantage in intraabdominal infection and generally are not drugs of first choice. Aztreonam may be used as an alternative to an aminoglycoside to avoid potential nephrotoxicity.

The dosage for aminoglycosides should be determined initially based on the patient's weight and renal function. Dosage adjustment should be performed by applying pharmacokinetic principles and by using peak and trough serum drug levels. Because enteric gram-negative bacilli usually are very susceptible to aminoglycosides and the aminoglycosides are well distributed into peritoneal fluid,^{33,34} high serum aminoglycoside concentrations generally are not required. Unless relatively resistant bacteria are suspected, a gentamicin or tobramycin peak concentration of 5-6 mcg/mL usually is effective. To achieve these serum concentrations, gentamicin or tobramycin dosage may range from 1-3 mg/kg per dose given as often as every 6 hours or as infrequently as every 48 hours if the patient has renal failure. Because aminoglycosides have concentration-dependent killing and a relatively long postantibiotic effect for aerobic gram-negative bacilli, once-daily administration (5-7 mg/kg) is a reasonable alternative and appears to be equivalent to multiple daily dosing.

When used for intraabdominal infection, aminoglycosides should be combined with agents that are effective against the majority of *B. fragilis*. Clindamycin or metronidazole is the agent of first choice, but others, such as antianaerobic cephalosporins (e.g., cefoxitin, cefotetan, or ceftizoxime), piperacillin, mezlocillin, and combinations of extended-spectrum penicillins with β -lactamase inhibitors, would be suitable alternatives. Clindamycin should be administered intravenously in a dosage of 600 or 900 mg every 8 hours. Patients receiving multiple broad-spectrum antimicrobial agents who are immunocompromised should receive an oral antifungal agent (nystatin) for prevention of fungal overgrowth in the mouth and GI tract. The benefits of systemic antifungal prophylaxis (with fluconazole) have not been established for intraabdominal infection and should not be used routinely.

With intraabdominal contamination from the upper GI tract (perforation of a peptic ulcer or biliary tract disease), *B. fragilis* is an uncommon pathogen, and other agents therefore may be substituted for clindamycin or metronidazole. Alternatives include ampicillin, penicillin, or first-generation cephalosporins.

TABLE 112-6. Recommended Agents for the Treatment of Community-Acquired Complicated Intraabdominal Infections

| Agents Recommended for Mild to Moderate Infections | Agents Recommended for High-Severity Infections |
|--|---|
| β-Lactam/β-Lactamase Inhibitor Combinations | |
| Ampicillin-sulbactam | Piperacillin-tazobactam |
| Ticarcillin-clavulanate | |
| Carbapenems | |
| Ertapenem | Imipenem/cilistatin Meropenem |
| Combination Regimens | |
| Cefazolin or cefuroxime plus metronidazole | Third- or fourth-generation cephalosporins (cefotaxime, ceftriaxone, ceftizoxime, ceftazidime, cefepime) plus metronidazole |
| Ciprofloxacin, levofloxacin, moxifloxacin, or gatifloxacin in combination with metronidazole | Ciprofloxacin in combination with metronidazole |
| | Aztreonam plus metronidazole |

From refs. 30, 31, and 32.

CLINICAL CONTROVERSY

Enterococci often are isolated from intraabdominal infections, and many antimicrobials are ineffective against enterococci (such as cephalosporins and fluoroquinolones). Regimens without activity against enterococci (gentamicin with clindamycin or cephalosporins) generally are effective in treating intraabdominal infections; however, there are numerous reports of enterococcal superinfection in immunocompromised patients, particularly after broad-spectrum antimicrobial use. The Infectious Disease Society of America guidelines state that "Routine coverage against enterococcus is not necessary for patients with community-acquired intraabdominal infections. Antimicrobial therapy for enterococci [e.g., ampicillin, penicillin, or vancomycin] should be given when enterococci are recovered from patients with health-care associated infections."

The failure of host defenses may be a critical factor in the pathogenicity of enterococci. In immunocompromised patients or patients with valvular heart disease or a prosthetic heart valve, there is justification to provide specific antimicrobial activity against enterococci. Ampicillin or other penicillins that are active against

^aCefoxitin, cefotetan, and ceftizoxime.

enterococci (e.g., penicillin, piperacillin, and mezlocillin) should be used in patients at high risk, patients with persistent or recurrent intraabdominal infection, or patients who are immunosuppressed, such as after organ transplantation. Ampicillin remains the drug of choice for this indication because it is most active in vitro against enterococcus and is relatively inexpensive. Vancomycin is active against most enterococci; however, resistance is increasing, and this agent should be reserved for established infections when first-line therapies cannot be used.

7 With peritonitis that occurs from CAPD, the antimicrobial regimen used should be tailored to the isolated organism. The

selection of a specific agent or combination should be based on culture and susceptibility data. If microbiologic data are unavailable, empirical therapy with a first-generation cephalosporin plus an aminoglycoside is recommended. In less severe infections, a first-generation cephalosporin alone given intraperitoneally may suffice. Infection with staphylococci may be treated with a penicillinase-resistant penicillin (e.g., methicillin, nafcillin, or oxacillin), first-generation cephalosporins, or vancomycin if the patient is allergic to penicillin or the isolate is resistant to methicillin. For streptococcal infections, penicillin or ampicillin would be preferable to penicillinase-resistant penicillins. Most aerobic gram-negative

bacilli may be treated effectively with an aminoglycoside. For infections caused by *P. aeruginosa*, an antipseudomonal penicillin (e.g., ticarcillin, piperacillin, mezlocillin, or azlocillin) or ceftazidime may be added.

Patients with peritonitis who are undergoing CAPD may receive parenteral as well as intraperitoneal antimicrobial agents. Intraperitoneal antimicrobial agents alone often are sufficient unless severe infection is present. A number of agents may be instilled through peritoneal catheters. Recommended concentrations of antimicrobial agents for intraperitoneal irrigation solutions are 8 mg/L for gentamicin and tobramycin, 1–3 mg/L for clindamycin, 50,000 units/L for penicillin G, 125 mg/L for cephalosporins, 100–150 mg/L for ticarcillin or carbenicillin, 50 mg/L for ampicillin, 100 mg/L for methicillin, 30 mg/L for vancomycin, and 3 mg/L for amphotericin B.³⁵

The usual duration of therapy for peritonitis associated with CAPD is 10 to 14 days, but up to 3 weeks of therapy may be required. Antimicrobial therapy should be continued until dialysate fluid is clear, cultures are negative for 2 to 3 days, and the patient is asymptomatic. When parenteral agents are administered, the initial dose would be the same as that for patients with normal renal function, whereas subsequent doses should be much less or given less frequently for renally excreted agents and should account for possible loss through peritoneal dialysis. Serum concentrations should be performed for aminoglycosides and vancomycin. Some studies have demonstrated that for patients with spontaneous bacterial peritonitis associated with cirrhotic ascites, treatment duration may be as short as 5 days when ascitic fluid polymorphonuclear cell counts are used to guide treatment.^{36,37}

After acute bacterial contamination, such as with abdominal trauma where GI contents spill into the peritoneum, combination antimicrobial regimens are not required. If the patient is seen soon after injury (within 2 hours) and surgical measures are instituted promptly, antianaerobic cephalosporins (such as cefoxitin or cefotetan) or extended-spectrum penicillins are effective in preventing most infectious complications. Antimicrobials should be administered as soon as possible after injury.

For appendicitis, the antimicrobial regimen used should depend on the appearance of the appendix at the time of operation, which may be normal, inflamed, gangrenous, or perforated. Because the condition of the appendix is unknown preoperatively, it is advisable to begin antimicrobial agents before the appendectomy is performed. Reasonable regimens would be antianaerobic cephalosporins or, if the patient is seriously ill, a carbapenem or β -lactam/ β -lactamase inhibitor combination. If, at operation, the appendix is normal or inflamed, postoperative antimicrobials are not required. If the appendix is gangrenous or perforated, a treatment course of 5 to 7 days with the agents listed in Table 112–7 is appropriate.

8 The necessary duration of treatment for intraabdominal infections is not clearly defined. Acute intraabdominal contamination, such as after a traumatic injury, may be treated with a very short course (24 hours).³⁸ For established infections (i.e., peritonitis or intraabdominal abscess), an antimicrobial course limited to 5 to 7 days is justified. This allows eradication of bacteria remaining in the peritoneum after a surgical procedure that may enter the peritoneum through healing suture lines. Under certain conditions, therapy for longer than 7 days would be justified, e.g., if the patient remains febrile or is in poor general condition, when relatively resistant bacteria are isolated, or when a focus of infection in the abdomen may still be present. For some abscesses, such as pyogenic liver abscess, antimicrobials may be required for a month or longer.

