URINARY TRACT INFECTIONS AND PROSTATITIS

Elizabeth A. Coyle and Randall A. Prince

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Urinary tract infections are classified as uncomplicated and complicated. *Uncomplicated* refers to an infection in an otherwise healthy female who lacks structural or functional abnormalities of the urinary tract. Most often complicated infections are associated with a predisposing lesion of the urinary tract; however, the term may be used to refer to all other infections, except for those in the otherwise healthy adult female.
- 2 Eighty-five percent of uncomplicated urinary tract infections are caused by *Escherichia coli*, and the remainder are caused primarily by *Staphylococcus saprophyticus*, *Proteus* spp., and *Klebsiella* spp. Complicated infections are more frequently associated with gram-negative organisms and *Enterococcus faecalis*.
- 3 Symptoms of lower urinary tract infections include dysuria, urgency, frequency, nocturia, and suprapubic heaviness, whereas upper urinary tract infections involve more systemic symptoms such as fever, nausea, vomiting, and flank pain.
- 4 Significant bacteriuria traditionally has been defined as bacterial counts of greater than 100,000 (10^5)/mL of urine. Many clinicians, however, have challenged this as too general a statement. Indeed, significant bacteriuria in patients with symptoms of a urinary tract infection may be defined as greater than 10^2 organisms per milliliter.
- 5 The goals of treatment of urinary tract infections are to prevent or treat systemic consequences of infections, eradicate the invading organism(s), and prevent the recurrence of infection.
- 6 Uncomplicated urinary tract infections can be managed most effectively with short-course (3 days) therapy with either trimethoprim-sulfamethoxazole or a fluoroquinolone. Complicated infections require longer treatment periods (2 weeks) usually with one of these agents.
- 7 In choosing appropriate antibiotic therapy, practitioners need to be cognizant of antibiotic resistance patterns, particularly to *E. coli*. Recently, trimethoprim-sulfamethoxazole has demonstrated diminished activity against *E. coli* in some areas of the country, with reported resistance up to 20%.
- 8 Acute bacterial prostatitis can be managed with many agents that have activity against the causative organism. Chronic prostatitis requires an agent that is not only active against the causative organism but also concentrates in the prostatic secretions. Therapy with trimethoprim-sulfamethoxazole or a fluoroquinolone is preferred for 4 to 6 weeks.

Infections of the urinary tract represent a wide variety of syndromes, including urethritis, cystitis, prostatitis, and pyelonephritis. Urinary tract infections (UTIs) are one of the most commonly occurring bacterial infections and account for 8 million patient visits annually.^{1–3} Approximately one in three females will have had a urinary tract infection by age 24.⁴ Infections in men occur much less frequently until the age of 65, at which point the incidence rates in men and women are similar.

A UTI is defined as the presence of microorganisms in the urinary tract that cannot be accounted for by contamination. The organisms present have the potential to invade the tissues of the urinary tract and adjacent structures. Infection may be limited to the growth of bacteria in the urine, which frequently may not produce symptoms. A UTI can present as several syndromes associated with an inflammatory response to microbial invasion and can range from asymptomatic bacteriuria to pyelonephritis with bacteremia or sepsis.

UTIs are classified by several methods. Typically, they have been described by anatomic site of involvement. Lower tract infec-

tions include cystitis (bladder), urethritis (urethra), prostatitis (prostate gland), and epididymitis. Pyelonephritis is an infection involving the kidneys and represents upper tract infection.

1 Also, UTIs are designated as uncomplicated or complicated. Uncomplicated infections occur in individuals who lack structural or functional abnormalities of the urinary tract that interfere with the normal flow of urine or voiding mechanism. These infections occur in females of childbearing age (15 to 45 years) who are otherwise normal, healthy individuals. Infections in males generally are not classified as uncomplicated because these infections are rare and most often represent a structural or neurologic abnormality.

Complicated UTIs are the result of a predisposing lesion of the urinary tract, such as a congenital abnormality or distortion of the urinary tract, a stone, indwelling catheter, prostatic hypertrophy, obstruction, or neurologic deficit that interferes with the normal flow of urine and urinary tract defenses. Complicated infections occur in both genders and frequently involve the upper and lower urinary tract.

TABLE 114–1. Diagnostic Criteria for Significant Bacteriuria

| |
|---|
| $\geq 10^2$ CFU coliforms/mL or $\geq 10^5$ CFU noncoliforms/mL in a symptomatic female |
| $\geq 10^3$ CFU bacteria/mL in a symptomatic male |
| $\geq 10^5$ CFU bacteria/mL in asymptomatic individuals on two consecutive specimens |
| Any growth of bacteria on suprapubic catheterization in a symptomatic patient |
| $\geq 10^2$ CFU bacteria/mL in a catheterized patient |

Recurrent UTIs are characterized by multiple symptomatic infections with asymptomatic periods occurring between each episode. Either reinfection or relapse causes these infections. Reinfections are caused by a different organism than originally isolated and account for the majority of recurrent UTIs. Relapse is the development of repeated infections with the same initial organism and usually indicates a persistent infectious source.

Asymptomatic bacteriuria is a common finding, particularly among those 65 years of age and older, when there is significant bacteriuria ($>10^5$ bacteria/mL of urine) in the absence of symptoms. Symptomatic abacteriuria or acute urethral syndrome consists of symptoms of frequency and dysuria in the absence of significant bacteriuria. This syndrome is commonly associated with *Chlamydia* infections.

Significant bacteriuria is a term used to distinguish the presence of microorganisms that represent true infection versus contamination of the urine as it passes through the distal urethra prior to collection. Historically, bacterial counts equal to or greater than 100,000 organisms/mL of urine in a “clean catch” specimen were judged to indicate true infection.⁵ Counts of less than 100,000, however, may represent true infection in certain situations, e.g., with concurrent antibacterial drug administration, rapid urine flow, low urinary pH, or upper tract obstruction.⁶ Table 114–1 lists the clinical definitions of significant bacteriuria, which are dependent on the clinical setting and the method of specimen collection.⁵ These criteria allow for more appropriate specificity and sensitivity in documenting infection under differing clinical circumstances.

EPIDEMIOLOGY

The prevalence of UTIs varies with age and gender. In newborns and infants up to 6 months of age, the prevalence of bacteriuria is about 1% and is more common in boys. Most of these infections are associated with structural or functional abnormalities of the urinary tract and have been correlated with the lack of circumcision.⁷ Between the ages of 1 and 5 years, UTIs occur more frequently in females. The prevalence of bacteriuria in females and males of this age group is 4.5% and 0.5%, respectively.⁸ Infections occurring in preschool boys usually are associated with congenital abnormalities of the urinary tract. These infections are difficult to recognize because of the age of the patient, but they often are symptomatic. In addition, it is believed that the majority of renal damage associated with UTI develops at this age.⁸

Through grade school and before puberty, the prevalence of UTI is about 1%, with 5% of females reported to have significant bacteriuria prior to leaving high school. This percentage increases dramatically to 1% to 4% after puberty in nonpregnant females primarily as a result of sexual activity. Approximately one in five women will suffer

a symptomatic UTI at some point in their lives. Many women have recurrent infections, with a significant proportion of these women having a history of childhood infections. In contrast, the prevalence of bacteriuria in adult men is very low ($<0.1\%$).⁹

In the elderly, the ratio of bacteriuria in women and men is dramatically altered and is approximately equal in persons over the age of 65.¹⁰ The overall incidence of UTI increases substantially in this population, with the majority of infections being asymptomatic. The rate of infection increases further for elderly persons who are residing in nursing homes, particularly those who are hospitalized frequently. The increase is probably the result of a number of factors, including obstruction from prostatic hypertrophy in males, poor bladder emptying as a result of prolapse in females, fecal incontinence in demented patients, neuromuscular disease, including strokes, and increased urinary instrumentation (catheterization).

ETIOLOGY

2 The bacteria causing UTIs usually originate from bowel flora of the host. Although virtually every organism is associated with UTIs, certain organisms predominate as a result of specific virulence factors. The most common cause of uncomplicated UTIs is *Escherichia coli*, which accounts for 85% of community-acquired infections. Additional causative organisms in uncomplicated infections include *Staphylococcus saprophyticus* (5% to 15%), *Klebsiella pneumoniae*, *Proteus* spp., *Pseudomonas aeruginosa*, and *Enterococcus* spp. (5% to 10%). Because *S. epidermidis* is frequently isolated from the urinary tract, it should be considered initially a contaminant. Repeat cultures should be performed to help confirm the organism as a real pathogen.

Organisms isolated from individuals with complicated infections are more varied and generally are more resistant than those found in uncomplicated infections. *E. coli* is a frequently isolated pathogen, but it accounts for less than 50% of infections. Other frequently isolated organisms include *Proteus* spp., *K. pneumoniae*, *Enterobacter* spp., *P. aeruginosa*, staphylococci, and enterococci. Enterococci represent the second most frequently isolated organisms in hospitalized patients.¹¹ In part, this finding may be related to the extensive use of third-generation cephalosporin antibiotics, which are not active against the enterococci. Vancomycin resistant *E. faecalis* and *S. faecium* (VRE) have become more widespread, especially in patients with long-term hospitalizations or underlying malignancies. VRE is a major therapeutic and infection control issue.^{11,12}

Staphylococcus aureus infections may arise from the urinary tract, but they are more commonly a result of bacteremia producing metastatic abscesses in the kidney. *Candida* spp. are common causes of UTI in the critically ill and chronically catheterized patient.

Most UTIs are caused by a single organism; however, in patients with stones, indwelling urinary catheters, or chronic renal abscesses, multiple organisms may be isolated. Depending on the clinical situation, the recovery of multiple organisms may represent contamination, and a repeat evaluation should be done.

PATHOPHYSIOLOGY

ROUTE OF INFECTION

In general, organisms gain entry into the urinary tract via three possible routes: the ascending, hematogenous (descending), and lymphatic pathways. The female urethra usually is colonized by bacteria believed

to originate from the fecal flora. The short length of the female urethra and its proximity to the perirectal area make colonization of the urethra likely. Other factors that promote urethral colonization include the use of spermicides and diaphragms as methods of contraception.^{2,3} Although there is evidence in females that bladder infections follow colonization of the urethra, the mode of ascent of the microorganisms is not completely understood. Massage of the female urethra and sexual intercourse allow bacteria to reach the bladder.¹³ Once bacteria have reached the bladder, the organisms quickly multiply and can ascend the ureters to the kidneys. This sequence of events is more likely to occur if vesicoureteral reflux (reflux of urine into the ureters and kidneys while voiding) is present. The fact that UTIs are more common in females than in males because of the anatomic differences in location and length of the urethra tends to support the ascending route of infections as the primary acquisition route.

Infection of the kidney by hematogenous spread of microorganisms usually occurs as the result of dissemination of organisms from a distant primary infection in the body. Infections via the descending route are uncommon and involve a relatively small number of invasive pathogens. Bacteremia caused by *S. aureus* may produce renal abscesses. Additional organisms include *Candida* spp., *Mycobacterium tuberculosis*, *Salmonella* spp., and enterococci. Of particular interest, it is difficult to produce experimental pyelonephritis by intravenously administering common gram-negative organisms such as *E. coli* and *P. aeruginosa*. Overall, less than 5% of documented UTIs result from hematogenous spread of microorganisms.

There appears to be little evidence supporting a significant role for renal lymphatics in the pathogenesis of UTIs. There are lymphatic communications between the bowel and kidney, as well as between the bladder and kidney. There is no evidence, however, that microorganisms are transferred to the kidney via this route.

After bacteria reach the urinary tract, three factors determine the development of infection: the size of the inoculum, the virulence of the microorganism, and the competency of the natural host defense mechanisms. Most UTIs reflect a failure in host defense mechanisms.

HOST DEFENSE MECHANISMS

The normal urinary tract generally is resistant to invasion by bacteria and is efficient in rapidly eliminating microorganisms that reach the bladder. The urine under normal circumstances is capable of inhibiting and killing microorganisms. The factors thought to be responsible include a low pH, extremes in osmolality, high urea concentration, and high organic acid concentration. Bacterial growth is further inhibited in males by the addition of prostatic secretions.^{14,15}

The introduction of bacteria into the bladder stimulates micturition, with increased diuresis and efficient emptying of the bladder. These factors are critical in preventing the initiation and maintenance of bladder infections. Patients who are unable to void urine completely are at greater risk of developing UTIs and frequently have recurrent infections. Also, patients with even small residual amounts of urine in their bladder respond less favorably to treatment than patients who are able to empty their bladders completely.¹⁶

An important virulence factor of bacteria is their ability to adhere to urinary epithelial cells, resulting in colonization of the urinary tract, bladder infections, and pyelonephritis. Various factors that act as antiadherence mechanisms are present in the bladder, preventing bacterial colonization and infection. The epithelial cells of the bladder are coated with a urinary mucus or slime called *glycosaminoglycan*. This thin layer of surface mucopolysaccharide is hydrophilic and strongly negatively charged. When bound to the uroepithelium, it attracts

water molecules and forms a layer between the bladder and urine. The antiadherence characteristics of the glycosaminoglycan layer are nonspecific, and when the layer is removed by dilute acid solutions, rapid bacterial adherence results.¹⁷

In addition, the Tamm-Horsfall protein is a glycoprotein produced by the ascending limb of Henle and distal tubule that is secreted into the urine and contains mannose residues. These mannose residues bind *E. coli* that contain small surface projecting organelles on their surfaces called *pili* or *fimbriae*. Type 1 fimbriae are mannose-sensitive, and this interaction prevents the bacteria from binding to similar receptors present on the mucosal surface of the bladder. Other factors that possibly prevent adherence of bacteria include immunoglobulins (Ig) G and A. Investigators have documented both systemic and local kidney Ig synthesis in upper tract infections. The role of Igs in preventing bladder infection is less clear. Patients with reduced urinary levels of secretory IgA are, however, at increased risk of infections of the urinary tract.¹⁴

After bacteria actually have invaded the bladder mucosa, an inflammatory response is stimulated with the mobilization of polymorphonuclear leukocytes (PMNs) and resulting phagocytosis. PMNs are primarily responsible for limiting the tissue invasion and controlling the spread of infection in the bladder and kidney. They do not play a role in preventing bladder colonization or infections and actually contribute to renal tissue damage.

Other host factors that may play a role in the prevention of UTIs are the presence of *Lactobacillus* in the vaginal flora and circulating estrogen levels. In premenopausal women, circulating estrogen supports the vaginal tract growth of lactobacilli, which produce lactic acid to help maintain a low vaginal pH, thereby preventing *E. coli* vaginal colonization. Spermicide use, β -lactam antimicrobials use, lower estrogen levels, intercourse with a new partner, and douching can lead to decreases in lactobacilli colonization.^{18,19}

BACTERIAL VIRULENCE FACTORS

Pathogenic organisms have differing degrees of pathogenicity (virulence), which play a role in the development and severity of infection. Bacteria that adhere to the epithelium of the urinary tract are associated with colonization and infection. The mechanism of adhesion of gram-negative bacteria, particularly *E. coli*, is related to bacterial fimbriae that are rigid hairlike appendages of the cell wall.²⁰ These fimbriae adhere to specific glycolipid components on epithelial cells. The most common type of fimbriae is type 1, which binds to mannose residues present in glycoproteins. Glycosaminoglycan and Tamm-Horsfall protein are rich in mannose residues that readily trap those organisms which contain type 1 fimbriae, which are then washed out of the bladder.²¹ Other fimbriae are mannose-resistant and are associated more frequently with pyelonephritis, such as P fimbriae, which bind avidly to specific glycolipid receptors on uroepithelial cells. These bacteria are resistant to washout or removal by glycosaminoglycan and are able to multiply and invade tissue, especially the kidney. In addition, PMNs, as well as secretory IgA antibodies, contain receptors for type 1 fimbriae, which facilitates phagocytosis, but they lack receptors for P fimbriae.

Other virulence factors include the production of hemolysin and aerobactin.²⁰ Hemolysin is a cytotoxic protein produced by bacteria that lyses a wide range of cells, including erythrocytes, PMNs, and monocytes. *E. coli* and other gram-negative bacteria require iron for aerobic metabolism and multiplication. Aerobactin facilitates the binding and uptake of iron by *E. coli*; however, the significance of this property in the pathogenesis of UTIs remains unknown.

PREDISPOSING FACTORS TO INFECTION

The normal urinary tract typically is resistant to infection and colonization by pathogenic bacteria. In patients with underlying structural abnormalities of the urinary tract, the typical host defenses previously discussed usually are lacking. There are several known abnormalities of the urinary tract system that interfere with its natural defense mechanisms, the most important of which is obstruction. Obstruction can inhibit the normal flow of urine, disrupting the natural flushing and voiding effect in removing bacteria from the bladder and resulting in incomplete emptying. Common conditions that result in residual urine volumes include prostatic hypertrophy, urethral strictures, calculi, tumors, bladder diverticula, and drugs such as anticholinergic agents. Additional causes of incomplete bladder emptying include neurologic malfunctions associated with stroke, diabetes, spinal cord injuries, tabes dorsalis, and other neuropathies.

Vesicoureteral reflux represents a condition in which urine is forced up the ureters to the kidneys. Urinary reflux is associated not only with an increased incidence of UTIs and pyelonephritis but also with renal damage.²² Reflux may be the result of a congenital abnormality or, more commonly, bladder overdistension from obstruction.

Other risk factors include urinary catheterization, mechanical instrumentation, pregnancy, and the use of spermicides and diaphragms.

CLINICAL PRESENTATION

3 The presenting signs and symptoms of UTIs in adults are recognized easily (Table 114–2). Women frequently will report gross hematuria. Systemic symptoms, including fever, typically are absent in this setting. Unfortunately, large numbers of patients with significant bacteriuria are asymptomatic. These patients may be normal, healthy patients, elderly patients, children, pregnant patients, and patients with indwelling catheters. It is important to note that attempts at differentiating upper tract from lower tract infections on the basis of symptoms alone are not reliable.

Elderly patients frequently do not experience specific urinary symptoms, but they will present with altered mental status, change in eating habits, or gastrointestinal symptoms. In addition, patients with indwelling catheters or neurologic disorders commonly will not have lower tract symptoms, whereas flank pain and fever may be recognized. Many of the aforementioned patients, however, frequently will develop upper tract infections with bacteremia and no or minimal urinary tract symptoms.

Symptoms alone are unreliable for the diagnosis of bacterial UTIs. The key to the diagnosis of UTI is the ability to demonstrate

TABLE 114–2. Clinical Presentation of Urinary Tract Infections in Adults

Signs and Symptoms

Lower UTI: Dysuria, urgency, frequency, nocturia, suprapubic heaviness
Gross hematuria

Upper UTI: Flank pain, fever, nausea, vomiting, malaise

Physical Examination

Upper UTI: Costovertebral tenderness

Laboratory Tests

Bacteriuria

Pyuria (white blood cell count >10/mm³)

Nitrite-positive urine (with nitrite reducers)

Leukocyte esterase-positive urine

Antibody-coated bacteria (upper UTI)

significant numbers of microorganisms in an appropriate urine specimen to distinguish contamination from infection. The type and extent of laboratory examination required depend on the clinical situation.

URINE COLLECTION

Examination of the urine is the cornerstone of laboratory evaluation for UTIs. There are three acceptable methods of urine collection. The first is the *midstream clean-catch method*. After cleaning the urethral opening area in both men and women, 20 to 30 mL of urine is voided and discarded. The next part of the urine flow is collected and should be processed immediately (refrigerated as soon as possible). Specimens that are allowed to sit at room temperature for several hours may result in falsely elevated bacterial counts. The midstream clean catch is the preferred method for the routine collection of urine for culture. When a routine urine specimen cannot be collected or contamination occurs, alternative collection techniques must be used.

The two acceptable alternative methods include catheterization and suprapubic bladder aspiration. Catheterization may be necessary for patients who are uncooperative or who are unable to void urine. If catheterization is performed carefully with aseptic technique, the method yields reliable results. Note, however, that introduction of bacteria into the bladder may result, and the procedure is associated with infection in 1% to 2% of patients. Suprapubic bladder aspiration involves inserting a needle directly into the bladder and aspirating the urine. This procedure bypasses the contaminating organisms present in the urethra, and any bacteria found using this technique generally are considered to represent significant bacteriuria. Suprapubic aspiration is a safe and painless procedure that is most useful in newborns, infants, paraplegics, seriously ill patients, and others in whom infection is suspected and routine procedures have provided confusing or equivocal results.

BACTERIAL COUNT

4 The diagnosis of UTI is based on the isolation of significant numbers of bacteria from a urine specimen. Microscopic examination of a urine sample is an easy-to-perform and reliable method for the presumptive diagnosis of bacteriuria. The examination may be performed by preparing a Gram stain of unspun or centrifuged urine. The presence of at least one organism per oil-immersion field in a properly collected uncentrifuged specimen correlates well with more than 100,000 bacteria/mL of urine. For detecting smaller numbers of organisms, a centrifuged specimen is more sensitive. Such examinations detect more than 10⁵ bacteria/mL with a sensitivity of greater than 90% and a specificity of greater than 70%.²³ Counts of less than 30,000/mL, however, usually are not recognized reliably by these methods.²⁴

PYURIA, HEMATURIA, AND PROTEINURIA

Microscopic examination of the urine for leukocytes is also used to determine the presence of pyuria. The presence of pyuria in a symptomatic patient correlates with significant bacteriuria.²⁵ Pyuria is defined as a white blood cell (WBC) count of greater than 10 WBCs/mm³ of urine. A count of 5 to 10 WBCs/mm³ is accepted as the upper limit of normal. It should be emphasized that pyuria is nonspecific and signifies only the presence of inflammation and not necessarily infection. Thus patients with pyuria may or may not have infection. Sterile pyuria has long been associated with urinary tuberculosis, as well as chlamydial and fungal urinary infections.

Hematuria, microscopic or gross, is frequently present in patients with UTI but is nonspecific. Hematuria may indicate the presence of

other disorders, such as renal calculi, tumors, or glomerulonephritis. Proteinuria is found commonly in the presence of infection.

CHEMISTRY

Several biochemical tests have been developed for screening urine for the presence of bacteria. A common dipstick test detects the presence of nitrite in the urine, which is formed by bacteria that reduce nitrate normally present in the urine. False-positive tests are uncommon. False-negative tests are more common and frequently are caused by the presence of gram-positive organisms or *P. aeruginosa* that do not reduce nitrate.²⁶ Other causes of false tests include low urinary pH, frequent voiding, and dilute urine.

The leukocyte esterase (LE) dipstick test is a rapid screening test for detecting the presence of pyuria. Leukocytes esterase is found in primary neutrophil granules and indicates the presence of WBCs. The LE test is a sensitive and highly specific test for detecting more than 10 WBCs/mm³ of urine. When the LE test is used with the nitrite test, the range of reported sensitivity and specificity is 45.5% to 100% and 60% to 98%, respectively, for the detection of bacteriuria.^{27,28} These tests can be useful in the outpatient evaluation of uncomplicated UTIs. However, urine culture is still the “gold standard” test in determining the presence of UTIs.

CULTURE

The most reliable method of diagnosing UTI is by quantitative urine culture. Urine in the bladder is normally sterile, making it statistically possible to differentiate contamination of the urine from infection by quantifying the number of bacteria present in a urine sample. This criterion is based on a properly collected midstream clean-catch urine specimen. Patients with infection usually have greater than 10⁵ bacteria/mL of urine. It should be emphasized that as many as one-third of women with symptomatic infection have less than 10⁵ bacteria/mL. A significant portion of patients with UTIs, either symptomatic or asymptomatic, also have less than 10⁵ bacteria/mL of urine.

Several laboratory methods are used to quantify bacteria present in the urine. The most accurate method is the pour-plate technique. This method is unsuitable for a high-volume laboratory because it is expensive and time-consuming. The streak-plate method is an alternative that involves using a calibrated-loop technique to streak a fixed amount of urine on an agar plate. This method is used most commonly in diagnostic laboratories because it is simple to perform and less costly.

After identification and quantification are complete, the next step is to determine the susceptibility of the organism. There are several methods by which bacterial susceptibility testing may be performed. Knowledge of bacterial susceptibility and achievable urine concentration of the antibiotics puts the clinician in a better position to select an appropriate agent for treatment.

INFECTION SITE

Several methods have been evaluated to determine the location of infection within the urinary system and differentiate upper tract from lower tract involvement. The most direct method is a ureteral catheterization procedure, as described by Stamey and colleagues.²⁹ The method involves the passage of a catheter into the bladder and then into each ureter, where quantitative cultures are obtained. History and physical examination were of little value in predicting the site of infection. Although this method provides direct quantitative evidence for UTI, it is invasive, technically difficult, and expensive. The Fairley bladder washout technique is a modification of the Stamey procedure that involves Foley catheterization only.³⁰ After the catheter is passed into the bladder, bladder samples are obtained, and the bladder is washed out, with culture samples taken at 10, 20, and 30 minutes. The procedure shows that up to 50% of patients have renal involvement regardless of signs and symptoms. Other investigators found 10% to 20% of tests to be equivocal.³¹

Noninvasive methods of localization may be more acceptable for routine use; however, they have limited clinical value. Patients with pyelonephritis can have abnormalities in urinary concentrating ability. The use of concentrating ability for localization of UTIs, however, is associated with high false-positive and false-negative responses and is not useful clinically.²⁶ The antibody-coated bacteria (ACB) test is an immunofluorescent method that detects bacteria coated with Ig in freshly voided urine, indicating upper urinary tract infection. The sensitivity and specificity of this test to localize the site of infection are reported to average 88% and 76%, respectively.³¹ Because of the high incidence of false-positive and false-negative results, ACB testing is not used routinely in the management of UTIs.

Virtually all patients with uncomplicated lower tract infections can be cured with a short course of antibiotic therapy, and this assumption sometimes can be used to distinguish patients with lower and upper tract infections. Patients who do not respond or who relapse do so because of upper tract involvement. It is rarely necessary to localize the site of infection to direct the clinical management of such patients.

► TREATMENT: Urinary Tract Infections

■ DESIRED OUTCOME

5 The goals of UTI treatments are (1) to prevent or to treat systemic consequences of infection, (2) to eradicate the invading organism(s), and (3) to prevent the recurrence of infection.

■ MANAGEMENT

The management of a patient with a UTI includes initial evaluation, selection of an antibacterial agent and duration of therapy, and follow-up evaluation. The initial selection of an antimicrobial agent for the

treatment of UTI is based primarily on the severity of the presenting signs and symptoms, the site of infection, and whether the infection is determined to be uncomplicated or complicated. Other considerations include antibiotic susceptibility, side-effect potential, cost, and the comparative inconvenience of different therapies.

Various pharmacologic factors may affect the action of antibacterial agents. Certainly the ability of the agent to achieve appropriate concentrations in the urine is of utmost importance. Factors that affect the rate and extent of excretion through the kidney include the patient's glomerular filtration rate and whether or not the agent is actively secreted. Filtration depends on the molecular size and degree of protein binding of the agent. Agents such as sulfonamides, tetracyclines, and aminoglycosides enter the urine via filtration. As the glomerular filtration rate is reduced, the amount of drug that enters the urine is reduced.

Most β -lactam agents and quinolones are filtered and are actively secreted into the urine. For this reason, these agents achieve high urinary concentrations despite unfavorable protein-binding characteristics or the presence of renal dysfunction.

The ability to eradicate bacteria from the urine is related directly to the sensitivity of the microorganism and the achievable concentrations of the antimicrobial agent in the urine. Unfortunately, most susceptibility testing is directed at achievable concentrations in the blood. There is a poor correlation between achievable blood levels of antimicrobial agents and the eradication of bacteria from the urine.³² In the treatment of lower tract infections, plasma concentrations of antibacterial agents may not be important, but achieving appropriate plasma concentrations appears critical in patients with bacteremia and renal abscesses.

A number of nonspecific therapies have been advocated in the treatment and prevention of UTIs. Fluid hydration has been used to produce rapid dilution of bacteria and removal of infected urine by increased voiding. A critical factor appears to be the amount of residual volume remaining after voiding. As little as 10 mL of residual urine can alter the eradication of infection significantly.¹⁶ Paradoxically, increased diuresis also may promote susceptibility to infection by diluting the normal antibacterial properties of the urine. Often in clinical practice the concentrations of antimicrobial agents in the urine are so high that dilution has little effect on efficacy.

The antibacterial activity of the urine is related to the low pH, which is the result of high concentrations of various organic acids. Large volumes of cranberry juice increase the antibacterial activity of the urine and prevent the development of UTIs.^{2,23} Apparently, the cranberry juice content of fructose and other unknown substances (condensed tannins) acts to interfere with adherence mechanisms of some pathogens, thereby preventing infection. Acidification of the urine by cranberry juice does not appear to play a significant role. The use of other agents (ascorbic acid) to acidify the urine to hinder bacterial growth does not achieve significant acidification. Therefore, attempts to acidify urine with systemic agents are not recommended. *Lactobacillus* probiotics also may aid in the prevention of female UTIs by the vaginal pH, thereby decreasing *E. coli* colonization.¹⁹ In postmenopausal women, estrogen replacement may be of help in the prevention of recurrent UTIs. After 1 month of topical estrogen replacement, decreases in vaginal *Lactobacillus*, as well as decreases in and pH and *E. coli* colonization, have been found.¹⁸

Urinary analgesics such as phenazopyridine hydrochloride are used frequently by many clinicians.² If the pain or dysuria present in a UTI is a consequence of infection, then urinary analgesics have little clinical role because most patients' symptoms respond quite rapidly to appropriate antibacterial therapy. Urinary analgesics also may mask signs and symptoms of UTIs not responding to antimicrobial therapy.

■ PHARMACOLOGIC THERAPY

Ideally, the antimicrobial agent chosen should be well tolerated, well absorbed, achieve high urinary concentrations, and have a spectrum of activity limited to the known or suspected pathogen(s). Table 114–3 lists the most common agents used in the treatment of UTIs along with comments concerning their general use. Table 114–4 presents an overview of various therapeutic options for outpatient therapy of UTI. Table 114–5 describes empirical treatment regimens for selected clinical situations.

The therapeutic management of UTIs is best accomplished by first categorizing the type of infection: acute uncomplicated cysti-

tis, symptomatic bacteriuria, asymptomatic bacteriuria, complicated UTIs, recurrent infections, or prostatitis. In choosing the appropriate antibiotic therapy, it is important to be aware of the increasing resistance of *E. coli* and other pathogens to many antimicrobials. Resistance to *E. coli* is as high as 30% for amoxicillin and cephalosporins.^{34,35} Overall, trimethoprim-sulfamethoxazole remains susceptible, although resistance as high as 22% has been reported in various places.^{35–39} However, resistant infections still may be treated successfully with trimethoprim-sulfamethoxazole, most likely owing to its high urinary concentrations. Current or recent antibiotic exposure is the most significant risk factor associated with *E. coli* resistance.^{36–38} Antibiotic therapy should be determined based on the geographic resistance patterns of the prescriber, as well as the patient's recent history of antibiotic exposure.

■ ACUTE UNCOMPLICATED CYSTITIS

Acute uncomplicated cystitis is the most common form of UTI. These infections typically occur in women of childbearing age and often are related to sexual activity. Although the presence of dysuria, frequency, urgency, and suprapubic discomfort frequently is associated with lower tract infection, a significant number of patients have upper tract involvement as well.⁴⁰ Because these infections are predominantly caused by *E. coli*, antimicrobial therapy initially should be directed against this organism. Other common causes include *S. saprophyticus* and, occasionally, *K. pneumoniae* and *Proteus mirabilis*. Because the causative organisms and their susceptibility generally are known, many clinicians advocate a cost-effective approach to management. This approach includes a urinalysis and initiation of empirical therapy without a urine culture⁴⁰ (Fig. 114–1).

The goal of treatment for uncomplicated cystitis is to eradicate the causative organism and to reduce the incidence of recurrence caused by relapse or reinfection. The ability to reduce the chance of recurrence depends on the agent's efficacy in eradicating the uropathogenic bacteria from the vaginal and gastrointestinal reservoir. In the past, conventional therapy consisted of an effective oral antibiotic administered for 7 to 14 days. It is now apparent, however, that acute cystitis is a superficial mucosal infection that can be eradicated with much shorter courses of therapy. Advantages of short-course therapy include increased compliance, fewer side effects, decreased cost, and less potential for the development of resistance.

CLINICAL CONTROVERSY

Single-dose therapy is used frequently, although it can be associated with lower cure rates and increased reoccurrence compared with longer therapies.^{1,32,44} Clinicians should not assume that all antimicrobial agents are effective as single-dose therapies. Data suggest that trimethoprim-sulfamethoxazole or the fluoroquinolones are most efficacious as single-dose therapies. Fosfomycin once daily also has been used, although other therapies appear superior.^{1,45} The efficacy of these agents probably is related to observations that *E. coli* causing community-acquired UTIs are increasingly resistant to ampicillin, amoxicillin, and sulfonamides. In addition, oral β -lactam antibiotics are eliminated more rapidly and do not achieve high renal tissue concentrations compared with trimethoprim-sulfamethoxazole and are less successful in eradicating uropathogens from the vaginal and gastrointestinal reservoirs.

TABLE 114–3. Commonly Used Antimicrobial Agents in the Treatment of Urinary Tract Infections

| Agent | Comments |
|--|---|
| Oral Therapy | |
| Sulfonamides | These agents generally have been replaced by more agents due to resistance. |
| Trimethoprim-sulfamethoxazole (TMP-SMX) | This combination is highly effective against most aerobic enteric bacteria except <i>Pseudomonas aeruginosa</i> . High urinary tract tissue levels and urine levels are achieved, which may be important in complicated infection treatment. Also effective as prophylaxis for recurrent infections. |
| <i>Penicillins</i> | |
| Ampicillin | Ampicillin is the standard penicillin that has broad-spectrum activity. Increasing <i>Escherichia coli</i> resistance has limited amoxicillin use in acute cystitis. Drug of choice for enterococci sensitive to penicillin. |
| Amoxicillin-clavulanic acid | Amoxicillin-clavulanate is preferred for resistance problems. Carbenicillin indanyl is only indicated for the treatment of urinary tract infections. |
| Carbenicillin indanyl | |
| <i>Cephalosporins</i> | |
| Cephalexin | There are no major advantages of these agents over other agents in the treatment of UTIs, and they are more expensive. They may be useful in cases of resistance to amoxicillin and trimethoprim-sulfamethoxazole. These agents are not active against enterococci. |
| Cephadrine | |
| Cefaclor | |
| Cefadroxil | |
| Cefuroxime | |
| Cefixime | |
| Cefzil | |
| Cefpodoxime | |
| <i>Tetracyclines</i> | |
| Tetracycline | These agents have been effective for initial episodes of urinary tract infections; however, resistance develops rapidly, and their use is limited. These agents also lead to candidal overgrowth. They are useful primarily for chlamydial infections. |
| Doxycycline | |
| Minocycline | |
| <i>Fluoroquinolones</i> | |
| Ciprofloxacin | The newer quinolones have a greater spectrum of activity, including <i>P. aeruginosa</i> . These agents are effective for pyelonephritis and prostatitis. Avoid in pregnancy and children. Moxifloxacin should not be used owing to inadequate urinary concentrations. |
| Norfloxacin | |
| Levofloxacin | |
| Nitrofurantoin | This agent is effective as both a therapeutic and prophylactic agent in patients with recurrent UTIs. Main advantage is the lack of resistance even after long courses of therapy. Adverse effects may limit use (GI intolerance, neuropathies, pulmonary reactions). |
| Azithromycin | Single-dose therapy for chlamydial infections. |
| Methanamine hippurate-mandalate | These agents are reserved for prophylactic therapy or suppressive use between episodes of infection. |
| Fosfomycin | Single-dose therapy for uncomplicated infections. |
| Parenteral Therapy | |
| <i>Aminoglycosides</i> | |
| Gentamicin | Gentamicin and tobramycin are equally effective; gentamicin is less expensive. Tobramycin has better pseudomonal activity, which may be important in serious systemic infections. Amikacin generally is reserved for multiresistant bacteria. |
| Tobramycin | |
| Amikacin | |
| Netilmicin | |
| <i>Penicillins</i> | |
| Ampicillin | These agents generally are equally effective for susceptible bacteria. The extended-spectrum penicillins are more active against <i>P. aeruginosa</i> and enterococci and often are preferred over cephalosporins. They are very useful in renally impaired patients or when an aminoglycoside is to be avoided. |
| Ampicillin-sulbactam | |
| Ticarcillin-clavulanate | |
| Piperacillin | |
| Piperacillin-tazobactam | |
| <i>Cephalosporins, first-, second-, and third-generation</i> | |
| | Second- and third-generation cephalosporins have a broad spectrum of activity against gram-negative bacteria but are not active against enterococci and have limited activity against <i>P. aeruginosa</i> . Ceftazidime and cefepime are active against <i>P. aeruginosa</i> . They are useful for nosocomial infections and urosepsis due to susceptible pathogens. |
| <i>Carbapenems</i> | |
| Imipenem-cilastatin | These agents have broad spectrum of activity, including gram-positive, gram-negative, and anaerobic bacteria. |
| Meropenem | Imipenem and meropenem are active against <i>P. aeruginosa</i> and enterococci, but ertapenem is not. All may be associated with candidal superinfections. |
| Ertapenem | |
| Aztreonam | A monobactam that is only active against gram-negative bacteria, including some strains of <i>P. aeruginosa</i> . Generally useful for nosocomial infections when aminoglycosides are to be avoided and in penicillin-sensitive patients. |
| <i>Quinolones</i> | |
| Ciprofloxacin | These agents have broad-spectrum activity against both gram-negative and gram-positive bacteria. They provide urine and high-tissue concentrations and are actively secreted in reduced renal function. |
| Levofloxacin | |
| Gatifloxacin | |

TABLE 114–4. Overview of Outpatient Antimicrobial Therapy for Lower Tract Infections in Adults

| Indications | Antibiotic | Dose ^a | Interval | Duration |
|---|-------------------------------|-------------------|---------------|-----------|
| Lower tract Infections Uncomplicated | | 2 DS tablets | Single dose | 1 day |
| | Trimethoprim-sulfamethoxazole | 1 DS tablet | Twice a day | 3 days |
| | Ciprofloxacin | 250 mg | Twice a day | 3 days |
| | Norfloxacin | 400 mg | Twice a day | 3 days |
| | Gatifloxacin | 200–400 mg | Once a day | 3 days |
| | Levofloxacin | 250 mg | Once a day | 3 days |
| | Lomefloxacin | 400 mg | Once a day | 3 days |
| | Enoxacin | 200 mg | Once a day | 3 days |
| | Amoxicillin | 6 × 500 mg | Single dose | 1 day |
| | | 500 mg | Twice a day | 3 days |
| | Amoxicillin-clavulanate | 500 mg | Every 8 hours | 3 days |
| | Trimethoprim | 100 mg | Twice a day | 3 days |
| | Nitrofurantoin | 100 mg | Every 6 hours | 3 days |
| | Fosfomycin | 3 g | Single dose | 1 day |
| Complicated | Trimethoprim-sulfamethoxazole | 1 DS tablet | Twice a day | 7–10 days |
| | Trimethoprim | 100 mg | Twice a day | 7–10 days |
| | Norfloxacin | 400 mg | Twice a day | 7–10 days |
| | Ciprofloxacin | 250–500 mg | Twice a day | 7–10 days |
| | Gatifloxacin | 400 mg | Once a day | 7–10 days |
| | Moxifloxacin (PO only) | 400 mg | Once a day | 7–10 days |
| | Lomefloxacin | 400 mg | Once a day | 7–10 days |
| | Levofloxacin | 250 mg | Once a day | 7–10 days |
| | Amoxicillin-clavulanate | 500 mg | Every 8 hours | 7–10 days |
| | Nitrofurantoin | 50 mg | Once a day | 6 months |
| Recurrent Infections | Trimethoprim | 100 mg | Once a day | 6 months |
| | Trimethoprim-sulfamethoxazole | 1/2 ss tablet | Once a day | 6 months |
| | Trimethoprim-sulfamethoxazole | 1 DS | Twice a day | 3 days |
| Acute urethral syndrome | Azithromycin | 1 g | Single dose | |
| Failure of TMP-SMX | Doxycycline | 100 mg | Twice a day | 7 days |
| | Trimethoprim-sulfamethoxazole | 1 DS tablet | Twice a day | 14 days |
| Acute pyelonephritis | Ciprofloxacin | 500 mg | Twice a day | 14 days |
| | Gatifloxacin | 400 mg | Once a day | 14 days |
| | Norfloxacin | 400 mg | Twice a day | 14 days |
| | Levofloxacin | 250 mg | Once a day | 14 days |
| | Lomefloxacin | 400 mg | Once a day | 14 days |
| | Enoxacin | 400 mg | Twice a day | 14 days |
| | Amoxicillin-clavulanate | 500 mg | Every 8 hours | 14 days |

^aDosing intervals for normal renal function.

6 Three-day courses of trimethoprim-sulfamethoxazole or a fluoroquinolone (e.g., ciprofloxacin, levofloxacin, norfloxacin, or gatifloxacin) are superior to single-dose therapies.^{41,42} The fluoroquinolone moxifloxacin is not recommended for use in UTIs owing to the inadequate urinary concentrations.⁴³ The use of amoxicillin and sulfonamides is not recommended because of the high incidence of resistant *E. coli*. For most adult females, short-course therapy is the treatment of choice for uncomplicated lower UTIs. Short-course therapy is inappropriate for patients who have had previous infections caused by resistant bacteria, for male patients, and for patients with complicated UTIs. If symptoms do not respond or recur, a urine culture should be obtained and conventional therapy with a suitable agent instituted.^{1,3,46–48}

SYMPTOMATIC ABACTERIURIA

Symptomatic abacteriuria or acute urethral syndrome represents a clinical syndrome in which females present with dysuria and pyuria, but the urine culture reveals less than 10⁵ bacteria/mL of urine. Acute urethral syndrome is estimated to account for more than half the complaints of dysuria seen in the community today. These women most

likely are infected with small numbers of coliform bacteria, including *E. coli*, *Staphylococcus* spp., or *Chlamydia trachomatis*. Additional causes include *Neisseria gonorrhoeae*, *Gardnerella vaginalis*, and *Ureaplasma urealyticum*.

Most patients presenting with pyuria will, in fact, have infection that requires treatment. Single-dose or short-course therapy with trimethoprim-sulfamethoxazole has been used effectively, and prolonged courses of therapy are not necessary for most patients. If single-dose or short-course therapy is ineffective, a culture should be obtained. If the patient reports recent sexual activity, therapy for *C. trachomatis* should be considered. Chlamydial treatment should consist of 1-g azithromycin or doxycycline 100 mg twice daily for 7 days. Often, concomitant treatment of all sexual partners is required to cure chlamydial infections and prevent reacquisition (see Chap. 115).

ASYMPTOMATIC BACTERIURIA

Asymptomatic bacteriuria represents patients who, in the absence of urinary symptoms, are found to have two consecutive urine cultures

TABLE 114–5. Empirical Treatment of Urinary Tract Infections and Prostatitis

| Diagnosis | Pathogens | Treatment | Comments |
|------------------------------|--|---|--|
| Acute uncomplicated cystitis | <i>E. coli</i> <i>S. saprophyticus</i> | 1. Trimethoprim-sulfamethoxazole × 3 days 2. Quinolone × 3 days | Short-course therapy more effective than single dose |
| Pregnancy | As above | 1. Amoxicillin-clavulanate × 7 days 2. Cephalosporin × 7 days 3. Trimethoprim-sulfamethoxazole × 7 days | Avoid trimethoprim-sulfamethoxazole during third trimester |
| Acute pyelonephritis | | | |
| Uncomplicated | <i>E. coli</i> | 1. Trimethoprim-sulfamethoxazole × 14 days 2. Quinolone × 14 days | Can be managed as outpatient |
| Complicated | <i>E. coli</i> <i>Proteus mirabilis</i> <i>K. pneumoniae</i> <i>Pseudomonas aeruginosa</i> <i>E. fecalis</i> | 1. Quinolone × 14 days 2. Extended-spectrum penicillin Plus aminoglycoside | Severity of illness will determine duration of IV therapy. Culture results should direct therapy Oral therapy may complete 14 days of therapy |
| Prostatitis | <i>E. coli</i> <i>K. pneumoniae</i> <i>Proteus spp</i> <i>P. aeruginosa</i> | 1. Trimethoprim-sulfamethoxazole × 4–6 weeks 2. Quinolone × 4–6 weeks | Acute prostatitis may require IV therapy initially Chronic prostatitis may require longer treatment periods or surgery |

with more than 10^5 organisms/mL of the same organism. Most patients with asymptomatic bacteriuria are elderly and female. Pregnant women are another group of patients that frequently presents with asymptomatic bacteriuria. Although this group of patients typically responds to treatment, relapse and reinfection are very common, and chronic asymptomatic bacteriuria is difficult to eradicate.

The management of asymptomatic bacteriuria depends on the age of the patient and whether or not the patient is pregnant. In children, because of a greater risk of developing renal scarring and long-standing renal damage, treatment should consist of conventional courses of therapy as that for symptomatic infection. The greatest risk of renal damage occurs during the first 5 years of life.⁴⁹ In the nonpregnant female, therapy is controversial; however, treatment has little effect on the natural course of infections. Two groups characterize asymptomatic bacteriuria in the elderly: those with persistent bacteriuria and those with intermittent bacteriuria.

CLINICAL CONTROVERSY

Most clinicians feel that asymptomatic bacteriuria in the elderly is a benign disease that does not warrant treatment. Most data indicate that the patient without urinary tract obstruction is not destined to develop progressive renal damage. Investigators who have demonstrated an association between bacteriuria and decreased survival, however, have questioned this approach. In this setting, there is no apparent urgency in initiating therapy, so two cultures should be obtained to confirm the presence of bacteriuria. Treating ambulatory, nonhospitalized elderly women is effective in eliminating bacteria for at least 6 months and may protect against the development of symptomatic bacteriuria; however, only 50% of patients remained free of bacteria after 1 year.⁵⁰

Several studies in hospitalized elderly subjects, however, have not found antimicrobial therapy to be efficacious.^{51,52} A number of questions remain unanswered, e.g., the effect of eradication of bacteri-

uria on life expectancy, the cost-effectiveness and risk-benefit ratio of therapy, and the effect on morbidity. Certainly, with the information available and the high adverse reaction rate in the elderly, vigorous treatment and screening programs cannot be advocated.

■ COMPLICATED URINARY TRACT INFECTIONS

■ Acute Pyelonephritis

The presentation of high-grade fever ($>38.3^{\circ}\text{C}$, or 100.9°F) and severe flank pain should be treated as acute pyelonephritis, warranting aggressive management. Severely ill patients with pyelonephritis should be hospitalized and intravenous antimicrobials administered initially (Table 114–5). However, milder cases may be managed with orally administered antibiotics in an outpatient setting. Symptoms of nausea, vomiting, and dehydration may require hospitalization.

At the time of presentation, a Gram stain of the urine should be performed, along with a urinalysis, culture, and sensitivity tests. The Gram stain should indicate the morphology of the infecting organism(s) and help to direct the selection of an appropriate antibiotic. However, the precise identity and susceptibility of the infecting organism(s) will be unknown initially, warranting empirical therapy. The goals of treatment include the achievement of therapeutic concentrations of an antimicrobial agent in the bloodstream and urinary tract to which the invading organism is susceptible and sufficient therapy to eradicate residual infection in the tissues of the urinary tract.

In the mildly to moderately symptomatic patient in whom oral therapy is considered, an effective agent should be administered for at least a 2-week period, although use of highly active agents for 7 to 10 days may be sufficient.^{1,53} Oral antibiotics that are highly active against the probable pathogens and that are sufficiently bioavailable are preferred. Although the sulfonamides and ampicillin or amoxicillin have been the primary choices for the treatment of gram-negative bacillary infections, they are no longer considered reliable agents for UTIs.³² Reports of increasing resistance to *E. coli* have tempered their

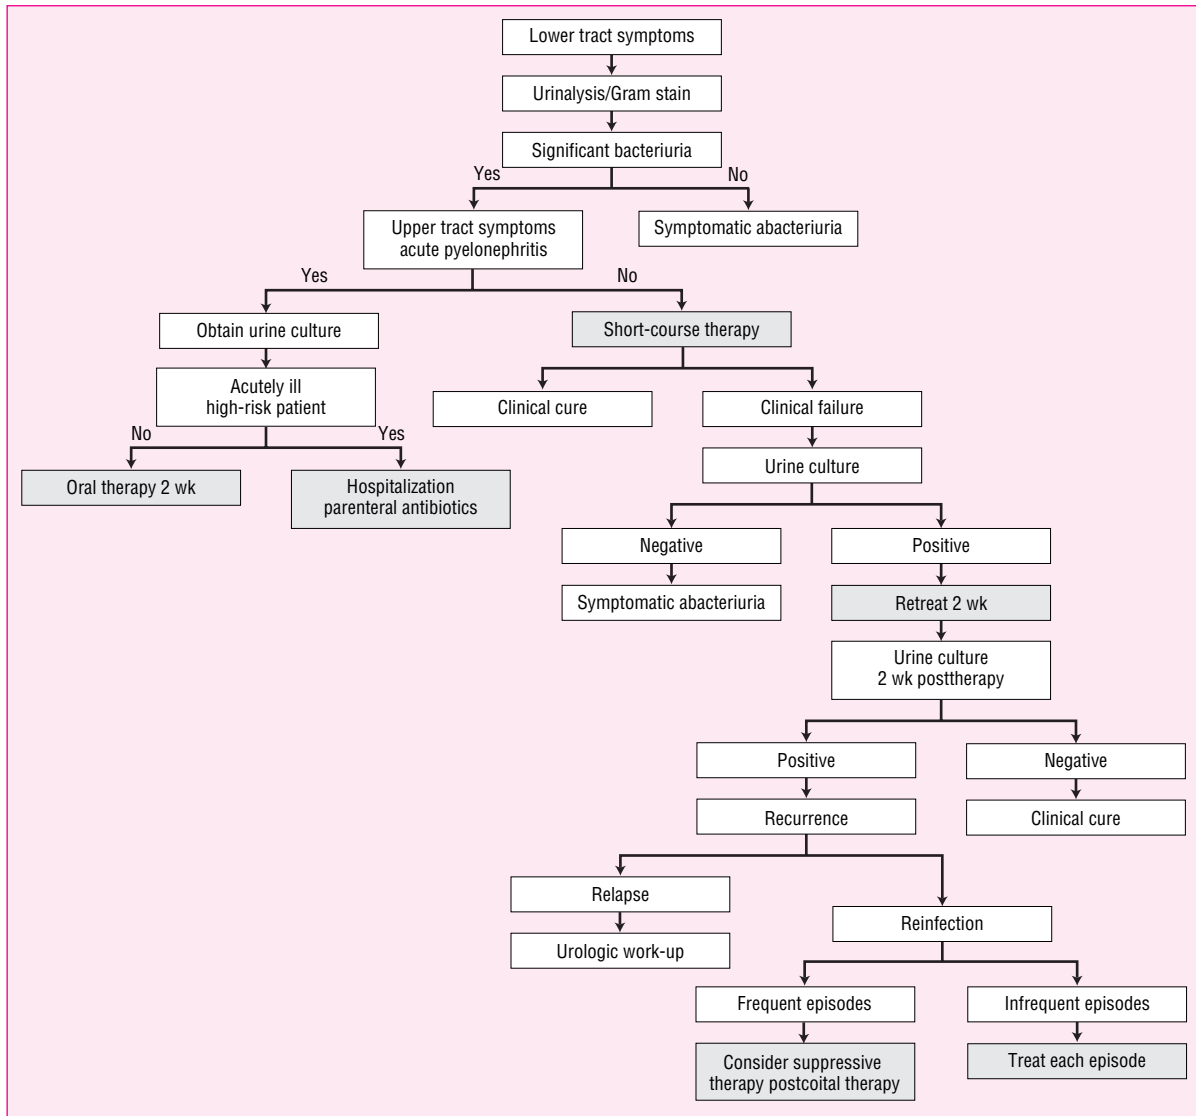

FIGURE 114-1. Management of UTIs in females.

use. In addition, treatment with trimethoprim-sulfamethoxazole (one double-strength tablet twice daily) for 2 weeks was superior to ampicillin, despite the organism being susceptible to both agents.⁵⁴ Agents such as trimethoprim-sulfamethoxazole and the fluoroquinolones are the agents of choice. If a Gram stain reveals gram-positive cocci, *S. faecalis* should be considered and treatment directed against this potential pathogen (ampicillin). Close follow-up of outpatient treatment is mandatory to ensure success.

In the seriously ill patient, parenteral therapy should be administered initially. Therapy should provide a broad spectrum of coverage and should be directed toward bacteremia or sepsis, if present. A number of antibiotic regimens have been used as empirical therapy, including an intravenous fluoroquinolone, an aminoglycoside with or without ampicillin, and extended-spectrum cephalosporins with or without an aminoglycoside.¹ Other options include aztreonam, the β -lactamase inhibitor combinations (e.g., ampicillin-sulbactam, ticarcillin-clavulanate, and piperacillin-tazobactam), carbapenems (e.g., imipenem, meropenem, or ertapenem), or intravenous trimethoprim-sulfamethoxazole. If the patient has been hospitalized within the past 6 months, has a urinary catheter, or is a nursing

home resident, the possibility of *P. aeruginosa* and enterococci, as well as multiply resistant organisms, should be considered. In this setting, ceftazidime, ticarcillin-clavulanate, piperacillin, aztreonam, meropenem, or imipenem in combination with an aminoglycoside is recommended. Ertapenem should not be used in this case owing to its inactivity against enterococci and *P. aeruginosa*.⁵⁵ The rationale for combination therapy is that in experimental animals, 3 days of aminoglycoside combination therapy followed by nonaminoglycoside single-agent therapy for 7 days resulted in a 100% cure rate.⁵⁶ If the patient responds to initial combination therapy, the aminoglycoside may be discontinued after 3 days. Although the aminoglycoside therapy is stopped, renal tissue concentrations of the aminoglycoside will persist for days. Based on sensitivity data, the patient then can be maintained or switched to a less expensive single agent, and ultimately, an appropriate oral agent may be used.

Effective therapy should stabilize the patient within 12 to 24 hours. A significant reduction in urine bacterial concentrations should occur in 48 hours. If bacteriologic response has not occurred, an alternative agent should be considered based on susceptibility testing. If the patient fails to respond clinically within 3 to 4 days or

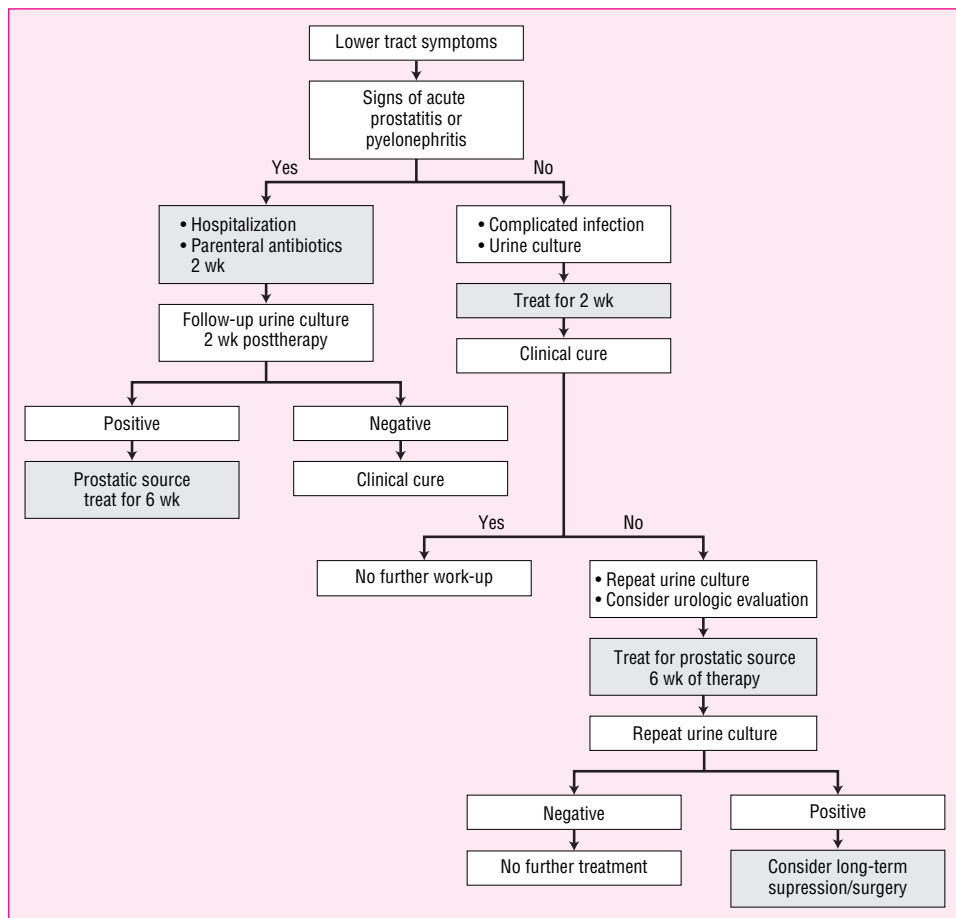

FIGURE 114–2. Management of UTIs in male.

has persistently positive blood or urine cultures, further investigation is needed to exclude bacterial resistance, possible obstruction, papillary necrosis, intrarenal or perinephric abscess, or some other disease process. Usually by the third day of therapy the patient is afebrile and significantly less symptomatic. In general, after the patient has been afebrile for 24 hours, parenteral therapy may be discontinued, and oral therapy instituted to complete a 2-week course. Follow-up urine cultures should be obtained 2 weeks after completion of therapy to ensure a satisfactory response and detect possible relapse.

■ Urinary Tract Infections in Males

The management of UTIs in males is distinctly different and often more difficult than in females. Infections in male patients are considered to be complicated because endogenous bacteria in the presence of functional or structural abnormalities that disrupt the normal defense mechanisms of the urinary tract cause them. The incidence of infections in males younger than 60 years of age is much less than the incidence in females. During the adult years, the occurrence of infection can be related directly to some manipulation of the urinary tract. The most common causes are instrumentation of the urinary tract, catheterization, and renal and urinary stones. Uncomplicated infections are rare, but they may occur in young males as a result of homosexual activity, lack of circumcision, and having sex with partners who are colonized with uropathogenic bacteria. As the patient ages, the most common cause of infection is related to bladder outlet

obstruction because of prostatic hypertrophy. In addition, the prostate gland may become infected and provide a nidus for recurrent infection in males.

The conventional view is that therapy in males requires prolonged treatment (Fig. 114–2). A urine culture should be obtained before treatment because the cause of infection in men is not as predictable as in women. Single-dose or short-course therapy is not recommended in this setting. Considerably fewer data are available comparing various antimicrobial agents in males as compared with females. If gram-negative bacteria are presumed, trimethoprim-sulfamethoxazole or the quinolone antimicrobials should be considered because these agents achieve high renal tissue, urine, and prostatic concentrations.¹⁵

Initial therapy should be for 10 to 14 days. Factors associated with treatment success are isolation of a single organism, the absence of significant obstruction or anatomic abnormalities, a normally functioning urinary tract, and the absence of prostatic involvement. Parenteral therapy may be required in certain situations, such as in severely ill patients, in the presence of acute prostatitis or epididymitis, and in patients who cannot tolerate oral medications. A comparison of 2-week versus 6-week therapy in males with recurrent infections who were given trimethoprim-sulfamethoxazole had cure rates of 29% and 62%, respectively.⁵⁷ Other investigators advocate longer treatment periods in males as well.⁵⁸ Follow-up cultures at 4 to 6 weeks after treatment are important in males to ensure bacteriologic cure. Many patients require longer periods of treatment and possible alterations in antibiotics depending on culture and sensitivity results and clinical response.

■ Recurrent Infections

Recurrent episodes of UTI account for a significant portion of all UTIs. Of the patients suffering from recurrent infections, 80% can be considered reinfections, i.e., the recurrence of infection by an organism different from the organism isolated from the preceding infection. These patients most commonly are female, and recurrence develops in about 20% of them with cystitis. Reinfections can be divided into two groups: those with less than two or three episodes per year and those who develop more frequent infections.

Management strategies depend on predisposing factors, number of episodes per year, and patient's preference. Factors that have been associated commonly with recurrent infections include sexual intercourse and diaphragm or spermicide use for birth control. Therapeutic options include self-administered therapy, postcoital therapy, and continuous low-dose prophylaxis. In patients with infrequent infections (less than three infections per year), each episode should be treated as a separately occurring infection. Short-course therapy is appropriate in this setting. Many women have been treated successfully with self-administered short-course therapy at the onset of symptoms.⁵⁹

In patients with more frequent symptomatic infections and no apparent precipitating event, long-term prophylactic antimicrobial therapy may be instituted. Prophylactic therapy has been found to reduce the frequency of symptomatic infections in elderly men, women, and children. In women, most studies show a reinfection rate of 2 to 3 per patient-year reduced to 0.1 to 0.2 per patient-year with treatment.⁶⁰ Before prophylaxis is initiated, patients should be treated conventionally with an appropriate agent. Trimethoprim-sulfamethoxazole (one-half of a single-strength tablet), trimethoprim (100 mg daily), a fluoroquinolone (one tablet), and nitrofurantoin (50 or 100 mg daily) all reduce the rate of reinfection as single-agent therapy.¹³ Full-dose therapy with these agents is unnecessary, and single daily doses can be used. Therapy generally is prescribed for a period of 6 months, during which time urine cultures are followed monthly. If symptomatic episodes develop, the patient should receive a full course of therapy with an effective agent and should be restarted on prophylactic therapy.

In women who experience symptomatic reinfections in association with sexual activity, voiding after intercourse may help to prevent infection. Also, single-dose prophylactic therapy with trimethoprim-sulfamethoxazole taken after intercourse has been found to reduce the incidence of recurrent infection significantly.⁶¹

In postmenopausal women with recurrent infections, the lack of estrogen results in changes in the bacterial flora of the vagina, resulting in increased colonization with uropathogenic *E. coli*. Topically administered estrogen cream is reported to reduce the incidence of infections in this population.⁴⁷

The remaining 20% of recurrent UTIs are relapses, i.e., persistence of infection with the same organism after therapy for an isolated UTI. The recurrence of symptomatic or asymptomatic bacteriuria after therapy usually indicates that the patient has renal involvement, a structural abnormality of the urinary tract, or chronic bacterial prostatitis. In the absence of structural abnormalities, relapse often is related to renal infection and requires a long duration of treatment. Women who relapse after short-course therapy should receive a 2-week course of therapy. In patients who relapse after 2 weeks of therapy, therapy should be continued for another 2 to 4 weeks. If relapse occurs after 6 weeks of therapy, urologic evaluation should be performed, and any obstructive lesion should be corrected. If this is not possible, therapy for 6 months or longer may be considered. Asymptomatic adults who have no evidence of urinary obstruction should not receive long-term therapy.

In males, relapse usually indicates bacterial prostatitis, the most common cause of persistent bacteriuria. Many agents have been used for long-term therapy of relapses; however, trimethoprim-sulfamethoxazole and the fluoroquinolones appear to be highly effective.

■ SPECIAL CONDITIONS

■ UTIs in Pregnancy

During pregnancy, significant physiologic changes occur to the entire urinary tract that dramatically alter the prevalence of UTIs and pyelonephritis. Severe dilation of the renal pelvis and ureters, decreased ureteral peristalsis, and reduced bladder tone occur during pregnancy.^{62,63} These changes result in urinary stasis and reduced defenses against reflux of bacteria to the kidneys. In addition, increased urine content of amino acids, vitamins, and nutrients encourages bacterial growth. All these factors increase the incidence of bacteriuria, resulting in symptomatic infections, especially during the third trimester.

Asymptomatic bacteriuria occurs in 4% to 7% of pregnant patients. Of these, 20% to 40% will develop acute symptomatic pyelonephritis during pregnancy. If untreated, asymptomatic bacteriuria has the potential to cause significant adverse effects, including prematurity, low birth weight, and stillbirth.⁶⁴ Since pyelonephritis is associated with significant adverse events during pregnancy, routine screening tests for bacteriuria should be performed at the initial prenatal visit and again at 28 weeks' gestation. In patients with significant bacteriuria, symptomatic or asymptomatic, treatment is recommended in order to avoid possible complications. Organisms associated with bacteriuria are the same as those seen in uncomplicated UTIs, with *E. coli* isolated most frequently.

Therapy should consist of an agent administered for 7 days that has a relatively low adverse-effect potential and is safe for the mother and baby. The administration of a sulfonamide, amoxicillin, amoxicillin-clavulanate, cephalosporin, or nitrofurantoin is effective in 70% to 80% of patients. Tetracyclines should be avoided because of teratogenic effects, and sulfonamides should not be administered during the third trimester because of the possible development of kernicterus and hyperbilirubinemia. In addition, the available fluoroquinolones should not be given because of their potential to inhibit cartilage and bone development in the newborn. A follow-up urine culture 1 to 2 weeks after completing therapy and then monthly until gestation is complete is recommended.

■ Catheterized Patients

The use of an indwelling catheter frequently is associated with infection of the urinary tract and represents the most common cause of hospital-acquired infection. The incidence of catheter-associated infection is related to a variety of factors, including method and duration of catheterization, the catheter system (open or closed), the care of the system, the susceptibility of the patient, and the technique of the health care personnel inserting the catheter. The incidence of infection from a single catheterization in a healthy ambulatory patient is 1%.⁶⁵

Bacteria may enter the bladder in a number of ways. During the catheterization, bacteria may be introduced directly into the bladder from the urethra. Once the catheter is in place, bacteria may pass up the lumen of the catheter via the movement of air bubbles, by motility of the bacteria, or by capillary action. In addition, bacteria may reach the bladder from around the exudative sheath that surrounds

the catheter in the urethra. Cleaning the periurethral area thoroughly and applying an antiseptic (povidone-iodine) can minimize infection occurring during insertion of the catheter. The use of closed drainage systems has reduced significantly the ability of bacteria to pass up the lumen of the catheter and cause infection. A bacterium passing around the catheter sheath in the urethra is probably the most important pathway for infection. Avoiding manipulation of the catheter and trauma to the urethra and urethral meatus can minimize this path of acquisition.

Patients with indwelling catheters acquire UTIs at a rate of 5% per day.⁶⁵ The closed systems are capable of preventing bacteriuria in most patients for up to 10 days with appropriate care. After 30 days of catheterization, however, there is a 78% to 95% incidence of bacteriuria despite use of a closed system.⁶⁵ Unfortunately, UTI symptoms in catheterized patient are not clearly defined. Fever, peripheral leukocytosis, and urinary signs and symptoms may be of little predictive value.⁶⁶ When bacteriuria occurs in the asymptomatic, short-term catheterized patient (<30 days), the use of systemic antibiotics should be withheld and the catheter removed as soon as possible. If the patient becomes symptomatic, the catheter should be removed and treatment as described for complicated infections started. The optimal duration of therapy is not known. In the long-term catheterized patient (>30 days), bacteriuria is inevitable.⁶⁵ The administration of

systemic antibiotics active against the infecting organism will sterilize the urine; however, reinfection occurs rapidly in more than 50% of patients. In addition, recolonization of the urine is with resistant organisms. Symptomatic patients must be treated because they are at risk of developing pyelonephritis and bacteremia. Bacteria have been found to adhere to the catheter and to produce a biofilm consisting of bacterial glycocalyxes, Tamm-Horsfall protein, as well as apatite and struvite salts, that act to protect the bacteria from antibiotics.⁶⁷ Recatheterization with a new, sterile unit should be performed in those symptomatic patients if the existing catheter has been in place for more than 2 weeks.

Various methods have been proposed to prevent the development of bacteriuria and infection in the patient with an indwelling catheter (see Table 114–5). The success of these methods depends on the type of catheter and the length of time it is in place. The use of constant bladder irrigation with antiseptic or antibacterial solutions has been investigated and found to reduce the incidence of infection in those with open drainage systems, but this approach has no advantage in those with closed systems. The use of prophylactic systemic antibiotics in patients with short-term catheterization reduces the incidence of infection over the first 4 to 7 days.⁶⁸ In long-term catheterized patients, however, antibiotics only postpone the development of bacteriuria and lead to the emergence of resistant organisms.

PROSTATITIS

Bacterial prostatitis is an inflammation of the prostate gland and surrounding tissue as a result of infection. It is classified as either acute or chronic. By definition, pathogenic bacteria and significant inflammatory cells must be present in prostatic secretions and urine to make the diagnosis of bacterial prostatitis. Prostatitis occurs rarely in young males, but it is commonly associated with recurrent infections in persons older than 30 years of age. As many as 50% of all males develop some form of prostatitis at some period in their life.⁶⁹ The acute form typically is an acute infectious disease characterized by a sudden onset of fever, tenderness, and urinary and constitutional symptoms. Chronic prostatitis presents with few symptoms related to the prostate but rather symptoms of urinating difficulty, low back pain, perineal pressure, or a combination of these. It represents a recurring infection with the same organism that results from incomplete eradication of bacteria from the prostate gland.

PATHOGENESIS AND ETIOLOGY

The exact mechanism of bacterial infection of the prostate is not well understood. The possible routes of infection are the same as those for UTIs. Reflux of infected urine into the prostate gland is thought to play an important role in causing infection. Intraprostatic reflux of urine occurs commonly and results in direct inoculation of infected urine into the prostate.⁷⁰ In addition, intraprostatic reflux of sterile urine can result in a chemical prostatitis and may be the cause of nonbacterial prostatitis. Sexual intercourse may contribute to infection of the prostate gland because prostatic secretions from men with chronic prostatitis and vaginal cultures from their sexual partners grew identical organisms. Other known causes of bacterial prostatitis include indwelling urethral and condom catheterization, urethral instrumentation, and transurethral prostatectomy in patients with infected urine.

A number of physiologic factors are believed to contribute to the development of prostatitis. Functional abnormalities found in

bacterial prostatitis include altered prostate secretory functions. Prostatic fluid obtained from normal males contains prostatic antibacterial factor (PAF). This heat-stable, low-molecular-weight cation is a zinc-complexed polypeptide that is bactericidal to most urinary tract pathogens.⁷¹ The antibacterial activity of PAF is related directly to the zinc content of prostatic fluid. Prostate fluid zinc levels and PAF activity also appear diminished in patients with prostatitis, as well as in the elderly.⁷⁰ Whether these changes are a cause or effect of prostatitis remains to be determined.

The pH of prostatic secretions in patients with prostatitis also has been reported to be altered.⁷² Normal prostatic secretions have a pH in the range of 6.6 to 7.6. With increasing age, the pH tends to become more alkaline. In patients with inflammation of the prostate, prostatic secretions may have an alkaline pH in the range of 7 to 9. These changes suggest a generalized secretory dysfunction of the prostate that not only can affect the pathogenesis of prostatitis but also can influence the mode of therapy.

Gram-negative enteric organisms are the most frequent pathogens in acute bacterial prostatitis.⁷⁰ *E. coli* is the predominant organism, occurring in 75% of cases. Other gram-negative organisms frequently isolated include *K. pneumoniae*, *P. mirabilis*, and less frequently, *P. aeruginosa*, *Enterobacter* spp., and *Serratia* spp. Occasionally, cases of gonococcal and staphylococcal prostatitis occur, but they are infrequent.

E. coli most commonly causes chronic bacterial prostatitis, with other gram-negative organisms isolated less frequently. The importance of gram-positive organisms in chronic bacterial prostatitis remains controversial. *S. epidermidis*, *S. aureus*, and diphtheroids have been isolated in some studies.

CLINICAL PRESENTATION

Acute bacterial prostatitis presents as other acute infections (Table 114–6). Massage of the prostate will express a purulent discharge that will readily grow the pathogenic organism. Prostatic massage is contraindicated in acute bacterial prostatitis, however, because of the

TABLE 114–6. Clinical Presentation of Bacterial Prostatitis**Signs and Symptoms**

Acute bacterial prostatitis: High fever, chills, malaise, myalgia, localized pain (perineal, rectal, sacrococcygeal), frequency, urgency, dysuria, nocturia, and retention

Chronic bacterial prostatitis: Voiding difficulties (frequency, urgency, dysuria), low back pain, and perineal and suprapubic discomfort

Physical Examination

Acute bacterial prostatitis: Swollen, tender, tense, or indurated gland

Chronic bacterial prostatitis: Boggy, indurated (enlarged) prostate in most patients

Laboratory Tests

Bacteriuria

Bacteria in expressed prostatic secretions

risk of inducing bacteremia and associated local pain. The diagnosis of acute bacterial prostatitis can be made from the patient's clinical presentation and the presence of significant bacteriuria. As with other UTIs, the infecting organism can be isolated from a midstream specimen.

In contrast, chronic bacterial prostatitis is more difficult to diagnose and treat. Chronic bacterial prostatitis typically is characterized by recurrent UTIs with the same pathogen and is the most common cause of recurrent UTI in males. The patient's clinical presentation can vary widely (see Table 114–6). Many adults, however, are asymptomatic.

Because physical examination of the prostate is often normal, urinary tract localization studies are critical to the diagnosis of chronic bacterial prostatitis. The method of quantitative localization culture, as described by Meares and Stamey,⁷³ remains the diagnostic standard

**FIGURE 114–3.** Segmented cultures of the lower tract in men.

(Fig. 114–3). The method compares the bacterial growth in sequential urine and prostatic fluid cultures obtained during micturition. The first 10 mL of voided urine is collected (voiding bladder 1, or VB1) and constitutes urethral urine. After approximately 200 mL of urine has been voided, a 10-mL midstream sample is collected (VB2). This specimen represents bladder urine. After the patient voids, the prostate is massaged, and expressed prostatic secretions (EPS) are collected. After prostatic massage, the patient voids again, and 10 mL of urine is collected (VB3).

The diagnosis of bacterial prostatitis is made when the number of bacteria in EPS is 10 times that of the urethral sample (VB1) and midstream sample (VB2). If no EPS is available, the urine sample following massage (VB3) should contain a bacterial count 10-fold greater than that of VB1 or VB2. If significant bacteriuria is present, ampicillin, cephalexin, or nitrofurantoin should be given for 2 to 3 days to sterilize the urine prior to performing the localization study.

► TREATMENT: Prostatitis

8 The goals in the management of bacterial prostatitis are, in general, the same as those for UTIs. Acute bacterial prostatitis responds well to appropriate antimicrobial therapy that is directed at the most commonly isolated organisms. Prostatic penetration of antimicrobials occurs because the acute inflammatory reaction alters the cellular membrane barrier between the bloodstream and the prostate. Most patients can be managed with oral antimicrobial agents, such as trimethoprim-sulfamethoxazole and the fluoroquinolones (e.g., ciprofloxacin, levofloxacin, and gatifloxacin) (see Table 114–5). Other effective agents in this setting include cephalosporins, and β -lactam/ β -lactamase combinations. Although intravenous therapy is rarely necessary for total treatment, intravenous to oral sequential therapy with trimethoprim-sulfamethoxazole or the fluoroquinolones is appropriate. The conversion to an oral antibiotic can be considered after the patient is afebrile for 48 hours or after 3 to 5 days of intravenous therapy. The total course of antibiotic therapy should be 4 weeks in order to reduce the risk of development of chronic prostatitis. Therapy may be prolonged with chronic prostatitis (6 to 12 weeks). Long-term suppressive therapy also may be initiated for recurrent infections, such as three times weekly ciprofloxacin, trimethoprim-sulfamethoxazole regular-strength tablet daily, or nitrofurantoin 100 mg daily.¹⁵

Chronic bacterial prostatitis often presents a more vexing situation because cures are obtained rarely. In the past, it was recognized that despite high serum concentrations of antibacterial drugs in excess of the minimal inhibitory concentrations (MICs) of the infecting or-

ganisms, bacteria persisted in prostatic fluid. Most likely the failure to eradicate sensitive bacteria was caused by the inability of antibiotics to reach sufficient concentrations in the prostatic fluid and cross the prostatic epithelium.

Several factors that determine antibiotic diffusion into prostatic secretions were delineated from the canine model. Lipid solubility is a major determinant in the ability of drugs to diffuse from plasma across epithelial membranes. The degree of ionization in plasma also affects the diffusion of drugs. Only un-ionized molecules can cross the lipid barrier of prostatic cells, and the drug's pK_a directly determines the fraction of unchanged drug.

The pH gradient across the membrane has an influence on tissue penetration as well. A pH gradient of at least 1 pH unit between separate compartments allows for ion trapping. As the un-ionized drug crosses the epithelial barrier into prostatic fluid, it becomes ionized, allowing less drug to diffuse back across the lipid barrier. In early studies with the canine model, the prostatic pH was reported to be acidic (6.4).⁷⁰ More recent studies in humans, however, have reported that the pH of prostatic secretions from an inflamed prostate is actually basic (8.1 to 8.3).⁷⁰

The choice of antibiotics in chronic bacterial prostatitis should include agents that are capable of reaching therapeutic concentrations in the prostatic fluid and which possess the spectrum of activity to be effective. Agents that achieve therapeutic concentrations include trimethoprim and the fluoroquinolones. Sulfamethoxazole penetrates poorly and probably contributes very little to trimethoprim.

The fluoroquinolones appear to provide the best therapeutic options in the management of chronic bacterial prostatitis. Trimethoprim-sulfamethoxazole is also effective. Therapy should be continued for

4 to 6 weeks initially. Longer treatment periods may be necessary in some cases. If therapy fails with these regimens, chronic suppressive therapy may be used or surgery considered.

PHARMACOECONOMIC CONSIDERATIONS

The cost-effective management of UTIs requires knowledge of its pathogenesis and causative organisms associated with the various clinical syndromes described in this chapter. The costs associated with managing a UTI include direct costs, such as laboratory tests, medication, and health care visits. The indirect costs include lost work time and general quality-of-life issues such as disease or therapy adverse effects.

Direct costs are those associated with diagnosis, treatment, and follow-up. Reported percentages for these costs in cystitis are physician consultation 23%, laboratory costs 64%, and pharmaceuticals 13%.⁷⁴ The cost of pharmaceuticals varies according to the agents used and the duration of therapy. When trimethoprim-sulfamethoxazole and amoxicillin have been compared, trimethoprim-sulfamethoxazole results in a higher cure rate, lower relapse, fewer symptoms, and lower costs.⁷⁵ The fluoroquinolones also have been found to be highly effective agents but generally are more expensive. The outcome and total cost depend on whether therapy is empirical or definitive (based on a culture diagnosis for acute infection).

ABBREVIATIONS

ACB: antibody-coated bacteria
 EPS: expressed prostatic secretions
 LE: leukocyte esterase
 PAF: prostatic antibacterial factor
 PMN: polymorphonuclear leukocyte
 UTI: urinary tract infection
 WBC: white blood cell

SEXUALLY TRANSMITTED DISEASES

Leroy C. Knodel

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 All recommended treatment regimens for gonorrhea also include antibiotic therapy directed against *Chlamydia* because of the high prevalence of coexisting *Chlamydia* infections in patients diagnosed with gonorrhea.
- 2 Parenteral penicillin is the treatment of choice for all syphilis infections. For patients who are penicillin-allergic, few well-studied alternative agents are available, and all are oral medications that require 2 to 4 weeks of therapy to be effective. Patient compliance and thus efficacy are a concern when alternative regimens must be used.
- 3 *Chlamydia* genital tract infections represent the most frequently reported communicable disease in the United States. In females, these infections are frequently asymptomatic or minimally symptomatic and, if left untreated, are associated with the development of pelvic inflammatory disease and attendant complications such as ectopic pregnancy and infertility. As a result, all sexually active females, females aged 20 to 25 years, and sexually active women with multiple sexual partners should be screened annually for this infection.
- 4 Oral acyclovir, famciclovir, and valacyclovir are effective in reducing viral shedding, duration of symptoms, and time to healing of first-episode genital herpes infections, with maximal benefits seen when therapy is initiated at the earliest stages of infection. Depending on the severity of recurrent infections, which generally tend to be of shorter duration and produce less severe symptoms, symptomatic benefits may not be as obvious.
- 5 Metronidazole and tinidazole are the only agents currently approved in the United States to treat trichomoniasis. Although a single 2-g dose of either agent is widely used for compliance and other reasons, the alternative 7-day metronidazole regimen may be a better choice if sexual partners of treated individuals cannot be treated concurrently.

The spectrum of sexually transmitted diseases (STDs) has broadened from the classic venereal diseases—gonorrhea, syphilis, chancroid, lymphogranuloma venereum, and granuloma inguinale—to include a variety of pathogens known to be spread by sexual contact (Table 115–1). Because of the large number of infected individuals, the diversity of clinical manifestations, the changing drug-susceptibility patterns of some pathogens, and the high frequency of multiple STDs occurring simultaneously in infected individuals, the diagnosis and management of patients with STDs are much more complex today than they were even a decade ago.^{1–4}

Despite a higher reported incidence of most major STDs in men, the complications of STDs generally are more frequent and severe in women. In particular, serious effects on maternal and infant health during pregnancy are well documented. Damage to reproductive organs, increased risk of cancer, complications associated with pregnancy, and transmission of disease to the fetus or newborn are associated with several STDs. As a result of the physiologic, psychosocial, and economic consequences of STDs, and because of the increasing prevalence of some viral STDs, such as human immunodeficiency virus (HIV) and genital herpes, for which curative therapy is not available, there is continuing research into STDs and the primary prevention of these diseases.^{2–5}

With the exception of HIV infection, which is reviewed in detail in Chap. 123, the most frequently occurring STDs in the United States are discussed in this chapter. For other less common STDs, only

recommended treatment regimens are presented. The most current information on the epidemiology, diagnosis, and treatment of STDs provided by the Centers for Disease Control and Prevention (CDC) can be obtained at the CDC Web site on the Internet (www.cdc.gov/).

Numerous interrelated factors contribute to the epidemic nature of STDs. Sociocultural, demographic, and economic factors, together with patterns of sexual behavior, host susceptibility to infection, changing properties of the causative pathogens, disease transmission by asymptomatic individuals, and environmental factors, are important determinants of the frequency and distribution of STDs in the United States and worldwide.

Age is one of the most important demographic determinants of STD incidence. Overall, two-thirds of STD cases each year occur in persons in their teens and twenties, the peak years of sexual activity. With increasing age, the incidence of most STDs decreases exponentially. In sexually active teenagers, STD rates are highest in the youngest, suggesting that physiologic differences may contribute to increased susceptibility.^{2–5}

Age-specific rates of STDs are higher in men than in women; however, reported rates may not represent true gender differences but rather may reflect greater ease of detection in men. In recent years, the ratio of male-to-female cases for most STDs has declined, possibly reflecting improvements in the diagnosis of STDs in asymptomatic women or changes in female sexual behavior following the availability of improved methods of contraception. Although some racial disparity

TABLE 115–1. Sexually Transmitted Diseases

| Disease | Associated Pathogens |
|--|---|
| Bacterial | |
| Gonorrhea | <i>Neisseria gonorrhoeae</i> |

| Enterobiasis | <i>Enterobius vermicularis</i> |

exists for rates of STD infection, it is possible that this is a reflection of socioeconomic differences.^{2–5}

The single greatest risk factor for contracting STDs is the number of sexual partners. As the number of sexual partners increases, the risk of being exposed to someone infected with an STD increases. Sexual preference also plays a major role in the transmission of STDs. For all major STDs, rates are disproportionately greater in men who have sex with men (MSM) than in heterosexuals. Also, a number of less common STDs, including several caused by enteric protozoans and bacterial pathogens, occur primarily in MSM. The major risk factors for MSM appear to be related to the greater number of sexual partners and the practice of unprotected anal-genital, oral-genital, and oral-anal intercourse. In addition, prostitution and illicit drug use are associated with a higher incidence of most STDs.^{1–4}

Some of the most serious sequelae of STDs are associated with congenital or perinatal infections. Most neonatal infections are acquired at birth, after infant passage through an infected cervix or vagina. Neonatal *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and herpes simplex virus (HSV) infections are associated with this type of spread. For pregnant women with syphilis, infection is usu-

ally transmitted transplacentally, producing a congenital infection. Depending on the organism, neonatal infections can manifest in a variety of ways, produce significant morbidity, and in some cases result in infant death.^{1–4}

Other than complete abstinence, the most effective way to prevent STD transmission is by maintaining a mutually monogamous sexual relationship between uninfected partners. Short of this, use of barrier contraceptive methods, such as the male and female condoms, diaphragm, cervical cap, vaginal sponges, and vaginal spermicides alone or in combination, provides varying degrees of protection from a number of STDs. When used correctly and consistently, male latex condoms with or without spermicide are more effective than natural skin condoms in protecting against STD transmission, including HIV, gonorrhea, chlamydia, HSV, and hepatitis B. When lubrication is desired with latex condoms, water-based products, such as K-Y Jelly, are recommended because oil-based agents (e.g., petroleum jelly) can weaken latex condoms and reduce their effectiveness. The female condom is a lubricated polyurethane sheath with a diaphragm-like ring on each end that can be used as a protective device for women with male sexual partners who do not desire to use a condom. Limited data suggest that the female condom blocks penetration of viruses, including HIV; for nonviral STDs, the female condom provides STD protection similar to the male condom.^{1,3,5,6} At one time, use of nonoxynol-9, a vaginal spermicide with cytolytic activity, was advocated to reduce the transmissibility of several STDs. This was based in large part on in vitro and animal data. However, recent data suggest that nonoxynol-9 does not reduce significantly the risk of transmission of common STDs but actually may increase the risk of HIV transmission in frequent users. Frequent use of nonoxynol-9 damages vaginal, cervical, and rectal epithelium, leading to increased transmissibility of HIV and possibly other STDs. Some evidence exists that diaphragms may protect against cervical gonorrheal, chlamydial, and trichomonal infections.^{1,6–8}

The varied spectrum of clinical syndromes produced by common STDs is determined not only by the etiologic pathogen(s) but also by differences in male and female anatomy and reproductive physiology. For a number of STDs, the signs and symptoms overlap sufficiently to prevent accurate diagnosis without microbiologic confirmation. Frequently, symptoms are minimal or absent despite the presence of infection. Table 115–2 lists common clinical syndromes associated with STDs.^{1–3}

GONORRHEA

EPIDEMIOLOGY AND ETIOLOGY

Neisseria gonorrhoeae is a gram-negative diplococcus estimated to cause up to 600,000 infections per year in the United States.¹ Of even greater concern are the substantial number of infections that remain undiagnosed and unreported.^{1,9} Humans are the only known natural host of this intracellular parasite. Because of its rapid incubation period and the large number of infected individuals with asymptomatic disease, gonorrhea is difficult to control.^{1,10–15}

The risk of a female acquiring a cervical infection after a single episode of vaginal intercourse with an infected male is approximately 50% to 60%, and the risk increases with multiple exposures.¹⁰ While the risk of disease transmission from an infected female to an uninfected male is less, it still is as high as 20% to 30% following a single act of coitus. No data are available on the risk of transmission after other types of sexual contact.^{10–12}

TABLE 115–2. Selected Syndromes Associated with Common Sexually Transmitted Pathogens

| Syndrome | Commonly Implicated Pathogens | Common Clinical Manifestations ^a |
|---------------------------|--|--|
| Urethritis | <i>Chlamydia trachomatis</i> , herpes simplex virus, <i>Neisseria gonorrhoeae</i> , <i>Trichomonas vaginalis</i> , <i>Ureaplasma urealyticum</i> | Urethral discharge, dysuria |
| Epididymitis | <i>C. trachomatis</i> , <i>N. gonorrhoeae</i> | Scrotal pain, inguinal pain, flank pain, urethral discharge |
| Cervicitis/vulvovaginitis | <i>C. trachomatis</i> , <i>Gardnerella vaginalis</i> , herpes simplex virus, human papillomavirus, <i>N. gonorrhoeae</i> , <i>T. vaginalis</i> | Abnormal vaginal discharge, vulvar itching/irritation, dysuria, dyspareunia |
| Genital ulcers (painful) | <i>Hemophilus ducreyi</i> , herpes simplex virus | Usually multiple vesicular/pustular (herpes) or papular/pustular (<i>H. ducreyi</i>) lesions that may coalesce; painful, tender lymphadenopathy ^b |
| Genital ulcers (painless) | <i>Treponema pallidum</i> | Usually single papular lesion |
| Genital/anal warts | Human papillomavirus | Multiple lesions ranging in size from small papular warts to large exophytic condylomas |
| Pharyngitis | <i>C. trachomatis</i> (?), herpes simplex virus, <i>N. gonorrhoeae</i> | Symptoms of acute pharyngitis, cervical lymphadenopathy, fever ^c |
| Proctitis | <i>C. trachomatis</i> , herpes simplex virus, <i>N. gonorrhoeae</i> , <i>T. pallidum</i> | Constipation, anorectal discomfort, tenesmus, mucopurulent rectal discharge |
| Salpingitis | <i>C. trachomatis</i> , <i>N. gonorrhoeae</i> | Lower abdominal pain, purulent cervical or vaginal discharge, adnexal swelling, fever ^d |

^aFor some syndromes, clinical manifestations may be minimal or absent.

^bRecurrent herpes infection may manifest as a single lesion.

^cMost cases of pharyngeal gonococcal infection are asymptomatic.

^dSalpingitis increases the risk of subsequent ectopic pregnancy and infertility.

PATHOPHYSIOLOGY

On contact with a mucosal surface lined by columnar, cuboidal, or noncornified squamous epithelial cells, the gonococci attach to cell membranes by means of surface pili and are then pinocytosed. The virulence of the organism is mediated primarily by the presence of pili and other outer membrane proteins. After mucosal damage is established, polymorphonuclear leukocytes (PMNs) invade the tissue, submucosal abscesses form, and purulent exudates are secreted.^{10,11}

CLINICAL PRESENTATION

Individuals infected with gonorrhea can be symptomatic or asymptomatic, have complicated or uncomplicated infections, and have infections involving several anatomic sites. Interestingly, most of the symptomatic patients who are not treated become asymptomatic within 6 months, with only a few becoming asymptomatic carriers of the disease.^{10–12} The most common clinical features of gonococcal infections are presented in Table 115–3.

TABLE 115–3. Presentation of Gonorrhea Infections

| | Males | Females |
|-------------------|---|---|
| General | Incubation period 1–14 days Symptom onset in 2–8 days | Incubation period 1–14 days Symptom onset in 10 days |
| Site of infection | Most common—urethra Others—rectum (usually due to rectal intercourse in MSM), oropharynx, eye | Most common—endocervical canal Others—urethra, rectum (usually due to perineal contamination), oropharynx, eye |
| Symptoms | May be asymptomatic or minimally symptomatic Urethral infection—dysuria and urinary frequency Anorectal infection—asymptomatic to severe rectal pain Pharyngeal infection—asymptomatic to mild pharyngitis | May be asymptomatic or minimally symptomatic Endocervical infection—usually asymptomatic or mildly symptomatic Urethral infection—dysuria, urinary frequency Anorectal and pharyngeal infection—symptoms same as for men |
| Signs | Purulent urethral or rectal discharge can be scant to profuse Anorectal—pruritus, mucopurulent discharge, bleeding | Abnormal vaginal discharge or uterine bleeding; purulent urethral or rectal discharge can be scant to profuse |
| Complications | Rare (epididymitis, prostatitis, inguinal lymphadenopathy, urethral stricture) Disseminated gonorrhea | Pelvic inflammatory disease and associated complications (i.e., ectopic pregnancy, infertility) Disseminated gonorrhea (three times more common than in men) |

Complications associated with untreated gonorrhea appear more pronounced in women, likely a result of a high percentage who experience signs and symptoms that are nonspecific and minimally symptomatic. As a result, many women do not seek treatment until after the development of serious complications, such as pelvic inflammatory disease (PID). Approximately 15% of women with gonorrhea develop PID. Left untreated, PID can be an indirect cause of infertility and ectopic pregnancies. In 0.5% to 3.0% of patients with gonorrhea, the gonococci invade the bloodstream and produce disseminated disease. Disseminated gonorrhea infection (DGI) is three times more common in women than in men. The usual clinical manifestations of DGI are tender necrotic skin lesions, tenosynovitis, and monarticular arthritis.^{1,10–13}

DIAGNOSIS

Diagnosis of gonococcal infections can be made by Gram-stained smears, culture, or methods based on the detection of cellular components of the gonococcus (e.g., enzymes, antigens, DNA, or lipopolysaccharide) in clinical specimens. Various stains have been used to identify gonococci microscopically, with the Gram stain the most widely used in clinical practice. Gram-stained smears are positive for gonococci when gram-negative diplococci of typical kidney bean morphology are identified within PMNs.^{1,10–13} In the presence of equivocal smears (extracellular gonococcal forms that can be nonpathogenic, commensal *Neisseria*, or gram-negative diplococci of atypical morphology), culture is mandatory. In urethral smears from men with symptomatic urethritis, the smear is highly sensitive and specific, and culture is considered optional. Gram-stained smears

are specific but insensitive for endocervical, rectal, cutaneous, and asymptomatic male urethral infections. In these situations, culture is the most reliable means of diagnosis. Because of the presence of nonpathogenic *Neisseria* in the pharynx, the Gram stain is not useful in the diagnosis of pharyngeal infection.^{1,10,11,14}

Culture is considered the most reliable means of diagnosing gonococcal infections. Anatomic sites to be cultured depend on the individual's sexual preferences and body areas exposed. In women, because the urethra and other sites are rarely the sole locus of infection, cervical cultures produce the highest yield and frequently are performed in conjunction with rectal cultures. Urethral cultures are recommended in women who have had hysterectomies and heterosexual men. In MSM, anorectal cultures generally produce the highest yields, and pharyngeal and urethral cultures are considered optional.^{1,10–14}

Because technical constraints and cost preclude the use of culture techniques in most office settings and clinics, alternative methods of diagnosis have been developed, including enzyme immunoassay, DNA probe techniques, and nucleic acid amplification techniques employing polymerase chain reaction (PCR) and ligase chain reaction (LCR). With the exception of Gram stain for symptomatic gonococcal urethritis, these tests offer increased sensitivity and/or specificity over both Gram stain and culture.¹⁰ Additionally, many of these tests can provide a more rapid means of diagnosis than culture. Of particular clinical importance is the high sensitivity of DNA probe and PCR methods for detecting *N. gonorrhoeae* either in first-void urine samples of infected individuals or from vaginal swabs of infected women, and the extension of this technology to concurrently test for *Chlamydia trachomatis* in a single specimen.^{1,14,17}

► TREATMENT: Gonorrhea

N. gonorrhoeae are susceptible to a variety of antibiotics. The development of chromosomally mediated and plasmid-mediated resistance has resulted, however, in an increasing number of isolates resistant to former first-line antibiotics such as penicillin, ampicillin, amoxicillin, and tetracycline.^{1,10–13,18,19}

◀ All gonorrhea treatment regimens recommended by the CDC consist of various oral or parenteral cephalosporins and fluoroquinolones given as a single dose¹ (Table 115–4). These regimens have documented efficacy in the treatment of urethral, cervical, rectal, and pharyngeal infections. Coexisting chlamydial infection, which is documented in up to 50% of women and 20% of men with gonorrhea, constitutes the major cause of postgonococcal urethritis, cervicitis, and salpingitis in patients treated for gonorrhea.^{1,15,16} As a result, concomitant treatment with doxycycline or azithromycin is recommended in all patients treated for gonorrhea. While none of the single-dose regimens recommended for gonorrhea in the CDC guidelines is effective against chlamydia, azithromycin (2 g) as a single dose is highly effective in eradicating both gonorrhea and chlamydia.

CLINICAL CONTROVERSY

Some clinicians advocate that a single 2-g dose of azithromycin should be the treatment of choice for gonorrhea because it is also effective in eradicating concomitant chlamydia infection. However, azithromycin therapy is associated with a greater incidence of gastrointestinal side effects and is much more expensive than other recommended first-line therapies.

Ceftriaxone, the only parenteral agent included in CDC recommended first-line agents for the treatment of gonorrhea, is administered intramuscularly (IM) as a single 125-mg dose, and in comparison with recommended oral antibiotics, it is an expensive alternative.^{1,14–19}

Although oral therapy offers a promising alternative to the expense and pain associated with parenteral therapy, it may not be preferred for all cases of gonorrhea. Of the regimens of choice, only ceftriaxone is effective in eradicating both gonorrhea and incubating syphilis. Because the overall incidence of concomitant infection with both gonorrhea and syphilis appears low in most areas, selection of ceftriaxone based on this criterion should be considered only in areas in which the incidence of syphilis infection is high.^{1,13,18,19} Resistance to the broad-spectrum cephalosporins recommended for the treatment of gonorrhea has not been reported. However, because of the increasing prevalence of high-level resistance to fluoroquinolones in some parts of the United States (i.e., Hawaii and California) and the world, these agents are no longer recommended for treating infections acquired in these locations. Similarly, fluoroquinolones are no longer recommended as first-line therapy in MSM due to data indicating increasing resistance in this population.^{1,19} Ofloxacin is useful in eradicating both *N. gonorrhoeae* and *C. trachomatis*; however, different dosage regimens are required for each pathogen, and it is unknown whether the lower, multiple-dose daily regimen used in chlamydial infections is effective in eradicating gonorrheal infections.^{1,18,19} Spectinomycin is still the preferred alternative for patients unable to tolerate the recommended cephalosporin or fluoroquinolone regimens. Although some resistance to spectinomycin is reported, its limited use appears to have prevented widespread resistance from developing.

TABLE 115-4. Treatment of Gonorrhea

| Type of Infection | Recommended Regimens ^a | Alternative Regimens ^b |
|--|---|--|
| Uncomplicated infections of the cervix, urethra, and rectum in adults ^{c,d} | Ceftriaxone 125 mg IM once ^e ; or ciprofloxacin 500 mg PO once ^e ; or cefixime 400 mg PO once ^f ; or ofloxacin 400 mg PO once ^e <i>plus</i> A treatment regimen for presumptive <i>C. trachomatis</i> coinfection (see Table 115-5) | Spectinomycin 2 g IM once; or ceftizoxime 500 mg IM once; or cefotaxime 500 mg IM once; or cefotetan 1 g IM once; or cefoxitin 2 g IM once with probenecid 1 g PO once; or lomefloxacin 400 mg PO once; or enoxacin 400 mg PO once; or norfloxacin 800 mg PO once <i>plus</i> A treatment regimen for presumptive <i>C. trachomatis</i> coinfection (see Table 115-5) |
| Gonococcal infections in pregnancy | Ceftriaxone 125 mg IM once ^{g,h} <i>plus</i> A recommended treatment regimen for presumptive <i>C. trachomatis</i> infection during pregnancy ^h (see Table 115-5) | Spectinomycin 2 g IM once <i>plus</i> a recommended treatment regimen for presumptive <i>C. trachomatis</i> infection during pregnancy ^h (see Table 115-5) |
| Disseminated gonococcal infection in adults (>45 kg) ^{h,i,j,k} | Ceftriaxone 1 g IM or IV every 24 hours ^l | Ceftizoxime 1 g IV every 8 hours ^l or Cefotaxime 1 g IV every 8 hours ^l |
| Uncomplicated infections of the cervix, urethra, and rectum in children (<45 kg) | Ceftriaxone 125 mg IM once ^m | Spectinomycin 40 mg/kg IM once (not to exceed 2 g) |
| Gonococcal conjunctivitis in adults | Ceftriaxone 1 g IM once ⁿ | |
| Ophthalmia neonatorum | Ceftriaxone 25–50 mg/kg IV or IM once (not to exceed 125 mg) | |
| Infants born to mothers with gonococcal infection (prophylaxis) | Ceftriaxone 25–50 mg/kg IV or IM once (not to exceed 125 mg) | |

^aRecommendations are those of the CDC.

^bA number of other antimicrobials have demonstrated efficacy in treating uncomplicated gonorrhea but are not included in the CDC guidelines.

^cTreatment failures are usually due to reinfection and necessitate patient education and sex-partner referral; additional treatment regimens for gonorrhea and chlamydia infections should be administered. Epididymitis should be treated for 10 days (see Table 115-8).

^dPatients allergic to β -lactams should receive a quinolone. Persons unable to tolerate a β -lactam (penicillin or cephalosporin) or a quinolone should receive spectinomycin.

^eAlso recommended for the treatment of uncomplicated infections of the pharynx in combination with a treatment regimen for presumptive *C. trachomatis* infection; fluoroquinolones are *not* recommended for treating infections in MSM or infections acquired in Hawaii, California, or other parts of the world where high-level resistance to fluoroquinolones is reported.