Intraperitoneal irrigation of antimicrobial agents for treatment of intraabdominal infection has been studied often with conflicting results.³⁹ Intraoperative antimicrobial irrigation does not improve patient outcomes in comparison with copious intraoperative irrigation with normal saline. Possibly the most important aspect of peritoneal irrigation is the dilutional effect on bacteria and adjuvants that promotes infection (intestinal contents and hemoglobin). Most systemically administered antimicrobials easily cross the peritoneal membrane so that peritoneal fluid concentrations are similar to serum.^{33,40} Confined areas, such as an abscess, can be expected to attain much lower antimicrobial concentrations.

EVALUATION OF THERAPEUTIC OUTCOMES

Whichever antimicrobial regimen is chosen, the patient should be reassessed continually to determine the success or failure of therapies. The clinician should recognize that there are many reasons for poor patient outcome with intraabdominal infection; improper antimicrobial administration is only one. The patient may be immunocompromised, which decreases the likelihood of successful outcome with any regimen. It is impossible for antimicrobials to compensate for a nonfunctioning immune system. There may be surgical reasons for poor patient outcome. Failure to identify all intraabdominal foci of infection or leaks from a GI anastomosis may cause continued intraabdominal infection. Even when intraabdominal infection is controlled, accompanying organ system failure, most often renal or respiratory, may lead to patient demise.

The outcome from intraabdominal infection is not determined solely by what transpires in the abdomen. Unsatisfactory outcomes in patients with intraabdominal infections may result from complications that arise in other organ systems. A complication commonly associated with mortality after intraabdominal infection is pneumonia.⁴¹ A high APACHE (Acute Physiology and Chronic Health Evaluation) II score, low serum albumin concentration, and high New York Heart Association cardiac function status were significantly and in-

dependently associated with increased mortality from intraabdominal infection.⁴²

9 Once antimicrobials are initiated and the other important therapies described earlier are used, most patients should show improvement within 2 to 3 days. Usually, temperature will return to near normal, vital signs should stabilize, and the patient should not appear in distress, with the exception of recognized discomfort and pain from incisions, drains, and nasogastric tube. At 24 to 48 hours, aerobic bacterial culture results should return. If a suspected pathogen is not sensitive to the antimicrobial agents being given, the regimen should be changed if the patient has not shown sufficient improvement. If the isolated pathogen is extremely sensitive to one antimicrobial and the patient is progressing well, concurrent antimicrobial therapy often may be discontinued.

CLINICAL CONTROVERSY

5 Although some investigators suggest that routine culturing of patients with community-acquired intraabdominal infections contributes little to their management,⁴³ other investigators suggest that antimicrobial therapy should be based on susceptibility of the bacteria collected from the operative site because this has been shown to correlate with clinical outcome.⁴⁴

With anaerobic culturing techniques and the slow growth of these organisms, anaerobes often are not identified until 4 to 7 days after culture, and sensitivity information is difficult to obtain. For this reason, there are usually few data with which to alter the antianaerobic component of the antimicrobial regimen. A report indicating that anaerobes were not isolated should not be the sole justification for discontinuing antianaerobic drugs because anaerobic bacteria that were present in the infectious process may not have been transported properly to the microbiology laboratory, or other problems may have led to cell death *in vitro*.

Reasons for antimicrobial failure may not always be apparent. Even when antimicrobial susceptibility tests indicate that an organism is susceptible *in vitro* to the antimicrobial agent, therapeutic failures may occur. Possibly there is poor penetration of the antimicrobial agent into the focus of infection, or bacterial resistance may develop after initiation of antimicrobial therapy. Also, it is possible that an antimicrobial regimen may encourage the development of infection by organisms not susceptible to the regimen being used. Superinfection in patients being treated for intraabdominal infection can be caused by *Candida*; however, enterococci or opportunistic gram-negative bacilli such as *Pseudomonas* or *Serratia* may be involved.

Treatment regimens for intraabdominal infection can be judged as successful if the patient recovers from the infection without recurrent peritonitis or intraabdominal abscess and without the need for additional antimicrobials. A regimen can be considered unsuccessful if a significant adverse drug reaction occurs, reoperation or percutaneous drainage is necessary, or patient improvement is delayed beyond 1 or 2 weeks.

PARASITIC DISEASES

JV Anandan

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- ▶ 1 Parasites normally inflict some degree of injury to the host, the extent of which depends on such factors as parasite load, nutritional status, and immunologic competence of the host.
- ▶ 2 The primary reasons for deaths due to malaria are failure to take chemoprophylaxis, inappropriate chemoprophylaxis, delay in seeking medical care, and misdiagnosis.
- ▶ 3 In adults (including pregnant women), the chemoprophylaxis for all species of plasmodia is chloroquine phosphate 300 mg (base) once weekly beginning 1 week prior to departure and continuing for 4 weeks after leaving an endemic area.
- ▶ 4 In an uncomplicated attack of malaria (for all plasmodia except chloroquine-resistant *Plasmodium falciparum*), the recommended regimen is chloroquine 600 mg (base) initially, followed by 300 mg (base) 6 hours later, and then 300 mg (base) daily for 2 days.
- ▶ 5 Because falciparum malaria is associated with serious complications including pulmonary edema, hypoglycemia, jaundice, renal failure, confusion, delirium, seizures, coma, and death, careful monitoring of fluid status and hemodynamic parameters is mandatory.
- ▶ 6 Intestinal amebiasis is diagnosed by demonstrating *Entamoeba histolytica* cysts or trophozoites (may contain ingested erythrocytes) in fresh stool or from a specimen obtained by sigmoidoscopy. Three stool samples obtained 24 hours apart will produce a 60% to 90% yield for *E. histolytica*.
- ▶ 7 All symptomatic adults and children older than 8 years of age with giardiasis should be treated with metronidazole 250 mg three times daily for 7 days.
- ▶ 8 In the adult, both the cutaneous and mucocutaneous forms of leishmaniasis (*Leishmania braziliensis* and *L. mexicana*) are treated with stibogluconate. An alternative drug for the visceral form is amphotericin B.
- ▶ 9 In chronic trypanosomiasis (Chagas' disease), patients present with cardiomyopathy and heart failure.
- ▶ 10 The agents used commonly for the treatment of enterobiasis include pyrantel pamoate, mebendazole, or albendazole.
- ▶ 11 The resistance of lice to permethrin is increasing, and 0.5% malathion is an effective alternative.

Parasitic diseases are receiving increasing attention from clinicians in the United States because of the high frequency of travel, deployment of personnel for humanitarian and military missions (e.g., Peace Corps volunteers), inflow of immigrants from a wider geographic distribution, and the presence of immunosuppressed populations (e.g., AIDS and transplant patients). Migrant farm workers who work and live in substandard hygienic conditions, the large and growing Central and South American immigrant population, and other poorly screened immigrants from Asia represent significant sources of parasitic infections in the United States.¹⁻⁹ Clinicians need to have a heightened awareness for parasitic diseases and how to treat them. Clinical signs and symptoms, together with the patient's travel history, should be used with other diagnostic aids in the identification of parasitic diseases. Parasitic infections caused by pathogenic protozoa or helminths affect more than 3 billion people worldwide and impose tremendous health and economic burdens on developing countries.⁹

This chapter discusses the major parasitic diseases, including protozoan diseases (amebiasis, malaria), helminthic infections (ascariasis, enterobiasis), and ectoparasitic infestations (head and body lice). Emphasis is placed on diseases seen more frequently in the

United States. World distribution of parasites depends on the presence of suitable hosts, habitats, and environmental conditions.⁹ A human parasite that does not use an intermediate host is likely to be found in any inhabited region of the world as long as the environmental conditions are suitable. *Ascaris* (round worm) and *Trichuris* (whip worm) require carelessness of habits for transfer and require time outside the body, where they are exposed to heat and dryness, to reach the infective stage. The distribution of the hookworm is more limited because the free-living forms are unprotected by resistant shells or cysts. African trypanosomiasis never occurs outside the range of the tsetse fly, malaria never occurs beyond the range of the infective *Anopheles* mosquito, and schistosomiasis never occurs in the absence of a specific water snail. The prevalence of clonorchiasis (Chinese liver fluke) is an example of the impact of both environmental and geographic factors. Clonorchiasis requires the simultaneous presence of not only humans, specific snail species, and certain fish but also unsanitary conditions that make the eggs accessible to the snails, an association of the snail and fish, and the established local habit of eating raw fish. The ability of some parasites to infect hosts other than humans may perpetuate an infection even when human habits

preclude the possibility of more than occasional access to the human body. In North America, the broad tapeworm (*Diphyllobothrium latum*) would perish if it were not that dogs and other carnivores, such as the brown bear, serve as reservoir hosts.