^fIn July, 2002, Wyeth Pharmaceutical discontinued manufacturing cefixime; at the time of publication, there were no generic manufacturers of cefixime.

^gAnother recommended IM or PO cephalosporin also may be used.

^hThe fluoroquinolones, doxycycline, and erythromycin ethylsuccinate are contraindicated during pregnancy.

ⁱPatients treated with one of the recommended regimens should be treated with doxycycline or azithromycin for possible coexistent chlamydial infection.

^jPatients with gonococcal meningitis should be treated for 10 to 14 days and those with endocarditis for at least 4 weeks with ceftriaxone 1–2 g IV every 12 hours.

^kAll treatment regimens should be continued for 24–48 hours after improvement begins; at this time therapy can be switched to one of the following oral regimens to complete a 7-day course of treatment: cefixime 400 mg PO 2 times daily, or ciprofloxacin 500 mg PO 2 times daily, or ofloxacin 400 mg PO 2 times daily.

^lAll regimens should be continued for 24–48 hours after improvement begins; at this time therapy can be switched to one of the following oral regimens to complete a 7-day course of treatment: cefixime 400 mg PO 2 times daily or ciprofloxacin 500 mg PO 2 times daily or ofloxacin 400 mg PO 2 times daily.

^mPatients with bacteremia or arthritis should receive ceftriaxone 50 mg/kg (maximum 1 g) IM or IV once daily for 7 days.

ⁿThe eye should be lavaged one time with saline solution.

Unlike ceftriaxone and the fluoroquinolones, spectinomycin has only limited efficacy in treating pharyngeal infections.

Pregnant women infected with *N. gonorrhoeae* should be treated with either a cephalosporin or spectinomycin because fluoroquinolones are contraindicated. For the treatment of presumed or diagnosed concurrent *C. trachomatis* infection, erythromycin and amoxicillin are the preferred treatments.^{1,10,11,18,19}

Ceftriaxone is the recommended therapy for DGI, gonococcal meningitis, endocarditis, and any type of gonococcal infection in children. Although oral antibiotic regimens have not been studied adequately in children who weigh less than 45 kg, oral cefixime may provide a more patient acceptable alternative (*Note:* As of July 2002, Wyeth Pharmaceuticals discontinued manufacturing cefixime, and at the time of publication, there were no generic manufacturers of cefixime.) In cases of DGI, patients should be hospitalized and treated initially with one of the recommended parenteral antibiotics (see

Table 115-4). Although marked improvement is usually noted within 48 hours of initiating therapy, treatment should be continued as an outpatient with one of the recommended oral antibiotics to complete at least 7 days of antibiotic therapy.^{1,18,19} Children and pregnant or lactating women should not receive fluoroquinolones because of the concern for bone and joint disorders. In MSM with DGI, ceftriaxone is preferred because of its efficacy in treating coexisting rectal, pharyngeal, and urethral infections.^{1,10,18}

Gonococcal ophthalmia is highly contagious in adults and neonates and requires IM ceftriaxone therapy. Single-dose therapy is adequate for gonococcal conjunctivitis, although some physicians recommend continuing therapy until cultures are negative at 48 to 72 hours. Topical antibiotics are not sufficiently effective when used alone for ocular infections and are not necessary with appropriate systemic therapy. Infants with either type of ophthalmologic infection should be evaluated for signs of DGI.^{1,10,18–20}

Treatment of gonorrhea during pregnancy is essential to prevent ophthalmia neonatorum. Gonococcal infection in newborns results primarily from passage through an infected birth canal, but it also can be transmitted in utero. Ophthalmia neonatorum is the most common ophthalmic infection in newborns (1.6% to 12%), although membranes of the vagina, pharynx, or rectum also can become colonized. Conjunctival involvement usually develops within 7 days of delivery and is characterized by intense, bilateral conjunctival inflammation with chemosis. If not treated promptly, corneal ulceration

and blindness can develop. Because the law in most states requires neonatal prophylaxis with topical ocular antimicrobials, gonococcal ophthalmia neonatorum is rare in the United States. The American Academy of Pediatrics recommends that either silver nitrate (1%), tetracycline (1%), or erythromycin (0.5%) be instilled in each conjunctival sac immediately postpartum. Infants born to infected mothers should receive an IM or intravenous (IV) injection of ceftriaxone 25–50 mg/kg (not to exceed 125 mg); topical therapy is not necessary in such cases.^{1,10–13,18,19}

EVALUATION OF THERAPEUTIC OUTCOMES

Although some clinicians recommend obtaining follow-up cultures at least 3 days after treatment, combination gonorrhea and chlamydial therapy rarely results in treatment failures, and routine follow-up of patients treated with a regimen included in the CDC guidelines is not recommended. Persistence of symptoms following any treatment requires culture of the site(s) of gonorrheal infection, as well as susceptibility testing if gonococci are isolated. In most cases, the presence of gonococci indicates reinfection rather than treatment failure and reflects the need for improved patient education and sex partner referral. Persistence of symptoms also can be caused by other infectious causes, such as *C. trachomatis*.^{1,18,19}

SYPHILIS

EPIDEMIOLOGY AND ETIOLOGY

Although syphilis was the fifth most frequently reported communicable disease in the United States in 2001, the incidence of this disease has declined by almost 80% since 1990.⁹ In addition to being highly contagious, syphilis is of major concern because, if left untreated, it can progress to a chronic systemic disease that can be fatal or seriously disabling.^{22–25}

Syphilis usually is acquired by sexual contact with infected mucous membranes or cutaneous lesions, although on rare occasions it can be acquired by nonsexual personal contact, accidental inoculation, or blood transfusion. The causative organism of syphilis is *Treponema pallidum*, a spirochete. The risk of acquiring syphilis from an infected individual after a single sexual encounter is approximately 50% to 60%. After sexual contact, the organism penetrates the intact mucous membrane or a break in the cornified epithelium, and spirochetemia occurs.^{24,25}

Evidence of a strong association between syphilis and HIV infection has been noted. Although complex and incompletely understood, it appears that syphilis, similar to other sexually transmitted genital ulcer diseases, can increase the risk of acquiring HIV in exposed individuals. Also, immunologic defects in HIV-infected individuals can modify the serologic response to syphilis. In particular, the possibility of delayed seroreactivity, markedly elevated serologic titers, and increased false-positive results could complicate the diagnosis, as well as assessment of treatment efficacy, in HIV-positive individuals infected with syphilis. Furthermore, anecdotal evidence suggests that compromised immune function may result in an accelerated progression of syphilis, particularly to neurosyphilis, requiring more aggressive antibiotic therapy in comparison with an immunocompetent host. As a result of this association, the CDC recommends that all patients diagnosed with syphilis be tested for HIV infection.^{1,22–24}

CLINICAL PRESENTATION

The clinical presentation of syphilis is varied, with progression through multiple stages possible in untreated or inadequately treated patients (Table 115–5).

PRIMARY SYPHILIS

The primary stage, characterized by the appearance of a chancre on cutaneous or mucocutaneous tissue exposed to the organism, is highly infectious. Even without treatment, chancres persist only for 1 to 8 weeks before healing spontaneously. Because syphilitic chancres can be confused with other infectious etiologies, appropriate diagnostic testing is important.^{22–24}

SECONDARY SYPHILIS

The secondary stage of syphilis is characterized by a variety of mucocutaneous eruptions resulting from widespread hematogenous and lymphatic spread of *T. pallidum*. Skin lesions can be either generalized or localized to a small portion of the body and, with the exception of follicular lesions, are nonpruritic. Generalized lymphadenopathy also is seen in the majority of patients, as are nonspecific symptoms such as mild and transitory malaise, fever, pharyngitis, headache, anorexia, and arthralgia. If untreated, secondary syphilis disappears in 4 to 10 weeks; however, lesions may recur at any time within 4 years.^{12,22–24}

LATENT SYPHILIS

By definition, persons with a positive serologic test for syphilis but with no other evidence of disease have latent syphilis. Latent syphilis is further divided into early and late latency. During early latency, the patient is considered potentially infectious because of the 25% risk of spontaneous mucocutaneous relapse. The U.S. Public Health Service defines early latency as 1 year from the onset of infection, although other investigators propose a longer interval, such as 2 to 4 years. With the exception of pregnancy in which the mother may pass the disease to the fetus, late latency is considered noninfectious, although the patient remains a host.^{1,22–24}

Most untreated patients with late latent syphilis have no further sequelae; however, approximately 25% to 30% progress either to neurosyphilis or to late syphilis with clinical manifestations other than neurosyphilis. Treatment of all patients with latent syphilis is essential because there is no way to predict which patients will have progression of their disease.^{22–24}

TERTIARY SYPHILIS AND NEUROSYPHILIS

If left untreated, syphilis can slowly produce an inflammatory reaction in virtually any organ in the body. Manifestations of this disease

TABLE 115–5. Presentation of Syphilis Infections

| | |
|---------------------------|--|
| General | |
| Primary | Incubation period 10–90 days (mean 21 days) |
| Secondary | Develops 2–8 weeks after initial infection in untreated or inadequately treated individuals |
| Latent | Develops 4–10 weeks after secondary stage in untreated or inadequately treated individuals |
| Tertiary | Develops in approximately 30% of untreated or inadequately treated individuals 10–30 years after initial infection |
| Site of Infection | |
| Primary | External genitalia, perianal region, mouth, and throat |
| Secondary | Multisystem involvement secondary to hematogenous and lymphatic spread |
| Latent | Potentially multisystem involvement (dormant) |
| Tertiary | CNS, heart, eyes, bones, and joints |
| Signs and Symptoms | |
| Primary | Single, painless, indurated lesion (chancre) that erodes, ulcerates, and eventually heals (typical); regional lymphadenopathy is common; multiple, painful, purulent lesions possible but uncommon |
| Secondary | Pruritic or nonpruritic rash, mucocutaneous lesions, flulike symptoms, lymphadenopathy |
| Latent | Asymptomatic |
| Tertiary | Cardiovascular syphilis (aortitis or aortic insufficiency), neurosyphilis (meningitis, general paresis, dementia, tabes dorsalis, eighth cranial nerve deafness, blindness), gummatous lesions involving any organ or tissue |

progression were referred to previously as *tertiary syphilis*.²⁴ These clinical manifestations now are differentiated into two subgroups based on the presence or absence of central nervous system (CNS) involvement: neurosyphilis or tertiary syphilis (i.e., gumma and cardiovascular syphilis).^{1,22–24}

Currently, the term *neurosyphilis* encompasses any patient with cerebrospinal fluid (CSF) abnormalities consistent with CNS infection.^{1,24} Approximately 40% of patients with primary or secondary syphilis exhibit such abnormalities, although most remain asymptomatic. Persistence of CSF abnormalities into late latency is associated with a greater risk of progression to symptomatic neurosyphilis. Although data are conflicting, some investigators suggest that HIV-infected patients are at greater risk of developing symptomatic neurosyphilis than patients with intact immune systems.^{1,22,25}

Rarely seen, the most common manifestations of disease progression from late latency are benign gumma formation and cardiovascular syphilis. The gumma, a nonspecific granulomatous lesion, is the classic lesion of late syphilis and develops in 50% of patients with disease progression. These chronic, destructive lesions characteristically infiltrate the skin, bone, soft tissue, and liver but can be found in any organ or tissue. Gummas of critical organs, such as the heart or brain, can be fatal.^{1,24–28}

CONGENITAL SYPHILIS

In pregnant women with syphilis, *T. pallidum* can cross the placenta at any time during pregnancy. The risk of fetal infection is greatest in pregnant women with primary and secondary syphilis and declines in pregnant women with late disease. Transmission of syphilis during pregnancy occurs primarily transplacentally and can result in fetal death, prematurity, or congenital syphilis. Symptoms can be seen during the first months of life (early congenital syphilis) or later in childhood or adolescence (late congenital syphilis). Manifestations of early congenital syphilis resemble those of secondary syphilis, whereas those of late congenital syphilis correspond to the tertiary stage in adults.^{22–25}

DIAGNOSIS

Because *T. pallidum* is difficult to culture in vitro, diagnosis is based primarily on microscopic examination of serous material from a suspected syphilitic lesion or on results from serologic testing. In primary syphilis, diagnosis is established by the presence of *T. pallidum* on dark-field microscopic examination of material from cutaneous lesions and enlarged lymph nodes in patients with secondary syphilis. In incubating syphilis, confirmation frequently is by dark-field microscopic examination because serologic tests can be unreactive early in the disease. Another method of direct microscopic examination, the direct fluorescent-antibody test (DFA-TP), which uses monoclonal or polyclonal antibodies specific for *T. pallidum*, has greater specificity and sensitivity than does dark-field examination, and does not require the immediate examination of fresh specimens.^{12,24–28}

Serologic tests are the mainstay in the diagnosis of syphilis and traditionally are categorized as nontreponemal or treponemal. Common nontreponemal tests include the Venereal Disease Research Laboratory (VDRL) slide test, rapid plasma reagin (RPR) card test, unheated serum reagin (USR) test, and the tuluidine red unheated serum test (TRUST). Nontreponemal tests, which are inexpensive and easily performed, rely on the detection of treponemal antibodies directed against an alcoholic solution of cardiolipin, lecithin, and cholesterol contained in these tests. A positive nontreponemal test can indicate the presence of any stage of syphilis or congenital syphilis, although incubating syphilis and very early primary syphilis produce a negative reaction; however, because they are nonspecific tests, false-positive reactions occur, making them inappropriate to confirm the diagnosis alone. Transiently false-positive results can be seen in patients with acute febrile illnesses, after immunizations, and during pregnancy. Chronic false-positive results are commonly associated with heroin addiction, aging, chronic infections, autoimmune diseases, and malignant disease. In some cases, false-positive reactions are familial and are related to abnormal serum globulin levels.^{23–28}

Nontreponemal tests are used primarily as screening tests; however, because *T. pallidum* antibody titers also can be quantitated by

testing serial dilutions of the patient's serum for reactivity, they are useful in following the progression of the disease, recovery after therapy, and possible reinfection. Because antibody titers vary to some extent between tests, it is important that sequential serologic testing be performed using the same method each time. In patients treated successfully for primary and secondary syphilis, nontreponemal tests almost always will return to seronegativity. If these tests are going to return to negative in patients with early latent syphilis, they will do so within the first 4 years after adequate therapy; patients with disease of longer duration usually remain seropositive for life. In addition to their use in serologic testing, nontreponemal tests often are used on CSF to diagnose neurosyphilis.^{23–28}

In some patients with secondary syphilis, a prozone phenomenon occurs that produces a negative VDRL test despite the presence of high reaginic antibody titers. This is corrected by diluting the patient's serum prior to testing.^{26,27} For HIV-positive individuals with syphilis, the reactivity of nontreponemal tests can vary depending on the stage of the HIV infection. In the early stages, reaginic titers higher than in non-HIV-infected patients have been seen, resulting in the prozone phenomenon. During the later stages of HIV infection, however, when immune function deteriorates to a greater extent, serologic responses can be reduced or delayed. As a result, the diagnosis of syphilis in HIV-infected individuals can be more difficult.^{1,24–28}

In diagnosing all stages of syphilis, treponemal tests are more sensitive than nontreponemal tests. Because these tests are technically

more demanding and are more expensive, they are used primarily as confirmatory rather than as screening tests. The fluorescent treponemal antibody absorption (FTA-ABS) test is the most frequently used treponemal test. The FTA-ABS test uses the *T. pallidum* antigen to detect specific antibodies to treponemal organisms. The FTA-ABS test becomes positive earlier than nontreponemal tests in primary syphilis. After adequate antibiotic therapy for any stage of syphilis, the FTA-ABS test usually remains reactive for life and therefore is not useful in assessing serologic response to therapy, relapse, or reinfection. In suspected neurosyphilis when the CSF is negative with nontreponemal tests, FTA-ABS testing of the CSF is sometimes recommended. While less specific than the VDRL test for CSF involvement, the FTA-ABS test appears to be highly sensitive. Other serologic tests that are specific for the treponemal antibody are the *T. pallidum* hemagglutination assay (TPHA), microhemagglutination assay for antibodies to *T. pallidum* (MHA-TP), and the *T. pallidum* particle agglutination assay (TPPA). Recently, several enzyme immunoassays for *T. pallidum* have become available and are gaining wide use as confirmatory tests. PCR-based tests also are being investigated, particularly in situations in which serologic testing has poor sensitivity and specificity (e.g., congenital syphilis, early primary syphilis, and neurosyphilis). Additionally, multiplex PCR tests that can identify the presence of *T. pallidum*, herpes simplex virus type 1 (HSV-1) and HSV-2, and *Hemophilus ducreyi* from genital ulcer specimens are under study.^{23,24,26–28}

► TREATMENT: Syphilis

Table 115–6 presents the CDC's treatment recommendations.¹ Parenteral penicillin G is the treatment of choice for all stages of syphilis. Because *T. pallidum* multiplies slowly, single doses of short- or intermediate-acting penicillins do not provide the prolonged, low-level exposure to penicillin required for eradication of the treponeme. As a result, benzathine penicillin G is the only penicillin effective for single-dose therapy.^{1,12,22–25,29}

The recommended treatment for syphilis of less than 1 year's duration is benzathine penicillin G 2.4 million units as a single dose. Although the relapse rate for this regimen is less than 3%, some investigators advocate that 2.4 million units be administered once a week for 2 consecutive weeks. In patients with syphilis of greater than 1 year's duration and normal CSF examination, benzathine penicillin G is administered weekly for three successive doses. Although not specifically recommended by the CDC, this three-dose regimen is used by some experts to treat HIV-infected patients with syphilis of less than 1 year's duration based on data suggesting a greater risk of treatment failure with single-dose therapy.^{1,24,25,29}

CLINICAL CONTROVERSY

Some experts even prefer to treat all patients with syphilis of less than 1 year's duration with the three-dose regimen because single-dose therapy is not consistently effective in eradicating treponemes from the CSF; this is of primary concern in patients with undiagnosed CSF involvement, such as HIV-infected individuals.

Patients with abnormal CSF findings should be treated as having neurosyphilis. Preferred regimens for neurosyphilis provide treatment over 10 to 14 days with parenteral penicillin G administered every 4 hours. Benzathine penicillin G alone in standard weekly doses and procaine penicillin G in doses under 2.4 million units do not consistently

provide treponemicidal levels in the CSF and have resulted in treatment failures.^{1,24,25,29} Because *T. pallidum* resistance to penicillin has not emerged, the primary need for alternative drugs in treating syphilis is for penicillin-allergic patients.^{1,24,25,29}

Alternative regimens recommended for penicillin-allergic patients are doxycycline 100 mg orally twice daily or tetracycline 500 mg orally four times daily for 2 to 4 weeks depending on the duration of syphilis infection. Although erythromycin 500 mg orally four times daily was recommended in the past as an alternative regimen in nonpregnant, penicillin-allergic patients, evidence suggests that it is not as effective as other recommended regimens.^{1,24,25,29}

Alternative treatment regimens should be used only in cases of documented penicillin allergy, and given concerns regarding patient compliance with these regimens, follow-up serologic testing is of particular importance.^{1,23,24}

Other antibiotics used successfully in treating syphilis include various β -lactam antibiotics; however, none offers significant advantages over benzathine penicillin G. Even though ceftriaxone is considered effective in eradicating incubating syphilis when given as a single 125-mg dose, higher doses and more frequent administration (e.g., 1000 mg daily for 8 to 10 days) appear necessary for more advanced syphilis, and treatment failures are reported in HIV-infected patients. Preliminary data indicate that azithromycin 2 g as a single dose produces good results in patients with early syphilis.^{1,24,25,29}

For pregnant patients, penicillin is the treatment of choice at the dosage recommended for that particular stage of syphilis. To ensure treatment success and prevent transmission to the fetus, some experts advocate an additional IM dose of benzathine penicillin G 2.4 million units 1 week after completion of the recommended regimen. In women allergic to penicillin, safe and effective alternatives are not available; therefore, skin testing should be performed to confirm a penicillin

TABLE 115–6. Drug Therapy and Follow-up of Syphilis

| Stage/Type of Syphilis | Recommended Regimens ^a | Follow-Up Serology |
|---|---|---|
| Primary, secondary, or latent syphilis of less than 1 year's duration (early latent syphilis) | Benzathine penicillin G 2.4 million units IM in a single dose ^b | Quantitative nontreponemal tests at 6 and 12 months for primary and secondary syphilis; at 6, 12, and 24 months for early latent syphilis ^c |
| Latent syphilis of more than 1 year's duration (late latent syphilis) or syphilis of unknown duration | Benzathine penicillin G 2.4 million units IM once a week for 3 successive weeks (7.2 million units total) | Quantitative nontreponemal tests at 6, 12, and 24 months ^d |
| Neurosyphilis | Aqueous crystalline penicillin G 18–24 million units IV (3–4 million units every 4 hours or by continuous infusion) for 10–14 days ^e <i>or</i> Aqueous procaine penicillin G 2.4 million units IM daily plus probenecid 500 mg PO four times daily, both for 10–14 days ^e | CSF ^f examination every 6 months until the cell count is normal; if it has not decreased at 6 months or is not normal by 2 years, retreatment should be considered |
| Congenital syphilis | Aqueous crystalline penicillin G 50,000 units/kg IV every 12 hours during the first 7 days of life and every 8 hours thereafter for a total of 10 days <i>or</i> Procaine penicillin G 50,000 units/kg IM daily for 10 days | Quantitative nontreponemal tests every 2–3 months until nonreactive or titers have decreased 4-fold |
| Penicillin-allergic patients ^g | | |
| Primary, secondary, or early latent syphilis | Doxycycline 100 mg PO two times daily for 2 weeks ^{h,i} <i>or</i> Tetracycline 500 mg PO four times daily for 2 weeks ^{h,i} | Same as for non-penicillin-allergic patients |
| Latent syphilis of more than 1 year's duration (late latent syphilis) or syphilis of unknown duration | Doxycycline 100 mg PO two times a day for 4 weeks ⁱ <i>or</i> Tetracycline 500 mg PO four times daily for 4 weeks ⁱ | Same as for non-penicillin-allergic patients |

^aRecommendations are those of the CDC.

^bSome experts recommend multiple doses of benzathine penicillin G or other supplemental antibiotics in addition to benzathine penicillin G in HIV-infected patients with primary or secondary syphilis; HIV-infected patients with early latent syphilis should be treated with the recommended regimen for latent syphilis of more than 1 year's duration.

^cMore frequent follow-up (i.e., 3, 6, 9, 12, and 24 months) recommended for HIV-infected patients.

^dMore frequent follow-up (i.e., 6, 12, 18, and 24 months) recommended for HIV-infected patients.

^eSome experts administer benzathine penicillin G 2.4 million units IM once per week for up to 3 weeks after completion of the neurosyphilis regimens to provide a total duration of therapy comparable to that used for late syphilis in the absence of neurosyphilis.

^fCSF = cerebrospinal fluid.

^gFor nonpregnant patients; pregnant patients should be treated with penicillin after desensitization.

^hAlthough less effective than either the doxycycline or tetracycline regimen, erythromycin 500 mg PO 4 times daily can be considered as an alternative regimen for nonpregnant patients.

ⁱPregnant patients allergic to penicillin should be desensitized and treated with penicillin.

allergy. It is recommended that women with positive skin tests undergo penicillin desensitization and receive the appropriate treatment regimen for their stage of disease.^{1,24,25}

Most patients treated for primary and secondary syphilis experience the Jarisch-Herxheimer reaction after treatment. This benign, self-limiting reaction is characterized by flulike symptoms, such as transient headache, fever, chills, malaise, arthralgia, myalgia, tachypnea, peripheral vasodilation, and aggravation of syphilitic lesions. The exact mechanism of the reaction is unknown, although proposed

etiologies, including immunologic mechanisms and release of endotoxin or other toxic treponemal products, are not substantiated. The Jarisch-Herxheimer reaction is independent of the drug and dose used and should not be confused with penicillin allergy. It usually begins within 2 to 4 hours of initiating therapy, peaks at 8 hours, and is complete within 12 to 24 hours. Most reactions can be managed symptomatically with analgesics, antipyretics, and rest. Steroids and antihistamines have been administered prior to initiation of syphilitic therapy but are of limited value.^{1,23–25}

EVALUATION OF THERAPEUTIC OUTCOMES

Table 115–6 lists the CDC recommendations for serologic follow-up of patients treated for syphilis.¹ Quantitative nontreponemal tests should be performed at 6 and 12 months in all patients treated for pri-

mary and secondary syphilis and at 6, 12, and 24 months for early and late latent disease. The CDC recommends more frequent monitoring of HIV-infected individuals (i.e., 3, 6, 9, 12, and 24 months after therapy). In general, the time to reach seronegativity is proportional to the duration of the disease. Table 115–6 also includes specific testing

recommendations for other stages of syphilis. Despite adequate therapy, some patients may remain seropositive based on nontreponemal test results. In these cases, stabilization of low antibody titers is indicative of adequate therapy. For women treated during pregnancy, monthly quantitative nontreponemal tests are recommended in those at high risk of reinfection.^{1,23–25}

CHLAMYDIA TRACHOMATIS

EPIDEMIOLOGY AND ETIOLOGY

Based on CDC data, the number of reported cases of *Chlamydia* infection, the most frequently reported infectious disease in the United States, has more than doubled in the past 10 years.^{1,7} Similar to other STDs, gross underreporting is believed to exist partly because of the large number of individuals who are treated presumptively without confirmatory microbiologic testing and partly because of the large number of individuals with asymptomatic infections. Chlamydial infections represent the most common cause of nongonococcal urethritis (NGU), accounting for as much as 50% of such infections.^{30,31}

PATHOPHYSIOLOGY

C. trachomatis is an obligate intracellular parasite that shares properties of both viruses and bacteria. Like viruses, chlamydiae require cellular material from host cells for replication; however, unlike viruses, chlamydiae maintain their cellular identity throughout development. Although *C. trachomatis* lacks a cell wall peptidoglycan, its major outer membrane is similar to gram-negative bacteria. At least 18 serovars (subspecies) of *C. trachomatis* exist, of which only the lymphogranuloma venereum strains produce potentially invasive infections. The remaining serovars are involved primarily with superficial infection of epithelial cells.^{31–33}

The risk of transmissibility of *Chlamydia* after exposure is unknown but is believed to be less than that following exposure to *N. gonorrhoeae*.^{31–33} Coinfection with *Chlamydia* occurs in a substantial number of individuals with gonorrhea. All individuals diagnosed with *N. gonorrhoeae* should be assumed also to have

C. trachomatis present.^{1,15,16,34} Of major concern are data indicating that chlamydial infections are associated with up to a fivefold increased risk of acquiring HIV infection.³³ In addition to genital infections, ocular infections in adults owing to autoinoculation and infants owing to vaginal delivery through an infected birth canal are reported. Pharyngeal and rectal infections can develop secondary to orogenital or receptive anal intercourse, respectively, with an infected individual.^{1,30–34}

CLINICAL PRESENTATION

In comparison with gonorrhea, chlamydial genital tract infections are more frequently asymptomatic, and when present, symptoms tend to be less noticeable. Urethral discharge usually is less profuse and more mucoid or watery than the urethral discharge associated with gonorrhea.^{30–34} Table 115–7 summarizes the usual clinical presentation of chlamydial infections.

Similar to gonorrhea, chlamydia may be transmitted to an infant during contact with infected cervicovaginal secretions. Nearly two-thirds of infants acquire chlamydial infection after endocervical exposure, with the primary morbidity associated with seeding of the infant's eyes, nasopharynx, rectum, or vagina. In exposed infants, neonatal conjunctivitis develops in as many as 50%, and pneumonia develops in up to 16%. Inclusion conjunctivitis in newborns is usually self-limited, but it can result in scarring and micropannus of the cornea. Interstitial pneumonitis occurring secondary to carriage in the nasopharynx typically is mild, but it can be severe and require hospitalization.^{1,30–34}

DIAGNOSIS

Because of the high rate of asymptomatic disease and the high prevalence of chlamydial infection in sexually active adolescent females, females aged 20 to 25 years, and sexually active women with multiple sex partners, the CDC recommends routine annual screening in these individuals. Laboratory confirmation of chlamydial infection is important because of the relative lack of specificity of symptoms when present.^{1,32}

TABLE 115–7. Presentation of *Chlamydia* Infections

| | Males | Females |
|-------------------|--|--|
| General | Incubation period—35 days Symptom onset—7–21 days | Incubation period—7–35 days Usual symptom onset—7–21 days |
| Site of infection | Most common—urethra Others—rectum (receptive anal intercourse), oropharynx, eye | Most common—endocervical canal Others—urethra, rectum (usually due to perineal contamination), oropharynx, eye |
| Symptoms | Over 50% of urethral and rectal infections are asymptomatic Urethral infection—mild dysuria, discharge Pharyngeal infection—asymptomatic to mild pharyngitis | Over 66% of cervical infections are asymptomatic Urethral infection—usually subclinical; dysuria and frequency uncommon Rectal and pharyngeal infection—symptoms same as for men |
| Signs | Scant to profuse, mucoid to purulent urethral or rectal discharge Rectal infection—pain, discharge, bleeding | Abnormal vaginal discharge or uterine bleeding, purulent urethral or rectal discharge can be scant to profuse |
| Complications | Epididymitis, Reiter's syndrome (rare) | Pelvic inflammatory disease and associated complications (i.e., ectopic pregnancy, infertility) Reiter's syndrome (rare) |

Cell culture is the reference standard against which all other diagnostic tests are measured. Because chlamydiae are obligate intracellular parasites, specimens for culture must be obtained from endocervical (women) or urethral (men) epithelial cell scrapings rather than from urine or urethral discharges. Although tissue culture techniques have close to 100% specificity, the sensitivity is reported to be as low as 70% in part because of problems of improper specimen collection, transport, or processing. Because of the technical demands, expense, and length of time until results are available (3 to 7 days), culture is not used widely for diagnostic purposes today. However, culture remains the diagnostic standard in medicolegal cases such as sexual assault and child abuse because of its high specificity and ability to detect only viable organisms.^{14,32,34,37–39}

Serologic tests are of limited value in diagnosing genital chlamydial infections because false-positive results may be obtained from previously infected individuals owing to persistence of chlamydial antibodies for prolonged periods.^{14,32,34,37–39}

Tests that detect chlamydial antigens and nucleic acid provide more rapid results, are technically less demanding to perform, are less costly, and in some situations have greater sensitivity than culture. Commonly used nonculture tests for detection of *C. trachomatis* are the enzyme immunoassay (EIA), DNA hybridization probe, and the direct fluorescent monoclonal antibody (DFA) test. In comparison with culture, these tests have reduced sensitivities and slightly reduced specificities overall. Although the DFA test can be conducted in a short period of time, its sensitivity is highly dependent on skilled personnel in preparing the specimen for viewing under a fluorescent microscope and in interpreting the results. This test is used frequently as a confirmatory test for positive results seen with other nonculture tests.^{14,32,34,37–39}

Most commercially available tests used to detect *C. trachomatis* use EIA techniques that detect chlamydial lipopolysaccharide (LPS) antigen. Some EIA methods, however, are not specific for

C. trachomatis, and false-positive results are reported with other *Chlamydia* species, as well as with some gram-negative bacteria. The sensitivity and specificity of the test are generally lower when urine specimens are used.^{14,32,34,37–40}

Rapid office tests that employ EIA technology for diagnosing chlamydial infections are widely available, and most provide results in 30 minutes. These tests generally are much less sensitive and specific than laboratory-performed EIA, and they are subject to a high false-positive rate because of the cross-reactivity of LPS from other microorganisms. As a result, a positive rapid office test should only be considered presumptive, and test results should be confirmed by a laboratory-based method.^{14,38–40}

The greatest advances in the detection of chlamydial infection involved the development of various nucleic acid detection methods. Similar to EIA, the DNA hybridization probe test is easy to perform, and a large number of samples can be processed at the same time. Overall, the sensitivity and specificity of the DNA probe tests are greater than with EIA.^{14,38–40}

Of all the advances in the diagnosis of *C. trachomatis* infections, the development of DNA amplification tests that can detect small amounts of chlamydial DNA such as PCR and LCR has been the most important. These tests are highly sensitive and specific for detecting infection in both urogenital specimens and urine. Use of self-collected vaginal specimens (swabs or tampons) or first-void urine samples offers greater patient acceptability, particularly when used to screen asymptomatic individuals. A further advantage of tests that can screen urine for the presence of infection is that up to 30% of women are reported to have urethral infection only, which would be missed using a test on endocervical samples. Because of their ability to detect as little as a single gene copy in a specimen, nucleic acid residues that persist following successful antibiotic therapy of a chlamydial infection can result in a false-positive test for several weeks following eradication of the organism.^{14,32–41}

▶ TREATMENT: Chlamydia

A number of antimicrobials, including tetracyclines, macrolides, azithromycin, and some fluoroquinolones, display good in vitro and in vivo activity against *C. trachomatis*. In most clinical trials, cure rates exceeding 90% are reported for these agents. All these antimicrobials also appear to have good efficacy against *Ureaplasma urealyticum*, the second most common cause of NGU.^{30–33}

Azithromycin 1 g orally as a single dose and doxycycline 100 mg orally twice daily for 7 days are the regimens of choice for the treatment of uncomplicated chlamydial infections¹ (Table 115–8). Because of its prolonged serum and tissue half-life, azithromycin is the only single-dose therapy that is effective in treating *C. trachomatis*. Of the fluoroquinolones, ofloxacin and levofloxacin are included in the CDC recommendations, but neither appears to offer an advantage over other first-line or alternative therapies. Although ciprofloxacin and some other fluoroquinolones have activity against *C. trachomatis* and *U. urealyticum*, high dosages have not consistently eradicated chlamydial infections.^{1,34–37,41,42}

For pregnant women with chlamydial urogenital infections, treatment can reduce the risk of pregnancy complications and transmission to the newborn significantly. Because the use of tetracyclines and fluoroquinolones is contraindicated during pregnancy, erythromycin base and amoxicillin are the recommended drug treatments (see Table 115–8). Some clinicians prefer amoxicillin to erythromycin because of better patient tolerability and, as a result, improved patient compliance. Patients intolerant of

the recommended erythromycin dosage can be treated with half the daily dose for 14 days instead of 7 days. Recommended alternatives to erythromycin base are erythromycin ethylsuccinate and azithromycin. Like erythromycin, azithromycin is in pregnancy category B and probably is an acceptable agent for use during pregnancy.^{1,34–37,41,42}

CLINICAL CONTROVERSY

Although not recommended as first-line therapy in pregnant patients with chlamydial infections because of limited data on its safety, azithromycin is the only agent with documented efficacy in a single dose.

It is recommended that posttreatment cultures be obtained for pregnant patients treated for chlamydial infections to ensure eradication of the infection.^{1,35–37}

C. trachomatis transmission during perinatal exposure can result in infections of the eye, oropharynx, lungs, urogenital tract, and rectum of the neonate or infant. Despite their efficacy in preventing gonococcal ophthalmia, topical erythromycin ointment (0.5%), tetracycline ointment (1%), and silver nitrate solution (1%) appear less effective in preventing chlamydial ophthalmia. Additionally, topical therapy has no effect on nasal carriage or colonization of other parts of the infant's body, so the potential for other infections, including

TABLE 115–8. Treatment of Chlamydial Infections

| Infection | Recommended Regimens ^a | Alternative Regimen |
|---|---|--|
| Uncomplicated urethral, endocervical, or rectal infection in adults | Azithromycin 1 g PO once, or doxycycline 100 mg PO 2 times daily for 7 days | Ofloxacin 300 mg PO 2 times daily for 7 days, or levofloxacin 500 mg PO once daily for 7 days, or erythromycin base 500 mg PO 4 times daily for 7 days, or erythromycin ethyl succinate 800 mg PO 4 times daily for 7 days |
| Urogenital infections during pregnancy | Erythromycin base 500 mg PO 4 times daily for 7 days, or amoxicillin 500 mg PO 3 times daily for 7 days | Erythromycin base 250 mg PO 4 times daily for 14 days, or erythromycin ethyl succinate 800 mg PO 4 times daily for 7 days (or 400 mg PO 4 times daily for 14 days), or azithromycin 1 g PO as a single dose ^b |
| Conjunctivitis of the newborn or pneumonia in infants | Erythromycin base 50 mg/kg/day PO in 4 divided doses for 14 days ^c | |

^aRecommendations are those of the CDC.

^bData are insufficient to recommend routine use of azithromycin in pregnant women at this time.

^cTopical therapy alone is inadequate and is unnecessary when systemic therapy is administered.

pneumonia, still remains. Because of the high percentage of treatment failures, topical therapy is not recommended to treat ophthalmia

caused by *C. trachomatis*. Instead, an oral erythromycin regimen is recommended.^{1,31–33}

EVALUATION OF THERAPEUTIC OUTCOMES

Treatment of chlamydial infections with the recommended regimens is highly effective; therefore, posttreatment laboratory testing is not recommended routinely unless symptoms persist or there are other specific concerns (e.g., pregnancy). Posttreatment tests should not be performed for at least 3 weeks following completion of therapy.¹ When posttreatment tests are positive, they usually represent noncompliance, failure to treat sexual partners, or laboratory error rather than inadequate therapy or resistance to therapy. Infants with pneumonitis should receive follow-up testing because erythromycin is only 80% effective, and a second course of therapy may be necessary.^{1,30–34,36}

GENITAL HERPES

EPIDEMIOLOGY AND ETIOLOGY

Genital herpes infections represent the most common cause of genital ulceration seen in the United States. More than 50 million Americans have genital herpes, and this number is increasing by at least 500,000 each year.^{1,7,43–48} Because of its morbidity, recurrent nature, and potential for complications, as well as its ability to be transmitted asymptotically, genital herpes is of major public health importance.^{45–54} Similar to syphilis and other STDs, the presence of genital herpes lesions is associated with an increased risk of acquiring HIV following exposure.^{1,47}

PATHOPHYSIOLOGY

Herpes comes from the Greek word meaning “to creep” and is used to describe two distinct but antigenically related serotypes of herpes simplex virus. Herpes simplex virus type 1 (HSV-1) is associated most commonly with oropharyngeal disease, and herpes simplex virus type

2 (HSV-2) is associated most closely with genital disease; however, each virus is capable of causing clinically indistinguishable infections in both anatomic areas.^{46,47,50,54}

Humans are the sole known reservoir for HSV. Infection is transmitted via inoculation of virus from infected secretions onto mucosal surfaces (e.g., urethra, oropharynx, cervix, and conjunctivae) or through abraded skin. Evidence that the virus survives for a limited time on environmental surfaces suggests the possibility of fomite transfer as a nonvenereal route of transmission.^{46,48–50}

The cycle of HSV infection occurs in five stages: primary mucocutaneous infection, infection of the ganglia, establishment of latency, reactivation, and recurrent infection. After viral inoculation, HSV infection is associated with cytoplasmic granulation, ballooning degeneration of cells, and production of mononucleated giant cells. Initially, the cellular response is predominantly polymorphonuclear, followed by a lymphocytic response. Replication occurs with viral spread to contiguous cells and peripheral sensory nerves. Latency then is established in sensory or autonomic nerve root ganglia. Latency appears to be lifelong, interrupted only by reactivation of the viral infection. It is unclear what factors are important in maintaining latency, but immune responses and emotional and physical stresses appear important in reactivating latent virus.^{46,48}

CLINICAL PRESENTATION

The signs and symptoms of genital herpes infection are influenced by many factors, including previous exposure to HSV, viral type, and host factors such as age and site of infection. Because a high percentage of initial and recurrent infections are asymptomatic, and because viral shedding can occur in the absence of apparent lesions or symptoms, identification and education of individuals with genital herpes are essential in controlling its transmission.^{46,53,55} A summary of the clinical presentation of genital herpes is provided in Table 115–9.

TABLE 115–9. Presentation of Genital Herpes Infections

| | |
|--|--|
| General | Incubation period 2–14 days (mean - 4 days) Can be caused by either HSV-1 or HSV-2 |
| Classification of Infection | |
| First-episode primary | Initial genital infection in individuals lacking antibody to either HSV-1 or HSV-2 |
| First-episode nonprimary | Initial genital infection in individuals with clinical or serologic evidence of prior HSV (usually HSV-1) infection |
| Recurrent | Appearance of genital lesions at some time following healing of first-episode infection |
| Signs and Symptoms | |
| First-episode infections | Most primary infections are asymptomatic or minimally symptomatic Multiple painful pustular or ulcerative lesions on external genitalia developing over a period of 7–10 days; lesions heal in 2–4 weeks (mean 21 days) Flulike symptoms (e.g., fever, headache, malaise) during first fews after appearance of lesions Others—local itching, pain or discomfort; vaginal or urethral discharge, tender inguinal adenopathy, paresthesias, urinary retention Severity of symptoms greater in females than in males Symptoms are less severe (e.g., fewer lesions, more rapid lesion healing, fewer or milder systemic symptoms) with nonprimary infections Symptoms more severe and prolonged in the immunocompromised On average viral shedding lasts approximately 11–12 days for primary infections and 7 days for nonprimary infections |
| Recurrent | Prodrome seen in approximately 50% of patients prior to appearance of recurrent lesions; mild burning, itching, or tingling are typical prodromal symptoms Compared to primary infections, recurrent infections associated with (1) fewer lesions that are more localized, (2) shorter duration of active infection (lesions heal within 7 days), and (3) milder symptoms Severity of symptoms greater in females than in males Symptoms more severe and prolonged in the immunocompromised On average viral shedding lasts approximately 4 days |
| Therapeutic implications of HSV-1 versus HSV-2 genital infection | Primary infections due to HSV-1 and HSV-2 virtually indistinguishable Recurrence rate is greater following primary infection with HSV-2 Recurrent infections with HSV-2 tend to be more severe |
| Complications | Secondary infection of lesions; extragenital infection due to autoinoculation; disseminated infection (primarily in immunocompromised patients); meningitis or encephalitis; neonatal transmission |

COMPLICATIONS

Complications from genital herpes infections result from both genital spread and autoinoculation of the virus and occur most commonly with primary first episodes. Lesions at extragenital sites, such as the eye, rectum, pharynx, and fingers, are not uncommon. CNS involvement is seen occasionally and may take several forms, including an aseptic meningitis, transverse myelitis, or sacral radiculopathy syndrome.^{47,50,51,54}

A major concern is the effect of genital herpes on neonates exposed during pregnancy. Neonatal herpes is associated with a high mortality and significant morbidity. It is transmitted to the newborn primarily through exposure to HSV in the birth canal but, in rare cases, also is transmitted transplacentally. The risk of transmission during birth appears much greater for first-episode primary infections than for recurrent infections. Neonatal herpes infection has a case-fatality rate of approximately 50%, with a large proportion of surviving infants experiencing significant morbidity, including permanent neurologic damage.^{49–51}

DIAGNOSIS

Confirmation of a genital herpes infection can be made only with laboratory testing. Tissue culture is the most specific (100%) and sensitive method (80% to 90%) of confirming the diagnosis of first-episode genital herpes; however, culture is relatively insensitive in detecting HSV in ulcers in the latter stages of healing and in recurrent infections, as a result, in part, of reduced viral load. Viral culture is expensive and time-consuming, and improper collection or transport of specimens can result in false-negative results. In most situations, HSV isolation on tissue culture takes 48 to 96 hours. Following isolation, it is recommended that typing of the virus be performed because of prognostic implications (HSV-1 is associated with a lower rate of asymptomatic and symptomatic recurrence).^{54–57} In instances in which rapid detection is necessary, such as an impending birth, other detection methods may be more useful. Amplified culture techniques that combine cell culture for 24 hours and subsequent staining for HSV antigen have sensitivities and specificities only slightly less than those of culture.^{47,49,50,52–57}

Several serologic tests capable of distinguishing HSV-1 and HSV-2 antibodies have been marketed recently. These tests detect antibodies to type-specific HSV-1 and HSV-2 proteins gG-1 and gG-2, respectively. While antibody formation begins immediately following a primary herpes infection, complete seroconversion (i.e., complete antibody development) may take several months. Until the full expression of all antigenic determinants of HSV-1 and HSV-2 occurs, these tests are not useful in differentiating HSV-1 and HSV-2 infection^{48,53,54,57} Older antibody detection tests, some of which are still marketed, are unable to distinguish between HSV-1 and HSV-2 owing to the considerable cross-reactivity between the two serotypes. Given the high prevalence of HSV-1 antibody in the adult population, accurate interpretation of positive results is not possible.^{46,54}

In recent years, PCR assays that detect HSV DNA and can differentiate HSV-1 and HSV-2 infections have become increasingly available. These assays are more sensitive than culture and are considered

the diagnostic test of choice for suspected CNS infections (i.e., HSV encephalitis and HSV meningitis). Although PCR assays are not used widely in diagnosing genital ulcer disease at this time, some data suggest that they also may prove useful in diagnosing asymptomatic viral shedding.^{52,55–57}

While the diagnosis of genital herpes can be confirmed only by laboratory tests, less stringent diagnostic criteria (e.g., characteristic physical findings or clinical history) frequently are used in clinical practice. A presumptive diagnosis of genital herpes commonly is made based on the presence of dark-field-negative, vesicular, or ulcerative genital lesions. A prior history of similar lesions or recent sexual contact with an individual with similar lesions also is useful in making the diagnosis. Other STDs, including chancroid, lymphogranuloma venereum, and granuloma inguinale, and causes such as trauma, allergic reactions, and bacterial or fungal infections are considered in the differential diagnosis.^{48,55–57}

► TREATMENT: Genital Herpes

The most achievable goals in the management of genital herpes are to relieve symptoms and to shorten the clinical course, to prevent complications and recurrences, and to decrease disease transmission. Although research has focused primarily on the treatment of active infection and suppression of recurrences, increasing emphasis is being placed on various approaches, including immunotherapy that might provide protection from disease transmission or possibly eliminate established latency.^{47,48,55}

Palliative and supportive measures are the cornerstone of therapy for patients with genital herpes. Pain and discomfort usually respond to warm saline baths or the use of analgesics, antipyretics, or antipruritics; good genital hygiene can prevent the development of bacterial superinfection.

4 Specific chemotherapeutic approaches to treating genital herpes include antiviral compounds, topical surfactants, photodynamic dyes, immune modulators, vaccines, and interferons. Few of these have undergone extensive evaluation, however, and only the antiviral agents have demonstrated any consistent clinical efficacy. The most recent CDC recommendations for the treatment of genital herpes include the antiviral agents acyclovir, valacyclovir, and famciclovir¹ (Table 115–10). The overall efficacy of these agents in treating genital HSV infection appears comparable, although once-daily valacyclovir and famciclovir regimens may have greater patient acceptability.^{1,42–51,58}

■ FIRST-EPISODE INFECTIONS

Oral formulations of acyclovir, famciclovir, and valacyclovir have demonstrated efficacy in reducing viral shedding, duration of symptoms, and time to healing of first-episode genital herpes infections, with maximal benefits seen when therapy is initiated at the earliest stages of infection.^{1,44–48,58–61} Table 115–10 lists the recommended acyclovir, famciclovir, and valacyclovir oral regimens for first-episode infections. In immunocompromised patients or those with severe symptoms or complications necessitating hospitalization, parenteral acyclovir may be beneficial; however, the IV regimen has been associated with renal, gastrointestinal, bone marrow, and CNS toxicity, particularly in patients with renal dysfunction receiving high doses. No antiviral regimen is known to prevent latency or alter the subsequent frequency and severity of recurrences in humans.^{1,42–51,61–64}

■ RECURRENT INFECTIONS

CLINICAL CONTROVERSY

The role of antiviral agents in the treatment of most recurrent genital herpes episodes is controversial. Because signs and symptoms of recurrent infections generally are milder and of shorter duration than those of first-episode infections in immunocompetent hosts, demonstration of clinically important therapeutic benefits is difficult.

There are two approaches to management of recurrent episodes: episodic or chronic suppressive therapy.^{1,47,50,51,55,56,61–64} Episodic therapy is initiated early during the course of the recurrence, preferably at the onset of prodromal symptoms, but no more than 24 hours after the appearance of lesions. In most patients, appreciable effects on symptomatology are not seen. Patients with prolonged episodes of recurrent infection or severe symptomatology are most likely to benefit from episodic therapy. Table 115–10 lists the recommended acyclovir, famciclovir, and valacyclovir suppressive regimens. Because of the relative mildness and brevity of recurrent infections, parenteral administration of acyclovir usually is not justifiable.^{32,47,51,55,56}

Cost and the potential for adverse effects preclude available antiviral agents from being recommended routinely for use as suppressive therapy in all patients with recurrent genital herpes. Patients with frequent (greater than six per year) and physically or psychologically distressing recurrences, however, are candidates for suppressive therapy.^{1,55,56,61–64}

Continuous therapy with recommended antivirals reduces the frequency and severity of recurrences in 70% to 90% of patients experiencing frequent recurrences. Asymptomatic viral shedding is markedly reduced in patients receiving suppressive therapy; however, the extent to which this decreases disease transmission to sexual partners remains to be determined. Despite antiviral suppressive therapy, low-level virus shedding still occurs. Since the frequency of recurrences tends to diminish over time, periodic “drug holidays” are advocated to assess changes in the underlying recurrence rate and determine if continued suppressive therapy is warranted.^{1,55,56,61–64}

Resistant HSV isolates have been identified in some patients experiencing breakthrough recurrences while taking acyclovir. Although there is concern about the development of resistant strains

TABLE 115–10. Treatment of Genital Herpes

| Type of Infection | Recommended Regimens ^{a,b} | Alternative Regimen |
|--|---|---|
| First clinical episode of genital herpes ^c | Acyclovir 400 mg PO 3 times daily for 7–10 days, <i>or</i> Acyclovir 200 mg PO 5 times daily for 7–10 days, <i>or</i> Famciclovir 250 mg PO 3 times daily for 7–10 days, <i>or</i> Valacyclovir 1 g PO 2 times daily for 7–10 days | Acyclovir 5–10 mg/kg IV every 8 hours for 2–7 days until clinical improvement occurs, followed by oral therapy to complete at least 10 days of total therapy ^d |
| First clinical episode of herpes proctitis or oral infection including stomatitis or pharyngitis | Acyclovir 400 mg PO 5 times daily for 7–10 days ^e | Acyclovir 5–10 mg/kg IV every 8 hours for 2–7 days until clinical improvement occurs, followed by oral therapy to complete at least 10 days of total therapy ^d |
| Recurrent infection Episodic therapy | Acyclovir 400 mg PO 3 times daily for 5 days, ^f <i>or</i> Acyclovir 800 mg PO 2 times daily for 5 days, ^f <i>or</i> Famciclovir 125 mg PO 2 times daily for 5 days, ^f <i>or</i> Valacyclovir 500 mg PO 2 times daily for 3–5 days, ^f <i>or</i> Valacyclovir 1 g PO once daily for 5 days ^f Acyclovir 400 mg PO twice daily, ^g <i>or</i> | |
| Suppressive therapy | Famciclovir 250 mg PO 2 times daily, <i>or</i> Valacyclovir 500 mg or 1000 mg PO once daily ^h | |

^aRecommendations are those of the CDC.

^bHIV-infected patients may require more aggressive therapy.

^cPrimary or nonprimary first episode.

^dOnly for patients with severe symptoms or complications that necessitate hospitalization.

^eRecommendations based on studies utilizing this dosage regimen rather than the lower dosage regimens recommended for first clinical episodes of genital herpes. It is not clear whether lower dosage regimens would have comparable efficacy. Famciclovir and valacyclovir are probably also effective for proctitis and oral infection, but clinical experience is limited.

^fRequires initiation of therapy within 24 hours of lesion onset or during the prodrome that precedes some outbreaks.

^gIndicated only for patients with frequent and/or severe recurrences; although safety and efficacy are documented in patients receiving acyclovir daily therapy for as long as 6 years and valacyclovir and famciclovir therapy for 1 year, it is recommended that therapy be discontinued periodically (e.g., once a year) to reassess the need for continued suppressive therapy.

^hValacyclovir 500 mg appears less effective than valacyclovir 1000 mg in patients with approximately 10 recurrences per year.

with suppressive therapy, clinical trials have found no evidence of cumulative toxicity or significant resistance in patients treated continuously with the recommended antivirals.^{44,46,47,50,56,58,60,61}

SELECTED POPULATIONS

Immunocompromised patients are at greatest risk for severe and recurrent HSV infections. Acyclovir, valacyclovir, and famciclovir have been used to prevent reactivation of infection in patients seropositive for HSV who undergo transplantation procedures or induction chemotherapy for acute leukemia. Immunocompromised individuals, such as patients with AIDS, who fail treatment or prophylaxis with recommended antiviral doses frequently demonstrate improved response with higher doses. If resistance is suspected or confirmed with recommended first-line antivirals, foscarnet is usually effective. However, its use is associated with a greater risk of serious

adverse effects.^{45,51,52,56} Lesional application of an extemporaneous compounded cidofovir gel or trifluridine ophthalmic solution appears to offer some benefits also.^{1,43}

The safety of acyclovir, famciclovir, and valacyclovir during pregnancy is not established, although considerable experience with acyclovir in pregnant patients has produced no evidence of teratogenic effects. Because of the high maternal and infant morbidity associated with first-episode primary genital infections or severe recurrent infections at or near term, many clinicians advocate the use of systemic acyclovir as the standard of care in such cases; however, the effectiveness of such therapy is unknown. The use of acyclovir to suppress recurrent episodes near term is more controversial primarily because of the lack of data demonstrating significant benefits in this situation.^{32,50,55,56,59–61}

With the increasing prevalence of genital herpes worldwide, the potential exists for widespread use and misuse of acyclovir, valacyclovir, and famciclovir, resulting in development of resistant HSV isolates. In vitro resistance to these three agents usually is mediated

by alterations in viral thymidine kinase; most resistant isolates are either thymidine kinase-deficient or have altered thymidine kinase. The incidence and clinical implications of HSV resistance require further study particularly with respect to immunocompromised hosts, in whom resistance may develop with greater frequency and be of greater clinical importance. Unlike acyclovir, valacyclovir, and famciclovir, foscarnet does not require the presence of thymidine kinase to be effective.^{47,50,52,55,56}

Numerous agents for the prophylaxis and treatment of genital herpes infections are being studied. Neither topical nor systemic interferons have demonstrated consistent beneficial effects in genital HSV infections; however, a reduction in pain and time of healing of lesions has been reported with an interferon preparation incorporated into a gel containing nonoxynol-9. Other treatments under investigation include cidofovir and immune modulators such as im-

iquimod and resiquimod.^{47,53,56} Agents that can eliminate ganglionic latency and prevent recurrent HSV infections are not expected to be available in the near future. Development of vaccines capable of protecting against HSV infection has proved challenging given the relative lack of protection offered by humoral and cell-mediated immunity in preventing naturally occurring recurrent infections. Safety concerns with live attenuated virus vaccines resulted in research focused primarily on recombinant protein vaccines that have exhibited relatively poor immunogenicity. In recent years, investigations using replication-defective HSV mutants that are not pathogenic, as well as DNA vaccines that foster host cell uptake of foreign DNA that encodes for an antigenic viral protein, have shown some promise in animal models. Use of heterologous vaccines (bacillus Calmette-Guérin and influenza vaccines) to stimulate the immune system in patients with recurrent genital herpes has proved of no significant benefit.^{47,55,62-64}

EVALUATION OF THERAPEUTIC OUTCOMES

Available antiviral compounds are of greatest benefit in patients experiencing first-episode primary infections, immunocompromised patients, and patients with frequent or severe recurrent infections. Antivirals, however, are palliative and not curative, and patients receiving these agents should be monitored closely for adverse drug effects. CDC guidelines suggest that discontinuation of suppressive therapy after 1 year should be considered to assess for possible changes in the patient's intrinsic pattern of recurrence. In many patients, decreases in recurrence rates and the severity of symptoms occur over time. However, some clinicians prefer to continue suppressive therapy indefinitely because it significantly reduces asymptomatic viral shedding, a potential benefit in reducing the risk of disease transmission to uninfected sexual partners.^{1,47,48,61}

TRICHOMONIASIS

EPIDEMIOLOGY AND ETIOLOGY

Trichomonas vaginalis, a flagellated, motile protozoan is responsible for 3 to 5 million cases of trichomoniasis annually in the United States.⁶⁵⁻⁶⁸ Humans are host to two other *Trichomonas* species, *T. tenax* and *T. hominis*, but *T. vaginalis* is the only species thought to be pathogenic. Although infection by nonsexual contact is reported, it is rare. Contamination of inanimate objects and spread of infection via communal bathing or contact with infected bath or toilet articles is possible because *T. vaginalis* can survive for several hours on moist surfaces.⁶⁵⁻⁷³ Neonatal infections also represent another possible nonvenereal route of disease transmission.^{67-71,73,74}

Coinfection with other STDs is not unusual in patients diagnosed with trichomoniasis. Women infected with *T. vaginalis* are three times more likely to have gonorrhea than those who do not have trichomoniasis; approximately 20% of men with gonococcal urethritis also have trichomoniasis.^{67,68} In patients treated appropriately for genital *C. trachomatis* or *U. urealyticum* infection, persistent urethritis can result from coexisting trichomonal infection.^{1,70,71} Although not well documented, it is proposed that the inflammatory response produced by trichomoniasis may increase the risk of acquiring HIV.^{66,68,74}

PATHOPHYSIOLOGY

Trichomonads typically can be isolated from the vagina, urethra, and paraurethral ducts and glands in the majority of infected women.

Infrequently, they are recovered from the endocervix. Extragenital sites are epidemiologically important because infection can persist and result in reinfection of the vagina if local therapy alone is used.^{68,71,72} This may account for the higher relapse rates reported for local versus systemic therapy.^{71,72,75} After attachment to the vaginal or urethral mucosa, trichomonads usually elicit an inflammatory response that manifests as a discharge containing large numbers of PMNs.⁶⁸⁻⁷²

CLINICAL PRESENTATION

Trichomonal infections are reported more commonly in women than in men. In part this may be due to the smaller number of organisms found in the male urethra making detection more difficult, greater disease transmission rates from males to females, and the nature of male infections, which have a high spontaneous cure rate even in the absence of treatment.^{66,67,70-72} The typical clinical presentation of trichomoniasis in males and females is presented in Table 115-11.

DIAGNOSIS

T. vaginalis produces nonspecific symptoms also consistent with bacterial vaginosis; as a result, laboratory diagnosis is required. Because *T. vaginalis* requires a pH range of 4.9 to 7.5 for survival, a vaginal discharge pH of greater than 5.0 usually indicates the presence of either *T. vaginalis* or *Gardnerella vaginalis*, a common cause of bacterial vaginosis. The simplest and most reliable means of diagnosis is a wet-mount examination of the vaginal discharge.^{67,70-72} Trichomoniasis is confirmed if characteristic pear-shaped, flagellating organisms are observed. The wet mount is only about 75% to 80% sensitive in detecting the presence of trichomonads, with lower sensitivities reported in men and in women with low-grade, subacute, or chronic infections.^{68-70,72}

Although the presence of trichomonads may be reported on a Papanicolaou (Pap) smear, the sensitivity of this cytologic technique is less than for wet mount and also is associated with a number of false-positive results. Stained smears of cervical specimens have been used in diagnosis, but they are less sensitive and more time-consuming than the wet mount and therefore are not recommended. Culture techniques for trichomonads are highly specific and more sensitive than the wet mount, but they are not useful in rapid diagnosis because up to 48 hours or longer is necessary for growth. Cultures may be

TABLE 115–11. Presentation of *Trichomonas* Infections

| | Males | Females |
|-------------------|---|---|
| General | Incubation period 3–28 days Organism may be detectable within 48 hours after exposure to infected partner | Incubation period 3–28 days |
| Site of infection | Most common—urethra Others—rectum (usually due to rectal intercourse in MSM), oropharynx, eye | Most common—endocervical canal Others—urethra, rectum (usually due to perineal contamination), oropharynx, eye |
| Symptoms | May be asymptomatic (more common in males than females) or minimally symptomatic Urethral discharge (clear to mucopurulent) Dysuria, pruritus | May be asymptomatic or minimally symptomatic Scant to copious, typically malodorous vaginal discharge (50–75%) and pruritus (worse during menses) Dysuria, dyspareunia |
| Signs | Urethral discharge | Vaginal discharge Vaginal pH 4.5–6 Inflammation/erythema of vulva, vagina, and/or cervix Urethritis |
| Complications | Epididymitis and chronic prostatitis (uncommon) Male infertility (decreased sperm motility and viability) | Pelvic inflammatory disease and associated complications (i.e., ectopic pregnancy, infertility) Premature labor, premature rupture of membranes, and low-birth-weight infants (risk of neonatal infections is low) Cervical neoplasia |

necessary, however, to confirm the diagnosis in the absence of a positive wet mount or to determine antimicrobial susceptibility in intractable cases.^{1,67–72}

Newer diagnostic tests such as monoclonal antibody or DNA probe techniques, as well as PCR tests that can detect small amounts of trichomonal DNA, have been developed. These tests are highly sensitive and specific for detecting infection in both urogenital spec-

imens and urine. Such tests could replace more traditional diagnostic tests in the future.^{66,68,71,72}

In males, demonstration of trichomonads in urethral specimens or urine sediment by wet mount is difficult, and diagnosis depends largely on culture. Specimens from males should be taken prior to first voiding because the small number of trichomonads in males may be reduced by micturition.^{70–72}

► TREATMENT: Trichomoniasis

Recommended treatment regimens for *T. vaginalis* have changed little over the past 20 years. Metronidazole is the only antimicrobial agent available in the United States that is consistently effective in treating these infections. In only a few cases have *T. vaginalis* isolates been resistant to standard metronidazole doses. In these instances, longer courses of therapy or doses higher than those recommended routinely as initial therapy usually produce a cure.^{1,67,68,70–76}

Table 115–12 provides treatment recommendations for *Trichomonas* infections.¹ The standard therapy for trichomoniasis is metronidazole 2 g orally as a single dose; cure rates are comparable with the recommended alternative regimen of 500 mg twice daily for 7 days. When sexual partners are treated simultaneously, cure rates greater than 95% are reported. If sexual partners are not treated concurrently, cure rates are somewhat lower. In limited clinical testing, single metronidazole doses of less than 1.5 g are associated with high failure rates.^{1,65,67,68,70–77}

Advantages of single-dose therapy over the multidose alternative regimen include better patient compliance, lower total dose, lower cost, and shorter exposure of the patient's gastrointestinal and urogenital anaerobic bacterial flora to the drug. As a result of the latter, the likelihood of developing pseudomembranous colitis or symptomatic candidal vulvovaginitis is decreased.^{68,69,71,76,77} Because high doses

of metronidazole have mutagenic effects in bacteria and oncogenic effects in mice, a reduced time of exposure in humans may be beneficial. There is no conclusive evidence for either of these effects in humans after short-term therapy with recommended doses.^{69,71,75,76} Gastrointestinal complaints (e.g., anorexia, nausea, vomiting, and diarrhea) are more common with the single 2-g dose, occurring in 5% to 10% of treated patients. Some patients also complain of a bitter metallic taste in the mouth. Patients intolerant of the single 2-g dose because of gastrointestinal adverse effects usually tolerate the multidose regimen.^{68–73,74,76}

5 To achieve maximal cure rates and prevent relapse with the single 2-g dose of metronidazole, simultaneous treatment of infected sexual partners is necessary. In women treated with the alternative 7-day course, however, relapse rates are not appreciably different regardless of whether or not sexual partners are treated. It is speculated that in men, spontaneous resolution of trichomonal infection or a reduction in the number of trichomonads below the inoculum necessary to transmit disease may occur during the 7 days of a female's therapy. In patients who fail to respond to an initial course of metronidazole therapy, a second course of therapy with metronidazole 500 mg twice daily for 7 days is recommended. Patients refractory to a second course of treatment usually respond to a regimen using higher

TABLE 115–12. Treatment of Trichomoniasis

| Type | Recommended Regimen ^a | Alternative Regimen |
|---|--|---|
| Symptomatic and asymptomatic infections | Metronidazole 2 g PO in a single dose ^b | Metronidazole 500 mg PO 2 times daily for 7 days ^c |
| Treatment in pregnancy | Metronidazole 2 g PO in a single dose ^d | |
| Neonatal infections ^e | Metronidazole 10–30 mg/kg daily for 5–8 days | |

Note: Tinidazole was approved by the FDA in 2004 for the treatment of trichomoniasis. The recommended dosage is 2 g PO in a single dose.

^aRecommendations are those of the CDC.

^bTreatment failures should be treated with metronidazole 500 mg PO 2 times daily for 7 days. Persistent failures should be managed in consultation with an expert. Metronidazole 2 g PO daily for 3–5 days has been effective in patients infected with *T. vaginalis* strains mildly resistant to metronidazole, but experience is limited; higher doses also have been used.

^cMetronidazole labeling approved by the FDA does not include this regimen. Dosage regimens for treatment of trichomoniasis included in the product labeling are the single 2 g dose; 250 mg 3 times daily for 7 days; and 375 mg 2 times daily for 7 days. The 250 mg and 375 mg dosage regimens are currently not included in the CDC recommendations.

^dMetronidazole is contraindicated in the first trimester of pregnancy. While the CDC recommends a single 2 g dose for treatment during pregnancy, a 7-day regimen is preferred by some since it produces lower peak serum drug concentrations.

^eOnly infants with symptomatic trichomoniasis or with urogenital trichomonal colonization that persists beyond the fourth week of life.

dosages of metronidazole (i.e., 2 to 4 grams daily for 3 to 14 days). Good response rates also are reported for metronidazole 2 to 3 g orally plus either a single 500-mg tablet administered intravaginally or intravaginal metronidazole gel (0.75%) for 7 to 14 days.^{65,67,68,70–77}

Topical vaginal therapy alone is associated with low cure rates because infections involving the urethra or periurethral glands are unaffected and can serve as source of reinfection.⁶⁷ Use of intravenous metronidazole may be warranted for rare cases of intolerance to oral medication or infections resistant to high-dose oral metronidazole. Sexual partners of all patients who require retreatment also should be treated or retreated because the majority of apparent treatment failures appear to be due to reinfection or noncompliance.^{65,67,68,70–77}

Concerns regarding the use of metronidazole in women who are pregnant or breast-feeding have been raised. Because metronidazole is secreted in breast milk, it is recommended that breast-feeding be interrupted for 12 to 24 hours after maternal ingestion of a single 2-g dose.^{1,70,74–77} Although metronidazole is contraindicated during the first trimester of pregnancy based on Food and Drug Administration (FDA)–approved labeling, and although some experts recommend avoiding its use throughout pregnancy, other experts advocate its use during any stage of pregnancy because of the potential adverse pregnancy outcomes associated with trichomoniasis.^{1,74,75} Metronidazole easily crosses the placenta, and fetal blood levels are comparable with maternal levels. However, a clear association between terato-

genic effects and maternal ingestion during pregnancy has not been shown.^{1,68–70,74–76} No consensus exists on whether or how to treat trichomonas infections in pregnant women.

Various local therapies for trichomoniasis have been proposed, particularly for pregnant patients. Clotrimazole vaginal suppositories, 100 mg at bedtime for 1 to 2 weeks, relieve symptoms in many women and produce cure rates of 50% or greater.^{68,72–74,76} An alternative therapy is gentle douching with either a diluted solution of vinegar or a 1% zinc sulfate solution until symptoms improve and then less frequently thereafter. This therapy generally provides some symptomatic improvement but few cures. Although once recommended, povidone-iodine douches should be avoided during pregnancy because of the risk of fetal thyroid suppression.^{70,71,74,75}

Several 5-nitroimidazole antibiotics related to metronidazole (e.g., tinidazole, nimorazole, ornidazole, and carnidazole) are being investigated worldwide for the treatment of trichomoniasis. Unfortunately, none of these agents differs significantly from metronidazole in terms of efficacy or toxicity against metronidazole-susceptible strains of *T. vaginalis*. Tinidazole is reported to have produced cures in some metronidazole-resistant infections, but overall, cross-resistance between metronidazole and other 5-nitroimidazoles is high.^{69–71,74,77}

Note: Since this chapter was prepared, tinidazole was approved by the FDA for the treatment of trichomoniasis. The recommended dosage is 2 g orally as a single dose.

EVALUATION OF THERAPEUTIC OUTCOMES

Follow-up is considered unnecessary in patients who become asymptomatic after treatment with metronidazole. When patients remain symptomatic, it is important to determine if reinfection has occurred. In these cases, a repeat course of therapy, as well as identification and treatment or retreatment of infected sexual partners, is recommended. In situations in which reinfection can be excluded, a relative resistance to metronidazole should be assumed, and an alternative multidose metronidazole regimen should be prescribed. Culture and

sensitivity are warranted for infections unresponsive to alternative metronidazole regimens.

HUMAN PAPILLOMAVIRUS AND OTHER STDs

Several STDs other than those just discussed occur with varying frequency in the United States and throughout the world. While an in-depth discussion of these diseases is beyond the scope of this chapter, Table 115–13 lists recommended treatment regimens.¹ Of notable

TABLE 115–13. Treatment Regimens for Miscellaneous Sexually Transmitted Diseases

| Infection | Recommended Regimen ^a | Alternative Regimen |
|---|---|--|
| Chancroid (<i>Haemophilus ducreyi</i>) | Azithromycin 1 g PO in a single dose, or Ceftriaxone 250 mg IM in a single dose, or Ciprofloxacin 500 mg PO 2 times daily for 3 days, ^b or Erythromycin base 500 mg PO 4 times daily for 7 days | |
| Lymphogranuloma venereum | Doxycycline 100 mg PO 2 times daily for 21 days | Erythromycin base 500 mg PO 4 times daily for 21 days |
| Human Papillomavirus Infection: External genital warts | <i>Provider-Administered Therapies:</i> Cryotherapy (e.g., liquid nitrogen or cryoprobe), or Podophyllin 10–25% in compound tincture of benzoin applied to lesions; repeat weekly if necessary, ^{c,d} or Trichloroacetic acid (TCA) 80–90% or bichloroacetic acid (BCA) 80–90% applied to warts; repeat weekly if necessary, or Surgical removal (tangential scissor excision, tangential shave excision, curettage, or electrocautery) | Intralesional interferon or laser surgery |
| Human Papillomavirus Infection: Vaginal, urethral meatus, and anal warts | <i>Patient-Applied Therapies:</i> Podofilox 0.5% solution or gel applied 2 times daily for 3 days, followed by 4 days of no therapy; cycle is repeated as necessary for a total of 4 cycles, ^d or Imiquimod 5% cream applied at bedtime 3 times weekly for up to 16 weeks ^d | |
| | Cryotherapy with liquid nitrogen, or TCA or BCA 80–90% as for external HPV warts; repeat weekly as necessary (<i>not</i> for urethral meatus warts) or Podophyllin 10–25% in compound tincture of benzoin applied at weekly intervals (<i>not</i> for vaginal or anal warts), ^d or Surgical removal (<i>not</i> for vaginal or urethral meatus warts) | |

^aRecommendations are those of the CDC.

^bCiprofloxacin is contraindicated for pregnant and lactating women and for persons aged <18 years.

^cSome experts recommended washing podophyllin off after 1–4 hours to minimize local irritation.

^dSafety during pregnancy is not established.

importance among these other STDs, however, is genital human papillomavirus (HPV) infection, the most common viral STD in the United States. More than 80 HPV types have been characterized by genomic makeup, with approximately 30 types associated with genital tract lesions.^{78–81} Of these, types 6 and 11 are associated most commonly with the development of low-grade dysplasia manifested as exophytic genital warts. In most individuals, genital infection with HPV is subclinical, and patients with visible acuminated warts represent less than 1% of all infected individuals. When present, genital warts can be large and multifocal, producing variable degrees of discomfort. Based on HPV DNA detection methods, most warts will regress spontaneously within 1 to 2 years of their initial appearance. However, reinfection is common in young, sexually active populations.^{1,80,81}

Infection with several HPV types, particularly HPV-16, HPV-18, and HPV-45, is considered the major risk factor for the development of cervical neoplasia, the second most common cancer in women worldwide. While epidemiologic, virologic, and clinical data strongly support this association, HPV infection alone is insufficient to cause cervical cancer development because only a small percentage of infected women develop the disease. It appears that the interplay of host immune defenses, genetic factors, and infection with HPV types containing a more aggressive variant all contribute to the risk of developing cervical neoplasia.^{78–81}

The Pap smear is the most cost-effective and frequently used diagnostic test for HPV. It can detect abnormal cytology in patients

with clinical manifestations and those with subclinical disease (i.e., no overt condylomata) but not latent HPV infection. Visual inspection of genital surfaces under magnification can assist in making the diagnosis. Various tests for detecting HPV DNA, although not used routinely, also are available.^{78–81}

No consensus exists on the best approach to treating patients with genital HPV infection, particularly because most cases appear to be transient with spontaneous regression of lesions. A number of treatments are recommended (see Table 115–13), but none is clearly superior to the others. Treatment generally is directed toward patients with manifestations of genital warts, with the goal of removing or destroying these lesions and grossly infected surrounding tissue. Because such treatment neither stops viral expression in surrounding tissue nor eliminates viral latency, recurrence of lesions is not uncommon.^{78–81}

The development of a vaccine against HPV is a major focus of research related to genital HPV infections. An important consideration in vaccine development is the need to incorporate viral particles from multiple HPV types because there is limited cross-protection between the different HPV types known to cause genital infections. Current research emphasis is on the development of polyvalent vaccines that would offer protection against the most common types of HPV, as well as those types known to be associated with cervical cancer. Additionally, therapeutic vaccines aimed at either suppressing replicating virus or reversing neoplastic transformation in infected individuals are being evaluated.^{78,81}

CONCLUSION

More than 20 different diseases have been identified for which sexual transmission is epidemiologically important. For most STDs, curative drug therapies are available; however, therapeutic approaches to viral STDs, such as genital herpes, provide only palliation and suppression of symptoms. Technologic advances in laboratory medicine have resulted in improved and more rapid diagnostic capabilities for many STDs. These advances are of particular importance for individuals with undiagnosed, asymptomatic disease who comprise a vast reservoir for continued disease transmission. Sexually active persons can reduce their risk of transmitting or acquiring an STD by avoidance of unsafe sexual practices, maintaining a mutually monogamous sexual relationship, or proper use of physical barriers during intercourse. In the future, vaccines providing protection from common STDs may have a significant effect on reducing the incidence of these infections.

BONE AND JOINT INFECTIONS

Edward P. Armstrong and Leslie L. Barton

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The most common cause of osteomyelitis (particularly that acquired by hematogenous spread) and infectious arthritis is *Staphylococcus aureus*.
- 2 Culture and susceptibility information are essential as a guide for antimicrobial treatment of osteomyelitis and infectious arthritis.
- 3 Joint aspiration and examination of synovial fluid are extremely important to evaluate the possibility of infectious arthritis.
- 4 The most important treatment modality of acute osteomyelitis is the administration of appropriate antibiotics in adequate doses for a sufficient length of time.
- 5 Antibiotics generally are given in high doses so that adequate antimicrobial concentrations are reached within infected bone and joints.
- 6 The standard duration of antimicrobial treatment for osteomyelitis is 4 to 6 weeks.
- 7 Oral antimicrobial therapy may be used for osteomyelitis to complete a parenteral regimen in children who have had a good clinical response to intravenous antibiotics and in adults without diabetes mellitus or peripheral vascular disease when the organism is susceptible to the oral antimicrobial, a suitable oral agent is available, and compliance is ensured.
- 8 The three most important therapeutic maneuvers in the management of infectious arthritis are appropriate antibiotics, joint drainage, and joint rest.

Bone and joint infections are comprised of two disease processes known, respectively, as *osteomyelitis* and *septic, or infectious, arthritis*. As such, they are unique and separate infectious entities with different signs and symptoms and infecting organisms. Despite advances in therapy, however, these infections continue to cause significant morbidity from residual damage and chronic recurring infections. Emphasis on initiating antibiotic therapy as soon as possible is important in reducing long-term complications.

EPIDEMIOLOGY

Osteomyelitis generally is an uncommon disease. One classic publication reported that 247 patients had osteomyelitis in a prominent American teaching hospital during a 4-year period.¹ Acute osteomyelitis has an estimated annual incidence of 0.1 per 1000 children.² Osteomyelitis caused by contiguous spread, including post-operative, direct puncture, and that associated with adjacent soft tissue infections, comprises 47% of infections. Hematogenous osteomyelitis comprises 19% of infections, and osteomyelitis occurring in patients with significant peripheral vascular disease comprises 34% of infections. A review of osteomyelitis cases based on duration of disease shows that acute disease constitutes 56% of patients and that chronic osteomyelitis, defined as having a previous hospitalization for the same infection, constitutes 44% of patients.

Infectious or septic arthritis is an inflammatory reaction within the joint space. Distinct from osteomyelitis, septic arthritis is a more common disease and is known to be one of the most common causes of new cases of arthritis. One study identified 1158 cases of septic

arthritis in a 4-year period.³ Another hospital study reported 64 children with septic arthritis during a 6-year time frame.⁴ A study from The Netherlands estimated the incidence of bacterial arthritis to be 5.7 cases per year per 100,000 inhabitants.⁵

ETIOLOGY

OSTEOMYELITIS

The most common method of classifying osteomyelitis is based on the route in which the infecting organism reaches the bone. Infection that results from spread through the bloodstream is termed *hematogenous osteomyelitis*. When the organism reaches the bone from an adjoining soft tissue infection, it is termed *contiguous osteomyelitis*. Osteomyelitis that results from direct inoculation, such as from trauma, puncture wounds, or surgery, generally is also classified under the contiguous osteomyelitis category. Patients with peripheral vascular disease are at risk for the development of osteomyelitis, and these patients often are separated into a third distinct category because of their unique management features.

Osteomyelitis also may be classified based on the duration of the disease. Acute osteomyelitis describes infections of recent onset, usually several days to 1 week, whereas chronic infections are those of a longer duration. Some authors describe chronic infections as those with symptoms for more than 1 month before therapy, whereas other authors define chronic infections as relapse of an initial infection. Yet a third system sometimes used to classify osteomyelitis is based on the anatomic location of the infection (medullary or superficial)

and the physiologic status of the patient (otherwise healthy, systemic immunologic compromise, local immunologic compromise).^{6,7} This classification system may be useful when comparing patients among different studies and attempting to categorize the severity of infection.

INFECTIOUS ARTHRITIS

Infectious arthritis may occur from many different types of microorganisms. Most infecting organisms are known to produce an infection in a single joint, termed *monarticular infections*; however, infections also may involve two or more joints.⁸ As with osteomyelitis, joint infections also may be classified according to the mechanisms by which the infecting organism reaches the joint. Infectious arthritis may result from the spread of an adjacent bone infection, direct contamination of the joint space, or hematogenous dissemination. Hematogenous spread of the disease comprises the majority of infections; spread from osteomyelitis and direct inoculation is much less frequent.⁹ Infectious arthritis occurs most commonly in patients older than age 16; 24% of cases occur in children 15 years of age or younger.¹⁰

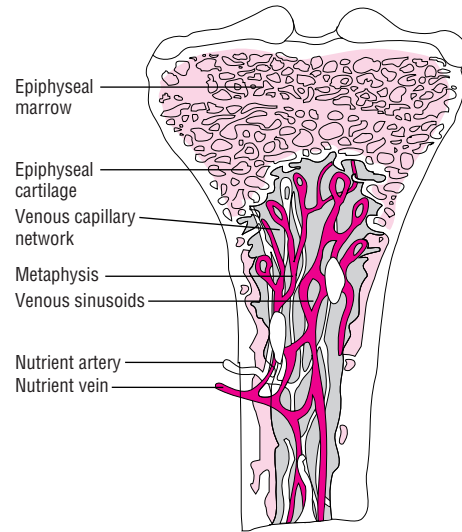

FIGURE 116-1. Cross-section of normal bone.

PATHOPHYSIOLOGY

HEMATOGENOUS OSTEOMYELITIS

Hematogenous osteomyelitis is described classically as a disease of children because most cases occur in patients younger than 16 years of age.⁷ Table 116-1 summarizes the primary characteristics of osteomyelitis. Less commonly, these infections occur in adults. One exception, vertebral osteomyelitis, involves the vertebrae and occurs most frequently in patients older than 50 years of age.

Unique features of the anatomy and physiology of some bones appear to predispose them to become infected.¹¹ The vascular structure within the long bones appears to predispose the bone for hematogenous infections to begin within the metaphyses (Fig. 116-1). The nutrient arteries of the long bones divide within the medullary canal of the bone into small arterioles. These end in hairpin turns near the growth plate and flow into veins, of much wider diameter, that drain the medullary cavity.¹ An infection in hematogenous disease is initiated within the bend of the arterioles. There is considerable slowing of blood flow passing through the hairpin turns within the arterioles and then into the wider venous structures. This sludging of blood flow allows bacteria present within the bloodstream to settle and initiate an inflammatory response. In addition to these structural

features, there also appears to be less active phagocytosis within the metaphysis. After the bacteria settle in the bone, avascular necrosis may occur from occlusion of the nutrient vessels and release of bacterial enzymes.

In addition to these anatomic and functional features, there is some evidence that trauma is associated with developing an infection in specific bones. Children who develop hematogenous osteomyelitis may report some type of trauma as an etiologic event. Animal data also indicate that traumatized bone is more likely to become infected than normal bone.

Once the infection is initiated, exudate begins to form within the bone, which produces increased pressure. The age of the patient largely determines the next stage in the pathophysiology. In children older than 12 to 18 months, the infection that started in the metaphysis of a long bone is prevented from spreading into the joint because of the growth plate; however, the exudate often expands laterally through the thin outer cortex of the bone and raises the loose periosteum. The periosteum is thick and not easily broken, and the resulting pus usually remains subperiosteal. If there is significant periosteal damage, a soft-tissue abscess may develop. Impairment of blood flow to the outer portion of the cortical bone may occur, producing dead bone that separates from healthy bone, termed *sequestra*. The elevated periosteum remains viable because its blood supply, derived from the

TABLE 116-1. Types of Osteomyelitis, Age Distribution, Common Sites, and Risk Factors

| Type of Osteomyelitis | Typical Age (yr) | Site(s) Involved | Risk Factors |
|------------------------|------------------|------------------------------------|---|
| Hematogenous | Less than 1 | Long bones and joints | Prematurity, umbilical catheter or venous cutdown, respiratory distress syndrome, perinatal asphyxia |
| | 1-20 | Long bones (femur, tibia, humerus) | Infection (pharyngitis, cellulitis, respiratory infections), trauma, sickle cell disease, puncture wounds to feet |
| | Older than 50 | Vertebrae | Diabetes mellitus, blunt trauma to spine, urinary tract infection |
| Contiguous | Older than 50 | Femur, tibia, mandible | Hip fractures, open fractures |
| Vascular insufficiency | Older than 50 | Feet, toes | Diabetes mellitus, peripheral vascular disease, pressure sores |

overlying muscle, is unaffected. The raised periosteum will continue to produce bone; however, this new bone is now separated from the cortex because the periosteum has been raised from the infection. This new bone is termed *involucrum*.

In adults, the periosteum is tightly bound, and the cortex is thick. These anatomic features generally cause the infections to remain intramedullary. As expected, subperiosteal abscess formations are less common in this population. The infection may spread to adjacent bone structures through the Haversian and Volkmann canals. Chronic osteomyelitis is more likely to occur if large segments of bone become avascular and necrotic.

Neonatal patients also have unique characteristics. In these patients, there are blood vessels that spread through the cortex of the metaphyses and up into the epiphyses. This enables an infection that started within the metaphyseal area to spread easily to involve the epiphyses and then into the joint. Therefore, in infants, not only can the infection spread to involve the periosteum and the shaft as in children, but the infection also can spread to involve the joint.

Hematogenous osteomyelitis also is known to have a predilection for certain bones. The specific bones most likely to be involved also depend on the age of the patient. Children most commonly develop infections within the femur, tibia, humerus, and fibula.¹² Vertebral infections are more common in patients older than 50 years of age. Neonatal infections commonly involve multiple bones.

▶ The bacteriology of hematogenous osteomyelitis is unique compared with osteomyelitis caused by other routes of infection. A single organism is responsible for the vast majority of hematogenous infections. *Staphylococcus aureus* is isolated most frequently with hematogenous infections in children. In immunocompetent children who have been fully vaccinated with the *Hemophilus influenzae* type b vaccine, this is now an uncommon pathogen causing bone and joint infections.¹³ However, neonatal osteomyelitis has a wider spectrum of infecting organisms.¹⁴ The three most common etiologic agents are *S. aureus*, group B *Streptococcus*, and *Escherichia coli*. The infections from *S. aureus* and *E. coli* have been linked to complications occurring during pregnancy or delivery, and they are involved most frequently in multiple-bone infections.

Vertebral osteomyelitis has several unique features. Vertebral osteomyelitis occurs most commonly in adults 50 to 60 years of age. The lumbar and thoracic regions are the locations of most infections. Hematogenous infections are most likely to develop in the vascular areas near the subchondral plate region of the vertebral body. Staphylococci cause approximately 60% of these infections; however, gram-negative organisms now play a significant role. It is presumed that these gram-negative organisms, particularly *E. coli*, most likely originate within the urinary tract. *E. coli* vertebral infections have been associated with urinary tract infections, positive urine cultures, and bacteremias. *Mycobacterium tuberculosis* also is known to cause infections in the spine. Skin and respiratory tract infections are other foci of infections known to lead to vertebral infections.

A unique category of osteomyelitis patients consists of individuals with a history of intravenous drug abuse. More than 50% of the osteomyelitis infections in this group of patients are found in the vertebral column. Less than 20% of infections are located in either the sternoarticular or pelvic girdle. Infections are much less frequent within the extremities. An unusual feature of osteomyelitis in the intravenous drug-abusing population is the spectrum of organisms. Gram-negative organisms are responsible for 88% of infections. *Pseudomonas aeruginosa*, either singly or in combination with other organisms, is cultured in 78% of all infections. *Klebsiella*, *Enterobacter*, and *Serratia* also may be found but less commonly.

In addition, staphylococcal and streptococcal organisms may be cultured.

Patients with sickle cell anemia and related hemoglobinopathies have a much higher rate of infection with *Salmonella* as compared with other populations. *Salmonella* spp. are responsible for two-thirds of the infections in these patients. Bowel infarctions from the sickle cell disease may facilitate salmonellae entry into the bloodstream from the colon and spread hematogenously to the bone. Osteomyelitis in patients with sickle cell disease may occur in any bone, but it is observed to be most common in the medullary cavity of long or tubular bones. Because of the difficulty in separating bone pain during a sickle cell crisis from that of an infection, osteomyelitis may be relatively advanced in these patients when the diagnosis is made. Although salmonellae are cultured most frequently, staphylococci and other gram-negative organisms also may be isolated.

CONTIGUOUS-SPREAD OSTEOMYELITIS

This category of osteomyelitis includes infections caused by direct entrance of organisms from a source outside the body or progressive spread of an infection from tissue adjacent to the bone. Penetrating wounds (e.g., trauma), open fractures, and various invasive orthopedic procedures may result in direct inoculation of organisms into the bone. Infections also may occur secondary to pressure ulcers.¹⁵ More than 80% of cases of postoperative osteomyelitis are known to occur following open reductions of fractures. Specifically, these infections occur most commonly after internal fixation of a hip fracture or femoral or tibial shaft fracture.

Osteomyelitis secondary to an adjoining soft tissue infection comprises another very important group of contiguous infections and most often involves the fingers and toes. Less commonly, infections may spread from infected teeth to involve the mandible or occur secondary to sinus infections by spreading through the mucosal lining of the sinuses into the vascular system surrounding the bone.

In contrast to hematogenous osteomyelitis, which occurs most commonly in children, contiguous-spread osteomyelitis occurs most commonly in patients older than age 50. Most likely this is so because important predisposing factors, such as hip fractures, are more common in this age group.

Contiguous-spread disease has several important differences compared with hematogenous osteomyelitis. Although *S. aureus* is still the most common organism isolated, infections with multiple organisms, including gram-negative bacilli, occur frequently. *P. aeruginosa*, *Proteus*, *Streptococcus*, *E. coli*, *S. epidermidis*, and anaerobes all may be isolated. One important exception to this wide range of organisms is puncture wounds of the feet. There is a strong correlation between puncture wounds of the feet and gram-negative osteomyelitis (often classified as *osteochondritis*), especially infections caused by *P. aeruginosa*.¹⁶

Patients with osteomyelitis in association with severe vascular insufficiency are extremely difficult to manage.^{17,18} As anticipated, most of these patients have diabetes mellitus or severe atherosclerosis, and they develop their infections from contiguous-spread mechanisms. Generally, these patients are between the ages of 50 and 70 years when they develop osteomyelitis. Frequently, patients with vascular disease develop osteomyelitis in their toes and fingers, and there is usually an adjacent area of infection, such as cellulitis or dermal ulcers.

Another important characteristic of osteomyelitis in association with vascular insufficiency is the spectrum of infecting organisms.

Infections in these patients almost always include multiple organisms. The mixed-flora infections often include *Staphylococcus* and *Streptococcus* or the combination of *Staphylococcus*, *Streptococcus*, and Enterobacteriaceae. Enterococci and anaerobic organisms also may be seen.

Anaerobic organisms also play a role in osteomyelitis. When anaerobes are grown from cultures, they usually are found in association with other organisms, including aerobic bacteria. The two most common predisposing factors in patients who have anaerobic osteomyelitis are previous fractures and diabetes mellitus. The anaerobic infections in association with diabetes mellitus almost always occur within the feet. *Bacteroides fragilis* and *B. melaninogenicus* comprise the majority of anaerobic isolates.

INFECTIOUS ARTHRITIS

Distinct from osteomyelitis, infectious arthritis usually is acquired by hematogenous spread.⁸ The synovial tissue is highly vascular and does not have a basement membrane, so organisms in the blood can easily reach the synovial fluid. Table 116–2 summarizes the characteristics of acute infectious arthritis. Some organisms, such as *Neisseria gonorrhoeae*, are especially likely to infect a joint during bacteremia. In addition, organisms also may gain access to the joint from a deep-penetrating wound, an intraarticular steroid injection, arthroscopy, prosthetic joint surgery, and contiguous osteomyelitis expansion into the joint.³

The risk factors associated with adult infectious arthritis (more than one factor may be present) are systemic corticosteroid use, pre-existing arthritis, arthrocentesis, distant infection, diabetes mellitus, trauma, and other diseases.

Trauma also appears to be a risk factor in facilitating microorganism entry into the synovial space. One study found that 35% of patients with infectious arthritis had preexisting joint disease.¹⁰ Unlike children, adults often have significant systemic diseases that predispose them to infectious arthritis, such as diabetes mellitus, immunosuppressive states (cancer, liver disease), or preexisting arthritis. Intravenous drug abusers also are prone to develop septic arthritis. Arthritis, joint trauma, and surgery are other important risk factors because chronic inflammation or trauma makes the joint more susceptible to infection.¹⁹ In addition, rheumatoid arthritis patients may be prone to

bacterial infection because of an inherent phagocytic defect, as well as concomitant corticosteroid therapy. Hormonal factors appear to play a role in *N. gonorrhoeae* infectious arthritis. Women are more prone to develop disseminated gonococcal infections than men. The second and third trimesters of pregnancy and during menstruation appear to be the times of greatest risk for developing gonococcal bacteremia.

After bacteria gain access to the joint, the organisms begin to multiply and produce a persistent purulent effusion within the joint. If this joint effusion is present beyond 7 days, chronic, and sometimes irreversible, damage may occur. Purulent effusions may promote cartilage destruction by increasing leukocyte enzyme activity. In conjunction with the development of the effusion, almost all patients will develop a hot, swollen, painful joint. The proteolytic enzymes within the effusion and pressure necrosis may lead to cartilage and bone damage.

▶ *S. aureus*, the single most common infecting organism, is found in 48% of cases of nongonococcal bacterial arthritis. Streptococcal infections account for 18% of cases, and gram-negative organisms are less common.¹⁰ Overall, *E. coli* is the most common of the gram-negative organisms; however, *P. aeruginosa* is the most frequent organism in intravenous drug abusers. Neonates may have infectious arthritis because of a broad range of organisms, with *S. aureus*, *Streptococcus*, and gram-negative organisms being most common. *S. aureus* and *Streptococcus* are the most common pathogens in children younger than 5 years of age. If the child has not been fully vaccinated or is immunocompromised, *H. influenzae* type b may be seen. Within the adult population, *S. aureus* is responsible for the vast majority of nongonococcal infections. The most common cause of bacterial arthritis in adults 18 to 30 years of age is *N. gonorrhoeae*, which are the most common infections in women.²⁰ Patients with a terminal complement deficiency (C5–C9) are at increased risk of disseminated infections with *Neisseria* spp. Although less common, nonbacterial causes of osteomyelitis and septic arthritis include fungi and viruses.²¹

CLINICAL PRESENTATION

The clinical presentation of acute hematogenous osteomyelitis is summarized in Table 116–3. Although neonatal hematogenous

TABLE 116–2. Characteristics of Acute Infectious Arthritis

| Feature | Finding |
|--------------------------------|---|
| Peak incidence | Children younger than 16 years Adults older than 50 years |
| Clinical findings | Fever of 38–40°C in children; painful swollen joint in the absence of trauma Physical exam: Effusion, restriction of joint motion, tenderness, and warmth of joint |
| Most commonly affected joints | Knee, hip, ankle, elbow, wrist, and shoulder |
| Laboratory findings: | |
| Erythrocyte sedimentation rate | Elevated in 90% of cases |
| White blood cell count | Elevated in 30–60% of cases |
| Left shift | Seen in two-thirds of patients |
| Blood culture | Positive in 40% of cases |
| Needle aspiration of joint | Gram-stain diagnostic in 30–50% of cases. Synovial fluid cultures are positive in 60–80% of cases. Synovial fluid differential reveals 90% polymorphonuclear leukocytes. Synovial fluid glucose decreased relative to serum glucose. Lactic acid levels elevated in nongonococcal infectious arthritis but not in gonococcal infectious arthritis |

TABLE 116–3. Clinical Presentation of Hematogenous Osteomyelitis**Signs and Symptoms**

Significant tenderness of the affected area, pain, swelling, fever, chills, decreased motion, and malaise

Laboratory Tests

Elevated erythrocyte sedimentation rate, C-reactive protein, and white blood cell count

50% of patients will have positive blood cultures

Diagnostic Studies

Bone changes observed on radiographs 10–14 days after the onset of infection. Technetium and gallium scans positive as early as 1 day after the onset of infection

osteomyelitis may spread rapidly to involve the joint, often there are few systemic symptoms present. A joint effusion is present in 60% to 70% of neonatal infections. Decreased limb motion and edema over the affected area may be the only signs from which to make a diagnosis. Pyogenic vertebral osteomyelitis produces nonspecific symptoms, such as severe back pain, fever or night sweats, and weight loss. The pain typically is present at rest and increases in severity with movement. Neurologic symptoms may occur if the infection extends and compresses the spinal cord. With contiguous-spread osteomyelitis there is often an area of localized tenderness, warmth, edema, and erythema over the infected site. Patients with significant vascular insufficiency usually have local symptoms, such as pain, swelling, and redness. Less commonly, patients with vascular disease also may have a fever and elevated white blood cell (WBC) count. The presentation of osteomyelitis from surgery or trauma depends on the precipitating cause. If the infection follows surgery or bone trauma, the symptoms usually are noted within 1 month. The most frequent symptom is simply pain in the area of infection. Less commonly, patients also may develop a fever and elevated WBC count.

Patients with nongonococcal bacterial arthritis almost always present with a fever, and 50% of patients have an elevated WBC count (see Table 116–2). The average initial synovial WBC count is 100,000 cells/mm³ or greater in nongonococcal bacterial disease. The most frequent initial sign of disseminated gonococcal infections is a migratory polyarthralgia. In addition, two-thirds of patients also complain of fever, dermatitis, and tenosynovitis (inflammation of the tendon sheath).

Nongonococcal bacterial arthritis almost always involves only a single joint. The knee is the most commonly involved joint, but infections also may occur in the shoulder, wrist, hip, ankle, interphalangeal joints, and elbow joints. Usually, the initial focus of infection that acted as the source for bacterial or microbial entrance can be identified. Common routes for bacterial entrance include infections of the respiratory tract, skin, and urinary tract. Blood cultures are important in these patients because they may be positive in 50% of patients.

Another type of infectious arthritis occurs following prosthetic joint surgery. With these infections, the erythrocyte sedimentation rate usually is elevated, although a leukocytosis often is absent. Infections that result from postoperative contamination usually become apparent within 1 year of surgery.

RADIOLOGIC AND LABORATORY TESTS

The evaluation of a patient who potentially may have osteomyelitis has several unusual aspects. Radiographs of the involved area should be obtained; however, bone changes characteristic of osteomyelitis

are not seen for at least 10 to 14 days after the onset of the infection.²² Radiologists may note soft tissue swelling before any bone changes become obvious. Bone lesions do not appear on roentgenogram films until 10 days after infection because more than 50% of the bone matrix must be removed before the lesions can be detected. As an aide to improve the diagnosis, bone scanning is used commonly.²³

Despite the seriousness of osteomyelitis, often there are few laboratory abnormalities. The erythrocyte sedimentation rate (ESR), C-reactive protein, and WBC count may be the only laboratory abnormalities.¹² The degree of abnormality of these laboratory findings does not correlate with the disease outcome; however, they are useful for monitoring therapy. C-reactive protein may be elevated because of the presence of inflammation, and it may be substituted for the ESR. C-reactive protein is generally the more sensitive and specific marker of response to therapy and often increases and decreases before the ESR.

When a clinical assessment of osteomyelitis is suspected, it is important to establish a bacteriologic diagnosis by culture of the infected bone. Accurate culture information is especially important as a guide for treatment of osteomyelitis. Bone aspiration is valuable in determining an accurate bacteriologic diagnosis.²⁴ In addition, performing a bone aspiration determines whether or not there is an abscess present. If an abscess is located, the pus is cultured, and a Gram stain is performed. If an abscess is found, the fluid needs to be drained and cultured. Aspirates of subperiosteal pus or metaphyseal fluid yield a pathogen in 70% of cases. Cultures should be done for both aerobic and anaerobic bacteria. A Gram stain of the aspirate may be useful in initiating empirical antibiotic therapy. This allows a more appropriate choice of antibiotics from the first day of therapy rather than waiting several days while culture results are pending.

If a specimen is obtained from a previously undrained or unopened wound abscess, the pathogen usually can be identified. In chronic osteomyelitis, however, identification may be more difficult. Open wounds and draining sinuses frequently are contaminated with other organisms and thus provide inaccurate culture information.²⁵ Therefore, because of the inaccuracies with sinus tract cultures, they cannot be relied on to reflect the pathogen. Cultures of loculated pus aspirates in the area of orthopedic devices removed from infected bone can be trusted, however, to identify the infecting organism. The preferable time to obtain culture material in a patient with a chronic draining sinus is at the time of open surgical débridement.

2 In addition to performing cultures from the involved bone, it also is important to obtain cultures from any site believed to be the source of a bacteremia. Blood cultures should be obtained. Approximately 50% of patients with hematogenous osteomyelitis will have positive blood cultures.

3 When evaluating the possibility of a patient having infectious arthritis, immediate joint aspiration with subsequent analysis of the synovial fluid is extremely important. The presence of purulent fluid usually indicates the presence of a septic joint. The synovial fluid WBC count is usually 50,000–200,000 cells/mm³ when an infection is present. Approximately half the patients with an infected joint have a low synovial glucose level, usually less than 40 mg/dL. Gram stains of joint fluid demonstrate bacteria in 50% of patients with septic arthritis; however, such stains may be positive in only 25% of patients with gonococcal arthritis infections. Synovial fluid cultures usually are positive in patients with nongonococcal infections. Both blood and joint fluid should be cultured aerobically and anaerobically in a patient suspected of having an infected joint. Blood cultures are positive in one-half of patients with nongonococcal infections but in only 20% of those with gonococcal infections. Pharyngeal, rectal, cervical, or urethral smears and cultures, as well as cultures of

cutaneous lesions, should be performed if a disseminated gonococcal infection is considered. As with osteomyelitis, most patients will have an elevated C-reactive protein concentration and ESR. Radiographs of infected joints often reveal distension of the joint capsule with soft

tissue swelling in the adjacent space. Magnetic resonance imaging may be helpful in identifying an infected hip. In patients who have developed an infected prosthetic joint, loosening of the prosthesis may be seen radiographically.

▶ TREATMENT: Bone and Joint Infections

■ DESIRED OUTCOME

The goals of treatment are resolution of the infection and prevention of long-term sequelae. The ultimate outcome of osteomyelitis depends on the acute or chronic nature of the disease and how rapidly appropriate therapy is initiated. Patients with acute osteomyelitis have the best prognosis. Cure rates exceeding 80% may be expected for patients with acute osteomyelitis who have surgery as indicated and received injectable antibiotics for 4 to 6 weeks.²⁶ In contrast, patients with chronic osteomyelitis have a much poorer prognosis.²⁷ Dead bone and other necrotic material from the infection act as a bacterial reservoir and make the infection very difficult to eliminate. Adequate surgical débridement to remove all the dead bone and necrotic material, combined with prolonged administration of antibiotics, provides the best chance to obtain a cure.²⁸ The inability to remove all the dead bone may allow residual infection and require suppressive antibiotics to control the infection.

In comparison, many patients who develop infectious arthritis recover with no long-term sequelae. Gonococcal arthritis usually resolves rapidly with antibiotics; however, patients with staphylococcal arthritis have a higher incidence of joint damage. Individuals at greatest risk for long-term sequelae are those who have symptoms present for more than 7 days before starting therapy and those with infections occurring within the hip joint and infections caused by gram-negative organisms. Common long-term residual effects following infectious arthritis are limited joint motion and persistent pain. Shortening of the affected extremity is another well-known complication. More than half the children who subsequently developed residual joint damage were believed normal at the time of hospital discharge.

■ GENERAL APPROACH TO TREATMENT

4 Following completion of the steps needed to determine the infecting organism, the most important treatment modality of acute osteomyelitis is the administration of appropriate antibiotics in adequate doses for a sufficient length of time. It is important to stress that early antibiotic therapy may mitigate the need for surgery.²⁹ A delay in treatment may allow bone necrosis to occur and make eradication of the infection much more difficult. In these patients, recurrent exacerbations of the infection may result if all necrotic tissue is not removed surgically and all microorganisms eliminated. Adjunctive treatment with hyperbaric oxygen or antibiotic-impregnated implants during surgery also has been used.^{30–32}

If a patient with hematogenous osteomyelitis does not respond by having a decrease in fever, local swelling, redness, and pain following the initiation of adequate antibiotic therapy, the patient should undergo surgical débridement of the infected area. It is important to emphasize the priority of starting antibiotics immediately after the cultures have been obtained. No treatment failures have been reported when injectable antibiotics were started within 48 hours of the onset of symptoms in children with osteomyelitis.

■ PHARMACOLOGIC THERAPY

■ ANTIBIOTIC BONE CONCENTRATION

5 Antibiotics used in the management of acute osteomyelitis generally are given in high doses (adjusted for weight, renal function, hepatic function, or both) so that adequate antimicrobial concentrations are reached within the infected bone and joint. Between 8 and 12 g/day of a penicillinase-resistant penicillin (nafcillin or oxacillin), ampicillin, or cephalosporin or a similar large dose of another parenteral antibiotic is used in the initial management of adults with osteomyelitis. These dosing recommendations, however, are empirical; the relationship between a specific dose of a given antibiotic and its resulting concentration within the infected bone is largely unknown.³³ Semisynthetic penicillins, cephalosporins, clindamycin, and the aminoglycosides can be detected in bone homogenates soon after their administration.

■ DURATION OF ANTIBIOTIC THERAPY

6 The specific duration of antibiotic therapy needed in the management of osteomyelitis is usually 4 to 6 weeks.³⁴ Failures approaching 20% have been observed in children treated with injectable antibiotics for 3 weeks or less. Thus, with the data indicating a minimum of 3 weeks of antibiotic therapy, the standard treatment for osteomyelitis has been parenteral antibiotics for 4 to 6 weeks.^{35–37} Although these data were determined in children, this duration-of-therapy recommendation is also used in adults. A trial assessing ceftriaxone 2 g intravenously once daily for at least 6 weeks for *S. aureus* osteomyelitis achieved a cure rate of 77%.³⁸ The failures in this study were in patients with infected necrotic bone or infected hardware (wires, plates, screws, and rods) that could not be removed.

A modification of this recommendation has been used in some patients. Children receiving an appropriate oral antibiotic regimen and adults receiving an oral fluoroquinolone antibiotic, such as ciprofloxacin, for a duration of 6 weeks have been treated successfully. Monitoring the patient's clinical signs and symptoms and the C-reactive protein level or ESR is an important parameter to assess therapy. If signs or symptoms are still present at 6 weeks, therapy should be extended. In contrast, children who have had a puncture wound of the foot resulting in *P. aeruginosa* osteochondritis and who have had surgical débridement of infected material may be treated with parenteral antibiotics for 10 days.³⁹

■ ORAL ANTIBIOTIC THERAPY

7 One of the most significant changes in the management of osteomyelitis is the use of oral antibiotics to complete therapy.⁴⁰ Criteria for the use of oral outpatient antibiotic therapy for osteomyelitis are

- Confirmed osteomyelitis
- Clinical response to parenteral antibiotics

- Suitable oral agent available
- Compliance ensured

Suitable candidates are children with good clinical response to intravenous therapy and adults without diabetes mellitus or peripheral vascular disease.

Two primary populations have benefited from oral treatment. Children responding to initial parenteral therapy may be excellent candidates to receive follow-up oral therapy with an agent such as dicloxacillin, cephalexin, or amoxicillin depending on their culture and sensitivity results.⁴¹ Although more controversial, the other population to benefit from oral therapy is adults with an infecting organism sensitive to a fluoroquinolone.⁴² These two populations now no longer routinely require expensive and complicated courses of long-term parenteral antibiotics.

The use of oral antibiotics is well studied in children. Several studies documenting the effectiveness of oral therapy used injectable antibiotics initially and then switched to oral antibiotics when there was a decrease in the signs of inflammation and the ESR or when the patient was afebrile for 3 days.⁴¹ If pus was obtained on the initial needle aspirate, or if a reduction in fever, local swelling, and tenderness did not occur despite adequate rest, immobilization, and intensive antibiotic therapy, the patients underwent surgical drainage.

The patients enrolled in oral antibiotic trials generally had disease of recent onset, identification of a specific infecting organism, enforced compliance, and surgery as indicated. In patients who meet these criteria, oral antibiotics appear to offer a great advantage in the treatment of osteomyelitis. Patients not meeting these criteria are more likely to develop chronic osteomyelitis with resulting recurrent exacerbations of the infection if oral therapy is attempted. One trial found no treatment failures in children with acute *S. aureus* osteomyelitis who were treated with either 150 mg/kg per day of cephadrine or 40 mg/kg per day of clindamycin that was started initially intravenously and was converted to oral therapy within 4 days.⁴³

Ciprofloxacin is effective in the treatment of osteomyelitis caused by gram-negative strains, such as *E. cloacae* and *S. marcescens*.⁴⁴ Many strains of streptococci are relatively resistant. Its activity against gram-negative bacilli allows patients to be treated orally and avoids the potential toxic complications of 4 to 6 weeks of aminoglycoside therapy. Ciprofloxacin and other fluoroquinolones also have demonstrated effectiveness in the treatment of chronic osteomyelitis along with adequate surgical débridement.^{45,46} Another benefit with this agent is that it may be administered on an every-12-hour schedule. An important limitation of this antibiotic class, however, is that fluoroquinolones should not be used in children younger than 16 to 18 years of age or in pregnant women because of the potential to cause cartilage damage. Other limitations of ciprofloxacin are that it has poor coverage against anaerobic organisms and staphylococci and that *P. aeruginosa* may develop resistance.⁴⁷ Newer fluoroquinolones have additional gram-positive activity; however, additional well-controlled clinical trials are needed to determine most appropriately their role in the treatment of osteomyelitis.^{48,49}

CLINICAL CONTROVERSY

Some clinicians believe that oral fluoroquinolones should be preferred treatments for osteomyelitis, whereas others believe that there have been inadequate studies to date to determine their comparative clinical effectiveness.

Concern has been raised about staphylococci resistance to fluoroquinolones. Methicillin-resistant *S. aureus* infections do not respond

well to ciprofloxacin; however, resistance also may be troublesome for methicillin-sensitive strains. It is now recommended that when ciprofloxacin is to be used to treat osteomyelitis with mixed etiologies that include *S. aureus*, ciprofloxacin should be combined with an antistaphylococcal drug such as dicloxacillin, cephalexin, or clindamycin.

ANTIBIOTIC SELECTION

A critical component in the management of osteomyelitis is the selection of appropriate antibiotics. Empirical therapy must be selected on the basis of the most likely infecting organism while the results of culture and sensitivity data are pending. Table 116-4 summarizes empirical therapy recommendations. Dosages expressed in terms of milligrams per kilograms per day generally are given in divided doses every 6 to 8 hours (three to four times a day).

Because *S. aureus*, streptococci, and *E. coli* are the most common infecting organisms in newborns, an intravenous dosage of 150 mg/kg per day (given in four divided doses) of oxacillin or nafcillin plus cefotaxime 150 mg/kg per day (given in three to four divided doses) is appropriate. For children 5 years of age or younger, *S. aureus* and streptococci are the most common infecting organisms. Appropriate therapy in this age group is nafcillin or oxacillin 150 mg/kg per day intravenously or cefazolin 100 mg/kg per day. If the patient is immunocompromised or has not been fully vaccinated, empirical therapy is needed to also cover *H. influenzae* type b. In this setting, intravenous cefuroxime 150 mg/kg per day is appropriate empirical therapy. For children older than 5 years, *S. aureus* is the most likely infecting organism, and either nafcillin 150–200 mg/kg per day intravenously or cefazolin 100 mg/kg per day intravenously is recommended. If patients are allergic to penicillins or cephalosporins or are infected with methicillin-resistant *S. aureus*, vancomycin, clindamycin, or linezolid may be used.⁵⁰ Children with culture-negative osteomyelitis can be managed as presumed staphylococcal disease with excellent long-term results.⁵¹ Children with osteomyelitis usually can be treated successfully with 4 weeks of parenteral therapy or parenteral followed by oral therapy.

CLINICAL CONTROVERSY

Some clinicians believe that empirical therapy of osteomyelitis and septic arthritis in a child younger than 5 years of age no longer requires *H. influenzae* type b coverage, whereas others are concerned about children not being fully vaccinated and desire to use an antibiotic with activity against this organism.

An oral regimen may be an alternative to the previous recommendation in many cases of osteomyelitis in children. Children who have undergone surgery, if needed, and have had a good clinical response to intravenous therapy may be candidates for the alternate oral antibiotic regimen. Parenteral antibiotic therapy should be initiated and continued until there has been a resolution in the erythema, swelling, and tenderness and until the patient is afebrile. Dicloxacillin, cloxacillin, and cephalexin (100 mg/kg per day) are effective oral agents. Patients should be monitored with periodic WBC counts, C-reactive protein (or ESR) determinations, and radiographic findings. When oral antibiotics are used, the total duration of oral and injectable therapy is usually at least 4 to 6 weeks. As stated previously, because of the risk of cartilage damage, fluoroquinolones should not be used in children. Hematogenous osteomyelitis in adults is caused most frequently by *S. aureus* and thus is treated appropriately with 8–12 g/day

TABLE 116–4. Empirical Treatment of Osteomyelitis

| Patient Subtype | Likely Infecting Organism | Antibiotic ^a |
|--------------------------------------|--|--|
| Newborn | <i>S. aureus</i> , streptococci, <i>E. coli</i> | Nafcillin or oxacillin 50–150 mg/kg/day IV plus cefotaxime 100–200 mg/kg/day IV |
| Children 5 years of age or younger | 1. If vaccinated for <i>H. influenzae</i> type b: <i>S. aureus</i> or streptococci 2. If not vaccinated against <i>H. influenzae</i> type b | 1. Nafcillin 150 mg/kg/day IV or cefazolin 100 mg/kg/day IV 2. Cefuroxime 150 mg/kg/day IV |
| Children older than 5 years of age | <i>S. aureus</i> | Nafcillin 150 mg/kg/day IV or cefazolin 100 mg/kg/day IV |
| Adults | <i>S. aureus</i> | Nafcillin 2 g IV every 4 hours or cefazolin 2 g IV every 8 hours |
| Intravenous drug abusers | <i>Pseudomonas</i> | Ciprofloxacin 750 mg PO twice daily or ceftazidime 2 g IV every 8 hours plus tobramycin 5 mg/kg/day IV |
| Postoperative or posttrauma patients | Gram-positive and gram-negative organisms | Nafcillin 2 g IV every 4 hours plus ceftazidime 2 g IV every 8 hours or ticarcillin-clavulanate 3.1 g IV every 4 hours |
| Patients with vascular insufficiency | Gram-positive and gram-negative organisms | Nafcillin 2 g IV every 4 hours or cefazolin 2 g IV every 8 hours plus ceftazidime 2 g IV every 8 hours |
| | If anaerobes suspected | Cefotetan 2 g IV every 12 hours or clindamycin 900 mg IV every 8 hours plus ceftazidime 2 g IV every 8 hours |

^aDosage should be adjusted for some agents in patients with renal and/or hepatic dysfunction.

of a penicillinase-resistant penicillin such as nafcillin. A similar dose of a first-generation cephalosporin (e.g., cefazolin), clindamycin 2.4 g/day, or vancomycin 2 g/day (with normal renal function) may be used in individuals allergic to penicillin; however, if the infection is located within the vertebrae, *E. coli* must be considered, and thus, depending on the culture and sensitivity data, a switch to a cephalosporin may be needed.⁵² After institution of appropriate antibiotic therapy, the antimicrobial agent should be continued for at least 4 to 6 weeks total (parenteral plus oral).

Special Populations

Osteomyelitis in a patient with a hemoglobinopathy, such as sickle cell anemia, is commonly caused by either *Salmonella* or *S. aureus*. Thus empirical antibiotics of first choice are ceftriaxone or cefotaxime. Alternatives are chloramphenicol and ciprofloxacin (in adults).

Bone infections in patients with a history of intravenous drug abuse require coverage for gram-negative organisms; therefore, empirical treatment with ceftazidime 2 g intravenously every 8 hours plus an aminoglycoside is indicated. If compliance can be ensured, these patients are excellent candidates to receive oral ciprofloxacin 750 mg twice daily. Antibiotic therapy in these patients should be continued for at least 4 to 6 weeks.

As discussed previously, several microorganisms can cause bone infections that occur after surgery or from contiguous spread of an adjacent soft tissue infection. *S. aureus* is the single most common organism, but multiple organisms may be involved. To provide the required broad-spectrum coverage, nafcillin 2 g intravenously every 4 hours plus ceftazidime 2 g intravenously every 8 hours should be used as initial therapy. An alternative single agent is ticarcillin-clavulanate potassium 3.1 g intravenously every 4 hours; however, there is less experience with this agent. Other broad-spectrum alternatives may be cefepime and imipenem. The antibiotic regimen may require modification after culture and sensitivity information is

evaluated. Based on the culture and sensitivity data, ciprofloxacin may be an appropriate oral alternative for these patients. Frequently, the antibiotics must be continued for 6 weeks to obtain a cure, and surgery often is required to remove any infected or devitalized tissue.

Patients with established vascular insufficiency who subsequently develop osteomyelitis are extremely difficult to manage.⁶ Impaired blood flow to the extremities impedes the healing process, possibly requiring vascular bypass surgery.⁵³ Infections in these patients involve a wide range of organisms, including *S. aureus*, *Streptococcus*, anaerobes, and gram-negative organisms. Broad-spectrum therapy with a penicillinase-resistant penicillin in combination with ceftazidime is the preferred initial therapy. If anaerobes are suspected, an antianaerobic cephalosporin (e.g., cefoxitin) or clindamycin plus ceftazidime may be substituted. Ampicillin may need to be added to the regimen to provide coverage against enterococci. Despite aggressive antibiotic therapy along with surgical débridement, these patients continue to have very low cure rates. Amputation of the involved area may be required to obtain a cure of the infection.⁵⁴

Home Antibiotic Therapy

Because the management of bone and joint infections frequently requires prolonged parenteral antibiotics, newer antibiotic regimens are being evaluated.⁵⁵ Administration of antibiotics in the home environment and the use of antibiotics with extended elimination half-lives are being studied.⁵⁶ Although acute osteomyelitis is one of the more common infectious diseases that may be treated with home intravenous antibiotics, not all patients are acceptable candidates for home administration.⁵⁷ Patients must be screened to include only those who are receiving a stable treatment program, those who are interested and are motivated in participating, and those who have good venous access, as well as those who have support from family members or neighbors and have home facilities for storage and refrigeration.⁵⁸

Patients with adequate vascular access may be able to use a peripheral intravenous catheter; however, a central intravenous catheter may be required if venous access difficulties occur. Certain exclusion criteria also must be considered. Complications of other preexisting diseases, such as diabetic retinopathy, intention tremor, disabling inflammation or degenerative joint disease, coagulopathies, or various neurologic disorders may prevent individuals from receiving home antibiotics. A history of alcoholism or of intravenous drug abuse also are important exclusion criteria. Patients who are fluent in only a foreign language and patients who are illiterate or hard of hearing may have to be excluded if a qualified guardian is unavailable. In addition to meeting these initial screening criteria, patients must complete a thorough training program successfully before hospital discharge. Aseptic technique, proper catheter care, and correct administration techniques must be documented. Once a patient is receiving therapy in the home environment, continued monitoring of their antimicrobial therapy is important. It is vital to ensure compliance with the antimicrobial regimen.

In addition, the specific antibiotic regimen characteristics must be considered when evaluating a patient for home antibiotics.⁵⁹ Some important features are microbiologic culture and sensitivity data, the number of required daily antimicrobial doses, antibiotic stability data, and requirements for unique monitoring for the specific antimicrobial regimen, such as serum creatinine and peak and trough concentration measurements with aminoglycosides. Although an organism may be sensitive to several antimicrobial agents, one antibiotic may provide practical benefits over other agents. Patients who have an infecting organism that is sensitive to one of the longer-acting (less frequently dosed) cephalosporins and is resistant to less expensive agents (cefazolin) may benefit from the newer antibiotics. It is important, however, to monitor for the development of resistant strains and superinfections.

■ Infectious Arthritis

8 The three most important therapeutic maneuvers in the management of infectious arthritis are appropriate antibiotics, joint drainage, and joint rest.⁶⁰ Smears of the synovial fluid may be useful to select appropriate antibiotic therapy initially.⁶¹ If bacteria are not observed on the Gram stain in a patient who has a purulent joint effusion, antibiotics still should be initiated because of the high risk of an infection being present.⁶² A delay in initiating antibiotics significantly increases the likelihood for long-term complications.

The specific antibiotic selected depends on the most likely infecting organism. In infants younger than 1 month of age, the infecting organisms vary widely, and empirical therapy thus must provide broad-spectrum coverage. A penicillinase-resistant penicillin such as nafcillin or oxacillin plus an aminoglycoside is appropriate. Children younger than 5 years of age who have been immunized for *H. influenzae* type b should receive nafcillin, oxacillin, or cefazolin.

In children older than 5 years of age and in adults, initial therapy with a penicillinase-resistant penicillin is appropriate to provide the necessary coverage against *S. aureus*. Therapy should be changed to clindamycin, vancomycin, or linezolid if the *S. aureus* is resistant to methicillin. Preliminary data indicate that children with infectious arthritis may be converted to oral therapy after initial intravenous therapy.^{63,64} As with osteomyelitis, intravenous drug abusers require coverage for *P. aeruginosa*, and therefore, combination therapy with an aminoglycoside is needed. The antibiotics selected usually are administered parenterally. Antibiotics administered by this route achieve sufficient concentrations within the synovial fluid, and thus intraarticular antibiotic injections are unnecessary. Although studies to define clearly the appropriate length of therapy have not been conducted, 2 to 3 weeks of antibiotic therapy generally is adequate in nongonococcal infections. Joint fluid cultures usually are no longer positive after 7 days of antibiotics.

Disseminated gonococcal infections often respond quickly to antibiotics.⁶⁵ Ceftriaxone 1 g/day for 7 to 10 days is the treatment of choice. After culture and sensitivity results are available and the organism is determined to be sensitive, therapy can be switched on the fourth day to oral amoxicillin or to doxycycline or tetracycline to complete the 7- to 10-day course. Clinical resolution of signs and symptoms usually is rapid.

Closed-needle aspiration is recommended for all infected joints except the hip. Joint drainage may be repeated daily for 5 to 7 days until effusions no longer reaccumulate. Open drainage is required in hip infections because closed-needle aspiration is difficult and inadequate. During the initial phase of the infection, weight bearing, such as walking, on the joint should be avoided. Passive range-of-motion exercises should be initiated when the pain begins to subside in order to maintain joint mobility.⁶⁶ Approximately one-third of patients with bacterial arthritis have a poor joint outcome, such as severe functional deterioration.⁶⁷ Poor joint outcomes are associated with older patients, those with preexisting joint disease, and patients with an infected joint containing synthetic material. Treatment guidelines have been shown to be useful with septic arthritis of the hip.⁶⁸

PHARMACOECONOMIC CONSIDERATIONS

Cost and outcome issues are important in osteomyelitis and infectious arthritis. If long-term sequelae develop, such as impaired joint motion or draining sinus tracts, or if amputation is required, patient quality of life may be significantly diminished. Cost and quality-of-life issues have clearly played a major role in evaluating other treatment alternatives (oral therapy or home antibiotic treatment) rather than requiring patients to remain hospitalized to receive 4 to 6 weeks of parenteral antibiotics.⁶⁹ One study compared a series of decision analytic models to provide estimates of the costs and outcomes of different regimens.⁷⁰ Another study used a Markov model to compare different treatments in non-insulin-dependent diabetes mellitus patients who had foot infections and suspected osteomyelitis.⁷¹ This study found that a 10-week course of culture-guided oral antibiotics after surgical débridement may be as effective as and less costly than other treatment approaches, such as immediate amputation.

EVALUATION OF THERAPEUTIC OUTCOMES

Patients with bone and joint infections must be monitored closely. Table 116-5 summarizes a pharmaceutical care monitoring protocol. An assessment of a therapy's success or failure is based on the patient's clinical findings and laboratory values. The clinical signs of inflammation, such as swelling, tenderness, pain, redness, and fever, should resolve with appropriate therapy. Initially, the clinical signs are assessed daily until improvement and then periodically thereafter. Elevations in WBC count also should decline gradually. The ESR usually is determined weekly. Elevations in the C-reactive protein or ESR may not return to normal for several weeks of therapy. The WBC count usually is obtained once or twice per week until it returns to the normal range. If by the end of the 4- to 6-week antibiotic course the clinical findings of osteomyelitis are no longer present and the C-reactive protein or ESR is within normal limits, the patient may be considered a clinical cure. Patients may relapse, however, after

TABLE 116–5. Monitoring Protocol

| Parameter | Frequency | Notes |
|---|--|---|
| Culture and sensitivity | At initiation of treatment | |
| White blood cell count | 1 time/week until within normal range | |
| C-reactive protein or erythrocyte sedimentation rate | Weekly | May not decrease to normal range until several weeks of therapy |
| Clinical signs of inflammation (redness, pain, swelling, tenderness, fever) | Daily during initiation of therapy | |
| Compliance of outpatient therapy | Reinforce before starting oral therapy and with each health care visit | Compliance is critical if treatment is to be successful |

initially appearing to be cured. No relapse for 1 year generally is considered a complete cure.

If a patient fails to resolve the clinical signs and symptoms of inflammation after appropriate empirical antibiotics, surgical débridement may be needed. In addition, the patient may have a resistant infecting organism or an atypical infecting organism that may require a modification of the antibiotic therapy. It is especially important to note the infecting organism and its sensitivity pattern. Follow-up cultures at subsequent débridements may be useful to assess the antibiotic therapy.

Despite apparently adequate surgery and antibiotics, some patients may fail therapy and have recurrent relapses in their infection. This scenario is more common in the population with chronic osteomyelitis. These patients may require long-term oral antibiotics in order to keep the infection under control.

ABBREVIATIONS

ESR: erythrocyte sedimentation rate

WBC: white blood cell count

SEPSIS AND SEPTIC SHOCK

S. Lena Kang-Birken and Joseph T. DiPiro

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The spectrum of microorganisms associated with sepsis has changed from predominantly gram-negative bacteria in the late 1970s and 1980s to gram-positive bacteria as the major pathogens since 1987.
- 2 The rate of fungal infections has increased more than 200% from 1979 to 2000, and despite the recent addition of several potent antifungal agents, mortality ranges from 41% to 71%.
- 3 Sepsis represents a complex pathophysiology characterized by the activation of multiple overlapping and interacting cascades leading to systemic inflammation, a procoagulant state, and decreased fibrinolysis.
- 4 Mortality rates with sepsis are higher for patients with preexisting disease, intensive care unit care, and multiple-organ failure.
- 5 Timely diagnosis and identification of the pathogen are critical to successful management of the septic patient.
- 6 Prompt, aggressive initiation of broad-spectrum parenteral antibiotic therapy is required owing to high incidence of complications and mortality.
- 7 Significant fluid leaks from the vasculature occur with sepsis, and administration of large volumes of crystalloid solution such as normal saline is required.
- 8 Early goal-directed therapy of sepsis consisting of hemodynamic monitoring with a central venous catheter, volume resuscitation, inotropic therapy, and red blood cell transfusions demonstrated a significant clinical outcome benefit with a 16% absolute reduction in 28-day mortality.
- 9 Recombinant human activated protein C, which has both anti-inflammatory and anticoagulant properties, was associated with a 6.1% reduction in 28-day all-cause mortality in comparison with placebo.

Sepsis represents a significant burden to the national health care system. In 2000, sepsis affected approximately 660,000 people, an increase of 8.7% per year since 1979.¹ Over half the patients were admitted to the intensive care unit (ICU) with a mean length of stay of 15.7 days.² The total number of deaths increased from 21.9 per 100,000 population in 1979 to 43.9 per 100,000 populations in 2000.¹ With the annual cost of approximately \$16.7 billion, there remains a vital need for clinicians to comprehend the pathophysiology and to appreciate the management options available for acutely ill patients with sepsis or septic shock.²

DEFINITIONS

In 1992, a joint committee of the American College of Chest Physicians and the Society of Critical Care Medicine standardized the terminology related to sepsis for several reasons: (1) widespread confusion with the use of these terms, (2) the need to provide a flexible classification scheme for patient identification, (3) identification of an earlier therapeutic intervention, and (4) standardization of research protocols.³

The criteria for the new terms provide specific physiologic variables that can be used to categorize a patient as having bacteremia, systemic inflammatory response syndrome (SIRS), sepsis, severe sepsis, septic shock, or multiple-organ-dysfunction syndrome (MODS),

suggesting an important continuum of progressive physiologic decline (Table 117–1). Introduction of the term *systemic inflammatory response syndrome* (SIRS) reflects the knowledge that a physiologically similar systemic inflammatory response can be seen even in the absence of identifiable infection^{4,5} (Fig. 117–1). It is important to note that progression from sepsis to MODS can occur in the absence of an intervening period of septic shock.

At the most recent consensus conference, the definitions were revised to include additional criteria for the diagnosis of SIRS and sepsis.⁶ A new staging system was developed to facilitate a more accurate staging of sepsis disease and the associated risks and prognosis. However, extensive testing and further refinement are needed before clinical application.

INFECTION SITES AND PATHOGENS

The leading primary sites of microbiologically documented infections that led to sepsis were the respiratory tract (40%), urinary tract (18%), and intraabdominal space (14%).⁷ While almost any microorganism can be associated with sepsis and septic shock, the most common etiologic pathogens are gram-positive bacteria, followed by gram-negative bacteria and fungi. Certain viruses and rickettsiae may produce a similar syndrome.

TABLE 117–1. Definitions Related to Sepsis

| Condition | Definition |
|---|---|
| Bacteremia (fungemia) Infection | Presence of viable bacteria (fungi) in the bloodstream. Inflammatory response to invasion of normally sterile host tissue by the microorganisms. |
| Systemic inflammatory response syndrome (SIRS) | Systemic inflammatory response to a variety of clinical insults which can be infection, but can be noninfectious etiology. The response is manifested by two or more of the following conditions: T > 38°C (100.4°F) or < 36°C (96.8°F); HR > 90 beats/min; RR > 20 breaths/min or P _a CO ₂ < 32 torr; WBC > 12,000 cells/mm ³ , < 4,000 cells/mm ³ , or > 10% immature (band) forms. |
| Sepsis Severe sepsis | The SIRS secondary to infection. Sepsis associated with organ dysfunction, hypoperfusion, or hypotension. Hypoperfusion and perfusion abnormalities may include, but are not limited to, lactic acidosis, oliguria, or acute alteration in mental status. |
| Septic shock | Sepsis with hypotension, despite fluid resuscitation, along with the presence of perfusion abnormalities. Patients who are on inotropic or vasopressor agents may not be hypotensive at the time perfusion abnormalities are measured. |
| Multiple-organ dysfunction syndrome (MODS) | Presence of altered organ function requiring intervention to maintain homeostasis. |
| Compensatory anti-inflammatory response syndrome (CARS) | Compensatory physiologic response to systemic inflammatory response syndrome that is considered secondary to the actions of anti-inflammatory cytokine mediators. |

HR = heart rate; RR = respiratory rate; T = temperature.
From ref. 3–6.

GRAM-POSITIVE BACTERIAL SEPSIS

Since 1987, gram-positive organisms are the predominant pathogens in sepsis and septic shock, accounting for approximately 50% of all cases.¹ The causes are *Staphylococcus aureus*, *Streptococcus pneumoniae*, coagulase-negative staphylococci, and enterococci. *Streptococcus pyogenes* and viridans streptococci are less commonly involved.^{7,8}

S. pneumoniae sepsis is associated with an overall mortality rate of over 25%. Factors related to a higher mortality include shock, respiratory insufficiency, preexisting renal failure, and the presence

of a rapidly fatal underlying disease. *Staphylococcus epidermidis* is related most often to infected intravascular devices, such as artificial heart valves and stents and the use of intravenous and intraarterial catheters. The rates of nosocomial enterococcal bacteremia and associated sepsis are also increasing. Enterococci are isolated most commonly in blood cultures following a prolonged hospitalization and treatment with broad-spectrum cephalosporins.

GRAM-NEGATIVE BACTERIAL SEPSIS

A greater proportion of patients with gram-negative bacteremia develop clinical sepsis, and gram-negative bacteria are also more likely to produce septic shock in comparison with gram-positive organisms (50% versus 25%, respectively).⁹

Escherichia coli is the most commonly isolated pathogen in sepsis.^{7–9} Other common gram-negative pathogens include *Klebsiella* spp., *Serratia* spp., *Enterobacter* spp., and *Proteus* spp. *Pseudomonas aeruginosa*, although not considered a predominant endogenous flora, is found widely in the environment and is the most frequent cause of sepsis fatality. These commensal organisms generally are not aggressive pathogens because normal host flora inhibit the overgrowth. However, when immunity breaks down, these organisms extend beyond normal sites and often progress from colonization to illness. With the administration of antimicrobial agents having broad spectra of activity, the protective microflora presumably are removed, thus allowing overgrowth of more virulent species. Additionally, the integrity of the gastrointestinal mucosa as a mechanical barrier is critical. The infectious implications of trauma, penetrating wounds, small surface ulcerations, mechanical obstructions, and ischemic necrosis of the bowel carry a high risk of subsequent gram-negative infection that often progresses to sepsis.

Gram-negative sepsis results in a higher mortality rate compared with sepsis from any other groups of organisms.^{10–12} The major factor

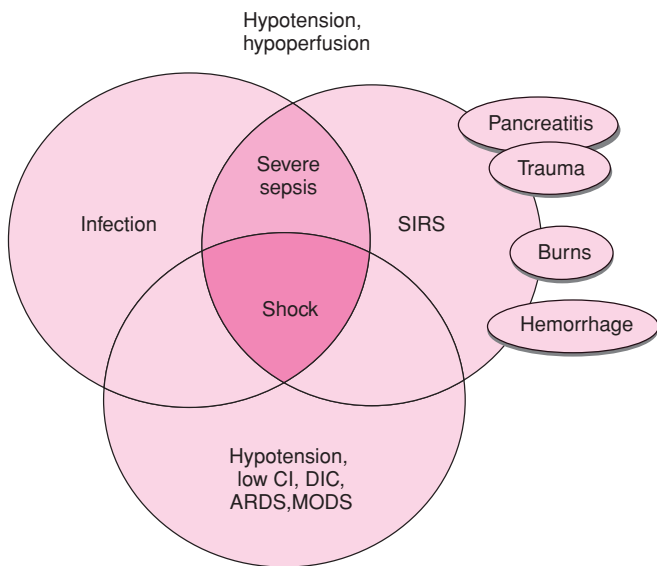

FIGURE 117–1. Relationship of infection, systemic inflammatory response syndrome (SIRS), sepsis, severe sepsis, and septic shock.

associated with the outcome of gram-negative sepsis appears to be the severity of any underlying condition. Patients with rapidly fatal conditions, such as acute leukemia, aplastic anemia, and more than 70% body surface area burn injury, have a significantly worse prognosis than do those patients with nonfatal underlying conditions, such as diabetes mellitus or chronic renal insufficiency.^{1,2,9}

ANAEROBIC AND MISCELLANEOUS BACTERIAL SEPSIS

Anaerobes usually are considered low-risk organisms for the development of sepsis. If present, anaerobes often are found together with other pathogenic bacteria that are found commonly in sepsis. Epidemiology reports suggested that polymicrobial infections accounted for 5% to 39% of sepsis.^{1,7} Mortality rates associated with polymicrobial infections are similar to sepsis caused by a single organism. Although some clinicians believe that the particular combination of organisms present in polymicrobial sepsis may provide clues to the source of infection, no clear source for the infection can be identified in up to 25% of cases. Other less common pathogens include meningococci, gonococci, rickettsiae, chlamydiae, and spirochetes.¹⁰

FUNGAL SEPSIS

2 The rate of fungal infections increased more than 200% from 1979 to 2000.¹ *Candida* spp. are common causes of fungal sepsis in hospitalized patients. While *C. albicans* remains the most dominant species, non-*albicans Candida* species, particularly *C. glabrata*, *C. parapsilosis*, *C. tropicalis*, and *C. krusei*, have emerged gradually from 24% in the 1980s to 46% between 1997 and 2000.^{11,12} Other fungi identified as causes of sepsis include *Cryptococcus*, *Coccidioides*, *Fusarium*, and *Aspergillus*. Risk factors for fungal infection include abdominal surgery, poorly controlled diabetes mellitus, prolonged granulocytopenia, broad-spectrum antibiotic treatment, corticosteroid treatment, prolonged hospitalization, central venous catheter, total parenteral nutrition, hematologic malignancy, and chronic indwelling bladder (Foley) catheter.

Mortality ranges from 41% to 71% in patients with fungemia.¹³ Hematologic diseases, neutropenia, and a higher number of positive blood cultures were associated with poor outcome irrespective of patient's gender, age, or days of antifungal drug treatment.

VIRAL SEPSIS

Viremia is common to many viral illnesses, but it does not usually lead to the development of clinical sepsis. Hypotension and disseminated intravascular coagulation (DIC) may occur with unusual viruses, such as Ebola virus and Lassa fever virus, and may be seen occasionally with influenza A, arbovirus, and possibly severe measles.¹⁰

PATHOPHYSIOLOGY

The pathophysiologic sequelae resulting from the interaction between the invading pathogen and the human host are diverse, complex, and incompletely understood.¹⁴ Definitive relationships between infection and progression to septic shock have been difficult to demonstrate. Furthermore, clinical and histopathologic changes attributed to infection may be similar to those of coexisting conditions. Finally, observations from work with animal models of sepsis are difficult to apply to humans because of potential marked differences in responses.

CELLULAR COMPONENTS FOR INITIATING THE INFLAMMATORY PROCESS

The pathophysiologic focus of gram-negative sepsis has been on the lipopolysaccharide component of the bacterial cell wall. Commonly referred to as *endotoxin*, this substance is unique to the outer membrane of the gram-negative cell wall and generally is released with bacterial lysis. Lipid A, the innermost region of the lipopolysaccharide, is highly immunoreactive and is considered responsible for most of the toxic effects observed with gram-negative sepsis. Although lipid A may affect tissues directly, its predominant effect is to activate macrophages and trigger inflammatory cascades critical in the progression to sepsis and septic shock.^{14,15} The endotoxin forms a complex with a protein called a *lipopolysaccharide-binding protein* that then engages the specific CD14 receptor on the surface of a macrophage. Subsequently, cytokine mediators are activated and released.

In gram-positive sepsis, peptidoglycan appears to exhibit proinflammatory activity. Peptidoglycan comprises up to 40% of gram-positive cell mass and is exposed on the cell wall surface. Although it competes with lipid A for similar binding sites on CD14, the potency of peptidoglycan is less than that of endotoxin.¹⁴

PRO- AND ANTI-INFLAMMATORY MEDIATORS

Sepsis involves activation of inflammatory pathways, and a complex interaction between proinflammatory and anti-inflammatory mediators plays a major role in the pathogenesis of sepsis. The key proinflammatory mediators include tumor necrosis factor- α (TNF- α), interleukin 1 β (IL-1 β), and interleukin 6 (IL-6), which are released by activated macrophages. Other mediators that may be important for the pathogenesis of sepsis include interleukin 8 (IL-8), platelet-activating factor (PAF), leukotrienes, and thromboxane A₂.^{14,16,17} The significant anti-inflammatory mediators include IL-1 receptor antagonist (IL-1ra), IL-4, and IL-10.^{15,17,18} These anti-inflammatory cytokines inhibit the production of the proinflammatory cytokines and down-regulate some inflammatory cells.

TNF- α is considered the primary mediator of sepsis.^{14–17} The TNF- α level is highly elevated very early in the inflammatory response in most patients with sepsis. In meningococemia, increased morbidity and mortality are associated with high plasma concentrations of TNF- α . TNF- α release leads to activation of other cytokines (IL-1 β and IL-6) associated with cellular damage. In addition, TNF- α stimulates the release of cyclooxygenase-derived arachidonic acid metabolites (thromboxane A₂ and prostaglandins) that contribute to vascular endothelial damage. TNF- α also causes endothelial cells to express adhesion molecules, facilitating influx of granulocytes.

The net effect of a given mediator can vary depending on the state of activation of the target cell, the presence of other mediators near the target cell, and the ability of the target cell to release mediators that can augment or inhibit the primary mediator. When the balance in the localized response is lost, the patient becomes systemically ill. As Fig. 117–2 illustrates, when there is a systemic spillover of excessive proinflammatory mediators, the patient presents with SIRS

FIGURE 117–2. The balance between pro- and anti-inflammatory mediators.

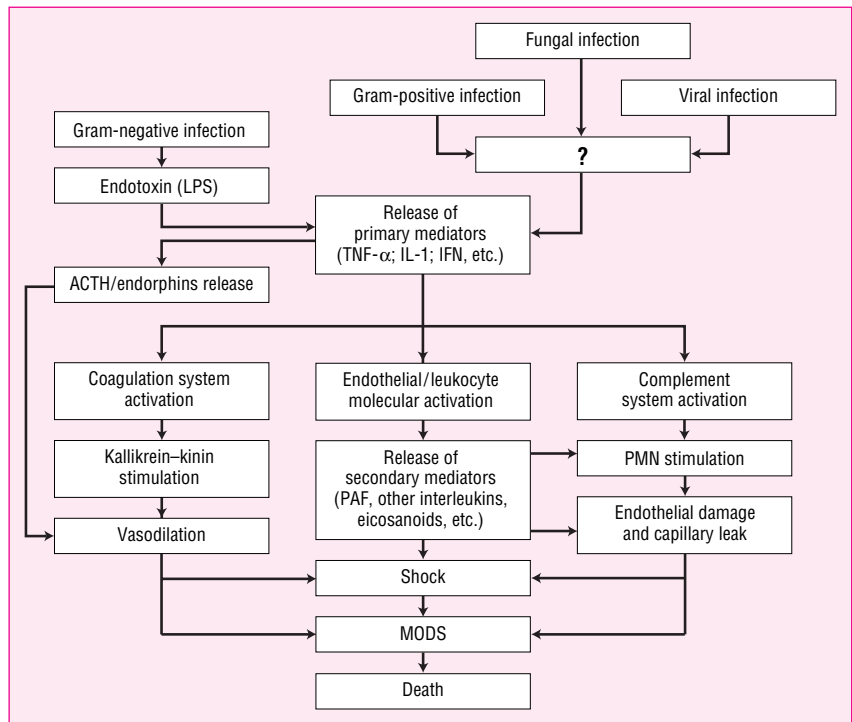

FIGURE 117-3. Cascades of sepsis. ACTH = adrenocorticotropic hormone.

and possibly MODS. Shortly after this initial phase, counterregulatory pathways become activated, and there is a systemic spillover of excessive anti-inflammatory mediators, representing a compensatory anti-inflammatory response syndrome (CARS). The balance between pro- and anti-inflammatory mechanisms determines the degree of inflammation, ranging from local antibacterial activity to systemic tissue toxicity or organ failure^{7,14,17}

CASCADE OF SEPSIS

3 The cascade leading to the development of sepsis is complex and multifactorial, involving various mediators and cell lines^{16,17,19} (Fig. 117-3). Through the actions of the mediators, a variety of cells become activated, initiating detrimental cascades. Initially, macrophages become activated and produce inflammatory cytokines. These cytokines then influence a wide range of cells, including endothelial cells, lymphocytes, hepatocytes, neutrophils, and platelets. Endothelial cells that respond to and produce a variety of cytokines mediate a primary mechanism of injury with sepsis. When injured, endothelial cells allow circulating cells such as granulocytes and plasma constituents to enter inflamed tissues, which may result in organ damage.

The microcirculation is affected by sepsis-induced inflammation.²⁰ The arterioles become less responsive to either vasoconstrictors or vasodilators. The capillaries are less perfused, and there is neutrophil infiltration and protein leakage into the venules. Pulmonary dysfunction may result from the destructive mechanisms of neutrophils that are attracted to lung tissue through the action mainly of IL-8.

Activation of complement in sepsis leads to pathophysiologic consequences including generation of anaphylactic toxins and other substances that augment or exaggerate the inflammatory response. Stimulation of leukocyte chemotaxis, phagocytosis with lysosomal enzyme release, increased aggregation and adhesion of platelets and neutrophils, and the production of toxic superoxide radicals is attributed in part to complement activation. Among these responses is

the release of histamine from mast cells and the resulting increase in capillary permeability and the “third spacing” of fluid in interstitial spaces.

The inflammatory process in sepsis is also directly linked to the coagulation system. Proinflammatory mechanisms that promote sepsis are also procoagulant and antifibrinolytic, whereas fibrinolytic mechanisms may be anti-inflammatory. A key endogenous substance involved in the inflammation of sepsis is activated protein C, which enhances fibrinolysis and inhibits inflammation. Levels of protein C are reduced in patients with sepsis.²¹

PREDICTIVE MARKERS OF SEPSIS PROGRESSION

Correlation between the plasma levels of endotoxin and cytokines and the progression of sepsis has been evaluated.²²⁻²⁶ While the TNF- α levels may be increased in patients with a variety of diseases and in many healthy people, there is a correlation of TNF- α levels with the severity of sepsis. High TNF- α levels are found in patients with septic shock. In contrast, IL-1 levels have been inconsistently associated with sepsis.²⁴ IL-6 may be a more consistent predictor of sepsis because it remains elevated for a longer period of time than does TNF- α , and it appears to be related to sepsis severity and mortality.^{23,25} Circulating concentrations of IL-8 also have been related to the severity of sepsis and mortality.²⁶ Although the plasma endotoxin concentration does not correlate with the development of gram-negative sepsis or outcome from infection, decreased antiendotoxin core immunoglobulin G concentrations are associated with increased mortality in patients with sepsis syndrome.²⁷

COMPLICATIONS

Shock is the most ominous complication associated with sepsis, and mortality occurs in approximately half the patients with septic shock. Severe hypotension appears to be caused in part by the release of

vasoactive peptides such as bradykinin and serotonin and by endothelial cell damage leading to the extravasation of fluids into interstitial spaces. Septic shock is associated with several complications, including DIC, acute respiratory distress syndrome (ARDS), and MODS.

DISSEMINATED INTRAVASCULAR COAGULATION (DIC)

Sepsis remains the most common cause of DIC. The incidence of DIC increases as the severity of sepsis increases. In sepsis alone, the incidence was 16%, in comparison with 38% in septic shock.²⁸ DIC occurs in up to 50% of patients with gram-negative sepsis, but it is also common in patients with gram-positive sepsis.

DIC begins with the activation and production of the proinflammatory cytokines such as TNF, IL-1, and IL-6, which appear to be the principal mediators, along with endotoxin, of endothelial injury, activation of the coagulation cascade, and inhibition of fibrinolysis. The combination of excessive fibrin formation, inhibited fibrin removal from a depressed fibrinolytic system, and endothelial injury results in microvascular thrombosis and DIC.²⁸

Complications of DIC vary and depend on the target organ affected and the severity of the coagulopathy. DIC may produce acute renal failure, hemorrhagic necrosis of the gastrointestinal mucosa, liver failure, acute pancreatitis, ARDS, and pulmonary failure. Furthermore, since the procoagulant state appears to be the key in the pathogenesis of MODS, coagulation dysfunction and MODS often coexist in sepsis.

ACUTE RESPIRATORY DISTRESS SYNDROME (ARDS)

Pulmonary dysfunction usually precedes dysfunction in other organs, and it may even initiate the development of SIRS with resulting MODS. In sepsis caused by *S. aureus*, pulmonary involvement was reported in 82% of the patients.²⁹ Overall mortality rate ranges from 19% to 90% depending on the causative microorganism.^{29,30}

Activated neutrophils and platelets adhere to the pulmonary capillary endothelium, initiating multiple inflammatory cascades with a release a variety of toxic substances. There is diffuse pulmonary endothelial cell injury, increased capillary permeability, and alveolar epithelial cell injury.³¹ Consequently, interstitial pulmonary edema occurs and gradually progresses to alveolar flooding and collapse. The end result is loss of functional alveolar volume, impaired pulmonary compliance, and profound hypoxemia.³²

HEMODYNAMIC EFFECTS

The hallmark of the hemodynamic effect of sepsis is the hyperdynamic state characterized by high cardiac output and an abnormally low systemic vascular resistance (SVR).³³ TNF- α and endotoxin directly depress cardiovascular function. Endotoxin depresses left ventricular function independent of changes in left ventricular volume or vascular resistance.

Persistent hypotension raises concern for the balance of oxygen delivery to the tissues (DO₂) and oxygen consumption by the tissues (VO₂).³¹ Sepsis results in a distributive shock characterized by inappropriately increased blood flow to selected tissues at the expense of other tissues that is independent of specific tissue oxygen needs. This perfusion defect is accentuated by an increased precapillary atrioventricular (AV) shunt. If perfusion decreases, oxygen extraction increases, and the AV oxygen gradient widens. Cellular DO₂ is decreased, but VO₂ remains unaffected. When increased oxygen demand

occurs without increased blood flow, the increased VO₂ is compensated by increased oxygen extraction. If perfusion decreases sufficiently in the face of high metabolic demands, then the reserve DO₂ can be exceeded, and tissue ischemia results. Significant tissue ischemia leads to organ dysfunction and failure. Therefore, systemic DO₂ relative to VO₂ should be optimized by increasing oxygen delivery or decreasing oxygen consumption in a hypermetabolic patient.

ACUTE RENAL FAILURE

Renal dysfunction such as acute oliguric or anuric renal failure occurs in approximately one-quarter of the patients, and in the event of severe sepsis and MODS, renal dysfunction is potentially lethal, with a mortality of 50% to 90%.^{2,31} Without normal urine output, fluid overload in the extravascular space, including the lungs, develops, leading to impairment of pulmonary gas exchange and severe hypoxemia. Consequently, compromised oxygen delivery would exacerbate peripheral ischemia and organ damage. Adequate renal perfusion and a trial of loop diuretics should be initiated promptly in oliguric or anuric patients with MODS. In addition, renal replacement therapy such as continuous hemofiltration should be used to facilitate volume and electrolytes.³¹

CLINICAL PRESENTATION

Table 117–2 lists some of the common clinical features of sepsis, although a number of these findings are not limited to infectious processes. The initial clinical presentation can be referred to as signs and symptoms of early sepsis, and they typically include fever, chills, and change in mental status. Hypothermia may occur with a systemic infection, and this is often associated with a poor prognosis.¹⁰ In patients with sepsis caused by gram-negative bacilli, hyperventilation may occur even before fever and chills, and it may lead to respiratory alkalosis as the earliest metabolic change.

Progression of uncontrolled sepsis leads to clinical evidence of organ system dysfunction, as represented by the signs and symptoms attributed to late sepsis. With the exception of rapidly progressing cases, as in meningococemia and *P. aeruginosa* or *Aeromonas* infection, the onset of shock is slow and usually follows a period of several hours of hemodynamic instability. Oliguria often follows hypotension. Increased glycolysis with impaired clearance of the resulting lactate by the liver and kidneys and tissue hypoxia because of hypoperfusion result in elevated lactate levels, contributing to metabolic

TABLE 117–2. Signs and Symptoms Associated with Sepsis

| Early Sepsis | Late Sepsis |
|----------------------|-----------------------------|
| Fever or hypothermia | Lactic acidosis |
| Rigors, chills | Oliguria |
| Tachycardia | Leukopenia |
| Tachypnea | DIC |
| Nausea, vomiting | Myocardial depression |
| Hyperglycemia | Pulmonary edema |
| Myalgias | Hypotension (shock) |
| Lethargy, malaise | Hypoglycemia |

| | Coma |

FIGURE 117-4. Mortality related to the number of failing organs.

acidosis. Altered glucose metabolism, including impaired gluconeogenesis and excessive insulin release, is evidenced by either hyperglycemia or hypoglycemia. The distinction between early and late sepsis is arbitrary, and it is recognized that sepsis represents a spectrum of clinical findings.

PROGNOSIS

4 As the patient progresses from SIRS to sepsis to severe sepsis to septic shock, mortality increases in a stepwise fashion. Mortality

rates are higher for patients with advanced age; preexisting disease, including chronic obstructive pulmonary disease (COPD), neoplasm, and human immunodeficiency virus (HIV) disease; ICU care; and more organ failure. Mortality increased with age from 10% in children to 38.4% in those ≥ 85 years.² ICU admission was required in 51.1% of the patients with severe sepsis, and of those patients, mortality was reported in 34.1%.² Mortality from severe sepsis and MODS is most closely related to the number of dysfunctional organs. As the number of failing organs increased from two to five, mortality increased from 54% to 100%³¹ (Fig. 117-4). Duration of organ dysfunction also may affect the overall mortality rate.

TREATMENT: Sepsis and Septic Shock

The primary goals of therapy for patients with sepsis include (1) timely diagnosis and identification of pathogen, (2) rapid elimination of the source of infection medically and/or surgically, (3) early initiation of aggressive antimicrobial therapy, (4) interruption of pathogenic sequence leading to septic shock, and (5) avoidance of organ failure. Supportive care such as stress ulcer prophylaxis and nutritional support is important to prevent complications during the stay in the ICU.

DIAGNOSIS AND IDENTIFICATION OF PATHOGEN

5 The presence of clinical features suggesting sepsis should prompt further evaluation of the patient. In addition to obtaining a careful history of any underlying conditions and recent travel, injury, animal exposure, infection, or use of antibiotics, a complete physical examination should be performed to determine the source of the infection.

A collection of specimens should be sent for culture prior to initiating any antimicrobial therapy. Generally, at least two sets of blood samples should be obtained for aerobic and anaerobic culture, as well as the samples of urine and sputum. A lumbar puncture is indicated in case of mental alteration, severe headache, or a seizure, assuming that no focal cranial lesions have been identified by computed tomographic (CT) scan. Further tests may be indicated to assess any systemic organ dysfunction owing to severe sepsis. The laboratory tests should include hemoglobin, white blood cell count with differential, platelet count, complete chemistry profile, coagulation parameters, serum lactate concentration, and arterial blood gases.³⁴

ELIMINATION OF SOURCE OF INFECTION

After the source of infection is identified, prompt efforts to remove or eliminate the source should be initiated. With an infected intravascular catheter, the catheter should be removed and cultured. Urinary tract catheters should be removed if association with sepsis is suspected. Suspicion of soft tissue (cellulitis or wound infection) or bone involvement should lead to aggressive débridement of the affected area. Evidence of an abscess or sepsis associated with any intraabdominal pathology should prompt surgical intervention.

ANTIMICROBIAL THERAPY

6 Aggressive, early antimicrobial therapy is critical in the management of septic patients because of high incidence of complications and mortality. Because of the inherent problems associated with timely identification of the infecting organism or organisms, empirical antimicrobial regimens usually are started initially. Selection of empirical regimen should be based on the suspected site of infection, the most likely pathogens, acquisition of the organism from the community or hospital, the patient's immune status, and the antibiotic susceptibility and resistance profile for the institution. All patients should be treated initially with parenteral antibiotics for optimal drug concentrations. Empirical therapy for an immunocompromised patient should consist of antimicrobial combinations likely to be

TABLE 117–3. Empirical Antimicrobial Regimens in Sepsis

| Infection (Site or Type) | Antimicrobial Regimen | | |
|-----------------------------|---|---|---------------------------------|
| | Community-Acquired | Hospital-Acquired | |
| Urinary tract | Ciprofloxacin or levofloxacin | Piperacillin or ceftazidime, ceftriaxone or ciprofloxacin, levofloxacin | } ± gentamicin |
| | Respiratory tract | Newer fluoroquinolone ^a or ceftriaxone + clarithromycin-azithromycin | |
| Intra-abdominal | β-Lactamase inhibitor combo ^b or ciprofloxacin + metronidazole | Piperacillin-tazobactam or meropenem | |
| Skin/soft tissue | Nafcillin or cefazolin | Ceftriaxone +/- vancomycin | |
| | Catheter-related Unknown | Vancomycin Piperacillin or ceftazidime-cefipime or meropenem | } +gentamicin +/- vancomycin |

^aLevofloxacin, gatifloxacin, moxifloxacin, gemifloxacin.^bAmpicillin–sulbactam, ticarcillin–clavulanic acid.

synergistic. Once the pathogen and its susceptibility pattern are known, antimicrobial regimen should be modified accordingly.

■ SELECTION OF ANTIMICROBIAL AGENTS

In a study evaluating 904 patients with microbiologically confirmed severe sepsis or septic shock, appropriate initial antimicrobial therapy was an important determinant of survival.⁷ The 28-day mortality was 24% in patients who received appropriate initial antimicrobial treatment versus 39% in those who received inappropriate initial treatment.

Table 117–3 lists antimicrobial regimens that can be used empirically based on the possible source of infection. In the nonneutropenic patient with an urinary tract infection, a third-generation cephalosporin, fluoroquinolone, or extended-spectrum penicillin, each with or without an aminoglycoside, should be considered.³⁵ *S. pneumoniae* is the most common cause of community-acquired pneumonia, and it accounts for approximately 60% of all deaths. The rising incidence of penicillin-resistant *S. pneumoniae* requires empirical use of newer “respiratory” fluoroquinolones. Newer fluoroquinolones, such as levofloxacin, gatifloxacin, moxifloxacin, and gemifloxacin, can be used as monotherapy because they offer excellent coverage against penicillin-resistant pneumococci and aerobic gram-negative bacteria, as well as atypical pathogens, including *Legionella pneumophila*, *Mycoplasma pneumoniae*, and *Chlamydia pneumoniae*.^{36,37} Newer macrolides, such as clarithromycin and azithromycin, are very effective against atypical pathogens and better tolerated than erythromycin.

In nosocomial pneumonia, enteric gram-negative bacteria such as *Enterobacter* and *Klebsiella* spp., and *P. aeruginosa* are the major pathogens in addition to *S. aureus*. If *P. aeruginosa* infection is suspected, a dual regimen of antipseudomonal penicillin or third- or fourth-generation cephalosporin and an aminoglycoside is

recommended because of the high mortality rate associated with *Pseudomonas* infection.³⁵ When an aminoglycoside is undesirable, an antipseudomonal fluoroquinolone such as ciprofloxacin or levofloxacin can be used instead. In case of methicillin-resistant *S. aureus*, vancomycin should be initiated. However, worldwide emergence of glycopeptide intermediately resistant *S. aureus* and vancomycin-resistant enterococci has led to development of alternative antimicrobial agents such as teicoplanin, quinupristin-dalfopristin, and linezolid.^{38–40}

Secondary peritonitis as a consequence of perforation of the gastrointestinal tract usually is polymicrobial, involving enteric aerobes and anaerobes, and as many as five organisms are isolated per patient. In addition to surgical intervention, broad-spectrum antibiotics such as β-lactamase inhibitor combination agents (piperacillin-tazobactam or ticarcillin-clavulanate) are appropriate in intraabdominal infections.⁴¹ Imipenem or meropenem may be indicated if resistance patterns prohibit the use of other, less expensive therapies.^{42,43} Currently, most clinicians prefer meropenem to imipenem because it offers similar activity as imipenem with less propensity to cause seizures. In a multicenter study, meropenem was efficacious and safe when compared with a combination regimen of cefuroxime and gentamicin for the treatment of sepsis syndrome in patients who were 65 years of age or older.⁴² Metronidazole is preferred over clindamycin against anaerobes because approximately 20% of *Bacteroides* spp. are resistant to clindamycin.⁴⁴

In soft tissue infection caused by group A *Streptococcus*, streptococcal toxic shock syndrome may occur. Although penicillin and cefazolin are efficacious, experimental models of group A streptococcal infection show clindamycin to be more effective than penicillin.³⁵

In addition to selecting the most appropriate antimicrobial agents, a clinician must ensure effective antibiotic usage, such as proper dosing, interval administration, optimal duration of treatment, monitoring of drug levels when appropriate, and avoidance of unwanted drug interactions. Lack of adherence to these requirements

may lead to suboptimal or excessive tissue concentrations that may promote antibiotic resistance, toxicity, and inadequate efficacy despite appropriate antibiotic selection.

■ THERAPEUTIC CONSIDERATIONS WITH AMINOGLYCOSIDES

In vitro, tobramycin appears somewhat more active (based on concentrations achievable in serum relative to usual minimum inhibitory concentration) than gentamicin against *P. aeruginosa*. Gentamicin, however, appears more active than tobramycin against *Serratia* spp. Overall, amikacin exhibits most potent in vitro activity against the *Klebsiella-Enterobacter-Serratia* group. In addition, amikacin is less susceptible than gentamicin and tobramycin to plasmid-mediated enzyme inactivation, and it should be reserved as an alternative in situations of suspected or established resistance to gentamicin and tobramycin.

CLINICAL CONTROVERSY

Although aminoglycosides traditionally have been administered in divided doses, there has been increasing acceptance of administering aminoglycosides in a single daily dose of 4 to 7 mg/kg for gentamicin and tobramycin and 10 to 15 mg/kg for amikacin.^{45–47} A single daily dose maximizes the well-defined, concentration-dependent killing activity of aminoglycosides, as well as the prolonged postantibiotic effect against gram-negative bacterial pathogens. Furthermore, nephrotoxicity is reduced significantly. With a single daily dose, there is a prolonged drug-free period during which the reported saturable or rate-limiting uptake of aminoglycosides into proximal renal tubular cells can be completed. Because of insufficient clinical data, single daily dose administration should not be used in pediatric patients, burn victims, pregnant patients, patients with preexisting or progressive renal dysfunction, or patients requiring aminoglycosides for synergy against gram-positive pathogens.

■ ANTIFUNGAL THERAPY

Candida species are associated most frequently with fungal infections, and the resulting candidemia frequently is associated with sepsis syndrome and a high mortality rate.^{11,12,48} Treatment of invasive candidiasis involves amphotericin B–based preparations, the azole antifungal agents, the echinocandin antifungal agents, or combination therapy with fluconazole plus amphotericin B. The choice depends on the clinical status of the patient, the fungal species and its susceptibility, the relative drug toxicity, the presence of organ dysfunction that would affect drug clearance, and the patient's prior exposure to antifungal agents. In general, suspected systemic mycotic infection leading to sepsis is treated frequently with parenteral amphotericin B empirically, especially if the patient is clinically unstable, because of its greater activity against *Candida* species and non-*albicans* species including *C. glabrata* and *C. krusei*.⁴⁸

Fluconazole is less toxic and easier to administer than amphotericin B. However, fluconazole resistance among *C. albicans* has been well described among HIV-infected individuals and is increasing in immunocompetent adults.⁴⁸ *C. glabrata* often has reduced susceptibility to fluconazole. Itraconazole exhibits a similar activity profile to fluconazole and is well known to be active against mucosal forms of candidiasis. However, formal clinical trials using intravenous

itraconazole are not available for invasive candidiasis. Voriconazole appears to be active against *Candida* species, including fluconazole-resistant isolates. A recently completed worldwide study will aid in analyzing voriconazole for the indication of treatment of serious invasive, fluconazole-resistant *Candida* infections including *C. krusei*.⁴⁸

CLINICAL CONTROVERSY

Three new lipid formulations of amphotericin (amphotericin B lipid complex, amphotericin B cholesteryl sulfate, and liposomal amphotericin B) offer several advantages over amphotericin B deoxycholate.⁴⁹ They are less nephrotoxic, allow increased daily doses, have high tissue concentrations in the reticuloendothelial organs such as lungs, liver, and spleen, and have decreased infusion-associated side effects. However, superior clinical efficacy over the conventional amphotericin B or between the lipid formulations has not established clearly in comparative clinical trials. Higher cost and the lack of overall benefit of using a lipid formulation have led to placing the lipid-associated preparations as primarily for patients who are intolerant of or have an infection refractory to the deoxycholate preparation.⁵⁰ However, recent data reported an association of amphotericin B–induced nephrotoxicity with increased mortality, up to 6.6-fold, suggesting the use of a lipid formulation initially for patients at high risk of being intolerant.^{48,51}

Caspofungin, the first echinocandin antifungal agent, appears to be potent against all *Candida* spp., including *C. glabrata*, *C. krusei*, and *C. lusitanae* and *Aspergillus* spp. Intravenous caspofungin was reported to be equally effective but better tolerated than amphotericin B deoxycholate for invasive candidiasis.⁵²

■ ANTIVIRAL THERAPY

When sepsis is caused by a systemic viral infection, parenteral antivirals such as acyclovir, ganciclovir, foscarnet, or ribavirin are used, depending on the suspected or documented viral pathogen. Aerosol administration of ribavirin may be indicated in serious illness secondary to respiratory syncytial virus.

■ DURATION OF THERAPY

The average duration of antimicrobial therapy in the normal host with sepsis is 10 to 14 days.^{7,48} However, the duration may vary depending on the site of the infection, as well as the overall response to therapy. After the patient is stable hemodynamically, has been afebrile for 48 to 72 hours, has a normalizing white blood cell (WBC) count, and is able to take oral medications, then a step-down from parenteral to oral antibiotics can be considered for the remaining duration of therapy. Treatment may continue considerably longer if the infection is persistent. In a neutropenic patient, therapy usually is continued until the patient is no longer neutropenic and has been afebrile for at least 72 hours.

■ HEMODYNAMIC SUPPORT

A high cardiac output and a low systemic vascular resistance characterize septic shock. Patients may have hypotension as a result of

low systemic vascular resistance and abnormal distribution of blood flow in the microcirculation, resulting in compromised tissue perfusion. Because approximately half of patients with septic shock die of MOSF, they should be monitored carefully, and aggressive hemodynamic support should be initiated.

Hemodynamics change rapidly in sepsis, and noninvasive evaluation may give inaccurate assessment of filling pressures and cardiac output, requiring a right-sided heart catheter in an intensive care unit.⁵³ Hemodynamic support can be divided into three main categories: fluid therapy, vasopressor therapy, and inotropic therapy.

■ FLUID THERAPY

7 Septic patients have enormous fluid requirements as a result of peripheral vasodilation and capillary leakage.⁵³ Rapid fluid resuscitation is the best initial therapeutic intervention for the treatment of hypotension in sepsis. The goal of fluid therapy is to maximize cardiac output by increasing the left ventricular preload, which ultimately will restore tissue perfusion.⁵³ Fluid administration should be titrated to clinical end points such as heart rate, urine output, blood pressure, and mental status. An increased serum lactate level, a by-product of cellular anaerobic metabolism, should normalize as the tissue perfusion improves.

Isotonic crystalloids, such as 0.9% sodium chloride (normal saline) or lactated Ringer's solution, are used commonly for fluid resuscitation. A patient in septic shock typically requires up to 10 L of crystalloid solution during the first 24-hour period. These solutions distribute into the extracellular compartment. Approximately 25% of the infused volume of crystalloid remains in the intravascular space, whereas the balance distributes to extravascular spaces. Although this could impair diffusion of oxygen to tissues, clinical impact is unproven.

The most commonly used colloids are 5% albumin, naturally occurring plasma protein, and 6% hetastarch, a synthetic colloid formulation. These solutions offer more rapid restoration of intravascular volume because they produce greater intravascular volume expansion per quantity of volume infused. Colloids produce less peripheral edema than crystalloid, but there is no significant clinical impact. The use of colloid solutions and blood products may be particularly important if there is significant blood loss associated with sepsis or if the patient had severe preexisting anemia.

The major complications with fluid resuscitation are pulmonary and systemic edema. Aggressive volume expansion may cause an increase in pulmonary capillary pressure leading to an increase in lung water and associated hypoxemia. Currently available studies and reports suggest that there is no significant difference in the incidence of pulmonary edema between the crystalloid and colloid solutions.

A meta-analysis of clinical studies comparing crystalloid and colloid resuscitation indicated no clinical outcome differences.⁵⁴

Although crystalloid solutions require two to four times more volume than colloids, they are generally recommended for fluid resuscitation owing to the lower cost. However, colloids may be preferred, especially when the serum albumin concentration is less than 2.0 g/dL.

■ VASOPRESSOR AND INOTROPIC THERAPY

When fluid resuscitation alone provides inadequate arterial pressure and organ perfusion, vasopressors and inotropic agents should be initiated. Inotropic agents such as dopamine and dobutamine have been effective in improving cardiac output. Vasopressors should be considered when a systolic blood pressure is less than 90 mm Hg or mean arterial pressure (MAP) is lower than 60 to 65 mm Hg after adequate left ventricular preload and inotrope therapy. Although inotropes and vasopressors are effective in life-threatening hypotension and in improving cardiac index, there are significant complications, such as tachycardia and myocardial ischemia and infarction, as a result of the change in myocardial oxygen consumption in patients with coexisting coronary disease. Thus a catecholamine infusion should be titrated gradually to restore MAP without impairing stroke volume.

Agents commonly considered for vasopressor or inotropic support include dopamine, dobutamine, norepinephrine, phenylephrine, and epinephrine^{55,56} (Table 117-4). Dopamine, an α - and β -adrenergic agent with dopaminergic activity, appears to increase MAP effectively in patients who remain hypotensive with reduced cardiac function after aggressive fluid resuscitation. Thus it is often the initial choice in sepsis because of combined vasopressor and inotropic effects. While low-dose dopamine (1 to 5 mcg/kg per minute) is effective in maintaining renal perfusion, higher doses (>5 mcg/kg per minute) exhibit α and β activity and are used frequently to support blood pressure and to improve cardiac function such as an increase in cardiac index (CI).

Dobutamine is a β -adrenergic inotropic agent that many clinicians consider to be the preferred drug for improvement of cardiac output and oxygen delivery, particularly in early sepsis before significant peripheral vasodilation has occurred. Doses of 2 to 20 mcg/kg per minute increases the CI, ranging from 20% to 66%. However, heart rate often increases significantly.⁵³ Dobutamine should be considered in severely septic patients with adequate filling pressures and blood pressure but low CI.

Norepinephrine is a potent α -adrenergic agent with less pronounced β -adrenergic activity, and it can be useful in septic shock when the clinician desires potent vasoconstriction of peripheral vascular beds. Doses of 0.01 to 3 mcg/kg per minute can reliably increase blood pressure with little change in heart rate or cardiac index. Norepinephrine is a more potent agent than dopamine in refractory septic shock. Despite the earlier concern of decreased renal blood flow associated with norepinephrine, data in humans and animals demonstrate a

TABLE 117-4. Receptor Activity of Cardiovascular Agents Commonly Used in Septic Shock

| Agent | α_1 | α_2 | β_1 | β_2 | Dopaminergic |
|----------------|------------|------------|-----------|-----------|--------------|
| Dopamine | ++/+++ | ? | ++++ | ++ | ++++ |
| Dobutamine | + | + | ++++ | ++ | 0 |
| Norepinephrine | +++ | +++ | +++ | + / ++ | 0 |
| Phenylephrine | ++/+++ | + | ? | 0 | 0 |
| Epinephrine | ++++ | ++++ | ++++ | +++ | 0 |

α_1 = α_1 -adrenergic receptor; α_2 = α_2 -adrenergic receptor; β_1 = β_1 -adrenergic receptor; β_2 = β_2 -adrenergic receptor; 0 = no activity; ++++ = maximal activity; ? = unknown activity.

norepinephrine-induced renal blood flow as well as urine and cardiac output.^{55–57}

Phenylephrine, a selective α_1 -agonist, has a rapid onset, short duration, and primary vascular effects, making it an attractive agent in the management of hypotension associated with septic shock. The limited available information suggests that it can increase blood pressure in fluid-resuscitated patients, and it does not appear to impair cardiac or renal function. Phenylephrine appears useful when tachycardia limits the use of other vasopressors.

Epinephrine, a nonspecific α - and β -adrenergic agonist, is capable of increasing CI and producing significant peripheral vasoconstriction in doses of 0.1 to 0.5 mcg/kg per minute. However, because of its undesirable effects, including a propensity to increase lactate level and to impair blood flow to the splanchnic system, it should be reserved for patients who fail to respond to traditional therapies for increasing or maintaining blood pressure.

During hypotension, endogenous vasopressin levels increase and maintain arterial blood pressure by vasoconstriction. However, there is a vasopressin deficiency in septic shock. Low doses of vasopressin (0.01 to 0.04 units/min) have been demonstrated to produce a significant rise in MAP in septic shock, leading to the discontinuation of other vasopressors.^{55,58} While it may be beneficial to patients requiring high-dose vasopressors, routine use is not currently recommended owing to a lack of large, randomized, prospective clinical trials.^{55,57}

In summary, for the septic patient with clinical signs of shock and significant hypotension unresponsive to aggressive fluid therapy, dopamine is the preferred agent for increasing the blood pressure. If dopamine does not produce the desired hemodynamic response, norepinephrine can be used. Epinephrine should be considered for refractory hypotension. Dopamine and epinephrine are more likely to induce or exacerbate tachycardia than norepinephrine and phenylephrine. In a septic patient with low CI after adequate fluid therapy and an adequate MAP, dobutamine is the first-line agent. Alternatively, dopamine in moderate doses (5 to 10 mcg/kg per minute) also can be used as an initial agent because of its selective effect on increasing cardiac output with its minimal effect on the systemic vascular resistance.

EARLY GOAL-DIRECTED THERAPY

8 A trial evaluated the timing of the goal-directed therapy involving adjustments of cardiac preload, afterload, and contractility to balance oxygen delivery with demand prior to admission to the intensive care unit. The mortality rate was 30% in the group receiving early goal-directed therapy including a placement of central venous catheter, more fluid than with traditional therapy, dobutamine therapy to a maximum of 20 mcg/kg per minute, and red blood cell transfusions during the first 6 hours. In comparison, the mortality rate was 46.5% in the traditional therapy group consisting of fluid resuscitation followed by vasopressor therapy if required.⁵⁹ Increased oxygen delivery from the red blood cell transfusions in the early goal-directed therapy group appeared to be the primary difference between the two groups.

ADJUNCTIVE THERAPIES

ARDS and hypoxia are common in septic patients, even in septic patients without pulmonary infection. Oxygen therapy is indicated to

maintain oxygen saturation greater than 90%, and with progressive pulmonary insufficiency, the patient may require assisted ventilation.

The management of patients with ARDS is primarily supportive. Uncontrolled reports suggest that intravenous methylprednisolone in doses of 75 to 250 mg every 6 hours may improve survival in severely ill patients with refractory late ARDS.^{60,61} Ketoconazole reduced the progression to ARDS and increased survival in a small study of septic surgical patients, possibly as a result of its inhibitory effects on alveolar macrophage production of leukotriene B₄ and thromboxane A₂.⁶²

Nitric oxide (NO), a potent endogenous vasodilator, improved arterial oxygenation and reduced pulmonary artery pressures in patients with ARDS. However, it is also associated with hypotension, as well as being a mediator of sepsis-induced refractoriness to the vasopressor effects of catecholamines.⁶³ Additional work is needed to define any role for NO and ketoconazole in the management of sepsis.

Hyperglycemia frequently is associated with sepsis, and it is usually quite refractory to exogenous insulin. Intensive insulin therapy, maintaining blood glucose level at 80 to 110 mg/dL resulted in lower morbidity and mortality among critically ill patients in comparison with those with blood glucose levels of 180 to 200 mg/dL.⁶⁴ Insulin therapy also reduced the rate of death from multiple-organ failure among patients with sepsis, regardless of presence of diabetes prior to sepsis.

The corticosteroids have been the subject of much controversy in the management of septic patients.^{65,66} Corticosteroids suppress the activation of polymorphonuclear leukocytes, complement activation, release of TNF, and activation of the coagulation system involved in the cascades of sepsis. A recent study demonstrated a decrease in mortality (absolute reduction of 10%) with lower doses of hydrocortisone and fludrocortisone in patients with adrenal insufficiency requiring high-dose or increasing vasopressor therapy within the first 8 hours of septic shock.⁶⁷ There was no benefit for those patients without adrenal insufficiency. In summary, routine use of corticosteroids in patients with sepsis or septic shock is not recommended until further study.

Heparin therapy for DIC is discouraged by most clinicians because there is no evidence that heparin prolongs the survival of patients despite its effect on the hypercoagulable condition found in DIC.⁶⁸ Hemorrhage is best managed by the replacement of clotting factors, platelets, and packed red blood cells.

Patients with severe sepsis are susceptible to progressive malnutrition secondary to the hypermetabolism associated with severe illness and injury.⁶⁹ Hence early enteral nutrition is recommended in patients with severe sepsis and septic shock to meet the increased energy and protein requirements. Protein requirements are increased to 1.5 to 2.5 g/kg per day, and increased amounts of branched-chain amino acids may be beneficial in septic patients.⁷⁰ Nonprotein caloric requirements range from 25 to 40 kcal/kg per day, and overfeeding of carbohydrates should be avoided to reduce the ventilatory requirements of the patient. The use of increased amounts of lipid to meet nonprotein caloric needs while reducing carbohydrate administration may be useful in this setting.

IMMUNOTHERAPY

A number of strategies have been used to reverse or control the inflammatory process initiated during sepsis⁷¹ (Table 117–5). Despite the initial enthusiasm in immunotherapeutic interventions for sepsis,

TABLE 117-5. Summary of Selected Clinical Trials for Sepsis

| Experimental Agent | Comments |
|---|--|
| HA-1A (antilipid A MAb) | No overall benefit; favorable trend in meningococemia (preliminary report) |
| E5 (antilipid A MAb) | No overall benefit; improved organ dysfunction in some subgroups |
| Interleukin 1 receptor antagonist | No overall benefit |
| Platelet-activating factor inhibitors | No overall benefit; favorable trend in gram-negative sepsis |
| Bradykinin antagonists | No overall benefit; favorable trend in gram-negative sepsis |
| Anti-TNF MAb | No overall benefit; some evidence of improvement in subgroups of shock patients |
| TNF receptor: immunoglobulin constructs | Phase II: p75 receptor worsened outcome ($p < .01$); p55 receptor no overall benefit in phase III despite favorable trends in phase II |
| L-N-Monomethylarginine | No overall benefit, preliminary report |

overall results generally have been disappointing with the exception of recombinant human activated protein C (Drotrecogin-alfa).

9 Recombinant human activated protein C, the first anti-inflammatory agent to be approved for sepsis, promotes fibrinolysis and associated anti-inflammatory mechanisms. The Recombinant Human Activated Protein C Worldwide Evaluation in Severe Sepsis (PROWESS) trial studied the effects of 96 hours of continuous infusion of recombinant activated protein C.²¹ All-cause mortality at 28 days was reduced significantly from 30.8% with placebo to 24.7% in those receiving activated protein C.

The debate regarding certain aspects of the study design, patient selection, and safety continues.^{72,73} A higher incidence of serious bleeding occurred during the 28-day period in the activated protein C group (3.5%) than in the placebo group (2.0%).²¹ Despite the controversy, activated protein C appears to have a significant role in the treatment of septic shock. Subgroup analysis of the four stratified Acute Physiology and Chronic Health Evaluation (APACHE) II and recent cost-benefit analysis studies suggests the patients with APACHE II scores greater than 25 are the optimal candidates for activated protein C therapy.^{21,74,75}

ABBREVIATIONS

APACHE: Acute Physiology and Chronic Health Evaluation
 ARDS: acute respiratory distress syndrome
 CARS: compensatory anti-inflammatory response syndrome
 CI: cardiac index
 DIC: disseminated intravascular coagulation
 Do₂: oxygen delivery to tissues
 ICU: intensive care unit
 IL: interleukin
 MAP: mean arterial pressure
 MODS: multiple organ dysfunction syndrome
 NO: nitric oxide
 PAF: platelet-activating factor
 SIRS: systemic inflammatory response syndrome
 SVR: systemic vascular resistance
 TNF: tumor necrosis factor
 Vo₂: tissue oxygen utilization
 WBC: white blood cell

SUPERFICIAL FUNGAL INFECTIONS

Thomas E. R. Brown and Thomas W. F. Chin

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Vulvovaginal candidiasis (VVC) can be classified as uncomplicated or complicated. This classification is useful in determining appropriate pharmacotherapy.
- 2 *Candida albicans* is the major pathogen responsible for VVC. The number of cases of non-*albicans* species appears to be increasing.
- 3 Signs and symptoms of VVC are not pathognomonic, and reliable diagnosis must be made with laboratory tests.
- 4 *Candida albicans* is the predominant species causing all forms of mucosal candidiasis. A number of host and exogenous factors have been identified as important risk factors predisposing an individual to the development of mucosal candidiasis. In oropharyngeal and esophageal candidiasis, the key risk factor is impaired host immune system.
- 5 A topical agent is the first choice for treating oropharyngeal candidiasis, whereas systemic therapy may be used in patients not responding to an adequate trial of topical treatment or unable to tolerate topical agents and in those at high risk for systemic candidiasis. Fluconazole and itraconazole solution are the most effective azole agents.
- 6 In esophageal candidiasis, topical agents are not of proven benefit; fluconazole or itraconazole solution is the first choice.
- 7 It is important that patients with human immunodeficiency virus (HIV) infection be on concurrent optimal antiretroviral therapy, which is important for the prevention of recurrent and refractory candidiasis.
- 8 Primary or secondary prophylaxis of fungal infection is not recommended routinely for HIV-infected patients; use of secondary prophylaxis should be individualized for each patient.
- 9 Topical agents are first-line agents for fungal skin infections. Exceptions are for the treatment of extensive or severe infection or those of tinea capitis or onychomycosis. Oral therapy is preferred in such situations.
- 10 Oral agents, in particular terbinafine and itraconazole, are first-line treatment for toenail and fingernail onychomycosis.

Superficial mycoses are among the most common infections in the world and the second most common vaginal infections in North America. Mucocutaneous candidiasis may occur in three forms, oropharyngeal, esophageal, and vulvovaginal disease, with oropharyngeal and vulvovaginal disease being the most common forms. These infections were reported in humans as far back as 1839. Over the last 15 to 20 years, the occurrence rates of some fungal infections have increased dramatically. The prevalence of fungal skin infections varies throughout different parts of the world from the most common causes of skin infections in the tropics to relatively rare disorders in the United States. This chapter reviews the pharmacotherapy of vulvovaginal candidiasis, oropharyngeal and esophageal candidiasis, and common dermatophyte infections.

VULVOVAGINAL CANDIDIASIS

1 *Vulvovaginal candidiasis* (VVC) refers to infections in individuals with or without symptoms who have positive vaginal cultures for *Candida*. Depending on episodic frequency, VVC can be classified as either sporadic or recurrent.¹ This classification is essential to understanding the pathophysiology, as well as the pharmacother-

apy, of VVC. Furthermore, VVC may be defined as *uncomplicated*, which refers to sporadic infections that are susceptible to all forms of antifungal therapy regardless of the duration of treatment, or *complicated*, in which consideration of factors affecting the host, microorganism, and pharmacotherapy all have an essential role in successful treatment.¹ Complicated VVC includes recurrent VVC, severe disease, non-*albicans* candidiasis, and abnormal host factors, including diabetes mellitus, immunosuppression, and pregnancy.¹

EPIDEMIOLOGY

Minimal information on the incidence and prevalence of VVC exists. Health care workers are not required to report cases of VVC; therefore, estimates are derived from self-reported histories. Epidemiologic data are limited because VVC usually is diagnosed without microscopy and/or cultures, and antifungal nonprescription preparations are available for self-treatment.¹ By 25 years of age, approximately 50% of college women will have had at least one episode of VVC.¹ It is rare before menarche and increases dramatically around 20 years of age, with the peak incidence between 30 and 40 years of age. It is associated with the initial act of sexual intercourse. As many as 75% of women experience one bout of symptomatic VVC in their lifetime.

Between 40% and 50% of women who experience one episode of VVC experience a second episode, and 5% experience recurrent VVC.^{2,3} Black women appear to be at higher risk of developing VVC as compared with whites (62.8% versus 55%, respectively).⁴ The incidence after menopause remains unknown.

PATHOPHYSIOLOGY

2 *Candida albicans* is the major pathogen responsible for VVC, accounting for 80% to 92% of symptomatic episodes. The remainder are caused by non-*albicans* species, with *C. glabrata* dominating.⁵ The number of cases of non-*albicans* candidiasis appears to be increasing, possibly related to the use of nonprescription vaginal antifungal preparations and short-course therapy and/or the increased use of long-term maintenance therapy in preventing recurrent infections.¹

Candida species can act as commensal members of the vaginal flora. Asymptomatic colonization with *Candida* has been found in 10% to 20% of reproductive-aged women.^{5,6} *Candida* organisms are dimorphic; blastospores are believed to be responsible for colonization (transmission and spread), whereas germinated *Candida* forms are associated with tissue invasion and symptomatic infections.⁷ To colonize the vagina, *Candida* must be able to attach to the mucosa. The attachment process is complex. Not only are candidal surface structures important for attachment, but appropriate receptors for attachment must be present in the epithelial tissue. Not all women have the same range of receptors, which may explain variation in colonization.⁶ Changes in the host's vaginal environment or response are necessary to induce a symptomatic infection. Unfortunately, in most cases of symptomatic VVC, no precipitating factor can be identified.⁷

RISK FACTORS

Several factors predispose a woman to VVC. Vulvovaginal candidiasis is not considered to be a sexually transmitted disease, although sexual factors may be important. There is a dramatic increase in the frequency of VVC when women become sexually active. In addition, oral-genital contact may increase the risk.¹ However, current guidelines do not recommend the treatment of asymptomatic partners.⁵ Contraceptive agents, including the diaphragm with spermicide, the contraceptive sponge, and the intrauterine device, increase the risk of VVC. Oral contraceptive users demonstrated increased risk of

TABLE 118–1. Clinical Presentation of Vulvovaginal Candidiasis

| | |
|------------------------|--|
| General Symptoms | Often involves both the vulva and the vagina Intense vulvar itching, soreness, irritation, burning on urination, and dyspareunia |
| Signs | Erythema, fissuring, curdy “cheese”-like discharge, satellite lesions, edema |
| Laboratory tests | Vaginal pH—normal, saline and 10% KOH microscopy—blastospores or pseudohyphae |
| Other diagnostic tests | <i>Candida</i> cultures not recommended unless classic signs and symptoms with normal vaginal pH and microscopy is inconclusive or recurrence is suspected |

candidiasis; however, these reports were with the higher-dose oral contraceptive pills, and the risk may not be as great with the lower-estrogen-dose oral contraceptives.⁸

Antibiotic use may increase the risk of VVC, but it is only significant in a small number of women. The mechanism by which antibiotics can increase the risk of VVC is unknown; colonization, however, is a prerequisite.¹ Diet (excess refined carbohydrate), douching, and tight-fitting clothing often are listed as important risk factors; however, no association has been established between these factors and increased risk of VVC.¹

CLINICAL PRESENTATION

3 The clinical presentation of VVC is given in Table 118–1.^{1,5} These signs and symptoms are not pathognomonic, and a reliable diagnosis cannot be made without laboratory tests. Self-diagnosis has a sensitivity of 35% and a specificity of 89% and a positive predictive value of 62%.⁴ More than 50% of women who had self-diagnosed VVC did not have yeast as the causative agent.⁹ Diagnosis should be based on both clinical presentation and investigations, including vaginal pH, saline microscopy, and 10% potassium hydroxide (KOH) microscopy. The vaginal pH remains normal in VVC, and microscopic investigations should detect blastospores or pseudohyphae. *Candida* cultures usually are not required in the diagnosis of uncomplicated VVC; however, they are recommended when an individual presents with classic signs and symptoms of VVC, has a normal vaginal pH, but microscopy is inconclusive or recurrence is suspected.⁵

► TREATMENT: Vulvovaginal Candidiasis

■ GOALS OF THERAPY

The goal of therapy is complete resolution of symptoms in patients who have symptomatic VVC. Test of cure is not necessary if symptoms resolve.⁵ Antimycotic agents used in the treatment of VVC do not meet the definition of being fungicidal agents because of their slower killing rate. At the end of therapy, the number of viable organisms drops below the detectable range. However, by 6 weeks after a course of therapy, 25% to 40% of women will have positive yeast cultures and remain asymptomatic.¹ Asymptomatic colonization with *Candida* does not require therapy.

■ GENERAL APPROACHES TO TREATMENT

The approach to therapy is to remove or improve any predisposing factors if they can be identified. A pharmacologic agent should have limited local and systemic side effects, a high cure rate, and easy administration. Additionally, it would be advantageous to use a therapy that is able to resolve symptoms within 24 hours, that has broad antimycotic activity (to cover increasing rates on non-*albicans Candida*), that prevents recurrence, and that can be used over a shortened period of time such as 1 to 3 days.

Avoid harsh soaps and perfumes that may cause or worsen vulvar irritation. Keep the genital area clean and dry by avoiding

constrictive clothing and frequent or prolonged exposure to hot tub use.³ Cool baths may soothe the skin.³ Daily ingestion of 240 mL yogurt containing *Lactobacillus acidophilus* decreased colonization and symptomatic infections of VVC in women with recurrent infections.¹⁰

■ PHARMACOLOGIC TREATMENTS

■ UNCOMPLICATED VULVOVAGINAL CANDIDIASIS

Cure rates for uncomplicated VVC are between 80% and 95% with topical or oral azoles and between 70% and 90% with nystatin preparations. Table 118–2 lists available topical and oral preparations for the treatment of uncomplicated VVC. There are many topical non-prescription preparations for the treatment of VVC. No significant differences in *in vitro* activity or clinical efficacy exist between the topical azole agents.^{1,3,5} The selection of a topical azole should be based primarily on an individual patient's preference as to product formulation. Some topical products may cause vaginal burning, stinging, or irritation; on the other hand, the vehicle used in topical creams or gels can provide initial symptomatic relief.¹ Of note, though, most topical preparations can decrease the efficacy of latex condoms or diaphragms.

Oral azoles have been used in the treatment of VVC. Patients' prefer oral therapy because of its convenience.¹¹ Oral and topical therapy are therapeutically equivalent.¹ In the treatment of uncomplicated VVC, the duration of therapy is not critical. Cure rates with different lengths of treatment have not demonstrated that one therapy is significantly better.^{12,13} Shorter-duration therapies (e.g., clotrimazole 1-day therapy) consist of higher concentrations of azoles that maintain the

local therapeutic effect for up to 72 hours and allow for resolution of signs and symptoms.¹⁴ A review of 14 trials that examined 1-day treatments showed less than 7% difference in short-term cure rates or improvement between any two treatments in any two studies and no significant differences in short- or long-term clinical cure rates among 1-day regimens.¹²

If the vulva is significantly irritated, topical application of a low-potency corticosteroid may be beneficial.^{1,3,5} Anecdotal evidence suggests that high-potency corticosteroids may exacerbate the burning sensation initially.¹ Table 118–2 lists the therapeutic options for the treatment of uncomplicated VVC.

■ COMPLICATED VULVOVAGINAL CANDIDIASIS

Complicated VVC occurs in patients who are immunocompromised or have uncontrolled diabetes mellitus.¹ The main approach to the treatment of these individuals is to increase the length of therapy. Current recommendations are to lengthen therapy to 10 to 14 days regardless of the route of administration.¹⁶ Therapeutic options include those listed in Table 118–2; however, regimens should be continued for 10 to 14 days. In a study of patients experiencing severe infections, better outcomes were achieved with 7-day topical azole therapy compared with single-dose fluconazole.¹⁶ Length of therapy also should be extended in infections caused by non-*albicans* species. Most of these organisms have higher minimum inhibitory concentrations (MICs) to the azoles compared with *C. albicans*. They are still susceptible to the azoles but require a longer duration of treatment.¹

VVC during pregnancy also may be considered complicated because consideration of host factors such as hormonal changes that

TABLE 118–2. Treatment for Uncomplicated Vulvovaginal Candidiasis

| Active Ingredient | Preparation | Regimen |
|--|---------------------|-------------------------------|
| Over the Counter/Topical Vaginal Products | | |
| Butoconazole | 2% cream | 1 applicator × 3 days |
| Clotrimazole | 1% cream | 1 applicator or |
| | 100-mg tablet | 1 100 mg tablet × 7 days |
| Miconazole ^a | 2% cream | 1 applicator or |
| | 200-mg tablet | 1 200 mg tablet × 3 days |
| | 10% cream | 1 applicator or |
| | 500-mg tablet | 1 500 mg tablet × 1 day |
| Ticonazole | 2% cream | 1 applicator or |
| | 100-mg suppository | 1 100 mg suppository × 7 days |
| | 200-mg suppository | 1 200 mg suppository × 3 days |
| Terconazole | 1200-mg ovule | 1 ovule × 1 day |
| | 6.5% cream | 1 applicator or |
| | 300-mg ovule | 1 ovule × 1 day |
| Prescription/Topical | | |
| Econazole | 150-mg tablet | 1 tablet × 3 days |
| Fenticonazole | 2% cream | 1 applicator × 7 days |
| Nystatin | 100,000-unit tablet | 1 tablet × 14 days |
| Terconazole | 0.4% cream | 1 applicator × 7 days |
| | 0.8% cream | 1 applicator or |
| | 80-mg suppository | 1 suppository × 3 days |
| Oral Products | | |
| Ketoconazole | 200 mg | 1 tablet twice daily × 5 days |
| Itraconazole | 200 mg | 1 tablet twice daily × 1 day |
| Fluconazole | 150 mg | 1 tablet × 1 day |

^aThe U.S. Food and Drug Administration warns of possible increase in anticoagulant effects of warfarin with concomitant use.

can affect normal flora are essential in selecting therapeutic regimens. Topical agents are considered to be safe throughout pregnancy. Nystatin topical cream used for treating VVC was the regimen of choice in the first trimester, but recent guidelines recommend the use of topical azoles and that 10 to 14 days of treatment may be necessary.⁵ Oral agents are contraindicated in pregnancy because of the concern for fetal complications. However, a prospective assessment of pregnancy outcomes in 226 women exposed to fluconazole in the first trimester did not indicate increased risk of congenital abnormalities or other adverse outcomes.¹⁷ The median dose of fluconazole was 200 mg, with 46.5% of the cohort receiving a single dose of fluconazole 150 mg.

■ RECURRENT VULVOVAGINAL CANDIDIASIS

Recurrent vulvovaginal candidiasis (RVVC) is defined as having more than four episodes of VVC within a 12-month period.^{1,5} Fewer than 5% of women develop RVVC, and its pathogenesis is poorly understood. A proper diagnosis should be obtained to rule out other infections or nonmycotic contact dermatitis. Most of the therapies are empirical and not based on proper randomized, controlled trials.⁵ Treatments include induction therapy, which should be administered for a minimum of 14 days or until clinical remission and negative cultures have been obtained.¹ Table 118–2 lists the medications used for induction therapy. Induction therapy should be followed by a

maintenance regimen that is used for 6 months. The following are recommended maintenance regimens:

- Clotrimazole 500 mg vaginally once weekly for 6 months
- Fluconazole 100 mg once weekly for 6 months
- Ketoconazole 100 mg daily for 6 months
- Itraconazole 400 mg once monthly for 6 months

Fifty percent of women may experience a relapse after maintenance therapy is discontinued.⁵ A relapse may be treated as an individual episode if relapses are infrequent. However, if the relapses establish a repetitive pattern, then induction and maintenance regimens are indicated.¹

■ ANTIFUNGAL RESISTANT VULVOVAGINAL CANDIDIASIS

Resistance to azole antifungals should be considered in individuals who have persistently positive yeast cultures and fail to respond to therapy despite adherence to prescribed regimens.¹ These infections can be treated with boric acid or 5-flucytosine.^{18,19} Boric acid is administered as a 600-mg intravaginal capsule daily for 14 days of induction therapy, followed by a maintenance regimen of one capsule intravaginally twice weekly. Boric acid is toxic if administered orally. 5-Flucytosine cream is administered vaginally, 1000 mg inserted nightly for 7 days.

PHARMACOECONOMIC CONSIDERATIONS

There is little information on the pharmacoeconomics associated with VVC. One study examined the direct costs, including medical expenses (medications and clinic charges) and nonmedical expenses (costs of travel and time required in obtaining treatment) of VVC. Indirect costs (output loss through disability and premature death) were excluded from their estimates. The estimated total cost for all episodes of VVC in the United States in 1995 was \$1.8 billion. The costs were higher in black women compared with white women (\$34 versus \$16 per capita cost, respectively). This difference is largely a result of the higher incidence of VVC among black women and because black women tend to seek medical advice rather than relying on self-diagnosis and treatment.⁴

EVALUATION OF THERAPEUTIC OUTCOMES

Treatment of VVC will be considered to have positive outcomes if the symptoms of VVC are resolved within 24 to 48 hours and no adverse medication events are experienced. Self-assessment of symptom relief is appropriate for most cases of VVC. If symptoms remain unresolved or recur, then further testing and treatment may be required.

OROPHARYNGEAL AND ESOPHAGEAL CANDIDIASIS

Oropharyngeal candidiasis (OPC) refers to an infection of the oral mucosa, and it is usually referred to informally as *thrush*. *Candida* is the predominant fungi responsible for the majority of oral fungal infections, and *C. albicans* is the principal species causing the infection, commonly referred to as *candidiasis* (the proper but less commonly used term being *candidosis*). The infection may extend into the esophagus, causing esophageal candidiasis.