HOST-PARASITE RELATIONSHIP

Symbiosis is the association of two species for the purpose of obtaining food for either one or the other. *Parasitism* is a symbiotic relationship in which one species, the host, is injured through the activities of the other. Through evolution, parasites have made specific morphologic adaptations. Adaptation to the host has taken a number of forms: loss of locomotor organelles in the protozoan *Sporozoa*, partial and complete lack of digestive systems in the trematodes and cestodes, respectively, elaboration of proteolytic enzymes to penetrate the host intestinal mucosa by *Entamoeba histolytica*, the cercariae of the blood fluke that penetrate the skin of the host by elaborate enzymes, and finally, the ability to infect an intermediate host to increase reproductive capacity, as seen among the cestodes and trematodes.⁹

Parasites normally inflict some degree of injury to the host, the extent of which depends on such factors as parasite load, nutritional status, and immunologic competence of the host. *Entamoeba coli* is considered commensal because it subsists on the bacterial flora of the gut and does not cause any harm to the host. Unlike *Entamoeba coli*, *Fasciolopsis buski*, the giant intestinal fluke, can produce severe local damage to the intestinal wall. *Ascaris*, the roundworm, can perforate the bowel wall, cause intestinal obstruction, and invade the appendix and bile duct. Malarial parasites destroy red cells by multiplying inside them. *Diphyllobothrium latum*, or the broad fish tapeworm, removes vitamin B₁₂ from the gastrointestinal tract (GI) tract, resulting in megaloblastic anemia.⁹

PROTOZOAN DISEASES

MALARIA

Malaria represents the most devastating disease in terms of human suffering and economics. It affects the largest number of people (between 300 and 500 million new infections are reported annually) in the world, with more than 2 million deaths worldwide.^{10,11} In the United States, deaths from malaria are preventable. The primary reasons for deaths are failure to take chemoprophylaxis, inappropriate chemoprophylaxis, delay in seeking medical care, and misdiagnosis.^{4,5,10,11}

EPIDEMIOLOGY

The exact geographic distribution of the various species is not well documented; however, it is reported that *Plasmodium vivax* is more prevalent in India, Pakistan, Bangladesh, Sri Lanka, and Central America, whereas *P. falciparum* is predominant in Africa, Haiti, Dominican Republic, the Amazon region of South America, and New Guinea. Both *P. falciparum* and *P. vivax* are prevalent in all of Southeast Asia, South America, Middle East, North Africa, Ethiopia, Somalia, and Sudan.^{10–13} Most of the infections with *P. ovale* occur in Africa, and the distribution of *P. malariae* is considered worldwide.

In the United States, most cases of malaria are reported in immigrants from endemic areas and in American travelers. Blood transfusion also has been cited as a cause of malarial infection.¹² The transmission of malaria from recent immigrants from endemic ar-

reas is a real threat because of the presence of a number of mosquito vectors—*Anopheles quadrimaculatus* and *A. punctipennis*—in the United States.¹⁴

ETIOLOGY

Malaria is transmitted by the bite of an infected *Anopheles* mosquito that introduces the sporozoites (tissue parasites) of the plasmodia (*P. falciparum*, *P. vivax*, *P. malariae*, and *P. ovale*) into the bloodstream. The asexual reproduction stage develops in humans, whereas the sexual stage occurs in the mosquito.^{9,12} The sporozoites invade parenchymal hepatocytes, multiply in stages referred to as *exoerythrocytic stages*, and become hepatic vegetative forms or schizonts. Schizonts rupture to release daughter cells, or merozoites, that then infect erythrocytes.

P. falciparum and *P. malariae* remain in the primary exoerythrocytic stage in the liver for about 4 weeks before invading erythrocytes, whereas *P. vivax* and *P. ovale* can exist in the liver in the latent exoerythrocytic form for extended periods, and therefore, infected subjects can experience relapses. The merozoites that invade the erythrocytes develop sequentially into ring forms, trophozoites, schizonts, and finally, merozoites, which can invade other erythrocytes or can develop into gametocytes, which undergo the sexual stage in the *Anopheles* vector. Erythrocytic forms never reinvade the liver without developing into sporozoites in the vector, and therefore, malaria infections from transfusion never result in the exoerythrocytic, or “liver,” form.^{9,12} *P. falciparum* can result in high levels of parasitemia because of its ability to invade erythrocytes of all ages, unlike *P. vivax* and *P. ovale*, which only invade young cells.¹²

PATHOLOGY

The erythrocytic phase causes extensive hemolysis, which results in anemia and splenomegaly. The most serious complications usually

TABLE 113–1. Clinical Presentation of Malaria

Initial Presentation

Nonspecific fever, chills, rigors, diaphoresis, malaise, vomiting¹²

Orthostatic hypotension

Electrolyte abnormalities

Erythrocytic Phase

Prodrome: Headache, anorexia, malaise, fatigue, myalgias

Nonspecific complaints such as abdominal pain, diarrhea, chest pain, and arthralgias

Paroxysm: High fever, chills, and rigor^{9–12}

Cold phase: Severe pallor, cyanosis of the lips and nail bed, and cutis anserina (“goose flesh”)^{9–12}

Hot phase: Fever between 40.5°C (104.9°F) and 41°C (105.8°F).

Sweating phase:

Follows hot phase by 2–6 hours

Fever resolves

Marked fatigue and drowsiness, warm, dry skin, tachycardia, cough, severe headache, nausea, vomiting, abdominal pain, diarrhea, and delirium

Lactic acidosis and hypoglycemia (with falciparum malaria)^{12,15}

Anemia

Splenomegaly

P. falciparum Infections

Hypoglycemia, acute renal failure, pulmonary edema, severe anemia, thrombocytopenia, high-output heart failure, cerebral congestion, seizures and coma, and adult respiratory syndrome^{15–21}

are associated with *P. falciparum* infections.^{15–21} Infants and children younger than 5 years of age and nonimmune women who are pregnant are at high risk for severe complications from falciparum malaria.^{15–19} The complications associated with falciparum malaria are primarily a result of the high parasitemia and the ability of the parasites to sequester in capillaries and postcapillary vessels of organs such as the brain and the kidney. It has been postulated that tissue hypoxia from anemia, together with *P. falciparum*–parasitized red blood cell adherence to endothelial cells in capillaries, contributes to extensive vascular disease and severe metabolic effects.^{12,15} *P. malariae*

► TREATMENT: Malaria

■ DESIRED OUTCOME

The primary goal in the management of malaria is the rapid diagnosis of the *Plasmodia* spp. by blood smears (repeated every 12 hours for 3 days) so as to initiate timely antimalarial therapy to eradicate the infection within 48 to 72 hours and to avoid complications such as hypoglycemia, pulmonary edema, and renal failure that are responsible for increased mortality in malaria.

■ PHARMACOLOGIC THERAPY

3 In adults (including pregnant women), the chemoprophylaxis for all species of *Plasmodium* is chloroquine phosphate 300 mg (base) once weekly beginning 1 week prior to departure and continued for 4 weeks after leaving an endemic area.^{10,12,13,23,27} The pediatric dose of chloroquine phosphate is 5 mg (base) per kilogram of body weight (maximum 300 mg). When visiting or leaving an area endemic for *P. vivax* or *P. ovale*, primaquine phosphate (Primaquine) 15 mg (base) daily for 14 days beginning the last 2 weeks of chloroquine prophylaxis should be added to the regimen. The pediatric dose of primaquine is 0.3 mg (base) per kilogram of body weight per day for 14 days. The pediatric doses of chloroquine can be calculated based on body weight, and the tablets can be pulverized and placed in gelatin capsules. Parents can be instructed to suspend the dose in food, simple syrup, chocolate milk, or drink.^{10,15}

In areas where chloroquine-resistant *P. falciparum* strains exist, travelers should receive mefloquine (Lariam) for prophylaxis. The adult dose of mefloquine is 250 mg once weekly beginning 1 week prior to departure and continuing for the full period of exposure, followed by 250 mg for 4 weeks after last exposure.^{23–30} The pediatric dose of mefloquine for prophylaxis is

| Body Weight (kg) | Dose |
|------------------|------------|
| 15–19 kg | 5 mg/kg |
| 15–19 kg | 1/4 tablet |
| 20–30 kg | 1/2 tablet |
| 31–45 kg | 3/4 tablet |
| >45 kg | 1 tablet |

In travelers who are at immediate risk for drug-resistant falciparum malaria, a loading dose of mefloquine may be considered. Mefloquine is administered at 250 mg daily for 3 days before travel, followed by 250 mg once weekly while in the endemic area and

is implicated in immune-mediated glomerulonephritis and nephrotic syndrome^{12,18} (Table 113–1).