EPIDEMIOLOGY AND MICROBIOLOGY

Candida can be isolated from the oral cavity in 30% to 60% of healthy adults but usually in low numbers and with no evidence of infection.^{20,21} This is referred to as *asymptomatic colonization*. *C. albicans* is the predominant colonizing *Candida* species (70% to 80%), but any of the non-*albicans* *Candida* species may be seen.^{20,21} Colonization rates are influenced by the severity and nature of the underlying medical illness and the duration of hospitalization, as well as age (highest in infants younger than 18 months of age and in adults over age 60 years). A variety of host and exogenous factors (Table 118–3) can lead to the transformation of asymptomatic colonization to symptomatic disease such as oropharyngeal and esophageal candidiasis. *C. albicans* is the most common species causing all forms of mucosal candidiasis in humans. Although OPC usually is linked synonymously with *C. albicans* infection, a number of other *Candida* species also can be pathogenic. These include *C. glabrata*, *C. tropicalis*, *C. krusei*, *C. guilliermondi*, *C. parapsilosis*, and others.^{20,22,23} *C. krusei*, although relatively uncommon, generally is recovered from mucosal surfaces of neutropenic patients with hematologic malignancies.²⁴ Another species, *C. dubliniensis*, has been identified in both human immunodeficiency virus (HIV)-infected and noninfected patients.^{23,24} There has been a noteworthy increase in the frequency of infections caused by the non-*albicans* species, which accounted for approximately 17% of *Candida* infections by the early 1990s.²² In patients with cancer, almost half (46%) of all *Candida* infections are caused by non-*albicans* species.²⁵

The incidence of OPC has increased significantly over the past 15 to 20 years. OPC is the most common opportunistic infection in patients with HIV disease, and it may be the first clinical manifestation of the HIV infection in the majority of untreated patients. Reported prevalence rates of OPC in the HIV-positive population vary from 12% to 96%.²² However, up to 90% of untreated advanced HIV-infected patients likely have developed at least one episode of OPC at some stage during the progressive course of their disease.^{22,23} The incidence

TABLE 118–3. Risk Factors for Development of Oropharyngeal and/or Esophageal Candidiasis

| Local Factors | Potential Mechanisms |
|---|---|
| Use of steroids and antibiotics | Suppression of cellular immunity and inhibition of phagocytosis by steroids, including chronic use of inhaled and topical steroids. Alteration of endogenous oral flora by broad-spectrum antibiotics, especially when used with steroids, creates a milieu for proliferation of <i>Candida</i> due to reduced environmental and nutritional competition. |
| Dentures | Enhanced adherence of <i>Candida</i> to acrylic material of dentures, reduced saliva flow under surfaces of denture fittings, improperly fitted dentures, or poor oral hygiene; these provide a milieu conducive to survival of microorganisms. |
| Xerostomia caused by drugs (e.g., tricyclic antidepressants, phenothiazine) and chemotherapy, radiotherapy to head-neck and various diseases, e.g., Sjögren's syndrome, HIV, cancer of head-neck, bone marrow transplant recipients | Reduced dilutional and cleansing effect due to low secretion rate and low pH in saliva. Saliva and mucosa secretions have defense factors, such as lactoferrin, sialoperoxidase, lysozyme, histidine-rich polypeptide, secretory IgA antibodies, specific anti- <i>Candida</i> antibodies which help prevent adhesion and overgrowth of <i>Candida</i> . |
| Smoking Disruption of oral mucosa due to chemotherapy and radiotherapy, ulcers, endotracheal intubation trauma, and burns | Oral mucositis induced by radiation and breaks in physical barrier of oral epithelium, which is protective against invasion by microorganisms; altered rate of mucosa regeneration by cancer chemotherapy, which increases vulnerability to infection. |
| Systemic Factors | Potential Mechanisms |
| Drugs (cytotoxic agents, corticosteroids, immunosuppressants after organ transplant), omeprazole, environmental chemicals (benzene, pesticides) | Reduced immunity due to drug-induced neutropenia or cell-mediated immunity. Potent inhibition of gastric acid by proton pump inhibitors (PPI) can facilitate growth of <i>Candida</i> ; PPI also may inhibit cytotoxic effect of lymphocytes and reduce salivary secretion. |
| Neonates or elderly | Immature immune system of neonates who usually acquire infection during birth to a mother with vaginal candidiasis or from exposure to infected bottle nipples or to skin of adult care giver. Elderly—Unclear if this is the direct effect of age per se or contribution from dentures or underlying comorbidity. |
| HIV infection/AIDS | Depletion of CD4 T-lymphocytes especially below 200–300 cells/mm ³ ; anti- <i>Candida</i> protective mechanism of T-lymphocytes at a mucosal level is unclear but may be due to altered cytokines, especially gamma-interferon which inhibit transformation of <i>Candida</i> blastoconidia to the more invasive hyphal phase. |
| Diabetes | Higher than normal numbers of <i>C. albicans</i> cultured from saliva of diabetic patients. May be related to the elevated glucose levels and reduced chemotactic factor in saliva, altered neutrophil function, and reduced saliva volume and flow. |
| Malignancies (e.g., leukemia, head-neck cancer) | Use of intensive radiotherapy and chemotherapy can disrupt oral mucosa and also cause xerostomia; also prolonged use of broad-spectrum antibiotics in neutropenic patients can alter the normal oral flora. Because of the prolonged neutropenia, the principal immune defect, seen especially in leukemic patients, the initial oropharyngeal candidiasis can become systemic or invasive. |
| Nutritional deficiencies (e.g., iron, folate, vitamins B ₁ , B ₂ , B ₆ , B ₁₂ , and C) | May be related to dietary restriction or GI absorption problems. Deficiencies may serve to enhance the pathogenic potential of the candida inhabitants, alter host defense mechanisms, or change epithelial barrier integrity. |

From refs. 2, 4, 5, and 8.

of OPC increases as the level of immunity (CD4 lymphocyte cell count) decreases, and OPC occurs in approximately 60% of those with a CD4 cell count of less than 100 to 200 cells/mm³, 50% to 60% of whom will experience frequent recurrences. In non-HIV diseases, such as cancer, the incidence of OPC varies depending on the type of malignant neoplastic disease, level of immune suppression, and type and duration of treatment. OPC is reported in up to one-third of leukemic patients.²¹

After the oropharynx, the esophagus is the most common site of gastrointestinal candidiasis. The prevalence of esophageal candidiasis has increased mainly because of acquired immune-deficiency syndrome (AIDS), as well as the increased numbers of other severely immunocompromised patients.²⁴ Esophageal candidiasis is the first

opportunistic infection in 3% to 10% of HIV-infected patients and is the second most common AIDS-defining disease after *Pneumocystis jiroveci* pneumonia.²⁵ The mean incidence of esophageal candidiasis among HIV-infected patients ranges from 15% to 20%.²⁵ The incidence of esophageal candidiasis in non-HIV-infected immunocompromised patients is not well established. *C. albicans* is also the most common cause of esophageal candidiasis, accounting for approximately 80% of cases, with the rest being caused by non-*albicans* species.^{24,25}

The epidemiology of mucosal candidiasis has been affected by two factors. The widespread use of the azoles has led to a decline in the prevalence of mucosal candidiasis while leading to the emergence of refractory infections that have become difficult to treat. The

introduction of highly active antiretroviral therapy (HAART) appears to have resulted in a significant decline in the incidence of OPC and esophageal candidiasis from over 30% to under 7%.^{22,23}

PATHOPHYSIOLOGY

Significant differences exist in the virulence among *Candida* species. Although host and yeast virulence factors responsible for the pathogenesis of esophageal candidiasis are not as well known as for OPC, it is likely that they apply in both diseases. One virulence factor is the ability of the organism to adapt and survive in response to changes in the host environment.²⁴ The genes required for virulence are regulated in response to the environmental signals (i.e., temperature, pH, osmotic pressure, and iron and calcium ion concentrations). The ability of *C. albicans* to undergo reversible morphologic transition between the budding pseudohyphal and the more invasive hyphal growth forms is also a determinant of virulence, and genes are recognized to play a role.²⁴ Other virulence factors include adhesive ability of *C. albicans* to epithelial cells and proteins and ability to invade host cells by means of phospholipase and proteinase enzymes.²⁴

The presence of *Candida* usually stimulates antibody formation and cell-mediated immunity in most healthy adults without causing any signs or symptoms of infection. Effective antifungal host-defense mechanisms in the oral cavity play an important role in maintaining the colonizing organisms in low numbers for years in the absence of inflammation. The changeover of the role of *Candida* from commensal to pathogenic in the human host usually occurs when host defenses are impaired, such as the T-lymphocyte-mediated immune system and neutrophils. In HIV disease, oral carriage of yeasts and risk of mucosal invasion increase with progressive decline in CD4 cells. Cytokines, especially interferon- γ , inhibit transformation of *Candida* blastoconidia to the more invasive hyphal phase.²⁰ Neutropenic patients are at highest risk of developing candidiasis, which underscores

the importance of neutrophils in host defense against *Candida*. Several host and exogenous factors contribute to the ability of *Candida* to cause infection (see Table 118–3). Oropharyngeal candidiasis is considered one of the earliest indicators of HIV infection and is a relatively reliable indirect marker of disease progression.²² Several studies show that OPC, regardless of CD4 cell count, predicts the development of AIDS-related illnesses.^{22,25}

Although OPC usually is not a life-threatening infection, it may predispose patients to develop more invasive disease, including esophageal candidiasis.²⁵ The combined presence of OPC and esophageal symptoms is both specific and sensitive in predicting esophageal disease. The presence of OPC or esophageal candidiasis usually suggests a reduced CD4 cell count and/or elevated HIV load and may be predictive of the progression and prognosis of HIV infection. The incidence of OPC increases, especially when the CD4 cell counts fall to between 500 and 200 cells/mm³.²⁶ Esophageal candidiasis can be as common or even more common than OPC in patients with more advanced HIV infection. It occurs more commonly later in the natural history of AIDS and almost invariably at a lower CD4 count (range 10–105 cells/mm³).²⁴ In more than half of HIV-infected patients, HIV infection evolves into AIDS as early as 1 to 3 years after the appearance of oral *Candida* lesions if the HIV infection remains inadequately controlled. Thus OPC has become one of the criteria frequently used in staging systems for HIV infection. For example, the Centers for Disease Control and Prevention (CDC) classifies OPC as indicative of symptomatic HIV infection but does not similarly classify it as AIDS.²⁵

RISK FACTORS

4 Local and systemic factors, as well as characteristics of the organism itself, can increase the susceptibility of an individual

TABLE 118–4. Clinical Presentation of Oropharyngeal and Esophageal

| Oropharyngeal Candidiasis | Esophageal Candidiasis |
|--|---|
| <p>General The clinical features can be quite diverse (see Table 118–5)</p> <p>Symptoms Symptoms are diverse and range from none to sore, painful mouth, burning tongue, metallic taste, and dysphagia and odynophagia with involvement of hypopharynx.</p> <p>Signs Signs are variable and may include diffuse erythema and white patches on the surfaces of buccal mucosa, throat, tongue, or gums. Constitutional signs are absent.</p> <p>Laboratory Tests Scraping of an active lesion for microscopic examination can help confirm the diagnosis (presence of pseudohyphae and budding yeast) but is usually not necessary. Cultures are also not necessary since isolation of <i>Candida</i> does not distinguish between colonization and true infection. Cultures may be taken in patients responding poorly to therapy to determine the infecting species and to predict likely drug resistance.</p> | <p>General This usually occurs as an extension of OPC. However, the esophagus can be the only site involved. The distal two-thirds, rather than the proximal one-third, is the most common site.</p> <p>Symptoms Typically the symptoms are dysphagia, odynophagia, and retrosternal chest pain but may be asymptomatic in some patients. Although rare, epigastric pain may be the dominant symptom.</p> <p>Signs Constitutional signs, including fever, occasionally occur. Physical findings may range from a few to numerous white or beige plaques of variable size. Plaques may be hyperemic or edematous, with ulceration in more severe cases. Most advanced cases may occur with increased mucosal friability and narrowing of lumen. Uncommon complications include perforation and aortic–esophageal fistula formation.</p> <p>Laboratory Tests The best test is upper GI endoscopy (more useful than barium swallow); helps exclude other causes of esophagitis (e.g., viral, aphthous ulcers). Diagnosis is confirmed by the histologic presence of <i>Candida</i> in biopsy lesions taken during endoscopy. Cultures to look for drug-resistant <i>Candida</i> are warranted in patients who require endoscopy.</p> |

TABLE 118–5. Clinical Classification of Oropharyngeal Candidiasis

| Types | Population at Risk | Clinical Signs and Appearance |
|---------------------------------------|--|--|
| Pseudomembranous (thrush) | Neonates, patients with HIV or cancer, debilitated elderly, patients on broad-spectrum antibiotics or steroid inhalers, patients with dry mouth from various causes, smokers | Classic “cottage cheese” appearance, yellowish-white, soft plaques (or milk-curd) overlying areas of erythema on the buccal mucosa, tongue, gums and throat; plaques are easily removed by vigorous rubbing but may leave red or bleeding sites when removed; lesions on the tongue dorsum gives it a bald depapillated appearance. |
| Erythematous (acute atrophic) | Patients with HIV, patients on broad-spectrum antibiotics or steroid inhalers | Sensitive and painful erythematous mucosa with few, if any, white plaques; lesions are generally on dorsal surface of tongue or hard palate, occasionally on soft palate, but any part of mucosa can be involved; appear as flat red patches on the palate or atrophic patches on tongue dorsum with loss of papillae. |
| Hyperplastic (candidal leukoplakia) | Smokers; uncommon in patients with HIV | Thick white and adherent keratotic plaques commonly seen on the buccal mucosa and lateral border of tongue; may also see on lips and bottom of mouth; plaques cannot be easily scraped off or only partially removed. This condition is distinct from oral hairy leukoplakia, and it may progress to severe dysplasia or malignancy. |
| Angular cheilitis | Patients with HIV, denture wearers | Painful red, ulcerative, cracking or fissuring lesion at one or both corners of the mouth due to inflammatory reaction; usually lesions are small and rather punctate, but occasionally may extend in a linear fashion from the angles onto the facial skin. |
| Denture stomatitis (chronic atrophic) | Denture wearers who tend to be elderly and have poor oral hygiene | Red, flat lesions on mucosa beneath the denture and extends to right up to the denture border; more commonly located beneath a maxillary denture, although can be encountered beneath a mandibular denture. |

From refs. 1, 2, 7, and 8.

to *Candida* infections^{21,23,24,27} (see Table 118–3). Endocrine disorders besides diabetes mellitus, such as hypothyroidism, hypoparathyroidism, and hypoadrenalism, also can predispose patients to *Candida* overgrowth. Patients with primary immune deficiencies such as lymphocytic abnormalities, phagocytic dysfunction, IgA deficiency, viral-induced immune paralysis, and severe congenital immunodeficiencies are also at risk for oropharyngeal candidiasis as well as disseminated candidiasis. Oral mucosal disease, such as lichen planus, can be pre-existent causes of candidiasis. Smoking has been suggested as a predisposing risk factor. In many cases, multiple concurrent predisposing factors to candidiasis may exist; e.g., xerostomia with mucositis and a break in the epithelial surface or immunosuppression, such as might occur in a leukemic patient receiving radiation and chemotherapy. The severity and extent of *Candida* infections increase with the number and severity of predisposing risk factors.

CLINICAL PRESENTATION AND DIAGNOSIS

The clinical signs and symptoms of OPC and the locations of the lesions can be quite diverse^{20,23,24,26} (Table 118–4). Oropharyngeal candidiasis can manifest in several major forms^{20,21,26,27} (Table 118–5). A presumptive diagnosis of OPC usually is made by the characteristic appearance on the oral mucosa, with resolution of signs and symptoms after antifungal therapy. Pseudomembranous candidiasis, commonly known as *oral thrush*, is the classic and most common form seen in immunosuppressed and immunocompetent hosts. Erythematous and hyperplastic candidiasis and angular cheilitis occur less commonly in the HIV-infected population. Complaints of dysphagia and/or odynophagia in the presence of OPC, along with a therapeutic trial of antifungal, can provide a reliable presumptive diagnosis of esophageal candidiasis. If antifungal therapy does not lead to resolution, more invasive tests can be undertaken.

► TREATMENT: Oropharyngeal Candidiasis

■ DESIRED OUTCOMES

The primary desired outcome in the management of OPC is a clinical cure, i.e., elimination of clinical signs and symptoms. Even when the patient is relatively asymptomatic, it is important to treat the initial episode of OPC to avoid progression to more extensive disease. In the most severe cases, the patient’s quality of life may be impaired, and this may result in decreased fluid and food intake. Lack of appropriate treatment of OPC may lead to more extensive oral disease, especially in patients who are immunocompromised. The most serious complication of untreated OPC is extension of the in-

fection to esophageal candidiasis. Because esophageal candidiasis is more debilitating, the patient’s quality of life is more affected. It is important to initiate appropriate antifungal therapy for both OPC and esophageal candidiasis. Preventing or minimizing the number of future recurrences of both types of candidiasis is an equally important outcome. The approach depends largely on the underlying predisposing conditions. Mycologic cure is not a necessary treatment outcome because it may not be feasible or realistic given that *Candida* species exist commonly as part of the normal mouth flora.

Minimizing toxicities and drug-drug interactions of systemic antifungal agents, as well as maximizing adherence by ensuring that the

patient understands directions to take the medication appropriately, is an important secondary outcome of therapy.

GENERAL APPROACH TO TREATMENT

The management of *Candida* infections should be individualized for each patient, taking into consideration the underlying immune status, other concurrent mucosal and medical diseases, concomitant medications, and exogenous infectious sources. If possible, it is desirable to minimize all predisposing factors, such as administration of corticosteroids, chemotherapeutic agents, and antimicrobials, as well as instituting proper oral hygiene and resolving concurrent conditions such as denture stomatitis. Selection of an appropriate antifungal agent for treatment of candidiasis requires consideration of several factors, including the patient's drug adherence, adequate saliva for dissolution of solid topical medications, risk of caries from sucrose- or dextrose-containing preparations, potential drug interactions, co-existing medication conditions (e.g., liver disease may affect certain systemic drugs), location and severity of the infection, and the need for long-term maintenance therapy. Another factor that could affect drug selection is overuse of fluconazole leading to the emergence of fluconazole-resistant species of *C. albicans*, and in some cases to all azoles, and other intrinsically more resistant species such as *C. krusei*, *C. glabrata*, and *C. tropicalis*.

Topical therapies should be the first choice for localized infections. The efficacy of antifungal agents for OPC varies in different patient populations. Until the polyene antifungal agents became available in the 1950s, gentian violet, an aniline dye, was used commonly to treat oropharyngeal candidiasis.²¹ Problems with gentian violet include fungal resistance, skin irritation, and especially the un-aesthetic staining of the oral mucosa. Topical agents, such as nystatin

and clotrimazole, have been the standard of treatment for uncomplicated OPC and generally are effective for treatment in otherwise healthy adults and infants with no underlying immunodeficiencies. Topical agents are available in an assortment of formulations, including oral rinses (suspension), troches, powder, vaginal tablets, and creams. The two most common types of formulations currently used are the suspension and troches (Table 118–6).

Topical agents require frequent applications because of the short contact time with the oral mucosa; the ideal contact time is 20 to 30 minutes. Sufficient saliva is needed to dissolve clotrimazole troches, and this may be problematic for patients with xerostomia. Also, the rough surface of the tablet may become irritating to the oral soft tissue. Troches also contain dextrose, which has cariogenic potential. Nystatin suspension may be a better choice for patients with xerostomia, but it is difficult to maintain adequate contact time with the oral mucosa. Some patients complain of the unpleasant taste of nystatin, which may cause nausea and vomiting, and this is problematic in cancer patients experiencing chemotherapy-induced nausea. The high sucrose content of nystatin suspension is cariogenic in dentate patients, and it should be used with caution in diabetic patients. Topical creams, such as clotrimazole, ketoconazole, miconazole, and nystatin (usually mixed with a steroid), are more appropriate for application three times daily to the corners of the mouth in treating angular cheilitis.²⁷

Systemic therapy is necessary in patients with OPC that is refractory to topical treatment, those who cannot tolerate topical agents, and those at high risk for disseminated systemic or invasive candidiasis. Effective treatment of esophageal candidiasis generally requires the use of systemic antifungal agents. However, these agents have the disadvantage of producing more side effects (see Table 118–6) and drug-drug interactions (see Chap. 119). Fluconazole is generally well tolerated, and its absorption is unaffected by food or gastric acidity. Ketoconazole requires gastric acidity for absorption,

TABLE 118–6. Therapeutic Options for Mucosal Candidiasis

| Antifungal | Preparation | Use ^a | Treatment Dosage/Duration | Common/Significant Side Effects |
|----------------|--|------------------|---|--|
| Clotrimazole | 10-mg troche | OC | Hold 1 troche in mouth for 15–20 minutes for slow dissolution 4–5 times daily for 7–14 days | Altered taste, mild nausea, vomiting |
| Nystatin | 100,000 units/mL suspension | OC | 5-mL swish and swallow four times daily for 7–14 days | Mild nausea, vomiting, diarrhea |
| Fluconazole | 100-mg tablets | OC EC | 100–200 mg daily for 7–14 days 100–400 mg daily for 14–21 days | GI upset; hepatitis not common |
| Itraconazole | 10 mg/mL solution ^b 100-mg capsule | OC EC | 100–200 mg (solution) or 200 mg (tablets) daily for 7–14 days 200-mg for 14–21 days | GI upset; not common: hepatotoxicity, CHF, pulmonary edema with long-term use ^e |
| Ketoconazole | 200-mg tablets ^c | OC EC | 200 mg daily for 7–14 days 400 mg daily for 14–21 days | Most common are nausea, vomiting, abdominal pain, itching, headache; endocrine effects; hepatotoxicity with long-term use—elevated ALT/AST in 2–10%; severe (hepatitis, liver failure) 1:10,000 to 1:2,000. ² |
| Amphotericin B | 100 mg/mL suspension ^d 50-mg injection | RC EC | 1–5 mL swish and swallow 4–5 times daily for 7–14 days 0.3–0.6 mg/kg/day or 10–20 mg IV infusion for 10–14 days or up to 21 days | Oral: Nausea, vomiting, diarrhea with higher dose. IV: Fever, chills, sweats, electrolyte disturbance, bone marrow suppression |

^aOC = oropharyngeal candidiasis; EC = esophageal candidiasis; RC = refractory candidiasis.

^bSolution is preferred over capsule; solution taken on empty stomach, capsules taken with food ± acidic beverage.

^cBest taken with acidic beverage, e.g., Coke.

^dSuspension is not marketed; can be prepared extemporaneously by pharmacy.²³

^eSee discussion under onychomycosis.

which may be problematic in AIDS patients with achlorhydria, and hence it is best given with an acidic beverage. Itraconazole capsules also suffer from the same absorption problem. In contrast, itraconazole solution is well absorbed, best in a fasting state; in addition, the solution provides the benefit of both topical effects to the oral mucosa and systemic effects and is beneficial to patients with mucositis or swallowing problems. Whenever possible, it is generally beneficial to limit the use of systemic azole agents to prevent unnecessary drug exposure and to minimize the potential for occurrence of drug-resistant candidiasis, particularly from fluconazole resistance.

Antifungal agents generally are less efficacious in patients with HIV infection than in patients with cancer, and the time to response is also more prolonged.²⁵ In addition, treatment in HIV-infected patients usually produces a transient clinical response by lowering the quantity of organisms in the affected area without completely eradicating the yeast. The relapse rates are also higher in the HIV-infected patients than in other patient populations. As HIV infection progresses, and if antiretroviral treatment is suboptimal, patients usually experience more frequent recurrences of OPC, as well as esophageal candidiasis. In patients with HIV disease, it is equally important for them to be receiving HAART because this would provide the best prophylaxis against recolonization and recurrence of symptoms.²⁶

■ OROPHARYNGEAL CANDIDIASIS—HIV-INFECTED PATIENTS

It is appropriate to initiate therapy with topical agents for initial or recurrent episodes of OPC, provided that clinical symptoms are not severe and that there is minimal risk of esophageal involvement.^{22,26} Clinical responses with the resolution of signs and symptoms generally occur within 5 to 7 days of starting treatment.²² Clotrimazole appears to be the most effective topical agent and demonstrates comparable clinical response rates with both fluconazole and itraconazole.^{20,22,23,25} However, the mycologic cure rates generally are significantly lower and the 4-week relapse rates tend to be higher for clotrimazole as compared with the systemic triazoles.²⁵ This may be of limited clinical significance in patients receiving effective HAART owing to their decreased susceptibility to opportunistic infection. Nystatin suspension, although still used frequently, appears to be the least effective agent and is associated with frequent treatment failures and early relapses, especially in patients with advanced HIV disease or neutropenia.^{20–22,25}

Systemic oral azoles should be reserved for use in the more severe episodes of OPC unresponsive to topical agents or in patients with concurrent esophageal involvement.^{20,22,25} Although clinical response in more than 80% of patients can be obtained with 50 to 200 mg/day of fluconazole, response occurs within 10 days with the 50-mg daily dose compared to within 5 days for 100- to 200-mg daily doses even for the most intractable forms of OPC.²⁰ The lower dose potentially may contribute to selection of resistance. Itraconazole oral solution with an improved absorption profile compared with the capsule formulation is comparable with fluconazole with respect to clinical and mycologic response and relapse rates.^{23,25} A 14-day treatment course of itraconazole seems to be more effective than a 7-day course—the shorter course is associated with lower rates of mycologic cure and higher relapse rates. Itraconazole solution can be used as first-line therapy for OPC, and it may be used for cases not responding to fluconazole.^{22,25,28} In clinical practice, fluconazole usually is the systemic azole agent of choice because of its favorable absorption, safety, and drug-interaction profiles.

CLINICAL CONTROVERSY

Ketoconazole was the first oral systemic azole agent to be used successfully to treat OPC in patients with malignancy and AIDS.²⁰ However, use of ketoconazole generally has fallen out of favor because of its potential for greater toxicity and drug interactions and lower efficacy.^{20,22} In several comparative trials, the clinical efficacy was greater with the newer triazoles such as fluconazole and itraconazole (>85%) than with ketoconazole (62% to 83%). Mycologic cure rates and relapse-free periods also generally are better with fluconazole and itraconazole than with ketoconazole.^{23,25}

■ OROPHARYNGEAL CANDIDIASIS—NON-HIV-INFECTED PATIENTS

This patient population includes patients with hematologic malignancy (e.g., leukemias) or blood and marrow transplant (BMT) with a long duration of neutropenia and chronic graft-versus-host disease, patients with solid tumors, patients with solid-organ transplants who are receiving immunosuppressive therapy, and patients with diabetes mellitus; as well as patients on prolonged courses of antibiotics or corticosteroids and the debilitated elderly. Factors to consider in deciding whether to use topical or systemic antifungal therapy include the severity and extent of mucosal involvement (oropharyngeal versus esophageal), predisposing risk factors, and risk for dissemination. Patients who develop neutropenia (e.g., leukemic and BMT patients) are usually at high risk for disseminated and invasive fungal disease, and treatment of oral candidiasis is more aggressive. Patients with cell-mediated immune deficits but normal or near-normal granulocyte function and number (e.g., solid tumors, solid-organ transplants, or diabetic patients) are at low risk for dissemination of infection.

Specific antifungal therapy may be unnecessary for asymptomatic patients at relatively low risk for disseminated candidiasis, such as those who are not granulocytopenic or who are expected to have a short duration of granulocytopenia.²⁹ Many of these infections will clear spontaneously after recovery of the granulocytes or discontinuation of antibiotic and/or immunosuppressive therapy. However, antifungal therapy usually is required for patients who have persistent infection or significant symptoms, usually pain, or who are granulocytopenic with a relatively high risk of fungal dissemination.²⁹ Topical agents first may be given a therapeutic trial depending on the severity of infection and degree of immunosuppression. Although both nystatin and clotrimazole can be effective in treating OPC, nystatin suspension does not effectively reduce the incidence of either oropharyngeal or systemic *Candida* infections in immunocompromised patients receiving chemotherapy or radiation; its use often is associated with treatment failures and early relapses.^{21,29,30} Clotrimazole appears to be more effective in reducing colonization and treating acute episodes in cancer patients who are immunocompromised.

Systemic azole agents are used for treating OPC in patients who have failed or who are unable to take topical therapy.^{21,28,29} The preceding discussion on the relative efficacy of fluconazole, itraconazole, and ketoconazole in HIV-infected patients may be extrapolated to the non-HIV-infected population. Fluconazole 100 to 200 mg daily is used more commonly because of more extensive experience with its use, and it is more effective and has a more favorable absorption and side-effect profile compared with ketoconazole.^{23,25} If the oral route is not feasible for reasons such as severe chemotherapy-induced mucositis, fluconazole may be administered intravenously. In patients unresponsive to azoles, intravenous amphotericin B in relatively low doses

of 0.1–0.3 mg/kg per day may be tried.²⁹ Because of the higher risk for dissemination in patients who are severely neutropenic ($<0.1 \times 10^9$ neutrophils/L) or clinically unstable (hypotensive, febrile), some clinicians may prefer to initiate therapy with intravenous amphotericin B at 0.6 mg/kg per day, with therapy continued until the neutropenia has resolved.²⁹

Topical therapy with clotrimazole or nystatin for 7 days is usually adequate for treating mucocutaneous candidiasis in most solid-organ transplant patients.³¹ Use of topical therapy will reduce the number of systemic drugs that these patients receive and hence minimize the risk of drug-drug interactions. Failure to respond to topical agents warrants the use of fluconazole. Low-dose amphotericin B 5–10 mg daily for 7 to 10 days is reserved for the unusual cases of treatment failure.

Patients who develop OPC because of prolonged antibiotic use or aerosolized corticosteroids use usually can be managed successfully by discontinuation of the offending agent, and the infection usually will resolve. If there is a strong desire to treat because of discomfort or need to hasten symptom resolution or an inability to stop the offending agent, therapy with a topical agent, either clotrimazole or nystatin, is effective in most cases. The advantage of systemic azoles is the convenience of less frequent dosing. Symptoms usually improve in 3 to 4 days. Infants should be given smaller amounts more frequently (e.g., nystatin 100,000 units every 2 to 3 hours) to ensure better contact time. For denture-related OPC, the patient should be instructed on proper daily oral hygiene. Dentures should be disinfected every night by soaking in antiseptic solution, such as chlorhexidine gluconate 0.12% to 0.25%.^{27,32}

■ ESOPHAGEAL CANDIDIASIS—HIV-INFECTED PATIENTS

6 Treatment of esophageal candidiasis has not been as well studied as OPC. Because of the significant morbidity of esophageal candidiasis and the absence of evidence supporting the value of topical antifungals, treatment requires systemic antifungal agents.^{20,23} Fluconazole is superior to ketoconazole with respect to endoscopic cure and clinical response and usually produces a more rapid onset of action and resolution of symptoms.²⁵ Fluconazole is more effective than oral itraconazole capsules but is as effective as itraconazole solution.^{20,25} Patients who fail to respond to fluconazole should be treated with itraconazole solution. The use of fluconazole solution may be an effective alternative, although no comparative trials have been conducted.

In more advanced esophageal disease, oral azoles may be ineffective. Until recently, intravenous amphotericin B deoxycholate has been the alternative for patients with endoscopically proven disease who have failed fluconazole or itraconazole therapy.^{22,24} Moderate disease may be treated adequately with low- to moderate-dose amphotericin B for 10 days, although higher doses may be necessary for patients with AIDS or advanced disease.^{24,28} Voriconazole, a new triazole antifungal available in both oral and intravenous preparations, produces comparable clinical response to fluconazole.³⁷ Voriconazole has been associated with more side effects and multiple pharmacokinetic drug interactions.^{24,38}

CLINICAL CONTROVERSY

Caspofungin, the first approved drug from a new class of antifungals, the echinocandins, has been demonstrated in three clinical trials to produce comparable clinical response to fluconazole and amphotericin B for esophageal candidiasis.^{33–35} The incidence of adverse events of caspo-

fungin is comparable with that of intravenous fluconazole and significantly less than that of amphotericin B.³⁶ Caspofungin is neither a significant substrate nor an inhibitor of the cytochrome P450 enzymes or P-glycoprotein, and there are fewer drug-drug interactions.^{24,36} However caspofungin is available only as an intravenous formulation and is more expensive than fluconazole and amphotericin B deoxycholate. Caspofungin thus is an appropriate alternative for patients who have failed on oral azoles and are intolerant of amphotericin B or have preexisting renal impairment.

■ ESOPHAGEAL CANDIDIASIS—NON-HIV-INFECTED PATIENTS

As in the case of HIV-infected patients, treatment of esophageal candidiasis requires systemic therapy. Patients may be started on fluconazole 100–200 mg/day for 2 to 3 weeks.²⁸ However, higher fluconazole doses (up to 400 mg/day) have been suggested for patients with severe symptoms or those who are neutropenic.²⁹ Itraconazole solution is an effective alternative for those not responding adequately to fluconazole. If the symptoms worsen or fail to respond, intravenous amphotericin B 0.6 mg/kg per day may be used. Intravenous amphotericin B may be considered for initial therapy in neutropenic patients who present with severe symptoms or who are at high risk for dissemination of *Candida*, such as those receiving other aggressive immunosuppressive therapy (e.g., corticosteroids, total-body irradiation, or antithymocyte globulin) and who have documented evidence of esophageal candidiasis or who have failed an initial empirical trial of oral nonabsorbable agents or systemic azoles.²⁹ Amphotericin B should be continued until at least the neutropenia resolves. For patients whose symptoms have resolved and who are afebrile and clinically stable, amphotericin B should be discontinued, and the patients should be monitored closely for infection recurrence. In high-risk patients, particularly those with persistent fever and neutropenia, the potential presence of clinically occult, diffuse gastrointestinal or disseminated candidiasis should be considered. With the availability of caspofungin and voriconazole, additional alternatives are present for patients who are intolerant of amphotericin B deoxycholate or who have preexisting renal impairment.^{24,36,38}

■ ANTIFUNGAL PROPHYLAXIS

7 Ensuring that the HIV-infected patient is receiving appropriate antiretroviral therapy to enhance the immune system is perhaps the most important measure in preventing future episodes of mucosal candidiasis (oropharyngeal, esophageal, and vulvovaginal).^{22,23} Initial success of treatment often is followed by symptomatic recurrences, especially in patients with advanced HIV disease. Current evidence only supports the efficacy of fluconazole in preventing recurrences or new infections of OPC; there is insufficient evidence to support prophylactic efficacy of the other antifungals.³⁹ However, the indications for antifungal prophylaxis and the best long-term management strategy still have not been well established. Although fluconazole is effective in reducing the risk for mucosal candidiasis in patients with advanced HIV disease, it does not provide complete protection, and breakthrough infections still may occur.^{20,23} The reduced risk of recurrence of OPC also has not been demonstrated to improve survival. In addition, continuous long-term exposure to fluconazole has been associated with emergence of resistance and refractory disease.^{22,23} Thus recent guidelines from the U.S.

8

Public Health Service and the Infectious Diseases Society of America, as well as other experts in the area, do not recommend routine primary prophylaxis for OPC.⁴⁰ The rationale includes effectiveness of therapy for acute episodes of OPC, low incidence of serious invasive fungal disease, low mortality associated with mucosal candidiasis, the potential development of resistant candidiasis, the possibility of drug interactions, and the prohibitive long-term cost of prophylaxis. For the same reasons, chronic suppressive therapy (i.e., secondary prophylaxis of recurrent OPC) is also not recommended routinely, but rather clinicians should treat each acute episode as it occurs.^{22,23,40}

The decision to use secondary prophylaxis should be individualized for each patient. Some clinicians may recommend secondary prophylaxis to HIV-infected patients with multiple recurrent episodes of symptomatic OPC or when the disease is sufficiently severe and affecting the quality of life or in those who are at risk of developing esophageal candidiasis or who have advanced AIDS (e.g., CD4 cell counts below 50 cells/mm³).^{22,23,40} Patients with a history of documented esophageal candidiasis may be candidates for chronic suppressive therapy if they are experiencing disabling recurrent infections, especially if associated with malnutrition.^{24,40} Fluconazole 100 mg daily is the preferred agent for OPC and esophageal candidiasis. Once-weekly fluconazole (200 mg) is also effective for preventing OPC recurrences in those with less advanced AIDS.^{23,41} Itraconazole solution 100 mg daily may be an alternative, although it has not been evaluated in controlled trials.²³

Patients with malignant neoplastic diseases who are receiving irradiation, cytotoxic, and/or immunosuppressive therapy are at high risk for fungal infections in addition to bacterial and viral infections. The value of antifungal prophylaxis in these patients needs to be considered in the broader context of not only reducing colonization and the risk of superficial candidiasis but also, more important, reducing the risk for invasive candidiasis and improving survival. Management of these infections is discussed in detail in Chap. 120.

■ ANTIFUNGAL-REFRACTORY ORAL MUCOSAL CANDIDIASIS

Treatment of refractory or recurrent oral mucosal candidiasis (i.e., defined as clinically unresponsive to appropriate antifungal regimen) is frequently unsatisfactory, and clinical response is usually short-lived, with rapid and periodic recurrences. The key risk factors for occurrence of refractory candidiasis are advanced stage of AIDS with low CD4 cell counts (<50 cells/mm³) and repeated or prolonged courses of various systemic antifungal agents, in particular

systemic azoles.^{20,22–24} Although not necessarily the case, emergence of fluconazole-resistant *C. albicans* or selection for more resistant *Candida* species may be associated with frequent or prolonged use of fluconazole.^{22,24} An important initial management strategy is to assess and optimize the antiretroviral therapy of the patient with refractory OPC to help improve the immune function. In fact, the incidence of fluconazole-refractory OPC, previously reported to be 5% or less in advanced HIV disease, is expected to be lower with the use of effective HAART.^{22,23} It is important to identify potentially correctable causes of clinical failures of mucosal candidiasis, such as poor drug adherence, reduced drug absorption associated with hypochlorhydria, and drug-drug interactions.^{22,23}

There have been few controlled studies that assess the effectiveness of antifungals. Doubling of the fluconazole dosage to 400 or 800 mg/day may be effective in some patients with infection caused by *Candida* of intermediate resistance, although the response may be only transient.²⁰ Fluconazole oral suspension may be beneficial in some patients because of increased salivary concentrations obtained when the suspension is taken with the swish-and-swallow technique.²⁰ Itraconazole oral suspension is effective in 55% to 70% of patients; however, the benefit is short-lived if chronic suppressive therapy is not maintained, and there is a high likelihood of the development of itraconazole resistance.²⁰ Amphotericin B oral suspension is limited primarily to use in azole-refractory patients.^{22,28} It has broad spectrum activity against many fungal species and low likelihood of *Candida* resistance. There are limited data and experience on its use in immunosuppressed patients, and results from small studies have yielded mixed results, with clinical efficacy of 50% to 75% and a high relapse rate.^{22,42} It is no longer available commercially in the United States, but it may be prepared extemporaneously by the pharmacy.⁴² Patients with severe disease unresponsive to other agents require intravenous amphotericin B 0.4–0.6 mg/kg per day for 7 to 10 days to achieve clinical response; higher dose or longer treatment duration may be needed in more severe disease.^{20,23,24} After response, suppressive therapy with amphotericin B is required to increase disease-free intervals. Patients who fail to respond to amphotericin B and require more than 1 mg/kg per day may be candidates for liposomal amphotericin B preparations because of renal and/or bone marrow toxicities, although at a markedly higher cost. Flucytosine usually is not used as monotherapy because of rapid development of resistance but may be used in combination with an azole or amphotericin B.^{20,23} Newer antifungal agents, such as caspofungin and voriconazole, as discussed earlier, may be considered when current agents have failed or produce serious adverse effects.^{24,36,38} Investigational agents for future use include micafungin and anidulafungin (both echinocandins), posaconazole, and ravuconazole.²⁴

EVALUATION OF THERAPEUTIC OUTCOMES

Efficacy end points for oropharyngeal and esophageal candidiasis include rapid relief of symptoms and prevention of complications without early relapse after completion of the course of therapy. Sterilization of the oral cavity is not a feasible end point because mycologic eradication is rarely achievable, especially in HIV-positive patients. Symptomatic relief of presenting signs and symptoms generally occurs within 2 to 3 days of starting therapy, with complete resolution by 7 to 10 days. Patients should be advised about the time course and told to return for reassessment when signs and symptoms recur. It is usually unnecessary for the patient to be reassessed soon after finishing the treatment course. However, HIV patients should be questioned and examined for the occurrence of mucosa candidiasis as part

of their regular follow-up. The frequency of monitoring may be more often in neutropenic patients because of concern for dissemination of candidiasis. During the period of neutropenia, temperature should be monitored daily, as well as signs of dissemination. Hospitalized patients who are receiving intravenous amphotericin B also require daily monitoring by the pharmacist.

Efficacy of the antifungal agent is partly influenced by patient adherence to the medication regimen. Patients must be counseled on proper administration and dosing, in particular for topical agents^{27,43} (Table 118–7). The likelihood of drug-related problems pertaining to drug toxicity and drug interactions depends on which antifungal agent is used. Safety end points include monitoring for occurrence of the relevant drug side effects and drug interactions.

TABLE 118–7. Patient Counseling Tips for Managing Oropharyngeal Candidiasis^{8,24}

1. Clean the oral cavity prior to administering the topical antifungal agent. Daily fluoride rinses may help reduce the risk of caries when using an agent containing sucrose or dextrose.
2. Use the topical antifungal agent after meals as saliva flow and mouth movements can reduce the contact time.
3. Troches should be slowly dissolved in mouth, not chewed or swallowed whole, over 15 to 30 minutes and the saliva swallowed.
4. Suspension should be swished around the mouth in the oral cavity to cover all areas for as long as possible, ideally at least 1 minute, then gargled and swallowed.
5. Remove dentures while medication is being applied to the oral tissues.
6. Use a suspension instead of a troche if xerostomia is present; if a troche is preferred, the patient should rinse or drink water prior to dosing. For xerostomia, suggest nonpharmacologic measures for symptomatic relief, e.g., ice chips, sugarless gum or hard candy, citrus beverages.
7. Dentures should be removed and disinfected overnight using an antiseptic solution, e.g., chlorhexidine 0.12–0.2%. Disinfect oral tissues in addition to dental prosthesis.
8. Complete treatment course even though symptomatic improvement may occur in 48–72 hours.
9. Maintain good oral hygiene. Brush teeth daily (twice daily) and floss, rinse mouth or brush teeth after eating sweets.
10. Stop smoking; avoid alcohol.

From refs. 8 and 24.

MYCOTIC INFECTIONS OF THE SKIN, HAIR, AND NAILS

Superficial mycotic infections of the skin are referred to as *dermatophytoses*. They are common infections that usually are caused by dermatophytes classified by genera: *Trichophyton*, *Epidermophyton*, or *Microsporum*.⁴⁴ Dermatophytes have the ability to penetrate keratinous structures of the body. These infections affect both male and female genders and all races. Reservoirs of mycotic infections include humans, animals, and soil.⁴⁴ Individuals may develop an infection if they come in contact with a reservoir in addition to having a conducive environment for mycotic growth (i.e., moist conditions).⁴⁵ Risk factors for the development of an infection include prolonged exposure to sweaty clothes, failure to bathe regularly, many skin folds, sedentariness, and confinement to bed.⁴⁵

Mycotic infections of the skin have a classic appearance that consists of a central clearing surrounded by an advancing red, scaly, elevated border.⁴⁵ Infections of the nail can appear chalky and dull yellow or white and become brittle and crumbly.

Diagnosis usually is based on patient history, as well as the physical examination.⁴⁶ Diagnostic tests include direct microscopic examination of a specimen after the addition of potassium hydroxide (KOH) or fungal cultures. The KOH test is quick, inexpensive, and easy to perform, whereas cultures are more expensive and take longer to obtain results. Diagnostic tests are recommended when systemic therapy is likely to be prescribed.⁴⁶

9 A general approach to treatment of superficial mycotic infections includes keeping the infected area dry and clean and limiting exposure to the infected reservoir. Topical agents generally are considered to be first-line therapy for infections of the skin. Oral therapy is preferred when the infection is extensive or severe or when treating tinea capitis or onychomycosis.^{47–49} Table 118–8 lists spe-

cific treatments for each mycotic infection. Superficial mycotic infections are categorized by the pattern and site of infection.⁴⁴ The most commonly occurring infections in North America are detailed below.

TINEA PEDIS

Tinea pedis is the most common dermatophytoses (affecting approximately 70% of adults). It is better known as “athletes foot” and occurs in hot weather, with exposure to surface reservoirs (locker room floors), and with use of occlusive footwear.⁴⁵ Treatment with topical therapy for 2 to 4 weeks often is adequate for mild infections; however, severe infections or involvement of the nails requires oral therapy⁴⁵ (see Table 118–8). Recurrence of infection occurs in up to 70% of individuals. Prolonged treatment with either topical or systemic therapy may be required.^{46,47}

TINEA MANUUM

Tinea manuum usually involves the palmar surface of the hands, is unilateral, and may involve the feet. Treatment of this infection is similar to tinea pedis (see Table 118–8). Emollients that contain lactic acid also may be useful.⁴⁵

TINEA CRURIS

Tinea cruris is an infection of the proximal thighs and buttocks.⁴⁸ It is referred to as “jock itch” and is more common in males. The scrotum and penis often are spared from infection. Treatment with topical therapy is recommended and should continue for 1 to 2 weeks after symptom resolution. Severe infections may require oral therapy (see Table 118–8). Relief of pruritus and burning may be facilitated by the use of short-term (2 to 3 days) topical steroids (2.5% hydrocortisone).⁴⁵

TINEA CORPORIS

Tinea corporis is an infection the glabrous skin of the trunk and extremities.⁴⁸ Therapy is similar to that for tinea pedis, tinea manuum, and tinea cruris (see Table 118–8).

TINEA CAPITIS

Tinea capitis is a mycotic infection involving the scalp, hair follicles, and adjacent skin^{49,50} that primarily affects children. Treatment should consist of oral therapy, as well as the cleaning of combs and brushes, which may be contaminated² (see Table 118–8). Daily shampooing is recommended for removal of scales. Some children and adults may be asymptomatic carriers, thereby facilitating spread of the infection.⁴⁹ Family members who culture positive for tinea tonsurans should be treated with a antifungal shampoo (e.g., ketoconazole, selenium sulfide, or povidone-iodine).⁴⁹

TINEA BARBAE

Tinea barbae affects the hairs and follicles of beards and mustaches.⁴⁹ Treatment is similar to that for tinea capitis (see Table 118–8). Removal of the beard or mustache is recommended.⁴⁵

PITYRIASIS VERSICOLOR

Hyperpigmented and hypopigmented scaly patches characterize pityriasis versicolor. These patches are found on the trunk and

TABLE 118–8. Treatment of Mycoses of the Skin, Hair, and Nails

| | Topical ^{a,b} | Oral ^c |
|-----------------------|--|--|
| Tinea pedis | Butenafine, daily | Fluconazole 150 mg 1 × per wk 1–4 wks |
| Tinea manuum | Ciclopirox, twice daily | Ketoconazole 200 mg daily × 4 wks |
| Tinea cruris | Clotrimazole, twice daily | Itraconazole 200–400 mg/day × 1 wk |
| Tinea corporis | Econazole, daily | Terbinafine 250 mg/d × 2 wks |
| | Haloprogen, twice daily | |
| | Ketoconazole cream, daily | |
| | Miconazole, twice daily | |
| | Naftifine cream, daily; gel, twice daily | |
| | Oxiconazole, twice daily | |
| | Sulconazole, twice daily | |
| | Terbinafine, twice daily | |
| | Tolnaftate, twice daily | |
| | Triacetin cream, solution, three times daily | |
| | Undecylenic acid, various preparations apply as directed | |
| Tinea capitis | Shampoo only in conjunction with oral therapy or for treatment | Terbinafine 250 mg/d 4–8 wks |
| Tinea barbae | of asymptomatic carriers | Ketoconazole 200 mg daily × 4 wks |
| | Ketoconazole 2 × per wk × 4 wks | Itraconazole 100–200 mg/day × 4–6 wks |
| | Selenium sulfide daily × 2 wks | Griseofulvin 500 mg/day × 4–6 wks |
| Pityriasis versicolor | Clotrimazole, twice daily | Ketoconazole 400 mg × 1 |
| | Econazole, daily | Fluconazole 400 mg × 1 |
| | Haloprogin, twice daily | Itraconazole 200 mg daily × 3–7 days |
| | Ketoconazole, daily | |
| | Miconazole, twice daily | |
| | Oxiconazole cream only, twice daily | |
| | Sulconazole, twice daily | |
| | Terbinafine, twice daily | |
| | Tolnaftate, three times daily | |
| Onychomycosis | Ciclopirox nail lacquer apply solution at night for up to 48 wks | Terbinafine 250 mg/d × 6 wks (finger), 12 wks (toe) |
| Fingernail | | Itraconazole ^a 200 mg twice daily × 1 wk per month for 2 months (finger), for 3 months (toe), or 200 mg daily for 2 months (finger), for 3 months (toe) |
| Toenail | | Fluconazole 150–300 mg once weekly × 3–6 months (finger), × 6–9 months (toe) |

^aOther products are available, including combination products.

^bLength of therapy depends on mycotic sensitivity and severity of infection.

^cOnly capsule formulation studied; give with food for increased absorption.

extremities.⁵¹ It is more common in adults and in areas with tropical ambient temperatures. Topical treatment usually is adequate unless there is extensive involvement, recurrent infections, or failure of topical therapy⁵¹ (see Table 118–8).

ONYCHOMYCOSIS (TINEA UNGUIUM)

Onychomycosis is a fungal infection of the nail apparatus, and it is a common condition that accounts for up to 50% of all nail problems.⁵² Onychomycosis more commonly affects the toenails, approximately 80% of cases, than the fingernails.² The dermatophyte *Trichophyton rubrum* is responsible for over 90% of onychomycosis.^{52–54} Less common fungi causing onychomycosis are the yeasts (mainly *C. albicans*) and nondermatophyte molds.^{52,54} There are four major clinical presentations of onychomycosis, of which the distal subungual is the most common type. In distal subungual infection, the nail plate, nail bed, and matrix areas are all affected.^{52,53} The worst case of onychomycosis is progression of the infection to total dystrophic onychomycosis, characterized by almost complete destruction of the nail plate.^{52,53} The prevalence of onychomycosis is higher with increasing age (especially above age 40 years), familial history, smoking, peripheral vascular disease, diabetes mellitus, and HIV disease.⁵² It

is important to differentiate onychomycosis from other causes of nail abnormalities so that the patient receives appropriate therapy and is not subjected to prolonged treatment with unnecessary drugs. Besides clinical history and physical examination, proper diagnosis of onychomycosis may include direct microscopy of nail scrapings to look for fungal hyphae, fungal cultures, and histology.^{52,55} Onychomycosis merits proper treatment because it can exert a negative impact on quality of life (cosmetic and psychosocial reasons, pain, discomfort, and decreased ambulation); it can lead to complications such as cellulitis or reduced mobility, which further compromises peripheral circulation in those with diabetes or peripheral vascular disease; and infected nails can serve as a source for transmission of fungi to other areas of the body, as well as to other people, such as close household contacts or in communal bathing places.^{53,55,56} The primary end point of treatment is eradication of the organism, with secondary end points being clinical cure or improvement.⁵³ Successful eradication of the fungus does not always result in normalization of the nails because they may have been dystrophic prior to infection.

10 Systemic therapy is the preferred route of treating onychomycosis. Terbinafine and itraconazole (capsule), the current first-line agents for treatment, have yielded higher efficacy rates using shorter treatment periods (generally 3 months or shorter) for toenail and fingernail onychomycosis compared with the traditional agents

(i.e., griseofulvin and ketoconazole). Terbinafine, an allylamine, exerts fungicidal activity and demonstrates the greatest in vitro activity against dermatophytes compared with the other oral antifungals; it has good activity against nondermatophyte molds and only marginal activity against *Candida*.⁵⁷ Itraconazole, generally considered fungistatic, has a broader antifungal spectrum and is very active against dermatophytes, nondermatophytes, and *Candida*.⁵⁷ Itraconazole can be administered as a daily regimen or as an intermittent regimen given daily for 1 week once monthly (pulse dosing). Both agents have lipophilic and keratinophilic properties, which explain their excellent penetration (appearing in the nail plate within days of treatment initiation) and accumulation in the nails, achieving concentrations far exceeding the MIC of most dermatophytes.^{54,57} Both drugs are slowly eliminated from the nail, with mean half-lives of approximately 88 and 80 days for terbinafine and itraconazole (daily dosing), respectively; the nail half-life of itraconazole is shorter with pulse dosing.⁵⁴ Thus effective drug concentrations persist in nails for 30 to 36 weeks after completion of treatment with terbinafine and for at least 24 weeks with itraconazole.^{54,57} This explains in part the long-term protection against relapses after the end of treatment.

Toenail onychomycoses usually are more difficult to treat than fingernail onychomycoses and require longer duration of treatment. Treatment of toenail onychomycosis requires a 12-week course, whereas a 6-week course generally is adequate for fingernail onychomycosis with either drug.^{53,55} Itraconazole pulse therapy is the preferred method over continuous dosing for fingernail infections, and it consists of twice-daily dosing for a 1-week cycle per month for 2 consecutive months (i.e., two pulses); although not approved by the Food and Drug Administration (FDA), three to four pulses are effective for toenail infections; otherwise, half the dose is taken daily for 3 to 4 months^{53,55,57} (see Table 118–8). In addition to lower drug cost, potential advantages of itraconazole pulse therapy compared with continuous therapy include a lower risk of adverse drug effects and improved patient adherence. Pulse dosing is as effective as continuous dosing.^{55,59} Terbinafine pulse therapy also may be effective, although data are insufficient to currently recommend this method of administration.^{55,57}

Direct comparative trials generally have shown that terbinafine is more effective than itraconazole either by continuous or pulse dosing. Mycologic and clinical cure rates for terbinafine ranged from 73% to 80% and from 69% to 76%, respectively; for itraconazole, the respective cure rates ranged from 38% to 63% and from 32% to 61%.^{58,59} Three systematic reviews of the literature also reported that continuous terbinafine therapy is more effective than continuous or pulse itraconazole therapy.^{59–61} In addition, a pharmacoeconomic analysis of oral and topical (ciclopirox) therapies showed that from a managed-care perspective, terbinafine was the most cost-effective therapy in terms of highest success rate, lowest relapse rate, and highest number of disease-free days for both fingernail and toenail infections.⁶²

Both terbinafine and itraconazole generally are well tolerated. The more common adverse effects reported with terbinafine are gastrointestinal (e.g., diarrhea, dyspepsia, nausea, and abdominal pain), dermatologic (e.g., rash, urticaria, and pruritus), and headache; less common adverse effects include taste disturbances, fatigue, inability to concentrate, and asymptomatic liver enzyme abnormalities.^{56,57} Although uncommon, severe adverse effects have been reported with terbinafine, including erythema multiforme, Stevens-Johnson syndrome and toxic epidermal necrolysis, neutropenia, lupus erythematosus, psoriasis, hair loss, and hepatotoxicity.^{56,57,61,63} Although the incidence of severe hepatotoxicity is considered rare, the FDA issued a Public Health Advisory in 2001 regarding the association of

terbinafine tablets with 16 possible cases of liver failure, including 2 liver transplants and 11 deaths.⁶⁴ Terbinafine thus is not recommended for patients with chronic or active liver disease, although hepatotoxicity may occur in patients with no preexisting liver disease or serious underlying medical condition. Prior to initiating terbinafine treatment, it is recommended to obtain appropriate nail specimens for laboratory testing to confirm the diagnosis of onychomycosis. Liver function parameters (serum transaminases) should be assessed prior to and periodically during treatment with terbinafine.

The common adverse effects of itraconazole are similar to those of terbinafine, such as gastrointestinal disturbance, dermatologic disorders, and headache; less common adverse effects include dizziness, fatigue, fever, decreased libido, and asymptomatic liver enzyme abnormalities (1% to 5% with continuous dosing and about 2% with pulse dosing).^{56,57,65} Although still considered rare, 24 serious cases of liver failure, including transplantation and death, have been reported with the use of itraconazole, resulting in a recent FDA Public Health Advisory warning.⁶⁴ Some of these patients did not have preexisting liver disease or serious underlying medical conditions, and some developed within the first week of treatment. It has been suggested to avoid itraconazole in patients with elevated liver enzymes or active liver disease or in those who have experienced other drug-induced liver toxicity. Liver function parameters (serum transaminases) should be assessed prior to and periodically during treatment. However, some experts have suggested that frequent monitoring is not as necessary if pulse therapy is used because symptomatic hepatotoxicity has not been reported with pulse therapy.⁶⁵ In addition, there is an FDA warning on the risk of developing congestive heart failure (CHF) associated with the use of itraconazole, possibly related to its potential negative inotropic effect.^{64,66} Therefore, itraconazole should not be used in patients with evidence of ventricular dysfunction, such as CHF. Symptomatic assessment for the development of CHF also should be included as part of therapy monitoring. Before a patient is subjected to several months of itraconazole treatment, it is important to confirm the diagnosis of onychomycosis.

In contrast to the azoles, terbinafine does not inhibit the cytochrome P450 3A4 isoenzymes, but it is a potent inhibitor of the CYP 2D6 isoenzymes, which are responsible for metabolism of tricyclic antidepressants and other psychotropic drugs.⁵⁴ The most significant drug interactions with terbinafine are decreased clearance of 33% by cimetidine and increased clearance of 100% by rifampin.^{54,56} Other drug interactions of variable clinical significance include cyclosporine, caffeine, theophylline, and terfenadine.^{54,56} A case was reported of nortriptyline toxicity when given concomitantly with terbinafine.⁵⁶ Itraconazole and its major metabolite can inhibit the CYP 3A4 isoenzymes and result in numerous clinically significant drug interactions.^{54,56} (Refer to Chap. 119 for specific examples.)

Fluconazole is also active against dermatophytes, *Candida*, and some nondermatophytes.^{55,56} Fluconazole does not have current FDA indication for treatment of onychomycosis. Limited studies showed that fluconazole pulse regimens produced mycologic cure rates from 51% to 87%.⁵⁶ The most effective dose and treatment duration have not been clearly established, with dosages ranging from 150 to 450 mg once weekly for 3 to 9 months (see Table 118–8). One study showed that a 9-month regimen of 450 mg once weekly was superior to 3- and 6-month durations.⁶⁷ In direct comparative studies, fluconazole was less effective than terbinafine or itraconazole.^{68,69} Advantages of fluconazole include a relatively good safety profile, few drug interactions, and infrequent dosing.

These three oral antifungal agents have superseded the use of griseofulvin and ketoconazole as treatments of choice for onychomycosis.^{53,55} Griseofulvin has a narrow antifungal spectrum,

low clinical efficacy, especially for toenail infections, high relapse rates, and the need for prolonged treatment duration (up to 12 to 18 months for toenails). Use of ketoconazole is also associated with high relapse rates, and the prolonged treatment duration carries an increased risk of hepatotoxicity.

A number of topical antifungal products are available, and they provide variable success rates. Topical treatment requires regular applications for prolonged periods and strict patient adherence, which can be problematic. The most recently approved topical agent is a nail lacquer—ciclopirox 8% (Penlac)—for the treatment of mild to moderate onychomycosis caused by *Tricophyton rubrum* that does not involve the lunula.⁷⁰ Ciclopirox, a hydroxypyridine, has a broad spectrum of antifungal activity. Initial improvement may take as long as 6 months to occur. However, complete cure is reported in less than 10% of treated patients, with only about 60% of responders still remaining disease-free at 12 weeks after stopping treatment. Most experts consider topical therapy a feasible alternative when the infection is superficial involving the nail plate and limited to a few nails and to a partial area of the nail plate (owing to difficulty of applying treatment to the margin of the nail) or in the very early stages of a distal subungual type of infection when it is still confined to the distal edge of the nail.^{53,54}

Recurrence rates of infection range from 20% to 30%, which could be either a relapse (original infection not completely cured) or reinfection (new infection after achieving a cure of the original).^{53,54,56} Factors associated with poor response to systemic therapy include a compromised immune system (AIDS), reduced blood flow (diabetes, peripheral vascular disease, vasculitis, connective tissue disease, congestive heart failure), coexisting nail disease (psoriasis), nail factors (slow growth, thick nails, severe disease), drug-resistant organisms because of extensive prior drug exposure, and reduced bioavailability (absorption problems, poor compliance, drug interactions).^{53,54,71} To help to improve treatment outcomes and reduce recurrence, patients should be counseled on the importance of proper foot hygiene, e.g., wearing breathable footwear and 100% cotton socks with frequent changes, keeping the nails short and clean, keeping the feet dry, protecting the feet in shared bathing areas, treating tinea pedis, and controlling other predisposing medical conditions.⁵⁶ The combined use of topical and systemic therapy has been proposed as a potential approach to help improve cure rates or shorten treatment duration, but randomized, controlled trials are needed to evaluate this approach.^{53,71} Physical interventions such as surgical or chemical nail avulsion are used primarily as adjunct therapy in patients with total dystrophic onychomycosis, in whom there is severe onycholysis and extensive nail thickening or longitudinal spikes; response to oral therapy may be improved with partial nail avulsion in these patients.^{55,71}

INVASIVE FUNGAL INFECTIONS

Peggy L. Carver

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Systemic mycoses may be caused by pathogenic fungi and include histoplasmosis, coccidioidomycosis, cryptococcosis, blastomycosis, paracoccidioidomycosis, and sporotrichosis, or infections by opportunistic fungi such as *Candida albicans*, *Aspergillus* spp., *Trichosporon*, *C. glabrata*, *Fusarium*, *Alternaria*, and *Mucor*.
- 2 The diagnosis of fungal infection generally is accomplished by careful evaluation of clinical symptoms, results of serologic tests, and histopathologic examination and culture of clinical specimens.
- 3 Histoplasmosis is caused by *Histoplasma capsulatum* and is endemic in parts of the central United States along the Ohio and Mississippi River valleys. Although most patients experience asymptomatic infection, some may experience chronic, disseminated disease.
- 4 Asymptomatic patients with histoplasmosis are not treated, although non-AIDS patients with evident disease are treated with either oral ketoconazole or intravenous amphotericin B; AIDS patients are treated with amphotericin B and then receive lifelong suppression.
- 5 Blastomycosis is caused by *Blastomyces dermatitidis* and generally is an asymptomatic, self-limited disease; however, reactivation can lead to chronic disease. Although treatment for self-limited disease is controversial, patients with chronic pulmonary disease or extrapulmonary disease should be treated with ketoconazole, and those with central nervous system (CNS), progressive, or life-threatening disease should receive amphotericin B.
- 6 Coccidioidomycosis is caused by *Coccidioides immitis* and is endemic in some parts of the southwestern United States. It may cause nonspecific symptoms, acute pneumonia, or chronic pulmonary or disseminated disease. Primary pulmonary disease (unless severe) frequently is not treated, whereas extrapulmonary disease is treated with amphotericin B, and meningitis is treated with fluconazole.
- 7 Cryptococcosis is caused by *Cryptococcus neoformans* and occurs primarily in immunocompromised patients. Patients with acute meningitis are treated with amphotericin B with flucytosine. Patients infected with HIV require long-term suppressive therapy with fluconazole or itraconazole.
- 8 A variety of *Candida* spp. (including *C. albicans*, *C. glabrata*, *C. tropicalis*, and *C. krusei*) may cause diseases such as mucocutaneous, oral, esophageal, vaginal, and hematogenous candidiasis, as well as candiduria.
- 9 Aspergillosis may be caused by a variety of *Aspergillus* spp. that may cause superficial infections, pneumonia, allergic bronchopulmonary aspergillosis, or invasive infection. Treatment with amphotericin B or voriconazole generally is instituted but often is not successful.

For many years, fungal infections were classified as either superficial “nuisance diseases,” such as athlete’s foot or vulvovaginal candidiasis, or as relatively rare infections confined primarily to endemic areas of the country. When invasive fungal infections were encountered, amphotericin B was the only consistently effective, systemically active agent available for the treatment of systemic mycoses. Advances in medical technology, including organ and bone marrow transplantation, cytotoxic chemotherapy, the widespread use of indwelling intravenous (IV) catheters, and the increased use of potent broad-spectrum antimicrobial agents all have contributed to the dramatic increase in the incidence of fungal infections worldwide.

Fungal infections have emerged as a major cause of death among cancer patients and transplant recipients.^{1–4} In addition, patients with acquired immune-deficiency syndrome (AIDS) experience substantially more frequent and severe forms of cryptococcosis, histoplasmosis, coccidioidomycosis, and mucocutaneous (esophageal, oral, and vulvovaginal) candidiasis.

Problems remain in the diagnosis, prevention, and treatment of fungal infections. Unlike the available diagnostic techniques for most bacterial pathogens, there remains a host of unresolved issues regarding standardization of susceptibility testing methods, in vitro and in vivo models of infection, the utility of monitoring antifungal plasma concentrations, and the development and identification of resistant pathogens.^{1,5–7} The Infectious Diseases Society of America published guidelines for the treatment of many commonly encountered fungal infections. These guidelines provide summaries of the literature and a consensus of expert opinions regarding the treatment of these difficult infections.⁷

MYCOLOGY

Fungi are eucaryotic organisms with a defined nucleus enclosed by a nuclear membrane; a cytoplasmic membrane containing lipids,

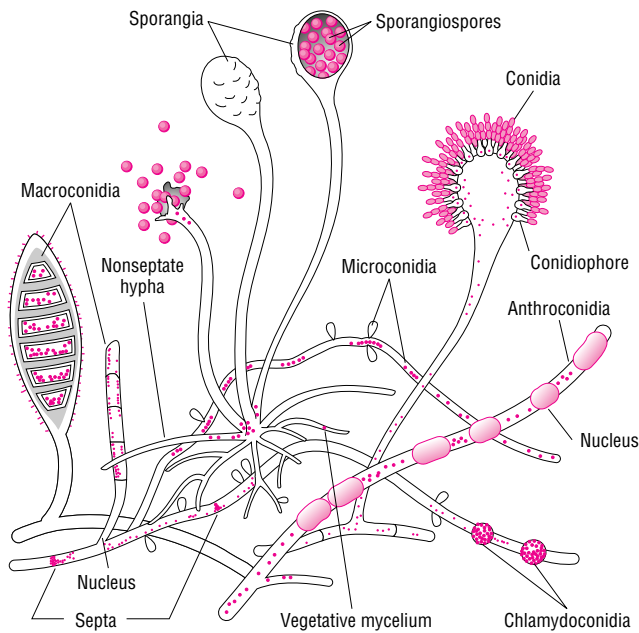

FIGURE 119-1. Forms of molds. The tubelike hyphae form their basic structure. Examples of spores and conidia and of the structures that bear them are shown. (From Ryan KJ. *Pathogenic fungi*, in Sherris JC (ed): *Medical Microbiology*, 2d ed. New York, Elsevier, 1990:630, with permission.)

glycoproteins, and sterols, mitochondria, Golgi apparatus, and ribosomes bound to endoplasmic reticulum; and a cytoskeleton with microtubules, microfilaments, and intermediate filaments. Fungi have rigid cell walls composed of chitin, cellulose, or both that stain with Gomori methenamine silver or periodic acid–Schiff reagent. Most fungi, except *Candida*, are too weakly gram-positive to be seen well on Gram’s stain. *Cryptococcus neoformans* has a polysaccharide capsule surrounding the cell wall.⁷

Morphologically, pathogenic fungi can be grouped as either filamentous molds or unicellular yeasts. *Molds* grow as multicellular branching, threadlike filaments (hyphae) that are either septate (divided by transverse walls) or coenocytic (multinucleate without

cross walls) (Fig. 119-1). On agar media, molds grow outward from the point of inoculation by extension of the tips of filaments and then branch repeatedly, interweaving to form fuzzy, matted growths called *mycelia*. Yeasts are oval or spherically shaped unicellular forms that generally produce pasty or mucoid colonies on agar medium similar to those observed with bacterial cultures. Yeasts have rigid cell walls and reproduce by budding, a process in which daughter cells arise from pinching off a portion of the parent cell.

Fungi reproduce by forming spores asexually via mitosis to produce motile sporangiospores or nonmotile conidia (singular, conidium), or they reproduce sexually through meiosis to produce ascospores, basidiospores, oospores, or zygospores. Although terms such as *spore* and *conidia* should no longer be used interchangeably, some newer literature and much of the older medical literature continue to confuse these terms.

Many pathogenic fungi, termed *dimorphic fungi*, exist as either a yeast or a mold, depending on pathogen, site of growth (in the host or in the laboratory setting), and temperature. Usually yeasts are the parasitic form that invades human or animal host tissue, whereas molds are the free-living form found in the environment. For example, *Histoplasma capsulatum* exists as a yeast in humans and as a mold in the laboratory.^{1,8}

SUSCEPTIBILITY TESTING OF ANTIFUNGAL AGENTS

Most laboratories do not routinely perform susceptibility tests on fungal isolates, but standardized methods for performing these tests are being developed and are now available for testing selected yeasts. To date, reference broth macrodilution and microdilution methods have been established for *Candida* and *Cryptococcus* spp., whereas broth the microdilution method has been standardized for filamentous fungi. Additionally, minimal inhibitory concentration (MIC) reference ranges for American Type Culture Collection (ATCC) quality control strains have been established against various antifungal agents, as well as interpretive breakpoints for fluconazole, itraconazole, and flucytosine against *Candida* spp⁵ (Table 119-1). For further detail, refer to the section outlining treatment of *Candida* infections. Reliable and convincing interpretive breakpoints are not yet available for amphotericin B. The National Committee for Clinical Laboratory Standards (NCCLS) M27-A methodology does not reliably identify

TABLE 119-1. General Patterns of Susceptibility and Interpretive Breakpoints of *Candida* Species^a

| <i>Candida</i> Species | Patterns of Susceptibility | | | |
|---------------------------------|----------------------------|------------------------|-------------|---------------------|
| | Fluconazole | Itraconazole | Flucytosine | Amphotericin B |
| <i>C. albicans</i> | S | S | S | S |
| <i>C. tropicalis</i> | S | S | S | S |
| <i>C. parapsilosis</i> | S | S | S | S |
| <i>C. glabrata</i> | S-DD to R ^b | S-DD to R ^c | S | S-I ^d |
| <i>C. krusei</i> | R | S-DD to R ^c | I-R | S-I ^d |
| <i>C. lusitaniae</i> | S | S | S | S to R ^e |
| Interpretive Breakpoints | | | | |
| Sensitive | ≤8 | ≤0.125 | ≤4 | NA |
| S-DD or I | S-DD: 16–32 | S-DD: 0.25–0.5 | I: 8–16 | NA |
| R | >32 | >0.5 | >16 | NA |

^aExcept for amphotericin B, interpretations are based on the use of a broth sensitivity test.

^bApproximately 15% of *C. glabrata* isolates are resistant to fluconazole.

^cApproximately 46% of *C. glabrata* isolates and 31% of *C. krusei* isolates are resistant to itraconazole.

^dA significant proportion of *C. glabrata* and *C. krusei* isolates have reduced susceptibility to amphotericin B.

^eAlthough frank resistance to amphotericin B is not observed in all isolates, it is well described for isolates of *C. lusitaniae*.

S = susceptible; S-DD = susceptible-dose dependent (see text); I = intermediate; R = resistant.

Adapted from refs. 5, and 9.

amphotericin B-resistant isolates; variations of the methodology using different media appear to enhance detection of resistant isolates.^{5,9} It is important that the breakpoints be used following testing with the standardized, reproducible laboratory methodology (NCCLS 27-A) used to develop the test and that they be interpreted in the context of the delivered dose of the antifungal agent.

Because *in vitro* correlations with *in vivo* outcomes in patients are not yet known, the role of routine susceptibility testing is unknown at this time. Several concerns need to be considered as the use of MIC breakpoints is incorporated into the clinical practice setting: First, MICs are not actual physical measurements; rather, they provide estimates of drug activity. Since the MICs obtained can span greater than three twofold dilutions for the same isolate despite meticulous technique, MICs must be interpreted with caution. Second, host factors contribute greatly to clinical outcome. The same isolate in an immunocompetent patient may not result in the same outcome as in an immunocompromised patient. Thus, *in vitro* susceptibility does not necessarily equate with *in vivo* clinical success, and *in vitro* resistance may not always correlate with treatment failure. Susceptibility testing occasionally is indicated, e.g., in a patient with prolonged fungemia with a presumed susceptible isolate. Because of wide interlaboratory variability in test results, isolates should be tested at specialty laboratories that routinely perform these specialized tests. Susceptibility testing is most helpful in dealing with infections caused by non-*albicans* species of *Candida*.^{5,9}

RESISTANCE TO ANTIFUNGAL AGENTS

It is important to distinguish between clinical resistance and microbial resistance. *Clinical resistance* refers to failure of an antifungal agent in the treatment of a fungal infection that arises from factors other than microbial resistance, such as failure of the antifungal agent to reach the site of infection or inability of a patient's immune system to eradicate a fungus whose growth is retarded by an antifungal agent.¹⁰

Microbial resistance can refer to *primary* or *secondary* resistance, as determined by *in vitro* susceptibility testing using standardized methodology. NCCLS resistance breakpoints are based on data relating treatment outcomes and fungal MICs and indicate the MIC at which clinical responses demonstrate a marked decline.¹⁰ However, they do not serve as absolute predictors of therapeutic success or failure.

Primary, or *intrinsic*, resistance refers to resistance recorded prior to drug exposure *in vitro* or *in vivo*. *Secondary*, or *acquired resistance* develops on exposure to an antifungal agent and can be either reversible, owing to transient adaptation, or acquired as a result of one or more genetic alterations. The clinical consequences of antifungal resistance can be observed in treatment failures and in changes in the prevalences of *Candida* spp. causing disease. The evidence for the emergence of antifungal-resistant yeasts in patients other than those with HIV infection is confounded by the lack of standardized susceptibility testing methods and definitions of resistance. Large-scale surveys of yeasts from blood cultures, tested by standardized methodology, do not yet suggest that antifungal resistance is a significant or growing therapeutic problem.¹⁰

It is possible for a patient to respond clinically to treatment with an antifungal agent despite resistance to that agent *in vitro* because the patient's own immune system may eradicate the infection, or the agent may reach the site of infection in high concentrations.¹⁰ Resistance to azole antifungal agents has been studied intensively partly because of the increased number of fluconazole-resistant *Candida* strains isolated from AIDS patients. Resistance may be acquired (i.e., transferred from other organisms or developed during therapy as a

result of exposure to the antifungal agent) or intrinsic (innate lack of susceptibility of the antifungal agent to a pathogen). This issue has been reviewed extensively.^{2,3,10}

The most exhaustive and definitive accounts of antifungal resistance have been described in *Candida* spp., in particular *Candida albicans* and, to a lesser extent, *C. glabrata*, *C. tropicalis*, and *C. krusei*, as well as in a few *Cryptococcus neoformans* isolates.^{11–13} There are four different mechanisms that result in azole resistance: (1) mutations or upregulation of *ERG11*, (2) expression of multidrug efflux transport pumps that decrease antifungal drug accumulation within the fungal cell, (3) alteration of the structure or concentration of antifungal drug target proteins, and (4) alteration of membrane sterol proteins (Fig. 119–2). It is beyond the scope of this chapter to provide a complete discussion of the biochemical mechanisms of fungal resistance. Interested readers are referred to several excellent reviews concerning this topic.^{10–13} Efflux pumps have been identified in *C. albicans*, *C. glabrata*, *C. tropicalis*, and *C. dubliniensis* and appear to be the most common mechanism of resistance encountered in clinical isolates. It is interesting to note that some of these mechanisms (efflux pumps in particular) appear to be reversible when selective pressure of antifungal agents is withdrawn.

Even though ketoconazole was used widely for the treatment of mucocutaneous candidiasis, resistant strains appeared very rarely. In patients with the uncommon syndrome of chronic mucocutaneous candidiasis, however, the chronic use of ketoconazole was associated with the emergence of ketoconazole-resistant *C. albicans*. Resistance likely developed in this specific population of patients because of two factors: the chronic use of ketoconazole and the inability of patients with this syndrome to eradicate the organism by normal host defense mechanisms. Fluconazole-resistant *C. albicans* have been noted almost entirely in AIDS patients and usually only after CD4 counts are less than 50 cells/mm³ and after fluconazole was used chronically for repeated episodes of thrush over months to years. It appears that resistance develops in a stepwise progression in patients who have repeated episodes of thrush with one or several persisting strains of *C. albicans*. *In vitro* susceptibility testing shows a progressive decrease in susceptibility to fluconazole, and this has been correlated with clinical failure. This type of resistance has not yet become a problem in hospitalized patients treated with short courses of fluconazole or in patients in whom fluconazole has been used for prophylaxis.^{14,15}

In the last few years, among hospitalized patients, there is increasing evidence for a shift toward isolation of other resistant species, such as *C. glabrata* and *C. krusei*, that have moderate or high-level resistance to fluconazole. This phenomenon has been especially common among patients in whom fluconazole has been used extensively.^{2,3}

Resistance has not been described widely with itraconazole. This may be partly related to the fact that the drug has been used primarily for the treatment of endemic mycoses and not candidiasis. Even in patients never treated with itraconazole, however, *C. albicans* strains that are resistant to fluconazole also show decreased susceptibility to itraconazole.

The most commonly reported mechanisms of azole resistance among *C. albicans* isolates include reduced permeability of the fungal cell membrane to azoles, alteration in the target fungal enzymes (cytochrome P450) resulting in decreased binding of the azole to the target site, and overproduction of the fungal cytochrome P450 enzymes.^{14,15} Studies also suggest the presence of efflux pumps capable of actively pumping azoles from the target pathogen, thereby conferring multidrug resistance to azole antifungals.^{14,15}

C. glabrata is intrinsically more resistant than *C. albicans* to ketoconazole. Several strains of *C. glabrata* have been well characterized in terms of the mechanism of ketoconazole resistance.

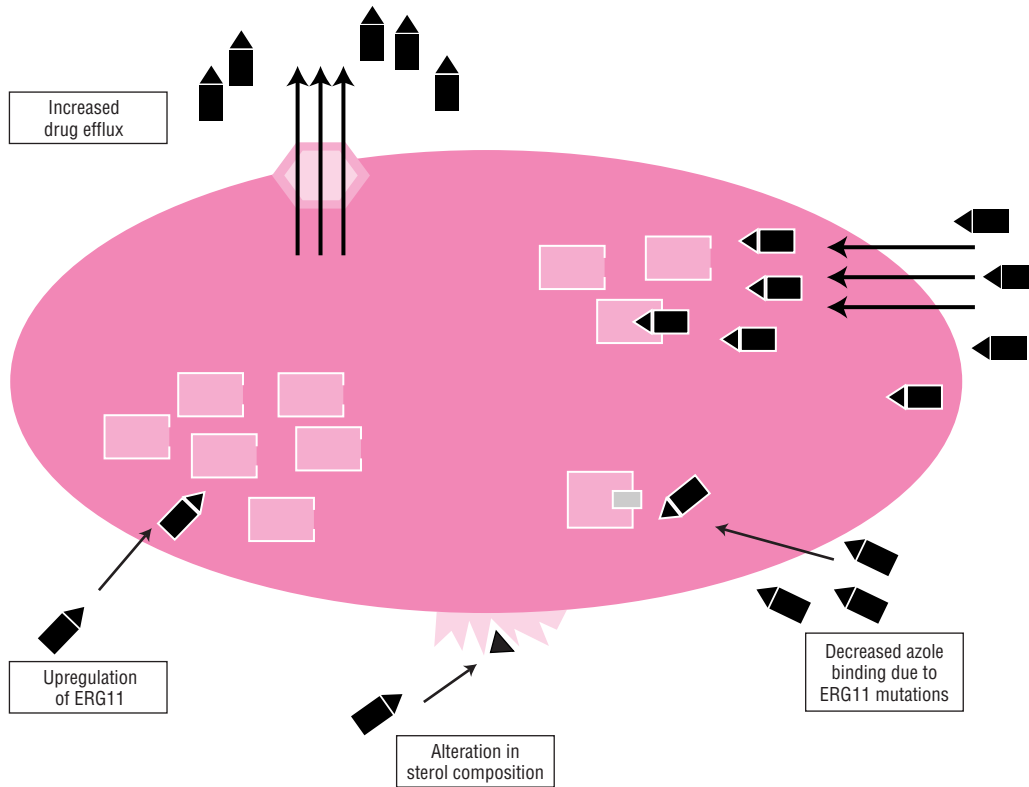

FIGURE 119–2. Resistance mechanisms of antifungal agents.

Decreased permeability to azoles has been described, but other strains show enhanced activity of the P450 cell membrane enzymes as well. *C. krusei* is inherently resistant to fluconazole, but it appears to be more susceptible to the other azoles. Decreased uptake of fluconazole into the fungal cell has been noted for several *C. krusei* strains.^{14,15}

While rare, *in vitro* intrinsic resistance to amphotericin B is described, mainly in *C. lusitanae*, *C. guilliermondii*, and some molds (*Fusarium* spp., and *Pseudallescheria boydii*).¹³ However, it is important to keep in mind that the current *in vitro* M27-A methodology discriminates poorly between rates of susceptibility of *Candida* spp. to amphotericin B. Although the rate of apparent resistance to amphotericin B appears to be quite low, breakthrough bacteremias in patients treated with amphotericin B have been observed. *C. glabrata*, *C. guilliermondii*, *C. krusei*, and *C. lusitanae* appear to have a higher propensity than other *Candida* spp. to develop resistance to amphotericin B; this point should be kept in mind when treating patients with infections caused by one of these pathogens.¹⁰ Since polyenes target ergosterol in the membranes of fungal cells, it is not surprising that amphotericin B-resistant strains of *Candida* generally have a marked decrease in ergosterol content compared with amphotericin B-susceptible strains. Resistant isolates of *Cryptococcus neoformans* have been reported to have a mutation in the C8 isomerization step of ergosterol synthesis.¹³

PATHOGENESIS AND EPIDEMIOLOGY

Systemic mycoses caused by primary or pathogenic fungi include histoplasmosis, coccidioidomycosis, cryptococcosis, blastomycosis,

paracoccidioidomycosis, and sporotrichosis. Primary pathogens can cause disease in both healthy and immunocompromised individuals, although disease generally is more severe or disseminated in the immunocompromised host. In contrast, mycoses caused by opportunistic fungi such as *C. albicans*, *Aspergillus* spp., *Trichosporon*, *Torulopsis (Candida) glabrata*, *Fusarium*, *Alternaria*, and *Mucor* generally are found only in the immunocompromised host.¹

Most fungal infections are acquired as a result of accidental inhalation of airborne conidia. For example, *H. capsulatum* is found in soil contaminated by bat, chicken, or starling excreta, and *C. neoformans* is associated with pigeon droppings. Although some fungi, including *C. albicans*, *C. neoformans*, and *Aspergillus* spp., are ubiquitous pathogens with worldwide distribution, other fungi have regional distributions associated with specific geographic environments.¹

Systemic fungal infections are a major cause of morbidity and mortality in the immunocompromised patient. Fungal infections account for 20% to 30% of fatal infections in patients with acute leukemia, 10% to 15% of fatal infections in patients with lymphoma, and 5% of fatal infections in patients with solid tumors. The frequency of fungal infections among transplant recipients ranges from 0% to 20% for kidney and bone marrow transplant recipients to 10% to 35% for heart transplant recipients and 30% to 40% for liver transplant recipients.⁴

Approximately 2% to 4% of all hospitalized patients develop a nosocomial infection. Of these, bacteria comprise the most common etiologic agent.¹ Fungi, however, are becoming increasingly significant nosocomial pathogens. Fungi account for 10% of all bloodstream isolates. *Candida* spp. (primarily *C. albicans*) are the fourth most commonly isolated bloodstream isolate and account for 78% of all nosocomial fungal infections.^{8,16}

Nosocomially acquired fungal infections may arise from either exogenous or endogenous flora. Endogenous flora may include normal commensals of the skin, gastrointestinal (GI), genitourinary, or respiratory tract. *C. albicans* is found as a normal commensal of the GI tract in 20% to 30% of humans.⁸

A complex interplay of host and pathogen factors influences the acquisition and development of fungal infections. Intact skin or mucosal surfaces serve as primary barriers to infection. Desiccation, epithelial cell turnover, fatty acid content, and low pH of the skin are believed to be important factors in host resistance. Bacterial flora of the skin and mucous membranes compete with fungi for growth. Alterations in the balance of normal flora caused by the use of antibiotics or alterations in nutritional status can allow the proliferation of fungi such as *Candida*, increasing the likelihood of systemic invasion and infection.¹

The growth of fungi within tissues is restrained by a number of mechanisms. For example, serum has fungistatic activity against *Candida* in part because of transferrins, the human iron-binding proteins that deprive microbes of the iron needed for synthesis of respiratory enzymes. Serum also contains globulins, which cause a nonimmunologic clumping of *Candida*, facilitating their elimination by inflammatory cells.^{1,8}

Tissue reaction in the presence of fungi varies with fungal species, site of proliferation, and duration of infection. Phagocytosis

by neutrophils and macrophages is the earliest mechanism that prevents the establishment of fungi. Consequently, patients with decreased neutrophil counts or decreased neutrophil function are at higher risk of infections, particularly infections caused by *Candida* and *Aspergillus* spp. Some mycoses are characterized by a low-grade inflammatory response that does not eliminate the fungi. Fungal cells sometimes can persist within macrophages without being killed, perhaps because of resistance to the effects of lysosomal enzymes.¹

DIAGNOSIS

2 The diagnosis of invasive fungal infections generally is accomplished by careful evaluation of clinical symptoms, results of serologic tests, and histopathologic examination and culture of clinical specimens. Skin tests generally are not useful diagnostically because they do not distinguish between active and past infection. They remain useful as screening tools and in epidemiologic studies to determine endemic areas. It is beyond the scope of this chapter to discuss the relative merits of each of the immunologic tests used in the diagnosis of invasive fungal infections. Interested readers, however, are referred to several excellent reviews concerning this topic.¹⁷

TREATMENT: Invasive Mycoses

Strategies for the prevention or treatment of invasive mycoses can be classified broadly as prophylaxis, early empirical therapy, empirical therapy, and secondary prophylaxis or suppression.¹ In patients undergoing cytotoxic chemotherapy, antifungal therapy is directed primarily at the prevention or treatment of infections caused by *Candida* and *Aspergillus*. Prophylactic therapy with topical, oral, or intravenous antifungal agents is administered prior to and throughout periods of granulocytopenia (absolute neutrophil count < 1000/L). The potential benefits of prophylactic therapy must be weighed against the potential risks inherent in each regimen. Perfect¹⁸ suggests that each clinician consider at least six criteria before justifying antifungal prophylaxis: (1) safety, (2) efficacy, (3) cost, (4) consequence, (5) prevalence, and (6) resistance.

Early empirical therapy is the administration of systemic antifungal agents at the onset of fever and neutropenia. Empirical therapy with systemic antifungal agents is administered to granulocytopenic patients with persistent or recurrent fever despite the administration of appropriate antimicrobial therapy.

Secondary prophylaxis (or suppressive therapy) is the administration of systemic antifungal agents (generally prior to and throughout the period of granulocytopenia) to prevent relapse of a documented invasive fungal infection that was treated during a previous episode of granulocytopenia.

Although these treatment classifications also have been applied to the treatment of fungal infections in AIDS, patients with AIDS

rarely acquire systemic infections caused by *Candida* or *Aspergillus* spp. unless they become granulocytopenic because of disease or drugs. The use of antifungal prophylaxis is much less widely studied in this population, although studies suggest that early antifungal prophylaxis decreases the incidence of invasive cryptococcal disease.¹⁹ Suppressive therapy generally is necessary following acute therapy for histoplasmosis, coccidioidomycosis, and cryptococcosis because of the high rates of relapse when antifungal therapy is discontinued.

PROPHYLAXIS OF FUNGAL INFECTION IN THE HIV-INFECTED PATIENT

The use of antifungal prophylaxis to prevent fungal infections in HIV-infected patients has been assessed. Fluconazole prevented cryptococcosis and local *Candida* infections, including esophagitis, in HIV-infected patients, but overall mortality was not improved.¹⁴ Because of the high costs of long-term prophylaxis, improved therapeutic regimens available for treating cryptococcal meningitis, and increasing reports of fluconazole resistance among *Candida* isolates from AIDS patients, many clinicians prefer not to use fluconazole prophylaxis in AIDS patients. For some patients with very low CD4 counts, however, some clinicians feel that it is cost-effective to use fluconazole prophylaxis to prevent cryptococcosis.¹⁴

HISTOPLASMOSIS

In humans, histoplasmosis is caused by inhalation of dust-borne microconidia of the dimorphic fungus *Histoplasma capsulatum*. Although there exist two dimorphic varieties of *H. capsulatum*, the

small-celled (2–5 microns) form (var. *capsulatum*) occurs globally, whereas the large-celled (8–15 microns) form (var. *duboisii*) is confined to the African continent and Madagascar. In tissues stained by conventional techniques, *H. capsulatum* appears as an oval or round, narrow-pore, budding, unencapsulated yeast.²⁰

EPIDEMIOLOGY

Although histoplasmosis is found worldwide, certain areas of North and Latin America are recognized as endemic areas; in the United States, most disease is localized along the Ohio and Mississippi River valleys, where more than 90% of residents may be affected. Precise reasons for this endemic distribution pattern are unknown but are thought to include moderate climate, humidity, and soil characteristics. *H. capsulatum* is found in nitrogen-enriched soils, particularly those heavily contaminated by avian or bat guano, which accelerates sporulation. Blackbird or pigeon roosts, chicken coops, and sites frequented by bats, such as caves, attics, or old buildings, serve as “microfoci” of infections. Although birds are not infected because of their high body temperature, bats (mammals) may be infected and can pass yeast forms in their feces, allowing the spread of *H. capsulatum* to new habitats. Air currents carry the spores for great distances, exposing individuals who were unaware of contact with the contaminated site.^{20–22}

PATHOPHYSIOLOGY

At ambient temperatures, *H. capsulatum* grows as a mold. The mycelial phase consists of septate branching hyphae with terminal micro- and macroconidia that range in size from 2 to 14 microns in diameter. When soil is disturbed, these conidia become aerosolized and reach the bronchioles or alveoli.²⁰

Animal studies demonstrate that within 2 to 3 days after reaching lung tissue, the conidia germinate, releasing yeast forms that begin multiplying by binary fission. During the next 9 to 15 days, organisms are ingested but not destroyed by large numbers of macrophages that are recruited to the infected site, resulting in small infiltrates. Infected macrophages migrate to the mediastinal lymph nodes and other sites within the mononuclear phagocyte system, particularly the spleen and liver. At this time, the onset of specific T-cell immunity in the non-immune host activates the macrophages, rendering them capable of fungicidal activity. Tissue granulomas form, many of which develop central caseation and necrosis over the next 2 to 4 months. Over a period of several years, these foci become encapsulated and calcified, often with viable yeast trapped within the necrotic tissue.^{20,23}

Cellular immunity, as measured by histoplasmin skin-test reactivity, wanes in the absence of occasional reexposure. Although exposure to heavy inocula may overcome these immune mechanisms, resulting in severe disease, reinfection occurs frequently in endemic areas. In the immune individual, the reactions of acquired immunity begin 24 to 48 hours after the appearance of yeast forms, resulting in milder forms of illness and little proliferation of organisms. Although viable organisms may be found within granulomas years after initial infection, the organisms appear to have little ability to proliferate within the fibrous capsules, except in immunocompromised patients.^{20,23}

CLINICAL PRESENTATION^{14,17,19,20,22,23}

GENERAL

The outcome of infection with *H. capsulatum* depends on a complex interplay of host, pathogen, and environmental factors. Host factors include the degree of immunosuppression and the presence of immunity (from prior infection). Environmental factors include inoculum size, exposure within an enclosed area, and duration of exposure. Hematogenous dissemination from the lungs to other tissues probably occurs in all infected individuals during the first 2 weeks of infection

before specific immunity has developed but is nonprogressive in most cases, which leads to the development of calcified granulomas of the liver and/or spleen. Progressive pulmonary infection is common in patients with underlying centrilobular emphysema.

A number of acute and chronic manifestations of histoplasmosis appear to result from unusual inflammatory or fibrotic responses to the pathogen, including pericarditis and rheumatologic syndromes during the first year after exposure, with chronic mediastinal inflammation or fibrosis, broncholithiasis, and enlarging parenchymal granulomas later in the course of disease.

ACUTE PULMONARY HISTOPLASMOSIS

In the vast majority of patients, low-inoculum exposure to *H. capsulatum* results in mild or asymptomatic pulmonary histoplasmosis. The course of disease generally is benign, and symptoms usually abate within a few weeks of onset. Patients exposed to a higher inoculum during an acute primary infection or reinfection may experience an acute, self-limited illness with flulike pulmonary symptoms, including fever, chills, headache, myalgia, and a nonproductive cough. Patients with diffuse pulmonary histoplasmosis may have diffuse radiographic involvement, become hypoxic, and require ventilatory support. A small percentage of patients present with arthritis, erythema nodosum, pericarditis, or mediastinal granuloma.

CHRONIC PULMONARY HISTOPLASMOSIS

Chronic pulmonary histoplasmosis generally presents as an opportunistic infection imposed on a preexisting structural abnormality, such as lesions resulting from emphysema. Patients demonstrate chronic pulmonary symptoms and apical lung lesions that progress with inflammation, calcified granulomas, and fibrosis. Patients with early, noncavitary disease often recover without treatment. Progression of disease over a period of years, seen in 25% to 30% of patients, is associated with cavitation, bronchopleural fistulas, extension to the other lung, pulmonary insufficiency, and often death.

DISSEMINATED HISTOPLASMOSIS

In patients exposed to a large inoculum and in immunocompromised hosts, successful containment of the organism within macrophages may not occur, resulting in a progressive illness characterized by yeast-filled phagocytic cells and an inability to produce granulomas. This disease, termed *disseminated histoplasmosis*, is characterized by persistent parasitization of macrophages. The clinical severity of the diverse forms of disseminated histoplasmosis (Table 119–2) generally parallels the degree of macrophage parasitization observed.

Acute (infantile) disseminated histoplasmosis is characterized by massive involvement of the mononuclear phagocyte system by yeast-engorged macrophages. Classically, this severe type of infection is seen in infants and young children and (rarely) in adults with Hodgkin’s disease or other lymphoproliferative disorders. In infants or children, acute disseminated histoplasmosis is characterized by unrelenting fever, anemia, leukopenia or thrombocytopenia, enlargement of the liver, spleen, and visceral lymph nodes, and GI symptoms, particularly nausea, vomiting, and diarrhea. The chest roentgenogram often demonstrates remnants of the initiating acute pulmonary lesion. Untreated disease is uniformly fatal in 1 to 2 months. A less severe “subacute” form of the disease, which occurs in both infants and immunocompetent adults, is characterized by focal destructive lesions in various organs, weight loss, weakness, fever, and malaise. Untreated disease generally is fatal in approximately 10 months.

TABLE 119–2. Clinical Manifestations and Therapy of Histoplasmosis

| Type of Disease and Common Clinical Manifestations | Approximate Frequency (%) ^a | Therapy/Comments |
|--|--|---|
| Nonimmunosuppressed Host | | |
| <i>Acute pulmonary histoplasmosis</i> Asymptomatic or mild disease | 50–99 | <i>Asymptomatic, mild, or symptoms <4 weeks:</i> No therapy generally required <i>Symptoms >4 weeks:</i> Itraconazole 200 mg once daily × 6–12 weeks ^b |
| Self-limited disease | 1–50 | <i>Self-limited disease:</i> Amphotericin B ^c 0.3–0.5 mg/kg/day × 2–4 weeks (total dose 500 mg) or ketoconazole 400 mg orally daily × 3–6 months may be beneficial in patients with severe hypoxia following inhalation of large inocula Antifungal therapy generally not useful for arthritis or pericarditis; NSAIDs ^d or corticosteroids may be useful in some cases |
| Mediastinal granulomas | 1–50 | Most lesions resolve spontaneously; surgery or antifungal therapy with amphotericin B 40–50 mg/day × 2–3 weeks or itraconazole 400 mg/day orally × 6–12 months may be beneficial in some severe cases; mild to moderate disease may be treated with itraconazole for 6–12 months |
| Severe diffuse pulmonary disease | | Amphotericin B 0.7 mg/kg/day, for a total dose of ≤35 mg/kg (or 3 mg/kg/day of one of the lipid preparations) + prednisone 60 mg daily tapered over 2 weeks, ^e followed by itraconazole 200 mg twice daily for 6–12 weeks; in patients who do not require hospitalization, itraconazole 200 mg once or twice daily for 6–12 weeks can be used |
| Inflammatory/fibrotic disease | 0.02 | <i>Fibrosing mediastinitis:</i> The benefit of antifungal therapy (itraconazole 200 mg twice daily × 3 months) is controversial but should be considered, especially in patients with elevated ESR ^f or CF ^g titers ≥1:32; surgery may be of benefit if disease is detected early; late disease may not respond to therapy <i>Sarcoid-like:</i> NSAIDs or corticosteroids may be of benefit for some patients |
| <i>Chronic pulmonary histoplasmosis</i> | 0.05 | <i>Pericarditis:</i> Severe disease: corticosteroids 1 mg/kg/day or pericardial drainage procedure Antifungal therapy generally recommended for all patients to halt further lung destruction and reduce mortality <i>Mild–moderate disease:</i> Itraconazole 200–400 mg PO daily × 6–24 months is the treatment of choice Itraconazole and ketoconazole (200–800 mg/day orally for 1 year) are effective in 74% to 86% of cases, but relapses are common; fluconazole 200–400 mg daily is less effective (64%) than ketoconazole or itraconazole, and relapses are seen in 29% of responders <i>Severe disease:</i> Amphotericin B 0.7 mg/kg/day for a minimum total dose of 35 mg/kg is effective in 59% to 100% of cases and should be used in patients who require hospitalization or are unable to take itraconazole due to drug interactions, allergies, failure to absorb drug, or failure to improve clinically after a minimum of 12 weeks of itraconazole therapy |
| Immunosuppressed Host | | |
| <i>Disseminated histoplasmosis</i> | 0.02–0.05 | <i>Disseminated histoplasmosis:</i> Untreated mortality 83% to 93%; relapse 5% to 23% in non-AIDS patients; therapy is recommended for all patients |
| Acute (Infantile) | | <i>Nonimmunosuppressed patients:</i> Ketoconazole 400 mg/day orally × 6–12 months or amphotericin B 35 mg/kg IV |
| Subacute | | <i>Immunosuppressed patients: (non-AIDS) or endocarditis or CNS disease:</i> Amphotericin B >35 mg/kg × 3 months followed by fluconazole or itraconazole 200 mg orally twice daily × 12 months |
| Progressive histoplasmosis (immunocompetent patients and immunosuppressed patients without AIDS) | | <i>Life-threatening disease:</i> Amphotericin B 0.7–1 mg/kg/day IV for a total dosage of 35 mg/kg over 2–4 months; once the patient is afebrile, able to take oral medications, and no longer requires blood pressure or ventilatory support, therapy can be changed to itraconazole 200 mg orally twice daily for 6–18 months <i>Non-life-threatening disease:</i> Itraconazole 200–400 mg orally daily for 6–18 months; fluconazole therapy 400–800 mg daily) should be reserved for patients intolerant to itraconazole, and the development of resistance may lead to relapses |
| <i>Progressive disease of AIDS</i> | 25–50 ^h | Amphotericin B 15–30 mg/kg (1–2 g over 4–10 weeks) ⁱ or itraconazole 200 mg 3 times daily for 3 days then twice daily for 12 weeks, followed by lifelong suppressive therapy with itraconazole 200–400 mg orally daily; a study is in progress to determine whether itraconazole therapy can be discontinued after one year if CD4+ counts are >150 cells/mm ³ |

^aAs a percentage of all patients presenting with histoplasmosis.^bItraconazole plasma concentrations should be measured during the second week of therapy to ensure that detectable concentrations have been achieved. If the concentration is below 1 mcg/mL, the dose may be insufficient or drug interactions may be impairing absorption or accelerating metabolism, requiring a change in dosage. If plasma concentrations are greater than 10 mcg/mL, the dosage may be reduced.^cDesoxycholate amphotericin B.^dNSAIDs = nonsteroidal anti-inflammatory drugs.^eEffectiveness of corticosteroids is controversial.^fESR = erythrocyte sedimentation rate.^gCF = complement fixation.^hAs a percentage of AIDS patients presenting with histoplasmosis as the initial manifestation of their disease.ⁱLiposomal amphotericin B (Ambisome) may be more appropriate for disseminated disease.

Compiled from refs. 20, 22, and 23.

Most adults with disseminated histoplasmosis demonstrate a mild, chronic form of the disease. Untreated patients often are ill for 10 to 20 years, demonstrating long asymptomatic periods interrupted by relapses of clinical illness characterized primarily by weight loss, weakness, and fatigue. Chronic disseminated histoplasmosis can be seen in patients with lymphoreticular neoplasms (Hodgkin's disease) and patients undergoing immunosuppressant chemotherapy for organ transplantation or for rheumatic diseases. Although CNS involvement occurs in 10% to 20% of patients with severe underlying immunosuppressive conditions, focal organ involvement is uncommon. The disease is characterized by the development of focal granulomatous lesions, often with bone marrow involvement resulting in thrombocytopenia, anemia, and leukemia. Fever, hepatosplenomegaly, and GI ulceration are common.

HISTOPLASMOSIS IN HIV-INFECTED PATIENTS

Adult patients with AIDS demonstrate an acute form of disseminated disease that resembles the syndrome seen in infants and children. Progressive disseminated histoplasmosis (PDH) can occur as the direct result of initial infection or because of the reactivation of dormant foci. In endemic areas, 50% of AIDS patients demonstrate PDH as the first manifestation of their disease. Progressive disseminated histoplasmosis is characterized by fever (75% of patients), weight loss, chills, night sweats, enlargement of the spleen, liver, or lymph nodes, and anemia. Pulmonary symptoms occur in only one-third of patients and do not always correlate with the presence of infiltrates on chest roentgenogram. A clinical syndrome resembling septicemia is seen in approximately 25% to 50% of patients.

DIAGNOSIS

Detection of single, yeastlike cells 2 to 5 microns in diameter with narrow-based budding by direct examination or by histologic study of blood smears or tissues should raise strong suspicion of infection with *H. capsulatum* because colonization does not occur as with *Aspergillus* or *Candida* infection. Identification of mycelial isolates from clinical cultures can be made by conversion of the mycelium to the yeast form (requires 3 to 6 weeks) or via a rapid (2-hour)

and 100% sensitive DNA probe that recognizes ribosomal DNA. In patients with suspected disseminated or chronic cavitary histoplasmosis, two to three blood, sputum, and bone marrow cultures and stains should be obtained using the lysis centrifugation technique, and the cultures should be held for 14 to 21 days for optimal yield of *H. capsulatum*. In patients with acute self-limited histoplasmosis, extensive testing to verify the diagnosis may not be necessary.

In most patients, serologic evidence remains the primary method in the diagnosis of histoplasmosis. Results obtained from commercially available complement fixation (CF), immunodiffusion (ID), and latex agglutination (LA) antibody tests are used alone or in combination. In general, the use of histoplasmin skin tests is of little value except in epidemiologic studies because histoplasmin reactivity waxes in the absence of occasional reexposure. In addition, histoplasmin skin testing may result in a false increase in the CF titer for mycelial antigen (CF-M) to *H. capsulatum*. A fourfold rise in the CF titer is usually indicative of recent infection, although some patients with severe disease or profound immunosuppression may demonstrate a weaker antibody response.

Because the ID test is not as sensitive as CF, it should be used to assess the importance of weakly reactive results obtained by CF rather than as a screening procedure. Radioimmunoassay (RIA), which measures immunoglobulin M (IgM) and IgG antibodies against a histoplasmin extract, is the most sensitive test, but it may show a large number of false-positive reactions in patients living in an endemic area.

In the AIDS patient with PDH, the diagnosis is best established by bone marrow biopsy and culture, which yield positive cultures in more than 90% of patients, although blood cultures and histopathologic examination and culture of pulmonary tissue, sputum, skin, and lymph nodes also may be helpful. Detection of *H. capsulatum* polysaccharide antigen (HPA) in urine, blood, or cerebrospinal fluid (CSF) by enzyme-linked immunosorbent assay (ELISA) or by modified radioimmunoassay offer promising new techniques for the rapid diagnosis of histoplasmosis. The HPA (RIA) levels also have been used successfully to monitor the course of therapy and to detect relapses in patients with AIDS, and the clearance of antigen from serum and urine correlates with clinical efficacy during maintenance therapy with itraconazole. Unfortunately, these tests are not yet available for clinical use.

► TREATMENT: Histoplasmosis

■ NON-HIV-INFECTED PATIENT

Table 119-2 summarizes the recommended therapy for the treatment of histoplasmosis. In general, asymptomatic or mildly ill patients and patients with sarcoid-like disease do not benefit from antifungal therapy. In the vast majority of patients, low-inoculum exposure to *H. capsulatum* results in *mild* or *asymptomatic* pulmonary histoplasmosis. The course of disease generally is benign, and symptoms usually abate within a few weeks of onset. Therapy may be helpful in symptomatic patients whose conditions have not improved during the first month of infection. Fever persisting more than 3 weeks may indicate that the patient is developing progressive disseminated disease, which may be aborted by antifungal therapy. Whether antifungal therapy hastens recovery or prevents complications is unknown because it has never been studied in prospective trials.

Patients with mild, self-limited disease, chronic disseminated disease, or chronic pulmonary histoplasmosis who have no underlying immunosuppression usually can be treated with either oral

ketoconazole or IV amphotericin B. The goals of therapy are resolution of clinical abnormalities, prevention of relapse, and eradication of infection whenever possible, although chronic suppression of infection may be adequate in immunosuppressed patients, including those with HIV disease.^{22,23}

Patients with arthritis, erythema nodosum, pericarditis, or mediastinal granuloma may require the addition of a 2-week course of corticosteroids to their therapy.²⁰

■ HIV-INFECTED PATIENT

In AIDS patients, intensive 12-week primary antifungal therapy (induction and consolidation therapy) is followed by lifelong suppressive (maintenance) therapy with itraconazole. Amphotericin B dosages of 50 mg/day (up to 1 mg/kg per day) should be administered intravenously to a cumulative dose of 15 to 35 mg/kg (1 to 2 g) in patients who require hospitalization. Amphotericin B can be replaced

with itraconazole 200 mg orally twice daily when the patient no longer requires hospitalization or intravenous therapy to complete a 12-week total course of induction therapy. In patients who do not require hospitalization, itraconazole therapy for 12 weeks may be used.

Fluconazole 800 mg/day orally as induction, followed by 400 mg/day, was effective in 88% of patients, but relapses occurred in

approximately one-third of patients, and in vitro resistance developed in approximately 50% of patients who relapsed.

In regions experiencing high rates of histoplasmosis (>5 cases/100 patient-years), itraconazole 200 mg/day is recommended as prophylactic therapy in HIV-infected patients. Fluconazole is not an acceptable alternative because of its inferior activity against *H. capsulatum* and its lower efficacy for the treatment of histoplasmosis.²²

EVALUATION OF THERAPEUTIC OUTCOMES

Response to therapy should be measured by resolution of radiologic, serologic, and microbiologic parameters and by improvement in signs and symptoms of infection. Although investigators are limited by the lack of standardized criteria to quantify the extent of infection, degree of immunosuppression, or treatment response, response rates (based on resolution or improvement in presenting signs and symptoms) of greater than 80% have been reported in case series in AIDS patients receiving varied dosages of amphotericin B. Rapid responses are reported, with the resolution of symptoms in 25% and 75% of patients by days 3 and 7 of therapy, respectively.

After the initial course of therapy for histoplasmosis is complete, lifelong suppressive therapy with oral azoles or amphotericin B (1–1.5 mg/kg weekly or biweekly) is recommended because of the frequent recurrence of infection.²⁵ Relapse rates in AIDS patients not receiving maintenance therapy range from 50% to 90%.²²

Antigen testing may be useful for monitoring therapy in patients with disseminated histoplasmosis. Antigen concentrations decrease with therapy and increase with relapse. Some investigators recommend that treatment should continue until antigen concentrations revert to negative or less than 4 units. If treatment is discontinued before antigen concentrations in serum and urine revert to negative, patients should be followed closely for relapse, and antigen levels should be monitored every 3 to 6 months until they become negative.²²

BLASTOMYCOSIS

North American blastomycosis is a systemic fungal infection caused by *Blastomyces dermatitidis*, a dimorphic fungus that infects primarily the lungs. Patients, however, may present with a variety of pulmonary and extrapulmonary clinical manifestations. Pulmonary disease may be acute or chronic and can mimic infection with tuberculosis, pyogenic bacteria, other fungi, or malignancy. Blastomycosis can disseminate to virtually every other body organ, and approximately 40% of patients with blastomycosis present with skin, bone and joint, or genitourinary tract involvement without any evidence of pulmonary disease.²⁴

Pulmonary infection probably occurs by inhalation of conidia, which convert to the yeast form in the lung. A vigorous inflammatory response ensues, with neutrophilic recruitment to the lungs followed by the development of cell-mediated immunity and the formation of noncaseating granulomas.

EPIDEMIOLOGY

Blastomycosis was renamed *North American blastomycosis* in 1942, when Conant and Howell named a similar fungus endemic to South America, *Blastomyces brasiliensis*, and the disease it caused *South American blastomycosis*. Although the disease is now recognized to be endemic to the southeastern and south central states of the United States (especially those bordering on the Mississippi and Ohio River basins) and the midwestern states and Canadian provinces bordering

on the Great Lakes, numerous cases of North American blastomycosis have been diagnosed in Africa, northern parts of South America, India, and Europe. Endemic areas have been defined primarily by analysis of sporadic cases and epidemics or clusters of disease because the lack of a dependable skin or laboratory test makes wide-scale epidemiologic testing to determine the incidence of infection unfeasible at present.^{23,25} Although initial review of sporadic cases suggested that males with outdoor occupations that exposed them to soil were at greatest risk for blastomycosis, more recent data suggest that there is no sex, age, or occupational predilection for blastomycosis.^{23,24}

Although *B. dermatitidis* generally is considered to be a soil inhabitant, attempts to isolate the organism in nature frequently have been unsuccessful. *B. dermatitidis* has been isolated from soil containing decayed vegetation, decomposed wood, and pigeon manure, frequently in association with warm, moist soil of wooded areas that is rich in organic debris.^{23,24}

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION^{16,17,23,24}

GENERAL

Colonization does not occur with *Blastomyces*. *Acute pulmonary blastomycosis* generally is an asymptomatic or self-limited disease characterized by fever, shaking chills, and productive, purulent cough, with or without hemoptysis, in immunocompetent individuals. The clinical presentation may be difficult to differentiate from other respiratory infections, including bacterial pneumonia, on the basis of clinical symptoms alone.

Sporadic (nonepidemic) pulmonary blastomycosis may present as a more chronic or subacute disease, with low-grade fever, night sweats, weight loss, and productive cough that resembles tuberculosis rather than bacterial pneumonia. *Chronic pulmonary blastomycosis* is characterized by fever, malaise, weight loss, night sweats, chest pain, and productive cough. Patients often are thought to have tuberculosis and frequently have evidence of disseminated disease that may appear 1 to 3 years after the primary pneumonia has resolved. Reactivation of disease may occur in the lungs or as the focus of new infection in other organs.

In approximately 40% of patients, dissemination is not accompanied by reactivation of pulmonary disease. The most common sites for disseminated disease include the skin and bony skeleton, although less commonly the prostate, oropharyngeal mucosa, and abdominal viscera are involved. CNS disease, while exceedingly uncommon, is associated with the highest mortality rate.

LABORATORY AND DIAGNOSTIC TESTS

The simplest and most successful method of diagnosing blastomycosis is by direct microscopic visualization of the large, multinucleated yeast with single, broad-based buds in sputum or other respiratory specimens following digestion of cells and debris with 10% potassium hydroxide. Histopathologic examination of tissue biopsies and

culture of secretions also should be used to identify *B. dermatitidis*, although it may require up to 30 days to isolate and identify a small inoculum.

No reliable skin test exists to determine the incidence and prevalence of disease in endemic populations, and reliable serologic diagnosis of blastomycosis has long been hampered by the lack of specific and standardized reagents. Serologic response does not always correlate with clinical improvement, although some investigators have noted that a decline in the number of precipitins or CF titers may offer evidence of a favorable prognosis in patients with established disease.

► TREATMENT: Blastomycosis

■ NON-HIV-INFECTED PATIENT

5 In patients with mild pulmonary blastomycosis, the clinical presentation of the patient, the immune competence of the patient, and the toxicity of the antifungal agents are the main determinants of whether or not to administer antifungal therapy. All immunocompromised patients and patients with progressive pulmonary disease or with extrapulmonary disease should be treated (Table 119–3). In the

Acute pulmonary blastomycosis generally is an asymptomatic or self-limited disease characterized by fever, shaking chills, and productive, purulent cough, with or without hemoptysis, in immunocompetent individuals. The clinical presentation may be difficult to differentiate from other respiratory infections, including bacterial pneumonia, on the basis of clinical symptoms alone. Sporadic (nonepidemic) cases of pulmonary blastomycosis may present as a more chronic or subacute disease with low-grade fever, night sweats, weight loss, and productive cough that resembles tuberculosis rather than bacterial pneumonia.

case of disease limited to the lungs, cure may have occurred before the diagnosis is made and without treatment. Regardless of whether or not the patient receives treatment, however, he or she must be followed carefully for many years for evidence of reactivation or progressive disease.^{23,24}

Some authors recommend ketoconazole therapy for the treatment of self-limited pulmonary disease, with the hope of preventing late extrapulmonary disease; however, data supporting the efficacy of these regimens are lacking.^{23,24} Itraconazole 200 to 400 mg/day

TABLE 119–3. Therapy of Blastomycosis

| Type of Disease | Preferred Treatment | Comments |
|--|--|---|
| Pulmonary^a | | |
| Life-threatening | Amphotericin B ^b IV 0.7–1 mg/kg/day IV (total dose 1.5–2.5 g) | Patients may be initiated on amphotericin B and changed to oral itraconazole 200–400 mg orally daily once patient is clinically stabilized and a minimum dose of 500 mg of amphotericin B has been administered |
| Mild to moderate | Itraconazole 200 mg orally twice daily × ≥6 months ^c | <i>Alternative therapy:</i> Ketoconazole 400–800 mg orally daily × ≥6 months or fluconazole 400–800 mg orally daily × ≥6 months ^d <i>In patients intolerant of azoles or in whom disease progresses during azole therapy:</i> Amphotericin B 0.5–0.7 mg/kg/day IV (total dose 1.5–2.5 g) |
| Disseminated or Extrapulmonary | | |
| CNS | Amphotericin B 0.7–1 mg/kg/day IV (total dose 1.5–2.5 g) | For patients unable to tolerate a full course of amphotericin B, consider lipid formulations of amphotericin B or fluconazole ≥ 800 mg orally daily |
| Non-CNS | | |
| Life-threatening | Amphotericin B 0.7–1 mg/kg/day IV (total dose 1.5–2.5 g) | Patients may be initiated on amphotericin B and changed to oral itraconazole 200–400 mg orally daily once stabilized |
| Mild to moderate | Itraconazole 200–400 mg orally daily × ≥6 months | Ketoconazole 400–800 mg orally daily or fluconazole 400–800 mg orally daily × ≥6 months <i>In patients intolerant of azoles or in whom disease progresses during azole therapy:</i> Amphotericin B 0.5–0.7 mg/kg/day IV (total dose 1.5–2.5 g) <i>Bone disease:</i> Therapy with azoles should be continued for 12 months |
| Immunocompromised Host (Including Patients with AIDS, Transplants, or Receiving Chronic Glucocorticoid Therapy) | | |
| Acute disease | Amphotericin B 0.7–1 mg/kg/day IV (total dose 1.5–2.5 g) | Patients without CNS infection may be switched to itraconazole once clinically stabilized and a minimum dose of 1 g of amphotericin B has been administered; long-term suppressive therapy with an azole is advised |
| Suppressive therapy | Itraconazole 200–400 mg orally daily | For patients with CNS disease or those intolerant of itraconazole, consider fluconazole 800 mg orally daily |

^aSome patients with acute pulmonary infection may have a spontaneous cure. Patients with progressive pulmonary disease should be treated.

^bDesoxycholate amphotericin B.

^cIn patients not responding to 400 mg, dosage should be increased by 200 mg increments every 4 weeks to a maximum of 800 mg daily.

^dTherapy with ketoconazole is associated with relapses, and fluconazole therapy achieves a lower response rate than itraconazole.

CNS = central nervous system.

Compiled from refs. 23, and 24.

demonstrated 90% efficacy as a first-line agent in the treatment of non-life-threatening non-CNS blastomycosis, and for compliant patients who completed at least 2 months of therapy, a success rate of 95% was noted. No therapeutic advantage was noted with the higher (400 mg) dosage as compared with patients treated with 200 mg.

All patients with disseminated blastomycosis, as well as those with extrapulmonary disease, require therapy. Ketoconazole 400 mg/day orally for 6 months cures more than 80% of patients with chronic pulmonary and nonmeningeal disseminated blastomycosis. Amphotericin B is more efficacious but more toxic and therefore is reserved for noncompliant patients and patients with overwhelming or life-threatening disease, CNS infection, and treatment failures. Cumulative amphotericin B dosages of more than 1 g have resulted in cure without relapse in 70% to 91% of patients with blastomycosis. Relapse rates depend on the total dosage of amphotericin B administered.^{23,24} Patients with genitourinary tract disease should be treated initially with 600–800 mg/day of ketoconazole because of the low concentrations of drug achieved in the urine and prostate tissue.

Patients should be monitored carefully for signs of clinical failure, and those who fail or are unable to tolerate itraconazole therapy or who develop CNS disease should be treated with amphotericin B for a total cumulative dose of 1.5 to 2.5 g.^{23,24}

Lipid preparations of amphotericin B are effective in animal models of blastomycosis, but they have not been evaluated adequately in humans. Limited clinical experience suggests that these preparations may provide an alternative for patients unable to experience standard therapy with amphotericin B because of toxicity. Surgery has only a limited role in the treatment of blastomycosis.

HIV-INFECTED PATIENT

For unclear reasons, blastomycosis is an uncommon opportunistic disease among immunocompromised individuals, including AIDS patients; however, blastomycosis may occur as a late (CD4 lymphocytes < 200 cells/mm³) and frequently fatal complication of HIV infection. In this population, overwhelming disseminated disease with frequent involvement of the CNS is common.²³ Following induction therapy with amphotericin B (total cumulative dose of 1 g), HIV-infected patients should receive chronic suppressive therapy with an oral azole antifungal. Despite its higher cost, itraconazole has become the drug of choice for non-life-threatening histoplasmosis (mild to moderate disease) in HIV-infected patients.²⁴

COCCIDIOIDOMYCOSIS

EPIDEMIOLOGY

Coccidioidomycosis is caused by infection with *Coccidioides immitis*, a dimorphic fungus found in the southwestern and western United States, as well as in parts of Mexico and South America. In North America, the endemic regions encompass the semiarid areas of the southwestern United States from California to Texas known as the Lower Sonoran Zone, where there is scant annual rainfall, hot summers, and sandy, alkaline soil. *C. immitis* grows in the soil as a mold, and mycelia proliferate during the rainy season. During the dry season, resistant arthroconidia form and become airborne when the soil is disturbed.

Although generally considered to be a regional disease, coccidioidomycosis has increased in importance in recent years because of the increased tourism and population in endemic areas, the increased use of immunosuppressive therapy in transplantation and oncology, and the AIDS epidemic. Although there is no racial, hormonal, or immunologic predisposition for acquiring primary disease, these factors affect the risk of subsequent dissemination of disease²⁵ (Table 119–4).

From ref. 25.

PATHOPHYSIOLOGY

When individuals come in contact with contaminated soil during ranching, dust storms, or proximity to construction sites or archaeological excavations, arthroconidia are inhaled into the respiratory tree, where they transform into spherules, which reproduce by cleavage of the cytoplasm to produce endospores. The endospores are released when the spherules reach maturity. Similar to histoplasmosis, an acute inflammatory response in the tissue leads to infiltration of mononuclear cells, ultimately resulting in granuloma formation.²⁵

CLINICAL PRESENTATION OF COCCIDIOIDOMYCOSIS^{13,23–26}

Coccidioidomycosis encompasses a spectrum of illnesses ranging from primary uncomplicated respiratory tract infection that resolves spontaneously to progressive pulmonary or disseminated infection. Initial or primary infection with *C. immitis* almost always involves the lungs. Although approximately one-third of the population in endemic areas is infected, the average incidence of symptomatic disease is only approximately 0.43%.

SIGNS AND SYMPTOMS

In *asymptomatic disease* (60% of patients), patients have nonspecific symptoms that are often indistinguishable from ordinary upper respiratory infections, including fever, cough, headache, sore throat, myalgias, and fatigue. A fine, diffuse rash may appear during the first few days of the illness. Primary pneumonia may be the first manifestation of disease, characterized by a productive cough that may be blood-streaked, as well as single or multiple soft or dense homogeneous hilar or basal infiltrates on chest roentgenogram. Chronic, persistent pneumonia or persistent pulmonary coccidioidomycosis (primary disease lasting more than 6 weeks) is complicated by hemoptysis, pulmonary scarring, and the formation of cavities or bronchopleural fistulas.

Necrosis of pulmonary tissue with drainage and cavity formation occurs commonly. Most parenchymal cavities close spontaneously or form dense nodular scar tissue that may become superinfected

with bacteria or spherules of *C. immitis*. These patients often have persistent cough, fevers, and weight loss.

Valley fever occurs in approximately 25% of patients and is characterized by erythema nodosum and erythema multiforme of the upper trunk and extremities in association with diffuse joint aches or fever. More commonly, a diffuse, mild erythroderma or maculopapular rash is observed. Patients may have pleuritic chest pain and peripheral eosinophilia.

Disseminated disease occurs in less than 1% of infected patients. The most common sites for dissemination are the skin, lymph nodes, bone, and meninges, although the spleen, liver, kidney, and adrenal gland also may be involved. Occasionally, miliary coccidioidomycosis occurs, with rapid, widespread dissemination, often in concert with positive blood cultures for *C. immitis*. Patients with AIDS frequently present with miliary disease. Coccidioidomycosis in AIDS patients appears to be caused by reactivation of disease in most patients.

CNS infection occurs in approximately 16% of patients with disseminated coccidioidomycosis. Patients may present with meningeal disease without previous symptoms of primary pulmonary infection, although disease usually occurs within 6 months of the primary infection. The signs and symptoms are often subtle and nonspecific, including headache, weakness, changes in mental status (lethargy and confusion), neck stiffness, low-grade fever, weight loss, and occasionally, hydrocephalus. Space-occupying lesions are rare, and the main areas of involvement are the basilar meninges.

DIAGNOSIS

LABORATORY TESTS

Recovery of *C. immitis* from infected tissues or secretions for direct examination and culture provides an accurate and rapid method of diagnosis. Direct microscopic examination and histopathologic studies of infected tissues will reveal the large, mature endospore-forming spherules. Young spherules without endospores may be confused, however, with other fungi. Silver stains of body fluids or tissue biopsies are also helpful.

With chronic, persistent pneumonia, *C. immitis* often can be cultured from the sputum for a period of several years. Chest radiographs usually demonstrate apical fibronodular lesions or slowly progressive cavitation. With CNS infection, analysis of the CSF generally reveals a lymphocytic pleocytosis with elevated protein and a decreased glucose concentration. Although serum usually is positive for coccidioidal CF antibodies, the coccidioidal skin test is often negative.

OTHER DIAGNOSTIC TESTS

Most patients develop a positive skin test within 3 weeks of the onset of symptoms. Baseline evaluation of skin test reactivity and serology is essential in order to assess cell-mediated immunity. Patients who develop early positive skin-test reactivity or whose coccidioidin skin-test reactivity turns from negative to positive during therapy have an improved prognosis compared with patients whose skin-test reactivity develops later or does not change during therapy. Patients with disseminated coccidioidomycosis whose skin tests are persistently negative are more likely to require prolonged therapy, and they are more likely to relapse after completion of therapy.

Antibody production can be used to follow the course of disease because most patients produce antibodies in response to infection with *C. immitis*. Early infection is characterized by the development of the IgM antibody, which peaks within 2 to 3 weeks of infection and then declines rapidly. The IgM antibody can be detected by either tube precipitin or immunodiffusion techniques.

The IgG antibody levels rise between 4 and 12 weeks after infection and decrease slowly over months to years, and IgG can be detected in many body fluids, including serum, CSF, and pleural fluid, by CF and ID techniques. Higher titers (>1:16 or 1:32) occur more frequently with severe disease. Titers can be followed serially to evaluate the efficacy of antifungal therapy.

Radiographic features tend to be quite variable; hilar adenopathy with alveolar infiltrates, tissue excavation of an infiltrate (resulting in a thin-walled cavity), or small pleural effusions are all seen commonly. With chronic persistent pneumonia, chest radiographs usually demonstrate apical fibronodular lesions or slowly progressive cavitation.

▶ TREATMENT: Coccidioidomycosis

■ GENERAL GUIDELINES

6 Therapy for coccidioidomycosis is difficult, and the results are unpredictable. Guidelines are available for treatment of this disease; however, optimal treatment for many forms of this disease still generates debate.²⁵ The efficacy of antifungal therapy for coccidioidomycosis is often less certain than that for other fungal etiologies, such as blastomycosis, histoplasmosis, or cryptococcus, even when in vitro susceptibilities and the sites of infections are similar. The refractoriness of coccidioidomycosis may relate to the ability of *C. immitis* spherules to release hundreds of endospores, maximally challenging host defenses.^{25,26} Fortunately, only approximately 5% of infected patients require therapy.²⁶

■ SPECIFIC AGENTS USED FOR THE TREATMENT OF COCCIDIOIDOMYCOSIS

Specific antifungals (and their usual dosages) for the treatment of coccidioidomycosis include intravenous amphotericin B (0.5 to 0.7 mg/

kg per day), ketoconazole (400 mg/day orally), intravenous or oral fluconazole (usually 400 to 800 mg/day, although dosages as high as 1200 mg/day have been used without complications), and itraconazole (200 to 300 mg orally twice daily as either capsules or solution).^{25,26} If itraconazole is used, measurement of serum concentrations may be helpful to ascertain whether oral bioavailability is adequate.

Amphotericin B generally is preferred as initial therapy in patients with rapidly progressive disease, whereas azoles generally are preferred in patients with subacute or chronic presentations. The lipid formulations of amphotericin B have not been studied extensively in coccidioidal infection but may offer a means of giving more drug with less toxicity. Fluconazole probably is the most frequently used medicine given its tolerability, although high relapse rates have been reported in some studies. Relapse rates with itraconazole therapy may be lower than with fluconazole.^{25,26}

■ PRIMARY RESPIRATORY INFECTION

Although most patients with symptomatic primary pulmonary disease recover without therapy, management should include follow-up visits

for 1 to 2 years to document resolution of disease or to identify as early as possible evidence of pulmonary or extrapulmonary complications.

CLINICAL CONTROVERSY

Because of the lack of prospective, controlled trials, there is continued disagreement among experts in endemic areas whether patients with coccidioidomycosis should be treated and, if so, which ones and for how long. The excellent tolerability of oral azoles has lowered the threshold for deciding to treat primary infection, and some clinicians treat all primary infections. Rationale for treating a primary self-limiting infection include the ability to lessen the morbidity associated with the acute infection and the possible ability to reduce the development of more serious complications. However, there is currently no evidence that treatment of the primary infection accomplishes either of these goals.²⁶

Patients with a large inoculum, severe infection, or concurrent risk factors (e.g., HIV infection, organ transplant, pregnancy, or high doses of corticosteroids) probably should be treated, particularly those with high CF titers, in whom incipient or occult dissemination is likely. Because some racial or ethnic populations have a higher risk of dissemination, some clinicians advocate their inclusion in the high-risk group. Common indicators used to judge the severity of infection include weight loss (>10%), intense night sweats persisting more than 3 weeks, infiltrates involving more than one-half of one lung or portions of both lungs, prominent or persistent hilar adenopathy, CF antibody titers of greater than 1:16, failure to develop dermal sensitivity to coccidial antigens, inability to work, or symptoms that persist for more than 2 months.^{25,26}

Commonly prescribed therapies include currently available oral azole antifungals at their recommended doses for courses of therapy ranging from 3 to 6 months.^{25,26} In patients with diffuse pneumonia with bilateral reticulonodular or miliary infiltrates, therapy usually is initiated with amphotericin B; several weeks of therapy generally are required to produce clear evidence of improvement. Consolidation therapy with oral azoles can be considered at that time. The total duration of therapy should be at least 1 year, and in patients with underlying immunodeficiency, oral azole therapy should be continued as secondary prophylaxis.

INFECTIONS OF THE PULMONARY CAVITY

Many pulmonary infections that are caused by *C. immitis* are benign in their course and do not require intervention. In the absence of

controlled clinical trials, evidence of the benefit of antifungal therapy is lacking, and asymptomatic infections generally are left untreated. Symptomatic patients may benefit from oral azole therapy, although recurrence of symptoms may be seen in some patients once therapy is discontinued. Surgical resection of localized cavities provides resolution of the problem in patients in whom the risks of surgery are not too high.^{25,26}

EXTRAPULMONARY (DISSEMINATED) DISEASE

NONMENINGEAL DISEASE

Almost all patients with disease located outside the lungs should receive antifungal therapy; therapy usually is initiated with 400 mg/day of an oral azole. Amphotericin B is an alternative therapy and may be necessary in patients with worsening lesions or with disease in particularly critical locations such as the vertebral column. Approximately 50% to 75% of patients treated with amphotericin B for nonmeningeal disease achieve a sustained remission, and therapy usually is curative in patients with infections localized strictly to skin and soft tissues without extensive abscess formation or tissue damage. The efficacy of local injection into joints or the peritoneum, as well as intraarticular or intradermal administration, remains poorly studied. Amphotericin B appears to be most efficacious when cell-mediated immunity is intact (as evidenced by a positive coccidioidin or spherulin skin test or low CF antibody titer). Controlled trials that document these clinical impressions are lacking, however.^{25,26}

MENINGEAL DISEASE

Fluconazole has become the drug of choice for the treatment of coccidioid meningitis.^{14,15} A minimum dose of 400 mg/day orally leads to a clinical response in most patients and obviates the need for intrathecal amphotericin B. Some clinicians will initiate therapy with 800 or 1000 mg/day, and itraconazole dosages of 400–600 mg/day are comparably effective. It is also clear, however, that fluconazole only leads to remission rather than cure of the infections; thus suppressive therapy must be continued for life. Ketoconazole cannot be recommended routinely for the treatment of coccidioid meningitis because of its poor CNS penetration following oral administration. Patients who do not respond to fluconazole or itraconazole therapy are candidates for intrathecal amphotericin B therapy with or without continuation of azole therapy. The intrathecal dose of amphotericin B ranges from 0.01–1.5 mg given at intervals ranging from daily to weekly. Therapy is initiated with a low dosage and is titrated upward as patient tolerance develops.^{14,15,25,26}

CRYPTOCOCCOSIS

EPIDEMIOLOGY

Cryptococcosis is a noncontagious, systemic mycotic infection caused by the ubiquitous encapsulated soil yeast *Cryptococcus neoformans*, which is found in soil, particularly in pigeon droppings, although disease occurs throughout the world, even in areas where pigeons are absent. Infection is acquired by inhalation of the organism. The incidence of cryptococcosis has risen dramatically in recent years, reflecting the increased numbers of immunocompromised patients, including those with malignancies, diabetes mellitus, chronic renal failure, and organ transplants and those receiving immunosuppressive

agents. The AIDS epidemic also has contributed to the increased numbers of patients; cryptococcosis is the fourth most common infectious complication of AIDS and the second most common fungal pathogen.²⁷

Although *C. neoformans* produces no toxins and evokes only a minimal inflammatory response in tissue, the polysaccharide capsule appears to allow the organism to resist phagocytosis by the host. The capsular polysaccharide of *C. neoformans* appears to comprise the major virulence factor for this pathogen. Four serotypes of *C. neoformans* (A through D) have been identified; they vary in their polysaccharide content, virulence, geographic foci, and response to antifungal therapy. Serotypes A and D are commonly associated with pigeon droppings and other environmental sites and generally require

shorter therapy than do infections caused by serotypes B or C, which have been found only in infected humans and animals. Serotypes B and C appear more resistant to antifungal agents in vitro. Patients with AIDS are almost always infected with serotypes A and D, even in areas endemic for serotypes B and C. There is no particular geographic area of endemic focus for *C. neoformans*.

Cell-mediated immunity appears to play a major role in host defense against infection with *C. neoformans*; 29% to 55% of patients with cryptococcal meningitis have a predisposing condition. Many patients with disseminated cryptococcosis demonstrate defects in cell-mediated immunity. The predilection of *C. neoformans* for the CNS appears to be caused by the lack of immunoglobulins and complement and the excellent growth medium afforded by CSF.²⁷

Disease may remain localized in the lungs or may disseminate to other tissues, particularly the CNS, although the skin also can be affected. Hematogenous spread generally occurs in the immunocompromised host, although it also has been seen in individuals with intact immune systems. Cryptococemia is the most common symptomatic extraneural infection associated with *C. neoformans*. Cryptococemia can be documented in 5% to 22% of non-AIDS patients, and CNS involvement of *C. neoformans* can be found in 18% to 50% of AIDS patients. Cryptococcal disease is present in 7.5% to 10% of AIDS patients. Therefore, patients with evidence of extraneural cryptococcosis should be evaluated for CNS disease.

CLINICAL PRESENTATION OF CRYPTOCOCCOSIS^{13,27,28}

Primary cryptococcosis in humans almost always occurs in the lungs, although the pulmonary focus usually produces a subclinical infec-

tion. Symptomatic infections usually are manifested by cough, rales, and shortness of breath that generally resolve spontaneously. In non-AIDS patients, the symptoms of cryptococcal meningitis are non-specific. Headache, fever, nausea, vomiting, mental status changes, and neck stiffness generally are observed. Less common symptoms include visual disturbances (photophobia and blurred vision), papilledema, seizures, and aphasia. In AIDS patients, fever and headache are common, but meningismus and photophobia are much less common than in non-AIDS patients. Approximately 10% to 12% of AIDS patients have asymptomatic disease, similar to the rate observed in non-AIDS patients.²⁸

LABORATORY TESTS

With cryptococcal meningitis, the CSF opening pressure generally is elevated. There is a CSF pleocytosis (usually lymphocytes), leukocytosis, a decreased glucose concentration, and an elevated CSF protein concentration. There is also a positive cryptococcal antigen (detected by latex agglutination). The test is rapid, specific, and extremely sensitive, but false-negative results can occur. False-positive tests can result from cross-reactivity with rheumatoid factor and *Trichosporon beigelli*. *C. neoformans* can be detected in approximately 60% of patients by india ink smear of CSF, and it can be cultured in more than 96% of patients. Occasionally, large volumes of CSF are required to confirm the diagnosis.

The CSF parameters in patients with AIDS are similar to those seen in non-AIDS patients, with the exception of a decreased inflammatory response to the pathogen, resulting in a strikingly low number of leukocytes in CSF and extraordinarily high cryptococcal antigen titers.

► TREATMENT: Cryptococcosis

The choice of treatment for disease caused by *C. neoformans* depends on both the anatomic sites of involvement and the host's immune status.

■ NONIMMUNOCOMPROMISED PATIENTS

For asymptomatic immunocompetent hosts with isolated pulmonary disease and no evidence of CNS disease, careful observation may be warranted; in the case of symptomatic infection, fluconazole or amphotericin B is warranted (Table 119-5). In individuals with non-CNS cryptococemia, a positive serum cryptococcal antigen titer (>1:8), cutaneous infection, a positive urine culture, or prostatic disease, the clinician must decide whether to follow the regimen for isolated pulmonary disease or the more aggressive regimen for patients with CNS (disseminated) disease.¹⁹

Prior to the introduction of amphotericin B, cryptococcal meningitis was an almost uniformly fatal disease; approximately 86% of patients died within 1 year. The use of large (1 to 1.5 mg/kg) daily doses of amphotericin B resulted in cure rates of approximately 64%.

◀ When amphotericin B is combined with flucytosine, a smaller dose of amphotericin B can be employed because of the in vitro and in vivo synergy between the two antifungal agents. Resistance develops to flucytosine in up to 30% of patients treated with flucytosine alone, limiting its usefulness as monotherapy.^{28,29} Combination therapy with amphotericin B and flucytosine will sterilize the CSF within

2 weeks of treatment in 60% to 90% of patients, and most immunocompetent patients will be treated successfully with 6 weeks of combination therapy.²⁷ However, because of the need for prolonged IV therapy and the potential for renal and hematologic toxicity with this regimen, alternative regimens have been advocated. Despite a lack of clinically controlled trials in this population, amphotericin B induction therapy for 2 weeks, followed by consolidation therapy with fluconazole for an additional 8 to 10 weeks, is frequently recommended based on data extrapolated from studies conducted in HIV-infected patients. Suppressive therapy with fluconazole 200 mg/day for 6 to 12 months after the completion of induction and consolidation therapy is optional.^{19,29-31}

Pilot studies evaluating combination therapy with fluconazole plus flucytosine as initial therapy yielded unsatisfactory results, and this approach is discouraged even in "low risk" patients. Ketoconazole has been used successfully in the treatment of cutaneous cryptococcosis, but it is not useful in the treatment of CNS disease, probably because of its poor penetration into the CNS.¹⁹

Despite low CSF concentrations of amphotericin B (2% to 3% of those observed in plasma), the use of intrathecal amphotericin B is not recommended for the treatment of cryptococcal meningitis except in very ill patients or in patients with recurrent or progressive disease despite aggressive therapy with IV amphotericin B. The dosage of amphotericin B employed is usually 0.5 mg administered via the lumbar, cisternal, or intraventricular (via an Ommaya reservoir) route two or three times weekly. Side effects of intrathecal amphotericin B include arachnoiditis and paresthesias. Intrathecal

TABLE 119–5. Therapy of Cryptococcosis^{a,b}

| Type of Disease and Common Clinical Manifestations | Therapy/Comments |
|---|--|
| Nonimmunocompromised Host | Comparative trials for amphotericin B ^c versus azoles not available |
| Isolated pulmonary disease (without evidence of CNS infection) | <i>Asymptomatic disease:</i> Durg therapy generally not required; observe carefully or fluconazole 400 mg orally daily × 3–6 months <i>Mild to moderate symptoms:</i> Fluconazole 200–400 mg orally daily × 3–6 months; <i>Severe disease or inability to take azoles:</i> Amphotericin B 0.4–0.7 mg/kg/day (total dose of 1–2 g) |
| Cryptococemia with positive serum antigen titer (>1:8), cutaneous infection, a positive urine culture, or prostatic disease | Clinician must decide whether to follow the pulmonary therapeutic regimen or the CNS (disseminated) regimen |
| Recurrent or progressive disease not responsive to amphotericin B | Amphotericin B ^d IV 0.5–0.75 mg/kg/day ± IT amphotericin B 0.5 mg 2–3 times weekly |
| Isolated pulmonary disease (without evidence of CNS infection) | <i>Mild to moderate symptoms or asymptomatic with a positive pulmonary specimen:</i> Fluconazole 200–400 mg orally daily × lifelong <i>or</i> Itraconazole 200–400 mg orally daily × lifelong <i>or</i> Fluconazole 400 mg orally daily + flucytosine 100–150 mg/kg/day orally × 10 weeks <i>Severe disease:</i> Amphotericin B until symptoms are controlled, followed by fluconazole |
| CNS disease | |
| Acute (induction/consolidation therapy) (follow all regimens with suppressive therapy) | Amphotericin B ^d IV 0.7–1 mg/kg/day + flucytosine 100 mg/kg/day orally × ≥2 weeks, then fluconazole 400 mg orally daily × ≥8 weeks ^e <i>or</i> Amphotericin B ^d IV 0.7–1 mg/kg/day + flucytosine 100 mg/kg/day orally × 6–10 weeks ^e <i>or</i> Amphotericin B ^d IV 0.7–1 mg/kg/day × 6–10 weeks ^e <i>or</i> Fluconazole 400–800 mg orally daily × 10–12 weeks <i>or</i> Itraconazole 400–800 mg orally daily × 10–12 weeks <i>or</i> Fluconazole 400–800 mg orally daily + flucytosine 100–150 mg/kg/day orally × 6 weeks ^e <i>or</i> Lipid formulation of amphotericin B IV 3–6 mg/kg/day × 6–10 weeks <i>Note:</i> Induction therapy with azoles alone is discouraged. |
| CNS disease | Amphotericin B ^d IV 0.7–1 mg/kg/day + flucytosine 100 mg/kg/day orally × 2 weeks, followed by fluconazole 400 mg orally daily for a minimum of 10 weeks (in patients intolerant to fluconazole, substitute itraconazole 200–400 mg orally daily) <i>or</i> Amphotericin B ^d IV 0.7–1 mg/kg/day + 5-FC 100 mg/kg/day orally × 6–10 weeks <i>or</i> Amphotericin B ^d IV 0.7–1 mg/kg/day × 10 weeks <i>Refractory disease:</i> Intrathecal or intraventricular amphotericin B |
| Immunocompromised Patients | |
| Non-CNS pulmonary and extrapulmonary disease | Same as nonimmunocompromised patients with CNS disease |
| CNS disease | Amphotericin B ^d IV 0.7–1 mg/kg/day × 2 weeks, followed by fluconazole 400–800 mg orally daily 8–10 weeks, followed by fluconazole 200 mg orally daily × 6–12 months (in patients intolerant to fluconazole, substitute itraconazole 200–400 mg orally daily) <i>Refractory disease:</i> Intrathecal or intraventricular amphotericin B |
| HIV-Infected Patients | |
| Suppressive/maintenance therapy | Fluconazole 200–400 mg orally daily × lifelong <i>or</i> Itraconazole 200 mg orally twice daily × lifelong <i>or</i> Amphotericin B IV 1 mg/kg 1–3 times weekly × lifelong |

^aWhen more than one therapy is listed, they are listed in order of preference.^bSee text for definitions of induction, consolidation, suppressive/maintenance therapy, and prophylactic therapy.^cDeoxycholate amphotericin B.^dIn patients with significant renal disease, lipid formulations of amphotericin B can be substituted for deoxycholate amphotericin B during the induction.^eOr until CSF cultures are negative

amphotericin B therapy should be administered in combination with IV amphotericin B.³¹

■ IMMUNOCOMPROMISED PATIENTS

Immunocompromised hosts with isolated pulmonary and extrapulmonary disease without CNS disease should be treated similarly to nonimmunocompromised patients with CNS disease. Immunocompromised patients with CNS infection require more prolonged therapy; treatment regimens are based on those used in the HIV-infected population and follow induction and consolidation therapy with 6 to 12 months of suppressive therapy with fluconazole.¹⁹

■ HIV-INFECTED PATIENTS

There are no controlled clinical trials evaluating the therapy of isolated pulmonary infection; thus the specific treatment of choice is unclear. However, because these patients are at high risk for disseminated infection, antifungal therapy is warranted in all patients. Lifelong therapy with fluconazole is recommended; in patients for whom fluconazole is not an option, itraconazole can be used.

Fluconazole is beneficial for both acute and chronic maintenance therapy for cryptococcal meningitis. Amphotericin B 0.4–0.5 mg/kg IV daily was compared with oral fluconazole 200 mg/day. Although the overall 10-week mortality was the same in both groups, the time until the CSF culture became negative was longer and there were more deaths in the first 2 weeks of therapy in the fluconazole group.³⁰ In later trials,³¹ amphotericin B 0.7 mg/kg IV daily for 2 weeks (with or without oral flucytosine 100 mg/kg per day), followed by consolidation therapy with either itraconazole 400 mg/day orally or fluconazole 400 mg/day orally, led to markedly improved outcomes in comparison with earlier regimens. This study confirmed the benefit of early high-dose (0.7 mg/kg per day) amphotericin B use, the utility of flucytosine added to amphotericin B for induction therapy, and the slight superiority of fluconazole over itraconazole for consolidation therapy.

Amphotericin B combined with flucytosine is the initial treatment of choice. In patients who cannot tolerate flucytosine, amphotericin B alone is an acceptable alternative. After the initially successful 2-week induction period, consolidation therapy with fluconazole can be administered for 8 weeks or until CSF cultures are negative. In patients in whom fluconazole cannot be given, itraconazole is an acceptable, albeit less effective, alternative. Combination therapy with fluconazole plus flucytosine is effective; however, it is recommended as an alternative to the preceding therapies because of its potential for toxicity. Lipid

formulations of amphotericin B are effective, but the optimal dosage is unknown.¹⁹

In HIV-infected patients with elevated intracranial pressure at the initiation of antifungal therapy, lumbar drainage should remove enough CSF to reduce the opening pressure by 50%. Patients initially should undergo daily lumbar punctures to maintain CSF opening pressure in the normal range. When the CSF pressure is normal for several days, the procedure can be suspended. Adjunctive steroid treatment is not recommended because therapy has resulted in mixed results and its impact on outcome is unclear. Similarly, neither mannitol nor acetazolamide therapy provides any clear benefit in the management of elevated intracranial pressure.¹⁹

■ SUPPRESSIVE (MAINTENANCE) THERAPY FOR CRYPTOCOCCAL MENINGITIS IN THE HIV-INFECTED PATIENT

Relapse of *C. neoformans* meningitis occurs in approximately 50% of AIDS patients after completion of primary therapy. Persistence of asymptomatic urinary *C. neoformans* has been documented in a high percentage of AIDS patients despite seemingly adequate courses of therapy for primary meningeal disease. The prostate appears to act as a sequestered reservoir of infection in these patients, resulting in systemic relapse. Fluconazole is recommended for chronic suppressive therapy of cryptococcal meningitis in AIDS patients. The AIDS Clinical Trials Group's (ACTG) 026 study demonstrated that oral fluconazole 200 mg/day was superior to IV administration of amphotericin B 1 mg/kg weekly in preventing relapse. In addition, the fluconazole-treated group showed a lower incidence of adverse drug reactions and bacterial infections.³¹ Randomized comparative trials also demonstrated the superiority of fluconazole versus itraconazole as maintenance therapy. Thus itraconazole should be reserved for patients intolerant to fluconazole. Ketoconazole is not effective as maintenance therapy.

Although some preliminary studies suggest lower relapse rates of opportunistic infections when patients have been treated successfully with potent antiretroviral therapy, until proven otherwise, maintenance therapy for cryptococcal meningitis should be continued for life. For selected patients who have responded very well to highly active antiretroviral therapy (HAART), the clinician may consider discontinuation of maintenance therapy following 12 to 18 months of successful suppression of HIV viral replication. A prospective, randomized trial confirmed that discontinuation of secondary prophylaxis is safe in patients after adequate treatment for cryptococcal meningitis who had CD4 cell increases of greater than 100 cells/mm³ and an HIV viral load of fewer than 50 copies/mL for more than 3 months.^{19,29–32}

EVALUATION OF THERAPEUTIC OUTCOMES

Once the CNS is involved, the usual course is weeks to months of progressive deterioration, with 80% of untreated patients dying within the first year. The prognosis of cryptococcal meningitis depends largely on the underlying predisposing factors of the host. Although cryptococcal antigen is positive in 90% of patients with cryptococcal meningitis, fewer than half the patients with cryptococcal meningitis develop antibody to capsular polysaccharide. Those who produce antibody have a slightly improved prognosis. In contrast, the presence of headache is a favorable symptom presumably because it leads to

an earlier diagnosis. A favorable outcome is also associated with a normal mental status on diagnosis and a CSF white blood cell (WBC) count of less than 20 cells/mm³. A poor outcome is predicted, however, by the presence of one or more underlying diseases (including hematopoietic disorders and AIDS), corticosteroid or immunosuppressive therapy, pretreatment serum cryptococcal antigen titers of 1:32, and posttherapy serum antigen titers of 1:8. In non-AIDS patients, the cryptococcal antigen titer can be followed during therapy to assess response to antifungal therapy. In AIDS patients, decreasing titers are not necessarily predictive of success, and titers rarely become negative at the completion of therapy.^{14,15}

CANDIDA INFECTIONS

Candida spp. are yeasts that exist primarily as small (4–6 microns), unicellular, thin-walled, ovoid cells that reproduce by budding. On agar medium, they form smooth, white, creamy colonies resembling staphylococci. Although there are more than 150 species of *Candida*, eight species—*C. albicans*, *C. tropicalis*, *C. parapsilosis*, *C. krusei*, *C. stellatoidea*, *C. guilliermondi*, *C. lusitanae*, and *C. glabrata*—are regarded as clinically important pathogens in human disease.^{8,16} Yeast forms, hyphae, and pseudohyphae may be found in clinical specimens.

PATHOPHYSIOLOGY

8 *C. albicans* is a normal commensal of the skin, female genital tract, and entire GI tract of humans. Therefore, the mere presence of hyphae or pseudohyphae in a clinical specimen is insufficient for the diagnosis of invasive disease. The majority of infections with *C. albicans* are acquired endogenously, although human-to-human transmission also can occur. Oral candidiasis in the newborn probably is acquired during passage through the birth canal, and balanitis in the uncircumcised male may be acquired through contact with a female with vaginal candidiasis.⁸ Although the term *fungemia* refers to the presence of fungi in the blood, the most commonly isolated organism is *C. albicans*. Candidiasis may cause mucocutaneous or systemic infection, including endocarditis, peritonitis, arthritis, and infection of the CNS. (Mucocutaneous infections caused by *Candida* are discussed in further detail in Chap. 118.)

The role of an intact integument is crucial in the prevention of mucocutaneous or hematogenous candidiasis. After *Candida* invades the dermis or enters the bloodstream, polymorphonuclear leukocytes (PMNs) play a major role in the defense of the patient because PMNs are capable of damaging pseudohyphae and can phagocytize and kill blastoconidia.⁸ In addition to neutrophils, lymphocytes, monocytes, macrophages, complement, and eosinophils play a role in the prevention of infection. Adherence of *C. albicans* is important in the pathogenesis of oral candidiasis and subsequent colonization of the GI tract. Because evidence suggests that the GI tract is often the portal of entry for *Candida* in disseminated disease, factors that alter the adherence of *Candida* are crucial in the development of local and systemic infection. *C. tropicalis* adheres to intravascular catheters at a higher rate than *C. albicans*, a factor that may help to account for the increased incidence of systemic infections caused by this pathogen.

HEMATOGENOUS CANDIDIASIS

EPIDEMIOLOGY

The incidence of fungal infections caused by *Candida* spp. has increased substantially in the past two decades, and *Candida* infections currently constitute a significant cause of morbidity and mortality among severely ill patients. *Candida* spp. now constitute the fourth most common cause of bloodstream infections (BSIs) for patients hospitalized in ICUs in the United States, following coagulase-negative staphylococci, *Staphylococcus aureus*, and enterococci. The Centers for Disease Control and Prevention's (CDC) National Nosocomial Infection Survey implicated fungi as the cause of 8% of nosocomial infections. Although *C. albicans* accounted for 53% of *Candida* spp.,¹⁵ non-*albicans* species of *Candida*, including *C. glabrata*, *C. tropicalis*, *C. krusei*, and *C. parapsilosis*, are increasingly frequent causes of invasive candidal infections.^{34–36} *C. lusitanae* infections are a

cause of breakthrough fungemia in cancer patients; *C. parapsilosis* has emerged as the second most common pathogen, following *C. albicans*, in neonatal ICU patients; and fungemia caused by *C. glabrata* is observed more commonly in adults whose age is greater than 65 years.^{34,37} The change in species is of concern clinically because certain pathogens, such as *C. krusei* and *C. glabrata*, are intrinsically more resistant to commonly used triazole drugs.

PATHOPHYSIOLOGY

Candida generally is acquired via the GI tract, although organisms also may enter the bloodstream via indwelling IV catheters. Immunosuppressed patients, including those with lymphoreticular or hematologic malignancies, diabetes, and immunodeficiency diseases and those receiving immunosuppressive therapy with high-dose corticosteroids, immunosuppressants, antineoplastic agents, or broad-spectrum antimicrobial agents, are at high risk for invasive fungal infections. However, a number of prospective, randomized, controlled trials have validated the efficacy of antifungal prophylaxis and the use of antifungal agents for the treatment of persistently febrile patients with neutropenia who do not respond to antibiotics.^{8,14,15,38} These efforts have resulted in a reduction in the frequency of bloodstream infections caused by *Candida* spp. and systemic candidiasis in patients with neutropenia. In fact, most bloodstream infections caused by *Candida* spp. now occur in patients who have been hospitalized in ICUs, especially adult and neonatal ICUs. Retrospective studies have identified a number of risk factors for candidal bloodstream infections in ICU patients, most of which have been verified in multiple studies, although some remain controversial³⁹ (Table 119–6). Major risk factors include the use of central venous catheters, total parenteral nutrition, receipt of multiple antibiotics, extensive surgery and burns, renal failure and hemodialysis, mechanical ventilation, and prior fungal colonization. Patients who have undergone surgery (particularly surgery of the GI tract) are increasingly susceptible to disseminated candidal infections.^{39,40}

CLINICAL PRESENTATION OF HEMATOGENOUS CANDIDIASIS^{8,13,16}

Dissemination of *C. albicans* can result in infection in single or multiple organs, particularly the kidney, brain, myocardium, skin, eye, bone, and joints. In most patients, multiple micro- and macroabscesses are formed. Infection of the liver and spleen is becoming recognized as a particularly common and difficult-to-treat site of infection that

characteristically occurs in patients undergoing chemotherapy for acute leukemia or lymphoma.

DIAGNOSIS

SIGNS AND SYMPTOMS

Several distinct presentations of disseminated *C. albicans* have been recognized.¹²

1. Patients present with the acute onset of fever, tachycardia, tachypnea, and occasionally, chills or hypotension. The clinical presentation generally is indistinguishable from that seen with sepsis of bacterial origin.
2. Patients develop intermittent fevers and are ill only when febrile.
3. Patient manifests progressive deterioration of their condition with or without fever.
4. Hepatosplenic candidiasis often is manifested only as fever while the patient remains neutropenic (<1000 WBCs/mm³).

LABORATORY TESTS

Patients with positive blood cultures for *C. tropicalis* should receive serious consideration as candidates for systemic antifungal therapy.

► TREATMENT: Hematogenous Candidiasis

Fraser and colleagues³⁹ documented the high rate of mortality in non-neutropenic patients with fungal blood cultures. Mortality was highest in patients with sustained positive blood cultures, those who did not receive antifungal therapy, and those infected with non-*albicans* strains of *Candida*. This study clearly documented the importance of early recognition and treatment of positive fungal blood cultures. However, despite increased awareness of the importance of treating patients with positive blood cultures, mortality associated with candidemia remains high (47% among adults versus 29% among children) in even non-neutropenic patients.^{41,42}

Treatment of candidiasis should be guided by knowledge of the infecting species; the clinical status of the patient; when available, the antifungal susceptibility of the infecting isolate; and whether the patient has received antifungal therapy previously (Table 119–7). Therapy should be continued for 2 weeks after the last positive blood culture and resolution of signs and symptoms of infection. All patients should undergo an ophthalmologic examination to exclude the possibility of candidal endophthalmitis.⁹ Amphotericin B may be switched to fluconazole (intravenous or oral) for the completion of therapy. Susceptibility testing of the infecting isolate is a useful adjunct to species identification during selection of a therapeutic approach because it can be used to identify isolates that are unlikely to respond to fluconazole or amphotericin B. However, this is not currently available at most institutions.

■ NONIMMUNOCOMPROMISED PATIENT

■ PROPHYLAXIS

In ICUs, the use of fluconazole for prophylaxis or empirical therapy has increased exponentially in the past decade. However, studies that

Although a variety of serologic tests have been proposed for the detection of *Candida* protein antigens, serum antibodies to *Candida*, and antibodies to cell wall components such as mannan, no test has demonstrated reliable accuracy in the clinical setting for the diagnosis of disseminated infection with *Candida*. Only 25% to 45% of neutropenic patients with disseminated candidiasis at autopsy had a positive blood culture with *C. albicans* prior to death. The interpretation of positive surveillance cultures of the skin, mouth, sputum, feces, or urine is hampered by their occurrence as commensal pathogens and in distinguishing colonization from invasive disease.

Until recently, a rapid presumptive identification of *C. albicans* could be made by incubation of the organism in serum; formation of a germ tube (the beginning of hyphae, which arise as perpendicular extensions from the yeast cell, with no constriction at their point of origin) within 1 to 2 hours offered a positive identification of *C. albicans*.⁸ Unfortunately, *C. dubliniensis*, a new species of *Candida* that was identified recently as an important cause of mucosal colonization and infection in HIV-infected individuals, also can produce a germ tube. A negative germ tube test does not rule out the possibility of *C. albicans*, but further biochemical tests must be performed to differentiate between other non-*albicans* species.^{8,33}

In patients with hepatosplenic candidiasis, as the WBC count increases to more than 1000 cells/mm³, imaging studies can detect the presence of abscess or microabscesses in the liver and spleen, often found with acute suppurative and granulomatous reactions.

demonstrated benefit in the prevention of invasive candidal bloodstream infections did so either by using highly selective criteria or by studying patients in an unusually high-risk ICU setting, and the role of antifungal prophylaxis in the surgical ICU remains extremely controversial.^{9,43,44}

■ EMPIRICAL THERAPY

Few data are available for assessing the role of fluconazole as empirical therapy for suspected fungemia or for isolates other than *C. albicans*. Because fluconazole has poor activity against *Aspergillus* spp. and some non-*albicans* strains of *Candida*, many clinicians advocate amphotericin B as the therapy of choice in patients with suspected fungemia. If therapy is given, its use should be limited to patients with (1) *Candida* colonization at multiple sites, (2) multiple other risk factors, and (3) the absence of any other uncorrected causes of fever.^{9,45}

■ SPECIFIC THERAPY

Three large randomized studies in nonneutropenic patients have demonstrated that fluconazole at 400 mg/day and deoxycholate amphotericin B at 0.5–0.6 mg/kg per day are similarly effective; however, fewer adverse effects are observed with fluconazole therapy.^{46,47} Similarly, caspofungin is at least as effective as amphotericin B 0.6–0.7 mg/kg per day in (mainly nonneutropenic) adult patients with candidemia with fewer drug-related adverse events. Although the use of combination therapy (high-dose fluconazole plus amphotericin B) was demonstrated recently to be superior to treatment with fluconazole alone, the routine use of combination therapy in this patient population is not yet recommended.^{48,49} Neonates with disseminated

| Urinary Candidiasis | <i>Asymptomatic disease:</i> Generally no therapy is required <i>Symptomatic <i>or</i> high-risk patients^f:</i> Removal of urinary tract instruments, stents, and Foley catheters, +7–14 days therapy with fluconazole 200 mg orally daily <i>or</i> amphotericin B IV 0.3–1 mg/kg/day |

^aPatients at significant risk for invasive candidiasis include those receiving standard chemotherapy for acute myelogenous leukemia, allogeneic bone marrow transplants, or high-risk autologous bone marrow transplants. However, among these populations, chemotherapy or bone marrow transplant protocols do not all produce equivalent risk, and local experience should be used to determine the relevance of prophylaxis.

^bRisk factors include retransplantation, creatinine of more than 2 mg/dL, choledochojunostomy, intraoperative use of 40 units or more of blood products, fungal coonization detected within the first 3 days after transplantation.

^cTherapy is generally the same for AIDS/non-AIDS patients except where indicated and should continued for 2 weeks after the last positive blood culture and resolution of signs and symptoms of infection. All patients should receive an ophthalmologic examination. Amphotericin B may be switched to fluconazole (intravenous *or* oral) for the completion of therapy. Susceptibility testing of the infecting isolate is a useful adjunct to species identification during selection of a therapeutic approach because it can be used to identify isolates that are unlikely to respond to fluconazole *or* amphotericin B. However, this is not currently available at most institutions.

^dOften defined as failure of ≥500 mg amphotericin B, initial renal insufficiency (creatinine ≥2.5 mg/dL *or* creatinine clearance <25 mL/min), a significant increase in creatinine (to 2.5 mg/dL for adults *or* 1.5 mg/dL for children), *or* severe acute administration-related toxicity.

^ePatients who are neutropenic at the time of developing candidemia should receive a recombinant cytokine (granulocyte colony-stimulating factor *or* granulocyte-monocyte colony-stimulating factor) that accelerates recovery from neutropenia.

^fPatients at high risk for dissemination include neutropenic patients, low-birth-weight infants, patients with renal allografts, and patients who will undergo urologic manipulation. IV = intravenous; PO = orally.

Compiled from refs. 5, 9, and 41.

candidiasis usually are treated with amphotericin B because of its low toxicity in this patient population and because of the lack of experience with other agents in this population.^{9,41} Treatment should continue until 2 weeks following the last positive blood culture and resolution of signs and symptoms of infection.

CLINICAL CONTROVERSY

Because *C. glabrata* often has reduced susceptibility to both fluconazole and amphotericin B, optimal therapy is unclear. Larger doses of fluconazole (800 mg/day in a 70-kg patient) have been used in less critically ill patients or amphotericin B (≥ 0.7 mg/kg per day). However, recent observational studies demonstrated no difference in mortality in nonneutropenic patients administered fluconazole versus amphotericin B for bloodstream infections caused by *C. glabrata*.⁴¹ The potential utility of caspofungin has not been assessed.^{9,41}

C. krusei infections should be treated with large doses of amphotericin B (≥ 1 mg/kg per day) or with caspofungin (70-mg IV loading dose, followed by 50 mg/day IV).⁹ *C. tropicalis*, and *C. parapsilosis* may be treated with either amphotericin B at 0.6 mg/kg per day or fluconazole at 6 mg/kg per day. Amphotericin B resistance remains relatively rare despite over 45 years of clinical use, although it has been reported in *C. lusitaniae* (now *Clavispora lusitaniae*) and *C. guilliermondii*. *C. rugosa* often is considered to be “polyene tolerant,” and these isolates are believed to be selected owing to the wide use of amphotericin B.

Among the lipid-associated formulations of amphotericin B, only liposomal amphotericin B (AmBisome) and amphotericin B lipid complex (Abelcet) have been approved for use in proven cases of candidiasis; however, patients with invasive candidiasis also have been treated successfully with amphotericin B colloid dispersion (Amphotec or Amphocil). The lipid-associated formulations are less toxic but as effective as amphotericin B deoxycholate.

CLINICAL CONTROVERSY

Owing to the higher cost and paucity of randomized trials showing the efficacy of lipid-associated formulations of amphotericin B against proven invasive candidiasis, many clinicians limit their first-line use for the treatment of these infections to individuals who are intolerant to, at high risk of intolerance to, or refractory to amphotericin B deoxycholate. However, the data demonstrating up to a 6.6-fold increase in mortality in patients with amphotericin B–induced nephrotoxicity have convinced other clinicians that high-risk patients (e.g., residence in an ICU care or intermediate care unit at the time of initiation of amphotericin B therapy) warrant first-line therapy with these agents.

IMMUNOCOMPROMISED PATIENTS

In immunocompromised patients, the presence of candidemia is associated with evidence of disseminated disease in more than 70% of patients and with a 70% to 80% fatality rate. Therapy should include removal of the catheter and administration of systemic antifungal therapy.⁹ The optimal agent, dose, and duration of therapy are unclear, and patients must be monitored carefully with serial blood cultures and careful physical examinations, particularly of the retina. Patients who are neutropenic at the time of developing candidemia should

receive a recombinant cytokine (granulocyte colony-stimulating factor or granulocyte-monocyte colony-stimulating factor) that accelerates recovery from neutropenia.⁹

PROPHYLAXIS

Recognition of the role of the GI tract in invasive *Candida* infections has led to efforts to decrease infections by prophylactic administration of topical or systemically absorbed antifungal agents in immunocompromised patients. The use of systemically absorbable agents such as azole antifungal agents appears to decrease the risk of invasive fungal infections.^{9,50,51}

A randomized, double-blind, placebo-controlled trial in mostly allogeneic marrow recipients has shown that fluconazole, given at 400 mg/day from the start of the conditioning regimen until day 75, can reduce the frequency of invasive *Candida* infections and decrease mortality at day 110.⁵¹ Moreover, 8 years after completion of the study, there was persistent protection against invasive candidiasis and *Candida*-related death and a decreased frequency of severe, gut-related graft-versus-host disease (GVHD). There also was an overall survival benefit of 17% in fluconazole-treated patients; this benefit in survival was independent of the underlying condition and the occurrence of relapses.⁵² In less risk-selected patients with hematologic malignancies who were undergoing remission-induction chemotherapy, both fluconazole (400 mg/day) and itraconazole cyclodextrin (2.5 mg/kg orally twice daily) have been shown to be effective in preventing systemic infection and death caused by *Candida* spp.^{53,54}

EMPIRICAL THERAPY

Many clinicians advocate early institution of empirical IV amphotericin B in patients with neutropenia and persistent (> 5 –7 days) fever. However, the potential toxicities (particularly nephrotoxicity) of this agent preclude its routine use in all patients. Suggested criteria for the empirical use of amphotericin B include (1) fever of 5 to 7 days' duration that is unresponsive to antibacterial agents, (2) neutropenia of more than 7 days' duration, (3) no other obvious cause for fever, (4) progressive debilitation, (5) chronic adrenal corticosteroid therapy, and (6) indwelling intravascular catheters. In patients who fail therapy with amphotericin B, lipid formulations of amphotericin B may be used (3–5 mg/kg per day).

Itraconazole and fluconazole have demonstrated efficacy equivalent to that of deoxycholate amphotericin B in patients with hematologic malignancy (not treated with allogeneic hematopoietic stem cell transplantation).^{55,56} However, since fluconazole is not active against filamentous fungi, its use in patients at high risk for these pathogens should be avoided. If used, the intravenous formulation of itraconazole should be used because the bioavailability of the oral formulations (including the solution) is unreliable.^{45,57} Recently, voriconazole was compared with liposomal amphotericin B in a large randomized, multicenter trial of empirical antifungal therapy in febrile neutropenic patients.⁵⁸ The results of this study showed comparable composite success rates; however, voriconazole did not fulfill the protocol-defined criteria for noninferiority (a difference in success rates between voriconazole and amphotericin B of no more than 10 percentage points) to liposomal amphotericin. Voriconazole was superior in reducing documented breakthrough infections, infusion-related toxicity, and nephrotoxicity. However, patients who received

voriconazole had more frequent episodes of transient visual disturbances and hallucinations.⁵⁸

SPECIFIC THERAPY

Amphotericin B and the azoles have roles in the treatment of hematogenous candidiasis, and the choice of therapy is guided by weighing the greater activity of amphotericin B for some non-*albicans* species (e.g., *C. krusei*) against the lower toxicity and ease of administration of fluconazole.⁹

Most clinicians recommend amphotericin B in total dosages of 0.5–1 g administered over approximately 1 to 2 weeks in patients with *Candida* endophthalmitis and in all neutropenic patients with candidemia.^{8,16,45} Longer courses of therapy may be needed in some patients.¹⁶ Observational studies suggest that fluconazole and amphotericin B are similarly effective for the treatment of *C. albicans* bloodstream infections in the neutropenic patient; controlled data, however,

are lacking. In patients with uncomplicated *C. albicans* fungemia who have not received systemic prophylaxis with antifungal azoles, therapy with fluconazole 400–800 mg/day IV may be considered.⁵⁹ However, in patients who have undergone allogeneic hematopoietic stem cell transplantation, the role of fluconazole is becoming more limited because of its widespread use for antifungal prophylaxis. In this setting, particularly if the patient has been treated previously with an azole antifungal agent, the possibility of microbiologic resistance must be considered.⁹ Infections with fluconazole-resistant *Candida* spp., including *C. glabrata*, *C. krusei*, and fluconazole-resistant *C. albicans*, are more likely. Susceptibility testing can be useful in dealing with infections caused by non-*albicans* species of *Candida*.

In patients intolerant to amphotericin B or fluconazole, one of the lipid formulations may be used. In a randomized trial, amphotericin B lipid complex (ABLC) was found to be equivalent to 0.6–1 mg/kg per day of amphotericin B, and open-label therapy with amphotericin B colloid dispersion (ABCD) has been successful.

CANDIDURIA

Within the urinary tract, most common lesions are either *Candida* cystitis or hematogenously disseminated renal abscesses. *Candida* cystitis often follows catheterization or therapy with broad-spectrum antimicrobial agents. The diagnosis of *Candida* cystitis may be problematic because of the frequent presence of *Candida* pseudohyphae and yeast cells in urine specimens secondary to urethral colonization. The usefulness of urine colony counts or antibody coating techniques is questionable. The recovery of 10,000 organisms or visualization of both yeast and pseudohyphae from fresh midstream urine or from bladder urine obtained by single catheterization (not indwelling) is suggestive of genitourinary candidiasis.⁸ In most patients, the infection is asymptomatic and clears spontaneously without specific antifungal therapy.

Initial therapy of candidal cystitis should focus on removal of urinary catheters whenever possible. Changing the catheter will eliminate candiduria in only 20% of patients, whereas discontinuation will eradicate *Candida* in 40% of patients. Asymptomatic candiduria rarely requires therapy. Therapy should be used in symptomatic patients and in neutropenic patients, as well as in patients with renal allografts and those who will undergo urologic manipulation, because of the risk of dissemination.^{60,61}

Fluconazole 200 mg/day for 14 days hastens the time to a negative urine culture as compared with placebo treatment, but 2 weeks after the end of therapy, the frequency of a negative urine culture remains the same with both treatments.⁶¹ Short courses of therapy are not recommended; treatment should include removal of catheters and stents whenever possible plus 7 to 14 days of therapy. Bladder irrigation with amphotericin B (50 mg in 500 mL sterile water instilled twice daily into the bladder via a three-way catheter) is only transiently effective. Minimal quantities (<3%) of amphotericin B are absorbed systemically from the bladder.^{21,61}

ROLE OF CATHETER REMOVAL

Although it is common practice in today's standard of care to place indwelling catheters in patients for the administration of medications and parenteral nutrition (TPN), catheter-related infections are a common complication. These foreign bodies (especially triple-lumen

catheters) double as entry ports for normal skin flora or other nosocomial pathogens, and they provide a readily available site for the binding of pathogens via microbiotic biofilms. Their subsequent role as a source of bloodstream infections is facilitated by frequent use, TPN, and the potential for contamination of catheters by medical staff who are colonized with *Candida* spp.

Most consensus recommendations urge that, if feasible, initial nonmedical management should include removal of all existing tunneled central venous catheters (CVCs) and implantable devices, particularly in patients with fungemia caused by *C. parapsilosis*, which is very frequently associated with catheters.^{9,62} Arguments against the removal of all catheters in patients with candidemia include the prominent role of the gut as a source for disseminated candidiasis, the significant cost and potential for complications, and the problems that can be encountered in patients with difficult vascular access.⁶³ However, in an individual patient it is often difficult to determine the relative contribution of gut versus catheter as the primary source of fungemia.⁶² The evidence for this recommendation is weakest in cancer patients with severe neutropenia and mucositis (e.g., acute leukemia, stem cell transplant), in whom candidemia is almost always primarily of gut origin, and removal of CVCs is least likely to have an impact on mortality.⁶⁴ Nucci and Anaissie⁵⁹ have proposed that CVCs be removed in nonneutropenic patients without a short life expectancy who have one of the following criteria: (1) otherwise unexplained hemodynamic instability, (2) lack of clinical improvement of resolution of candidemia after more than 72 hours of an optimal dose of an appropriate antifungal agent, (3) established or at high risk for endocarditis or septic thrombophlebitis, or (4) a pocket infection or cellulitis. In patients with more than one CVC, they recommend removal if one tunneled or implanted CVC is the likely source of infection and the patient meets the preceding criteria.⁵⁹

ASPERGILLOSIS

EPIDEMIOLOGY

Aspergillus is an ubiquitous mold that grows well on a variety of substrates, including soil, water, decaying vegetation, moldy hay or straw, and organic debris. Although more than 300 species of

Aspergillus have been characterized, three species are most commonly pathogenic: *A. fumigatus*, *A. flavus*, and *A. niger*. The varying degrees of pathogenicity of each species depend on their relative geographic prevalence, conidial size and shape, thermotolerance, and production of mycotoxins. For example, transport of *A. fumigatus* conidia into the lungs is facilitated by their smaller diameter in comparison with *A. flavus* and *A. niger*.

9 The term *aspergillosis* may be broadly defined as a spectrum of diseases attributed to allergy, colonization, or tissue invasion caused by members of the fungal genus *Aspergillus*. A single satisfactory classification system for these disease entities is difficult because different populations of patients may develop the same type of infection. For example, osteomyelitis may result from local trauma or hematogenous dissemination in an immunocompromised host. Colonization in normal hosts can lead to allergic diseases ranging from asthma to allergic bronchopulmonary aspergillosis or, rarely, invasive disease.⁶⁵

PATHOPHYSIOLOGY

Aspergillosis generally is acquired by inhalation of airborne conidia that are small enough (2.5–3 microns) to reach alveoli or the paranasal sinuses. Each conidiophore releases 10^4 conidia that remain suspended for long periods and are viable for months in dry locations. Although some authors advocate monitoring of hospital air for *Aspergillus* conidia, guidelines for interpreting results do not exist. The use of high-efficiency particulate air (HEPA) filters in operating rooms and laminar flow rooms and removal of immunocompromised patients from hospital renovation sites may be helpful in preventing infection in this population. Although the fate of *Aspergillus* conidia in the GI tract has not been closely studied, limited evidence suggests that this route may provide an important portal of entry for disseminated infections in humans.⁶⁶

SUPERFICIAL INFECTION

Superficial or locally invasive infections of the ear, skin, or appendages often can be managed with topical antifungal therapy. Skin infections in patients with burn wounds, although uncommon, may progress to deep-tissue invasion despite the use of topical or parenteral antifungal agents. Risk factors for deep infection include extensive thermal injuries, malnutrition, cirrhosis, and previous infection with *Pseudomonas aeruginosa*.⁶⁶

ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS

Allergic manifestations of *Aspergillus* range in severity from mild asthma to allergic bronchopulmonary aspergillosis (BPA). BPA, which is almost always caused by *A. fumigatus*, is characterized by severe asthma with wheezing, fever, malaise, weight loss, chest pain, and a cough productive of blood-streaked sputum. Following recurrent episodes of severe asthma, the disease usually progresses to fibrosis and bronchiectasis with granuloma formation. When *Aspergillus* conidia become trapped in the viscous mucus of asthmatic patients, BPA develops. The fungus grows, releasing toxins and antigens. The resulting host sensitization results in a variety of immune reactions. Early in the course of disease, an IgE-mediated (type I) immune reaction results in bronchospasm, eosinophilia, and immediate skin reactivity. The ensuing fibrosis and pulmonary infiltrates appear to be mediated by circulating or precipitating antibody

complexes of IgG antibody, followed by granuloma formation and mononuclear infiltration because of a type IV delayed hypersensitivity reaction. Therapy is aimed at minimizing the quantity of antigenic material released in the tracheobronchial tree. Management of acute asthma attacks minimizes trapping of *Aspergillus* by bronchial secretions, and administration of parenteral corticosteroids clears lung infiltrates.^{66,67} Antifungal therapy generally is not indicated in the management of allergic manifestations of aspergillosis, although some patients have demonstrated a decrease in their corticosteroid dose following therapy with itraconazole. A recent double-blind, randomized, placebo-controlled trial showed that itraconazole 200 mg twice daily for 16 weeks resulted in significant differences in the amelioration of disease, as measured by the reduction in corticosteroid dose and improvement in exercise tolerance and pulmonary function.⁶⁵

ASPERGILLOMA

In the nonimmunocompromised host, *Aspergillus* infections of the sinuses most commonly occur as saprophytic colonization (aspergillomas or “fungus balls”) of previously abnormal sinus tissue. An aspergilloma is composed of intertwined *Aspergillus* hyphae matted together with fibrin, mucus, and cellular debris. Infection usually is localized in the maxillary sinus and rarely is associated with local invasion of adjacent bone or brain tissue. Sinus aspergillosis also can present as allergic sinusitis with nasal drainage of brownish mucous plugs. Therapy with corticosteroids and surgery generally is successful. In the immunocompromised host, subacute, chronic, or fulminant invasive disease can be seen, and a combination of antifungal and surgical therapy generally is required.^{66–69}

Pulmonary aspergillomas are fungus balls arising in preexisting cavities because of tuberculosis, histoplasmosis, lung tumors, or radiation fibrosis, although occasionally no previous pulmonary disease is present. The diagnosis of aspergilloma generally is made on the basis of chest radiographs, on which aspergillomas appear as a solid rounded mass, sometimes mobile, of water density within a spherical or ovoid cavity and separated from the wall of the cavity by an airspace of variable size and shape. Patients generally experience chest pain, dyspnea, and sputum production. Hemoptysis is observed in 50% to 80% of patients probably because of ulceration of the epithelial lining of the cavity with formation of granulation tissue, and hemoptysis is the cause of death in up to 26% of patients with aspergilloma. A poor prognosis is associated with increasing size or number of aspergillomas, immunosuppression (including corticosteroids), increasing *Aspergillus*-specific titers, underlying sarcoidosis, and HIV infection. Although *Aspergillus* can be cultured in only 50% to 60% of patients, precipitating antibodies are positive in virtually 100% of patients.

Invasive disease occurs rarely, and therapy therefore is controversial. There are no controlled clinical trials with which to guide therapy, and recommendations for treatment have been generated from uncontrolled trials and case reports.⁶⁹ Concern regarding the risk of severe hemorrhage has led some clinicians to use aggressive surgical excision of aspergillomas or pulmonary resection in patients with hemoptysis. Complications, including bronchopulmonary fistulas, hemorrhage, empyema, and persistent airspace problems, have led to the recommendation that surgical intervention be reserved for patients with severe (>500 mL/24 h) hemoptysis, however. Bronchial artery embolization (BAE) has been used to occlude the vessel that supplies the bleeding site in patients experiencing hemoptysis. Unfortunately, BAE generally is unsuccessful or only temporarily

effective. Collateral circulation eventually develops, supplying blood flow to the affected area, and hemoptysis often recurs; consequently, reemolization is often unsuccessful. BAE should be used as a temporizing procedure in a patient with life-threatening disease who might respond to more definitive therapy if hemoptysis is stabilized. Mild to moderate hemoptysis should be managed conservatively. Although IV amphotericin B generally is not useful in eradicating aspergillomas, inhaled or intracavitary instillation of amphotericin B has been employed successfully in a limited number of patients. Itraconazole has been efficacious in uncontrolled studies; however, the dose and duration of therapy have not been standardized. Hemoptysis generally ceases when the aspergilloma is eradicated.^{66,67,69}

INVASIVE ASPERGILLOSIS

Although exposure to *Aspergillus* conidia is nearly universal, impaired host defenses are required for the development of invasive disease. Phagocytes (neutrophils, monocytes, and macrophages) rather than antibodies or lymphocytes constitute the primary host defense system against invasive disease with aspergillosis. Macrophages prevent germination of conidia and also eradicate conidia, providing the first line of defense against invasive disease. Administration of corticosteroids appears to impair the killing of conidia by macrophages and to impair mobilization of neutrophils. Neutrophils halt hyphal growth and dissemination and kill mycelia, constituting a second line of defense. Prolonged neutropenia appears to be the most important predisposing factor to the development of invasive aspergillosis, accounting for the high frequency of disease in patients with acute leukemia. Complement provides a source of chemotactic factor and facilitates neutrophil damage to hyphae and monocyte killing of conidia. Complement is not necessary for the attachment or ingestion of conidia by human alveolar macrophages.^{66,67,70}

Until recently, aspergillosis was an uncommon fungal infection in patients with AIDS. AIDS patients may be at less risk for aspergillosis than other fungal infections because the primary cellular defect in AIDS patients is in the T-lymphocytes, whereas neutrophils and macrophages constitute the primary lines of defense to infection with aspergillosis. Until recently, aspergillosis was reported as a late complication of disease in AIDS patients with additional risk factors for aspergillosis, such as corticosteroid use, neutropenia, previous *Pneumocystis carinii* or cytomegalovirus pneumonia, marijuana smoking, or the use of broad-spectrum antibiotics. However, approximately 50% of patients with aspergillosis have no classic risk factors. The majority of these patients had CD4 counts of fewer than 50 cells/mm³. Although some patients diagnosed early in their infection responded to treatment, most patients do not respond to therapy with amphotericin B 0.5 mg/kg per day or itraconazole 200–600 mg/day.⁷¹

Invasive disease with *Aspergillus* can arise de novo or from any of the allergic or colonizing forms of aspergillosis. Predisposing factors to the development of invasive aspergillosis include glucocorticoid therapy, particularly following chronic administration or with higher dosages (30–200 mg/day of prednisone), cytotoxic agents, and recent or concurrent therapy with broad-spectrum antimicrobial agents. Patients with chronic hepatitis, alcoholism, diabetes mellitus, chronic granulomatous disease, leukopenia (<1000 cells/mm³), leukemia (particularly acute lymphocytic or myelogenous leukemia), lymphoma, and acute rejection of an organ transplant are also at a higher risk of invasive disease. Although rare, invasive aspergillosis has been reported in apparently normal hosts.^{66,67}

CLINICAL PRESENTATION^{66–69}

The lung is the most common site of invasive disease. In the immunocompromised host, aspergillosis is characterized by vascular invasion leading to thrombosis, infarction, necrosis of tissue, and dissemination to other tissues and organs in the body. Survival beyond 2 or 3 weeks is uncommon. If bone marrow function returns, cavitation of the pulmonary lesion generally occurs, and the spread of infection may be halted. The progressive nature of the disease and its refractoriness to therapy are, in part, caused by the organism's rapid growth and its tendency to invade blood vessels.

Signs and Symptoms

Patients often present with classic signs and symptoms of acute pulmonary embolus: pleuritic chest pain, fever, hemoptysis, and friction rubs. The CNS, liver, spleen, heart, GI tract, pericardium, and other body sites are involved in a substantial minority of cases. In neutropenic patients with *Aspergillus* pneumonia, hyphae invade the walls of bronchi and surrounding parenchyma, resulting in an acute necrotizing, pyogenic pneumonitis. As a result, patients often present with classic signs and symptoms of acute pulmonary embolus: pleuritic chest pain, fever, hemoptysis, and friction rubs.

DIAGNOSIS

The diagnosis of aspergillosis is complicated by the presence of *Aspergillus* as a normal commensal in the human GI tract and respiratory secretions, and establishment of a definitive diagnosis of disease is difficult. Though suggestive of infection, the presence of hyphae in a smear or biopsy specimen is not diagnostic. Demonstration of *Aspergillus* by repeated culture and microscopic examination of tissue provides the most firm diagnosis. The appearance of *Aspergillus* in tissues varies with increasing host resistance from the normal vegetative hyphae found with necrotic tissue and exudate in the alveoli of immunocompromised hosts to the compact, tangled filaments ("granules") observed in fungal balls. Identification of *Aspergillus* generally is based on the appearance of 2- to 4-micron-wide septate hyphae that are dichotomously branched at 45-degree angles. Sporulation is observed rarely in tissue.¹⁷ Although growth on Sabouraud dextrose or brain-heart infusion agar may be used for primary culture, bronchoscopy or bronchoalveolar lavage cultures are positive in only 40% of histopathologically identified specimens. Blood, CSF, and bone marrow cultures are rarely positive for *Aspergillus*.

Many clinicians treat positive respiratory cultures of *Aspergillus* as a common contaminant and argue that a minimum of two to three positive cultures is necessary before antifungal therapy is indicated. Any positive culture, however, may be indicative of true infection in the immunocompromised host, and the positive predictive value may be as high as 80% to 90% in patients with leukemia or bone marrow transplants.

Diagnostic Tests

A rapid test to detect galactomannan antigen in blood was approved recently in the United States. Late findings on radiographic studies include wedge-shaped pleural-based infiltrates or cavities on chest radiographs. Findings on computed tomographic (CT) scans include the halo sign (an area of low attenuation surrounding a nodular lung lesion) initially (caused by edema or bleeding surrounding an ischemic area) and, later, the crescent sign (an air crescent near the periphery of a lung nodule caused by contraction of infarcted tissue). CT abnormalities are best documented in neutropenic marrow transplant recipients and commonly precede plain chest radiograph abnormalities.

► TREATMENT: Invasive Aspergillosis

Therapy for invasive aspergillosis is far from optimal at this time in part because of the difficulties in establishing a diagnosis and in part because of a lack of truly effective antifungal agents. Administration of amphotericin B appears to decrease mortality from more than 90% to approximately 45%. These data, however, are difficult to interpret because many patients were diagnosed postmortem, or amphotericin B therapy was not administered until the patient had very advanced disease. Mortality from pulmonary aspergillosis in bone marrow transplant recipients exceeds 94% regardless of therapy.⁶⁶ Although early diagnosis and administration of antifungal therapy may result in higher response rates, correction of underlying immune deficits (in particular, return of neutrophil counts) is of paramount importance in eradication of infection.^{68,69}

Until the diagnosis of aspergillosis can be determined more rapidly and definitively, empirical therapy must be instituted when invasive disease is suspected. In patients at highest risk for invasive disease (acute leukemia and bone marrow transplant recipients), the most important predisposing factors include prolonged severe neutropenia (<100 cells/mm³ for more than 1 week), graft rejection, chronic administration of corticosteroids, and tissue damage from preexisting infection. In these patients, antifungal therapy should be instituted in any of these conditions: (1) persistent fever or progressive sinusitis unresponsive to antimicrobial therapy, (2) an eschar over the nose, sinuses, or palate, (3) the presence of characteristic radiographic findings, including wedge-shaped infarcts, nodular densities, and new cavitary lesions, or (4) any clinical manifestation suggestive of orbital or cavernous sinus disease or an acute vascular event associated with fever. Isolation of *Aspergillus* spp. from nasal or respiratory tract secretions should be considered confirmatory evidence in any of the previously mentioned clinical settings.^{66,67}

■ NON-HIV-INFECTED PATIENT

■ PROPHYLAXIS

Unfortunately, effective chemoprophylaxis against infections by *Aspergillus* spp. has not been demonstrated thus far.⁹ Apart from studies that compare prophylaxis with itraconazole or current investigational agents with prophylaxis with fluconazole, clinical trials are under way that investigate preventive approaches in patients with allogeneic hematopoietic stem cell transplantation during phases of aggressive immunosuppression for chronic graft-versus-host disease.

■ SPECIFIC THERAPY

Intravenous therapy with amphotericin B remains the preferred therapy, at least initially, in acutely ill patients. Because *Aspergillus* is only moderately susceptible to amphotericin B, full doses (1–1.5 mg/kg per day) generally are recommended, with response measured by defervescence and radiographic clearing. To treat microfoci, therapy should be continued after resolution of clinical and radiographic abnormalities until cultures (if they can be obtained) are negative, and reversible underlying predispositions have abated. Clinical response rather than any arbitrary total dose should guide duration of therapy. The optimal dosage or duration of amphotericin B therapy for the treatment of invasive disease is unknown and depends on the extent of disease, the response to therapy, and the patient's underlying

disease(s) and immune status. Unfortunately, the response rate averages only 37% (range 14% to 83%), and the response to therapy is largely related to the extent of aspergillosis at the time of diagnosis and host factors such as resolution of neutropenia and the return of neutrophil function, lessening immunosuppression, and the return of graft function from a bone marrow or organ transplant.

Lipid formulations of amphotericin B may be indicated in patients with impaired renal function and in those who develop nephrotoxicity while receiving deoxycholate amphotericin B. The lipid-based formulations may be preferred as initial therapy in patients with marginal renal function or in patients receiving other nephrotoxic drugs. Although these preparations appear less toxic than standard preparations, only limited data regarding their relative efficacy for invasive aspergillosis are available at this time because the studies with the lipid preparations have been open label or with historical conventional amphotericin B controls.^{71–73}

Even though older azole antifungal agents (miconazole and ketoconazole) possess poor in vitro activity against *Aspergillus* spp., newer triazoles demonstrate improved activity both in vitro and in animal models of infection.⁷⁵ Itraconazole (100–500 mg/day for 11 to 192 days) shows therapeutic benefit in patients with pulmonary, skeletal, and pericardial aspergillosis, particularly in patients who are less immunocompromised.^{65–69} The wide range of dosages, durations of therapy, and degrees of immunosuppression in these trials makes selection of an appropriate regimen difficult. Jennings and Hardin⁶⁷ reviewed the role of itraconazole for aspergillosis and recommended that itraconazole be reserved as a second-line agent for patients intolerant or not responding to high-dose amphotericin B. If itraconazole is used, a loading dose of 200 mg three times daily for 2 to 3 days should be employed, followed by itraconazole 200 mg twice daily for a minimum of 6 months. Although early studies employing relatively low dosages (50–100 mg/day) of fluconazole demonstrated some activity against less invasive forms of aspergillosis, including chronic pulmonary disease and aspergillomas, data regarding the use of higher dosages (>100 mg/day) in patients with invasive disease are not available. Oral itraconazole is an alternative for patients who can take oral medication, are likely to be adherent, can be demonstrated (by serum level monitoring) to absorb the drug, and are unlikely to experience interactions with other medications and as follow-up therapy in patients who respond to initial IV therapy.⁶⁹

Caspofungin was approved by the Food and Drug Administration (FDA) for use as salvage therapy in patients who are intolerant or who fail therapy with one of the amphotericin B formulations.^{57,76} Caspofungin has in vitro activity against *Aspergillus* spp. and is indicated for the treatment of invasive aspergillosis in patients who are refractory to or intolerant of other therapies such as conventional amphotericin B, lipid formulations of amphotericin B, and/or itraconazole. Caspofungin has not yet been studied for first-line therapy for patients with aspergillosis. Because of the high risk of mortality from invasive aspergillosis even following treatment with standard therapy such as amphotericin B or itraconazole, caspofungin may offer a new mechanism for salvage therapy for patients with this disease.

A large, randomized, multicenter trial that compared voriconazole with liposomal amphotericin B for empirical antifungal therapy showed comparable composite success rates; however, voriconazole did not fulfill the protocol-defined criteria for noninferiority to liposomal amphotericin. Voriconazole was superior in reducing documented breakthrough infections, infusion-related toxicity, and nephrotoxicity. However, patients who received voriconazole had more frequent

episodes of transient visual disturbances and hallucinations.^{58,75} A recent randomized trial, which compared voriconazole with amphotericin B (followed by other licensed antifungal therapy) for primary therapy of aspergillosis, noted better responses, improved survival, and fewer severe side effects with voriconazole.⁵⁸

The use of adjuvant therapies, such as granulocyte transfusions or recombinant colony-stimulating factors, remains controversial, and controlled trials are lacking at this time. Although some authors advocate combination therapy with azoles, flucytosine, or rifampin plus amphotericin B, controlled clinical studies verifying the efficacy of these combination therapies are lacking.

■ SECONDARY PROPHYLAXIS

The use of prophylactic antifungal therapy to prevent primary infection or reactivation of aspergillosis during subsequent courses of chemotherapy is controversial.^{22,67} Studies assessing the utility of IV administration of amphotericin B in low doses (0.1 mg/kg per day) as prophylactic therapy or with higher dosages (0.5–0.6 mg/kg per day) as empirical therapy for invasive fungal infections in patients with granulocytopenia have not included sufficient numbers of patients to enable detection of differences in the number of *Aspergillus* infections.⁶⁷ The prophylactic use of intranasal

amphotericin B aerosol sprays (5 or 10 mg/day in three divided doses) appeared beneficial in small studies in human and animal models. A larger randomized trial found, however, that amphotericin B sprays reduced colonization of the nasal mucosal without any reduction in the frequency of invasive pulmonary infections with aspergillosis. Because failure of amphotericin B sprays may be a result of the ability of small airborne conidia to access the alveolar spaces directly and to establish infection, use of aerosolized forms of amphotericin B capable of reaching the alveolar spaces may be required.⁶⁷

In granulocytopenic patients who recover from an episode of invasive aspergillosis, the risk of relapse of aspergillosis during subsequent courses of chemotherapy is greater than 50%. Secondary prophylaxis of aspergillosis with empirical administration of high-dose amphotericin B decreases the risk of relapse. Amphotericin B 1 mg/kg per day is started 24 to 48 hours prior to the start of chemotherapy and continued throughout the period of granulocytopenia. Some investigators recommend the addition of flucytosine (dosed to achieve peak serum concentrations of 30–60 mcg/mL) to the amphotericin B regimen. Although the use of itraconazole (alone or in combination with amphotericin B or flucytosine) may be beneficial in this patient population, little is known regarding its efficacy in this setting. If itraconazole is administered, serum levels should be monitored to assess absorption because poor absorption of drug has been documented in this patient population.⁷⁶

EMERGING PATHOGENS

The increased frequency of fungal pathogens that were once rare is gaining attention from the medical community. Permissive environmental conditions, selective antifungal pressure, and increased numbers of immunosuppressed patients have led to increased numbers of infections caused by filamentous fungi such as *Scedosporium* or *Fusarium* spp. Unfortunately, the early presentation of *Fusarium* and *Scedosporidium* infections often mimics that of aspergillosis. On histopathology, *Scedosporidium* resembles *Aspergillus* spp. with dichotomously branching, septate hyphae and has a tendency for invasion of vascular structures.⁷⁷ These pathogens often demonstrate intrinsic resistance to amphotericin B and are associated with high mortality rates.^{83,89} For example, mortality due to *Scedosporidium prolificans*, previously known as *S. inflatum*, exceeds 85%; *S. apiospermum* (the asexual state of *Pseudallescheria boydii*), was uniformly fatal in 23 solid-organ transplant recipients with disseminated disease.⁷⁷ However, in vitro data suggest that *S. prolificans* is more sensitive to voriconazole than to amphotericin B or itraconazole. Voriconazole recently received FDA approval for the treatment of serious fungal infections caused by *S. apiospermum* and *Fusarium* spp., including *F. solani*, in patients intolerant of or refractory to other therapy.⁷⁹

ANTIFUNGAL THERAPY

The antifungal armamentarium for the treatment of invasive fungal infections includes (1) inhibitors of the fungal cell membrane, such as polyenes (e.g., amphotericin B) and azole antifungals, (2) inhibitors of DNA (5-flucytosine), and more recently, (3) inhibitors of cell wall biosynthesis such as the recently approved agent caspofungin.^{14,15}

Antifungal therapy generally uses one or more of these agents depending on the severity of infection and the patients' immune status. Rarely are the agents used in combination. Often therapy is initiated

with an intravenous agent such as amphotericin B, and therapy is changed to an oral (azole) regimen as the patient's clinical status improves and oral therapy is tolerated. The most widely used combination therapy consists of flucytosine plus amphotericin B. The role of combination therapy is unclear at this time; controlled trials are lacking, and the possibility of therapeutic antagonism when using azoles in combination with amphotericin B remains debated. Controlled trials are needed to define the role of azoles plus amphotericin B and azoles or amphotericin B plus caspofungin.

AMPHOTERICIN B

Amphotericin B remains the therapy of choice for many systemic fungal infections despite a lack of controlled clinical trials documenting the optimal dosage, duration of therapy, or relative efficacy of this agent in comparison with newer azole antifungal agents such as ketoconazole, itraconazole, and fluconazole. During pregnancy, amphotericin B remains the treatment of choice for most fungal infections because azole antifungals are teratogenic.^{21,80}

The side effects of amphotericin B generally are categorized as acute (infusion related) or long term. Gallis and Drew²¹ recently reviewed the side effects and clinical uses of amphotericin B.

LIPID FORMULATIONS OF AMPHOTERICIN B

The use of deoxycholate amphotericin B frequently is associated with the development of induced nephrotoxicity. In an attempt to decrease the incidence of nephrotoxicity, three lipid formulations of amphotericin B have been developed and approved for use in humans: amphotericin B lipid complex (ABLCL, Abelcet; Enzon Pharmaceuticals), amphotericin B colloidal dispersion (ABCD, Amphotec; Intermune Pharmaceuticals), and liposomal amphotericin B (AmBisome; Gilead Pharmaceuticals). In these preparations, amphotericin B is incorporated into the phospholipid bilayer membrane rather than in the enclosed aqueous phase.

The various lipid formulations of amphotericin B exhibit markedly different pharmacokinetics; however, the clinical implications of these differences remain unclear.⁷² Although larger doses of these preparations are required to achieve similar pharmacologic effects as the deoxycholate form of amphotericin B, the toxicity appears to be much lower.⁸⁰ Although the FDA-approved dosages of these agents are 5 mg/kg per day (amphotericin B lipid complex), 3–6 mg/kg per day (amphotericin B colloid dispersion), and 3–5 mg/kg per day (liposomal amphotericin B), the agents appear generally equipotent. The optimal dose of these compounds for serious *Candida* infections is unknown; however, dosages of 3–5 mg/kg per day appear reasonable. The relative efficacy of these agents is unknown; whether differences in pharmacokinetic features result in different outcomes in the treatment of specific types of infections (e.g., CNS infections) is unclear.^{9,72}

Lipid formulations of amphotericin B are indicated for patients intolerant of, refractory to, or at high risk of being intolerant to conventional antifungal therapy.^{9,72,81} Intolerance generally is defined as initial renal insufficiency (creatinine > 2.5 mg/dL or creatinine clearance < 25 mL/min), a significant increase in creatinine (to 2.5 mg/dL for adults or 1.5 mg/dL for children), or severe acute administration-related toxicity, whereas refractory infections are defined as therapeutic failure of more than 500 mg amphotericin B.

Only ABLC and liposomal amphotericin B have been approved for use in proven candidiasis. Both in vivo and clinical studies indicate that these compounds are less toxic but as effective as amphotericin B when used in appropriate dosages. Nevertheless, their higher cost and the paucity of randomized trials in proven invasive candidiasis limit their front-line use in these infections.⁸¹

CLINICAL CONTROVERSY

Should lipid formulations of amphotericin B be used rather than the traditional deoxycholate formulation? Many clinicians feel that lipid formulations have shown clear superiority in the treatment of aspergillosis and histoplasmosis and are “at least as good” as deoxycholate amphotericin B for the treatment of *Candida*, cryptococcosis, and febrile neutropenia. However, they lack FDA approval for these infections except (in some cases) as salvage therapy.⁸¹

FLUCYTOSINE

Flucytosine (also known as 5-flucytosine or 5-FC) is a fluorinated pyrimidine analogue that is highly water-soluble. Patients with creatinine clearances of less than 40 mL/min should receive 100–150 mg/kg daily in four divided doses. The dosage should be reduced by 50% in patients with a creatinine clearance of 25–50 mL/min and by 75% in patients with a clearance of 13–25 mL/min. Peak serum concentrations (2 hours after an oral dose) should be monitored in all patients (particularly those with a creatinine clearance of less than 10 mL/min) to maintain peak serum concentrations of more than 100 mg/L.^{28,29}

Flucytosine generally is associated with very few side effects in patients with normal renal, GI, and hematologic function, although rash, GI discomfort, diarrhea (5% to 10%), and reversible elevations in hepatic enzymes are observed occasionally. In patients with renal dysfunction or concomitant amphotericin B therapy, leukopenia, thrombocytopenia, and (rarely) enterocolitis may occur. Although studies have suggested that little or no conversion of flucytosine to fluorouracil occurs in vitro, serum concentrations of greater than 1000 ng/mL (therapeutic for the treatment of malignancies) have been

documented in some patients. Investigators have theorized that flucytosine may be secreted into the GI tract, deaminated by intestinal bacteria, and reabsorbed as 5-fluorouracil.^{28,29}

Flucytosine is used in combination with amphotericin B or fluconazole in the treatment of cryptococcosis or (less commonly) candidiasis. The rapid development of resistance to flucytosine, however, precludes its use as single-agent therapy. Mechanisms for drug resistance may include loss of deaminase and decreased permeability to the drug.^{28,29}

ECHINOCANDINS

The echinocandins are a new class of antifungal agents that act as concentration-dependent, noncompetitive inhibitors of the formation of $\beta(1,3)$ -D-glucan synthase, an essential component of the cell wall of susceptible filamentous fungi that is absent in mammalian cells. Caspofungin is the first of this class of agents approved in the United States; clinical trials are currently evaluating several other agents from this class, including micafungin (FK463) and anidulafungin (VER-002).⁷⁶

CASPOFUNGIN

Caspofungin is metabolized by hydrolysis and *N*-acetylation, and excretion of the drug and its metabolites in humans is 35% of the dose in feces and 41% of the dose in urine. Renal clearance of caspofungin is low, and total clearance of the drug is 12 mL/min. Therefore, no dosage adjustment is necessary for patients with renal insufficiency. Because caspofungin is not dialyzable, supplementary dosing is not required following hemodialysis.⁷⁶

Adverse effects of caspofungin include histamine release resulting in rash, facial swelling, and itchiness. In clinical trials, concomitant use of cyclosporine and caspofungin resulted in elevated liver function tests two to three times the upper limit of normal. Therefore, it is generally not recommended to use these two drugs in combination. Additionally, when caspofungin was administered concurrently with tacrolimus, tacrolimus levels were reduced by 20% compared with when the healthy volunteers received tacrolimus alone. The mechanism for these interactions is not yet known. Caspofungin is not a cytochrome P450 inducer of enzyme 3A4 and is considered a poor substrate of P450 enzymes. Overall, caspofungin was found to show no cytochrome P450 inhibition in clinical studies and did not interact when administered concomitantly with amphotericin B, itraconazole, or mycophenolate.⁷⁶

The recommended dose for an adult patient is a 70-mg loading dose administered on day 1 of therapy, followed by subsequent doses of 50 mg once daily. Duration of treatment should be based on the severity of the patient's underlying disease, recovery from immunosuppression, and clinical response. Caspofungin should be administered slowly via intravenous infusion over 1 hour.⁷⁶

AZOLE ANTIFUNGAL AGENTS

The introduction of the azole antifungal agents has rapidly expanded the armamentarium of agents useful in the treatment of systemic fungal infections.¹¹ Adverse effects of azoles include GI disturbances (primarily nausea, vomiting, epigastric pain, and diarrhea), which appear to be more common in patients receiving ketoconazole and the solution formulation of itraconazole. Although cyclodextrin is not absorbed following oral administration, use of the intravenous formulation of itraconazole is limited to 2 weeks because of concerns

for potential nephrotoxicity secondary to accumulation of the cyclodextrin vehicle.^{14,15,82} Fluconazole is well tolerated; intestinal complaints are the most frequently reported, followed by headaches and rash. Unlike ketoconazole, fluconazole does not inhibit testicular or adrenal steroidogenesis in healthy volunteers or hospitalized patients. Reversible alopecia occurs not infrequently and usually appears after several months of treatment with higher doses of fluconazole. Azoles are potentially teratogenic and should be avoided in pregnant women.^{14,15,82}

ITRACONAZOLE

Itraconazole is triazole antifungal with a broad spectrum of antifungal activity. Despite its marked structural similarity to ketoconazole, itraconazole differs in several important respects. Itraconazole appears to have greater specificity against fungal versus mammalian cytochrome P450, resulting in greater potency and a decrease in P450-mediated side effects. In addition, itraconazole possesses excellent *in vitro* activity against *Aspergillus* and *Sporothrix* spp.

Like ketoconazole, the capsule formulation of itraconazole depends on the availability of low gastric pH for dissolution and absorption. Administration with food appears to enhance significantly the bioavailability of itraconazole capsules, whereas it decreases the bioavailability of the oral solution. Because itraconazole exhibits pH-dependent dissolution and absorption, absorption of the capsule formulation is impaired in patients receiving antacids or H₂-receptor antagonists and in patients with achlorhydria.⁸² Plasma concentrations of itraconazole following a single oral dose (capsules) in HIV-infected patients are approximately 50% lower than concentrations observed in healthy volunteers. The capsule formulation of itraconazole exhibits unpredictable oral bioavailability, particularly in subjects with hypochlorhydria and in patients with enteropathy caused by mucositis or graft-versus-host gut disease. Recently, oral suspension and IV formulations of itraconazole became available; both use cyclodextrin as a solubilizing vehicle to increase the solubility of the drug. The oral bioavailability of the solution is unaffected by alterations in gastric pH or in patients with enteropathy.^{8,9,82}

FLUCONAZOLE

Fluconazole is a triazole antifungal agent with markedly different pharmacologic features than previously marketed azole antifungals. The small molecular weight, low protein binding, and increased water solubility of fluconazole result in rapid, essentially complete absorption of drug following oral administration. Since fluconazole is excreted primarily (>80%) as unchanged drug in the urine, dosage adjustments are necessary in patients with renal dysfunction.

VORICONAZOLE

The most common side effect of voriconazole is a reversible disturbance of vision (photopsia), which occurs in approximately 30% of patients but rarely leads to discontinuation of the drug. Symptoms tend to occur during the first week of therapy and decrease or disappear despite of continued therapy. Patients experience altered color discrimination, blurred vision, the appearance of bright spots and wavy lines, and photophobia. Patients should be cautioned that driving may be hazardous because of the risk of visual disturbances. The visual effects are associated with changes in electroretinogram tracings, which revert to normal when treatment with the drug is stopped; no permanent damage to the retina has been demonstrated.⁷⁵

DRUG INTERACTIONS WITH AZOLE ANTIFUNGAL AGENTS

Drug interactions with azole antifungals generally can be placed into three broad categories: (1) decreases in azole bioavailability because of chelation or secondary to increases in gastric pH, (2) interactions with other cytochrome P450–metabolized drugs, and (3) interactions caused by inhibition of *p*-glycoprotein. Drug interactions in the latter two categories may result in increases or decreases in the azole antifungal, in the interacting drug, or in both drugs.^{14,15}

The interaction of azole antifungal agents with other cytochromes P450–metabolized drugs is well recognized. The azoles appear to be metabolized almost entirely via the cytochrome P450 3A4 subfamily. As expected, they interact with other drugs metabolized partly or wholly via this enzyme pathway. In addition, fluconazole and voriconazole use the cytochrome P450 2C19 pathway. Numerous clinically significant interactions have been documented with azole antifungals and a variety of other drugs. In most cases, the azole interferes with the metabolism of the other cytochrome P450–metabolized drug.^{14,15}

The interaction between ketoconazole and cyclosporine has been exploited in order to reduce drug costs associated with administration of cyclosporine following organ transplantation. Relative to ketoconazole and itraconazole, fluconazole appears to be intermediate in its ability to inhibit human cytochromes P450. The magnitude of fluconazole-induced inhibition of cyclosporine metabolism appears, however, to depend on the dosage of fluconazole.