To ensure a positive diagnosis, blood smears should be obtained every 12 to 24 hours for 3 consecutive days.^{9,12,15} The presence of parasites in the blood 3 to 5 days after initiation of therapy suggests drug resistance. Recent advances for detecting malaria parasite have included DNA or RNA probes by polymerase chain reaction (PCR) and a rapid dipstick test (PARASIGHT F, Becton-Dickinson, Cockeysville, MD).^{9,12,22,23} The dipstick is reported to have a sensitivity of 88% and a specificity of 97%, which is comparable with microscopy.²²

continued for 4 weeks after last exposure.^{24,26} Some patients may experience neuropsychiatric reactions from this regimen and may need to be monitored closely.^{12,24}

An alternative regimen for prophylaxis in chloroquine-resistant areas for those who cannot tolerate mefloquine is to take doxycycline 100 mg daily starting 1 to 2 days prior to departure, during the exposure period, and continuing for 4 weeks after leaving the endemic area.^{12,24} Children older than 8 years of age should receive 2 mg/kg per day (up to 100 mg) of doxycycline. Doxycycline is contraindicated in children younger than 8 years of age, in pregnant women, and during breast-feeding.^{13,24}

Another alternative regimen for chemoprophylaxis is the combination of atovaquone and proguanil (Malarone): 1 tablet daily beginning 1 to 2 days prior to travel and continuing for the duration of stay and 1 week after leaving the area.^{13,14} Daily primaquine 15 mg (base) also has been recommended for prophylaxis for both *P. vivax* and *P. falciparum* malaria.³⁰

4 In an uncomplicated attack of malaria (for all plasmodia except chloroquine-resistant *P. falciparum*), the recommended regimen is chloroquine 600 mg (base) initially, followed by 300 mg (base) 6 hours later, and then 300 mg (base) daily for 2 days. In severe illness or when oral therapy is not tolerated or parenteral quinine is not available, quinidine gluconate 10 mg/kg as a loading dose (maximum 600 mg) in 250 mL normal saline should be administered slowly over 1 to 2 hours, followed by continuous infusion of 0.02 mg/kg per minute until oral therapy can be started.^{23,24} In patients who have received either quinine or mefloquine, the loading dose of quinidine should be omitted. Oral quinine (300 mg every 8 hours) should follow the intravenous dose of quinidine to complete 3 days for all infections, except for *P. falciparum* acquired in Thailand, in which case a full 7-day course should be given.^{23,24} The pediatric dose of intravenous quinidine gluconate is the same as the dose for adults.²⁴ The pediatric dose of quinine is 25 mg/kg per day in three divided doses for 3 or 7 days.²⁴

In *P. falciparum* (chloroquine-resistant) infections, a dose of 750 mg mefloquine followed by 500 mg 12 hours later is recommended. The pediatric dose of mefloquine is 15 mg/kg (<45 kg) followed by 10 mg/kg 8 to 12 hours later.²⁴ Intravenous quinidine gluconate followed by oral quinine should be administered for severe illness, as already indicated.^{12,24} A second drug needs to be administered in chloroquine-resistant *P. falciparum*, and this second drug should follow the oral quinidine regimen: either a single dose of three tablets of pyrimethamine-sulfadoxine (Fansidar) on the last day of intravenous quinidine or clindamycin 900 mg three times daily for 3 to 5 days.^{23,24} An alternative oral treatment for chloroquine-resistant *P. falciparum* infection in adults, especially in those with a history of seizures or psychiatric disorders, is the combination of atovaquone 250 mg and proguanil 100 mg (Malarone) (4 tablets daily

for 3 days).^{13,23,24} The intravenous quinidine regimen requires close monitoring of the electrocardiogram and other vital signs (e.g., **5** hypotension and hypoglycemia).^{15,23,24} Because falciparum malaria is associated with serious complications, including pulmonary edema, hypoglycemia, jaundice, renal failure, confusion, delirium, seizures, coma, and death, careful monitoring of fluid status and hemodynamic parameters is mandatory.^{15–21,23} Exchange transfusion that may be required in patients with *P. falciparum* malaria in whom parasitemia is 5% to 15% remain a questionable modality.²⁰ Either peritoneal or hemodialysis may be indicated in renal failure.²³

EVALUATION OF THERAPEUTIC OUTCOMES

When advising potential travelers on prophylaxis for malaria, be aware of the incidence of chloroquine-resistant *P. falciparum* malaria and the countries where this is prevalent.^{11,13,23,24,29} Detailed recommendations for prevention of malaria may be obtained by checking the World Wide Web (e.g., www.cdc.gov/travel/ or www2.cdc.gov/mmwr/)^{34,41} or by calling the Centers for Disease Control and Prevention (CDC) (see Appendix 113–1). A number of newer drugs are under active study and include the water-soluble artesunate and the oil-soluble artemether (Lumefantrine, also known as benflumetol) and combinations of this with other agents and the recently approved combination atovaquone and proguanil (Malarone) in the United States.^{10,13,23,36–40} Halofantrine (Halfan) has poor bioavailability, prolongs the QTc interval at the recommended doses, and has been reported to have therapeutic failures.²⁴

Acute *P. falciparum* malaria resistant to chloroquine should be treated with intravenous quinidine. These patients should have a central venous catheter to follow fluid status, and the electrocardiogram should be monitored closely. Hypoglycemia that is associated with *P. falciparum* should be checked and corrected with dextrose infusions.¹⁵ Quinidine infusion should be slowed temporarily or stopped if there is a QT interval of greater than 0.6 second, an increase in the QRS complex to greater than 50%, or hypotension unresponsive to fluid challenge results. The suggested quinidine levels should be maintained at 3–7 mg/L.^{15,23} Blood smears should be checked every 12 hours until parasitemia is less than 1%. Resolution of fever should take place between 36 and 48 hours after initiation of the intravenous quinidine therapy, and the blood should be clear of parasites in 5 days.^{15,23} If parenteral therapy is required for more than 48 hours, it is suggested that the dose of quinidine be lowered by half.²⁴

Travelers to endemic areas for malaria should be advised to remain in well-screened areas, to wear clothes that cover most of the body, and to sleep in mosquito nets.^{4,41} It is prudent to carry the insect repellent DEET (*N,N*-diethylmetatoluamide) or other insect sprays containing DEET for use in mosquito-infested areas.⁴¹ Readers are urged to check publications from the CDC for the list of countries where chloroquine-resistant *P. falciparum* exist.^{24,34}

AMEBIASIS

EPIDEMIOLOGY AND ETIOLOGY

Because of its worldwide distribution and serious gastrointestinal manifestations, amebiasis is one of the most important parasitic diseases of humans.^{9,42–45} The major causative organism in amebiasis is *Entamoeba histolytica*, which inhabits the colon and must be differentiated from the *E. dispar*, which is associated with an asymptomatic carrier state and is considered nonpathogenic. Although *E. histolytica* and *E. dispar* are indistinguishable morphologically, recent research

Malarial infection does not produce immunity in patients, and active research has been initiated to develop a malaria vaccine.^{23,31–35} A vaccine that blocks the entry of sporozoites into the liver cells will prevent malaria at this stage. However, immunity to sporozoites does not protect the host against parasites in the erythrocytic cycle.³³ Infective sporozoites of *P. falciparum* are covered by a polypeptide, circumsporozoite protein.³⁵ Isolation and identification of the gene encoding for this circumsporozoite protein have led to the development of a monoclonal antibody by recombinant DNA technology; *P. falciparum* sporozoite vaccine is now under investigation.^{33,35}

using monoclonal antibodies has been able to separate the two.^{44,45} Invasive amebiasis is almost exclusively the result of *E. histolytica* infection. Approximately 50 million cases of invasive disease result each year worldwide, leading to an excess of 100,000 deaths.^{43,44} In the United States, the incidence of amebiasis is estimated at about 4% in the general population.⁴⁵ The highest incidence is found in institutionalized mentally retarded patients, sexually active homosexuals, patients with acquired immune deficiency syndrome (AIDS), the Native American population, and new immigrants from endemic areas (e.g., Mexico, India, West and South Africa, and portions of Central and South America).^{44–49}

PATHOLOGY

E. histolytica invades mucosal cells of colonic epithelium, producing the classic flask-shaped ulcer in the submucosa.^{42,44,45} The trophozoite has a cytolethal effect on cells through a toxin. If the trophozoite gets into the portal circulation, it will be carried to the liver, where it produces abscess and periportal fibrosis.^{46,47,50–51} Amebic ulcerations can affect the perineum and genitalia, and abscesses may occur in the lung and brain.^{42,43,45,52}

CLINICAL PRESENTATION

The most frequent clinical manifestations of the disease are gastrointestinal (Table 113–2).