Predictably, drugs such as rifampin, rifabutin, isoniazid, phenytoin, and carbamazepine, which are known to induce the activity of cytochromes P450, result in increased metabolism of the azole antifungals and may result in therapeutic failures. Increased dosages of azole antifungals may be required in patients receiving these combinations of drugs.^{14,15}

Itraconazole is an inhibitor of intestinal *p*-glycoprotein. Significant increases in digoxin (a *p*-glycoprotein substrate) have been observed in patients receiving both agents concurrently. Interactions with other substrates of *p*-glycoprotein would be expected to occur.

COMBINATION ANTIFUNGAL THERAPY

Based on extensive experience in the management of bacterial and, more recently, retroviral infections, the use of combination agents for synergistic or additive effects is now common practice. However, studies supporting the use of combinations of antifungal agents have produced less definitive results. *In vitro* and animal data have produced conflicting results, and human studies are lacking. Thus there are as yet no firm recommendations regarding the use of such combinations in humans. A recent study comparing the use of high-dose fluconazole alone or in combination with amphotericin B in nonimmunocompromised patients with candidemia demonstrated no antagonism and a trend toward improved success and more rapid clearance of *Candida* from the bloodstream.⁴⁹

PLASMA CONCENTRATION MONITORING OF ANTIFUNGAL AGENTS

Routine monitoring of plasma concentrations of antifungal agents to assess efficacy or toxicity of these agents generally is not available. Correlations between plasma concentrations of antifungal agents and therapeutic outcomes have been poorly studied. Under certain circumstances, serum or plasma concentration monitoring is warranted, e.g., in patients susceptible to flucytosine toxicity or to document adequate

oral absorption of ketoconazole or itraconazole in cases of suspected treatment failure, concern about compliance or absorption, or when drug interactions that might reduce the solubility or accelerate the metabolism of azoles are suspected. Although “therapeutic” levels have not been defined, some investigators recommend maintenance of serum concentrations of itraconazole (2 to 4 hours after administration) of 1 mcg/mL, measured by bioassay.^{6,22} Among AIDS patients, those receiving a dosage of 200 mg once or twice daily achieved median plasma concentrations of 3 or 6 mcg/mL, respectively.²²

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 An *immunocompromised host* is a patient with defects in host defenses that predispose to infection. Risk factors include neutropenia, immune system defects (from disease or immunosuppressive drug therapy), compromise of natural host defenses, environmental contamination, and changes in normal flora of the host.
- 2 Immunocompromised patients are at high risk for a variety of bacterial, fungal, viral, and protozoal infections. Bacterial infections caused by gram-positive cocci (staphylococci and streptococci) occur most frequently, followed by gram-negative bacterial infections caused by Enterobacteriaceae and *Pseudomonas aeruginosa*. Fungal infections caused by *Candida* and *Aspergillus*, as well as certain viral infections (herpes simplex virus, cytomegalovirus), are also important causes of morbidity and mortality.
- 3 Risk of infection in neutropenic patients is associated with both the severity and duration of neutropenia. Patients with severe neutropenia (absolute neutrophil count [ANC] <500 cells/mm³) for greater than 7 to 10 days are considered to be at high risk of infection.
- 4 Fever (single oral temperature of 38.3°C [101°F] or greater or a temperature of 38°C [100.4°F] or greater for 1 hour or more) is the most important clinical finding in neutropenic patients and usually is the stimulus for further diagnostic work-up and initiation of antimicrobial treatment. Infection should be considered as the cause of fever until proved otherwise. Usual signs and symptoms of infection may be altered or absent in neutropenic patients. Appropriate empirical broad-spectrum antimicrobial therapy must be instituted rapidly to prevent excessive morbidity and mortality.
- 5 Empirical antimicrobial regimens for neutropenic infections should take into account patients' individual risk factors, as well as institutional infection and susceptibility patterns. The significant morbidity and mortality associated with gram-negative infections require that initial empirical regimens for treatment of febrile neutropenia have good activity against *Pseudomonas aeruginosa* and Enterobacteriaceae. Inpatient parenteral regimens most commonly recommended for initial treatment include monotherapy with an antipseudomonal cephalosporin or carbapenem or a combination regimen consisting of an antipseudomonal cephalosporin or carbapenem plus an aminoglycoside. Low-risk patients may be treated successfully with oral antibiotics (ciprofloxacin plus amoxicillin-clavulanate), with the treatment setting determined by the patient's clinical status.
- 6 Neutropenic patients who remain febrile after 3 to 5 days of initial antimicrobial therapy should be reevaluated to determine whether treatment modifications are necessary. Common regimen modifications include the addition of vancomycin (if not already present) and antifungal therapy (amphotericin B or fluconazole). Therapy should be directed at causative organisms, if identified, but broad-spectrum regimens should be maintained during neutropenia.
- 7 The optimal duration of therapy for febrile neutropenia is controversial. The decision to discontinue antimicrobials is based on resolution of neutropenia, defervescence, culture results, and clinical stability of the patient.
- 8 Prophylactic antimicrobials are administered to cancer patients expected to experience prolonged neutropenia, as well as to both hematopoietic stem cell and solid-organ transplant recipients. Prophylactic regimens may include antibacterial, antifungal, antiviral, or antiprotozoal agents, or a combination of these, selected according to risk of infection with specific pathogens. Optimal prophylactic regimens should take into account individual patient risk for infection and institutional infection and susceptibility patterns.
- 9 Patients undergoing hematopoietic stem cell transplantation are at an extremely high risk of infection because of prolonged neutropenia following intensive chemotherapy with or without irradiation, whereas solid-organ transplant recipients are at high risk because of prolonged administration of immunosuppressive drugs. Fungal (*Aspergillus*) and viral (cytomegalovirus) infections are particularly troublesome in these populations, and prophylactic regimens directed against these pathogens are used commonly. When documented, these infections must be treated aggressively in order to optimize patient outcomes. Nevertheless, mortality rates are often very high despite appropriate and aggressive antimicrobial therapy.

10 Immunocompromised patients must be assessed continuously for evidence of infection and response to antimicrobial therapy. Because a large number of antimicrobials potentially may be used, the occurrence of drug-related ad-

verse effects also must be assessed carefully. Efforts should be directed at designing cost-effective treatment strategies that promote optimal patient outcomes.

An immunocompromised host is a patient with intrinsic or acquired defects in host defenses that predispose to infection. Advances in modern medicine are creating more immunocompromised hosts than ever before. Historically, many of these patients died from their underlying diseases. Dramatic improvements in survival have been achieved by more aggressive therapy of underlying diseases and improved supportive care. Because aggressive therapy often renders patients profoundly immunosuppressed for long periods, however, opportunistic infections remain important causes of morbidity and mortality. This chapter focuses on risk factors for infection, common pathogens and infection sites, and prevention and management of suspected or documented infections in cancer patients (including hematopoietic stem cell transplant [HSCT] patients) and solid-organ transplant recipients. Chapter 123 discusses infectious complications associated with human immunodeficiency virus (HIV) infection.

RISK FACTORS FOR INFECTION/EPIDEMIOLOGY

NEUTROPENIA

1 2 3 Neutropenia is an abnormally reduced number of neutrophils circulating in peripheral blood. Although exact definitions of neutropenia often vary, an absolute neutrophil count (ANC) of fewer than 1000 cells/mm³ indicates a reduction sufficient to predispose patients to infection.¹ The ANC is the sum of the absolute numbers of both mature neutrophils (polymorphonuclear cells [PMNs], also called *polys* or *segs*) and immature neutrophils (*bands*). The absolute number of PMNs and bands is determined by dividing the percentage of these cells (obtained from the white blood cell [WBC] differential) by 100 and then multiplying the quotient obtained by the total number of WBCs.

The degree or severity of neutropenia, rate of neutrophil decline, and duration of neutropenia are important risk factors for infection.^{1–6} All neutropenic patients are considered to be at risk for infection, but those with an ANC of fewer than 500 cells/mm³ are at greater risk than those with ANCs of 500 to 1000 cells/mm³. Most treatment guidelines use an ANC of fewer than 500 cells/mm³ as the critical value in making therapeutic decisions regarding the management of suspected or documented infections.^{1,3–6} Risk of infection and death are greatest among patients with fewer than 100 neutrophils/mm³.² In patients with chemotherapy-induced neutropenia, the risk of infection is increased according to the rapidity of ANC decline. Infection risk also increases as the duration of neutropenia increases; patients with severe neutropenia of more than 7 to 10 days' duration are considered to be at especially high risk for serious infections.³ The duration of chemotherapy-induced neutropenia varies considerably among subsets of cancer patients according to the specific chemotherapeutic agents used and the intensity of treatment. Patients undergoing hematopoietic stem cell transplantation (HSCT) may have no detectable granulocytes in peripheral blood for up to 3 to 4 weeks and are at particular risk for severe infections with a variety of pathogens.⁷

Bacteria and fungi commonly cause infections in neutropenic patients. Gram-positive cocci (*Staphylococcus aureus*, *S. epidermidis*, streptococci, and enterococci) have emerged as the most common

cause of acute bacterial infections among neutropenic patients. Gram-negative bacilli (*Escherichia coli*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*) traditionally were the most common causes of bacterial infection and remain frequent pathogens, although now they are not as common as gram-positive bacteria.^{4,5,8} However, gram-negative infections are associated with significant morbidity and mortality. Patients who are neutropenic for extended periods of time and who receive broad-spectrum antibiotics are at risk for fungal infection, usually due to *Candida* or *Aspergillus* spp.⁴ Viral infections, although not as common as bacterial and fungal infections, also may cause severe infection in the neutropenic patient.^{6,9} Successful treatment of infections in neutropenic patients depends on resolution of neutropenia.^{1–4,6}

Although not readily quantifiable, abnormalities may exist in granulocyte function, as well as in cell numbers. Defects in phagocyte function may be caused by underlying disease (e.g., leukemia) or its treatment (e.g., corticosteroids, antineoplastic agents, and radiation).^{3,10,11}

IMMUNE SYSTEM DEFECTS

In addition to neutropenia, defects in T-lymphocyte and macrophage function (cell-mediated immunity) and B-cell function (humoral immunity) or both predispose patients to infection. Cellular immune dysfunction is the result of underlying disease or immunosuppressive drug therapy; these defects result in a reduced ability of the host to defend against intracellular pathogens. Patients with Hodgkin's disease and transplant patients receiving immunosuppressive drugs such as cyclosporine, tacrolimus, sirolimus, mycophenolate, corticosteroids, antineoplastic agents, or azathioprine are at risk for a variety of bacterial, fungal, viral, and protozoal infections (Table 120–1). While some of these pathogens are associated with asymptomatic or mild disease in normal hosts, they can cause disseminated, life-threatening infections in immunocompromised hosts.

Underlying disease frequently causes defects in humoral immune function. Patients with multiple myeloma and chronic lymphocytic leukemia have progressive hypogammaglobulinemia that results in defective humoral immunity. Splenectomy performed as a part of the staging process for Hodgkin's disease places patients at risk for infectious complications. Disease states with humoral immune dysfunction predispose the patient to serious, life-threatening infection with encapsulated organisms such as *Streptococcus pneumoniae*, *Hemophilus influenzae*, and *Neisseria meningitidis*.

DESTRUCTION OF PROTECTIVE BARRIERS

Loss of protective barriers is a major factor predisposing immunocompromised patients to infection. Damage to skin and mucous membranes by surgery, venipuncture, intravenous (IV) and urinary catheters, radiation, and chemotherapy disrupts natural host defense systems, leaving patients at high risk for infection. Chemotherapy-induced mucositis may erode mucous membranes of the oropharynx and gastrointestinal (GI) tract and establish a portal for subsequent infection by bacteria, herpes simplex virus, and *Candida*.¹² Medical and surgical procedures, such as transplant surgery, indwelling IV

TABLE 120–1. Risk Factors and Common Pathogens in Immunocompromised Patients

| Risk Factor | Patient Conditions | Common Pathogens |
|--------------------------------------|---|--|
| Neutropenia | Acute leukemia Chemotherapy | Bacteria: <i>Staphylococcus aureus</i> , <i>Staphylococcus epidermidis</i> , <i>Escherichia coli</i> , <i>Klebsiella pneumoniae</i> , <i>Pseudomonas aeruginosa</i> , streptococci, enterococci Fungi: <i>Candida</i> , <i>Aspergillus</i> , <i>Zygomycetes</i> Viruses: Herpes simplex |
| Impaired cell-mediated immunity | Lymphoma Immunosuppressive therapy (steroids, cyclosporine, chemotherapy) | Bacteria: <i>Listeria</i> , <i>Nocardia</i> , <i>Legionella</i> , Mycobacteria Fungi: <i>Cryptococcus neoformans</i> , <i>Candida</i> , <i>Aspergillus</i> , <i>Histoplasma capsulatum</i> Viruses: Cytomegalovirus, varicella-zoster, herpes simplex Protozoal: <i>Pneumocystis jiroveci</i> |
| Impaired humoral immunity | Multiple myeloma Chronic lymphocytic leukemia Splenectomy Immunosuppressive therapy (steroids, chemotherapy) | Bacteria: <i>S. pneumoniae</i> , <i>H. influenzae</i> , <i>N. meningitidis</i> |
| Loss of protective barriers | | |
| Skin | Venipuncture, bone marrow aspiration, urinary catheterization, vascular access devices, radiation, biopsies | Bacteria: <i>S. aureus</i> , <i>S. epidermidis</i> , <i>Bacillus</i> spp., <i>Corynebacterium jeikeium</i> Fungi: <i>Candida</i> |
| Mucous membranes | Respiratory support equipment, endoscopy, chemotherapy, radiation | Bacteria: <i>S. aureus</i> , <i>S. epidermidis</i> , streptococci Enterobacteriaceae, <i>P. aeruginosa</i> , <i>Bacteroides</i> spp. Fungi: <i>Candida</i> Viruses: Herpes simplex |
| Surgery | Solid organ transplantation | Bacteria: <i>S. aureus</i> , <i>S. epidermidis</i> , Enterobacteriaceae, <i>P. aeruginosa</i> , <i>Bacteroides</i> spp. Fungi: <i>Candida</i> Viruses: Herpes simplex |
| Alteration of normal microbial flora | Antimicrobial therapy Chemotherapy Hospital environment | Bacteria: Enterobacteriaceae, <i>P. aeruginosa</i> , <i>Legionella</i> , <i>S. aureus</i> , <i>S. epidermidis</i> Fungi: <i>Candida</i> , <i>Aspergillus</i> |
| Blood products, donor organs | Bone marrow transplantation Solid organ transplantation | Fungi: <i>Candida</i> Viruses: Cytomegalovirus, Epstein-Barr virus, hepatitis B, hepatitis C Protozoal: <i>Toxoplasma gondii</i> |

Compiled from refs. 1, 3, 5, 6, 8, 10, 16, 17, 20, 22, 23, and 26.

catheter placement, bone marrow aspiration, biopsies, and endoscopy, further damage the integument and predispose patients to infection. Infections resulting from disruption of protective barriers usually are a result of skin flora, such as *S. aureus*, *S. epidermidis*, and various streptococci.^{1,6,10,12}

ENVIRONMENTAL CONTAMINATION/ALTERATION OF MICROBIAL FLORA

Infections in immunocompromised patients are caused by organisms either colonizing the host or acquired from the environment. Microorganisms may be transferred easily from patient to patient on the hands of hospital personnel unless strict infection control guidelines are followed. Contaminated equipment, such as nebulizers or ventilators, and contaminated water supplies have been responsible for outbreaks of *P. aeruginosa* and *Legionella pneumophila* infections, respectively. Foods, such as fruits and green leafy vegetables, which are often colonized with gram-negative bacteria and fungi, are also sources of microbial contamination in immunocompromised hosts.^{3,13}

Most infections in cancer patients are caused by organisms colonizing body sites, such as the skin, oropharynx, and GI tract.^{12,13} About 80% of infecting bacterial pathogens are from the patient's endogenous flora.¹⁴ The GI tract is the most common site from which infections in immunocompromised hosts originate. Periodontitis,

pharyngitis, esophagitis, colitis, perirectal cellulitis, and bacteremias are caused predominantly by normal flora of the gut; bloodstream infections are thought to arise from microbial translocation across injured GI mucosa.^{12,13} Normal flora may be significantly disrupted and altered; oropharyngeal flora rapidly change to primarily gram-negative bacilli in hospitalized patients. Many cancer patients already may be colonized with gram-negative bacilli on admission as a result of frequent hospitalizations and clinic visits. In hospitalized cancer patients, 50% of infections, however, are caused by colonizing organisms acquired after admission.¹⁴

Although hospitalization and severity of illness are risk factors for colonization by gram-negative bacilli, administration of broad-spectrum antimicrobial agents has the greatest impact on flora of immunocompromised hosts. Use of these agents disrupts the delicate balance of GI tract flora and predisposes patients to infection with more virulent pathogens. Antineoplastic drugs (e.g., cyclophosphamide, doxorubicin, and fluorouracil) and acid-suppressive therapy (e.g., H₂-receptor antagonists, proton pump inhibitors, and antacids) also may result in changes in GI flora and possibly predispose patients to infection.¹⁵

Numerous factors, such as underlying disease, immunosuppressive drug therapy, and antimicrobial administration, determine the immunocompromised host's risk of developing infection. Several risk factors are present concomitantly in many patients (see Table 120–1).

ETIOLOGY OF INFECTIONS IN NEUTROPENIC CANCER PATIENTS

2 Infection remains a significant cause of morbidity and mortality in neutropenic cancer patients. More than 50% of febrile neutropenic patients have an established or occult infection.^{1,6} Patients with profound neutropenia are at greatest risk for systemic infection, with at least 20% of these individuals developing bacteremia. Areas of impaired or damaged host defenses, such as the oropharynx, lungs, skin, sinuses, and GI tract, are common sites of infection. These local infections may progress to cause systemic infection and bacteremia.¹² Febrile episodes in neutropenic cancer patients can be attributed to microbiologically documented infection in only about 30% of cases, about one-half of which are due to bacteremia. Further, infections can be documented clinically in another 30% to 40% of patients, with the remaining 30% of patients manifesting infection only by fever.^{3,10}

Table 120–1 lists organisms commonly infecting immunocompromised patients. About 60% of bacteremic episodes in cancer patients are the result of gram-positive organisms as compared with less than 30% of episodes documented during the 1970s and 1980s.^{1,4,5} This shift is attributed to the frequent use of indwelling IV catheters and broad-spectrum antibiotics with excellent gram-negative activity but relatively poor gram-positive coverage, higher rates of mucositis caused by aggressive cancer treatments, and prophylaxis with trimethoprim-sulfamethoxazole or quinolones.^{4,5,8,10,13} *S. aureus* and coagulase-negative staphylococci (especially *S. epidermidis*) are the most common organisms, but *Bacillus* spp. and *Corynebacterium jeikeium* are also important pathogens.^{1,6,10} Data from the United States Centers for Disease Control and Prevention's (CDC) National Nosocomial Infection Surveillance System (NNIS) indicate increasing rates of methicillin-resistant staphylococcal infections in the hospital setting,¹⁶ and resistance also is being observed in community-acquired staphylococcal infections. Viridans streptococci, which may be resistant to β -lactams, also have emerged as important pathogens, particularly in patients with chemotherapy-induced mucositis of the oropharynx.^{5,10,17} Enterococci, including vancomycin-resistant strains, also may be problematic in many institutions.^{4,8} Bacteremia caused by vancomycin-resistant enterococci (VRE) in neutropenic patients is associated with a mortality rate exceeding 70%.⁵

Overall, gram-positive infections do not always cause immediately life-threatening infections and are associated with somewhat lower mortality rates as compared with gram-negative infections.^{1,10} However, gram-positive infections may cause severe complications, such as disseminated intravascular coagulation (DIC) and acute respiratory distress syndrome (ARDS). Methicillin-resistant *S. aureus* infections are associated with increased morbidity and mortality and hospital costs compared with susceptible organisms.¹⁸ Thus prevention and timely diagnosis and treatment of gram-positive infections are clearly of great importance in the management of neutropenic cancer patients.

Gram-negative infections remain important causes of morbidity and mortality in immunocompromised cancer patients, but the relative frequency of infection owing to specific pathogens has been shifting among gram-negative infections. *Escherichia coli* and *Klebsiella* spp. remain the most common isolates at many centers. Strains of *Klebsiella* spp. producing plasmid-mediated extended-spectrum β -lactamases that hydrolyze extended-spectrum cephalosporins have emerged and are cause for concern.¹ The frequency of infections resulting from other gram-negative organisms, such as *Enterobacter*, *Serratia*, and *Citrobacter*, has been increasing.⁸ *Enterobacter* spp.

are important causes of bacteremias; the use of broad-spectrum antibiotics, particularly third-generation cephalosporins, is thought to have played a major role in this trend. Infections owing to *Enterobacter*, *Serratia*, and *Citrobacter* may be difficult to treat because of the ease of β -lactamase induction and the more frequent development of resistance to multiple antibiotics.^{3,8,10}

P. aeruginosa has long been an important pathogen in cancer patients. *P. aeruginosa* infection rates are decreasing in patients with solid tumors but not in patients with hematologic malignancies.^{4,19,20} Infections caused by *P. aeruginosa* are associated with significant morbidity and mortality in neutropenic patients, with mortality rates of 33% to 75% reported.¹⁰ The frequency of infection caused by difficult-to-treat organisms such as *Stenotrophomonas maltophilia* and *Burkholderia cepacia* appears to be increasing at many centers, probably because of selective pressures of broad-spectrum antimicrobial use.^{5,10} Although the GI tract is a common site of bacterial infection, severe infections caused by anaerobic organisms are relatively infrequent. Anaerobes are found most frequently in mixed infections, such as perirectal cellulitis and mucositis-associated oropharyngeal infections.¹⁰

In addition to bacterial infections, neutropenic cancer patients are at risk for invasive fungal infections. Patients with extended periods of profound neutropenia who have been receiving broad-spectrum antibiotics, corticosteroids, or both are at the highest risk for invasive fungal infection. Up to one-third of febrile neutropenic patients who fail to respond to a week of broad-spectrum antibiotic therapy will have a systemic fungal infection.¹ A large international autopsy study revealed that up to 40% of patients with hematologic malignancies had deep fungal infections, many of which were undiagnosed prior to the time of death. Approximately 65% of these infections were the result of *Candida* spp., and another 30% were caused by *Aspergillus* spp.²¹

C. albicans is the most common fungal pathogen in neutropenic cancer patients.^{5,22} Other species of *Candida*, such as *C. tropicalis*, *C. parapsilosis*, and *C. krusei*, are being isolated with increasing frequency. An increase also has been noted in infections caused by *C. glabrata*, *Trichosporon* spp., *Fusarium* spp., and *Curvularia*.^{22–24} Because candidal species are normal flora, alteration of body host defenses is an important risk factor for the development of these infections. Oral thrush is the most common clinical manifestation of fungal infection. Mucous membranes damaged from chemotherapy and radiation serve as areas of candidal surface colonization and subsequent entry into the bloodstream; disease may then disseminate throughout the body. Organs such as the liver, spleen, kidney, and lungs are commonly involved in disseminated disease.^{11,21,23} Hepatosplenic candidiasis, also known as *chronic disseminated candidiasis*, is an important infection in patients with hematologic malignancies.^{3,25} Diagnosis of candidal infections is difficult and often requires invasive tissue sampling.⁷ Overall mortality attributed to candidal infections in patients with invasive candidiasis is as high as 38%.⁵

Invasive infections caused by *Aspergillus* spp. are a very serious complication of neutropenia, with mortality approaching 80% in patients with prolonged neutropenia and/or patients undergoing allogeneic HSCT.⁵ Infections resulting from *Aspergillus* spp. (including *A. fumigatus*, *A. terreus*, *A. flavus*, and *A. niger*) usually are acquired via inhalation of airborne spores. After colonizing the lungs, *Aspergillus* invades the lung parenchyma and pulmonary vessels, resulting in hemorrhage, pulmonary infarcts, and a high mortality rate. Invasive pulmonary disease is the dominant manifestation of infection in patients with neutropenia. However, *Aspergillus* spp.

also may cause other infections in neutropenic patients, including sinusitis, cutaneous infection, and disseminated disease involving multiple organs, including the central nervous system (CNS).²⁶ Prolonged neutropenia is the primary risk factor for invasive pulmonary aspergillosis in neutropenic patients with acute leukemia; use of corticosteroids also may predispose patients to disease.²⁶ Invasive aspergillosis should be suspected in neutropenic cancer patients colonized with *Aspergillus* (in sputum and/or nasal cultures) who remain persistently febrile despite a week or more of broad-spectrum antibiotic therapy.^{1,26}

Chemotherapy-induced mucous membrane damage may predispose neutropenic cancer patients to the reactivation of herpes simplex virus (HSV), manifesting as gingivostomatitis or recurrent genital infections. Untreated oropharyngeal HSV infections may spread to involve the esophagus and often coexist with candidal infections. Clinical disease resulting from HSV occurs most often in patients with serologic evidence (e.g., serum antibodies to HSV) of prior infection. Both HSV-seropositive HSCT patients and HSV-seropositive leukemics receiving intensive chemotherapy are at high risk for recurrent HSV disease during periods of immunosuppression.⁷

Pneumocystis jiroveci and *Toxoplasma gondii* are the most common parasitic pathogens in immunocompromised cancer patients. Patients with hematologic malignancies (i.e., acute lymphocytic leukemia, lymphoma, and Hodgkin's disease) and those receiving high-dose corticosteroids as part of chemotherapy regimens are at the greatest risk of infection.⁷ Routine use of trimethoprim-sulfamethoxazole prophylaxis, however, has reduced the incidence of these infections substantially.^{1,27}

Because the majority of infecting organisms in cancer patients are from the host's own flora, some centers have employed routine surveillance cultures in an attempt to prospectively identify causes of fever and suspected infection. In a typical surveillance culture program, cultures of the nose, mouth, axillae, and perirectal area are performed twice weekly, and culture results are correlated with the clinical status of the patient. Because these cultures are costly and of low diagnostic yield, the utility of surveillance culture programs is felt to be limited. Surveillance cultures are, however, useful as research tools and in certain clinical situations; these situations include patients with prolonged profound neutropenia and in institutions with high rates of antimicrobial resistance or that have problems with virulent pathogens such as *P. aeruginosa* or *A. flavus*. Surveillance cultures should be limited to the anterior nares for detecting colonization with methicillin-resistant *S. aureus*, *Aspergillus*, and penicillin-resistant pneumococci and to the rectum for detecting *P. aeruginosa*, multiple-antibiotic-resistant gram-negative rods, and VRE.^{1,10}

Knowledge of infection rates and local susceptibility patterns is essential for guiding optimal management of febrile neutropenia. These parameters must be monitored closely because the spectrum of infectious complications is related to multiple factors, including cancer chemotherapy regimens and antimicrobial therapy used for treatment and prophylaxis.

CLINICAL PRESENTATION

4 The most important clinical finding in the neutropenic cancer patient is the presence of fever. Because of the potential for significant morbidity and mortality associated with infection in these patients, fever should be considered to be the result of infection until proved otherwise. At the appearance of fever, the patient should be evaluated carefully for other signs and symptoms of infection (see below).

CLINICAL PRESENTATION OF FEBRILE NEUTROPENIA^{1,3,4,6,10}

GENERAL

- Because neutropenic cancer patients are at high risk for serious infections, frequent (at least daily), careful clinical assessments must be performed to search for possible evidence of infection.
- Physical assessment should include examination of all common sites of infection, including mouth/pharynx, nose and sinuses, respiratory tract, gastrointestinal tract, urinary tract, skin, soft tissues, perineum, and intravascular catheter insertion sites.

SYMPTOMS

- Usual signs and symptoms of infection may be absent or altered in neutropenic patients owing to low numbers of leukocytes and an inability to mount an inflammatory response (e.g., no infiltrate on chest x-ray, urinary tract infection without pyuria).
- Pain may be present at the infection site(s).

SIGNS

- Fever in this setting is defined as a single oral temperature of 38.3°C (101°F) or greater in the absence of other causes or a temperature 38°C (100.4°F) or greater for 1 hour or more. Other causes of fever unrelated to infection in this patient population include reactions to blood products, chemotherapeutic agents (and other drugs, including biologics), cell lysis, and the underlying malignancy.
- Usual signs of infection may be absent or altered; patients with bacteremia commonly exhibit no signs of infection other than fever.

LABORATORY TESTS

- Neutropenia (ANC \leq 1000 cells/mm³)
- Blood cultures (two or more sets, including vascular access devices) for bacteria and fungi; cultures of other suspected infection sites (infection can be documented microbiologically in only about 30% of cases, about one-half of which are due to bacteremia).
- Other cultures should be obtained as indicated clinically according to the presence of signs or symptoms.
- Recent surveillance cultures (nasal, rectal) should be reviewed, if available.
- Complete blood count and blood chemistries should be obtained frequently to monitor neutropenia, plan supportive care, guide drug dosing, and assess patient's overall status.

OTHER DIAGNOSTIC TESTS

- Chest x-ray
- Aspiration, biopsy of skin lesions
- Other diagnostic tests as indicated clinically on the basis of physical examination and other assessments

► TREATMENT: Infections in Cancer Patients

■ FEBRILE EPISODES IN NEUTROPENIC CANCER PATIENTS

4 5 The goals of antimicrobial therapy in neutropenic patients (including HSCT recipients) are (1) to protect the neutropenic patient from early death caused by undiagnosed infection, (2) to prevent breakthrough bacterial, fungal, viral, and protozoal infections during periods of neutropenia, and (3) to treat established infections effectively, all aimed at reducing patient morbidity and mortality and allowing for administration of optimal neoplastic therapy. All these goals must be achieved at the lowest possible toxicity and cost.

■ APPROACH TO TREATMENT

Guidelines for management of febrile episodes and documented infections in neutropenic patients are presented in Fig. 120–1 (from the Infectious Diseases Society of America [IDSA], revised in 2002).¹ Although many controversies remain regarding optimal management of these patients, the IDSA guidelines and those of other expert panels, such as the National Comprehensive Cancer Network (NCCN), offer an evidence-based consensus approach to the management of febrile neutropenia.

Because fever in the neutropenic cancer patient is considered the result of infection until proved otherwise, high-dose broad-spectrum bactericidal, usually parenteral, empirical antibiotic therapy should be initiated at the onset of fever or at the first signs or symptoms of infection. Withholding antibiotic therapy until isolation of an organism results in unacceptably high mortality rates. At least 50% of febrile neutropenic cancer patients have an established or occult infection, and at least 20% of profoundly neutropenic patients (ANC < 100 cells/mm³) experience bacteremia.^{1,6} In immunocompromised patients, undiagnosed infection can disseminate rapidly and

result in death if left untreated or if treated improperly. Failure to initiate appropriate antibiotic therapy for *P. aeruginosa* bacteremia at the onset of fever in neutropenic cancer patients resulted in mortality rates of 15% and 70% within 12 and 48 hours, respectively.¹⁹ Empirical antibiotic therapy is 70% to 90% effective at reducing early morbidity and mortality.¹⁰ Therapy must be appropriate, however, and initiated promptly. Antimicrobial therapy also should be initiated promptly in afebrile cancer patients with signs and symptoms of infection.

When designing optimal empirical antibiotic regimens, clinicians must consider infection patterns and antimicrobial susceptibility trends in their respective institutions. Also, patient factors, such as risk for infection, drug allergies and concomitant nephrotoxins, and previous antimicrobial exposure (including prophylaxis), must be considered.⁶ The first step in choosing empirical antimicrobial therapy is to determine the patient's risk of infection, which will help to guide the route and setting for therapy administration. Patients with neutropenia can be divided into low-, moderate-, and high-risk groups based on the projected duration of neutropenia and other risk factors for serious infection^{5,28} (Table 120–2). Patients with neutropenia of short duration (≤ 7 days) are considered to be at relatively low risk of severe infection. Patients with neutropenia lasting 7 to 14 days are considered to be at moderate risk for severe infection. High-risk patients are those with neutropenia for 14 or more days; these patients are at increased risk for severe infection from bacteria, as well as from fungi, viruses, and parasites. Oral empirical antimicrobial therapy may be appropriate for low-risk patients. The patient's overall clinical condition and other risk factors for infection determine whether this oral therapy is administered on an inpatient or outpatient basis. If therapy is administered on an outpatient basis, the patient must be compliant with treatment and have prompt access to medical care around the clock, should his or her condition worsen. Patients considered at moderate risk of infection should receive at least the first few days of therapy administered parenterally in the hospital

TABLE 120–2. Risk-Based Therapy for Febrile Patients with Neutropenia

| Risk Group | Patient Characteristics | Treatment Strategies |
|---------------|---|---|
| High risk | <p><i>Neutropenia:</i> Severe (ANC < 100/mm³) and/or prolonged (≥ 14 days)</p> <p><i>Malignancy/treatment:</i> Hematologic malignancy or allogeneic HSCT</p> <p><i>Comorbidities:</i> Substantial comorbidity; poor performance status</p> <p><i>Clinical status:</i> Clinical or hemodynamic instability (e.g., shock) and/or complex infection (e.g., pneumonia, bacteremia)</p> <p><i>Response to initial therapy:</i> Slow response</p> | <p><i>Therapy/setting:</i> Broad-spectrum, parenteral (IV) therapy, hospital-based for duration of febrile neutropenia</p> |
| Moderate risk | <p><i>Neutropenia:</i> Moderate duration (7–14 days)</p> <p><i>Malignancy/treatment:</i> Solid tumor treated with autologous HSCT</p> <p><i>Comorbidities:</i> Minimal medical comorbidity</p> <p><i>Clinical status:</i> Clinically stable</p> <p><i>Response to initial therapy:</i> Favorable (e.g., early defervescence)</p> | <p><i>Therapy/setting:</i> Initial parenteral, hospital-based therapy, followed by early discharge on a parenteral or oral regimen (sequential)</p> |
| Low risk | <p><i>Neutropenia:</i> Short duration (≤ 7 days)</p> <p><i>Malignancy/treatment:</i> Solid tumor treated with conventional chemotherapy</p> <p><i>Comorbidities:</i> None</p> <p><i>Clinical status:</i> Clinically stable at onset of fever; no identified focus of infection, or simple infection (e.g., UTI)</p> | <p><i>Therapy/setting:</i> Broad-spectrum outpatient therapy (parenteral, sequential, or oral) for the entire episode</p> |

TABLE 120–3. Comparative Advantages and Disadvantages of Various Antibiotic Regimens for Empiric Therapy of Febrile Neutropenic Cancer Patients

| Regimen | Potential Advantages | Potential Disadvantages |
|---|--|--|
| β -Lactam monotherapy (ceftazidime 1–2 g every 8 h, cefepime 1–2 g every 12 h, piperacillin/tazobactam 4.5 g every 6 h, imipenem/cilastatin 0.5 g every 6 h, or meropenem 1 g every 8 h) ^a | Efficacy comparable to combination regimens; decreased drug toxicities; ease of administration; possibly less expensive | Possibly less efficacy in profound neutropenia or prolonged neutropenia; limited gram-positive activity; no potential for additive/synergistic effects; increased selection of resistant organisms; increased colonization and superinfection rates |
| Antipseudomonal β -lactam plus aminoglycoside (e.g., cefepime 1–2 g every 12 h or ceftazidime 1–2 g every 8 h + gentamicin or tobramycin) ^{a,b} | Traditional regimen, broad-spectrum coverage; optimal therapy of <i>Pseudomonas aeruginosa</i> ; rapidly bactericidal; synergistic activity; decreased bacterial resistance; reduction of superinfections | Limited gram-positive activity; potential for nephrotoxicity; need for therapeutic monitoring of aminoglycoside concentrations |
| Empirical regimens containing vancomycin (ceftazidime 1–2 g every 8 h + vancomycin 0.5–1 g every 6–12 h) ^a ± gentamicin or tobramycin ^b | Early effective therapy of gram-positive infections | No demonstrated benefit of vancomycin empirical therapy vs. addition of vancomycin if needed later; increased risk of selection for vancomycin-resistant enterococci; risk of toxicities; excessive cost; need for therapeutic monitoring of vancomycin concentrations |
| Empirical regimens containing fluoroquinolones (ciprofloxacin 0.4 g every 8–12 h + ceftazidime 1–2 g every 8 h, aminoglycoside, or vancomycin 0.5–1 g every 6–12 h) ^a | Efficacy similar to other regimens when used in combination therapy; no cross-resistance with β -lactams; possibility for oral administration; may be useful in patients with renal impairment in whom aminoglycosides are undesirable | Marginal gram-positive activity; fluoroquinolones not recommended as monotherapy; resistance may develop rapidly |
| Oral antibiotic regimens (e.g., ciprofloxacin 0.75 g every 12 h or levofloxacin 0.75 g every 24 h + amoxicillin-clavulanate 0.75 g every 12 h) | Efficacy comparable with parenteral therapy in low-risk patients; less expensive; reduced exposure of patients to nosocomial pathogens | Least studied treatment approach; less potent than parenteral antibiotics; requires compliant patient with 24 h access to medical care should clinical instability develop |

^aDosing guidelines in patients with normal renal function.

^bGentamicin or tobramycin 2 mg/kg loading dose, followed by maintenance dose determined by serum concentrations. Choice of specific agent determined according to institutional susceptibilities to individual drugs.

^cVancomycin dosing may be guided by serum concentrations.

setting. High-risk patients generally are treated with hospital-based parenteral therapy for the entire course of their treatment.

The optimal antibiotic regimen for empirical therapy in febrile neutropenic cancer patients remains controversial. Although empirical antimicrobial therapy for febrile neutropenia has been studied extensively for more than three decades, no single regimen can be recommended for all patients. Because of their frequency and relative pathogenicity, *P. aeruginosa* and other gram-negative bacilli and staphylococci remain the primary targets of empirical antimicrobial therapy.¹⁰ Although *P. aeruginosa* is documented in fewer than 5% of bloodstream infections in the population of hospitalized patients, adequate antipseudomonal antibiotic coverage still must be included in empirical regimens because of the significant morbidity and mortality associated with this pathogen.^{1,10,16,20}

At least four different types of empirical parenteral antibiotic regimens are in use: (1) monotherapy with an antipseudomonal cephalosporin (cefepime or ceftazidime) or antipseudomonal carbapenem (imipenem-cilastatin or meropenem), (2) combination therapy with an aminoglycoside plus an antipseudomonal penicillin (piperacillin-tazobactam or ticarcillin-clavulanate), an antipseudomonal cephalosporin, or an antipseudomonal carbapenem, (3) vancomycin plus an antipseudomonal cephalosporin or antipseudomonal carbapenem, with or without an aminoglycoside, and (4) a fluoroquinolone (ciprofloxacin or levofloxacin) in combination with an

antipseudomonal cephalosporin, antipseudomonal carbapenem, aminoglycoside, or vancomycin.^{1,3,6,10} Each of these regimens has advantages and disadvantages, which are summarized in Table 120–3. There is no overwhelming evidence that any one of these regimens is superior to the others. The overall response to empirical antibiotic regimens in febrile neutropenic cancer patients is about 70% to 90% regardless of whether or not a pathogen is isolated or which antimicrobial regimen is used.^{5,10}

Regardless of initial antibiotic selection, all empirical regimens must be monitored appropriately and revised on the basis of documented infections, susceptibilities of bacterial isolates, development of more defined clinical signs and symptoms of infection, or a combination of these factors. Consensus guidelines recommend three general empirical parenteral antibiotic regimens (monotherapy with an antipseudomonal cephalosporin or carbapenem): two-drug therapy without vancomycin (aminoglycoside plus antipseudomonal penicillin, cephalosporin, or carbapenem), and vancomycin plus one to two other drugs (antipseudomonal cephalosporin or carbapenem, with or without an aminoglycoside), as shown in Fig. 120–1.^{1,6} However, other alternative regimens also may be appropriate, based on specific patient characteristics.

Prompt initiation of broad-spectrum empirical antibiotic therapy is essential to prevent early morbidity and mortality in febrile neutropenic patients with cancer. Choice of empirical regimens

should take into account the patient's risk of infection and clinical status, as well as patterns of hospital infections and susceptibility.

■ β -LACTAM MONOTHERAPY

Several β -lactam antibiotics in current use have been evaluated as monotherapy for the management of febrile episodes in neutropenic cancer patients, including antipseudomonal cephalosporins (ceftazidime and cefepime), antipseudomonal penicillins (ticarcillin-clavulanic acid and piperacillin-tazobactam), and antipseudomonal carbapenems (imipenem-cilastatin and meropenem).^{1,3,6,10} An early landmark study compared ceftazidime monotherapy with a three-drug combination (cephalothin, gentamicin, and carbenicillin) in 550 episodes of fever and neutropenia.³⁴ Ceftazidime monotherapy was as effective as combination therapy in initial empirical management (first 72 hours); 78% of febrile patients with undocumented infections were managed successfully with one antibiotic, and no morbidity or mortality resulted from adding other antimicrobial agents only when indicated clinically. Similar favorable results were reported with cefepime and the antipseudomonal carbapenems.^{1,35–38} A meta-analysis of 29 randomized clinical trials involving almost 4800 patients revealed that monotherapy with an antipseudomonal cephalosporin or carbapenem is at least as effective as aminoglycoside-containing combination regimens in the empirical treatment of febrile neutropenia.³⁹ These results were confirmed in a second meta-analysis of 46 clinical trials involving more than 7600 patients that revealed no significant differences between monotherapy and combination therapy (β -lactam/aminoglycoside) in rates of survival, treatment response, and bacterial/fungal superinfections but a higher rate of adverse events in patients receiving combination therapy.⁴⁰

The use of monotherapy has several potential advantages and disadvantages (see Table 120–3). Perhaps the most common concerns are those regarding the selection of resistant strains of organisms, such as *P. aeruginosa*, *Enterobacter* spp., and *Serratia* spp., through extended-spectrum β -lactamases and type I β -lactamases, especially with ceftazidime.^{1,6,41} Activity against gram-positive organisms, such as coagulase-negative staphylococci, methicillin-resistant *S. aureus*, enterococci (including vancomycin-resistant enterococci), penicillin-resistant *S. pneumoniae*, and some strains of viridans streptococci is poor with some single β -lactams, but cefepime and antipseudomonal carbapenems have good activity against viridans streptococci and pneumococci.¹ Although ceftazidime has been studied widely and used in the treatment of febrile neutropenia, newer agents may be more optimal owing to ceftazidime's susceptibility to β -lactamase induction and lower activity against gram-positive organisms.¹ For example, higher clinical response rates are achieved with meropenem than with ceftazidime.⁴²

As with all empirical antibiotic regimens, patients receiving monotherapy should be monitored closely for treatment failure, secondary infections, and the development of resistance. Use of monotherapy may not be appropriate in institutions with high rates of gram-positive infections or infections caused by gram-negative pathogens such as *P. aeruginosa* and *Enterobacter* spp. Imipenem-cilastatin and meropenem, however, are less susceptible to inducible β -lactamases and often may be used effectively in these institutions. Overall, similar efficacy has been observed with monotherapy with antipseudomonal β -lactams and aminoglycoside combination therapy in the treatment of *P. aeruginosa* infections.²⁰

■ AMINOGLYCOSIDE PLUS ANTIPSEUDOMONAL β -LACTAM

Regimens consisting of an aminoglycoside plus an antipseudomonal penicillin, antipseudomonal cephalosporin, or antipseudomonal carbapenem traditionally have been the most commonly used regimens for empirical treatment of febrile neutropenia, although many such regimens may lack adequate gram-positive activity¹⁴ (see Table 120–3). This relative lack of activity remains a concern because of the increasing frequency of gram-positive infections. The choice of aminoglycoside and β -lactam for inclusion in empirical regimens should be based on institutional epidemiology and antimicrobial susceptibility patterns. If *P. aeruginosa* is a common institutional pathogen, use of empirical tobramycin or amikacin may be strongly considered because they are generally more active than gentamicin against this organism. However, gentamicin is still an appropriate choice in many institutions based on known susceptibility patterns in those locations. Similar efficacy is observed with an antipseudomonal penicillin, antipseudomonal cephalosporin, or antipseudomonal carbapenem in combination with an aminoglycoside.¹

Combinations of broad-spectrum β -lactams and aminoglycosides often provide synergistic activity against bacteria commonly infecting neutropenic patients. The exact role of synergy in the outcome of febrile neutropenic patients treated with empirical antibiotic therapy, however, remains somewhat controversial, particularly in light of the efficacy of single-drug regimens. Nevertheless, synergistic combinations of antibiotics appear to be beneficial in patients with persistent, profound neutropenia. Moreover, administration of antipseudomonal β -lactams in combination with an aminoglycoside may result in a lower rate of drug resistance.⁵

Aminoglycoside toxicity may be a concern in patients receiving these regimens who are already receiving other nephrotoxic drugs, such as cisplatin and cyclosporine. Administration of aminoglycosides in large single daily doses (once-daily dosing) may be as effective, less costly, and no more toxic than conventional dosing methods.⁴³ A review of randomized, prospective trials in febrile neutropenia failed to find significant differences in either efficacy or toxicity between once-daily dosing and traditional dosing of aminoglycosides.⁴³ Although once-daily aminoglycoside dosing regimens appear to be safe and effective in these patients, there are not yet sufficient data to recommend once-daily dosing for routine use in this population.⁵

■ EMPIRICAL REGIMENS CONTAINING VANCOMYCIN

There has been considerable debate over the inclusion of vancomycin in initial empirical therapy of febrile neutropenic cancer patients. This controversy continues because of the increasing incidence of gram-positive infections in this population. One approach is to include vancomycin in the initial empirical antibiotic regimen, thereby providing early effective treatment of possible gram-positive infections. Decreased mortality from penicillin-resistant viridans streptococcal infections has been observed when vancomycin was included in initial therapy.^{1,5} A second approach is to withhold vancomycin from initial empirical regimens, later adding the drug if gram-positive organisms are isolated from cultures or if there is no response to initial therapy. Support for both these approaches can be found in the medical literature.^{1,6,10,44} Prospective studies indicate that there is no advantage to adding vancomycin to initial empirical regimens

routinely if vancomycin can be added later as needed.^{14,44,45} In addition to increased costs of therapy, there is overwhelming evidence that the selection of vancomycin-resistant enterococci (VRE) is associated with excessive vancomycin use.⁴⁶

Inclusion of vancomycin in initial empirical regimens may be more appropriate today because of higher rates of methicillin-resistant staphylococcal infections, as well as aggressive chemotherapy regimens causing significant mucosal damage that increases the risk for streptococcal infections. Vancomycin is recommended for inclusion in initial empirical regimens in patients at high risk of gram-positive infection, particularly due to methicillin-resistant *S. aureus* and coagulase-negative staphylococci (including those with evidence of infection of central venous catheters and other indwelling lines), high risk of viridans streptococcal infection due to severe mucositis, or pneumonitis in hospitals with high rates of methicillin-resistant staphylococcal infections.^{1,3,6,10,17,46} Rates of β -lactam resistance among viridians streptococci are in the range of 18% to 29%.⁶ Empirical vancomycin use also may be justified in institutions employing empirical or prophylactic antibiotic regimens without good activity against streptococci (e.g., ciprofloxacin) and in patients known to be colonized with methicillin-resistant staphylococci or β -lactam-resistant pneumococci. In patients with preliminary culture results indicating gram-positive infection, empirical vancomycin is appropriate while the susceptibility results are pending. Lastly, empirical use of vancomycin may be recommended in patients with hypotension or other evidence of cardiovascular impairment without an identified pathogen.^{6,17,46} If empirical vancomycin therapy is initiated and no evidence of gram-positive infection is found after 24 to 48 hours, the drug should be discontinued.^{1,5,6} Continuing vancomycin when not warranted results in higher costs, more toxicities, and greater risk of development of VRE.⁴⁴

Vancomycin plus carbapenem regimens may have advantages over vancomycin plus cephalosporin regimens because of lower rates of carbapenem resistance to gram-negative bacilli.¹ Newer antimicrobial agents such as quinupristin-dalfopristin and linezolid should be reserved for documented infections caused by multiresistant gram-positive pathogens such as VRE; the role of these drugs in the routine treatment of fever in neutropenic patients is undetermined, and linezolid is associated with myelosuppression.^{1,6}

CLINICAL CONTROVERSY

Inclusion of vancomycin into empirical antimicrobial regimens for febrile neutropenia remains controversial. Vancomycin should be included in initial regimens for patients with evidence of gram-positive infections or at high risk for these infections, as determined by patient characteristics and institutional infection and susceptibility patterns.

■ FLUOROQUINOLONES AS A COMPONENT OF EMPIRICAL REGIMENS

Because the fluoroquinolone antibiotics have broad-spectrum activity (particularly against gram-negative pathogens), rapid bactericidal activity, and favorable pharmacokinetic and toxicity profiles, these agents have been investigated as empirical therapy in febrile neutropenic cancer patients. Ciprofloxacin is the preferred quinolone for use in this clinical setting because of its relatively better activity against *P. aeruginosa*. Response rates of quinolone-containing combination regimens are comparable with those obtained with the other regimens described previously.^{1,5,47,48} Ciprofloxacin is not rec-

ommended for monotherapy, however, because of its relatively poor activity against gram-positive pathogens, particularly streptococci, and variable response rates in clinical studies.¹ Quinolones should not be used as empirical therapy in patients who have received quinolones as infection prophylaxis because of the risk of drug resistance.^{1,6,10} Rates of fluoroquinolone resistance are increasing, and streptococcal treatment failures are a concern.⁴⁹ Although fluoroquinolones are not generally considered first-line empirical therapy, they may be useful as one component of combination regimens in patients with allergies or other contraindications to first-line agents.

■ ORAL ANTIBIOTIC THERAPY FOR MANAGEMENT OF FEBRILE NEUTROPENIA

An individual patient's risk of severe infection (influenced by degree/duration of neutropenia and other patient variables) determines appropriate antibiotic therapy and setting for administration (see Table 120–2 for patient characteristics and levels of infection risk in patients with neutropenia).^{1,5,6,28} Risk stratification is based on several parameters, including duration and extent of neutropenia, type of cancer and its management (including history of HSCT), clinical status, comorbidities, and response to empirical antimicrobial therapy.²⁸ Because of the excellent spectrum of activity and favorable pharmacokinetics of relatively newer oral antibiotics, particularly the fluoroquinolones, oral antibiotics may have a role in the management of selected patients. In patients at low risk for severe bacterial infection, empirical therapy with broad-spectrum oral antibiotic agents achieves similar patient outcomes as parenteral antibiotics, with response rates of 77% to 95%.^{5,29,30} The availability of oral antibiotics with broad spectra of activity has made possible the treatment of febrile neutropenia in low-risk patients completely in the outpatient setting. Patients with solid tumors undergoing conventional chemotherapy with an expected duration of neutropenia of less than 7 to 10 days and who are clinically stable may be appropriate candidates for oral antibiotic therapy administered on an outpatient basis.^{5,28–31} Fluoroquinolones, either as monotherapy or in combination with amoxicillin-clavulanate (or clindamycin for penicillin-allergic patients) for enhanced gram-positive coverage, have been studied most commonly for outpatient therapy in low-risk patients. IDSA and NCCN guidelines recommend oral antibiotic therapy with ciprofloxacin plus amoxicillin-clavulanate in clinically stable low-risk adults (particularly those with recovering neutrophils) with no focus of bacterial infection and no signs of infection other than fever.^{1,6} Oral cephalosporins such as cefixime also may be suitable for outpatient treatment.¹ Careful patient selection obviously is required for such management strategies; important patient characteristics include a history of medication compliance, good caregiver support, and close proximity to medical care in the event of failure to respond to outpatient antibiotic therapy. Benefits of oral therapy on an outpatient basis include increased convenience and quality of life for patients and caregivers and reduced exposure to multidrug-resistant institutional pathogens.⁵ Outpatient therapy of low-risk patients is now common practice in many institutions.

In patients at moderate risk for severe bacterial infection, oral antibiotics may place a role in step-down therapy. Carefully selected neutropenic patients may be switched safely from broad-spectrum parenteral therapy to oral antibiotic regimens (e.g., ciprofloxacin plus amoxicillin-clavulanate) with response rates comparable to patients remaining on IV therapy.^{10,28,32} Patient selection criteria generally include defervescence within 72 hours of initiation of parenteral therapy, hemodynamic stability, absence of positive cultures or a discernible site of infection, and ability to take oral medications. Many of these patients are able to complete their course of therapy at home.^{1,10,28,32}

Changing parenteral antimicrobials to oral regimens in carefully selected patients is now relatively common practice and allows for less expensive hospitalizations and earlier patient discharges.

■ ANTIMICROBIAL THERAPY AFTER INITIATION OF EMPIRICAL THERAPY

6 After initiation of empirical antimicrobial therapy, judicious assessment of febrile neutropenic cancer patients is mandatory to evaluate response, clinical status, laboratory data, and potential need for therapy adjustments. After the administration of 72 hours or more of empirical antimicrobial therapy, the clinical status and culture results of febrile neutropenic patients should be reevaluated to determine whether or not therapeutic modifications are necessary. Additions or modifications to the initial antimicrobial regimen likely will be required in patients with ANC of fewer than 500 cells/mm³ for greater than a week. Modifications of antimicrobial therapy should be based on clinical and laboratory data; antibiotic therapy should be optimized based on culture results. However, during periods of neutropenia, patients generally should continue to receive broad-spectrum therapy because of the risk of secondary infections or breakthrough bacteremias when antimicrobial coverage is too narrow.^{1,5,10}

In patients who become afebrile after 3 to 5 days of therapy with no infection identified, it is generally optimal to continue antibiotic therapy until neutropenia has resolved (ANC \geq 500 cells/mm³). Some clinicians elect to switch therapy from IV antibiotics to an oral regimen of ciprofloxacin plus amoxicillin-clavulanate after 2 days of IV therapy in low- to moderate-risk patients who become afebrile and have no evidence of infection. This approach may facilitate earlier hospital discharge. In high-risk patients, the parenteral antibiotic regimen should be continued for 7 days or more.^{1,6} However, in afebrile patients with prolonged neutropenia but no signs or symptoms of infection, consideration can be given to discontinuing antibiotic therapy, provided patients can be observed carefully and have ready access to medical care.

The optimal management of patients who remain febrile in the absence of microbiologic or clinical documentation of infection remains highly controversial. The median time to defervescence of febrile neutropenic cancer patients receiving empirical antibiotic therapy is 5 to 7 days.⁵⁰ Persistently febrile patients should be evaluated carefully, but modifications generally are not made to initial antimicrobial regimens within the first 5 days of therapy unless there is evidence of clinical deterioration^{1,5,6,14} (see Fig. 120–1). It is important to note that the persistence of fever does not necessarily mean failure of a given antimicrobial regimen. This is particularly true if patients are otherwise clinically stable. Fever after 3 or more days of antibiotic therapy can be due to a number of causes, including nonbacterial infection, resistant bacterial infection or infection slow to respond to therapy, emergence of a secondary infection, inadequate drug concentrations, drug fever, cell wall-deficient bacteremia, and fever at an avascular site (e.g., catheter infection or abscess).^{1,5} Patients with documented infection who are receiving appropriate antimicrobial therapy (based on *in vitro* susceptibility tests) often will remain febrile until resolution of neutropenia occurs.

Need for modification of antimicrobial therapy should be evaluated in neutropenic cancer patients who remain febrile despite 3 to 5 days of antibiotic therapy. The same antibiotic regimen can be continued in febrile but stable patients, especially if neutropenia is expected to resolve within a week. The antibiotic regimen may require modification in patients experiencing toxicities, as well as in patients

with evidence of progressive disease or documentation of an organism not covered by the initial regimen. When a causative organism is identified, specific therapy directed at the organism should be included; however, patients should continue to receive broad-spectrum therapy while they remain neutropenic.^{1,3,5,10} Need for the addition of vancomycin should be considered as warranted by clinical and laboratory findings; however, if vancomycin was a component of the initial empirical regimen and the patient is still febrile after 3 days of therapy, discontinuation of vancomycin should be considered to reduce the risk of resistance.

■ INITIATION OF ANTIFUNGAL THERAPY

Neutropenic patients who remain febrile despite 5 or more days of broad-spectrum antibiotic therapy are candidates for antifungal therapy. A high percentage of febrile patients who die during prolonged neutropenia have evidence of invasive fungal infection on autopsy, even though many had no evidence of fungal disease before death.²¹ Persistence of fever or development of a new fever during broad-spectrum antibiotic therapy may indicate the presence of a fungal infection most commonly due to *Candida* and *Aspergillus* spp. in approximately 33% of patients.¹⁰ Blood cultures are positive in fewer than 50% of neutropenic patients with invasive fungal infections.¹⁰ The lack of rapid, sensitive diagnostic tests for fungi and the high morbidity and mortality associated with waiting for isolation of fungal organisms justify the empirical addition of antifungal therapy in this clinical setting.¹⁰ Therefore, empirical antifungal therapy should be initiated after 5 to 7 days of broad-spectrum antibiotic therapy at adequate doses to treat undiagnosed fungal infection and prevent fungal superinfection in high-risk febrile neutropenic patients.²²

The optimal empirical antifungal regimen is not known presently. Empirical coverage for both *Candida* spp. and *Aspergillus* should be considered because these organisms are responsible for more than 90% of fungal infections in neutropenic cancer patients.⁷ *Aspergillus* is particularly common in patients with hematologic malignancies and in patients undergoing HSCT; therefore, amphotericin B usually is preferred in these patients.^{10,21} In the setting of febrile neutropenia, lipid-associated amphotericin B products are similar in efficacy to conventional amphotericin B while causing fewer toxicities.^{51,52} However, the relative lack of experience with these products and significantly higher cost in comparison with conventional amphotericin B make their role in the empirical therapy of febrile neutropenia uncertain at this time.^{1,10,51,52} Amphotericin B lipid-associated drugs may be appropriate in patients with preexisting renal dysfunction, renal dysfunction or infusion-related toxicities from conventional amphotericin B therapy, and in patients experiencing treatment failure of suspected/documentated fungal infections on conventional amphotericin B therapy.^{1,12}

The azole compounds fluconazole and itraconazole are used in the management of febrile neutropenia. Despite the high rate of amphotericin B toxicities, concerns regarding the emergence of azole-resistant fungi have prevented these agents from replacing amphotericin B as the “gold standard” in persistently febrile neutropenic patients. However, fluconazole can be a useful alternative to amphotericin B for empirical antifungal use in hospitals in which *Aspergillus* infections and infections due to *C. krusei* and drug-resistant *C. glabrata* are not common.¹ If fluconazole is used as antifungal prophylaxis in cancer patients, it should not be included in empirical antifungal regimens. Itraconazole has similar efficacy as amphotericin B, with fewer toxicities, and availability in both parenteral and oral forms provides a platform for step-down therapy if

TABLE 120-4. Infectious Complications after Bone Marrow and Solid Organ Transplantation: Syndromes of Disease and Treatment Guidelines

| Pathogen | Syndromes of Disease | Treatment |
|---|---|--|
| Bacterial | | |
| Gram-negative aerobic bacilli (Enterobacteriaceae, <i>Pseudomonas aeruginosa</i> , <i>Hemophilus influenzae</i>) | Blood, urinary tract, pulmonary, abdomen | <i>Empiric:</i> Ceftazidime 1–2 g every 8 h + Aminoglycoside, ^{a,b} cefepime 1–2 g every 12 h + aminoglycoside; ^{a,b} piperacillin-tazobactam 3.375–4.5 g every 4–6 h; imipenem-cilastatin 0.25–0.5 g every 6 h ± aminoglycoside ^{a,b} <i>Definitive:</i> According to culture and sensitivity results |
| Gram-positive cocci (<i>Staphylococcus aureus</i> , <i>S. epidermidis</i> , <i>Streptococcus pneumoniae</i> , <i>E. faecalis</i>) | Skin, blood, urinary tract, pulmonary, abdomen | <i>Empiric:</i> Nafcillin 1–2 g every 4–6 h; vancomycin 0.5–1 g every 6–12 h ^c <i>Definitive:</i> According to culture and sensitivity results |
| <i>Legionella</i> spp. | Pulmonary | Erythromycin 0.5–1 g every 6 h |
| <i>Listeria monocytogenes</i> | Central nervous system | Ampicillin 1–2 g every 4–6 h with gentamicin; ^a TMP-SMX 4 mg/kg every 12 h ^d |
| <i>Nocardia</i> spp. | Skin, pulmonary, central nervous system | Sulfadiazine 1 g every 4–6 h; TMP/SMX 4 mg/kg every 12 h ^d |
| Fungal | | |
| <i>Candida</i> spp. | Blood, urinary tract, mucous membranes, skin | Clotrimazole 10 mg five times daily; nystatin 100,000 U every 6 h; ketoconazole 200 mg daily; fluconazole 100–400 mg daily; itraconazole 200–400 mg daily; amphotericin B 0.5–0.7 mg/kg/day ± 5-flucytosine 100–150 mg/kg/day divided every 6 h |
| <i>Aspergillus</i> spp. | Skin, pulmonary, central nervous system | Amphotericin B 1 mg/kg/day ± 5-flucytosine; itraconazole 200–400 mg daily; lipid-associated amphotericin B 4–5 mg/kg daily; ^e caspofungin 50 mg daily ^e ; voriconazole 4 mg/kg every 12 h ^e |
| <i>Cryptococcus neoformans</i> | Skin, pulmonary, central nervous system | Amphotericin 0.5 mg/kg/day ± 5-flucytosine; fluconazole 400 mg daily |
| <i>Zygomycetes (Mucor)</i> | Rhinocerebral disease | Amphotericin B 1 mg/kg/day; lipid-associated amphotericin B 4–5 mg/kg daily ^e |
| Viral | | |
| Herpes simplex virus | Skin, central nervous system, mucous membranes, pulmonary | Acyclovir 5–10 mg/kg every 8 h; foscarnet 60 mg/kg every 8 h |
| Cytomegalovirus | Pulmonary, blood, urinary tract, GI tract | Ganciclovir 5 mg/kg every 12 h; foscarnet 60 mg/kg every 8 h; hyperimmune globulins 100–500 mg/kg every 1–2 wk |
| Varicella-zoster virus | Skin, disseminated disease | Acyclovir 10 mg/kg every 8 h; foscarnet 60 mg/kg every 8 h |
| Epstein-Barr virus | Lymphoproliferative disease | No effective treatment |
| Papovaviruses (BK, JC) | Skin, central nervous system | No effective treatment |
| Protozoal/parasitic | | |
| <i>Pneumocystis jiroveci</i> | Pulmonary | TMP-SMX 15–20 mg/kg/day divided every 6 h ^d ; atovaquone 750 mg every 12 h; pentamidine 4 mg/kg daily; dapsone 100 mg daily + TMP 15–20 mg/kg/day divided every 6 h; clindamycin 450–600 mg every 6 h + primaquine 15 mg daily |
| <i>Toxoplasma gondii</i> | Central nervous system | Pyrimethamine 50–100 mg daily + sulfadiazine 1 g every 4–6 h ^f ; pyrimethamine 50–100 mg daily + clindamycin 450–600 mg every 6 h ^f |
| <i>Strongyloides stercoralis</i> | Pulmonary, central nervous system | Thiabendazole 25 mg/kg every 12 h (max 3 g/day) |

^aGentamicin or tobramycin 2 mg/kg loading dose, followed by maintenance dose determined by serum concentrations. Choice of specific agent determined according to institutional susceptibilities to individual drugs.

^bFor penicillin-allergic adults, use ciprofloxacin 0.4 g every 8–12 h plus an aminoglycoside.

^cVancomycin dosing may be guided by serum concentrations.

^dBased on the trimethoprim component of the combination.

^eFor use in cases refractory to amphotericin B or itraconazole.

^fFolinic acid (5–10 mg/day) often recommended in conjunction with pyrimethamine-containing regimens for prevention of bone marrow toxicity.

TMP-SMX = trimethoprim-sulfamethoxazole

indicated clinically.⁵³ Use of voriconazole should be limited to allogeneic HSCT patients and patients with relapsed leukemia, and the role of caspofungin in the setting of neutropenic fever remains to be determined.^{22,54}

As with antibiotic therapy, the optimal duration of antifungal therapy remains controversial. Most clinicians agree that antifungal therapy can be discontinued when neutropenia has resolved in clinically stable patients with no evidence of fungal infection. In neutropenic patients, antifungal therapy generally should be continued for at least 2 weeks in the absence of signs and symptoms of active fungal disease, but many experts advocate continuing therapy until resolution of the neutropenia.^{5,22} In neutropenic patients with documented fungal disease, antifungal therapy should be directed at the causative organism, and therapy should be continued for at least 2 weeks and clinical and culture data indicate resolution of the infection. In addition to fungal infections, other causes of persistent fever of unknown origin include resistant bacterial infection, tissue necrosis as a result of underlying tumor, nonbacterial and nonfungal infection (e.g., viral, mycobacterial, or parasitic), and drug or blood product administration. Treatment recommendations for specific fungal infections can be found in Table 120–4.

■ INITIATION OF ANTIVIRAL THERAPY

Febrile neutropenic patients with vesicular or ulcerative skin or mucosal lesions should be evaluated carefully for infection due to herpes simplex virus (HSV) or varicella-zoster virus (VZV). Mucosal lesions from viral infections provide a portal of entry for bacteria and fungi during periods of immunosuppression. If viral infection is presumed or documented, neutropenic patients should receive aggressive antiviral therapy to aid healing of primary lesions and prevent disseminated disease. Acyclovir traditionally has been used in this population. However, the newer antivirals valacyclovir and famciclovir have better oral absorption and more convenient dosing schedules. Routine use of antiviral agents in the management of patients without mucosal lesions or other evidence of viral infection generally is not recommended.¹ Treatment recommendations for viral infections are located in Table 120–4.

■ MANAGEMENT OF CATHETER INFECTIONS

Cancer patients are at high risk for the development of catheter-related infections, most often owing to coagulase-negative staphylococci or *S. aureus*.^{1,5} Strategies for prevention and management of catheter-related infections are outlined in the practice guidelines published jointly by the IDSA in conjunction with other professional organizations.^{55,56}

■ DURATION OF ANTIMICROBIAL THERAPY

◀ The optimal duration of antimicrobial therapy in the neutropenic cancer patient remains controversial. Decisions regarding discontinuation of empirical antimicrobial therapy often are more difficult and complex than those regarding initiation of therapy (see Fig. 120–1). One point on which experts agree, however, is that the most important determinant of the total duration of antibiotic therapy is the patient's ANC.^{1,3,4,6,10} If the ANC is 500 cells/mm³ or greater for 2 consecutive days, if the patient is afebrile and clinically stable

for 48 to 72 hours or more, and if no pathogen has been isolated, then antibiotics may be discontinued. Some clinicians advocate that patients with ANCs of fewer than 500 cells/mm³ be maintained on antibiotic therapy until resolution of neutropenia, even if afebrile. However, prolonged antibiotic use has been associated with superinfections resulting from resistant bacteria and fungi and increases the risk of antibiotic-related toxicities.¹⁰ If low-risk patients are stable clinically but the ANC is still fewer than 500 cells/mm³, antibiotics may be discontinued after a total of 5 to 7 afebrile days. Patients, however, who experience profound neutropenia (ANC < 100 cells/mm³), have mucosal lesions, or have unstable vital signs or other risk factors should continue to receive antibiotics until the ANC has increased to 500 cells/mm³ or greater or the patient is stable clinically.

Patients who are persistently neutropenic and febrile but who are stable clinically with no active site of infection often may be discontinued successfully from antimicrobial therapy after 2 weeks or more. These patients, however, must be monitored carefully because reinstitution of antibiotics may be necessary.^{1,10} An alternative approach is to place these patients on antimicrobial prophylaxis, as discussed below. Patients with documented infections should receive antimicrobial therapy until the infecting organism is eradicated and signs and symptoms of infection have resolved (at least 10 to 14 days of therapy).

Consensus guidelines provide useful information regarding the management of febrile episodes in cancer patients with neutropenia.^{1,6} However, therapy (including initial empirical regimens, modifications, and duration of treatment) must be individualized based on individual patient parameters and response to therapy.

CLINICAL CONTROVERSY

A key controversy in the management of febrile neutropenia in cancer patients is the optimal time to stop empirical antimicrobial therapy in patients who remain persistently febrile. Patients' individual risk of severe infection (determined by extent and duration of neutropenia, as well as other risk factors) helps to guide treatment decisions in this setting.

■ COLONY-STIMULATING FACTORS

Because resolution of neutropenia is the most important determinant of patient outcome from both febrile episodes and documented infections, numerous studies have evaluated hematopoietic colony-stimulating factors (CSFs) (sargramostim, granulocyte-macrophage colony-stimulating factor, and filgrastim, granulocyte colony-stimulating factor) as adjunct therapy to antimicrobial treatment of febrile neutropenic cancer patients.⁵⁷ These studies consistently found that the use of CSFs reduces the total duration and severity of chemotherapy-related neutropenia. However, these studies failed to demonstrate consistent benefits of CSFs compared with placebo related to important outcome variables, such as overall survival and disease-free survival, but use of CSFs did result in fewer hospitalizations.^{57,58} An expert panel of the American Society of Clinical Oncology (ASCO) has concluded that there is no clear support for the routine use of CSFs in uncomplicated fever and neutropenia.⁵⁷ The ASCO panel reported that the use of CSFs may be useful in patients with ANC of 500 cells/mm³ or fewer, uncontrolled primary disease, pneumonia, invasive fungal infections, multiorgan dysfunction, sepsis syndrome, hypotension, or other factors likely to cause rapid clinical deterioration, but the panel emphasized that even under these severe circumstances, the benefits of CSF therapy were not substantiated.⁵⁷ Clinical judgment must be exercised in determining which patients

likely may benefit from judicious use of these expensive agents. Patients with prolonged neutropenia and documented infections who are not responding to appropriate antimicrobial therapy may benefit from treatment with CSFs.⁵⁷ Primary prophylaxis with CSFs may be warranted in patients with preexisting neutropenia or other risk factors for severe infection, especially when the risk of febrile neutropenia is 40% or greater.⁵⁷

The direct transfusion of neutrophils also has been studied for the treatment of febrile neutropenia or opportunistic infections. Routine use of neutrophil transfusions is not supported, but use should be considered in profoundly neutropenic patients with documented infections in whom causative organisms cannot be eradicated with appropriate antimicrobial therapy in combination with CSFs.^{1,6} At present, the use of neutrophil transfusions is considered experimental and is not recommended for routine management of febrile neutropenic patients.⁵⁹

PROPHYLAXIS OF INFECTIONS IN NEUTROPENIC CANCER PATIENTS

8 Owing to the potential morbidity and mortality of infections in neutropenic cancer patients, measures have been taken to prevent these complications through a number of environmental modifications and prophylactic antimicrobial regimens. The goal of antimicrobial prophylaxis in cancer patients is to decrease the number and severity of systemic infections during prolonged periods of neutropenia. Decisions regarding prophylactic antimicrobials must be made with the realization of associated issues, such as resistance concerns.

GENERAL MEASURES

Because approximately 50% of pathogens infecting neutropenic cancer patients are acquired in the hospital, reducing acquisition of infectious organisms from the environment is a basic component in controlling nosocomial infection rates.^{13,14} Neutropenic patients should be placed in reverse isolation (isolation to protect patients from contracting infections after exposure to others) with strict adherence to infection control guidelines by hospital personnel.⁷ Proper, meticulous hand washing by hospital personnel is a simple yet very effective infection control measure.

To reduce the risk of infection caused by airborne pathogens, such as *Aspergillus* spp., laminar airflow rooms are in use at some cancer centers performing HSCTs. Laminar airflow rooms work by directing filtered air away from the patient, thus minimizing the risk of infection from airborne or environmental pathogens. Laminar airflow rooms are expensive, however, and use of these protective environments does not improve overall survival in HSCT recipients.^{7,14}

BACTERIAL INFECTIONS

Early attempts at pharmacologic reduction of flora colonizing the GI tract used combinations of nonabsorbable antibiotics, including gentamicin, nystatin, vancomycin, polymyxin B, and colistin. The goal is to preserve colonization resistance to reduce gut colonization with virulent pathogens, such as *P. aeruginosa*, and their translocation into the bloodstream. When anaerobic flora are preserved by selective gut decontamination to prevent colonization by potentially pathogenic gram-negative organisms, this is termed *colonization resistance*.³ This

concept is based on studies conducted in immunosuppressed animals in which selective gut decontamination resulted in a lower number of infections and minimal colonization by potential pathogens.¹⁴

Although clinical trials have demonstrated that oral nonabsorbable antibiotics reduce infections successfully, these regimens are not recommended routinely for infection prophylaxis because of several problems, including unpalatability, high cost, and frequent adverse effects (e.g., nausea, vomiting, and diarrhea).^{1,13,14} Use of nonabsorbable antibiotic regimens also has been associated with the development of resistance to aminoglycosides among gram-negative bacilli, rendering the aminoglycosides useless as treatment alternatives for ensuing infections.^{1,13,14} Owing to concerns regarding development of resistance, prophylaxis with aminoglycosides and vancomycin should be avoided.¹

The concept of combining selective intestinal decontamination with systemic antimicrobial prophylaxis has been employed using oral agents, particularly the fluoroquinolones.¹⁴ Prospective clinical trials have shown that orally absorbed prophylactic antibiotics, including trimethoprim-sulfamethoxazole and fluoroquinolones, are more effective and better tolerated than nonabsorbable antibiotics.¹ Data from most placebo-controlled studies indicate that trimethoprim-sulfamethoxazole significantly reduces infection rates in cancer patients.¹ Although trimethoprim-sulfamethoxazole is also effective as prophylaxis against *P. jiroveci*, its lack of activity against *P. aeruginosa* is worrisome, particularly in institutions in which pseudomonal infections are frequent.¹ Other concerns with trimethoprim-sulfamethoxazole prophylaxis include selection of resistant organisms, predisposition to development of oral fungal infections, and delay in bone marrow recovery resulting in prolonged neutropenic episodes.^{10,13,14}

Numerous studies have shown that oral fluoroquinolones (ciprofloxacin and ofloxacin) are more effective than placebo, nonabsorbable antibiotics, and trimethoprim-sulfamethoxazole in preventing gram-negative infections in neutropenic cancer patients.^{60,61} Fluoroquinolone prophylaxis during periods of neutropenia decreases the incidence of fever and microbiologically documented gram-negative infections.^{60–62} There are, however, several limitations to their use. In particular, quinolones may lack adequate gram-positive activity. As a result, combination of a quinolone with a second agent providing enhanced gram-positive activity (e.g., rifampin, penicillin, or a macrolide) may be required for effective prophylaxis.⁶³ Fluoroquinolone prophylaxis has been associated with the development of resistant gram-negative organisms.⁶⁰ Rates of quinolone-resistant gram-negative bacilli infections exceed 25% in some centers at which quinolones have been used for prophylaxis.⁸ Use of fluoroquinolone prophylaxis precludes these agents from consideration for inclusion in empirical antibiotic regimens in febrile neutropenic patients. Moreover, patients experiencing breakthrough infection during fluoroquinolone prophylaxis should not be placed on a fluoroquinolone subsequently for empirical therapy.

The use of antibacterial prophylaxis remains controversial owing to a lack of consistent efficacy, potential for development of resistant bacteria, high cost, and lack of impact on patient survival.¹ Therefore, antibacterial prophylaxis is not recommended routinely for all neutropenic patients. Prophylaxis (with trimethoprim-sulfamethoxazole or quinolone-penicillin) generally is indicated for patients expected to be profoundly neutropenic for more than 1 week, such as HSCT patients.^{1,7} Additional risk factors that may provide justification for prophylaxis include mucous membrane or skin lesions, presence of indwelling catheters, need for instrumentation, severe periodontal disease, or other risk factors.¹ Neutrophil recovery eliminates the need for continued prophylaxis, and recovery may be facilitated by use of

CSFs.⁵⁷ In contrast to their unclear role in the treatment of febrile neutropenia, CSFs have been formally recommended by the ASCO for prevention of febrile neutropenia in high-risk patients.⁵⁷ Such patients include those receiving chemotherapy regimens that produce a high rate of febrile neutropenia (>40% incidence) or patients with active tissue infection at the time of chemotherapy, history of febrile neutropenia with previous courses of chemotherapy, or underlying bone marrow compromise.⁵⁷

■ FUNGAL INFECTIONS

Because neutropenic patients are at risk for mucocutaneous and invasive fungal infections that are difficult to diagnose and treat in this population, antifungal prophylaxis may be considered during high-risk periods at institutions where fungal infections in cancer patients are frequent.⁶⁴ The goal of antifungal prophylaxis is to prevent development of invasive fungal infections during periods of risk, thereby reducing morbidity and mortality. A meta-analysis of antifungal prophylaxis in 38 trials involving more than 7000 cancer patients reported a decrease in the use of parenteral antifungal therapy, superficial and invasive systemic fungal infections, and fungal infection–related mortality rate.⁶⁵ Antifungal prophylaxis resulted in decreased mortality in patients with prolonged neutropenia and HSCT but had no effect on rates of invasive *Aspergillus* infections.

Although the choice of antifungal prophylaxis agents remains controversial, fluconazole prophylaxis (400 mg/day) has been particularly well studied and reduces the incidence of both superficial and systemic fungal infections, as well as significantly decreases mortality from fungal infections in patients with leukemia and HSCT recipients.^{63,66–68} However, the use of fluconazole prophylaxis has resulted in the emergence of infections caused by *C. krusei* and *C. glabrata*, pathogens that frequently are resistant to fluconazole and other azole-type antifungal agents.^{64,69} Routine antifungal prophylaxis with oral fluconazole (400 mg/day) or itraconazole oral solution (2.5 mg/kg every 12 hours) therefore should be limited to patients undergoing allogeneic HSCT (usually administered from

the day of HSCT until engraftment to prevent candidiasis).^{7,22} Prophylaxis against fungal infection is beneficial in leukemic patients, and the choice of either fluconazole, itraconazole, or amphotericin B should be determined by the types of fungal isolates at individual institutions.^{22,68} Recent data indicate that itraconazole may be more effective than fluconazole for long-term antifungal prophylaxis in allogeneic HSCT recipients; however, itraconazole use was associated with more frequent GI side effects.⁷⁰ After initiation, antifungal prophylaxis should be continued until resolution of neutropenia or the need for institution of antifungal therapy for suspected/documented infection.²²

Antifungal prophylaxis does not decrease the incidence of invasive mold infections.⁶⁵ In addition to environmental precautions, strategies being investigated for *Aspergillus* prophylaxis in neutropenic patients include oral itraconazole, low (0.1–0.25 mg/kg per day) to moderate (0.5 mg/kg per day) doses of amphotericin B, intranasal and aerosolized amphotericin B, and lipid-associated amphotericin B products.⁷ None of these interventions can be recommended routinely in clinical practice at this time.

■ OTHER INFECTIONS

The use of trimethoprim-sulfamethoxazole in cancer patients at risk for *P. jiroveci* pneumonia has reduced the incidence of this protozoal infection substantially.²⁷ Antiviral prophylaxis with acyclovir or newer agents (valacyclovir and famciclovir) is employed in most centers to reduce the risk of HSV reactivation in patients with acute leukemia undergoing intensive chemotherapy. Varicella vaccine provides good protection (90%) in leukemic children and also may be useful in seronegative adults, although the vaccine has been less well studied in this population.

When considering use of antimicrobial (antibacterial, antifungal, antiprotozoal, and antiviral) prophylaxis in neutropenic patients with cancer, the risks and benefits of the prophylaxis versus issues with development of resistance, toxicities, and other concerns must be weighed.

PHARMACOECONOMIC CONSIDERATIONS

As in all areas of modern health care, attention has been directed increasingly to providing cost-effective management of febrile neutropenia in cancer patients. Use of oral and/or outpatient antimicrobial therapy in low-risk patients is an effective, less costly alternative that is preferred by patients.⁷¹ Potent oral antimicrobials facilitate the conversion from IV antibiotics to oral therapy when appropriate. Judicious use of antimicrobials, such as reserving lipid-associated amphotericin B products for patients intolerant to conventional amphotericin B, helps to contain costs. In the situation of febrile neutropenia in a cancer patient, one may be tempted to “throw the kitchen sink” at suspected/documented infections; however, following guidelines such as those published by the IDSA and NCCN helps to guide the most appropriate use of available antimicrobials. Future consequences of antimicrobial overuse, such as resistance and limited treatment options, must be considered when choosing antimicrobial therapy for any indication, including management of febrile neutropenia. Each institution should examine its own infection and susceptibility patterns and use this information to guide empirical treatment decisions while individualizing therapy for each patient.

EVALUATION OF THERAPEUTIC OUTCOMES

Close monitoring of febrile neutropenic patients, including both clinical and laboratory parameters, is essential for early detection and treatment of infectious complications. Three general therapeutic outcomes have been defined in the setting of febrile neutropenia: (1) success (survival during the febrile episode until resolution of neutropenia by judicious selection of empirical antimicrobial therapy), (2) success with modification (same as 1 but with additions/modifications to empirical therapy), and (3) failure (death during febrile neutropenia).¹⁰ Because many of the drugs that may be used in this setting have significant toxicity potential (e.g., aminoglycosides and amphotericin B), careful attention must be paid to the prevention and management of drug-related adverse effects. Evaluations of the parameters in the “Clinical Presentation” box are appropriate to help monitor and guide therapy. In addition, the NCCN guidelines for febrile neutropenia provide comprehensive recommendations on clinical/laboratory monitoring parameters, including schedules.⁶ The reader is referred to individual chapters within this book for more detailed discussions of monitoring parameters related to specific types of infections (e.g., pneumonia and urinary tract infections).

INFECTIONS IN PATIENTS UNDERGOING HEMATOPOIETIC STEM CELL TRANSPLANTATION (HSCT)

1 Infection remains a major barrier to successful HSCT. Numerous advances in HSCT have taken place over the past decade and have resulted in greatly improved patient outcomes. Recipients of HSCT are at enhanced risk of infection because of prolonged periods of neutropenia. In addition, patients receiving allogeneic or matched unrelated donor transplants have added immune system insults imposed by prolonged immunosuppressive drug therapy for the prevention and treatment of graft-versus-host disease (GVHD). Intensive pretransplant conditioning regimens (high-dose chemotherapy and total-body irradiation), as well as GVHD itself, often disrupt protective barriers, such as mucous membranes, skin, and the GI tract, placing patients at further risk of infection. Patients experiencing marrow graft failure have extended periods of profound neutropenia often resulting in death from infectious causes. The Food and Drug Administration (FDA) approved sargramostim for marrow graft failure in both autologous and allogeneic transplants.

ETIOLOGY AND CLINICAL PRESENTATION OF INFECTIONS

2 10 The timing with which specific types of infections typically occur following HSCT is represented in Fig. 120–2. Although the figure illustrates the general time course for infections

in all types of HSCT, the relative incidence and importance of specific pathogens vary greatly according to the specific type of HSCT performed. Patients receiving allogeneic transplants are at greatest risk of infection at all times after HSCT and are predisposed to earlier and more severe infections with opportunistic pathogens such as *Aspergillus*. The presence of GVHD also has an impact on the incidence and timing of various infections.

After the administration of intensive conditioning regimens to eliminate malignant cells and prevent rejection of donor marrow, patients may remain profoundly neutropenic for 3 to 4 weeks. During this preengraftment period, they are at risk for the same types of infectious complications noted in other granulocytopenic cancer patients (e.g., bacterial and fungal infections) and should be managed accordingly (see Table 120–1). Table 120–4 lists regimens for the treatment of specific infections.

Fungal infections, especially those caused by *Candida* and *Aspergillus* spp., are serious and often fatal complications associated with HSCT. Fungi remain a serious cause of infection, particularly in allogeneic HSCT recipients, for up to 1 to 2 years following transplantation and may occur in as many as 10% of patients.⁷² Mortality rates associated with invasive aspergillosis infections may be as high as 90%.⁷³

In addition to bacterial and fungal infections, HSCT recipients also are at risk for serious HSV infections manifesting as severe gingivostomatitis, esophagitis, genital lesions, and rarely, pneumonia during the first month after transplant. Clinical disease is more common in patients with serologic evidence (e.g., serum antibodies)

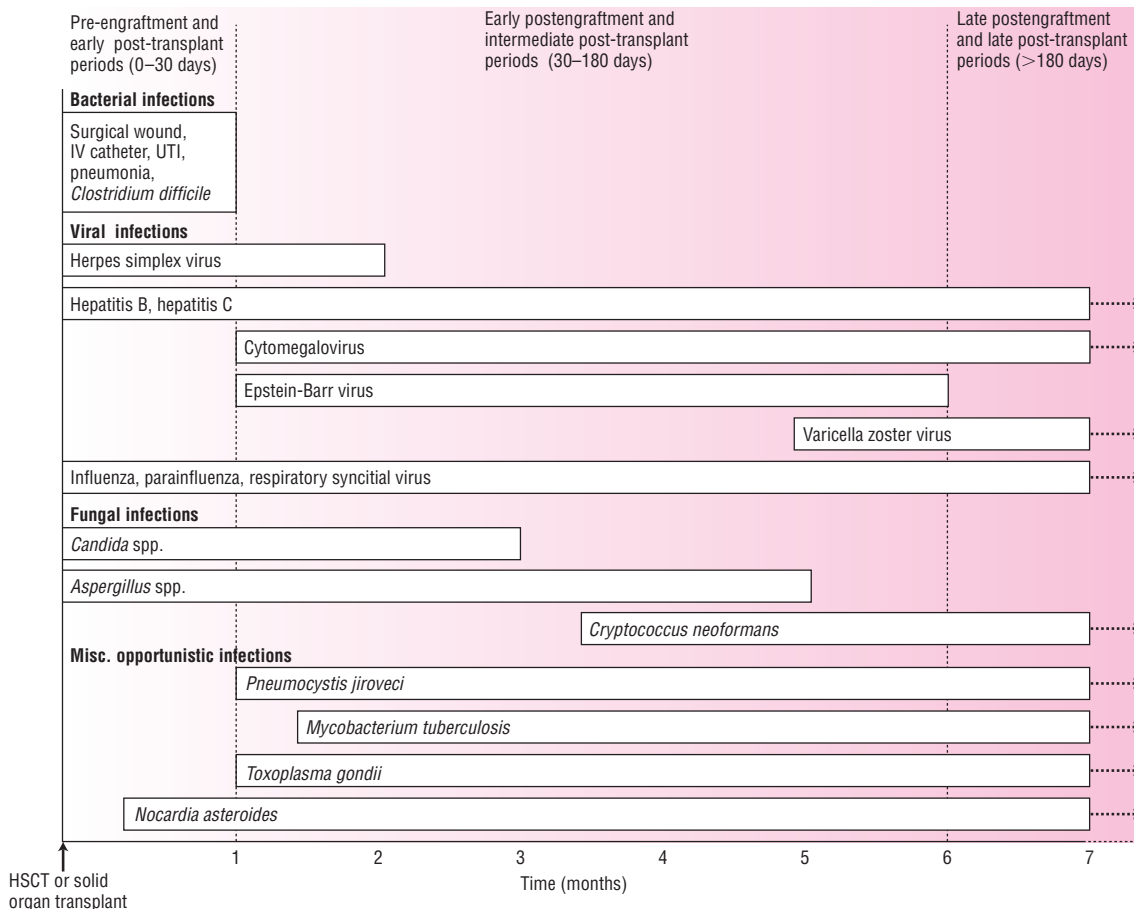

FIGURE 120–2. Timetable for the occurrence of infections in HSCT and solid organ-transplant patients. IV = intravenous; UTI = urinary tract infection.

of prior exposure and latent HSV infection pretransplant. Therefore, reactivation of latent disease during periods of immunosuppression is the most common etiology of HSV infection. Without prophylaxis, as many as 80% of HSV-seropositive patients experience mucocutaneous disease after intensive chemotherapy as compared with fewer than 25% of seronegative patients.^{72,74} The HSV infections often coexist with candidal infection and mucositis secondary to chemotherapy, radiation, or both.⁷⁵ Acyclovir-resistant HSV infections also occur following HSCT but are not common.^{72,76} Painful swallowing associated with these conditions often makes it difficult for patients to take oral medications and maintain adequate nutritional intake. Because of the considerable morbidity associated with reactivation of HSV after transplantation, the HSV serologic status of patients should be determined prior to transplant.

Recipients of HSCT remain at high risk for infection after bone marrow engraftment has occurred. Significant defects in neutrophil function and cell-mediated and humoral immunity, persisting for several months after transplantation, predispose patients to infectious complications. Acute and chronic GVHD also result in prolonged periods of immunosuppression and increased infection rates.

Bone marrow transplant patients are at high risk for cytomegalovirus (CMV) infections during the early postengraftment period. These range in severity from asymptomatic viral shedding (urine, throat, lungs) to life-threatening disseminated disease and interstitial pneumonia.^{72,75}

As with HSV, patients seropositive for CMV before transplantation are at high risk for recurrent disease during periods of immunosuppression; about 70% of seropositive patients develop recurrent CMV disease after transplantation compared with only 3% of seronegative patients.^{72,74,75} Other risk factors for CMV disease in HSCT patients include advanced age, human lymphocyte antigen (HLA) mismatch, total-body irradiation, multiagent conditioning regimens, and the presence of GVHD.⁷² Patients without evidence of latent CMV infection (CMV seronegative) before transplantation may

develop primary CMV disease after receiving bone marrow or blood products from CMV-seropositive donors. Although the typical onset of both primary and recurrent CMV infection is 1 to 2 months after transplantation, late-onset infections occurring more than 100 days after transplantation are increasing in frequency.^{72,74,75,77} Patients receiving allogeneic transplants are at highest risk for CMV disease.^{72,74,75}

The most serious clinical manifestation of CMV disease and the leading cause of infectious death in HSCT recipients is interstitial pneumonia (IP), which is associated with an 85% mortality rate if untreated.^{72,74} This clinical syndrome manifests as fever, dyspnea, hypoxia, nonproductive cough, and diffuse pulmonary infiltrates. As many as 40% of allogeneic HSCT patients will develop IP; of these patients with IP, up to 40% of cases are the result of CMV.^{72,74} IP also may result from other infectious (*P. jiroveci*, varicella-zoster virus) and noninfectious causes (pulmonary damage by radiation and chemotherapy).⁷²

During the late postengraftment period (beginning about 100 days after transplantation), infections remain a major problem in patients suffering from chronic GVHD. Additional immunosuppressive therapy for the treatment of GVHD places these patients at added risk for infection. Infections common during the late postengraftment period include those caused by encapsulated bacteria, such as *S. pneumoniae* and *H. influenzae*, and viruses, including CMV and VZV.^{72,74} Patients not undergoing allogeneic transplantation or suffering from chronic GVHD generally have few infections in this period.

Up to 50% of all patients surviving up to 10 months after transplantation develop an infection caused by VZV.⁷² Infection with VZV is most common in patients receiving allogeneic transplants with acute or chronic GVHD.^{72,74,75} Both primary (varicella) or recurrent disease (herpes zoster) usually present as skin lesions, most of which remain contained to local areas; however, 30% to 45% of these infections may disseminate to other cutaneous areas or body organs, causing mortality as high as 50%.^{72,74,75}

► PROPHYLAXIS AND MANAGEMENT: Infections in Recipients of HSCT

8 **9** The goals of antimicrobial drug use in HSCT patients include (1) prevention of bacterial, fungal, viral, and protozoal infections during preengraftment and postengraftment periods and (2) effective treatment of established infections. The overall goal of prophylaxis and treatment of infection in HSCT patients is the prevention of infectious morbidity and mortality. These goals must be achieved at the lowest possible toxicity and cost. Prophylactic therapy should be specifically aimed at pathogens known to cause a high incidence of infection within the HSCT population, the specific institution, or both. In addition, prophylactic therapy should be limited to regimens proved to be effective through well-designed clinical trials.

Appropriate immunizations should be a primary consideration in the prevention of infections in HSCT recipients. Immunizations against common bacterial and viral pathogens are timed to avoid periods of severe immunosuppression following HSCT when the protective response to vaccination potentially would be decreased.⁷⁸ Current recommendations for immunization of HSCT patients include three doses each of diphtheria-pertussis-tetanus or diphtheria-tetanus, inactivated polio, conjugated *H. influenzae* type b, and hepatitis B vaccines at 12, 14, and 24 months after transplantation. The 23-valent pneumococcal vaccine should be administered at 12 and 24 months after HSCT, and the influenza vaccine should be administered prior to HSCT, resumed at least 6 months after transplantation, and con-

tinued for life. Family, close contacts, and health care providers of HSCT patients also should be vaccinated annually against influenza. Finally, the measles-mumps-rubella vaccine should be administered no sooner than 24 months after HSCT when the patient is considered to be immunocompetent. The varicella vaccine is contraindicated for administration to HSCT patients owing to the live-attenuated nature of the product and the risk of VZV infection.⁷⁸

■ BACTERIAL INFECTIONS

Prophylaxis of infections in HSCT patients is in many ways similar to that used in other neutropenic patients. Selective decontamination with oral antimicrobials is used commonly; considerations are the same as those discussed previously. Although some studies have shown decreased rates of bacteremia and other bacterial infections after HSCT, overall mortality rates were not reduced.^{72,78} The routine use of prophylactic antibiotics in HSCT therefore is still controversial. Fluoroquinolones have become the most frequently used agents, often combined with another agent (e.g., macrolides or rifampin) for enhanced gram-positive activity.^{72,74} These regimens usually are begun

either within 72 hours of beginning the chemotherapy conditioning regimens or on the day of hematopoietic stem cell infusion and continued throughout the neutropenic period. Patients who become febrile while receiving prophylaxis should be managed according to general guidelines for febrile neutropenic patients.

The routine use of parenteral vancomycin for prophylactic therapy is not recommended. Prophylaxis with vancomycin has been studied because of the high incidence of gram-positive infections following transplantation. Vancomycin prophylaxis appears to decrease the overall incidence of gram-positive bacterial infections, number of days of empirical antimicrobial therapy, and cost of therapy.^{72,78} However, important mortality benefits were not demonstrated consistently, and there are significant concerns regarding the selection of vancomycin-intermediate *S. aureus* and vancomycin-resistant enterococci. Prophylactic vancomycin use thus is not generally recommended except in institutions with high rates of infection with methicillin-resistant staphylococci among HSCT recipients.^{74,78} There is currently no role for linezolid or quinupristin-dalfopristin except in documented infections caused by VRE.

Antibiotic prophylaxis against bacterial infection is recommended in the late postengraftment period (>100 days after transplantation) in certain high-risk patients, specifically allogeneic transplant recipients with chronic GVHD.⁷⁸ Antibiotics should be targeted against encapsulated bacteria such as *S. pneumoniae* and *H. influenzae* and should be selected based on local susceptibility patterns for these organisms. Patients receiving trimethoprim-sulfamethoxazole for prophylaxis of other opportunistic infections may be protected adequately and do not necessarily require an additional antibiotic.⁷² Prophylaxis should be continued as long as the chronic GVHD is being actively treated.

■ VIRAL INFECTIONS

Prophylaxis of recurrent HSV infection is recommended for all HSV-seropositive patients undergoing HSCT.^{72,78} Approximately 0% to 10% of HSV-seropositive patients receiving acyclovir experienced viral shedding, clinical symptoms of viral reactivation, or both as compared with 60% to 80% of patients receiving placebo.⁷⁴ Acyclovir doses recommended for prophylaxis are 250 mg/m² (5 mg/kg) IV every 12 hours or 200 mg orally three times daily.^{72,78} Intravenous therapy eventually will be necessary in most patients because of the development of severe mucositis from conditioning regimens. Oral acyclovir, however, is effective and considerably less expensive in patients who can take oral medications. Valacyclovir also has been used in doses of 500–1000 mg/day, but clinical experience is limited, and it is not currently recommended as first-line prophylaxis therapy.⁷⁸ Although the duration of antiviral prophylaxis differs between centers, acyclovir usually is begun at the time of the conditioning regimen and continued until bone marrow engraftment or until resolution of mucositis (approximately 30 days after HSCT).⁷⁸ Besides preventing recurrence of HSV disease, acyclovir prophylaxis also may reduce the incidence of CMV reactivation.⁷⁹ Patients developing active HSV or VZV infection should be treated with high-dose acyclovir (10 mg/kg IV every 8 hours).

Although high-dose oral acyclovir given for 6 months after transplantation also significantly reduces reactivation of VZV infections, routine use of long-term acyclovir is controversial and not generally recommended for this indication.^{72,78} Patients who received HSCT within the previous 24 months or those beyond 24 months after HSCT who have chronic GVHD or are on immunosuppressive

therapy should receive varicella-zoster immunoglobulin 625 units intramuscularly within 48 to 96 hours after close contact with persons with chickenpox or shingles for prevention of VZV-related disease.⁷⁸

Acyclovir-resistant HSV has been reported occasionally in HSCT patients receiving acyclovir prophylaxis. Foscarnet is the drug of choice for treatment of acyclovir-resistant HSV. Foscarnet, however, has not been well studied for HSV prophylaxis.^{72,74,78}

Prevention of CMV disease has been studied extensively in HSCT patients and is a well-accepted indication for prophylaxis because of the high associated infectious morbidity and mortality. If possible, CMV-seronegative patients should receive donor marrow and supportive blood products from seronegative donors only; however, CMV-seropositive patients are not at additional risk by receiving blood or marrow from seropositive donors.⁷² Although acyclovir has relatively poor in vitro activity against CMV, a decrease in CMV infection and an improvement in overall survival were reported in HSV- and CMV-seropositive allogeneic HSCT recipients receiving IV acyclovir.⁷⁹

CLINICAL CONTROVERSY

Although acyclovir is used commonly in many transplant centers for prophylaxis of CMV infection, this practice is somewhat controversial and is not universally recommended because of the intrinsically poor activity of acyclovir against CMV.⁷²

Ganciclovir also has been well studied for prophylaxis because of its superior activity against CMV compared with acyclovir. Although administration of prophylactic ganciclovir to CMV-seropositive patients may decrease the occurrence of CMV disease significantly, studies found no clear survival benefit, and ganciclovir-related bone marrow suppression frequently was problematic. Ganciclovir prophylaxis therefore is only recommended routinely among allogeneic HSCT recipients for the first 100 days after transplantation.^{72,78} The recommended dose of ganciclovir in these patients is 5 mg/kg IV every 12 hours for the first 5 to 7 days, followed by 5–6 mg/kg IV once daily five times per week until day 100 after HSCT.⁷⁸

Perhaps a more appropriate role for ganciclovir is in early or preemptive therapy, in which ganciclovir is administered at first isolation of CMV from the blood or bronchoalveolar lavage (BAL) fluid. Detection of CMV may be accomplished through the use either of a monoclonal antibody–based test for viral antigens or by detection of viral DNA through polymerase chain reaction (PCR)–based tests. Preemptive therapy was evaluated in several studies and significantly reduced the occurrence of CMV disease (including CMV pneumonia), and it improved survival significantly up to 180 days after transplantation.⁷² Because CMV viremia and BAL cultures are highly predictive of subsequent CMV disease, preemptive ganciclovir therapy should be considered for autologous HSCT recipients within the first 100 days after transplantation or in allogeneic HSCT recipients at any time point after transplantation.^{72,78} The dose of ganciclovir for preemptive therapy is the same as that used for prophylaxis. Foscarnet may be used for either prophylaxis or preemptive therapy of CMV disease in patients intolerant of ganciclovir; the recommended foscarnet dose is 60 mg/kg IV every 12 hours for 7 days, followed by 90–120 mg/kg IV daily.⁸⁰ Oral valganciclovir 900 mg every 12 hours has not been well studied in the setting of HSCT and is not recommended routinely. CSFs are beneficial in this setting, providing benefits similar to those noted in neutropenic AIDS patients receiving ganciclovir therapy for CMV retinitis.

Pharmacologic prevention of CMV disease with either intravenous immunoglobulin (IVIG) or hyperimmune CMV-IVIG produced variable and inconclusive results.^{74,81} The benefits of immunoglobulins for CMV prophylaxis in HSCT patients have not been demonstrated conclusively, and their use is not currently recommended.⁷²

Ganciclovir is the drug of choice in the treatment of active CMV infection in HSCT patients (see Table 120–4). Foscarnet is effective in the treatment of severe CMV disease in AIDS patients and also may be of benefit for the treatment or prevention of infections in HSCT patients. Foscarnet may be used as an alternative to ganciclovir because of its relative lack of bone marrow toxicity. Foscarnet-related nephrotoxicity may be problematic, however, especially in the post-transplant period when patients may be receiving other nephrotoxic agents. Use of cidofovir also is limited by the risk of nephrotoxicity, and this agent has not been well studied in HSCT patients.

Numerous single-agent treatments, such as vidarabine, interferon, and ganciclovir, have been employed unsuccessfully as treatment for CMV pneumonitis. The combination of high-dose IVIG and ganciclovir, however, may decrease the mortality of this syndrome from 85% to only 30% to 50%.⁷² Ganciclovir plus hyperimmune CMV-IVIG is also considered to be effective for the treatment of CMV disease, although this regimen has not been studied as extensively in the HSCT population in a controlled fashion. The potential for ganciclovir-associated bone marrow suppression prior to marrow engraftment and in patients who are just recovering from granulocytopenia remains a concern, especially in patients with unstable renal function. Ganciclovir plus CMV-IVIG is employed widely as the treatment regimen of choice for severe or life-threatening CMV disease. Ganciclovir plus IVIG also is used frequently, although CMV-IVIG is replacing IVIG in most institutions.^{74,81}

FUNGAL INFECTIONS

Fluconazole prophylaxis is safe and efficacious for prevention of mucocutaneous and disseminated candidal infections in high-risk HSCT patients.^{22,72,78,82} Patients specifically recommended for prophylaxis include all allogeneic transplant recipients and autologous recipients who are expected to have prolonged neutropenia, have received intensive conditioning regimens associated with extensive mucositis, or have recently received fludarabine.^{72,78} Fluconazole 400 mg IV or orally given once daily is begun on the day of transplantation and continued until engraftment or resolution of neutropenia.^{22,72,78} The variable activity of fluconazole against non-*albicans* species of *Candida* may be problematic in this population, as is lack of activity against

Aspergillus.⁸² Prophylaxis with fluconazole (as well as itraconazole), although effectively reducing colonization and infection with yeasts, has not been demonstrated consistently to reduce overall mortality or invasive infections such as aspergillosis in HSCT recipients.^{72,82,83} Low-dose amphotericin B (0.10–0.25 mg/kg per day) is used occasionally in institutions with high rates of *Aspergillus* infection after HSCT. Low-dose liposomal amphotericin B (1 mg/kg per day) also has been studied.^{82,84} As with the azoles, amphotericin B prophylaxis has not been demonstrated clearly to provide benefits in either overall or infection-related mortality following HSCT.^{13,22,74,83} Despite the controversies regarding absolute benefits of prophylaxis, fluconazole generally is recommended for most patients undergoing HSCT.^{74,78,83} Low-dose amphotericin B prophylaxis should be reserved for institutions with high rates of infection owing to azole-resistant yeasts (e.g., *C. krusei*) or high rates of invasive disease such as aspergillosis.⁷⁴ Fluconazole and other azole antifungals may cause significant elevations in serum cyclosporine concentrations and predispose to cyclosporine toxicities; this interaction should be monitored closely in HSCT patients receiving these agents concurrently.²²

PROTOZOAL INFECTIONS

Pulmonary infection with *P. jiroveci* is a relatively infrequent complication of HSCT. Mortality rates in this population, however, are approximately 60% and are especially high in patients with GVHD.^{72,74,78} Prophylactic use of trimethoprim-sulfamethoxazole (one double-strength tablet three times per week or one single-strength tablet daily) is employed commonly in this setting. Toxoplasmosis is not a common infection in HSCT patients but is associated with mortality rates of approximately 70%.⁸⁵ Toxoplasmosis also should be prevented by trimethoprim-sulfamethoxazole prophylaxis.^{72,78}

USE OF COLONY-STIMULATING FACTORS

Several studies have evaluated the use of filgrastim and sargramostim in HSCT patients in an effort to speed bone marrow recovery, to reduce the period of neutropenia, and to decrease infectious complications. Although the time to neutrophil recovery was consistently decreased, these studies failed to show significant differences in infection rates, transplant-related mortality, or overall survival. The use of CSFs appears to be safe, but their use in HSCT patients has not been formally recommended because of lack of clear benefits.⁵⁷

EVALUATION OF THERAPEUTIC OUTCOMES

Close monitoring of HSCT patients, including both clinical and laboratory data, is essential for early detection and treatment of infectious complications. In addition, because many of the drugs that may be used commonly in this setting have significant toxicity potential in HSCT patients (e.g., ganciclovir, amphotericin B, and trimethoprim-sulfamethoxazole), careful attention must be paid to the prevention and management of drug-related adverse effects. Monitoring parameters related to specific types of infections (e.g., pneumonia and urinary tract infections) should be applied as appropriate. The reader is referred to other chapters within this book for more specific information.

INFECTIONS IN SOLID-ORGAN TRANSPLANT RECIPIENTS

Since the introduction of cyclosporine in 1980, solid-organ transplantation has become an established mode of treatment for end-stage diseases of the kidney, liver, heart, lungs, and pancreas; small bowel transplantation is also now becoming more common. Both patient and allograft survival rates greatly exceed those of the past. Reasons for improved survival include continuous improvements in immunosuppressive drug therapy, candidate selection, and transplant surgery techniques and more experience in the management of complications (including infection) in these patients. Major hindrances to successful

transplantation and extended long-term survival include problems with allograft dysfunction and rejection and infectious complications. Despite advances in diagnostic techniques and antimicrobial therapy, infection remains an important cause of morbidity and mortality.

RISK FACTORS

1 Many of the risk factors for infection discussed at the beginning of this chapter are present in solid-organ transplant patients (see Table 120–1). The most important risk factor in this population is the immunosuppressive drug therapy that patients receive for prevention and treatment of allograft rejection. Risk of infection depends on specific immunosuppressive drug regimens as well as on the intensity (dose) and duration of immunosuppression. Most opportunistic infections in transplant patients occur during the first 6 months after transplantation when the intensity and total cumulative doses of immunosuppressive therapy are very high.^{84,86}

Current immunosuppressive regimens may have an impact on the pattern of infections after transplantation. Tacrolimus may be associated with lower rates of serious bacterial and viral infections than are seen with cyclosporine-based immunosuppressive regimens,⁸⁷ possibly because of a steroid-sparing effect of tacrolimus that enables patients to be maintained on greatly reduced doses of corticosteroids. Mycophenolate has been associated with higher rates of CMV disease and VZV infections compared with older azathioprine-based immunosuppressive regimens but conversely may have protective effects against *P. jiroveci* in patients undergoing renal transplantation.⁸⁶ Compared with mycophenolate-based regimens, sirolimus has been associated with significantly higher rates of surgical wound infections in renal transplant patients.⁸⁶ When evaluating published literature on infection patterns after solid-organ transplantation, one always must consider the organ being transplanted and the nature of the immunosuppressive drug regimens in use at reporting centers.

Immunosuppressive drugs, often in escalated doses, also are used to treat episodes of graft rejection. Drugs used to treat rejection include immunoglobulins directed against T cells (e.g., antithymocyte globulin [ATG]), murine monoclonal antibodies (muronomab), antibodies against interleukin 2 receptors (daclizumab and basiliximab), and high-dose IV or oral corticosteroids. Rejection episodes often occur during the posttransplant period when the overall cumulative dose or net state of immunosuppression is highest (2 to 4 months).⁸⁴ Therefore, patients already at risk for infection are placed at even higher risk if additional immunosuppressive therapy is needed to treat one or more episodes of graft rejection. Immunosuppressive drug therapy must be evaluated carefully when infections occur because, in many cases, immunosuppression may have to be reduced in order for the patient to survive the infectious episode; this is done at the expense of increased risk of graft rejection. Risk of increased infectious complications from immunosuppressive therapy used to treat rejection episodes is also determined, at least in part, by the specific therapy employed.^{84,86}

ETIOLOGY

2 As with cancer patients, microorganisms infecting solid-organ transplant patients are present before transplantation or are acquired from exogenous sources. All transplant recipients are at risk for mucocutaneous candidiasis from species colonizing body sites. Invasive fungal infection is less common following kidney and pancreas transplantation (5% to 15%) but also may occur in 30% to 60% of heart, lung, liver, and small bowel transplant recipients; rates are high-

est following liver and small bowel transplantation and are associated with mortality rates of up to 60% to 70%.^{73,84,88,89} Approximately 50% to 90% of all systemic fungal infections in transplant recipients are caused by *Candida* spp.^{73,84,88,89} Abdominal surgery, especially the demanding operations required for liver and small bowel transplantation, predispose patients to serious fungal disease most likely as a consequence of entering an area highly colonized with *Candida* spp.⁸⁸ Lung and heart transplant recipients are particularly at risk for invasive aspergillosis; these infections may occur in up to 10% of patients.⁸⁸ Liver and lung transplant recipients are also at particularly high risk for serious gram-negative bacterial infections as a result of the technically difficult surgical procedures.⁸⁴

Organisms present as latent tissue infections may reactivate and cause clinical disease after transplantation after the administration of immunosuppressive drug therapy. Disease resulting from infection reactivation has been noted with viral (HSV I and II, CMV, VZV, Epstein-Barr virus [EBV]), protozoal (*Toxoplasma gondii*, *P. jiroveci*), and mycobacterial (*Mycobacterium tuberculosis*) pathogens. Serologic or immunologic tests are performed prior to transplantation to assess the risk for infection because of reactivation and identify other subclinical infections (hepatitis B, *Legionella*). Many patients with reactivated disease have no clinical symptoms; often the only evidence of active infection is a rise in antibody titer from the pretransplant baseline, a positive culture, or histologic evidence. Reactivation of latent infection also may result in severe, life-threatening disease in immunosuppressed hosts.

Exogenous sources of infection in transplant patients include environmental contamination and transmission of microorganisms via transplanted organs and blood products. Environmental sources of infection are similar to those noted in other immunocompromised hosts, such as cancer patients. Airborne pathogens, especially fungi, such as *Aspergillus* and *C. neoformans*, may cause infections in transplant patients; this is thought to be a direct cause of increased *Aspergillus* infections among lung transplant patients.^{84,88} Transplant patients are also at risk for common nosocomial infections and infections occurring as hospital outbreaks (*P. aeruginosa* and *Legionella*). Optimal prevention and management of nosocomial infections in transplant patients require knowledge of the current epidemiology of infections and susceptibility patterns in the institution.

Infections transmitted via donor organs or blood products are major causes of morbidity and mortality in transplant patients and may include HSV, *T. gondii*, and hepatitis B and C. The most important infections transmitted from the donor, however, are caused by CMV. These infections may cause serious disease (e.g., pneumonia, hepatitis, hematologic disorders, and chorioretinitis), as well as predisposing patients to other opportunistic infections and contributing to allograft dysfunction.⁸⁴ In contrast to reactivation disease, transplant patients contracting primary CMV disease are at increased risk for serious, life-threatening infections.^{84,90,91} The most important source of primary CMV infection in transplant patients is the donor organ. Efforts are made to avoid transplanting organs from CMV-seropositive donors into CMV-seronegative recipients because of the potentially severe consequences. With the relative scarcity of suitable organs and the rapidity with which transplant decisions often must be made, however, this is not always possible. The consequences of transplanting an organ from a CMV-seropositive donor into an already CMV-seropositive recipient are less clear. Evidence exists that CMV reinfection (as well as reactivation) syndromes may occur in these patients.^{84,86} Organs from donors seropositive for *T. gondii* or HSV generally are not withheld from seronegative patients. Organs from known HIV-infected donors, however, are not used for transplantation. Asymptomatic

HIV-seropositive individuals with a CD4+ lymphocyte count of greater than 400 cells/mm³ may be considered for liver, heart, or lung transplantation without prohibitively high risk of acceleration of HIV disease.^{91,92} However, this practice is not widespread because of the shortage of donor organs. The impact of protease inhibitors and highly active antiretroviral therapy (HAART) on long-term outcome of HIV-infected patients following transplantation is not known precisely but is felt to have improved the overall feasibility of transplanting these individuals.⁹²

In addition to transmission from donor organs, primary CMV disease also may be transmitted from seropositive blood products, although this is a much less common mode of transmission. Risk of such transmission increases with the administration of large numbers of blood products.

Table 120–4 contains information on microbiology, clinical presentation, and treatment of infections in HSCT and solid-organ transplant recipients. Although opportunistic viral, fungal, and protozoal infections may occur commonly, bacterial infections remain the most frequent infectious complications after transplantation in all allograft recipients.

TIMING OF INFECTIONS AFTER TRANSPLANTATION

Although risk of infection with specific pathogens varies with the type of transplant, the time course of infections is similar in all transplant recipients. The overall risk of infection is greatest during the first 6 months after transplantation when the greatest number of risk factors are present. Both daily and cumulative doses of immunosuppressive drugs are at high levels, and additional agents may be necessary for the treatment of acute rejection episodes.^{84,86}

As with HSCT, the overall time course for infections can be divided into three general periods after transplantation (see Fig. 120–2). During the early posttransplant period (within the first month after transplantation), patients are at risk for infections already present and brought forward from the pretransplant period (e.g., hepatitis B); postoperative infections, such as surgical wound and catheter infections; infection resulting from colonized donor organs (pneumonia following lung transplant); and reactivation of HSV.^{84,86} In the intermediate posttransplant period (2 to 6 months after transplant), risk is highest for viral infections, including CMV, EBV, and hepatitis B and C. The combination of these “immunomodulating” viruses plus sustained immunosuppressive therapy leads to a high risk for opportunistic infections with pathogens such as *P. jiroveci*, *Aspergillus*, and *Nocardia asteroides*.^{84,86,88} In the late posttransplant period (>6 months after transplant), the patient is at risk for persistent infections (particularly viral) from earlier posttransplant periods, reactivation of VZV and *C. neoformans*, and routine infections affecting the general population.⁸⁴ In addition, patients who have required additional immunosuppression therapy for acute or chronic rejection are at continued high risk for opportunistic infections (*Aspergillus* and *P. jiroveci*).^{84,86,88} Although Fig. 120–2 illustrates infection patterns common to all solid-organ transplants, the relative incidence and importance of a particular pathogen will vary according to the type of transplant.

TYPES OF INFECTIONS AND CLINICAL PRESENTATION

◀ Transplant patients are at risk for infections occurring at a variety of sites, including skin, surgical wound, urinary tract,

lungs, blood, abdomen, and CNS; however, most infections occur at or near the site of the transplanted organ. For example, heart transplant and heart and lung transplant recipients most often are infected within the lungs or thoracic cavity. Urinary tract infections remain an important cause of morbidity in renal transplant patients, especially in the early posttransplant period. Administration of prophylactic antibiotics, such as trimethoprim-sulfamethoxazole, to these patients has, however, reduced the incidence and severity of urinary tract infections.^{84,86} Serious, life-threatening bacterial and fungal infections originating from the abdomen and GI tract are most common after liver transplantation and are related to variables such as length of surgery and surgical procedures performed. Risk of bacteremia, usually originating from the gut, is highest in liver transplant patients. Renal transplant recipients are at the lowest risk of infections and infectious deaths, whereas patients receiving heart, lung, and liver transplants are at the highest risk of infection-related morbidity and mortality.^{84,86,88}

CLINICAL PRESENTATION OF INFECTIONS IN SOLID-ORGAN TRANSPLANT PATIENTS

GENERAL

- Because transplant patients are at high risk for serious infections, frequent (at least daily), careful clinical assessments must be performed to search for possible evidence of infection.
- Clinical presentation of infection is variable and depends on the type and site of infection, type of transplant, time after transplantation, immune status of the host, and dose and duration of immunosuppressive therapy.
- Primary viral disease usually is more symptomatic and severe than disease caused by reactivation.
- Physical assessment should include examination of all common sites of infection, including mouth/pharynx, nose and sinuses, respiratory tract, GI tract, urinary tract, skin, soft tissues, perineum, and intravascular catheter insertion sites.

SYMPTOMS

- Usual signs and symptoms of infection may be absent or altered in patients receiving intensive immunosuppressive regimens owing to an inability to mount a typical inflammatory response (e.g., no infiltrate on chest x-ray, urinary tract infection without pyuria).
- Pain may be present at infection site(s).

SIGNS

- Fever is the single most important clinical sign indicating the presence of infection. Other causes of fever unrelated to infection in this patient population include reactions to blood products, drugs, embolic events, and ischemic injury.
- Usual signs of infection may be absent or altered.
- Signs of allograft dysfunction may be related to infection. Distinguishing fever as a result of allograft rejection versus infection often is very difficult and frequently requires allograft biopsy.

LABORATORY TESTS

- Blood cultures (two or more sets, including vascular access devices) for bacteria and fungi; cultures of other suspected or potential infection sites (urine, lungs, etc.).
- Other cultures should be obtained as clinically indicated according to the presence of signs or symptoms.
- Complete blood count and chemistries should be obtained frequently to monitor allograft function, plan supportive care, guide drug dosing, and assess patient's overall status.
- Surveillance cultures for CMV and HSV may be useful during first 3 months after transplantation for early detection of infection.

OTHER DIAGNOSTIC TESTS

- Chest x-ray
- Aspiration, biopsy of skin lesions
- Other diagnostic tests as indicated clinically on the basis of physical examination and other assessments

In contrast to febrile neutropenic patients, the threshold for initiating empirical antimicrobial therapy is higher in febrile transplant patients. As seen in Table 120–4, appropriate therapy for the large numbers of pathogens that may cause infections in transplant patients varies greatly from organism to organism. Therefore, careful attempts at definitive diagnosis of suspected infections must be made. If comprehensive work-up reveals no source of infection, careful observation of the febrile transplant patient (rather than empirical therapy) is a common practice. Surveillance cultures may be useful during the first 3 months for detecting CMV and HSV infections.^{84,88,90,91} Management and monitoring of documented infections, such as urinary tract infections, pneumonias, and intraabdominal infections, are similar to that in other types of patients.

PREVENTION OF INFECTION IN SOLID ORGAN TRANSPLANTATION

8 The goals of antimicrobial drug use in solid-organ transplant recipients include (1) prevention of infectious complications in the immediate postoperative period, (2) prevention of late infectious complications associated with prolonged periods of immunosuppression, and (3) effective treatment of established infections in order to prevent graft dysfunction and rejection and decrease patient morbidity and mortality. All these goals must be achieved at the lowest possible toxicity and cost.

Prevention of infection in the transplant patient can be accomplished in a number of ways. First, risk of environmental contamination should be minimized.⁹³ Patients should be protected from institutional infectious outbreaks. Transplant patients should receive the pneumococcal vaccine once and the influenza vaccine yearly; however, their immunologic responses to these vaccines may be blunted by immunosuppressive therapy.⁸⁴

Because the most important source of primary CMV disease is an infected donor organ, CMV-seronegative patients should not receive organs or blood products from seropositive donors if possible. A number of pharmacologic strategies also have been studied in an attempt to prevent CMV infection. Prophylactic ganciclovir (administered either as 5 mg/kg IV every 12 hours or as oral valganciclovir in doses ranging from 900 mg once daily to 1000 mg three times daily) is effective in reducing the incidence of both primary and re-

tivated CMV disease in solid-organ transplantation.^{80,84,86,90,91} Ganciclovir prophylaxis also may reduce reactivation of CMV disease significantly in seropositive patients receiving ALG or muronomb for treatment of acute rejection.^{86,91} High-dose oral acyclovir effectively reduces the incidence of CMV infection and disease following renal transplantation.⁹⁴ However, acyclovir is less efficacious in high-risk renal transplant patients (donor positive, recipient negative for CMV serum antibodies) and other nonrenal transplant types.^{84,86,91,95} Preemptive ganciclovir (initiated following actual isolation of CMV from blood, urine, BAL fluid, or other site) is more effective than acyclovir in the prevention of both primary and reactivation disease in liver transplant recipients. Preemptive ganciclovir effectively prevents CMV disease in other types of solid-organ transplants as well.^{90,91} Ganciclovir-related bone marrow suppression is not as problematic in solid-organ transplant recipients as in HSCT patients; most studies report the drug as being reasonably well tolerated.^{84,91,95}

Whether prophylaxis or preemptive therapy is the best approach to prevention of CMV disease is still controversial.^{84,90,91} Prophylaxis is effective and easy to administer without the need for careful discrimination among suitable patients. However, universal prophylaxis results in unnecessary exposure of low-risk individuals to adverse effects of drugs, and there are concerns that prolonged exposure may increase the risk of viral resistance to drugs.^{90,91,95} Preemptive therapy is effective and results in exposure of fewer patients to drugs. However, this strategy requires the availability and routine use of sensitive and specific diagnostic tests in order to identify high-risk individuals at an early stage of CMV infection. Although currently available PCR-based methods make this latter consideration less of an issue, PCR testing is not available at all centers. Prophylactic therapy should be used primarily in patients at highest risk of disease (i.e., seronegative patients receiving organs from seropositive donors), whereas other lower-risk patients should receive only preemptive therapy.^{84,90,91} These recommendations are not universally accepted or practiced, however.

A number of studies also have demonstrated the value of CMV hyperimmune globulin (CMV-IVIG) in decreasing the incidence and severity of CMV disease following kidney, heart, lung, and liver transplantation.^{84,90} Although prophylaxis with CMV-IVIG has been strongly recommended for CMV-seronegative transplant recipients receiving organs from seropositive donors, the benefits of CMV-IVIG relative to other therapies (e.g., prophylactic or preemptive ganciclovir) are not well known, and available studies are sometimes conflicting in their results. Whether or not the combination of CMV-IVIG plus ganciclovir offers advantages over the use of either agent alone, either for primary prophylaxis or for treatment of established CMV disease, is also unclear in solid-organ transplantation.^{84,90}

Although the use of prophylactic acyclovir in HSV-seropositive patients undergoing HSCT is well accepted, prophylaxis in solid-organ transplant recipients remains controversial. Reactivation disease caused by HSV occurs in approximately 25% of HSV-seropositive patients who are not receiving prophylaxis.⁸⁴ Oral or genital mucocutaneous disease is the most common presentation, but HSV pneumonitis also is seen occasionally and is associated with a mortality rate of approximately 75%.⁸⁴ Acyclovir is being used at some centers because of the high incidence of clinical HSV infection, including pneumonias, after transplantation.

Prophylactic antimicrobial agents are of benefit to transplant patients in certain clinical situations. Antibiotic prophylaxis, with agents such as cefazolin begun perioperatively and continued for less than 24 hours is considered to reduce wound infection rates effectively following renal transplantation.^{84,93} Although the benefits of

perioperative prophylaxis have not been well demonstrated in other types of transplantation procedures, surgical prophylaxis usually is considered mandatory in liver, heart, and lung transplant patients because of the high risk of perioperative bacterial infections.^{84,93} Pulmonary infections are particularly common in lung and heart-lung transplant recipients, and these infections often are caused by bacteria colonizing the airways prior to transplantation. Perioperative antibiotics for lung and heart-lung procedures therefore often are selected based on pretransplant sputum cultures.^{84,93} In addition, posttransplant antibiotic prophylaxis is effective in decreasing the number of bacterial infections in renal transplant patients. Prophylactic trimethoprim-sulfamethoxazole traditionally has been used because it is inexpensive and well tolerated; other antibiotics, such as the fluoroquinolones, have been evaluated.⁸⁴ Administration of oral low-dose trimethoprim-sulfamethoxazole (one double-strength tablet daily) for 6 to 12 months for prevention of *P. jiroveci* infection following heart and lung transplantation is common, although the efficacy and optimal duration are still somewhat controversial.^{84,96} Selective bowel decontamination with nonabsorbable antibiotics in combination with a low-bacterial diet (no fresh fruits and vegetables) effectively reduces oropharyngeal and GI colonization with gram-negative aerobes and *Candida* in liver transplant patients. However, selective bowel contamination is less efficacious when administered for a period of less than 1 week prior to transplantation.⁹³ Since liver transplantation usually is performed without advance notice as organs become emergently available, the practice of selective bowel decontamination remains controversial and is not recommended routinely.^{84,93}

Because immunosuppressed transplant recipients are at risk for mucocutaneous fungal infections, prophylactic oral or topical antifungal agents may be indicated in these patients. Liver transplant patients are clearly at high risk for invasive fungal infections and should receive prophylaxis with fluconazole (400 mg/day).^{22,84,88,97} It also has been suggested that lung and heart-lung transplant recipients receive high-dose fluconazole prophylaxis, although data for this recommendation are lacking.^{22,88} Cyclosporine concentrations should be monitored closely in transplant patients receiving fluconazole and otherazole antifungal agents.

Transplant patients, especially heart and heart-lung recipients, without serologic evidence of prior exposure to *T. gondii* who receive organs from seropositive donors are at high risk for toxoplasmosis.⁸⁴ Many of these patients will be receiving trimethoprim-sulfamethoxazole for prophylaxis of *P. jiroveci* infection; this agent also will provide effective prophylaxis against *T. gondii*, as well as against *N. asteroides*. Although prophylaxis is not given routinely at all centers, this therapy may be justified in high-risk patients because of the delays in diagnosis and serious infections associated with toxoplasmosis.⁸⁴

The use of prophylactic isoniazid therapy for transplant patients with evidence of exposure to *M. tuberculosis* (those with a positive purified protein derivative skin test) remains controversial. Risk of reactivation and development of clinical tuberculosis is enhanced with posttransplant immunosuppression. Some clinicians believe, however, that the risk of isoniazid-induced hepatotoxicity, especially in liver transplant recipients, in whom the rate of hepatotoxicity has been reported as high as 40%, outweighs the benefits of treatment. High-risk patients who may be considered for isoniazid prophylaxis include those with a positive skin test, those with previously diagnosed tuberculosis who may not have been treated adequately, patients in close contact with individuals with active pulmonary disease, and patients with abnormal chest radiographs consistent with old tuberculosis who have not received prior prophylaxis.⁸⁴

EVALUATION OF THERAPEUTIC OUTCOMES

Close monitoring of transplant recipients, including both clinical and laboratory data, is essential for early detection and treatment of potentially severe opportunistic infections.

ANTIMICROBIAL PROPHYLAXIS IN SURGERY

Salmaan Kanji and John W. Devlin

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Prophylactic antibiotic therapy differs from *presumptive* and *therapeutic* antibiotic therapy in that the latter two involve treatment regimens for documented or presumed infections, whereas the goal of prophylactic therapy is to prevent infections in high-risk patients or procedures.
- 2 The risk of a surgical site infection (SSI) is determined from both the type of surgery and patient-specific risk factors; however, most commonly used classification systems only account for procedure-related risk factors.
- 3 Timing of antimicrobial prophylaxis is of paramount importance. Antibiotics should be administered 1 hour before the surgery to ensure adequate drug levels at the surgical site prior to the initial incision.
- 4 Antimicrobial agents with short half-lives (e.g., cefazolin) may need to be redosed intraoperatively during long (>3 hours) procedures.
- 5 One must consider the type of surgery, intrinsic patient risk factors, the most commonly identified pathogenic organisms, institutional antimicrobial resistance patterns, and cost when choosing an antimicrobial agent for prophylaxis.
- 6 Single-dose prophylaxis is appropriate for many types of surgery. First-generation cephalosporins (e.g., cefazolin) are the mainstay for prophylaxis in most surgical procedures because of their spectrum of activity, safety, and cost.
- 7 Vancomycin as a prophylactic agent should be limited to cases in which there is a documented history of life-threatening β -lactam hypersensitivity or where the incidence of infections with organisms resistant to cefazolin (e.g., methicillin resistant *Staphylococcus aureus* [MRSA]) is high enough to justify use.

According to the National Center for Health Statistics, approximately 46 million surgical procedures are performed annually in the United States, the majority of which are done in an outpatient setting.¹ Infection is the most common complication of surgery.² Surgical-site infections (SSIs) occur in about 3% to 6% of patients and prolong hospitalization by an average of 7 days at a direct annual cost of \$5 to \$10 billion.^{3,4} SSIs are the third (14% to 16%) most frequent cause of nosocomial infections among hospitalized patients and the primary (40%) cause of nosocomial infection in surgical patients.³ The prophylactic administration of antibiotics decreases the risk of infection after many surgical procedures and represents an important component of care for this population.

Antibiotics administered prior to the contamination of previously sterile tissues or fluids are deemed *prophylactic* antibiotics. The goal of therapy is to *prevent* an infection from developing. While eradication of distal (preexisting, unrelated to surgery) infections lowers the risk for subsequent postoperative infections, it does not, per se, constitute a prophylactic regimen. In fact, surgical prophylaxis often is prescribed concurrently under these circumstances because of important antimicrobial spectrum- and timing-related concerns. Both SSIs and infections not directly related to the surgical site are termed *nosocomial* (e.g., urinary tract infections, pneumonia, etc.). Prevention of these hospital-acquired infections is a major goal of antibiotic prophylaxis.

1 *Presumptive* antibiotic therapy is administered when an infection is suspected but not yet proven. Clinical scenarios where presumptive therapy is employed commonly include acute cholecystitis, open compound fractures, and acute appendicitis of less than

24 hours' duration. In these situations, if signs of perforation or infection are absent during surgery, then routine prophylactic rather than presumptive therapy is warranted. An operative finding of a gangrenous gallbladder or a perforated appendix, however, is suggestive of an established infectious process, and thus a *therapeutic* antibiotic regimen would be required.³

According to the Center for Disease Control and Prevention's (CDC) National Nosocomial Infections Surveillance System (NNIS),³ SSIs can be categorized as either incisional (e.g., cellulitis of the incision site) or organ/space (e.g., meningitis) (Fig. 121–1). Incisional SSIs are further subcategorized into superficial (involving only the skin or subcutaneous tissue) and deep (fascial and muscle layers) infections. Organ/space SSIs can involve any anatomic area other than the incision site. For example, a patient who develops bacterial peritonitis after bowel surgery would have an organ/space SSI. By definition, SSIs must occur within 30 days of surgery. If a prosthetic implant is involved, however, a deep incisional or organ/space SSI still can be reported up to 1 year from the date of surgery. Although microbiologic testing of surgical drainage material or sites may help to guide care, the specificity of a negative culture is poor and generally does not rule out an SSI.³

SSI RISK FACTORS

2 SSI incidence depends on both procedure- and patient-related factors. Traditionally, the risk for SSIs has been stratified by surgical procedure in a classification system developed by the National

FIGURE 121–1. Cross section of abdominal wall depicting CDC classifications of SSIs. (From ref. 3).

Research Council (NRC)⁵ (Table 121–1). The NRC classification system proposes that the risk of an SSI depends on the microbiology of the surgical site, the presence of a preexisting infection, the likelihood of contaminating previously sterile tissue during surgery, and events during and after surgery.^{5,6} A patient’s NRC procedure classification is the primary determinant of whether antibiotic prophylaxis is warranted. It should be emphasized, however, that because a patient’s NRC wound classification is influenced by surgical findings (e.g., gangrenous gallbladder) and perioperative events (e.g., major technique breaks), that categorization generally occurs intraoperatively.⁷

INHERENT PATIENT RISK

The NRC classification system does not account for the influence of underlying patient risk factors for SSI development, instead categorizing the risks for SSIs simply based on a specific surgical procedure. Disease states and conditions known to increase SSI risk are presented in Table 121–2. Preexisting distal infections increase SSI rates and should be resolved prior to surgery whenever possible. Diabetic patients have an increased risk of SSIs, especially those with uncon-

TABLE 121–2. Patient and Operation Characteristics that May Influence the Risk of SSI

| Patient | Operation |
|--|--------------------------------------|
| Age | Duration of surgical scrub |
| Nutritional status | Preoperative skin preparation |
| Diabetes | Preoperative shaving |
| Smoking | Duration of operation |
| Obesity | Antimicrobial prophylaxis |
| Coexisting infections at distal body sites | Operating room ventilation |
| Colonization with resistant microorganisms | Sterilization of instruments |
| Altered immune response | Implantation of prosthetic materials |
| Length of preoperative stay | Surgical drains |
| | Surgical technique |

trolled perioperative blood sugars.⁸ Preoperative smoking has been identified as an independent risk factor for SSI because of the deleterious effects of nicotine on wound healing. Preoperative immunosuppression, including corticosteroid use, also may increase infection risk. Malnutrition is a well-described risk factor for postoperative complications, including SSI, impaired wound and colonic anastomosis healing, and prolonged hospital stay. While enteral feeding in the perioperative period can reduce bacterial translocation by maintaining the integrity of the intestinal mucosa, nutritional supplementation has not been shown to decrease the incidence of infection.⁹

CLINICAL CONTROVERSY

Several recent studies have investigated the role of specialized enteral formulas fortified with a variety of immunomodulating micronutrients thought to enhance the immune response and gut function after trauma or surgery. While many clinicians are exploring the role of supplements such as glutamine, arginine, omega-3 fatty acids, and nucleotides, no study to date has shown a significant reduction in postoperative infection rates using these formulations.

TABLE 121–1. NRC^a Wound Classification, Risk of SSI^b, and Indication for Antibiotics

| Classification | SWI Rate (%) | | Criteria | Antibiotics |
|--------------------|--------------------------|-----------------------------|--|---|
| | Preoperative Antibiotics | No Preoperative Antibiotics | | |
| Clean | 5.1 | 0.8 | No acute inflammation or transection of gastrointestinal, oropharyngeal, genitourinary, biliary, or respiratory tracts. Elective case, no technique break | Not indicated unless high-risk procedure ^c |
| Clean-contaminated | 10.1 | 1.3 | Controlled opening of aforementioned tracts with minimal spillage/minor technique break. Clean procedures performed emergently or with major technique breaks. | Prophylactic antibiotics indicated |
| Contaminated | 21.9 | 10.2 | Acute, nonpurulent inflammation present. Major spillage/technique break during clean-contaminated procedure | Prophylactic antibiotics indicated |
| Dirty | N/A | N/A | Obvious preexisting infection present (abscess, pus, or necrotic tissue present) | Therapeutic antibiotics required |

^aNRC = National Research Council.

^bSSI = surgical-site infection.

^cHigh-risk procedures include implantation of prosthetic materials and other procedures where surgical-site infection is associated with high morbidity (see text).

| 4 | N/A | N/A | 23.9 | 27.4 |

^aThe Study on the Efficacy of Nosocomial Infection Control (SENIC) risk factors include abdominal operation, operations lasting >2 hours, contaminated or dirty procedures by National Research Council (NRC) classification, and more than three underlying medical diagnoses.

Adapted from ref. 13.

Colonization of the nares with *Staphylococcus aureus* is a well-described SSI risk factor.³ Two small prospective trials suggest that eradication of nasal *S. aureus* with mupirocin significantly reduces the incidence of SSI when compared with historical controls in patients undergoing both cardiac and upper gastrointestinal surgery. Larger prospective trials, however, are needed before this therapy can be advocated routinely. Other factors shown to increase the risk of SSI include age, length of preoperative hospital stay, and obesity.³

IDENTIFYING SSI RISK

Two large epidemiologic studies have objectively quantified SSI risk based on specific patient- and procedure-related factors. The Study on the Efficacy of Nosocomial Infection Control (SENIC) analyzed more than 100,000 surgery cases to identify and validate risk factors for SSI.¹⁰ Abdominal operations, operations lasting longer than 2 hours, contaminated or “dirty” procedures (as per NRC classification), and more than three underlying medical diagnoses each were associated with an increased incidence of SSI. When NRC classification was stratified by number of SENIC risk factors present, SSI incidence varied by as much as a factor of 15 within the same NRC operative category¹¹ (Table 121–3).

The NNIS, in a subsequent analysis of more than 84,000 surgical cases, attempted to simplify and refine the SENIC system by quantifying intrinsic patient risk using the American Society of Anesthesiologists’ (ASA) preoperative assessment score^{12,13} (Table 121–4). An ASA score of 3 or greater was found to be a strong predictor for the development of an SSI. Other factors associated with increased SSI incidence include contaminated or “dirty” operations (NRC criteria) and surgical procedures lasting longer than average. Similar to the SENIC study, the SSI rate was linked to the number of risk factors present and varied considerably within NRC class.

Although evidence-based recommendations for antimicrobial prophylaxis during surgery are best established using the results of

TABLE 121–4. American Society of Anesthesiologists Physical Status Classification

| Class | Description |
|-------|---|
| 1 | Normal healthy patient |
| 2 | Mild systemic disease |
| 3 | Severe systemic disease that is not incapacitating |
| 4 | Incapacitating systemic disease that is a constant threat to life |
| 5 | Not expected to survive 24 hours with or without operation |

From ref. 15.

randomized clinical trials, many studies have small sample sizes and do not stratify patients according to overall SSI risk. Future studies, particularly those involving clean procedures, should be stratified by SSI risk so that the subset of high-risk patients who might benefit the most from prophylaxis is clearly established.

BACTERIOLOGY

The most important consideration when choosing antibiotic prophylaxis is the bacteriology of the surgical site. Organisms involved in an SSI are acquired one of two ways: endogenously (from the patient’s own normal flora) and exogenously (from contamination during the surgical procedure). Based on the type and anatomic location of the procedure and the NRC classification (see Table 121–1), resident flora can be predicted, and appropriate antibiotic choices can be made. According to NNIS data, *S. aureus*, coagulase-negative staphylococci, enterococci, *Escherichia coli*, and *Pseudomonas aeruginosa* are the pathogens most commonly isolated³ (Table 121–5). With the widespread use of broad-spectrum antibiotics, however, *Candida* spp. and methicillin-resistant *S. aureus* are becoming more prevalent.⁹

Factors affecting the ability of an organism to induce an SSI depend on organism count, organism virulence, and host immunocompetency. Organisms in the commensal flora generally are not pathogenic. These organisms often serve the host as a form of protection against invasive organisms that otherwise would colonize the surgical site. Opportunistic organisms usually are kept in check by normal flora and rarely are problematic unless they are found in large numbers. Loss of this normal flora through the use of broad-spectrum antibiotics can destabilize this homeostasis, thus allowing pathogenic bacteria to proliferate and infection to occur.¹⁴

If translocated to a normally sterile tissue site or fluid during a surgical procedure, normal flora can become pathogenic. For example, *S. aureus* or *S. epidermidis* may be translocated from the surface of the skin to deeper tissues or *E. coli* from the colon to the peritoneal cavity, bloodstream, or urinary tract. Studies in animals and healthy volunteers have shown bacterial virulence to be an important determinant in the development of secondary infections.^{15,16} Animal models of infection have demonstrated that while more than 1 million *S. aureus* per square centimeter or gram of tissue are required to produce infection, less than 100,000 *Streptococcus pyogenes* per square centimeter or gram of tissue would be required at the same site.^{16,17}

Impaired host defense reduces the number of bacteria required to establish an infection. A breach of normal host defenses through surgical intervention (e.g., insertion of a prosthetic device) may

TABLE 121–5. Major Pathogens in Surgical Wound Infections

| Pathogen | Percent of Infections ^a |
|----------------------------------|------------------------------------|
| <i>Staphylococcus aureus</i> | 20 |
| Coagulase-negative staphylococci | 14 |
| Enterococci | 12 |
| <i>Escherichia coli</i> | 8 |
| <i>Pseudomonas aeruginosa</i> | 8 |
| <i>Enterobacter</i> spp. | 7 |
| <i>Proteus mirabilis</i> | 3 |

| Other <i>Streptococcus</i> spp. | 3 |
| <i>Candida albicans</i> | 3 |
| Group D streptococci | 2 |
| Other gram-positive aerobes | 2 |
| <i>Bacteroides fragilis</i> | 2 |

^aData reported by the NNIS from 1990–1996, adapted from ref. 5.

enable organisms to cause infection. In addition, the loss of specific immune factors, such as complement activation, tissue-derived inhibitors (e.g., proinflammatory cytokines), cell-mediated response (e.g., T-cell function), and granulocytic or phagocytic function (e.g., neutrophils or macrophages) can greatly increase the risk for SSI development.¹⁸ Vascular occlusive states related to the surgical procedure or those occurring from hypovolemic shock can greatly affect blood flow to the surgical site, thus diminishing host defense mechanisms against microbial invasion. Traumatized tissue, hematomas, and the presence of foreign material also lead to more infections. When a foreign body is introduced during a surgical procedure, fewer than 100 bacterial colony-forming units (CFUs) are required to cause an SSI.¹⁹ Studies examining *S. aureus*-contaminated wound infections on the skin of healthy volunteers demonstrate a 10,000-fold reduction in the number of organisms required to establish a wound infection if sutures are not present.¹⁵

ANTIMICROBIAL RESISTANCE

Colonization of the host with antibiotic-resistant hospital flora prior to or during surgery may lead to an SSI that is unresponsive to routine antibiotic therapy. Epidemiologic studies demonstrate that the most common cause for nosocomially acquired multiresistant organisms is transmission from hospital personnel.²⁰ Patients treated with broad-spectrum antibiotic therapy also are at increased risk of colonization with hospital flora.

With cephalosporins established as first-line agents for prophylaxis over the past decade, organisms resistant to cephalosporins represent the majority of pathogens causing SSIs. The CDC has reported an alarming increase in the incidence of vancomycin-resistant enterococci (VRE) infections, particularly those with *E. faecium*.³ Risk factors for VRE colonization include severe concomitant diseases, immunosuppression, admission to the intensive care unit, previous intraabdominal or cardiothoracic surgery, placement of indwelling catheters, and prolonged courses of antimicrobials, particularly vancomycin.²¹ In an effort to control the spread of VRE, the CDC has published recommendations that include strict criteria for the use of vancomycin as surgical prophylaxis.²² The guidelines suggest vancomycin substitution for cefazolin as SSI prophylaxis only when there is a high suspicion of methicillin-resistant *S. aureus* or in patients who have a documented history of a life-threatening allergy to penicillins or cephalosporins. Other limitations to vancomycin use, besides the risk of inducing resistant organisms, include its narrow spectrum of activity, its poor penetration into some tissues, and the potential for infusion-related reactions. The emergence of *S. aureus* displaying intermediate resistance (minimum inhibitory concentration [MIC] ≥ 8 mcg/mL) further underscores the need to limit routine use of vancomycin for prophylaxis.²³

Although cefazolin remains a mainstay in cardiovascular SSI prophylaxis, its failure has been reported in cases involving methicillin-sensitive *S. aureus* (MSSA). In a comparison trial between cefamandole and cefazolin, significantly more failures were attributed to cefazolin, even though the primary pathogen was MSSA.²⁴ A similar trial comparing cefazolin and cefuroxime, however, did not show any difference in SSI incidence between the two regimens.²⁵ It has been proposed that the β -lactamase expressed by some MSSA is capable of hydrolyzing cefazolin more readily than cefuroxime or cefamandole. Although this trend is disturbing, the overall incidence of cefazolin failure remains low, and cefazolin remains the drug of choice for SSI prophylaxis in cardiovascular surgery.

The increase in frequency of fungal infections in surgical patients has drawn concern. In hospitalized patients, the incidence of nosocomial *Candida* infections has approximately doubled from 1991 to 1996.²⁶ Overzealous use of broad-spectrum antibiotics is the most likely cause for this increase. A study in patients undergoing cardiovascular surgery identified sex (female), length of stay in the intensive care unit, and duration of central venous catheterization as risk factors for postoperative *Candida* infections.²⁷ While presurgical *Candida* colonization is associated with a higher risk of fungal SSIs, the routine preoperative use of prophylactic antifungal agents is not being advocated at this time.^{26,28}

SCHEDULING ANTIBIOTIC ADMINISTRATION

3 4 The following principles must be considered when providing antimicrobial surgical prophylaxis: (1) The agents should be delivered to the surgical site prior to the initial incision, and (2) bactericidal antibiotic concentrations should be maintained at the surgical site throughout the surgical procedure. While animal and human models have demonstrated the efficacy of a single dose of an antibiotic administered just prior to bacterial contamination, long operations often require intraoperative doses of antibiotics to maintain adequate concentrations at the surgical site for the duration of the surgery.²⁹ Antibiotics should be administered with anesthesia just prior to the initial incision. Administration of antibiotics too early may result in concentrations below the MIC toward the end of the operation, and administration too late leaves the patient unprotected at the time of the initial incision. In a study examining the timing of antibiotics in 2847 patients receiving prophylaxis, Classen and colleagues²⁹ evaluated patients who received prophylaxis early (2 to 24 hours before surgery), preoperative prophylaxis (0 to 2 hours prior to surgery), perioperative prophylaxis (up to 3 hours after first incision), and postoperative prophylaxis (>3 hours after the first incision). The risk of infection was lowest (0.6%) for those patients who received preoperative prophylaxis, moderate (1.4%) for those who received perioperative antibiotics, and greatest for those who received postoperative antibiotics (3.3%) or preoperative antibiotics too early (3.8%). These results indicate that the risk for an SSI increases dramatically with each hour that elapses from the initial incision to the time when antibiotics are administered eventually. For these reasons, prophylactic antibiotics should not be prescribed to be given “on call to the OR,” which can occur 2 or more hours prior to the initial incision, nor should concurrent therapeutic antibiotics be relied on to provide adequate protection. In both situations, the chance for improperly timed doses is high.

Despite the importance of appropriately timed prophylactic antibiotic therapy, few patients receive antibiotics at the optimal time in relation to surgery. Potential barriers include antibiotics ordered after the patient has arrived in the operating room, delayed antibiotic preparation or delivery, and the use of antibiotics that require long infusion times. One study assessed the timing of prophylactic antibiotics in 100 patients and found that only 26% of patients received an antibiotic dose within 2 hours of the initial surgical incision.³⁰

Although most studies comparing single versus multiple doses of prophylactic antibiotics have failed to show a benefit of multi-dose regimens, the duration of operations in these studies may not be as long as that which is frequently observed in clinical practice. Proponents of administering a second antibiotic dose during lengthy operations suggest that the risk for SSI is just as great at the end of surgery, during wound closing, as it is during the initial incision.³¹ One study in patients undergoing clean-contaminated operations suggests

that procedures longer than 3 hours require a second intraoperative dose of cefazolin or the substitution of cefazolin with a longer-acting antimicrobial agent.³² A second study of patients undergoing elective colorectal surgery suggests that low serum antimicrobial concentrations at the time of surgical closure is the strongest predictor of postoperative SSI.³³ Studies in patients undergoing cardiac surgery also have demonstrated a higher infection rate among patients with undetectable antibiotic serum concentrations at the conclusion of the procedure.³⁴

One strategy to ensure appropriate redosing of prophylactic antibiotics during long operations is to employ a visual or auditory reminder system. One hospital has published its experience with such a system and found that an automated reminder improved compliance and reduced SSIs. However, even with the reminder system, intraoperative redosing was done in only 68% of eligible patients.³⁵ Another strategy currently being evaluated is the role of continuous infusions of cefazolin. One pilot study has found this a feasible way to ensure adequate serum concentrations of antibiotic during prolonged surgeries.³⁶ Further trials are required before such an intervention can be recommended.

Underlying disease states that may affect antibiotic metabolism and/or elimination should be considered when developing a prophylactic regimen. For example, patients with thermal burn and spinal cord injuries eliminate certain classes of antibiotics, primarily the aminoglycosides and β -lactams, at unusually high rates compared with controls.³⁷ Individuals undergoing cardiac bypass may have altered antibiotic disposition related to increased volume of distribution and reduced total-body clearance and thus require special dosing consideration.³⁸

ANTIMICROBIAL CHOICE

5 The choice of prophylactic antibiotic depends on the type of surgical procedure, the most frequent pathogens seen with this procedure, the safety and efficacy profile of the antimicrobial agent, the current literature evidence to support its use, and cost. Although most SSIs involve the patient's normal flora, antimicrobial selection also must take into account the susceptibility patterns of nosocomial pathogens within each institution. Typically, gram-positive coverage should be included in the choice of surgical prophylaxis because organisms such as *S. aureus* and *S. epidermidis* are encountered commonly as skin flora. The decision to broaden antibiotic prophylaxis to agents with gram-negative and anaerobic spectra of activity depends on both the surgical site (e.g., upper respiratory tract, gastrointestinal tract, genitourinary tract, etc.) and whether the operation will transect a hollow viscous or mucous membrane that may contain resident flora.³

Although antimicrobial prophylaxis may be administered through a variety of routes (e.g., oral, topical, intramuscular, etc.), the parenteral route is favored because of the reliability by which adequate tissue concentrations may be achieved.³⁹ Cephalosporins are the most commonly prescribed agents for surgical prophylaxis because of their broad antimicrobial spectrum, their favorable pharmacokinetic profile, their low incidence of adverse side effects, and low cost. First-generation cephalosporins, such as cefazolin, are the preferred choice for surgical prophylaxis, particularly for clean surgical procedures.^{3,7,14} In cases where broader gram-negative and anaerobic coverage is desired, antianaerobic cephalosporins, such as cefoxitin or cefotetan, are appropriate choices. Although third-generation cephalosporins (e.g., ceftriaxone) have been advocated for prophylaxis because of their increased gram-negative coverage and

prolonged half-lives, their inferior gram-positive and anaerobic activity, in addition to their high cost, has discouraged the widespread use of these agents.^{3,7,14}

Allergic reactions are the most common side effects associated with cephalosporin use. These can range from minor skin manifestations at the site of infusion to rash, pruritus, and on rare occasions anaphylaxis (<0.02%). The structural similarity between penicillins and cephalosporins (each containing a β -lactam ring) has led to considerable confusion about the cross-allergenicity between these two classes of drugs. Twenty percent of the general population is labeled "penicillin allergic," yet studies suggest that of these patients, only 10% to 20% will have positive results in a penicillin skin test.⁴⁰ The rate of cross-reactivity is approximately 2%, but since only 20% of all "penicillin allergic" patients are truly penicillin-allergic, the true incidence of cross-reactivity is likely less than 1%. Routine penicillin skin testing is not cost-effective.⁴⁰ In summary, the administration of cephalosporins is both safe and cost-effective for many patients who are labeled "penicillin allergic," and they may be used in patients who have not experienced an immediate or type I penicillin allergy.

Vancomycin may be considered for prophylactic therapy in surgical procedures involving implantation of a prosthetic device in which the rate of MRSA is high.²² If the risk of MRSA is low and a β -lactam hypersensitivity exists, clindamycin can be used for many procedures instead of cefazolin in order to limit vancomycin use. Infusion-related side effects, such as thrombophlebitis and hypotension, particularly with vancomycin, usually can be controlled by adequate dilution and slower administration rates.⁴¹

Pseudomembranous colitis secondary to cephalosporins is uncommon and generally easily treated with a short course of oral metronidazole. Although infrequent, bleeding abnormalities related to cephalosporin use have been reported.⁴² The primary hematologic effect appears to be an inhibition of vitamin K–dependent clotting factors that results in a prolongation of the prothrombin time. The mechanism for this effect, most commonly seen with cefotetan, is related to the methylthiotetrazole side chain of the β -lactam molecule. Patients at greatest risk for this hypoprothrombinemic effect have received a prolonged course of these agents and have underlying risk factors for vitamin K deficiency, such as malnutrition.⁴³

Since inappropriate prophylactic antibiotic use not only can induce antibiotic resistance but also can negatively affect an institution's antibiotic budget, initiatives to curtail inappropriate antibiotic use have become the focus of many drug use evaluation efforts. Potential sources of inappropriate antibiotic prophylaxis include the use of broad-spectrum antimicrobials when a narrow-spectrum agent is warranted, extending prophylaxis for durations beyond that recommended in published guidelines, and using expensive antibiotics when equivalent, cheaper agents are available. The most effective tools to ensure appropriate prophylactic antibiotic prescribing are knowledge of one's institutional postoperative infection rate for each type of surgical procedure and the bacterial epidemiology patterns for each surgical population. Individualized institutional guidelines that take into account best literature evidence, institution-based antibiotic susceptibility data, and surgeon preference are also important tools to rationalize antibiotic prophylaxis use.⁴⁴

RECOMMENDATIONS FOR SPECIFIC TYPES OF SURGERY

Guidelines for surgical prophylaxis usually are structured according to the affected tissues during an operation. While many different surgical procedures may be performed at any one anatomical site, this

method of categorization is still optimal because the factors related to the success of a prophylactic regimen such as the endogenous flora that is expected and the pharmacokinetics, pharmacodynamics, and spectrum of selected antimicrobials generally are constant for a particular surgical site (see section on antimicrobial choice). The choice of antimicrobial prophylaxis is always best evaluated using the results of properly conducted clinical trials. In the absence of studies specific to the procedure in question, extrapolation from data on regimens for different procedures in the same anatomic site in question usually can be made. Subsequent modifications to each prophylactic regimen should be based on intraoperative findings or events.

6 While a comprehensive review of the surgical prophylaxis literature is beyond the scope of this chapter, there are important factors that should be reviewed for each type/site of surgery. Specific recommendations are summarized in Table 121–6. The reader is also referred to recently published guidelines and review articles.^{3,7,14,39,45}

GASTROINTESTINAL SURGERY

Gastrointestinal surgery can be categorized according to surgical site and infectious risk. Gastroduodenal surgery and hepatobiliary surgery generally are considered to be clean or clean-contaminated surgeries with SSI rates generally less than 5%. Colorectal surgery, including appendectomies, is considered contaminated owing to the large quantities and polymicrobial nature of bacterial flora within the colon. SSI rates for these types of surgeries generally range from 15% to 30%. Emergent abdominal surgery involving bowel perforation or peritonitis is considered a dirty surgical procedure, associated with more than a 30% risk of SSI, and should be treated with *therapeutic* rather than *prophylactic* antibiotics.³

GASTRODUODENAL SURGERY

Insignificant numbers of bacteria usually are found in the stomach and duodenum because of their acidity. The rate of SSIs in gastroduodenal

TABLE 121–6. Most Likely Pathogens and Specific Recommendations for Surgical Prophylaxis

| Type of Operation | Likely Pathogens | Recommended Prophylaxis Regimen ^a | Comments |
|-------------------|---|---|--|
| Gastroduodenal | Enteric gram-negative bacilli, gram-positive cocci, oral anaerobes | Cefazolin 1 g × 1 (see text for recommendations for percutaneous endoscopic gastrotomy) | High-risk patients only (obstruction, hemorrhage, malignancy, acid suppression therapy, morbid obesity) |
| Biliary tract | Enteric gram-negative bacilli, anaerobes | Cefazolin 1 g × 1 for high-risk patients Laparoscopic: None | High-risk patients only (acute cholecystitis, common duct stones, previous biliary surgery, jaundice, age >60, obesity, diabetes mellitus) |
| Colorectal | Enteric gram-negative bacilli, anaerobes | PO: Neomycin 1 g + erythromycin base 1 g at 1 P.M., 2 P.M., and 11 P.M. 1 day preop plus mechanical bowel prep. IV: Cefoxitin or cefotetan 1 g × 1 | Benefits of oral plus IV is controversial except for colostomy reversal and rectal resection |
| Appendectomy | Enteric gram-negative bacilli, anaerobes | Cefoxitin or cefotetan 1 g × 1 | A second intraoperative dose of cefoxitin may be required if procedure lasts longer than 3 hours |
| Urologic | <i>E. coli</i> | Cefazolin 1 g × 1 | Generally not recommended in patients with sterile pre-op urine cultures |
| Cesarean section | Enteric gram-negative bacilli, anaerobes, group B streptococci, enterococci | Cefazolin 2 g × 1 | Give after cord is clamped |
| Hysterectomy | Enteric gram-negative bacilli, anaerobes, group B streptococci, enterococci | Vaginal: Cefazolin 1 g × 1 Abdominal: Cefotetan 1 g × 1 or Cefazolin 1 g × 1 | Antibiotic prophylaxis should not exceed 24 hours |
| Head and neck | <i>S. aureus</i> , streptococci oral anaerobes | Cefazolin 2 g or clindamycin 600 mg at induction and q8h × 2 more doses | Addition of gentamicin to clindamycin is controversial |
| Cardiothoracic | <i>S. aureus</i> , <i>S. epidermidis</i> , <i>Corynebacterium</i> , enteric gram-negative bacilli | Cefazolin 1 g q8h × 48h | Second-generation cephalosporins also have been advocated In areas with high prevalence of <i>S. aureus</i> resistance, vancomycin should be considered |
| Vascular | <i>S. aureus</i> , <i>S. epidermidis</i> , enteric gram-negative bacilli | Cefazolin 1 g at induction and q8h × 2 more doses | Abdominal and lower extremities have the highest infection rates |
| Orthopedic | <i>S. aureus</i> , <i>S. epidermidis</i> | Joint replacement: Cefazolin 1 g × 1 preop, then q8h × 2 more doses Hip fracture repair: Same as above except continue for 48 hours | Open fractures assumed contaminated with gram-negative bacilli; aminoglycosides often used—see text |
| Neurosurgery | <i>S. aureus</i> , <i>S. epidermidis</i> | CSF shunt procedures: Cefazolin 1 g × 1 or ceftriaxone 2 g × 1 Craniotomy: Cefazolin 1 g × 1 or cefotaxime 1 g × 1 or trimethoprim-sulfamethoxazole (160/800) IV × 1 | No agents have been shown better than cefazolin in randomized control comparative trials. |

^aOne-time doses are optimally infused at induction of anesthesia except as noted. Repeat doses may be required for long procedures. See text for references.

surgery generally is low, and thus procedures in this region can be classified as clean procedures. The risk for an SSI in this population increases with any condition that can lead to bacterial overgrowth, such as obstruction, hemorrhage, malignancy, or increasing the pH of gastroduodenal secretions with concomitant acid suppression therapy. Antimicrobial prophylaxis is of clinical benefit only in this high-risk population. In most cases, a single dose of intravenous cefazolin will provide adequate prophylaxis.⁴⁵ For patients with a β -lactam allergy, oral ciprofloxacin is as efficacious as parenteral cefuroxime as prophylactic therapy for gastroduodenal surgery.⁴⁶ Antimicrobial prophylaxis is only indicated in esophageal surgery in the presence of obstruction. Postoperative *therapeutic* antibiotics may be indicated if perforation is detected during surgery, depending on whether an established infection is present.

The use of antibiotic prophylaxis for percutaneous endoscopic gastrostomy (PEG) is controversial. Although postoperative peristomal infection can occur in up to 30% of patients, clinical trials with cefazolin given 30 minutes preoperatively in this population are conflicting. A pharmacoeconomic study using a meta-analysis of available studies to determine efficacy suggested that antibiotic prophylaxis cost was effective for patients undergoing PEG placements.^{47,48}

HEPATOBIILIARY SURGERY

Although bile is normally sterile, and the SSI rate after biliary surgery is low, antibiotic prophylaxis has been proved to be of benefit in this population. Bile contamination (bactobilia) can increase the frequency of SSIs and is present in many patients (e.g., acute cholecystitis, biliary obstruction, and advanced age).⁴⁵ In general, however, the correlation between bactobilia in surgical specimens and the subsequent pathogens implicated in an SSI is poor. The most frequently encountered organisms include *E. coli*, *Klebsiella* spp., and enterococci. *Pseudomonas* is an uncommon finding in the absence of cholangitis. Trials comparing first-, second-, and third-generation cephalosporins have not demonstrated benefit over single-dose cefazolin prophylaxis even in high-risk patients (e.g., age greater than 60 years, previous biliary surgery, acute cholecystitis, jaundice, obesity, diabetes, and common bile duct stones).⁴⁹ Ciprofloxacin and levofloxacin are effective alternatives for β -lactam-allergic patients undergoing open cholecystectomy.^{50,51} In fact, orally administered levofloxacin appears to provide similar intraoperative gallbladder tissue concentrations.⁵¹ For low-risk patients undergoing elective laparoscopic cholecystectomy, antibiotic prophylaxis is not of benefit and is not recommended.⁵² The risk for SSIs in cirrhotic patients undergoing transjugular intrahepatic portosystemic shunt (TIPS) surgery may be reduced with a single prophylactic dose of ceftriaxone⁵³ but not with single doses of shorter-acting cephalosporins.⁵⁴ Antibiotic prophylaxis is not currently recommended prior to endoscopic retrograde cholangiopancreatography (ERCP).⁵⁵

While surgeons may use *presumptive* antibiotic therapy for patients with acute cholecystitis or cholangitis and defer surgery until the patient is afebrile in an effort to decrease the risk of subsequent infections, this practice is controversial. Detection of an active infection during surgery (e.g., gangrenous gallbladder, suppurative cholangitis) is an indication for a course of postoperative *therapeutic* antibiotics. In either case, antibiotics with additional antianaerobic activity (e.g., cefoxitin or cefotetan) are indicated.⁵⁶

COLORECTAL SURGERY

In the absence of adequate prophylactic therapy, the risk for SSI after colorectal surgery is large because of the significant bacterial

counts in fecal material present in the colon (frequently exceeds 10^9 per gram). Anaerobes and gram-negative aerobes predominate, although gram-positive aerobes also may play an important role. Reducing this bacteria load with a thorough bowel preparation regimen (4 L polyethylene glycol solution or 90 ml sodium phosphate solution administered orally the day before surgery) is controversial, even though 99% in a recent survey of surgeons routinely use mechanical preparation.⁵⁷ Risk factors for SSIs include age greater than 60 years, hypoalbuminemia, poor preoperative bowel preparation, corticosteroid therapy, malignancy, and operations lasting longer than 3.5 hours.⁷

CLINICAL CONTROVERSY

A recent randomized trial of 380 patients undergoing elective colorectal surgery suggests that SSIs are not reduced by preoperative mechanical bowel preparation.⁵⁸ This has been confirmed by a recent meta-analysis that shows that mechanical bowel preparation does not reduce the risk of anastomotic leakage or other complications, including postoperative infection.⁵⁹ Despite this new evidence, mechanical bowel preparations continue to be a standard of practice prior to elective bowel surgery.

Antimicrobial prophylaxis reduced mortality from 11.2% to 4.5% in a pooled analysis of trials comparing antimicrobial prophylaxis with no prophylaxis for colon surgery.⁶⁰ Effective antibiotic prophylaxis reduces the risk for an SSI even further. Several oral regimens designed to reduce bacterial counts in the colon have been studied.⁶¹ The combination of 1 g neomycin and 1 g erythromycin base given orally 19, 18, and 9 hours preoperatively is the most commonly used regimen in the United States.⁶¹ Neomycin, while poorly absorbed, provides intraluminal concentrations that are high enough to effectively kill most gram-negative aerobes. Oral erythromycin, although partially absorbed, still produces concentrations in the colon that are sufficient to suppress common anaerobes. If surgery is postponed, the antibiotics must be readministered to maintain efficacy. Optimally, the bowel preparation regimen should be completed prior to starting the oral antibiotic regimen. This is of particular concern because most procedures are now performed electively on a “same-day surgery” basis. In this case, the bowel preparation regimen is self-administered by the patient at home on the day prior to hospital admission, and thus compliance cannot be monitored carefully.

Patients who cannot take oral medications should receive parenteral antibiotics. Cefoxitin or cefotetan is used most commonly, but a number of other second-generation and some third-generation cephalosporins are also effective.⁶² The role of metronidazole in combination with cephalosporin therapy is unclear. Currently, only retrospective evidence suggests that the addition of metronidazole to a cephalosporin or extended-spectrum penicillin may provide additional benefit.⁶³ Until this can be confirmed in prospective studies, metronidazole should be reserved for combination therapy with cephalosporins with poor anaerobic coverage (e.g., cefazolin). At this time, there is not enough evidence to recommend the addition of metronidazole to cephalosporins with anaerobic activity (e.g., cefotaxime, cefoxitin, and ceftriaxone). For β -lactam-allergic patients, perioperative doses of gentamicin and metronidazole have been used.⁶⁴ It is controversial whether the addition of preoperative parenteral antibiotics to the standard preoperative oral antibiotic regimen described earlier will decrease SSI rates lower than oral prophylaxis alone; however, combination therapy is superior to parenteral therapy alone.⁶⁵ Postoperative antibiotics generally are unnecessary in the absence of any untoward events or findings during surgery. Intravenous

antibiotics are required for colostomy reversal and rectal resection because enterally administered antibiotics will not reach the distal segment that is to be reanastomosed or resected.⁶⁶

APPENDECTOMY

Suspected appendicitis is a frequent cause for abdominal surgery. Numerous antibiotic regimens, all with activity against gram-positive and gram-negative aerobes and anaerobic pathogens, have been studied and found to be effective in reducing SSI incidence. A cephalosporin with antianaerobic activity, such as cefoxitin or cefotetan, is recommended as first-line therapy; however, a comparative trial of cefoxitin and cefotetan suggests that cefotetan may be superior, possibly because of its longer duration of action.⁶⁷ In the case of β -lactam allergy, metronidazole in combination with gentamicin is also an effective regimen. Broad-spectrum antibiotics covering nosocomial pathogens (e.g., *Pseudomonas*) do not further reduce SSI risk⁶⁸ and instead may increase the cost of therapy and promote bacterial resistance. While single-dose therapy with cefotetan is adequate, prophylaxis with cefoxitin may require intraoperative dosing if the procedure extends beyond 3 hours in duration. Established intraabdominal infections (e.g., gangrenous or perforated appendix) require an appropriate course of postoperative *therapeutic* antibiotics. Laparoscopic appendectomy produces lower postoperative infection rates than open appendectomy; however, antimicrobial prophylaxis was used in all patients in these studies, and thus the role for prophylaxis in this population remains unstudied.⁶⁹

UROLOGIC PROCEDURES

Preoperative bacteruria is the most important risk factor for development of an SSI after urologic surgery. All patients should have a preoperative urinalysis and should receive *therapeutic* antibiotics if bacteruria is detected. Patients with sterile urine preoperatively are at low risk for developing an SSI, and the benefit of *prophylactic* antibiotics in this setting is controversial.⁷⁰ Reviews suggest that antibiotic prophylaxis is warranted in high-risk patients (e.g., prolonged indwelling catheterization, positive urine cultures, and neutropenia) undergoing transurethral, perineal, or suprapubic resection of the prostate, resection of bladder tumors, or cystoscopy.⁷⁰ The exact incidence of SSIs in this population is obscured, however, by the frequent use of postoperative urinary catheters and the subsequent risk of bacteriuria. *E. coli* is the most frequently encountered organism. Routine use of broad-spectrum antibiotics such as third-generation cephalosporins and fluoroquinolones has not been demonstrated to decrease SSI rates more than cefazolin, and thus such regimens are not recommended. One comparative trial determined that a single dose of oral ciprofloxacin was as effective as intravenous cefazolin and suggests that this may be a cheaper and easier alternative for outpatient urologic surgery.⁷¹ Regimens longer than a single dose do not improve outcome. Urologic procedures requiring an abdominal approach, such as a nephrectomy or cystectomy, require antibiotic prophylaxis similar to that which would be used for a clean-contaminated abdominal procedure.⁷⁰

CESAREAN SECTION

Cesarean section is the most frequently performed surgical procedure in the United States.⁷ Prophylactic antibiotics are given to avoid endometritis, the most commonly occurring SSI. In the past, antibiotics were recommended for only high-risk patients, including those with premature membrane rupture or those not receiving prenatal care. Several large trials, as well as a meta-analysis, have shown bene-

fit in administering prophylactic antibiotics to all women undergoing emergent cesarean section regardless of their underlying risk factors.⁷² Cefazolin remains the drug of choice despite a wide spectrum of potential pathogens, and a single 2-g dose appears to be superior to single or multiple 1-g doses.⁷³ Providing a broader spectrum of coverage with cefoxitin (for anaerobes) or piperacillin (for *Pseudomonas* or enterococci), does not lower postoperative infection rates further. For patients with a β -lactam allergy, preoperative metronidazole is an acceptable alternative.⁷²

During a cesarean section, unlike other surgical procedures, antibiotics should be administered *after* the initial incision is made and after the umbilical cord is clamped. This will minimize infant drug exposure and thus potentially decrease the incidence of neonatal sepsis. Longer durations of prophylactic therapy have not been shown to result in lower infection rates.⁷⁴

HYSTERECTOMY

The most important factor affecting the incidence of SSI after hysterectomy is the type of procedure that was performed. Vaginal hysterectomies are associated with a high rate of postoperative infection when performed without the benefit of prophylactic antibiotics because of the polymicrobial flora normally present at the operative site.⁷⁵ As with cesarean sections, cefazolin is the drug of choice for vaginal hysterectomies despite the wide spectrum of possible pathogens.⁷⁵ Single-dose therapy should be adequate, but most reports use a 24-hour regimen. The American College of Obstetricians and Gynecologists (ACOG) recommends the use of a first-, second-, or third-generation cephalosporin.⁷⁶ For patients with a β -lactam allergy, a single preoperative dose of doxycycline also is effective.⁷⁵

Prophylactic antibiotics are recommended for abdominal hysterectomy despite the lack of bacterial contamination from the vaginal flora. Both cefazolin and antianaerobic cephalosporins (e.g., cefoxitin and cefotetan) have been studied extensively. Single-dose cefotetan is superior to single-dose cefazolin,⁷⁸ and the investigators suggest that cefotetan should be the drug of choice for abdominal hysterectomies. However, other authors suggest that either agent is appropriate, provided that 24 hours of antimicrobial coverage is not exceeded.⁷ ACOG guidelines suggest that first-, second-, or third-generation cephalosporins can be used for prophylaxis.⁷⁶ Metronidazole is also effective and may be used if patients are allergic to β -lactam antibiotics.⁷⁵ Antibiotic prophylaxis may not be required in laparoscopic gynecologic surgery or tubal microsurgery.⁷⁹ Similar to other surgical procedures, perioperative events and findings may require the use of *therapeutic* antibiotics after surgery.

HEAD AND NECK SURGERY

Use of prophylactic antibiotics during head and neck surgery depends on the procedure type. Clean procedures (as per NRC definition), such as parotidectomy or simple tooth extraction, are associated with a very low incidence of SSI. Head and neck procedures involving an incision through a mucosal layer carry with them a higher risk for SSI. The normal flora of the mouth is polymicrobial; both anaerobes and gram-positive aerobes predominate. While typical doses of cefazolin usually are ineffective for anaerobic infections, a 2-g dose produces concentrations high enough to inhibit these organisms. A pharmacokinetic study suggested that a single dose of clindamycin is adequate for prophylaxis in maxillofacial surgery unless the procedure lasts longer than 4 hours, when a second dose should be administered intraoperatively.⁸⁰ A combination of clindamycin plus gentamicin also has been described but was found to offer no advantage over

clindamycin alone.⁸¹ For most head and neck cancer resection surgeries, including free-flap reconstruction, 24 hours of clindamycin is appropriate, and there is no additional benefit in extending therapy beyond 24 hours.⁸² Topical therapy with clindamycin, amoxicillin-clavulanate, and ticarcillin-clavulanate has been described in small trials, but the exact role for topical antibiotics has yet to be defined.⁸³ Antimicrobial prophylaxis is not indicated for endoscopic sinus surgery without nasal packing.³⁹

CARDIOTHORACIC SURGERY

Although cardiac surgery generally is considered a clean procedure, antibiotic prophylaxis has been demonstrated to lower SSI incidence. The substantial morbidity related to an SSI in this population, coupled with the routine implementation of prosthetic devices, further justifies the routine use of prophylaxis.⁸⁴ Patients who develop SSIs after coronary artery bypass graft (CABG) surgery have a mortality rate of 22% at 1 year compared with 0.6% for those who do not develop an SSI.⁸⁵ Risk factors for developing an SSI after cardiac surgery include obesity, renal insufficiency, connective tissue disease, reexploration for bleeding, and poorly timed administration of antibiotics.⁸⁴ Skin flora pathogens predominate; gram-negative organisms are rare.

Cefazolin has been studied extensively and is considered the drug of choice.²⁵ Although several studies and a meta-analysis have been published that advocate the use of second-generation cephalosporins (e.g., cefuroxime) rather than cefazolin, various methodologic flaws in these studies have limited the extrapolation of these results to practice. Cefazolin is as effective as cefuroxime in a large randomized trial of 702 patients undergoing open heart surgery and thus remains the standard of care.⁸⁶ Both patient weight and timing of cefazolin administration relative to surgery must be considered when developing a dosing strategy. Patients weighing more than 80 kg should receive 2 g cefazolin rather than 1 g. Doses should be administered no earlier than 60 minutes before the first incision and no later than at the beginning of induction.⁸⁴ Extending therapy beyond 48 hours does not lower SSI rates further.⁸⁷ Single-dose cefazolin therapy, in fact, may be sufficient.⁸⁸

Routine vancomycin administration is potentially justified in hospitals having a high incidence of MRSA or when sternal wounds are to be explored surgically for possible mediastinitis. However, a recent large comparative trial enrolling almost 900 patients in a single center with a high prevalence of MRSA infections found that both cefazolin and vancomycin had similar efficacy in preventing SSI in patients undergoing cardiac surgery that required sternotomy.⁸⁹ Mediastinitis constitutes a failure of a prior prophylactic regimen. Continued postoperative vancomycin should be guided by culture and sensitivity data.⁴⁰ Subsequent antibiotic therapy is guided by intraoperative findings.

Pulmonary resection is associated with significant SSI risk, and prophylactic antibiotics have an established role in preventing postoperative infectious morbidity. Pleuropulmonary infections are much more common than wound infections, and pathogenic organisms likely migrate from the oral cavity or pharynx.⁹⁰ First-generation cephalosporins are inadequate; 48 hours of cefuroxime is preferred. A regimen of ampicillin-sulbactam is superior to first-generation cephalosporins, but further studies are required before this agent can be recommended as first-line prophylactic therapy.⁹¹

VASCULAR SURGERY

Vascular surgery, like cardiac surgery, generally is considered a clean surgery by NRC criteria. Although vascular graft infections occur

infrequently (3% to 5%), the associated morbidity and mortality are extensive because treatment often requires surgical graft removal along with *therapeutic* antibiotic therapy.⁹² Prophylactic antibiotics are of benefit, particularly for procedures involving the abdominal aorta and the lower extremities. Cefazolin is regarded as the drug of choice.⁹³ Twenty-four hours of prophylaxis with cefazolin is adequate; longer courses may lead to bacterial resistance.⁹⁴ For patients with β -lactam allergy, 24 hours of oral ciprofloxacin also has been shown to be effective.⁹²

ORTHOPEDIC SURGERY

Most orthopedic surgery is clean by definition, and thus prophylactic antibiotics generally are indicated only when prosthetic materials (e.g., pins, plates, and artificial joints) are implanted.¹⁹ A late-occurring infectious complication in this surgical population can result in substantial morbidity and may lead to prosthesis failure and subsequent removal. Staphylococci are the most frequently encountered pathogens; gram-negative aerobes are infrequent. Similar to many other surgical sites, cefazolin use is supported by substantial literature evidence and therefore is the prophylactic agent of choice. Vancomycin, although effective, is not recommended for routine use unless a patient has a documented history of a serious allergy to β -lactams or the propensity for MRSA infections at a particular institution necessitates its use. The current recommended duration of prophylaxis for joint replacement and hip fracture surgery is 24 hours.⁷ Antibiotic-impregnated cement and beads have been used to lower SSI rates, but conclusive data regarding their efficacy are lacking.¹⁹

Patients suffering open (compound) fractures are particularly susceptible to infection because bacterial contamination almost always has occurred already. The use of antibiotics is *presumptive* under these circumstances. Cefazolin is often combined with an aminoglycoside in this setting, but controlled trials are lacking.⁹⁵ A clinical trial comparing clindamycin and cloxacillin suggests that clindamycin is superior and may be appropriate as monotherapy for Gustillo type I and II open fractures but not for type III fractures, where added gram-negative activity is recommended.⁹⁶ Duration of antibiotic therapy is highly variable and depends on surgical findings during débridement, results of intraoperative cultures, and clinical status. A prospective trial comparing short (<24 hours) and long (>24 hours) courses of antimicrobial prophylaxis for severe trauma suggests that longer courses of antibiotics do not offer additional benefit and may be associated with the development of resistant infections.⁹⁷ However, established joint infections and osteomyelitis require an extended course of *therapeutic* antibiotics.

NEUROSURGERY

Definitive recommendations on the role of antibiotic prophylaxis in neurosurgery cannot yet be made at this time.⁹⁸ While the rates of SSI after these generally clean operations are low, the morbidity and mortality of SSI, should it occur, are high. Procedures involving cerebrospinal fluid (CSF) shunt placement should be considered separately because this involves placement of a foreign body and is associated with higher infection rates. When choosing an antibiotic, one must consider not only the spectrum of activity but also the penetration of the agent into the site of action (CSF). A meta-analysis suggested that single doses of cefazolin or, where required, vancomycin appear to lower SSI risk after craniotomy.⁹⁹ The largest prospective, randomized trial to date of 826 patients undergoing clean neurosurgical procedures suggested that a single dose of ceftizoxime was as effective

as a combination regimen of single-dose vancomycin and gentamicin. The authors also report that ceftizoxime was better tolerated and more consistently achieved adequate CSF levels to inhibit the most common organisms.¹⁰⁰ A more recent study of 780 patients undergoing neurosurgical procedures that included shunt surgery reported that single doses of cefotaxime and trimethoprim-sulfamethoxazole are equally effective in preventing SSIs.¹⁰¹ Studies performed on procedures involving a shunt have been small in size and do not consistently show lower infection rates with antibiotic prophylaxis, although the results of two meta-analyses suggest that they may.^{102,103} Since no trials have shown superiority of any one agent, single doses of cefazolin appear to be an acceptable choice.⁹⁹

SSIs associated with spinal surgery are rare but devastating when they occur. The use of antimicrobial prophylaxis in this setting therefore is warranted and recommended by a meta-analysis.¹⁰⁴ Large randomized, controlled trials are lacking, but cefazolin is the antibiotic recommended most commonly. Cefazolin penetration into both intervertebral disks and CSF may not be adequate, and a combination of cefuroxime and gentamicin may be better. There is a paucity of clinical trials comparing these two regimens.¹⁰⁵

MINIMALLY INVASIVE AND LAPAROSCOPIC SURGERY

Laparoscopic surgeries are being performed more frequently for a variety of different operations, including gynecologic, orthopedic, and biliary surgeries. This minimally invasive technique is associated with smaller wounds, fewer infectious complications, less of an inflammatory response, and therefore a better-preserved immune response to infection when compared with the open surgical approach.¹⁰⁶ The role of antimicrobial prophylaxis in this setting depends on the type of surgery performed and preexisting risk factors for infection. Unfortunately, there are few large prospective, placebo-controlled trials to determine in which patients and surgeries antimicrobial prophylaxis is warranted.

In addition to the recommendations for previously mentioned laparoscopic procedures, there is a variety of levels of evidence for prophylaxis in other laparoscopic and endoscopic procedures. Patients undergoing endoscopic retrograde cholangiopancreatography (ERCP) do not need antimicrobial prophylaxis unless biliary obstruction is evident. In these situations, a single 1-g dose of cefazolin will suffice.¹⁰⁷ The role of antimicrobial prophylaxis for transurethral resection of the prostate (TURP) is better established. A third-generation cephalosporin such as ceftriaxone (or cotrimoxazole for severely β -lactam-allergic patients) can be recommended as single-dose prophylaxis, especially for patients with nonsterile urine preoperatively or indwelling catheters.¹⁰⁷ The insertion of peritoneal dialysis catheters by laparoscopic technique is associated with significantly lower rates of postoperative infection. With SSI rates of less than 5%, prophylactic antimicrobial therapy may not be warranted, but this has not been studied in a large enough placebo-controlled trial. If the decision to provide antimicrobial prophylaxis is made, a single dose of cefazolin will suffice.¹⁰⁷

NONPHARMACOLOGIC INTERVENTIONS

Besides antimicrobial strategies and aseptic technique, other strategies have been investigated in different types of surgeries to reduce postoperative infections. The most commonly cited and practiced interventions include maintenance of normothermia intraoperatively,

provision of supplemental oxygen in the perioperative period, and aggressive perioperative glucose control.

Core body temperature can fall by 1 to 1.5°C intraoperatively in patients under general anesthesia. Intraoperative hypothermia has been associated with impaired immune function, decreased blood flow to the surgical site, decreased tissue oxygen tension, and an increased risk of SSI. Efforts to maintain intraoperative normothermia should be exercised and may include the use of warming blankets and intravenous fluid warmers to maintain core body temperature above 36°C. One prospective trial of 200 patients undergoing colorectal surgery found that maintenance of normothermia reduced postoperative infection rates along with other morbidity parameters, including length of stay.¹⁰⁸

Low oxygen tension in the tissues that make up the surgical site increases the risk of bacterial colonization and subsequent SSI by decreasing the efficiency of neutrophil activity. Administration of high concentrations of oxygen (80% via ventilator or 12 L/min via a nonrebreather mask) reduced postoperative infection rates significantly in a multicenter randomized trial of 500 patients undergoing colorectal surgery.¹⁰⁹

Diabetes and poor glucose control are well-known risk factors for SSI. The increased risk of infection is thought to be due to both macrovascular (vasculopathy and venoocclusive disease) and microvascular (subtle immunologic deficiencies, including neutrophil dysfunction and reduced complement and antibody activity) complications. Aggressive control of perioperative blood glucose decreases the incidence of SSI in diabetics undergoing cardiac surgery and is currently being evaluated in other types of surgery and in nondiabetic patients.¹¹⁰

CLINICAL CONTROVERSY

Although interventions to maintain normothermia intraoperatively, provide supplemental oxygen in the perioperative period, and aggressively control perioperative glucose show a significant reduction in SSI, they cannot be generalized to all types of surgeries. However, given the simplicity and low cost of these interventions, many clinicians are considering the applicability of such measures outside the studied population. At this time, pending further research, these interventions can only be recommended for routine use in the type of patient or surgery for which it was studied.

PHARMACOECONOMIC AND SAFETY IMPLICATIONS

It is paramount to consider the cost implications of pharmacotherapy guidelines that affect a large number of patients. While investigators have incorporated basic financial analysis into the results of antibiotic prophylaxis comparative trials,^{40,44,47,85} robust pharmacoeconomic studies of various regimens of antimicrobial prophylaxis in surgery are lacking. Most of these studies are cost-minimization studies because only drug acquisition costs are considered. Studies that incorporate all relevant drug and treatment costs in relation to pertinent patient outcomes such as incidence of SSIs, hospital length of stay, and antibiotic related adverse events are needed.

The recommendations and literature reviewed in this chapter show that SSIs are preventable with appropriately chosen and timed prophylactic therapy in combination with meticulous aseptic technique and a variety of nonantimicrobial methods. Despite this, infection is the most common complication postoperatively. For this

TABLE 121–7. Strategies for Implementing an Institutional Program to Ensure the Appropriate Use of Antimicrobial Prophylaxis in Surgery**1. Educate**

Develop an educational program that enforces the importance and rationale of timely antimicrobial prophylaxis. Make this educational program available to all health care practitioners involved in the patient's care.

2. Standardize the Ordering Process

Establish a protocol (e.g., a preprinted order sheet) that standardizes antibiotic choice according to current published evidence, formulary availability, institutional resistance patterns, and cost.

3. Standardize the Delivery and Administration Process

Employ a system that ensures that antibiotics are prepared and delivered to the holding area in a timely fashion. Standardize the administration time to less than 1 hour preoperatively. Designate responsibility and accountability for antibiotic administration. Provide visible reminders to prescribe/administer prophylactic antibiotics (e.g., checklists). Develop a system to remind surgeons/nurses to readminister antibiotics intraoperatively during long procedures.

4. Provide Feedback

Follow up with regular reports of compliance and infection rates.

reason, many institutions, including the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), have mandated a formalized approach to improving patient safety and reducing SSIs. Standardized institutional guidelines can effectively ensure appropriate prophylactic antimicrobial therapy and ultimately reduce SSIs at individual institutions. Strategies to implement such a program are outlined in Table 121–7.

EVALUATION OF THERAPEUTIC OUTCOMES

When evaluating the outcome of surgical antibiotic prophylaxis, it is important to differentiate any potential SSI from other postoperative infection or complication. While fever and leukocytosis are common in the immediate postoperative period, they typically resolve with prompt ambulation, timely removal of invasive devices, prevention and/or resolution of atelectasis through optimal respiratory care, and effective analgesia. It is also important to remember that the emergence of distal infections, such as pneumonia, does not constitute a failure of surgical prophylaxis. Prophylaxis should be as short as possible because prolonged prophylactic regimens may contribute to the selection of resistant organisms and may make any infection more difficult to treat.

Surgical-site appearance is the most important determinant of the presence of an infection. Drainage of pus from the incision accompanied by redness, warmth, and pain or tenderness is highly suggestive of an SSI. By definition, any surgical site that requires incision and drainage by the surgeon is considered infected regardless of appearance. Failure to heal and wound dehiscence also are seen commonly with SSIs, although surgical technique and nutritional status may be important contributing factors.

The presentation of signs and symptoms consistent with an SSI in relation to previous surgery is an important consideration when evaluating therapeutic outcomes after surgical prophylaxis. Many SSIs will not be evident during acute hospitalization. In fact, SSIs may not become evident until up to 30 days later or, in the case of prosthe-

sis implantation, up to 1 year later. Thus the true incidence of SSI can only be determined by completing comprehensive postdischarge surveillance. All studies investigating the efficacy of surgical prophylaxis must include adequate postdischarge follow-up in order to be able to thoroughly assess the success of any prophylactic regimen.

VACCINES, TOXOIDS, AND OTHER IMMUNOBIOLOGICS

Mary S. Hayney

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

Vaccines have become modern medical miracles along with bypass surgery and the CAT scan, but with this difference—vaccines have saved more lives and prevented more deaths than any other modern medical intervention since the chlorination of water and the pasteurization of milk.

Richard M. Krause,

“The Jordan Report: Accelerated Development of Vaccines 1996,” NIAID/NIH

Immunization is defined as rendering a person protected from an infectious agent. Immunity to an infectious agent can be acquired by exposure to the disease, by the transfer of antibodies from mother to fetus, through the administration of immune globulin, and from vaccination. Immunization is the process of introducing an antigen into the body to induce protection against the infectious agent without causing disease. An antigen is a substance that induces an immune response. The antibody produced by the humoral arm of the immune system is usually the response that is measured as evidence of successful vaccination. However, increasing evidence exists that the cellular immune response, which is much more difficult to measure, is also a very important aspect of vaccine response.

This chapter introduces the reader to three groups of agents: vaccines, toxoids, and immune sera (together known as *immunobiologics*). These groups are defined, and related agents are dealt with concurrently to illustrate total immunotherapy. Obscure agents and agents with a limited scope of use, such as agents for bioterrorism, are not included in the interest of brevity.

PRODUCTS TO PRODUCE IMMUNIZATION

Vaccines and toxoids are separate and distinct products. Both types of products, however, act to induce active immunity, i.e., immunity generated by a natural immunologic response to an antigen. Viral vaccines can be live attenuated or killed. Killed viral vaccines may consist of whole or split viral particles, specific viral fragments (subunits), or virus-like particles. Bacterial vaccines generally are killed whole bacteria or specific bacterial antigens or conjugates. Live attenuated vaccines induce an immunologic response more consistent with that occurring with natural infection. Because the organisms in live attenuated vaccines undergo limited replication in the vaccinated individual after administration, they may confer lifelong immunity with one dose (as does a primary natural infection). Multiple doses of killed vaccines usually are needed to induce long-lasting, effective immunity. Often, additional doses at varying time intervals (booster doses) are required to maintain immunity. The booster doses of such

vaccines elicit memory responses from the B cells that produce immunoglobulin G (IgG). The immune system has developed an array of antibodies to the antigen already, and on restimulation with a booster dose, the B cells that produce the most specific antibodies against the antigen are activated. This restimulation allows the most active antibodies against the antigen to be selected and maintained in the “immunologic memory.” Thus the booster dose results in a rapid, intense antibody response that is long-lasting. Killed vaccines also can differ in immunity potential depending on their composition. For example, polysaccharide vaccines tend to be poorly immunogenic in infants, whereas conjugated vaccines of the same antigen tend to be highly immunogenic (e.g., pneumococcal polysaccharide vaccine versus pneumococcal conjugated vaccine). A T-cell-independent immune response is made to polysaccharide antigens that stimulate B cells directly.¹ There is no maturation or booster response with a T-cell-independent immune response, and children younger than 2 years of age cannot make this type of response. Protein-polysaccharide conjugate vaccines stimulate T cells and promote interactions between T cells and B cells when producing the protective immune responses consisting of immunologic memory and high-affinity IgG.

Toxoids are inactivated bacterial toxins that generally are combined with aluminum salts to enhance their antigenicity by prolonging antigen absorption and exposure. These adjuvants also increase local tissue irritation when injected. Toxoids stimulate the production of antibodies against the bacterial toxins rather than the infecting bacterial pathogens.

Immune sera are sterile solutions containing antibody derived from human (immunoglobulin) or equine (horse antitoxin) sources. Immunoglobulins are derived from donor pools of blood plasma and are processed using cold ethanol fractionation in order to inactivate known potential pathogens. Antitoxins are made by immunizing animals with an antigen and then harvesting the antibodies (antitoxins) made against the antigens. These sera are indicated for induction of passive immunity (temporary immunity to infection as a result of the administration of antibodies not produced by the host). Human immune sera is preferred because of its lower incidence of serum sickness and other allergic reactions as compared with equine derived sera (see the section “Other Immunobiologics” below).

In addition to the active component in an immunobiologic, other active and inert ingredients are often present. Suspending agents, such as water, saline, or complex fluids containing proteins (such as albumin) or antigens, are used as the vehicle for the immunobiologic agent. Preservatives, stabilizers, and antibiotics often are added to help maintain sterility. Immunized individuals may respond with allergic reactions not to the immunobiologic agent itself but to the other components of the pharmaceutical preparation. Different manufacturers of the same immunobiologic may have different active and

inert ingredients or different quantities of these ingredients in their products.

The use of combination vaccines can decrease the number of injections required at a single visit. The childhood immunization schedule has become increasingly complex with up to seven injections in a single immunization visit. Licensed combination vaccines should be used whenever any of their components are indicated.²

Certain vaccines manufactured by various companies are considered interchangeable. Hepatitis A and hepatitis B vaccines are considered interchangeable. It is preferable to use diphtheria-tetanus-acellular pertussis (DTaP) vaccine from the same manufacturer to complete the entire primary series. However, immunization should not be delayed if the particular type of vaccine administered for the initial doses cannot be ascertained easily. Finally, all licensed *Hemophilus influenzae* type b conjugate vaccines are considered interchangeable for the primary series of three doses of vaccine.³

In general, vaccines and toxoids must be kept refrigerated because breaking the “cold chain” may result in loss of potency. Certain vaccines, such as measles-mumps-rubella (MMR), also may be frozen. Immune sera generally should be kept refrigerated and not frozen except for lyophilized intravenous human immunoglobulin (IVIG), which can be stored at room temperature. Certain vaccines, such as yellow fever, live attenuated influenza, and varicella, are sensitive to increased temperature. While some vaccines may be stored below 0°C (32°F), toxoids in general tend to aggregate on freezing, leading to increased adverse local effects. On the other hand, some vaccines, when stored under incorrect conditions, may not be easily distinguished from potent vaccines.

FACTORS AFFECTING RESPONSE TO IMMUNIZATION

Various factors are known to affect response to vaccines and toxoids. Viability of the antigen is an important factor (live attenuated versus killed), as discussed previously. Total dose is also important because there seems to exist a threshold dose above which no further increase in antibody titer is seen. The use of split doses or multiple reduced doses of a vaccine (such as those used in patients with allergies to some immunobiologic component as both a desensitization and an immunization program), however, may result in inadequate protection. In such instances, serologic testing should be performed to ascertain whether or not protection to the antigen had been attained. The interval between immunization doses, the number of doses given, or both may change immune response to an agent. For hepatitis B vaccine nonresponders, a significant proportion of individuals will mount a vaccine response when given additional doses of vaccine.⁴ Alternatively, additional doses of influenza vaccine are minimally effective in immunocompetent elderly individuals, individuals with human immunodeficiency virus (HIV) infections, or patients with cancer.^{5,6} Generally, intervals longer than those recommended between vaccine doses do not reduce immune response.³

The route and site of administration of the immunobiologic also are important. This is best illustrated by the hepatitis B vaccine, which elicits a satisfactory antibody response when given in the deltoid muscle but not consistently when administered in the gluteal area.⁷ Injections should be administered in a site where there is little likelihood of site damage. Immunobiologics containing adjuvants should be given into muscle mass because they can cause irritation when given subcutaneously or intradermally.

Host factors also influence vaccine response. Immunodeficiency, increasing age, underlying disease, and genetic background have been associated with poor response rates.^{8–11}

VACCINE ADMINISTRATION

Subcutaneous injections should be administered into the thigh of infants and in the upper arm area of older children and adults. A $5/8$ -in, 25-gauge needle should be used, being careful not to administer the dose intradermally or intramuscularly. For intramuscular (IM) injection, the anterolateral aspect of the upper thigh (infants and toddlers) or the deltoid muscle of the upper arm (children and adults) should be used. When giving an IM injection to an adult, at least a 1-in needle should be used for persons weighing less than 90 kg and a 1.5-in needle for persons weighing more than 90 kg to ensure injection in the muscle.⁷ The buttock should not be used because of the potential for inadequate immunologic response and because of the potential risk of injury to the sciatic nerve. When the buttock must be used (as for large doses of immunoglobulin), only the upper outer quadrant should be used, with the needle being inserted anteriorly. Intradermal injections should be administered on the volar surface of the forearm, except for human diploid cell (rabies) vaccine (HDCV), which should be given into the deltoid area to reduce reactions. A $3/8$ - to $3/4$ -in, 25- or 27-gauge needle should be used, with care being taken to not inject the immunobiologic substance into the subcutaneous tissue.

For orally administered vaccines, the general recommendation is to readminister the vaccine at the same visit if the vaccine is regurgitated within 5 to 10 minutes of administration. If the second dose is not retained, that dose should not be counted, and the vaccine should be readministered at the next visit.

The live attenuated influenza vaccine is administered intranasally. A specially designed sprayer is inserted just inside the nostril, and the dose is squirted by depressing the plunger of the sprayer. The clip is removed from the plunger so that the second half of the dose can be administered into the other nostril. The vaccinated individual should breathe normally. There is no need to repeat the dose if the individual sneezes during or shortly after administration.¹²

Questions often arise concerning the simultaneous administration of vaccines. In general, inactivated and live attenuated vaccines can be administered simultaneously at separate sites. If two or more killed antigens cannot be administered simultaneously, they may be administered without regard to spacing between doses. Killed and live antigens may be administered simultaneously or, if they cannot be administered simultaneously, at any interval between doses, with the exception of cholera (killed) and yellow fever (live) vaccine, which should be given at least 3 weeks apart. If live vaccines are not administered simultaneously, their administration should be separated by at least 4 weeks. Live viral vaccines may interfere with purified protein derivative (PPD) response; thus tuberculin testing should be postponed 4 to 6 weeks after live virus vaccine administration.

The simultaneous administration of immunoglobulin and live attenuated vaccines may inhibit host antibody response because of impairment of viral replication. A dose relationship between administration of immunoglobulin and inhibition of immune response to a vaccine exists (Table 122–1). Whole blood and other blood products containing antibodies may interfere with the response to the MMR and varicella vaccines. For rubella-seronegative women who are immediately postpartum and have received a blood product in the last trimester or anti-RhoD immunoglobulin (IG) at the time of delivery, vaccination with MMR should be done immediately, with rubella antibody testing at least 3 months later to determine vaccine response. In any patient, if vaccination with MMR or varicella is followed by emergency immunoglobulin administration, the vaccine can be repeated or seroconversion to the viral antigens can be confirmed after sufficient time has elapsed (see Table 122–1). Immunoglobulin does not interfere with the response to oral vaccines or yellow fever vaccine.³

TABLE 122–1. Suggested Intervals Between Administration of Antibody-Containing Products for Different Indications and Measles-Containing Vaccine and Varicella Vaccine^a

| Product/Indication | Dose, Including mg Immunoglobulin G (IgG)/kg of Body Weight ^a | Recommended Interval before Measles or Varicella (months) |
|---|--|---|
| Respiratory syncytial virus immune globulin (IG) ^b | 15 mg/kg intramuscularly (IM) | None |
| Tetanus IG | 250 units (10 mg IgG/kg) IM | 3 |
| Hepatitis A IG | | |
| Contact prophylaxis | 0.02 mL/kg (3.3 mg IgG/kg) IM | 3 |
| International travel | 0.06 mL/kg (10 mg IgG/kg) IM | 3 |
| Hepatitis B IG | 0.05 mL/kg (10 mg IgG/kg) IM | 3 |
| Rabies IG | 20 IU/kg (22 mg IgG/kg) IM | 4 |
| Varicella IG | 125 units/10 kg (20–40 mg IgG/kg) IM | 5 |
| Measles prophylaxis IG | | |
| Standard (i.e., nonimmunocompromised) contact | 0.25 mL/kg (40 mg IgG/kg) IM | 5 |
| Immunocompromised contact | 0.50 mL/kg (80 mg IgG/kg) IM | 6 |
| Blood transfusion | | |
| Red blood cells (RBCs), washed | 10 mL/kg negligible IgG/kg | None |
| RBCs, adenine-saline added | 10 mL/kg (10 mg IgG/kg) IV | 3 |
| Packed RBCs (hematocrit 65%) ^c | 10 mL/kg (60 mg IgG/kg) IV | 6 |
| Whole blood (hematocrit 35%–50%) ^c | 10 mL/kg (80–100 mg IgG/kg) IV | 6 |
| Plasma/platelet products | 10 mL/kg (160 mg IgG/kg) IV | 7 |
| Cytomegalovirus intravenous immune globulin (IVIg) | 150 mg/kg maximum | 6 |
| Respiratory syncytial virus prophylaxis IVIG | 750 mg/kg | 9 |
| IVIg | | |
| Replacement therapy for immune deficiencies ^d | 300–400 mg/kg IV ^d | 8 |
| Immune thrombocytopenic purpura | 400 mg/kg IV | 8 |
| | 1000 mg/kg IV | 10 |
| Kawasaki disease | 2 g/kg IV | 11 |

^aThis table is not intended for determining the correct indications and dosages for using antibody-containing products. Unvaccinated persons might not be fully protected against measles during the entire recommended interval, and additional doses of Immune globulin or measles vaccine might be indicated after measles exposure. Concentrations of measles antibody in an immune globulin preparation can vary by manufacturer's lot. Rates of antibody clearance after receipt of an immune globulin preparation might vary also. Recommended intervals are extrapolated from an estimated half-life of 30 days for passively acquired antibody and an observed interference with the immune response to measles vaccine for 5 months after a dose of 80 mg IgG/kg. [Source: Mason W, Takahashi M, Schneider T. Persisting passively acquired measles antibody following gamma globulin therapy for Kawasaki disease and response to live virus vaccination (abstract 311). Presented at the 32nd meeting of the Interscience Conference on Antimicrobial Agents and Chemotherapy, Los Angeles, California, October 1992.]

^bContains antibody only to respiratory syncytial virus.

^cAssumes a serum IgG concentration of 16 mg/mL.

^dMeasles and varicella vaccination is recommended for children with asymptomatic or mildly symptomatic human immunodeficiency virus (HIV) infection but is contraindicated for persons with severe immunosuppression from HIV or any other immunosuppressive disorder.

From *MMWR* 2002;53(2).

Simultaneous administration of killed vaccines along with immunoglobulins is not contraindicated. Different sites are recommended, however, for killed vaccine and immunoglobulin administration. It is not recommended to increase the dose or number of vaccines used in this circumstance.

IMMUNIZATION OF SPECIAL POPULATIONS

NEONATES, INFANTS, AND PREGNANT WOMEN

The age of the recipient is another important determining factor in vaccine and toxoid response. In the first few months of life, maternal antibodies acquired via transplacental transfer during the third trimester of gestation protect an infant. However, the maternal antibody also inhibits the immune response to live vaccines because the circulating antibodies neutralize the vaccine before the infant has the opportunity to mount an immune response. For this reason, live vaccines are not administered until maternal antibody has waned, generally by age 12 months.³

Premature infants should be vaccinated at the same chronologic age using the same schedule and precautions as full-term infants. The full recommended doses of vaccines should be used, regardless of

age or birth weight. Hepatitis B vaccine should be administered if the infant weighs 2000 g, or it should be held until the infant is 2 months of age. Breast-fed infants should be vaccinated according to standard pediatric schedules.

Most vaccines are pregnancy category C. As with most drugs, this category assignment is not because there is a known risk to the fetus but rather because of lack of information. No birth defect has ever been attributed to vaccine exposure.³ For example, no cases of congenital rubella syndrome from inadvertent administration of rubella vaccine to a pregnant woman have ever been reported. Despite this, vaccination of pregnant women generally is deferred until after delivery because of concern over potential risk to the fetus.