Liver abscesses that are located in the right lobe can spread to the lungs and pleura.^{42–45} Pericardial infection, although rare, may be associated with extension of the amebic abscess from the left lobe of the liver. Erosion of liver abscesses also present as peritonitis.^{42,47,50,51}

6 Review of the patient's history and recent travel cannot be overemphasized. Intestinal amebiasis is diagnosed by demonstrating *E. histolytica* cysts or trophozoites (may contain ingested erythrocytes) in fresh stool or from a specimen obtained by

TABLE 113–2. Most Common Manifestations of Amebiasis

Intestinal Disease

Vague abdominal discomfort, malaise to severe abdominal cramps, flatulence, bloody diarrhea (heme-positive in 100% of cases) with mucus^{42–45}

Eosinophilia is usually absent, although mild leukocytosis is not unusual⁴²

Amebic Liver Abscess

High fever, significant leukocytosis with left shift, elevated alkaline phosphatase, and liver tenderness on palpation^{42,44,45}

Right upper quadrant pain, hepatomegaly, and liver tenderness, with referred pain to the left or right shoulder

Erosion of liver abscesses also present as peritonitis^{42,47,50,51}

sigmoidoscopy. Three stool samples obtained 24 hours apart will produce a 60% to 90% yield for *E. histolytica*. Microscopy may not differentiate between the pathogenic *E. histolytica* and the nonpathogenic *E. dispar* in stools. Sensitive techniques are available to detect *E. histolytica* in stool, including antigen detection and PCR.^{43–45,51} Endoscopy with scraping or biopsy may provide more definitive diagnosis where stool examinations do not provide adequate evidence.⁴⁵

▶ TREATMENT: Amebiasis

■ DESIRED OUTCOME

In amebiasis, the goals of therapy are initially to eradicate the parasite by use of specific amebicides and then to render supportive therapy.

■ TREATMENT REGIMENS

A number of different regimens have been suggested depending on the category of amebiasis: asymptomatic cyst passers, intestinal amebiasis, and amebic liver abscess.^{42–45} Electrolyte replacement and nutritional support are essential adjunctive treatment modalities. Large hepatic abscess or amebic pericarditis may require needle aspiration, percutaneous catheter drainage, or rarely, surgery before drug therapy.^{42,44,45} Most regimens require a combination of drugs administered concurrently or sequentially.^{24,45}

A careful history should be taken when one of the differential diagnoses is ulcerative colitis because corticosteroid administration has the potential to unmask amebiasis and produce toxic megacolon.⁴⁵ All patients diagnosed as having inflammatory bowel disease should have their stools examined carefully and serologic testing done for amebiasis to avoid the serious consequence that results from the administration of corticosteroids.

■ PHARMACOLOGIC THERAPY

Metronidazole (Flagyl), tetracycline, dehydroemetine, and chloroquine (Aralen) are tissue-acting agents, whereas iodoquinol

When amebic liver abscess is suspected from initial physical examination and history, confirmatory diagnostic procedures will include serology and liver scans (using isotopes by ultrasound or computed tomography) or magnetic resonance imaging.^{42,45} Leukocytosis ($>10,000/\text{mm}^3$) and an elevated alkaline phosphatase concentration ($>75\%$) are common findings. In rare instances, needle aspiration of the hepatic abscess may be attempted using ultrasound guidance.^{45,50}

(Yodoxin), diloxanide furoate (Furamide), and paromomycin (Humatin) are luminal amebicides. A systemic agent may be so well absorbed that only small amounts of the drug stay in the bowel, which might prove ineffective as a luminal agent.^{24,42,45,53,54} A luminal-acting agent, on the other hand, may be too poorly absorbed to be effective in the tissue. In the asymptomatic cyst passer, it is necessary to eradicate the causative agent from the lumen to prevent intestinal amebiasis or the development of amebic liver abscess. Drug effectiveness must be monitored by stool examination, i.e., from one to three negative specimens from 1 to 3 months after treatment.

Asymptomatic cyst passers and patients with mild intestinal amebiasis should receive one of the following luminal agents: paromomycin 25–30 mg/kg per day three times daily for 7 days, iodoquinol 650 mg three times daily for 20 days, or diloxanide furoate 500 mg three times daily for 10 days. These regimens have cure rates of between 84% and 96%.⁴⁵ Diloxanide furoate is only available from Ponorama Compounding Pharmacy [6744 Balboa Blvd., Van Nuys, CA 91406; (800)-247-9767].²⁴ The pediatric dose for paromomycin is the same as in adults, whereas the dose of iodoquinol is 30–40 mg/kg per day in three doses for 20 days, and the dose of diloxanide furoate is 20 mg/kg per day in three doses for 10 days.²⁴ Paromomycin is the preferred luminal agent in pregnant patients.^{24,45}

Patients with severe intestinal disease or liver abscess should receive metronidazole 750 mg three times daily for 10 days, followed by a course of one of the luminal agents indicated earlier.^{24,42–45} An alternative regimen of metronidazole 2.4 g/day for 2 days has been suggested to treat intestinal amebiasis.⁴⁵ In the pediatric patient, the dose of oral metronidazole is 50 mg/kg per day in divided doses to be followed by a luminal agent.²⁴ Patients who are too ill to take oral metronidazole should receive the drug in equivalent doses by the intravenous route.^{42,45}

EVALUATION OF THERAPEUTIC OUTCOMES

Follow-up in patients with amebiasis should include repeat stool examination, serology, colonoscopy (in colitis), or computed tomography (CT; in liver abscess) between days 5 and 7, at the end of the course of therapy, and a month after the end of therapy.⁴² Most patients with either intestinal amebiasis or colitis will respond in 3 to 5 days with amelioration of symptoms. Patients with liver abscesses may take from 7 to 10 days to respond; patients not responding during this period may require aspiration of abscesses or exploratory laparotomy. Serial liver scans have demonstrated healing of liver abscesses over 4 to 8 months after adequate therapy.⁴²

SANITATION AND PREVENTIVE MEASURES

Travelers and tourists visiting an epidemic area should avoid local tap water, ice, salads, and unpeeled fruits. Water can be disinfected by the

use of iodine (tincture of iodine or commercial sources: Potable Aqua tablet, Wisconsin Pharmacal, or Globaline, Wallace & Tremain) or a strong chlorine (laundry bleach) solution, but boiled water is probably the safest. An alternative or additional measure may be to carry a portable water purifier (Safewater, Durango, CO; www.outgear.com). Because food handlers in Asia and Latin America may be a source of amebiasis, travelers should avoid eating at food stalls and open markets.

GIARDIASIS

EPIDEMIOLOGY AND ETIOLOGY

Giardia lamblia (also known as *G. intestinalis* or *G. duodenalis*), an enteric protozoan, is the most common intestinal parasite responsible for diarrheal syndromes throughout the world.^{55–69} *Giardia* is the

most frequently identified intestinal parasite in the United States, with a prevalence rate of 16% in some areas. *G. lamblia* has been identified as the first enteric pathogen seen in children in developing countries, with prevalence rates between 15% and 30%.⁵⁷

There are two stages in the life cycle of *G. lamblia*: the trophozoite and the cyst. *G. lamblia*, which is found in the small intestine, the gallbladder, and biliary drainage, is a pear-shaped trophozoite with four pairs of flagella. Two nuclei lie in the area of the sucking disk, giving the protozoan a characteristic facelike image.

The distribution of giardiasis is worldwide. Children seem to be affected more frequently than adults. Children in day-care centers may infect parents and other family members.⁶⁷ In less developed countries, fecal contamination of the environment and lack of potable water, education, and housing continue to be risk factors for giardiasis among children.

PATHOLOGY

Giardiasis results from ingestion of *G. lamblia* cysts in fecally contaminated water or food. The protozoan excysts under the stimulus of low gastric pH to release the trophozoite.⁵⁶ Colonization and multiplication of the trophozoite lead to mucosal invasion, localized edema, and flattening of the villi, resulting in malabsorption states in the host.^{57–69}

Lactose intolerance precipitated by giardiasis can persist even after eradication of the protozoan. Achlorhydria, hypogammaglobu-

TABLE 113–3. Clinical Presentation of Giardiasis

Acute Onset

Diarrhea, cramplike abdominal pain, bloating, and flatulence^{55–68}
Malaise, anorexia, nausea, and belching⁶⁰

Chronic

Diarrhea: Foul-smelling, copious, light-colored, fatty stools; weight loss

Periods of diarrhea alternating with constipation

Steatorrhea, vitamin B₁₂ and fat-soluble vitamin deficiencies^{60–62}

linemia, or deficiency in secretory immunoglobulin A (IgA) are predispositions for giardiasis^{55,57–69} (Table 113–3).

Diagnosis of giardiasis is made by examination of fresh stool or a preserved specimen during the acute diarrheal phase. Fresh stool specimens may show the trophozoites, whereas preserved specimens usually yield the cysts. If both the stool examination and string test prove unsuccessful, it may be necessary to attempt duodenal aspiration and biopsy to confirm the diagnosis; this may be more important in AIDS patients and in patients with hypogammaglobulinemia.^{42,45} Most clinicians would advocate a clinical trial of the standard therapy before undertaking invasive diagnostic tests.^{56,57} An indirect fluorescent antibody (IFA) test that uses a monoclonal antibody to a protein in *Giardia* cysts is available commercially for the detection of the *Giardia* antigen (Meridian Diagnostics, Cincinnati, OH).^{66,67}

► TREATMENT: Giardiasis

■ DESIRED OUTCOME

To reduce morbidity and to avoid complications in patients identified with prolonged diarrhea and malabsorption and who have a recent history of travel to an endemic area, rapid identification by ova and parasite (O&P) examination or by antigen detection test should be used to institute appropriate therapy.

■ PHARMACOLOGIC THERAPY

◀ All symptomatic adults and children older than 8 years of age should be treated with metronidazole 250 mg three times daily

for 7 days. The alternative drugs include furazolidone 100 mg four times or paromomycin 25–30 mg/kg per day in divided doses daily for 1 week.^{24,55–68} Paromomycin 25–30 mg/kg per day in three doses for 7 days or bacitracin or bacitracin zinc may be safe agents in pregnancy.^{24,55,56} The pediatric dose for metronidazole is 15 mg/kg per day three times daily for 5 to 7 days.²⁴ Furazolidone suspension 6 mg/kg per day in four doses for 7 to 10 days and nitazoxanide (Alinia) suspension (a recently approved agent) 100–200 mg every 12 hours for 3 days are alternative drugs for children.^{24,63} Quinacrine, which was the drug of choice in giardiasis, has been discontinued by the manufacturer but is obtained in the United States from a Specialized Pharmacy (see Appendix 113–1). Albendazole 400 mg daily for 5 days has been cited to produce cure rates of 97% and as being equivalent to metronidazole in children. However, other investigators have disputed the efficacy of this agent.⁵⁶

EVALUATION OF THERAPEUTIC OUTCOMES

Patients with symptomatic giardiasis, positive stool samples, or the detection of *Giardia* antigen by IFA or enzyme-linked immunosorbent assay (ELISA) should be treated with metronidazole for 7 days. Metronidazole produces cure rates of between 85% and 95%.^{56–67} Diarrhea will stop within a few days, although in some patients it may take 1 to 2 weeks. Cyst excretion will cease within days; however, intestinal dysfunction (manifested as increased transit time) and radiologic changes (irregular thickening of the folds in the upper small intestine) may take a few months to resolve.⁶⁷ Patients who fail initial therapy with metronidazole should receive a second course of therapy. Pregnant patients can receive paromomycin 25–30 mg/kg per day in divided doses for 7 days. Metronidazole has been used in the second and third trimesters of pregnancy.^{66,57}

Giardiasis can be prevented by good personal hygiene and by caution in food and drink consumption. Preventive measures are similar to those discussed under amebiasis (see “Sanitation and Preventive Measures”).

LEISHMANIASIS

EPIDEMIOLOGY AND ETIOLOGY

This disease is caused by a protozoan belonging to the genus *Leishmania*. The three variations of the disease are visceral leishmaniasis (*kala-azar*, “black fever,” or Assam fever), cutaneous leishmaniasis, and mucocutaneous leishmaniasis.^{64–67} The visceral form is caused predominantly by *L. donovani*, whereas the other two forms are caused

by other species. Leishmaniasis is a complex disease, but space constraints do not justify an extended discussion here; interested readers are urged to consult other sources.^{64,67,68}

Leishmania exist in two forms: as a flagellated extracellular parasite in the sandfly vector (*Phlebotomus* in the Indian subcontinent and *Lutzomyia* and *Psychodopygus* in North and South America, Africa, or the Middle East) and an aflagellar amastigote (intracellular form) in the host.^{67,68} The major reservoirs for *Leishmania*, depending on geographic location, are dogs, foxes, squirrels, and rodents. The sandflies ingest the parasite when they feed on the reservoir animals. After metamorphosis in the gut of the sandfly, the parasite is transferred to the human host when the infected sandfly takes a blood meal. Cutaneous leishmaniasis seen most frequently in the United States is caused by either *L. braziliensis* or *L. mexicana*, which are endemic to south Mexico and Central America.^{67,68}

The disease can range from cutaneous ulcers to the mucocutaneous form affecting the nose, oral cavity, and pharynx. The highest incidence usually is seen in the summer months, especially in subjects working near forested areas. Visceral leishmaniasis may be ac-

TABLE 113–4. Clinical Manifestation of Leishmaniasis

| |
|---|
| Visceral: Early |
| Papule that may ulcerate |
| Asymptomatic period (dissemination of the amastigote to organs: spleen, liver, bone marrow, and lymphatic tissue) |
| Visceral: Late (3–8 Months) ^{65,67} |
| Fever, chills, malaise, weight loss, abdominal distension, and hepatosplenomegaly ^{65,67} |
| Persisting raised ulcer |
| Cutaneous and Mucocutaneous |

quired from transfusion of contaminated blood and accidental needle stick injuries.^{64,67} Patients with advanced-stage acquired immunodeficiency syndrome (AIDS) are reported to be highly susceptible to leishmaniasis⁶⁷ (Table 113–4).

Demonstration of amastigote in tissue or bone marrow confirms the diagnosis of leishmaniasis.^{64–67}

▶ TREATMENT: Leishmaniasis

■ DESIRED OUTCOME

The major goal is to eradicate the amastigote in the tissue and to minimize the ensuing complications of leishmaniasis.

■ PHARMACOLOGIC THERAPY

8 All three forms of leishmaniasis are treated with stibogluconate sodium (antimony sodium gluconate-pentavalent antimony, Pentostam), which is obtained from the CDC. In adults, both

the cutaneous and mucocutaneous forms (*L. braziliensis* and *L. mexicana*) are treated with stibogluconate 20 mg/kg per day for 20 to 28 days.²⁴ The drug may be administered by either the intravenous or intramuscular route. Therapy for all forms of leishmaniasis may be repeated.²⁴ An alternative drug for the visceral form is amphotericin B (Fungizone) or liposomal amphotericin B (AmBisome). Liposomal amphotericin B is also recommended for mucocutaneous and cutaneous forms.^{24,70–73} Pediatric patients receive the same dose as adults (see Appendix 113–1 for side effects of the drugs). Pentavalent antimony therapy combined with interferon- γ or liposomal amphotericin may be alternatives in refractory leishmaniasis.²⁴ Other combination therapies and alternative agents for the various forms of leishmaniasis are discussed in detail by a number of authors.^{64,72,73}

EVALUATION OF THERAPEUTIC OUTCOMES

The presence of dead amastigotes in tissue and bone marrow, resolution of anemia and leukopenia, and disappearance of splenomegaly and hepatomegaly may be used as monitoring parameters for the disease. Travelers to endemic areas should use insect repellents and sleep in fine-mesh netting to avoid exposure to the sandfly.^{67,68} No effective chemoprophylaxis against leishmaniasis is available.

The reduviid bug is infected by sucking blood from animals (e.g., opossums, dogs, and cats) or humans infected with circulating trypanomastigotes (Table 113–5).

9 In chronic disease, patients present with cardiomyopathy and heart failure. Electrocardiograms are usually abnormal, demonstrating extrasystoles, first-degree heart block, right bundle-branch block, and other serious conduction disturbances.^{75,78} Degeneration

AMERICAN TRYPANOSOMIASIS

ETIOLOGY

Two distinct forms of the genus *Trypanosoma* occur in humans. One is associated with African trypanosomiasis (sleeping sickness) and the other with American trypanosomiasis (Chagas' disease).^{74–76} *T. brucei gambiense* and *T. brucei rhodesiense* are the causative organisms for African trypanosomiasis. In Chagas' disease, the trypanomastigote is found in the bloodstream, and an ovoid, unflagellated intracellular form is found in cardiac and other tissues.^{74,75}

T. cruzi is the agent that causes American trypanosomiasis. American trypanosomiasis is transmitted by a number of species of a reduviid bug (*Triatoma infestans*, *Rhodrium prolixus*) that live in wall cracks of houses in rural areas of North, Central, and South America.

TABLE 113–5. Clinical Presentation of South American Trypanosomiasis

| |
|---|
| Acute |
| Unilateral orbital edema (“Romana’s sign”) ^{74,76} |
| Granuloma or “chagoma” |
| Fever, hepatosplenomegaly, and lymphadenopathy |
| Chronic |
| Cardiac: Cardiomyopathy and heart failure |
| ECG: First-degree heart block, right bundle-branch block, and arrhythmias ^{75,78} |
| Gastrointestinal: Enlargement of esophagus and colon (“mega” syndrome) ^{74,76,77} |
| Central nervous system: Meningoencephalitis, strokes, seizures, and focal paralysis ^{74,76,79–81} |

of the autonomic ganglia in the smooth muscle of the esophagus and colon leads to uncoordinated peristalsis. The end result has been reported to be “megasyndromes” of affected organs.^{74,76,77} Penetration of central nervous system results in meningoencephalitis, strokes, seizures, and focal paralysis.^{74,76,79–81}

A history to verify the possible exposure to *T. cruzi* should be an important initial diagnostic work-up. Recovery of *T. cruzi* is defini-

tive, but this is not always possible, especially in chronic disease. Positive serologic tests using indirect hemagglutination tests, ELISA (Chagas EIA, Abbott Labs), and a complement fixation (CF) test are diagnostic.⁷⁴ The CDC has used PCR to diagnosis *T. cruzi*.⁸² Specimens may be sent to the CDC for testing. False-positive reactions are seen, especially in those exposed to leishmaniasis, syphilis, or malaria.⁷⁴

► TREATMENT: American Trypanosomiasis

■ DESIRED OUTCOME

The primary goal of drug therapy in trypanosomiasis is to reduce the duration and severity of the illness and possibly to decrease mortality.

■ PHARMACOLOGIC THERAPY

The drugs that have been used to treat *T. cruzi* infections include nifurtimox (Lampit, Bayer 2502) and benznidazole (Rochagan).^{24,83,84}

However, it has been suggested that benznidazole and related compounds may not be safe treatment for *T. cruzi*.⁸⁴ Oral nifurtimox is available from the CDC, whereas benznidazole is only available in Brazil. The adult dose of nifurtimox is 8–10 mg/kg per day in divided doses for 120 days. Because pediatric patients tolerate the drug better than adults, the dose for children aged 1 to 10 years is 15–20 mg/kg per day, and for children aged 11 to 16 years it is 12.5–15 mg/kg per day in divided doses.²⁴ Symptomatic treatment for heart failure includes digitalis and diuretics; the gastrointestinal complications, however, may require surgical revisions and reconstruction.⁷⁶

EVALUATION OF THERAPEUTIC OUTCOMES

American trypanosomiasis (Chagas’ disease), which is endemic in all Latin American countries, can be transmitted congenitally, by blood transfusion, and by organ transplantation.^{74,76} Treatment with nifurtimox of the acute phase (i.e., fever, malaise, edema of face, generalized lymphadenopathy, and hepatosplenomegaly) produces between 50% and 75% cure rates.^{74,76} Treatment of chronic infection with nifurtimox is not recommended. It is essential to identify *T. cruzi*-infected patients by serology and to monitor the cardiovascular status of these patients by electrocardiogram periodically. The congestive failure of cardiomyopathic Chagas’ disease is treated the same way as cardiomyopathies from other causes.^{75,76}

HELMINTHIC DISEASES

Most intestinal helminthic infections may not be associated with clearly defined manifestation of disease, but they can cause significant pathology.^{85–94} One factor that determines the pathogenicity of helminths is their population density. Light infections may be fairly well tolerated, whereas high populations of intestinal helminths can result in predictable disease presentations. In the United States, these infections are seen most frequently in recent immigrants from Southeast Asia, the Caribbean, Mexico, and Central America.^{1,3,9} There is a higher incidence of helminthic infections in the southern states. Other populations that have a high risk of infestation include institutionalized patients (both young and elderly), preschool children in day-care

centers, residents of Indian reservations, and homosexual individuals. Certain conditions and drugs (fever, corticosteroids, and anesthesia) can cause atypical localization of worms.^{93,94} Immunocompromised hosts can be overwhelmed by some helminthic infections, such as strongyloidiasis.⁹⁴

NEMATODES

HOOKWORM DISEASE

This is an infection of the small intestine caused by either *Ancylostoma duodenale* or *Necator americanus*. *N. americanus* is found in the southeastern United States, where the temperature and humidity provide the proper environment. *Ancylostoma* is seen rarely in the United States.

The life cycles of both species of hookworm are similar. The adult worms live in the small intestine attached to the mucosa. The females liberate eggs, which are eliminated in the feces and develop into larvae. Infective larva enter the host in contaminated food or water or penetrate the skin, where a papular eruption with localized edema and erythema can result.

In the small intestine, where the adult worm lives attached to the mucosa, injury is usually caused by mechanical and lytic destruction of tissue. The loss of blood can lead to anemia and hypoproteinemia.^{89–91}

Stool should be examined for eggs and the rhabditiform larvae. Eosinophilia (30% to 60%) is present in patients with chronic infection.

► TREATMENT: Hookworm Disease

Mebendazole (Vermox), an oral synthetic benzimidazole, is the agent of first choice. It is also effective against ascariasis, enterobiasis, and trichuriasis.^{24,25,95,96} The adult dose for treatment of

hookworm infestation is 100 mg twice daily for 3 days. Pediatric patients older than 2 years of age should receive the same dose as adults.²⁴

ASCARIASIS

Ascariasis is caused by the giant roundworm *Ascaris lumbricoides*. Female worms range from 20 to 35 cm in length. The worm is found worldwide but more commonly in areas where sanitation is poor. In the United States, endemic areas include southeastern parts of the Appalachian range and the Gulf Coast states. Approximately 4 million people in the United States have ascariasis.⁸⁵

▶ TREATMENT: Ascariasis

In both adults and pediatric patients older than 2 years of age, the treatment for ascariasis is mebendazole (Vermox) 100 mg twice daily

Clinical Manifestations

During migration of the larvae through the lungs, patients can present with pneumonitis, fever, cough, eosinophilia, and pulmonary infiltrates.^{9,85,93} Other symptoms of ascariasis include abdominal discomfort, abdominal obstruction, vomiting, and appendicitis.^{86–88,93} Diagnosis is made by demonstrating the characteristic egg in the stool.

for 3 days. An alternative drug for ascariasis is pyrantel pamoate (Antiminth).^{24,98}

ENTEROBIASIS

Enterobiasis, or pinworm infection, is caused by *Enterobius vermicularis*. The pinworm is a small, threadlike, spindle-shaped worm about 1 cm in length. It is the most widely distributed helminthic infection in the world. There are estimated to be 42 million cases in the United States.^{85,99} The majority of those infected are children.

There are no significant pathologic changes with the infection. The most common problem is cutaneous irritation in the perianal

region, made by the migrating females or the presence of eggs. The intense pruritus and scratching can cause dermatitis and secondary bacterial infections. In children, the itching can cause loss of sleep and restlessness.

The most effective method of diagnosing pinworm infections is by the use of perianal swab using adhesive Scotch tape. The Scotch tape, which is applied to the perianal region with a tongue depressor, is examined microscopically for eggs.^{9,85,99}

▶ TREATMENT: Enterobiasis

◀ Helminthic drugs are used to eradicate or reduce the parasitic load in patients. The common agents for treatment include pyrantel pamoate, mebendazole, or albendazole (Zentel). The dose of pyrantel pamoate is 11 mg/kg (maximum 1 g) as a single dose that can be repeated in 2 weeks. The dose of mebendazole for adults and children older than 2 years of age is 100 mg as a single dose; this may be repeated in 2 weeks.^{24,98} The dose of albendazole for

adults and children older than 2 years of age is 400 mg, and this dose should be repeated in 2 weeks.⁹⁸ Following treatment, all bedding and underclothes should be sterilized by steaming or washing in the hot water cycle of a regular washing machine; this will eradicate the eggs. Bathroom rugs and toilet accessories also should be cleaned in a similar way.

EVALUATION OF THERAPEUTIC OUTCOME: NEMATODES

Morbidity and disease with intestinal nematodes are related to the intensity of infection or worm burden; subjects with transient exposure have less severe disease. The major adverse effects of intestinal nematodes are malnutrition, fatigue, and diminished work capacity. Treatment with antihelminthic agents results in complete eradication and significant change in the well-being of patients. Unlike other nematodes, strongyloidiasis can perpetuate itself by autoinfection, and under immunosuppression, the filariform can invade various organs (e.g., lungs, central nervous system, and the like) to produce disseminated infection that can be fatal.^{9,85,94}

body lice, and *Phthirus*, with only one species, the crab louse.^{9,100–105} The human louse is detectable to the human naked eye and measures approximately 2 to 3 mm in length.

LICE

The two species that belong to this group include *Pediculus humanus capitis* (head louse) and *P. humanus corporis* (body louse). Female lice deposit eggs on the hair. The eggs (or nits) remain firmly attached to the hair, and in about 10 days, the lice hatch to form nymphs, which mature in 2 weeks. Using both their piercing mouth parts and a pumping device, the larvae and adults feed on the blood of the host. The body louse and head louse are essentially identical, although they live on different parts of the body. Unlike the head louse, which lives on the hair, the body louse is more frequently found on clothing of the infected host.

Pubic or crab lice are found on the hairs around the genitals, although they can occur in other areas of the body (e.g., eyelashes, beards, and axillae). Patients usually complain of severe pruritus from papular lesions produced by the bite of the louse. Hypersensitivity to foreign material injected by the lice can produce macular swellings and occasionally can lead to secondary bacterial infections.¹⁰¹

ECTOPARASITES

A parasite that lives on the outside the body of the host is called an *ectoparasite*. Approximately 6 to 12 million people become infested with pediculosis yearly in the United States.¹⁰⁸ Pediculosis usually is associated with poor personal hygiene, and infections are passed from person to person through social and sexual contact. The three types of human lice belong to two genera: *Pediculus*, including the head and

► TREATMENT: Lice

The goal of therapy is to eradicate the causative organisms and provide symptomatic relief to patients. The agent of choice for all three infections (body, head, and crab lice) is 1% permethrin (Nix).^{100–109} Permethrin is a derivative of the flowers of the plant *Chrysanthemum cinerariifolium*. The term *pyrethrin* is usually applied to several esters of chrysanthemic acid and pyrethric acid. Permethrin has both pediculicidal and ovicidal activity against *P. humanus* var. *capitis*. The cure rate is reported to be in the range of 90% to 97%.^{106–109} Individuals who have a history of ragweed or chrysanthemum allergy should use this compound with caution. The side effects reported with permethrin products include itching, burning, stinging, and tingling.¹⁰⁹ Permethrin 1% is applied to the scalp after the hair has been dried following a shampooing. The scalp should be saturated with permethrin liquid, and a towel should be wrapped around the scalp to allow the application to stay on for 10 minutes. The hair then should be rinsed

off. A cream rinse of permethrin 1% (Nix-Creme Rinse) is also available. To ensure complete eradication, especially of newly hatched lice, it may be necessary to repeat the application.¹⁰⁴ Recent reports have suggested increasing lice resistance to permethrin 1%.^{105–109} An alternative preparation for lice is 0.5% malathion (Ovide), which is very effective.^{24,105} To ensure complete eradication of lice infestation, the malathion application should be left on the scalp for about 90 minutes.¹⁰⁹ For the relief of pruritus, a soothing lotion of calamine liniment or lotion with 0.1% menthol may be used. Other members of the family or sexual partners also should be treated. All bedding and clothes should be sterilized by boiling or washing in the hot water cycle of the washing machine to avoid reinfections. Seams of clothes should be examined to verify that all organisms are eradicated. An ocular lubricant (e.g., Lacri-Lube S.O.P.) applied twice daily may be used to remove crab louse infection of the eyelids.

SCABIES

Scabies is caused by the itch mite *Sarcoptes scabiei*, which affects both humans and animals. Mange in domestic animals is caused by the same organism. Infection usually affects the interdigital and popliteal folds, axillary folds, the umbilicus, and the scrotum.^{100,102,110}

CLINICAL PRESENTATION

Patients will complain of severe itching and an inability to sleep and may have excoriations in the interdigital web spaces, wrists, elbows, buttocks, groin, and scalp. Excoriations may lead to secondary bacterial infections. The diagnosis is made by looking for burrows formed by the mite and taking skin scrapings, which will demonstrate the mite on a wet mount.

► TREATMENT: Scabies

Because these infections cause a great deal of discomfort and distress to patients and families, the goals of therapy are to eradicate the infestations rapidly, to institute symptomatic treatment, and to provide counseling and reassurance. The treatment of choice is permethrin 5% (Elimite) cream.^{24,100,102,110} To initiate the treatment, the skin should be scrubbed thoroughly in a warm soapy bath using a soft brush to remove all scabs. The lotion is then applied to the whole body, avoiding the face, mucous membranes, and eyes. The application should be left on for 8 to 14 hours before bathing.²⁴ A single application eradicates 97% of scabies in subjects.¹¹⁰ All close contacts should be checked and treated appropriately.

Other agents used to treat scabies are Crotamiton 10% (Eurax) and oral ivermectin (Stromectal) 200 mcg/kg once.^{24,100,110} These should be used in patients who have hypersensitivity to permethrin preparations. Topical corticosteroids and antihistamines may be used to decrease pruritus.

Permethrin (1% to 5%) for pediculosis and scabies is the preferred agent and remains the safest agent, especially in infants and children.^{100,102} One application of permethrin is consistently effective in eradicating more than 90% of all infections. However, pruritus may persist for 2 to 4 weeks because of the remnants of mite parts in the skin.

APPENDIX 113–1

Antiparasitic Drugs

| Drug | Indications | Side Effects | Comments | References |
|---|--|--|---|----------------------------|
| Albendazole 200 mg tablet (zentel) | Giardiasis Ascariasis Neurocysticercosis | GI: Abdominal pain, nausea, diarrhea, increase in liver function enzymes | Not recommended in children <2 years old | 9, 24, 94, 96, 98 |
| Atovaquone 250 mg <i>plus</i> Proguanil 100 mg (Malarone) ^a | Prevention and treatment of <i>P. falciparum</i> malaria | Abdominal pain, nausea, vomiting and headache | | 13, 23, 24, 25, 39–40 |
| Chloroquine phosphate (Aralen, Nivaquine) 250- and 500-mg tablets; 50 mg/mL (as HCl); 5-mL ampule | Malaria | GI: Nausea, vomiting, diarrhea CNS: Dizziness, headache, blurring of vision, confusion, fatigue Derm.: Pruritus | Administer oral dose after meals IV route: Recommend ECG monitoring <i>Contraindication:</i> Patients with psoriasis or porphyria | 10, 13, 15, 23, 24, 27, 28 |
| Diloxanide furoate ^b (Furamide) 500-mg tablet | Amebiasis | GI: Nausea, flatulence Derm.: Pruritus | | 9, 24, 42, 44, 45, 53, 54 |
| Furazolidone (Furoxone) 100-mg tablet Suspension: 50 mg/5 mL | Giardiasis Alternative to metronidazole | GI: Nausea, vomiting Hypersensitivity: Hypotension, fever, arthralgia, urticaria Other: Headache | Disulfiram-like reaction with alcohol; avoid in G6PD ^c deficiency; may cause hemolysis; chances color of urine to brown | 9, 24, 42, 45, 53, 54 |
| Halofantrine (Halfan) 250-mg tablet | <i>P. falciparum</i> malaria | GI: Abdominal pain, diarrhea Card.: Prolongation of QT interval | Should <i>not</i> be taken with fatty meals. <i>Contraindication:</i> Preexisting conduction defects. | 23, 24, 27 |
| Iodoquinol (Yodoxin) 210-mg tablet | Amebiasis | GI: Abdominal pain, diarrhea Derm.: Rash | May interfere with thyroid function test <i>Contraindication:</i> Patients with iodine intolerance | 24, 42–45, 53, 54 |
| Ivermectin (Stromectal) 6-mg tablet | Strongyloidiasis Pediculosis | Dizziness, somnolence, tremor, vertigo, pruritus, abdominal pain | Should be taken with a full glass of water | 24, 98, 100, 101, 109, 110 |
| Mebendazole (Vermox) 100-mg chewable tablet | Ascariasis, trichuriasis, hookworm, pinworm, | GI: Abdominal pain, diarrhea CNS: Headache, dizziness Other: Pyrexia, neutropenia | Drug should be taken with meals <i>Contraindication:</i> Pregnancy <i>Drug interaction:</i> Can increase serum levels of theophylline | 9, 24, 85, 93, 98 |
| Mefloquine (Lariam) 250-mg tablet | <i>P. falciparum</i> malaria | Incidence 17% GI: Nausea, vomiting, abdominal pain, diarrhea Card.: Sinus bradycardia CNS: vertigo, dizziness, confusion, hallucinations, psychosis, convulsions Derm.: Itching, skin rash | Patients given doses in excess of 12 mg/kg should be monitored carefully because the side effects are dose-related | 10–13, 15, 23, 24, 25, 26 |
| Metronidazole (Flagyl) Oral: 250-mg, 500-mg tablets | Amebiasis Giardiasis | GI: Nausea, anorexia, vomiting, diarrhea, abdominal cramping, glossitis, metallic taste CNS: Dizziness, vertigo, headache, paresthesias | Avoid alcohol; alcohol ingestion will cause the disulfiram reaction: abdominal distress, vomiting, hypotension <i>Contraindication:</i> First trimester of pregnancy | 9, 24, 54–59 |

(continued)

| Drug | Indications | Side Effects | Comments | References |
|--|--|--|--|-----------------------|
| Nifurtimox ^d (Lampit, Bayer 2502) | South American trypanosomiasis | GI: Anorexia, nausea CNS: Peripheral neuritis, psychosis Hemat: Hemolysis in G6PD ^c deficiency patients | Monitor pulmonary function and hematologic parameters | 24, 74, 76 |
| Nitazoxanide (Alinia) 100 mg/5 mL suspension | Cryptosporidiosis Giardiasis | Abdominal pain, diarrhea, vomiting, and headache | Rarely may produce yellow sclerae | 59, 63 |
| Primaquine phosphate 26.3-mg tablet | Malaria (<i>P. vivax</i>) (<i>P. ovale</i>) | GI: Nausea, abdominal pain CNS: Mental depression | In G6PD deficiency can cause hemolysis | 9, 10–13, 23, 24, 25 |