Universal influenza immunization is recommended for women who will be pregnant during influenza season. Tetanus-diphtheria (Td) vaccine is recommended for pregnant women who have not received a Td booster in the past 10 years. Although live vaccines generally are avoided because of the theoretical risk of transmission of the vaccine organism to the fetus, inactivated vaccines may be administered to pregnant women when the benefits outweigh the risks.³ Hepatitis B, hepatitis A, meningococcal, inactivated polio, and pneumococcal polysaccharide vaccines should be administered to pregnant women who are at risk for contracting these infections.¹³

IMMUNOCOMPROMISED HOSTS

Vaccination in compromised hosts (e.g., those with chronic disease, such as diabetes, connective tissue disease, or alcoholics or those with cancer or HIV disease) must be individualized based on the disease state and its treatment. The Centers for Disease Control and Prevention (CDC) has classified persons with immunocompromised conditions into three groups¹⁴:

1. Persons with a condition that causes limited immune deficiency (e.g., renal disease, diabetes, liver disease, and asplenia)
2. Individuals who are severely immunocompromised but not as a result of HIV infection (e.g., congenital immunodeficiency, drug- or radiation-induced disease, hematologic disease, or solid tumor)
3. Persons with HIV infection

Patients with chronic pulmonary, renal, hepatic, or metabolic disease who are not receiving immunosuppressants may receive both live attenuated and killed vaccines and toxoids to induce active immunity. These patients often need higher doses of vaccines or more frequent dosing to induce immunity. Generally, immunization should be considered early in the course of the disease in an attempt to induce immunity at a point when the disease is less severe.

Patients with active malignant disease may receive killed vaccines or toxoids but should not be given live vaccines. The MMR vaccine is not contraindicated for close contacts, however. Live virus vaccines may be administered to persons with leukemia who have not received chemotherapy for at least 3 months. Vaccines should be timed to avoid coinciding with the start of chemotherapy or radiation therapy. Annual influenza vaccine should be administered 2 weeks prior to chemotherapy or between cycles.⁶ If vaccines cannot be given at least 2 weeks or more before the start of these therapies, immunization should be postponed until 3 months after the therapy has been completed. Passive immunization with immunoglobulin may be used in place of active immunization regardless of the history of immunization.

Glucocorticoids may cause suppressed responses to vaccines. For the purposes of immunization, the immunosuppressing dose of corticosteroids is prednisone 20 mg or more daily or 2 mg/kg daily, or an equivalent dose of another steroid, for at least 2 weeks. Patients receiving long-term alternate-day steroid therapy with short-acting agents, administration of maintenance physiologic doses of steroids (such as 5–10 mg/day of prednisone) via topical, aerosol, intraarticular, bursal, or tendon steroid injections require no special consideration for immunization. If patients have been receiving high-dose corticosteroids or have had a course lasting longer than 2 weeks, then at least 1 month should pass before immunization with live virus vaccines.³

The patient with HIV infection requires special consideration. Responses to live and killed antigens generally are suboptimal and decrease as the disease progresses because HIV produces defects in cell-mediated immunity and humoral immunity.

For children up to age 16 years with HIV infection, immunization following the standard schedules is recommended for hepatitis B, DTaP, pneumococcal conjugate vaccine (PCV7), *H. influenzae* type b (Hib), inactivated polio vaccine (IPV), and annual influenza. Two doses of MMR vaccine should be administered at least 1 month apart as soon as possible after the first birthday. MMR should be administered only to children who have no evidence or moderate evidence of immunosuppression. Two doses of varicella vaccine separated by 3 months are recommended only in children with no evidence of

immunosuppression.¹⁵ Children with HIV infection are at high risk for invasive pneumococcal disease, so children aged 24 to 59 months who did not receive the primary series as infants also should receive two doses of PCV7 separated by at least 2 months. These children also should receive pneumococcal polysaccharide vaccine (PPV23). Other killed vaccines may be used without concern for increased risk. Live typhoid vaccine should be avoided. Yellow fever vaccine may be used if absolutely necessary, but it may pose a theoretical risk of encephalitis.¹⁶

TRANSPLANT PATIENTS

SOLID-ORGAN TRANSPLANT PATIENTS

Organ transplantation has become a routine treatment for end-stage organ disease of many causes. Although the number of organ transplants performed is severely limited by the availability of donor organs, survival of transplant recipients is increasing. Solid-organ transplant patients remain on immunosuppressive regimens for the rest of their lives. These immunosuppressive regimens result in a higher risk of infection and also decrease the protection conferred by immunization.¹⁷

Whenever possible, transplant patients should be immunized prior to transplantation. Live vaccines generally are not given after transplantation. Posttransplantation diphtheria, tetanus, pneumococcal, and influenza vaccine responses are unpredictable. Decreased immune response has been documented following hepatitis B vaccine.^{18–23}

HEMATOPOIETIC STEM CELL TRANSPLANT PATIENTS

Reimmunization of hematopoietic stem cell transplant (HSCT) patients is necessary because antibody concentrations wane rapidly. Annual influenza immunization may begin as soon as 6 months following successful engraftment. Reimmunization with diphtheria-tetanus-pertussis (DTaP) vaccine if age 7 or younger, *H. influenzae* type b, inactivated polio, hepatitis B, and pneumococcal polysaccharide vaccines should begin approximately 12 months following HSCT. MMR can be administered at 24 months. Varicella, meningococcal, and pneumococcal conjugate vaccines are not recommended. Immunization of household contacts and health care workers is also necessary.²⁴

CONTRAINDICATIONS AND PRECAUTIONS

There are very few contraindications to the use of vaccines except those outlined earlier. These contraindications include a history of anaphylactic reactions to the vaccine or a component of the vaccine or an unexplained encephalopathy occurring within 7 days of a dose of pertussis vaccine. Immunosuppression and pregnancy are temporary contraindications to live vaccines. An interval of time must elapse based on the dose of immunoglobulin before a live vaccine can be administered (see Table 122–1). Precautions for DTaP administration include hypotonic hyporesponsive episode, fever of 40.5°C (104.9°F) or greater, crying lasting more than 3 hours within 48 hours of a previous dose, and seizures with or without fever within 3 days after a dose.³ Generally, mild to moderate local reactions, mild acute illnesses, concurrent antibiotic use, prematurity, family history of adverse events, diarrhea, and breast-feeding are not contraindications to immunization.

OBTAINING AN IMMUNIZATION HISTORY

An immunization history should be obtained from every patient, regardless of the reason for the health care visit. Ideally, any history provided by the patient from memory should be verified by reviewing the patient's personal written immunization record or a database that contains the complete immunization history. State-based immunization registries are being developed to improve immunization coverage by allowing health care providers access to records at any contact with the health care system. Registries are aimed primarily at facilitating childhood immunization records.²⁵ If an official written record is not available, patient characteristics (e.g., military service, travel history, and occupation) may provide clues as to the immunization history. Serologic testing for immunity against certain diseases can provide specific information, but it is employed routinely for only a few selected diseases (e.g., measles, rubella, hepatitis A and B, and varicella) and selected circumstances (e.g., employment in a health care facility). If a written record does not exist, one should be generated at the time of initiation of immunization. Patients without a written record should be considered susceptible and an immunization program started and completed unless a serious adverse reaction occurs. As a general rule, the risks associated with overimmunization are minimal relative to the risks associated with contracting vaccine-preventable diseases.³

VACCINE DELIVERY

Shortfalls in vaccine coverage targets exist in both the adult and pediatric populations.²⁶ Among children, those of preschool age historically have been the most neglected. Entry into public school is contingent on receipt of certain required immunizations, resulting in vaccine coverage rates above 97% in children 6 years of age and older. The lack of a similar enforcement mechanism in younger patients, however, has contributed to exceptionally low immunization rates (<50%), particularly in children younger than 2 years of age. From 1989 to 1991, the United States experienced a national measles epidemic largely caused by inadequately immunized preschool-aged children. Additionally, other segments of the population (i.e., adolescents and senior citizens) have been identified as needing better vaccine coverage.^{26,27}

According to the CDC, every health care visit, regardless of its purpose, should be viewed as an opportunity to review a patient's immunization status and to administer needed vaccines. Immunization is perhaps the most cost-effective medical practice available. Each visit should encompass assessment of individuals' vaccine needs, administration of indicated agents, and documentation of immunization histories. The outcome measurement of what percentage of patients in a particular practice site is completely immunized is extremely important because the benefits of optimal vaccine use extend beyond the individual patient to the public as a whole.

NATIONAL VACCINE INJURY COMPENSATION ACT

The National Child Vaccine Injury Act of 1986 was passed by the U.S. Congress in response to reports of vaccine side effects and liability concerns of vaccine manufacturers and health care providers. With vaccine safety being questioned and manufacturers ceasing the development and marketing of vaccines, the National Vaccine Injury Compensation Program was instituted to offer a no-fault alternative

means to compensate victims for injury owing to vaccination. The program offers liability protection to manufacturers and an efficient means of recovering damages for individuals potentially injured by vaccines. Compensation for vaccine-related injuries is outlined in the Vaccine Injury Table.²⁸ The act also instituted mandatory record keeping by health care providers in the permanent medical record. Specifically, the manufacturer and lot number of the vaccine, date of administration, and name, address, and title of the person giving the vaccine must be recorded. Additionally, the act mandates that health care providers report to their local health department or to the Food and Drug Administration (FDA) any occurrence of adverse reactions.

Health care providers must report all events requiring medical attention within 30 days of vaccination to the Vaccine Adverse Event Reporting System (VAERS), which serves as a central depot for vaccine-related adverse effects. Only a temporal association between the adverse event and vaccine administration needs to be made. No adverse event rates can be determined because only the number of adverse events reported is known; the number of vaccines administered is not known. This database can be used to determine changes in adverse-event frequencies, to evaluate risk factors for adverse events, and to find rare adverse events.²⁹ VAERS report forms can be obtained by calling 1-800-822-7967, or reports can be made online at www.vaers.com.

USE OF VACCINES AND TOXOIDS

Appendices 122–1 and 122–2 show the recommended schedules for routine immunization of children and adults. Many states require children to be fully immunized prior to entering elementary school; however, optimal protection is achieved by immunizing at the recommended ages, which requires special attention to children younger than 2 years of age. Adults and adolescents also require vaccination and often are unaware of this need. Adults should receive routine tetanus-diphtheria boosters and be immune to measles, mumps, rubella, and varicella by either immunization or history of infection. Certain individuals with conditions or lifestyles that put them at high risk for vaccine-preventable diseases also should be immunized as described in the text that follows and outlined in the immunization schedules in the appendices.

TOXOIDS

DIPHTHERIA TOXOID ADSORBED AND DIPHTHERIA ANTITOXIN

Diphtheria is an acute illness caused by the toxin released by a *Corynebacterium diphtheriae* infection. The toxin inhibits cellular protein synthesis, with membranes forming on mucosal surfaces. Systemic toxemia can result in myocarditis, neuritis, and thrombocytopenia. Membrane formation can cause respiratory obstruction, and significant toxin absorption can lead to severe illness and death.

Diphtheria toxoid adsorbed is a sterile suspension of modified toxins of *C. diphtheriae* that induces immunity against the exotoxin of this organism. Two strengths of diphtheria toxoid are available in the United States: the pediatric strength (D) and the adult strength (d), which contains less antigen because of the higher rate of adverse effects seen when the pediatric strength is used in adult patients.³⁰ The widespread use of diphtheria toxoid essentially has eliminated diphtheria from the United States.

Primary immunization with diphtheria toxoid (D) is indicated for children older than 6 weeks of age. The usual dose is 0.5 mL IM at rotating sites. Generally, the toxoid is given in combination with tetanus toxoid and acellular pertussis vaccine (as DTaP or in combination with hepatitis B surface antigen and IPV as well) at 2, 4, and 6 months of age. Additional doses are given at 15 to 18 months of age and again at 4 to 6 years of age.^{30,31} Completing the primary diphtheria toxoid immunization series usually induces immunity of at least 10 years' duration in 90% of persons. Booster doses should be given every 10 years.

If primary immunization is given to an immunosuppressed patient, an additional dose of diphtheria toxoid should be administered 1 month following the return to normal immune status. Diphtheria toxoid may be administered to persons with mild febrile illnesses and with other live or killed vaccines.³⁰

For unimmunized adults, a complete three-dose series of diphtheria toxoid should be administered, with the first two doses given at least 4 weeks apart and the third dose given 6 to 12 months after the second. The combined preparation diphtheria-tetanus (Td) is recommended in adults because it contains less diphtheria toxoid than the pediatric dose and is associated with fewer reactions to the diphtheria component. It also includes the recommended tetanus toxoid, but it omits the pertussis component, which is not used in patients older than 7 years of age. All adults should receive booster doses of Td every 10 years. Adverse effects of diphtheria toxoid include mild to moderate tenderness, erythema, and induration at the injection site. Systemic reactions occur very rarely.³⁰

Diphtheria antitoxin is a sterile antitoxin derived from hyperimmunized horses and is indicated for immediate use in patients with diphtheria. Diphtheria antitoxin is used in addition to antibiotics. Antibiotics have no effect on the diphtheria toxin but must be used to control transmission of the organism. Sensitivity testing by performing an intradermal or scratch test and a conjunctival test should be done before administration. Desensitization should be performed prior to administration of diphtheria antitoxin in anyone with a positive hypersensitivity test. The diphtheria antitoxin is given IM or IV in a dosage related to the site and size of the diphtheric membrane, severity of illness, and duration of illness. The dose is the same for adults and children. The usual dose of diphtheria antitoxin is 20,000–40,000 units for pharyngeal disease, 40,000–60,000 units for nasopharyngeal lesions, and 80,000–120,000 units for extensive disease of 3 days or more. When given IV, the dose should be diluted 1:20 in 0.9% saline or dextrose 5% in water and infused at 1 mL/min after being warmed to 32 to 34°C (89.6 to 93.2°F).³⁰

Adverse reactions to diphtheria antitoxin include anaphylactic reactions in 7% of patients, serum sickness occurring 12 days postadministration, or both. Serum sickness may be accelerated (7 to 12 days) in persons previously sensitized. Fortunately, the widespread use of diphtheria toxoid has greatly reduced the incidence of the disease and thus the use of diphtheria antitoxin.

TETANUS TOXOID, TETANUS TOXOID ADSORBED, AND TETANUS IMMUNOGLOBULIN

Tetanus is a severe acute illness caused by the exotoxin of *Clostridium tetani*. Sustained muscle contractions are characteristic of tetanus. Tetanus toxin interferes with neurotransmitters that promote muscle relaxation leading to continuous muscle spasms. Death can be due to the tetanus toxin itself or secondary to a complication such as aspiration pneumonia, dysregulation of the autonomic nervous system, or pulmonary embolism.

TABLE 122–2. Tetanus Prophylaxis

| | Clean, Minor | | All Other | |
|-----------------------------------|-----------------|-----|-----------------|-----|
| Vaccination history | Td | TIG | Td | TIG |
| Unknown or fewer than three doses | Yes | No | Yes | Yes |
| Three or more doses | No ^a | No | No ^b | No |

^aYes if more than 10 years since last dose.

^bYes if more than 5 years since last dose.

Tetanus toxoid and tetanus toxoid adsorbed (adsorbed onto aluminum hydroxide, phosphate, or potassium sulfate to increase antigenicity) are sterile suspensions of the toxoid derived from *C. tetani*. Both toxoids are used to promote active immunity against tetanus; however, tetanus toxoid adsorbed is the preferred agent because it elicits a greater immune response and is associated with fewer adverse reactions.

Although a single dose of tetanus toxoid in a nonimmunized individual does not produce sufficient antibody response, a series of three 0.5-mL doses results in protection for 90% of vaccinees. Primary vaccination provides protection for at least 10 years. Additional doses of tetanus toxoid (combined with diphtheria toxoid, i.e., Td) are recommended as part of traumatic wound management if a patient has not received a dose of tetanus toxoid within the preceding 5 years. For minor or clean wounds, no dose is given. Table 112–2 summarizes these recommendations. Tetanus immunoglobulin (TIG) also should be given to individuals who have received fewer than three doses of tetanus toxoid and have more serious wounds. It can be administered with tetanus toxoid, provided that separate syringes and separate injection sites are used.³¹

In children, primary immunization against tetanus usually is offered in conjunction with diphtheria and pertussis vaccination (using DTaP or a combination vaccine that includes hepatitis B and polio vaccines as well). A 0.5-mL dose is recommended at 2, 4, 6, and 15 to 18 months of age, but the first dose can be administered as early as 6 weeks of age.³¹ In children 7 years old and older and in adults who have not been immunized previously, a series of three 0.5-mL doses of Td are administered IM initially. The first two doses are given 1 to 2 months apart, and the third dose is recommended at 6 to 12 months after the second dose. Boosters are recommended every 10 years, and unless there is contraindication to diphtheria toxoid, Td should be used. Tetanus toxoid may be given simultaneously with other killed and live vaccines, and if indicated, it may be given to immunosuppressed patients.

Adverse reactions to tetanus toxoid include mild to moderate local reactions at the injection site, such as warmth, erythema, and induration. Rarely, fever, malaise, aches and pains, or neurologic disorders have been reported. In general, major local reactions occur within 2 to 8 hours of administration to patients with high serum tetanus antitoxin levels. This type of reaction is indicative of high preexisting antibody concentrations, and additional doses of toxoid should not be given any sooner than 10 years. Local reactions do not limit the use of the toxoid for further dosing. Although safety during pregnancy has not been definitely established, tetanus toxoid has been administered to pregnant women for the prevention of neonatal tetanus. Generally, waiting until the second trimester is suggested.

TIG is a sterile, concentrated, nonpyrogenic solution of immunoglobulins prepared from hyperimmunized humans. It is used to provide passive immunity to tetanus following the occurrence of traumatic wounds in nonimmunized or suboptimally immunized persons (see Table 122–2). A dose of 250–500 units IM should be

administered. When administered with tetanus toxoid, separate sites for administration should be used. Also, TIG is used for the treatment of tetanus. In this setting, a single dose of 3000–6000 units IM is administered.

Adverse effects of TIG include pain, tenderness, erythema, and muscle stiffness at the injection site, which may persist for several hours. Systemic reactions occur rarely. IV administration has been associated with severe adverse reactions and is not recommended.

VACCINES

H. INFLUENZAE TYPE B VACCINES

Before 1995, *H. influenzae* type b (Hib) was responsible for thousands of cases of serious illnesses (e.g., meningitis, epiglottitis, pneumonia, sepsis, and septic arthritis). The incidence of Hib disease has declined more than 99% since introduction of the conjugate vaccines based on the organism's capsular substance, polyribosyl ribitol phosphate (PRP).³²

The Hib vaccines in use are conjugate products consisting either of a polysaccharide or oligosaccharide of PRP covalently linked to a protein carrier. The protein carrier is important because it provides for T-lymphocyte–dependent immunologic response, whereas earlier Hib vaccines that consisted of only unconjugated PRP elicited a response that was T-cell-independent. T-cell involvement in the response provides for (1) a greater antibody response regardless of the age of the patient receiving the vaccine, (2) immunologic response at an earlier age (including infants), and (3) a booster effect on subsequent exposure to the Hib capsule, whether through revaccination or natural exposure. The protein carrier is not considered a vaccine and should not be substituted for immunization against tetanus, diphtheria, or *Neisseria meningitidis*.

The Hib conjugate vaccines are stable at 2 to 8°C (35.6 to 46.4°F) and should not be frozen. They are indicated for routine use in all infants and children younger than 5 years of age. Additionally, these three products differ in their immunogenicity and schedule of administration (Table 122–3). The primary series of Hib vaccination consists of a 0.5-mL IM dose at ages 2, 4, and 6 months if HbOC (HibTITER) or PRP-T (ActHIB) is used. If PRP-OMP is being used, the primary series consists of doses given at 2 and 4 months of age. A combination vaccine containing hepatitis B and Hib conjugate vaccines can be used for the primary series to decrease the number of injections needed for infant immunization.³³ The series should not be initiated in an infant younger than 6 weeks of age. Although use of one product for the entire primary series is desirable, adequate protection is achieved even when different products are used during the initial doses. Following the primary series, a booster dose is recommended at age 12 to 15 months. Any of the Hib conjugate vaccines are suitable for the booster dose regardless of which conjugate was used for the

TABLE 122–3. *H. influenzae* Type b Conjugate Vaccine Products

| Vaccine | Trade Name | Protein Carrier |
|---------|---------------------------|--|
| HbOC | HibTITER (Wyeth Vaccines) | Mutant diphtheria toxin protein |
| PRP-T | ActHIB (Aventis Pasteur) | Tetanus toxoid |
| PRP-OMP | PedvaxHIB (Merck) | <i>Neisseria meningitidis</i> serogroup B outer membrane protein |

The polysaccharide is polyribosyl-ribitol-phosphate (PRP).

primary series of doses.^{3,32} Additionally, the DTaP-Hib combination can be used for this booster dose.

Schedules become more complex for infants who do not begin their Hib immunization at the recommended age or who have fallen behind in the immunization schedule. For infants 7 to 11 months of age who have not been vaccinated, three doses of HbOC, PRP-OMP, or PRP-T should be given: two doses spaced 4 weeks apart and then a booster dose at age 12 to 15 months (but at least 8 weeks since dose two). For unvaccinated children ages 12 to 14 months, two doses should be given, with an interval of 2 months between them. In a child older than 15 months, a single dose of any of the four conjugate vaccines is indicated.³³ The American Academy of Pediatrics has made recommendations for children with lapsed immunization. For infants 7 to 11 months who have received one or two doses of Hib vaccine, one dose of vaccine with a booster dose give at least 8 weeks later at age 12 to 15 months should be given. For children 12 to 14 months who received two doses, a single dose is indicated. If the child received only one dose before 12 months of age, two additional doses separated by 8 weeks should be given. A single dose of vaccine is needed for a child who is 15 to 59 months of age and who has received any incomplete schedule.³⁴

Vaccines for Hib are recommended for routine use only for patients up through 59 months of age; beyond this age, most individuals will have natural immunity to Hib infection. Patients with certain underlying conditions (e.g., HIV infection, IgG₂ subclass deficiency, sickle cell disease, splenectomy, and bone marrow transplants and those receiving chemotherapy for malignancies) are at higher-than-normal risk for Hib infection, and use of at least one dose of vaccine in these patients should be considered, although efficacy data are lacking in most of these situations.^{14,35}

Adverse reactions to the Hib vaccine are uncommon. Erythema and induration at the injection site occur in approximately 25% of children and resolve within 24 hours. Fever, diarrhea, and vomiting are reported occasionally. Fever of greater than 38°C (100.4°F) is reported in 2.4% of children.

HEPATITIS VACCINES

Information on vaccination for viral hepatitis can be found in Chap. 40.

INFLUENZA VIRUS VACCINE

Influenza is respiratory illness that is characterized by abrupt onset of fever, myalgia, headache, severe malaise, cough, sore throat, and rhinitis. The illness typically resolves in several days but can exacerbate a chronic medical condition or lead to secondary bacterial pneumonia. Influenza activity each winter results in increased numbers of physician visits, hospitalizations, and deaths.

The Advisory Committee on Immunization Practices (ACIP) makes yearly recommendations concerning the use and composition of influenza virus vaccine. These are published in *Morbidity and Mortality Weekly Report* annually. The reader should refer to these annual guidelines as a supplemental update to this chapter.

Influenza is classified as type A or B, with influenza A further subtyped based on hemagglutinin (H) and neuraminidase (N) surface antigens. Influenza A causes significant disease in humans, and the virus is subject to mutation by a phenomenon known as *antigenic drift and shift*, resulting in the development of different influenza strains. Previous exposure to or vaccination against one strain does not confer protection against other strains. Influenza B, also a significant cause of

human disease, is less likely to mutate. The antigenic composition of influenza vaccine is determined from year to year by the predominant circulating strains worldwide and generally changes on a yearly basis.

Influenza vaccines are available as inactivated trivalent split or subunit vaccine or as a live attenuated vaccine administered intranasally. Though both types of influenza vaccine probably are equally effective in protection from infection,³⁶ they are indicated for distinct populations and should not be considered interchangeable.

The inactivated influenza vaccine preparations generally contain 45 mcg antigen in 15-mcg trivalent units per 0.5 mL and are administered by IM injection. Split-virus vaccine must be used for children from 6 months to 12 years of age. Children 6 to 35 months old receive 0.25 mL of split-virus vaccine. Two doses of vaccine administered at least 1 month apart are necessary for all children younger than 9 years of age who are receiving the vaccine for the first time. Split-virus vaccine is less reactogenic than whole-virus vaccine, particularly in children. Whole- or split-virus vaccine can be administered to individuals older than 12 years of age. However, whole-virus vaccines are not available in the United States.⁵

The live attenuated influenza vaccine (LAIV) is derived from a master influenza vaccine strain that has been adapted to grow at 25°C most efficiently. The hemagglutinin and neuraminidase antigens specific to the circulating strains are inserted into the master strain. LAIV is administered by spraying into each nostril of the vaccine recipient. The vaccine virus undergoes limited replication in the upper respiratory tract, inducing a local and systemic response. LAIV is indicated for healthy individuals aged 5 to 49 years. It should not be used in individuals who are at high risk of complications from influenza infection. Two doses separated by at least 6 weeks are needed for children aged 5 to 8 years who are receiving it for the first season. LAIV is packaged in a prefilled sprayer that must be frozen until use.^{36–39}

Response to influenza vaccine generally is measured in terms of antibody response and, more important, efficacy. The elderly and individuals with chronic diseases are less likely to develop antibody levels that are considered protective and may remain susceptible to influenza infection. However, vaccination confers protection from secondary complications and reduces the risk of hospitalization or pneumonia by 50% to 60% and death by 80%. Influenza vaccine is cost-effective in nursing home populations, in the elderly who live in the community, and in healthy working adults.^{39–41}

Annual influenza vaccination is strongly recommended for individuals over the age of 6 months with chronic medical conditions that make them at increased risk for the complications of influenza. Annual influenza vaccination should be given to (1) all individuals 50 years of age and older, (2) residents of nursing homes, (3) adults and children with chronic cardiovascular or pulmonary diseases including asthma, (4) adults and children with chronic metabolic disease, renal dysfunction, hemoglobinopathies, or immunosuppression (including immunosuppression from medications or HIV), (5) children and teenagers receiving chronic aspirin therapy, and (6) pregnant women. Children younger than 2 years of age have a risk of hospitalization equivalent to other individuals with high-risk conditions, and immunization of children aged 6 to 23 months is recommended. The inactivated influenza vaccine has not been studied in infants younger than 6 months. Immunization of their household contacts and out-of-home caregivers may decrease the risk of influenza infection in these young infants. In addition, the influenza vaccination should be recommended for the following groups that can transmit influenza to high-risk groups: (1) health care workers in both inpatient and outpatient settings, (2) employees of residential care facilities for high-risk patients, and (3) household members (including children)

of persons in high-risk groups. Finally, influenza vaccination should be offered to anyone wishing to avoid influenza infection.⁵ The optimal time period for influenza vaccination administration is October through mid-November. However, the vaccine can be administered to unvaccinated individuals in high-risk groups throughout the influenza season, which typically lasts until April. Administration of influenza vaccines is contraindicated in persons with known anaphylactic reaction to eggs or another component of the vaccine. Adults with acute febrile illness should be vaccinated when their symptoms have subsided. Vaccination need not be delayed in individuals with minor illness with or without fever.

Antiviral prophylaxis should be considered in individuals for whom the vaccine is contraindicated or for unvaccinated high-risk individuals as a bridge until a response to the vaccine has been mounted, usually about 2 weeks. Both amantadine and rimantadine are highly effective in preventing influenza A infection. Rimantadine is much better tolerated in the nursing home population.⁴² The neuraminidase inhibitors zanamivir and oseltamivir are effective for infection prophylaxis, although only oseltamivir is approved for influenza prevention.^{43,44}

Adverse reactions to the vaccine include local tenderness and low-grade fever in 3% to 5% of vaccinees beginning 6 to 12 hours postimmunization and lasting 1 to 2 days. Treatment with salicylates or acetaminophen is recommended. A slight increase in the risk of Guillain-Barré syndrome may follow in the weeks after influenza vaccination. The risk is estimated to be one case of Guillain-Barré syndrome per million doses of influenza vaccine administered.⁴⁵ Runny nose is the most commonly reported adverse reaction in both adults and children following administration of LAIV. Adults complained of headache and sore throat more frequently after receiving LAIV than after placebo. Children experienced higher rates of fever, vomiting, abdominal pain, and myalgias with vaccine than placebo. An increase in asthma and reactive airways disease was noted in a study of children aged 12 to 59 months. Therefore, the vaccine should not be used for children younger than 5 years old.⁴⁶

MEASLES VACCINE

Measles (rubeola) is a highly contagious viral illness that is characterized by rash and high fever. Complications of measles infections include severe diarrhea, otitis media, pneumonia, and encephalitis. Measles results in 1 to 2 deaths per 1000 cases, with the death rate being much higher in developing countries. With widespread vaccination, measles is on the verge of eradication in the Americas.⁴⁷

The measles vaccine is a live attenuated viral vaccine that produces a subclinical, noncommunicable infection. Approximately 95% of vaccine recipients seroconvert after a single dose, and most are protected for life.⁴⁸ Most persons failing to respond to the initial dose of measles vaccine will seroconvert following a second dose, and this forms the basis for the two-dose vaccine strategy that was implemented in the United States in 1989.

The measles vaccine is administered subcutaneously as a 0.5-mL dose in the arm (or in the thigh if the patient is younger than 15 months of age). The vaccine is administered routinely for primary immunization to persons 12 to 15 months of age, usually as the MMR vaccine. The measles vaccine is not administered earlier than 12 months (except in certain outbreak circumstances) because persisting maternal antibody that was acquired transplacentally late in gestation can neutralize the vaccine virus before the vaccinated person can mount an immune response. A second dose of MMR is recommended when

children are aged 4 to 6 years.³³ The second dose of vaccine results in seroconversion in 95% of those individuals who were first-dose nonresponders.⁴⁹

Measles-containing vaccine should not be given to pregnant women or immunosuppressed patients. The one exception is HIV-infected patients, who are at very high risk for severe complications if they develop measles.³ Persons with HIV infection who have never had measles or have never been vaccinated against it should be given measles-containing vaccine unless there is evidence of severe immunosuppression. The second dose should be given 1 month later rather than waiting for entry to school.

Recent administration of immunoglobulin interferes with measles vaccine response, so the recommended interval between the immunoglobulin and vaccine is determined by the dose of immunoglobulin³ (see Table 122-1). The administration of other live vaccines not administered on the same day should be delayed for at least 30 days following measles or MMR vaccine. Live measles vaccine may suppress a positive tuberculin skin test for up to 6 weeks postadministration.³ Historically, persons with a history of anaphylactic reaction to egg protein were considered to be at high risk for serious reactions to measles vaccine, a product derived from chick embryo fibroblasts. However, the risk of measles vaccination to egg-allergic patients has been shown to be exceedingly low. Therefore, individuals in need of measles vaccine should receive it regardless of a history of egg allergy.⁴⁸ A history of serious neomycin hypersensitivity remains a contraindication to measles vaccine use because each 0.5-mL dose contains 25 mcg neomycin. Finally, mild febrile illness and upper respiratory tract infections are not contraindications to vaccination.⁴⁸

Measles vaccination is indicated in all persons born after 1956 or in those who lack documentation of wild virus infection either by history or antibody titers. Persons who received killed measles vaccine alone, who were given live vaccine within 3 months of receiving killed vaccine, or who received a vaccine of unknown type between 1963 and 1967 should be revaccinated. Revaccination should be considered for students entering college because of outbreaks on college campuses. It is also important to vaccinate health care workers who have no documentation of vaccination and who were born in 1957 or later because of the possibility of becoming infected by patients and transmitting the disease to their patients.⁵⁰ If two doses are needed (the person has never been vaccinated), the doses should be given at least 1 month apart. Following vaccination, antibodies may be detected within 2 to 3 weeks in patients 12 months of age or older.

For postexposure prophylaxis, the vaccine is effective if given within 72 hours of exposure. In addition, immunoglobulin may be administered at a dose of 0.25 mg/kg IM (maximum dose 15 mL) if given within 6 days of exposure. In infants, postexposure vaccination may be given as early as 6 months of age, but it should be repeated at 12 to 15 months of age.

The measles vaccine has an excellent safety record. The most common side effect following vaccination is fever, which occurs in 5% to 15% of vaccinees. Transient generalized rash may occur in about 5% of vaccine recipients. These reactions generally appear 5 to 12 days postvaccination and last 2 to 5 days. Other adverse effects, such as headache, cough, sore throat, eye pain, malaise, and transient thrombocytopenia, occur less frequently. Local reactions at the injection site, while rare, may occur in subjects who have been vaccinated previously with killed vaccine. No association between MMR vaccination and the development of autism has been made following extensive study.⁵¹⁻⁵³ Febrile seizures occur rarely, and there is no association between MMR vaccination and the development of a subsequent seizure disorder.⁵⁴

MENINGOCOCCAL POLYSACCHARIDE VACCINE

N. meningitidis is a leading cause of meningitis and sepsis in children and young adults in the United States. The vast majority of cases are sporadic, although the frequency of outbreaks, most often involving serogroup C, is increasing.

A quadrivalent vaccine containing capsular polysaccharides for serotypes A, C, Y, and W-135 has been available since the early 1970s. Although serogroup B causes approximately one-third of all cases, it has not been incorporated into the vaccine because group B polysaccharide is not immunogenic. The meningococcal polysaccharide vaccine is indicated in high-risk populations, such as those exposed to the disease, those in the midst of uncontrolled outbreaks, travelers to an area with epidemic or hyperendemic meningococcal disease, or individuals who have terminal complement component deficiencies or asplenia.

College freshmen, particularly those living in dormitories or residence halls, are at modestly increased risk of invasive meningococcal disease as compared with the rest of the population in this age group.^{55,56} The Advisory Committee on Immunization Practices recommends that health care providers inform students and parents about the increased risk and that a safe, effective vaccine is available. The meningococcal polysaccharide vaccine should be made easily available for college freshmen wishing to decrease their risk for meningococcal disease.

Meningococcal polysaccharide vaccine is administered subcutaneously as a single 0.5-mL dose. Vaccinees should be older than 2 years of age because of the difficulty younger patients have responding to polysaccharide antigens. Younger children may produce sufficient antibody levels against serogroup A, however, if given two doses 3 months apart. Antibody levels thought to be protective are attained within 10 to 14 days. Revaccination may be considered in 2 to 3 years in high-risk children who are younger than 4 years of age on initial vaccination because of rapid antibody decline. Older children and adults who remain at high risk should be revaccinated after 3 to 5 years. The vaccine shows documented effectiveness in preventing meningococcal disease in 85% to 95% of recipients for serotypes A and C.⁵⁶ Efficacy of the vaccine for serotypes Y and W-135 is presumed but not documented. Adverse effects of meningococcal polysaccharide vaccine include fever and erythema at the injection site lasting 1 to 2 days.

MUMPS VACCINE

Mumps is a viral illness that classically causes bilateral parotitis 16 to 18 days after exposure. Fever, headache, malaise, myalgia, and anorexia may precede the parotitis. Serious complications are rare, although more common in adults. The mumps vaccine is a lyophilized live attenuated vaccine prepared from chick embryo cultures. Each 0.5-mL dose of the vaccine also contains 25 mcg neomycin. The vaccine is available alone or in combinations with measles and rubella vaccines.

The mumps vaccine is used to produce active immunity while producing a subclinical, noncommunicable infection. A single dose induces antibody formation in 97% of children older than 12 months of age and 93% of adults. Clinical efficacy ranges from 75% to 95%. The duration of immunity following vaccination is unknown, but data collected in the 30 years of use indicate that the efficacy persists.⁴⁸

The vaccine usually is given in combination with measles and rubella vaccines (as MMR) and is administered as a 0.5-mL subcutaneous injection in the upper arm. Dosing recommendations coincide with those for measles vaccine, with the first dose being administered

at age 12 to 15 months and the second dose prior to entry into elementary school. If the vaccine is given before 12 months of age, revaccination is necessary and should be given after reaching 1 year of age. The vaccine is also indicated in previously unvaccinated adults born in 1957 or later, in those who have been vaccinated previously with killed mumps vaccine (an older product no longer available), and in those with an uncertain history of wild virus infection. Postexposure vaccination is of no benefit.⁴⁸

Mumps vaccine should not be given to pregnant women or immunosuppressed patients. Additionally, conception should be avoided for 28 days following vaccination.⁵⁷ Anaphylactic reactions to mumps-containing vaccines are very rare and generally not associated with hypersensitivity to eggs. Therefore, egg allergy is not a contraindication to vaccination. The effect of immunoglobulin preparations on mumps vaccine response is unknown, but the response to measles and rubella is compromised if administered after immunoglobulins. The recommended interval between the immunoglobulin and vaccine is determined by the dose of immunoglobulin³ (see Table 122–1). Finally, the vaccine should not be given to individuals with anaphylactic reactions to neomycin.

Serious adverse reactions to the vaccine are reported rarely. Parotitis, rash, pruritus, and purpura occur rarely. Local reactions, including soreness, burning, and stinging, may occur at the injection site.

PERTUSSIS VACCINE

Pertussis is caused by a bacterial infection with *Bordetella pertussis*. The illness is characterized by paroxysms of coughing to expel thick mucus. In the early part of this century, pertussis was a common childhood infection and was a significant cause of childhood mortality. In recent years, the incidence of disease has been increasing in all age groups. Although infants and young children remain at highest risk for infections and its complications, investigators recently determined that older adults also are at increased risk of complications from pertussis.⁵⁸

Acellular pertussis vaccines contain selective components of the *B. pertussis* organism. All acellular vaccines contain pertussis toxin (PT), and some contain one or more additional bacterial components (e.g., filamentous hemagglutinin [FHA], pertactin [a 69-kDa outer membrane protein], and fimbriae types 2 and 3). Acellular pertussis vaccine is recommended for all doses of the pertussis schedule at 2, 4, 6, and 15 to 18 months of age. A fifth dose of pertussis vaccine is given to children 4 to 6 years of age.^{33,59} Pertussis vaccine is administered in combination with diphtheria and tetanus (DTaP). Although the pertussis vaccine is not recommended for individuals 7 years of age and older, booster doses for adolescents and adults may be incorporated into future recommendations because members of these groups are important reservoirs of infection.

Local administration site reactions occur relatively commonly. Systemic reactions, such as moderate fever, occur in 3% to 5% of vaccinees. Very rarely, high fever, febrile seizures, persistent crying spells, and hypotonic hyporesponsive episodes occur following vaccination. Allergy to a vaccine component and encephalopathy without known cause within 7 days of a pertussis vaccine are contraindications to future doses of vaccine. Efficacy of the vaccine is estimated to be about 80%.⁵⁹

PNEUMOCOCCAL VACCINES

S. pneumoniae is a common pathogen with a range of manifestations including asymptomatic upper respiratory tract colonization,

sinusitis, acute otitis media, pharyngitis, pneumonia, meningitis, and bacteremia. Rates of invasive infections are highest in children under 2 years of age (approximately 200 per 100,000 population). The incidence increases again to 61 per 100,000 population in the elderly. In between the two age extremes, the incidence of invasive disease is about 24 per 100,000 population. Invasive pneumococcal infections cause approximately 40,000 deaths annually. Most of the deaths occur in the elderly or in those with underlying medical conditions. Approximately half the deaths could be vaccine-preventable. Two pneumococcal vaccine preparations, 23-valent pneumococcal polysaccharide vaccine (PPV23) and heptavalent pneumococcal conjugate vaccine (PCV7), are available. The vaccines have different indications and are not interchangeable.

PNEUMOCOCCAL POLYSACCHARIDE VACCINE

Pneumococcal polysaccharide vaccine (Pneumovax 23 and Pnu-Immune 23) is a mixture of highly purified capsular polysaccharides from 23 of the most prevalent or invasive types of *S. pneumoniae* seen in the United States. Serotypes included are 1, 2, 3, 4, 5, 6B, 7F, 8, 9N, 9V, 10A, 12F, 14, 15B, 17F, 18C, 19A, 20, 22F, 23F, and 33F. These 23 types represent 85% to 90% of all blood isolates and 85% of pneumococcal isolates from other generally sterile sites seen in the United States. The vaccine is administered intramuscularly or subcutaneously as a single 0.5-mL dose. Each 0.5-mL dose of vaccine contains 25 mcg of each polysaccharide type dissolved in isotonic saline solution (for a total of 575 mcg polysaccharide) and 0.25% phenol as preservative. Significant cross-reactivity with other pneumococcal capsular antigens not represented in the vaccine does not occur.⁶⁰

PPV23 is recommended for the following immunocompetent persons⁶⁰:

- Persons 65 years of age or older (If an individual received vaccine more than 5 years earlier and was younger than age 65 at the time of administration, revaccination should be given.)
- Persons aged 2 to 64 years with a chronic illness
- Persons aged 2 to 64 years with functional or anatomic asplenia (When splenectomy is planned, PPV23 should be given at least 2 weeks prior to surgery. A single revaccination is recommended at 5 years in subjects older than 10 years of age and at 3 years in subjects younger than 10 years of age.)
- Persons aged 2 to 64 years of age living in environments where the risk of invasive pneumococcal disease or its complications is increased (This does not include day-care center employees and children.)

PPV23 is recommended for immunocompromised persons 2 years of age or older with (1) HIV infection, (2) leukemia, (3) lymphoma, (4) Hodgkin's disease, (5) multiple myeloma, (6) generalized malignancy, (7) chronic renal failure or nephrotic syndrome, (8) patients receiving immunosuppressive therapy including corticosteroids, and (9) organ and bone marrow transplant recipients. A single revaccination should be given if 5 years or more have passed since receipt of the first dose in subjects older than 10 years of age. In subjects 10 years of age or younger, revaccination should be given 3 years after the previous dose.

PPV23 induces type-specific antibodies (T-cell-independent mechanisms) with a twofold rise within 2 to 3 weeks in 80% of young healthy adults. No correlation of antibody levels and protection has been determined. Antibody levels to these strains remain elevated for at least 5 years. In certain individuals, these levels decline within 10 years. Children may be protected for only 3 to 5 years. Elderly

individuals and patients with chronic disease may have lower antibody levels produced with the vaccine. Children younger than 2 years of age do not respond adequately to the vaccine.

A number of other groups, including immunocompromised patients (e.g., leukemia, lymphoma, and multiple myeloma), dialysis patients, and acquired immunodeficiency syndrome (AIDS) patients, have reduced antibody production with the vaccine. Asymptomatic HIV-infected patients respond sufficiently to the vaccine. Patients with Hodgkin's disease respond to the vaccine better before splenectomy, chemotherapy, or radiation therapy.

PPV23 vaccine efficacy has been debated in the literature. Although prelicensure trials in young, healthy gold miners in South Africa showed a reduction in nonbacteremic disease rates, in the postmarketing period, randomized clinical trials performed in elderly persons with chronic disease did not confirm these findings.⁶⁰ A large study of elderly individuals demonstrated a decreased risk of pneumonia caused by *S. pneumoniae* in vaccinated individuals but showed no change in the risk of community-acquired pneumonia even though most community-acquired pneumonias are caused by *S. pneumoniae*.⁶¹ For invasive disease, reduction rates of 56% to 81% have been shown with the vaccine. A meta-analysis of nine randomized, controlled trials concluded that the vaccine was efficacious in reducing the frequency of bacteremic pneumococcal disease among adults in low-risk groups. Cost-effectiveness also has been shown.⁶⁰

While the safety of PPV23 during the first trimester of pregnancy has not been evaluated, no adverse effects have been seen in newborns whose mothers received the vaccine during pregnancy.⁶⁰

PPV23 safety is well documented. Local reactions occur frequently within the first 48 hours and generally are mild. Local erythema and induration (30%), local discomfort (40%), and local swelling (3%) are the side effects observed most commonly. Revaccination has been associated with self-limited injection-site reactions more commonly than after the first dose.⁶² Rarely, severe systemic reactions can occur, and they consist of weakness, myalgia, headache, photophobia, chills, and fever. Guillain-Barré syndrome has not been reported. In patients with HIV infection, pneumococcal vaccine may cause a transient increase in viral replication, but the importance of this is unknown.

PNEUMOCOCCAL CONJUGATE POLYSACCHARIDE VACCINE

Because of the lack of immune responsiveness in children younger than 2 years of age when exposed to polysaccharide vaccines, manufacturers have been developing conjugate vaccines to offer children protection from certain strains of *S. pneumoniae*. Formation of serotype conjugates to ensure stability and immunogenicity of each strain is complex and difficult. Thus work has progressed slowly.

Currently, a heptavalent vaccine (Prevnar) is available for use in children. This vaccine contains the conjugated capsular polysaccharides of serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F, which cause approximately 80% of pediatric pneumococcal bacteremias in the United States.⁶³ The vaccine elicits a primary T-cell-dependent antibody response with the first dose and an immunologic memory effect after four doses.

PCV7 is administered as a 0.5-mL IM injection at 2, 4, and 6 months of age and between 12 and 15 months of age. PCV7 also should be used in older children aged 24 to 59 months who are at high risk. Children with sickle cell disease or splenic dysfunction, HIV infection, immunocompromising conditions, or chronic illnesses should be immunized. PPV23 can be used in conjunction with

PCV7. PPV23 should be administered after 2 years of age and at least 2 months after the last dose of PCV7.

The vaccine was 100% effective in preventing invasive disease by vaccine serotypes.⁶⁴ In clinical use, the vaccine is associated with a dramatic decline in invasive disease not only in vaccinees but also in adults. A 35% decline in the rate of disease caused by penicillin-resistant isolates also has been noted.⁶⁵

The vaccine series generally is well tolerated. Injection-site reactions and fever were the most commonly reported adverse effects.⁶³

POLIOVIRUS VACCINES

Poliomyelitis is a contagious viral infection that usually causes asymptomatic infection but in its serious form causes acute flaccid paralysis. Poliovirus is spread via the fecal-oral route. The virus replicates in the upper respiratory tract, gastrointestinal tract, and local lymphatics. The vast majority of polio infections are subclinical and asymptomatic. Indigenous polio has been absent from the United States since 1979, and the last case in the Americas was reported in 1991. Global eradication efforts are entering the final stages, and the eradication of polio should be accomplished in the next few years.

An inactivated trivalent vaccine developed by Jonas Salk was licensed for use in 1955. In 1987, an enhanced-potency inactivated polio vaccine (IPV) was introduced, and it has replaced the original inactivated vaccine. A live attenuated oral polio vaccine (OPV) was developed by Albert Sabin in 1962. OPV was the primary immunizing agent for poliovirus infection. Widespread OPV use is responsible for eradication of wild-type polio in most of the world. However, with no poliovirus circulation in the United States for years, IPV is the recommended vaccine for the primary series and booster dose for children. OPV will continue to be used in the areas of the world that have circulating poliovirus. The CDC maintains a stockpile of OPV to be used only in case of an outbreak.⁶⁶

The IPV series is administered routinely to children at ages 2, 4, and 6 to 18 months, and 4 to 6 years. Protective antibodies to all three serotypes develop in 90% to 100% of children after two doses of vaccine. After three doses, 99% to 100% develop protective immunity, and the fourth dose results in long-term immunity.⁶⁶

Primary poliomyelitis immunization is recommended for all children up to age 18. Primary immunization of adults over the age of 18 is not recommended routinely because a high level of immunity already exists in this age group and the risk of exposure in developed countries is exceedingly small. Unimmunized adults who are at increased risk for exposure because of travel, residence, or occupation should, however, receive IPV series. Incompletely immunized adults or children should complete the series of IPV regardless of the interval since initiation of primary immunization. Adults do not need a booster dose routinely unless there is an increased risk of exposure (travel), in which case a single dose of IPV can be given.⁶⁶

Allergies to any component of IPV, including streptomycin, polymyxin B, and neomycin, are contraindications to vaccine use. There are no serious side effects attributable to IPV, and the only other contraindication is pregnancy, in which case IPV should be given only if there is a clear need, such as women who will be traveling or living in an area with endemic or epidemic poliovirus. IPV is recommended for immunodeficient individuals and their household contacts. Although the response may be lower, some protection against infection may be conferred.⁶⁶

The routine use of OPV in the United States has been discontinued because OPV is rarely associated with vaccine-associated paralytic poliomyelitis (VAPP) in vaccinees (1 in 6.2 million doses) or

contacts (1 in 7.6 million doses). Individuals with primary immune deficiency are at increased risk for this adverse reaction,⁶⁷ and for this reason, OPV is not recommended for persons who are immunodeficient or for normal individuals who reside in a household with an immunocompromised person. The use of OPV is reserved for polio outbreak control.⁶⁶

RABIES VACCINE

Human diploid cell vaccine (HDCV), rabies vaccine adsorbed (RVA), and purified chick embryo cell culture rabies vaccine (PCEC) are killed vaccines used for preexposure and postexposure rabies virus prophylaxis. Transmission of rabies can occur via percutaneous, mucosal, or airborne exposure to the rabies virus. Circumstances favoring such transmission include animal bites or attacks and contamination of scratches, cuts, abrasions, or mucous membranes with saliva or other infectious material (brain tissue). Unprovoked attacks and daytime attacks by nocturnal animals are considered highly suspect. Common wild animal transmitters include skunks, coyotes, foxes, and raccoons. Almost 60% of human rabies deaths in the United States since 1980 were associated with bat contact. Canine rabies is very common in many foreign countries (most of Asia, Africa, and Latin America). Rodents, rabbits, and hares are infected rarely. There have been a few reports of a person-to-person transmission.^{68,69}

Preexposure indications for using HDCV, RVA, or PCEC include persons whose vocation or avocation place them at high risk for rabies exposure, e.g., veterinarians, animal handlers, laboratory workers in rabies research laboratories, and field personnel (trappers, hunters, cave explorers). Travelers who will be in a country or area of a country where there is a constant threat of rabies, whose stay is likely to extend beyond 1 month, and who may not have readily available medical services (e.g., Peace Corps workers and missionaries) also should be considered for preexposure prophylaxis.⁶⁹ Rabies immunization of immunocompromised individuals should be postponed until the immunosuppression has resolved, or activities should be modified to minimize the potential exposure to rabies. If the vaccine is used in immunocompromised persons, it should be given by the IM route only, and antibody titers should be checked postimmunization. Pregnancy is not a contraindication if the risk of rabies is great. A rabies immunization series should be completed with the same product because no data exist on interchangeability of products.

All three vaccine preparations may be administered for preexposure prophylaxis as a three-dose series of 1 mL IM on days 0 and 7 and once between days 21 and 28. Alternatively, HDCV can be administered intradermally in a dose of 0.1 mL using the same schedule. HDCV must be given using the specific intradermal dosage form and syringe. Lower rabies antibody concentrations have been observed in individuals immunized using the intradermal route while taking malaria prophylaxis concurrently. The IM route is recommended in this situation.⁶⁹

Individuals with ongoing risk of exposure—either continuous risk (e.g., research laboratory staff or those involved in rabies biologics production) or individuals with frequent exposures (e.g., those involved with rabies diagnosis, spelunkers, veterinarians, animal control workers, and wildlife workers in rabies-zoonotic areas) should undergo serologic testing every 6 months and 2 years, respectively, to monitor rabies antibody concentrations. An IM or intradermal booster dose is recommended if the complete virus neutralization is below 1:5 serum dilution by the rapid fluorescent focus inhibition test.

Preexposure prophylaxis does not eliminate the need for postexposure therapy. Persons previously immunized with HDCV, RVA,

or PCEC or those who have received postexposure prophylaxis previously should receive two 1-mL IM doses of HDCV, RVA, or PCEC on postexposure days 0 and 3. Rabies immunoglobulin should not be given to this group.

Postexposure prophylaxis should be given after percutaneous or mucosal exposure to saliva or other infectious material from a high-risk source. Each case needs to be considered individually. Consideration needs to be given to the geographic area, species of animal, circumstances of the incident, and type of exposure. Local or state health departments should be contacted for assistance. Thorough cleansing of the wound with soap and water followed by irrigation with a virucidal agent such as povidone-iodine solution is an extremely important part of the management of rabies-prone wounds. Individuals who have not been immunized previously should receive the recommended regimen of rabies immunoglobulin (see rabies immunoglobulin section) and five doses of HDCV, RVA, or PCEC 1 mL IM on days 0, 3, 7, 14, and 28 after exposure.⁶⁹ The intradermal route should not be used for postexposure prophylaxis.

Intramuscular vaccine should be given in the deltoid muscle in adults and in the anterolateral thigh in children. The gluteal region should not be used. The lateral aspect of the deltoid should be used for intradermal injection of HDCV when used for preexposure prophylaxis.

Adverse reactions to HDCV, RVA, and PCEC are less common and less serious with the currently available vaccines compared with previously used preparations. Injection-site reactions, including pain, erythema, swelling, and itching, are reported frequently. Another 5% to 40% of vaccinees may have headache, nausea, abdominal pain, muscle aches, dizziness, or a combination of these. Systemic allergic reactions ranging from hives to anaphylaxis occur in a very small number of subjects. Given the lack of alternative therapy and that rabies infection is almost always fatal, persons exposed to rabies who do have adverse reactions should continue the vaccine series in a setting with medical support services. In persons receiving booster doses of HDCV, an immune-complex-like disease has been seen 2 to 21 days later in as many as 6% of vaccinees.⁶⁹

RABIES IMMUNOGLOBULIN

Human rabies immunoglobulin is used in conjunction with rabies vaccine as part of postexposure rabies management for previously unvaccinated individuals. The product is derived from plasma obtained from donors who have been hyperimmunized with rabies vaccine and have high titers of circulating antibody.

In persons who have not been immunized against rabies previously, rabies immunoglobulin is given simultaneously with rabies HDCV, RVA, or PCEC to provide optimal coverage in the interval before immune response to the vaccine occurs. The efficacy of this regimen has been clearly demonstrated. In situations in which a vaccine has been used alone, mortality rates of 50% to 60% have been observed. Mortality after the combination vaccine and rabies immunoglobulin regimens is an exceedingly rare event; however, failures have been reported when the wound was not infiltrated with rabies immunoglobulin.⁷⁰

Rabies immunoglobulin does not interfere with vaccine-induced antibody formation. Its use is not recommended beyond 8 days after initiation of the vaccine series nor in persons previously immunized to rabies.

Human rabies immunoglobulin is administered in a dose of 20 IU/kg (0.133 mL/kg). If anatomically feasible, the entire dose should be infiltrated around the wound(s). Any remaining volume should be administered intramuscularly at a site distant from the

rabies vaccination site. This product should never be administered by the intravenous route. Because other antibodies in the rabies immunoglobulin may interfere with the response to live-virus vaccines (MMR and varicella), it is recommended that these immunizations be delayed for 3 months.³

Side effects are rare but may include local soreness at the wound or IM injection site and mild temperature elevations. Caution is advised when administering this product to persons with known systemic allergies to immunoglobulin or thimerosal. Pregnancy is not a contraindication for its use.

RUBELLA VACCINE

An erythematous rash, lymphadenopathy, arthralgia, and low-grade fever characterize rubella (German measles). As many as 20% to 50% of rubella infections are asymptomatic.⁷¹ The most important consequence of rubella infection occurs during pregnancy, particularly during the first trimester. Congenital rubella syndrome is associated with auditory, ophthalmic, cardiac, and neurologic defects. Rubella infection during pregnancy also can result in miscarriage or stillbirth. The primary goal of rubella immunization is to prevent congenital rubella syndrome.

Rubella vaccine contains lyophilized live attenuated rubella virus grown in human diploid cell culture. The vaccine is available alone or in combination with measles or mumps vaccine or both. Each 0.5-mL dose also contains 25 mcg neomycin.

Rubella vaccine induces antibodies that are protective against wild-virus infection. Following a single 0.5-mL subcutaneous dose, 98% of children 1 year of age or older become rubella antibody-positive within 2 to 6 weeks.⁷² The duration of immunity has not been established. A second dose is recommended, however, at the same time measles vaccine is administered (as a second dose of MMR). The vaccine is indicated for children older than 1 year of age. Although individuals born before 1957 are assumed to be immune to rubella, this is not sufficient for women who could become pregnant. Therefore, all women of childbearing potential should have documentation of receiving at least one dose of a rubella-containing vaccine or laboratory evidence of immunity.⁷¹ Recent administration of immunoglobulin interferes with rubella vaccine response for at least 3 months and depends on the dose of immunoglobulin that is administered.^{3,48,71} Table 122-1 can be used as a guide for the recommended interval. The vaccine should not be given to immunosuppressed individuals, although MMR vaccine should be administered to young children with HIV infection without severe immunosuppression as soon as possible after their first birthday.⁴⁸ The vaccine should not be given to individuals who have experienced anaphylactic reactions to neomycin.⁴⁸

Adverse effects of the rubella virus vaccine tend to increase with the age of the recipient. Symptoms are similar to wild-virus infection and include lymphadenopathy, rash, urticaria, fever, malaise, sore throat, headache, myalgias, and paresthesias of the extremities. These occur 7 to 12 days after vaccination and last 1 to 5 days. Joint symptoms occur more often in susceptible postpubertal females. Arthralgia occurs in 25% of such vaccinees, and 10% will have arthritis-like symptoms. These symptoms usually begin 1 to 3 weeks after vaccination and persist for 1 day to 3 weeks. A very small excess risk of chronic arthropathy exists.⁷³ The vaccine may cause suppression of tuberculin skin tests for up to 6 weeks after vaccination. While the vaccine virus may be excreted in nose and throat secretions, it is not contagious.

Although the rubella vaccine has never been associated with congenital rubella syndrome, its use during pregnancy is contraindi-

cated. However, routine pregnancy testing prior to vaccination is not recommended. Women should be counseled not to become pregnant for 4 weeks following vaccination.⁵⁷ Termination of pregnancy is not indicated in women who are accidentally given the vaccine or who become pregnant during the month after vaccination.

VARICELLA VACCINE

Varicella is a highly contagious disease caused by varicella-zoster virus. The clinical illness is characterized by the appearance of successive waves of pruritic vesicles that rapidly crust over. Malaise and fever are common and last for 2 to 3 days. The virus remains dormant in the dorsal ganglia and reactivates as herpes zoster, also known as *shingles*. Although the exact stimulus for reactivation is unknown, a decrease in varicella-specific cell-mediated immunity associated with age or immunosuppression appears to be necessary but not sufficient for reactivation.

Live attenuated varicella vaccine contains the Oka-Merck strain of varicella virus, which was attenuated by propagation through several different cell culture lines. Varicella vaccine is a lyophilized product that must be kept frozen and protected from light. Once reconstituted, it must be administered subcutaneously within 30 minutes. Each 0.5-mL dose contains a minimum of 1350 plaque-forming units of virus, as well as 12.5 mg of hydrolyzed gelatin and trace amounts of neomycin, fetal bovine serum, and residual components from cell culture.¹⁵

The varicella vaccine is safe and immunogenic in healthy children and adults. A single dose results in seroconversion in greater than 94% of healthy children, and over 90% have persisting antibodies 1 year later. Studies in normal, healthy adults have shown lower seroconversion rates (as low as 80%) following a single dose, but this increases to 95% when a two-dose regimen is used. In clinical studies, varicella vaccine has been 70% to more than 95% effective in preventing chickenpox. Vaccinated individuals who develop chickenpox typically experience milder disease, with less fever and fewer skin lesions, many of which do not vesiculate. Similarly, vaccinated individuals who develop breakthrough infections transmit the varicella virus to others at a lower rate.⁷⁴

The duration of protection provided by varicella vaccine is unknown but is believed to be long lasting. Potential self-boosting of vaccinated individuals as the latent vaccine virus reactivates in those with the lowest varicella antibody titer is one possibility by which lifelong immunity may be conferred.⁷⁵ Additionally, children who are immunized against varicella and then exposed to wild-virus experience an immunologic boost.⁷⁵ As varicella vaccine use becomes more widespread, the circulation of wild virus can be expected to diminish, and the opportunity for immunologic boosting because of natural exposure also will decline. It is not known whether booster doses will be needed under these circumstances or if reactivation of latent vaccine virus will be sufficient to confer long-term protection. Long-term studies assessing the duration of protection and the advisability of booster doses are ongoing.

The varicella vaccine is recommended for all children at 12 to 18 months of age. It is also recommended for patients above this age if they have not already had chickenpox. Individuals who are 12 months to 12 years of age require one dose. Persons 13 years of age and older should receive two doses, separated by 4 to 8 weeks.⁷⁴ Varicella vaccine can be used for postexposure prophylaxis. The vaccine is effective in the prevention or modification of varicella infection when given within 3 days and possibly 5 days of exposure.⁷⁶ Because the varicella vaccine is a live vaccine, it is contraindicated in pregnant

or immunocompromised individuals. An exception is that children with asymptomatic or mildly symptomatic HIV infection should receive two doses of varicella vaccine 3 months apart. Also, children with humoral immune deficiencies may be immunized.¹⁵ Varicella vaccination is contraindicated in individuals with a history of anaphylactic reaction to any component of the vaccine. Persons who have received blood, plasma, or immunoglobulin products in recent past should not receive varicella vaccine because of concern that passively acquired antibody will interfere with response to the vaccine. The recommended time interval between antibody-containing products and varicella vaccine depends on the dose of immune globulin (see Table 122-1). Although no adverse events associated with salicylate use after vaccination have been reported, salicylates should be avoided for 6 weeks after vaccination because of the association of salicylate use and Reye's syndrome following varicella infection.⁷⁴

The varicella vaccine has an excellent safety record. Pain, local swelling, and erythema at the injection site occur in up to 32% of patients and fever in 10% to 15%. A varicella-like rash occurs in approximately 4% of vaccinees, accompanied by few, if any, systemic symptoms. The rash may be localized at the injection site or generalized. Lesions are usually few in number (2 to 10) and often papular rather than vesicular. Transmission of vaccine virus to susceptible close contacts has occurred, but it is very rare and is believed to occur only when the vaccinee develops a rash. Because the risk of vaccine virus transmission is very low and primary infection can be very severe, vaccination of household contacts of immunocompromised patients is recommended to prevent introduction of varicella into the household.^{15,74}

Acquisition of either wild virus or the vaccine strain of varicella renders an individual susceptible to zoster (shingles) at a later date because of reactivation of latent virus. Data indicate that following varicella vaccination, zoster occurs less frequently than following natural infection.¹⁵ In fact, the varicella vaccine is being investigated as a means to boost cellular immunity in the elderly to prevent shingles.⁷⁷

VARICELLA-ZOSTER IMMUNOGLOBULIN

Varicella-zoster immunoglobulin (VZIG) is used for passive immunization of susceptible immunodeficient patients exposed to varicella infection. VZIG is prepared from plasma found in routine screening of normal volunteer blood donors to contain high titers of varicella antibody. On average, VZIG contains 10 to 20 times more varicella antibody than immunoglobulin.⁷⁴

Postexposure prophylaxis with VZIG is indicated for the following susceptible individuals: (1) children with primary or acquired immunodeficiency, with neoplastic disease, or who require immunosuppressive therapy, (2) neonates whose mothers develop varicella within 5 days before or 2 days after delivery, (3) preterm infants (<28 weeks' gestation or who weigh <1000 g) who are exposed to varicella while hospitalized, (4) susceptible pregnant women, and (5) immunosuppressed adults and adolescents. Because healthy adults and adolescents who develop varicella are at increased risk for severe disease, complications, and death, VZIG could be considered in this population, with disease modification rather than prevention being the goal. If varicella is prevented, vaccination should be offered at a later date. Exposure to varicella is defined as direct indoor contact for more than 1 hour with an infectious person. A negative history of clinical disease is not a reliable indicator of varicella susceptibility. Most people with a negative clinical history will have detectable antibody on laboratory testing. Caution is warranted when interpreting a low positive result in an immunosuppressed patient who has received

blood products or immunoglobulin because the circulating antibody may be acquired passively.

The clinical efficacy of VZIG can be measured by the rate at which it prevents infection, modifies disease, or prevents subclinical disease. Following household exposure, 30% to 50% of immunocompromised children who receive VZIG will develop disease. Neonates receiving VZIG exposed in utero will develop infection at about the same rate as neonates who did not receive VZIG, but the complication rate is substantially reduced among the infants treated with VZIG.⁷⁴

For maximum effectiveness, VZIG must be given within 48 hours and not more than 96 hours following exposure. Because this agent may only attenuate infection, patients who receive VZIG still may have a period of communicability, and VZIG may prolong the incubation period to 28 days. Exact duration of antibody protection is not known but is assumed to be at least one half-life of the immunoglobulin or approximately 3 weeks.

VZIG is distributed by the American Red Cross Services. Contact with the distribution centers must be made within 72 hours of exposure, and specific criteria must be met in order for the product to be released.

Administration of VZIG is by the IM route (never intravenously) at doses of 125 units/10 kg of body weight up to 625 units (five vials) for patients weighing more than 40 kg. The dose for newborn infants is 125 units. VZIG may be indicated for individuals with bleeding diatheses, in whom IM injection generally should be avoided; the benefits of VZIG likely may outweigh the risks in many cases. Common adverse events include injection-site reactions.

OTHER IMMUNOBIOLOGICS

IMMUNOGLOBULIN

Immunoglobulin is available as both intramuscular (IMIG) and intravenous preparations (IVIG). The IMIG preparation, or the Cohn fraction II, is prepared from pooled plasma of several thousand donors by cold ethanol fractionation. It typically contains greater than 95% IgG and trace amounts of IgM, IgA, and other plasma proteins. Because Ig is harvested from a large donor pool, it contains a wide spectrum of IgG antibodies to the pathogens prevalent in the area from which the donors were obtained. In the fractionation process, high-molecular-weight IgG aggregates are formed, which can activate complement in the absence of antigen and precipitate anaphylactoid reactions. For this reason, IMIG is unsuitable for IV administration. IMIG typically contains 15% to 18% protein and not less than 90% IgG. A number of IVIG preparations are available commercially in the United States. Generally, these preparations contain greater than 90% IgG monomers and trace to small amounts of IgA. These products are available as lyophilized powders or solutions.

When administered either IV or IM, immunoglobulin distributes in approximately 5% of the body weight of the recipient. The plasma half-life of immunoglobulin ranges from 18 to 32 days. This range of half-life probably is attributable to the variation in the half-life of IgG subclasses. Peak serum concentrations occur immediately with IVIG, whereas IMIG produces peak concentrations within 2 days. After the initial period of equilibration, circulating IgG levels are superimposable between IV and IM equivalent dosages. No dosage adjustment is necessary in patients with renal or hepatic insufficiency, or both, or dialysis patients or geriatric patients.

Immunoglobulin is indicated in a wide variety of circumstances to provide passive immunity to individuals.⁷⁸ The indications for IMIG differ from those for IVIG. IMIG is indicated for providing

TABLE 122-4. Indications and Dosage of Intramuscular Immune Globulin in Infectious Diseases

| | |
|---------------------------------|---|
| Primary immunodeficiency states | 1.2 mL/kg IM then 0.6 mL/kg every 2–4 weeks |
| Hepatitis A exposure | 0.02 mL/kg IM within 2 weeks |
| Hepatitis A prophylaxis | 0.02 mL/kg IM for exposure <3 months' duration 0.06 mL/kg IM for exposure up to 5 months' duration |
| Hepatitis B exposure | 0.06 mL/kg (HBIG preferred in known exposures) |
| Measles exposure | 0.25 mL/kg (maximum dose 15 mL) as soon as possible 0.5 mL/kg (maximum dose 15 mL) as soon as possible for immunocompromised individuals |
| Varicella exposure | 0.6–1.2 mL/kg as soon as possible when VZIG not available |

passive immunity in hepatitis A infections, hepatitis B exposures (however, HBIG is significantly more effective), measles, varicella, and primary immunodeficiency diseases. Although IMIG is indicated for the treatment of primary immunodeficiency, IVIG is better tolerated and more effective. IMIG is not indicated for prevention of rubella, mumps, or poliomyelitis. Table 122-4 lists the suggested dosages for IMIG for the prevention or attenuation of various infectious diseases.

There are many approved indications, as well as off-label uses, for IVIG. The therapeutic dose of IVIG is set empirically at 2 g/kg. Often this dose is given in five daily doses of 400 mg/kg each, but it may be preferable to divide the total dose into two daily doses of 1 g/kg if the patient can tolerate the volume of the infusion.^{78,79}

- **Primary immunodeficiency states.** In primary immunodeficiency states, monthly doses of between 100 and 800 mg/kg are administered, with the average dose being 200–400 mg/kg. The immunodeficiency states for which IVIG is indicated include both antibody deficiencies and combined immune deficiencies. Significant reactions can occur in patients with low intrinsic levels of IgA given IVIG with greater amounts of IgA. An IVIG product with very low amounts of IgA should be used for these patients. IVIG is indicated for some patients with HIV infection; however, the data to support its use are better in the pediatric population.¹⁶ With the advent of new antiretroviral agents and combination therapies, the usefulness of IVIG may be even more limited.
- **Immune thrombocytopenic purpura.** For the treatment of hemorrhage associated with immune (or idiopathic) thrombocytopenic purpura (ITP), doses of 1 g/kg daily for 2 to 3 days plus high-dose methylprednisolone are indicated. Rh₀(D) immunoglobulin may be used in Rh-positive individuals as an alternative to IVIG (see next section). Adults tend to respond less well to IVIG than do children. IVIG is acceptable for treatment of both chronic and acute ITP, and IVIG has been used in ITP associated with pregnancy without adverse effects on the fetus. Corticosteroids remain the drugs of choice for adult ITP.⁸⁰ In thrombotic thrombocytopenia purpura, IVIG is reported to be effective in patients who do not respond to plasmapheresis. Other platelet disorders in which IVIG may be useful include neonatal immune thrombocytopenia, perinatal autoimmune thrombocytopenia,

drug-induced thrombocytopenia, thrombocytopenia secondary to infection, and transfusion-refractory thrombocytopenia; however, the data to support these uses are minimal.^{78–80}

- **Chronic lymphocytic leukemia (CLL).** IVIG is used as a prophylactic measure in CLL patients who have had a serious bacterial infection. Doses of 400 mg/kg every 3 to 4 weeks are used.
- **Kawasaki disease (mucocutaneous lymph node syndrome).** This disease, which generally occurs in children, carries the hallmark of development of coronary artery abnormalities. Generally, it is recommended by the American Academy of Pediatrics that if the strict criteria for Kawasaki disease are met, an IVIG dose of 400 mg/kg per day for 4 consecutive days be used or, preferably, 2 g/kg as a single dose. The dose should be administered within 10 days of disease onset. Aspirin therapy also should be initiated.⁸¹
- **Bone marrow transplant.** IVIG is approved for reducing graft-versus-host disease and infections in patients over the age of 20 years. Patients receive 500 mg/kg 7 and 2 days before transplantation and weekly up to 3 months after. At 100 days posttransplant, patients receive a monthly dose of IVIG for 1 year. Following this regimen, infection (e.g., cytomegalovirus, fungal, bacterial, and interstitial pneumonia) decreased from 51% to 34% in bone marrow transplant patients. IVIG is not indicated in patients younger than 20 years of age.
- **Varicella-zoster.** Another approved indication for IVIG is in the prophylaxis of varicella-zoster if VZIG is not available.

A number of other proposed uses of IVIG can be identified. It is important to note that these are off-label uses but generally may be accepted in the medical community for routine treatment.⁷⁸ These uses include

- **Neonatal sepsis.** Neonatal sepsis can cause significant morbidity within 24 hours of birth. While group B *Streptococcus* and *Escherichia coli* remain the primary infecting organisms, other bacteria and fungi may be associated with sepsis. IVIG appears to be effective in neonates older than 34 weeks' gestational age or who weigh less than 1500 g. Routine use is not recommended; however, IVIG may be useful in neonates with recurrent infections.
- **Guillain-Barré syndrome.** IVIG is effective and is considered an alternative to plasmapheresis.⁸²
- **Autoimmune diseases.** IVIG may be effective in self-limited immunoregulatory diseases but less effective in chronic diseases such as systemic lupus erythematosus. Overall, there is little evidence that IVIG is useful in the management of autoimmune diseases, except for patients with severe active disease who have not responded to or tolerated other interventions.⁸³
- **Intractable epilepsy.** In patients who have confirmed IgG deficiency, IVIG may be useful. For certain syndromes, such as West or Lennox-Gastaut syndrome, IVIG may be considered.⁷⁸
- **Chronic inflammatory demyelinating polyneuropathy.** Although steroids are the first-line therapy, IVIG may be used in patients who fail steroids or do not tolerate steroids.⁷⁹
- **Cytomegalovirus (CMV) infection.** The use of CMV-IVIG is recommended instead of the use of IVIG.

Adverse effects of immunoglobulin vary with the route of administration. Following IMIG, pain, tenderness, and muscle stiffness persisting for hours or days are common. Repeat courses may cause sensitization with resulting allergic reactions. With IVIG, adverse

effects occur in fewer than 1% of immunocompetent patients and in fewer than 10% of others. Chills, fever, nausea, and vomiting often are related to the rate of the infusion. Infusion should be given at a rate of 0.01–0.02 mL/kg per minute for 30 minutes and then, if no reactions occur, increased to 0.02–0.04 mL/kg per minute. Although infusion-rate recommendations vary slightly depending on the preparation, the guidelines presented can be followed for the various IV preparations.

Most adverse reactions are mild and transient. Arthralgia, myalgia, fever, pruritus, nausea, vomiting, chest tightness, palpitations, diaphoresis, dizziness, pallor, and respiratory distress have been reported. Rarely, aseptic meningitis has occurred from a few hours to 2 days after high-dose infusion. The syndrome resolves within days without sequelae. Also, acute renal failure has been reported primarily in individuals with underlying renal dysfunction, diabetes, sepsis, volume depletion, other nephrotoxic drugs, or age greater than 65 years. To minimize the risk, ensure adequate hydration prior to infusion, and choose an IVIG product that does not contain high sucrose concentrations for individuals at high risk.⁸⁴

Immunoglobulin products are derived from human blood. Precautions such as donor screening and fractionation procedures and solvent-detergent treatment during the manufacturing process render the IVIG products free of HIV and hepatitis B and C viruses. Although no manufacturing process can guarantee that there is no viral contamination, the potential infection risk from immunoglobulin preparations is very small.⁸⁵

RH₀(D) IMMUNOGLOBULIN

Second only to the ABO blood group system, Rhesus antigen D [Rh₀(D)] is an important antigen in human blood. The Rh₀(D) locus encodes this antigen, but this locus is absent in approximately 15% of the population. These individuals are Rh₀(D)-negative and have the potential to mount an antibody response to erythrocytes with the Rh₀(D) present. Rh₀(D) incompatibility during pregnancy can lead to sensitization of the mother. The maternal antibodies developed following normal fetal leakage of erythrocytes to the mother can cause hemolytic disease of the newborn during subsequent pregnancies.

Rh₀(D) immunoglobulin (RDIg) is a sterile solution of immunoglobulins prepared from human sera with high titers of Rh₀(D) antibody. RDIg suppresses the antibody response and formation of anti-Rh₀(D) in Rh₀(D)-negative women exposed to Rh₀(D)-positive blood. Administration of RDIg prevents hemolytic disease of the newborn in subsequent pregnancies with a Rh₀(D)-positive fetus. When administered within 72 hours of delivery of a full-term infant, RDIg reduces active antibody formation from 12% to 1% to 2%. The reduction in antibody formation is lower when RDIg is given beyond 72 hours postpartum. Smaller doses of RDIg are used after abortion, miscarriage, amniocentesis, or abdominal trauma. In addition, RDIg is also used in the case of a premenopausal woman who is Rh₀(D)-negative and who has inadvertently received Rh₀(D)-positive blood or blood products.

The dosage of RDIg varies with the indication. A standard dose of 300 mcg is given within 72 hours of a term delivery. Occasionally, where the fetus is known to be Rh₀(D)-positive, a 300-mcg dose is given at 28 weeks' gestation and within 72 hours after delivery. For postpregnancy termination occurring up to 13 weeks' gestation, one microdose (50 mcg) vial is given within 72 hours. For pregnancy termination after 13 weeks, one standard dose (300 mcg) is given within 72 hours. In other circumstances, such as in abdominal trauma, amniocentesis, or transfusion accidents, the dosage (number of standard dose vials) is based on the estimated packed red blood cell volume of

the fetal/maternal hemorrhage divided by 15. RDIg is administered intramuscularly only.

When considering RDIg for use, one must be certain of the mother's Rh₀(D) antigen status; RDIg should not be given to individuals positive for this antigen or to those with anti-Rh₀(D) antibodies. Occasionally, a large fetal bleed of Rh₀(D)-positive blood may make cross-matching of the mother difficult. In these cases, RDIg should be given only if previous tests have shown the mother to be Rh₀(D)-negative with no anti-Rh₀(D) antibody.

Adverse reactions to RDIg include injection-site tenderness and fever. Rh₀(D) does not interfere with response to rubella vaccine. Rubella-seronegative women should be immunized at hospital discharge even if they received RDIg postpartum.

CYTOMEGALOVIRUS IMMUNOGLOBULIN

CMV intravenous immunoglobulin (CMV-IVIG) contains IgG antibodies obtained from healthy persons with high titers of antibodies to CMV.

Attenuation of primary CMV disease associated with solid-organ transplantation in seronegative recipients of seropositive organs is the indication for CMV-IVIG. It is dosed using a tapering schedule. Dosage is 150 mg/kg preoperatively or within 72 hours postoperatively; 100 mg/kg at 2, 4, 6, and 8 weeks; and 50 mg/kg at weeks 12 and 16. These doses are for all ages. The use of CMV-IVIG has resulted in a significant decrease in CMV-related syndromes. Further studies are needed to determine the efficacy of CMV-IVIG in bone marrow transplantation. CMV-IVIG has been effective in some studies but ineffective in others.

Adverse effects of CMV-IVIG are seen in fewer than 5% of recipients and include flushing, chills, muscle cramps, back pain, chest tightness, fever, nausea, vomiting, hypotension, and tachycardia. These adverse events may be related to the infusion rate and can be managed by temporarily discontinuing the infusion. The infusion may be restarted at a decreased rate. Anaphylaxis occurs rarely and should be considered if hypotension develops during the infusion. Because CMV-IVIG contains other antibodies, live-virus vaccines should be withheld until 3 months after CMV-IVIG administration.

VACCINES FOR TRAVEL

The use of a few vaccines is reserved for individuals who travel to areas of the world where these vaccine-preventable infections are common. Immunization is only a part of travel medicine. Recommendations for the use of hepatitis A and hepatitis B vaccines can be found in Chap. 40. Meningococcal polysaccharide vaccine is recommended for seasonal travel in sub-Saharan Africa, and the use of this vaccine was described earlier in this chapter.

The CDC publishes annual editions of *Health Information for International Travel* (commonly referred to as the "Yellow Book"). The information contained in the book can be viewed and used at www.cdc.gov/travel. Additionally, this Web site offers information on disease outbreaks and updates of interest to the international traveler and to health care providers caring for international travelers.

JAPANESE ENCEPHALITIS VIRUS VACCINE

Japanese encephalitis is an arboviral infection spread by mosquitoes in Asia and Oceania. Infection leads to encephalitis in 1 in 20 to 1 in 1000 cases. However, the encephalitis is fatal in about 25% of cases, and neurologic sequelae are manifest in about 30% of cases. Transmission

is seasonal, with the highest times of transmission occurring in the summer and early fall. Although the risk for the most travelers is quite low, the risk for individuals depends on the season, rural location, and duration of travel.⁸⁶ The Japanese encephalitis virus vaccine is recommended for U.S. expatriates residing in areas where Japanese encephalitis is endemic or epidemic. The vaccine is not recommended routinely for travelers to Asia.

Monovalent inactivated Japanese encephalitis virus vaccine has been available commercially in the United States since 1992. Three doses are needed to provide protective concentrations of neutralizing antibodies. The vaccine series produced higher antibody concentrations when administered in a 0-, 7-, and 30-day schedule rather than in a 0-, 7-, and 14-day regimen, but all subjects mounted a protective response regardless of regimen. Duration of antibody protection is unknown. Protective titers have been reported for up to 3 years after primary immunization. Additionally, single booster doses given 1 year after primary immunization have resulted in substantial rises in antibody titers. The Japanese encephalitis vaccine is administered to individuals at least 3 years of age as 1 mL given subcutaneously on days 0, 7, and 30. The 0-, 7-, and 14-day schedule can be used if time is a constraint. In addition, a 0- and 7-day schedule can be used if absolutely necessary, and it will provide protection for 80% of persons. The last dose should be administered at least 10 days before traveling to observe for adverse reactions. For children ages 1 to 3 years, 0.5 mL of vaccine is administered subcutaneously using the schedules already noted. No data are available for infants. Booster doses are recommended every 36 months, with 1-mL booster doses being given to children 3 years of age or older even if they received 0.5 mL as the initial dose. Pregnant women who travel to an epidemic or endemic area should be vaccinated. No data are available for immunocompromised patients.

Adverse reactions include pain and tenderness at the injection site (20%) and systemic side effects such as fever, headache, malaise, rash, chills, dizziness, myalgia, nausea, vomiting, and abdominal pain in 10%.⁸⁶ In addition, there are sporadic reports of hypersensitivity reactions to the vaccine. The manifestations of this type of reaction include urticaria, angioedema, and respiratory distress. These reactions have generally occurred after a median of 12 hours after the first dose of vaccine, with 88% of reactions occurring within 3 days. After a second dose, these hypersensitivity reactions may occur 3 to 14 days after injection.

TYPHOID VACCINE

Typhoid fever is an illness caused by infection with *Salmonella typhi*. Typhoid is spread via the fecal-oral route. Clinical illness in its severe form is characterized by gradually rising fever that reaches 39 to 41°C (102.2 to 105.8°F) and persists for up to 2 weeks. Headaches, abdominal discomfort, malaise, myalgia, and anorexia usually are present. Older children and adults usually have constipation, whereas diarrhea is common in infants. Complications include intestinal perforation and hemorrhage. Between 2% and 5% of patients become chronic gallbladder carriers of *S. typhi*.

Although rare in developed countries, typhoid is common in Africa, Asia, Central America, and South America. Travelers to these areas should be advised that careful selection of food and beverages is the most effective means of preventing infection but should be offered immunization if the itinerary puts the travelers at high risk for typhoid.

Three typhoid vaccines are available in the United States. The oral typhoid vaccine is a live attenuated preparation that is given as a four-dose series with one capsule administered every other day. The

capsules should be taken on an empty stomach with cool or lukewarm liquid. The series should be completed 1 week prior to travel and should not be used in anyone younger than 6 years of age. The oral vaccine should not be administered during a course of antibiotics. The injectable typhoid vaccine (ViCPS) is a polysaccharide vaccine given as a single intramuscular dose at least 2 weeks before travel. This polysaccharide vaccine should not be given to children younger than 2 years of age. Another injectable typhoid vaccine is also available (Typhoid Vaccine USP). It is a heat-phenol-inactivated bacterial vaccine. This vaccine can be used in adults and children as young as 6 months of age. The vaccine series consists of two doses at least 4 weeks apart. This inactivated typhoid vaccine should be used only when the other two preparations cannot be used because Typhoid Vaccine USP is associated with significantly more adverse effects and is no more effective.⁸⁷

Booster doses of all three vaccine preparations are recommended if continued or repeated exposure is expected. The entire four-dose oral vaccine series should be repeated every 5 years. The ViCPS preparation requires revaccination every 2 years, whereas the Typhoid Vaccine USP should be readministered every 3 years. A single dose is required even if more than 3 years have elapsed since the primary series.

Because the oral vaccine is a live attenuated preparation, its use in the immunocompromised should be avoided. Both parenteral vaccines can be administered to immunocompromised persons because they are inactivated. None of the vaccines should be given to febrile individuals. Pregnancy is not an absolute contraindication to use of any of the vaccines, but the benefits versus the risks must be weighed.⁸⁷

The oral typhoid vaccine is well tolerated, with rare reports of gastrointestinal discomfort, fever, headache, or rash. Local injection-site reactions are the most commonly reported adverse event following the injectable typhoid vaccine (ViCPS). Systemic symptoms, such as fever, flulike symptoms, gastrointestinal discomfort, tremor, or neck pain, are reported occasionally. Most vaccinees will report injection-site reactions after the injectable Typhoid Vaccine USP. Malaise, headache, muscle aches, and fever also may occur. Very rarely, serious adverse events, such as chest pain, hypotension, and shock, have been reported.

YELLOW FEVER VACCINE

Yellow fever is caused by a virus transmitted via *Aedes* mosquito bites. Yellow fever is endemic in areas of South America and Africa. Symptoms of infection include fever, prostration, headache, photophobia, myalgias, arthralgias, anorexia, and vomiting. Management consists solely of supportive care. The fatality rate is approximately 20%.

Live attenuated yellow fever virus vaccine is recommended for persons who will be traveling to or living in areas where yellow fever infection occurs and is required for entry into certain countries.⁸⁸ The reconstituted vaccine is thermolabile, and unused portions must be discarded 1 hour after reconstitution.

The recommended dose is 0.5 mL subcutaneously given once, with similar booster doses recommended every 10 years. The vaccine, however, has been shown to be highly immunogenic, with antibodies persisting for at least 35 years and perhaps for life.

Mild side effects consisting of headache, myalgias, and low-grade fever 1 to 2 weeks after vaccination occur in fewer than 10% of vaccinees; treatment should be symptomatic. Immediate hypersensitivity reactions are rare and occur primarily in persons who have

anaphylactic reactions to eggs or other substances. Neurotropic disease following yellow fever immunization is very rare (23 reported cases to date). Infants are likely more susceptible to neurotropic disease, and use of the yellow fever vaccine in infants younger than 9 months of age should be avoided.⁸⁸

Yellow fever vaccine-associated viscerotropic syndrome occurs in a clinical spectrum from moderate illness with focal organ dysfunction to severe disease with multiple-organ-system failure and death. Yellow fever vaccine virus has been isolated from clinical samples collected from individuals with viscerotropic syndrome. The viscerotropic syndrome is more likely to occur with the first dose of vaccine than in individuals who have been vaccinated previously.

On theoretical grounds, the vaccine should be avoided during pregnancy unless travel to a high-risk area is imperative. It may be given to breast-feeding mothers. The vaccine may be used in immunocompromised patients if the risk of infection in an endemic area outweighs the potential vaccine risk. Additionally, it should not be given to infants younger than 4 months of age and, in general, should be used only if a child is 9 months of age or older. Children 4 to 9 months of age must be considered on an individual basis. Individuals 65 years of age and older appear to be at higher risk for serious vaccine-related adverse effects.⁸⁹ Decisions about travel to yellow fever endemic areas and vaccine use must be considered carefully given the seriousness of yellow fever infection.⁸⁸ It is contraindicated in persons with a history of an anaphylactic reaction to eggs. Where the history is in question, intradermal testing consisting of 0.02-mL doses of vaccine and normal saline control applied to the volar surface of the forearm should be done. The demonstration of an erythematous, urticarial wheal and negative control constitutes a positive response and contraindicates vaccination. This intradermal testing may be sufficient to produce antibodies, but serologic testing should be done to confirm this.

Yellow fever vaccine may be administered simultaneously with all other vaccines except cholera; a 3-week interval between vaccines is recommended. Simultaneous administration of immunoglobulin does not interfere with the immune response to this agent.

VACCINE INFORMATION RESOURCES

The field of vaccinology is developing ever more rapidly, with numerous changes being made in recommendations for vaccine use each year. Keeping up to date with the current recommendations can be a challenge. The childhood and adolescent immunization schedule is updated each January. Recommendations for the use of influenza vaccine are issued annually. Updates to the adult immunization schedule are made periodically. Health care providers involved in primary care and immunization delivery must keep themselves abreast of these changes in a systematic way. Reading electronic newsletters and browsing reliable Web sites are efficient methods of obtaining information (Table 122–5). Although several excellent, reliable, and timely Web sites exist, hundreds of sites with misleading and incorrect information also exist. Many of these sites are targeted at parents.

Vaccines are the only class of medications to which nearly every patient is exposed. Knowledge of these agents is critical in providing pharmaceutical care. Dramatic progress in public health has been made through the appropriate use of immunization. Additional improvements in quality of life and mortality can be made through continued increases in vaccination coverage with careful attention to this aspect of care by all health care providers.

APPENDIX 122-1

2004 Childhood Immunization Schedule

| Vaccine | Age | Range of Recommended Ages | | | | Catch-up Immunization | | | | Preadolescent Assessment | | | |
|--|-----|---------------------------|--------------------------|---------|--------------------|-----------------------|-------|-------|-----------|--------------------------|--------|---------|---------|
| | | Birth | 1 mo | 2 mo | 4 mo | 6 mo | 12 mo | 15 mo | 18 mo | 24 mo | 4-6 y | 11-12 y | 13-18 y |
| Hepatitis B ¹ | | HepB #1 | only if mother HBsAg (-) | HepB #2 | HepB #3 | | | | | HepB series | | | |
| Diphtheria, tetanus, pertussis ² | | | | DTaP | DTaP | | | DTaP | | DTaP | Td | Td | |
| <i>Hemophilus influenzae</i> type b ³ | | | Hib | Hib | Hib ³ | Hib | | | | | | | |
| Inactivated poliovirus | | | IPV | IPV | IPV | | | | IPV | | | | |
| Measles, mumps, rubella ⁴ | | | | | | MMR #1 | | | | MMR #2 | MMR #2 | | |
| Varicella ⁵ | | | | | | Varicella | | | Varicella | | | | |
| Pneumococcal ⁶ | | | PCV | PCV | PCV | PCV | | | | | | | |
| Influenza ⁸ | | | | | Influenza (yearly) | | | | | | | | |
| | | | | | | | | | | PCV | PPV | | |
| | | | | | | | | | | Hepatitis A series | | | |
| Hepatitis A ⁷ | | | | | | | | | | | | | |

Vaccines below this line are for selected populations

This schedule indicates the recommended ages for routine administration of currently licensed childhood vaccines, as of December 1, 2003, for children through age 18 years. Any dose not given at the recommended age should be given at any subsequent visit when indicated and feasible. Indicates age groups that warrant special effort to administer those vaccines not previously given. Additional vaccines may be licensed and recommended during the year. Licensed combination vaccines may be used whenever any components of the combination are indicated and the vaccine's other components are not contraindicated. Providers should consult the manufacturers' package inserts for detailed recommendations. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS). Guidance about how to obtain and complete a VAERS form can be found on the Internet: <http://www.vaers.org/> or by calling 1-800-822-7967.

1. Hepatitis B (HepB) vaccine. All infants should receive the first dose of hepatitis B vaccine soon after birth and before hospital discharge; the first dose may also be given by age 2 months if the infant's mother is hepatitis B surface antigen (HBsAg) negative. Only monovalent HepB can be used for the birth dose. Monovalent or combination vaccine containing HepB may be used to complete the series. Four doses of vaccine may be administered when a birth dose is given. The second dose should be given at least 4 weeks after the first dose, except for combination vaccines, which cannot be administered before age 6 weeks. The third dose should be given at least 16 weeks after the first dose and at least 8 weeks after the second dose. The last dose in the vaccination series (third or fourth dose) should not be administered before age 24 weeks.

Infants born to HBsAg-positive mothers should receive HepB and 0.5 mL of Hepatitis B Immune Globulin (HBIG) within 12 hours of birth at separate sites. The second dose is recommended at age 1 to 2 months. The last dose in the immunization series should not be administered before age 24 weeks. These infants should be tested for HBsAg and antibody to HBsAg (anti-HBs) at age 9 to 15 months.

Infants born to mothers whose HBsAg status is unknown should receive the first dose of the HepB series within 12 hours of birth. Maternal blood should be drawn as soon as possible to determine the mother's HBsAg status; if the HBsAg test is positive, the infant should receive HBIG as soon as possible (no later than age 1 week). The second dose is recommended at age 1 to 2 months. The last dose in the immunization series should not be administered before age 24 weeks.

2. Diphtheria and tetanus toxoids and acellular pertussis (DTaP) vaccine. The fourth dose of DTaP may be administered as early as age 12 months, provided 6 months have elapsed since the third dose and the child is unlikely to return at age 15 to 18 months. The final dose in the series should be given at age ≥ 4 years. **Tetanus and diphtheria toxoids (Td)** is recommended at age 11 to 12 years if at least 5 years have elapsed since the last dose of tetanus and diphtheria toxoid-containing vaccine. Subsequent routine Td boosters are recommended every 10 years.

3. Haemophilus influenzae type b (Hib) conjugate vaccine. Three Hib conjugate vaccines are licensed for infant use. If PRP-OMP (PedvaxHIB or ComVax [Merck]) is administered at ages 2 and 4 months, a dose at age 6 months is not required. DTaP/Hib combination products should not be used for primary immunization in infants at ages 2, 4, or 6 months but can be used as boosters following any Hib vaccine. The final dose in the series should be given at age ≥ 12 months.

4. Measles, mumps, and rubella vaccine (MMR). The second dose of MMR is recommended routinely at age 4 to 6 years but may be administered during any visit, provided at least 4 weeks have elapsed since the first dose and both doses are administered beginning at or after age 12 months. Those who have not previously received the second dose should complete the schedule by the 11- to 12-year-old visit.

5. Varicella vaccine. Varicella vaccine is recommended at any visit at or after age 12 months for susceptible children (i.e., those who lack a reliable history of chickenpox). Susceptible persons age ≥ 13 years should receive 2 doses, given at least 4 weeks apart.

6. Pneumococcal vaccine. The heptavalent pneumococcal conjugate vaccine (PCV) is recommended for all children age 2 to 23 months. It is also recommended for certain children age 24 to 59 months. The final dose in the series should be given at age ≥ 12 months.

Pneumococcal polysaccharide vaccine (PPV) is recommended in addition to PCV for certain high-risk groups. See *MMWR* 2000;49(RR-9):1-38.

7. Hepatitis A vaccine. Hepatitis A vaccine is recommended for children and adolescents in selected states and regions and for certain high-risk groups; consult your local public health authority. Children and adolescents in these states, regions, and high-risk groups who have not been immunized against hepatitis A can begin the hepatitis A immunization series during any visit. The 2 doses in the series should be administered at least 6 months apart. See *MMWR* 1999;48(RR-12):1-37.

8. Influenza vaccine. Influenza vaccine is recommended annually for children age ≥ 6 months with certain risk factors (including but not limited to children with asthma, cardiac disease, sickle cell disease, human immunodeficiency virus infection, and diabetes; and household members of persons in high-risk groups [see *MMWR* 2003;52(RR-8):1-36]) and can be administered to all others wishing to obtain immunity. In addition, healthy children age 6 to 23 months are encouraged to receive influenza vaccine if feasible, because children in this age group are at substantially increased risk of influenza-related hospitalizations. For healthy persons age 5 to 49 years, the intranasally administered live-attenuated influenza vaccine (LAIV) is an acceptable alternative to the intramuscular trivalent inactivated influenza vaccine (TIV). See *MMWR* 2003;52(RR-13):1-8. Children receiving TIV should be administered a dosage appropriate for their age (0.25 mL if age 6 to 35 months or 0.5 mL if age ≥ 3 years). Children age ≤ 8 years who are receiving influenza vaccine for the first time should receive 2 doses (separated by at least 4 weeks for TIV and at least 6 weeks for LAIV).

APPENDIX 122-2

2004 Adult Immunization Schedule

by Medical Conditions

| Medical Conditions ▼ | Vaccine ▶ | Tetanus-Diphtheria (Td)*.1 | Influenza ² | Pneumococcal (polysaccharide) ^{3,4} | Hepatitis B*.5 | Hepatitis A ⁶ | Measles, Mumps, Rubella (MMR)*.7 | Varicella*.8 |
|---|-----------|----------------------------|------------------------|--|----------------|--------------------------|----------------------------------|--------------|
| Pregnancy | | | A | | | | | |
| Diabetes, heart disease, chronic pulmonary disease, chronic liver disease, including chronic alcoholism | | | B | C | | D | | |
| Congenital Immunodeficiency, leukemia, lymphoma, generalized malignancy, therapy with alkylating agents, antimetabolites, radiation or large amounts of corticosteroids | | | | E | | | | F |
| Renal failure / end stage renal disease, recipients of hemodialysis or clotting factor concentrates | | | | E | G | | | |
| Asplenia including elective splenectomy and terminal complement component deficiencies | | H | | E, I, J | | | | |
| HIV infection | | | | E, K | | | L | |

For all persons in this group

Catch-up on childhood vaccinations

For persons with medical / exposure indications

Contraindicated

Special Notes for Medical Conditions

- A. For women, vaccinate if pregnancy will be during influenza season. For women with chronic diseases/conditions, vaccinate at any time during the pregnancy.
- B. Although chronic liver disease and alcoholism are not indicator conditions for influenza vaccination, give 1 dose annually if the patient is ≥ 50 years, has other indications for influenza vaccine, or if the patient requests vaccination.
- C. Asthma is an indicator condition for influenza but not for pneumococcal vaccination.
- D. For all persons with chronic liver disease.
- E. For persons <65 years, revaccinate once after 5 years or more have elapsed since initial vaccination.
- F. Persons with impaired humoral immunity but intact cellular immunity may be vaccinated. *MMWR* 1999;48 (RR-06): 1-5.

- G. Hemodialysis patients: Use special formulation of vaccine (40 ug/mL) or two 1 mL 20 ug doses given at one site. Vaccinate early in the course of renal disease. Assess antibody titers to hep B surface antigen (anti-HBs) levels annually. Administer additional doses if anti-HBs levels decline to <10 milliinternational units (mIU)/ mL.
- H. There are no data specifically on risk of severe or complicated influenza infections among persons with asplenia. However, influenza is a risk factor for secondary bacterial infections that may cause severe disease in asplenic.
- I. Administer meningococcal vaccine and consider Hib vaccine.
- J. Elective splenectomy: vaccinate at least 2 weeks before surgery.
- K. Vaccinate as close to diagnosis as possible when CD4 cell counts are highest.
- L. Withhold MMR or other measles containing vaccines from HIV-infected persons with evidence of severe immunosuppression. *MMWR* 1998;47 (RR-8):21-22; *MMWR* 2002;51 (RR-02): 22-24.

by Age Group

| Age Group ▶ | 19–49 Years | 50–64 Years | 65 Years and Older |
|---------------------------------------|---|------------------------------|-----------------------|
| Tetanus, Diphtheria (Td)* | 1 dose booster every 10 years ¹ | | |
| Influenza | 1 dose annually ² | 1 dose annually ² | |
| Pneumococcal (polysaccharide) | 1 dose ^{3,4} | | 1 dose ^{3,4} |
| Hepatitis B* | 3 doses (0, 1–2, 4–6 months) ⁵ | | |
| Hepatitis A | 2 doses (0, 6–12 months) ⁶ | | |
| Measles, Mumps, Rubella (MMR)* | 1 dose if measles, mumps, or rubella vaccination history is unreliable; 2 doses for persons with occupational or other indications ⁷ | | |
| Varicella* | 2 doses (0, 4–8 weeks) for persons who are susceptible ⁸ | | |
| Meningococcal (polysaccharide) | 1 dose ⁹ | | |

For all persons in this group

Catch-up on childhood vaccinations

For persons with medical / exposure indications

*Covered by the Vaccine Injury Compensation Program.

This schedule indicates the recommended age groups for routine administration of currently licensed vaccines for persons 19 years of age and older. Licensed combination vaccines may be used whenever any components of the combination are indicated and the vaccine's other components are not contraindicated. Providers should consult the manufacturers' package inserts for detailed recommendations.

Report all clinically significant post-vaccination reactions to the Vaccine Adverse Event Reporting System (VAERS). Reporting forms and instructions on filing a VAERS report are available by calling 800-822-7967 or from the VAERS website at www.vaers.org.

For additional information about the vaccines listed above and contraindications for immunization, visit the National Immunization Program Website at www.cdc.gov/nip/ or call the National Immunization Hotline at 800-232-2522 (English) or 800-232-0233 (Spanish).

1. Tetanus and diphtheria (Td)—Adults including pregnant women with uncertain histories of a complete primary vaccination series should receive a primary series of Td. A primary series for adults is 3 doses: the first 2 doses given at least 4 weeks apart and the 3rd dose, 6–12 months after the second. Administer 1 dose if the person had received the primary series and the last vaccination was 10 years ago or longer. Consult *MMWR* 1991; 40 (RR-10): 1–21 for administering Td as prophylaxis in wound management. The ACP Task Force on Adult Immunization supports a second option for Td use in adults: a single Td booster at age 50 years for persons who have completed the full pediatric series, including the teenage/young adult booster.
Guide for Adult Immunization, 3rd ed. ACP 1994: 20.

2. Influenza vaccination—Medical indications: chronic disorders of the cardiovascular or pulmonary systems including asthma; chronic metabolic diseases including diabetes mellitus, renal dysfunction, hemoglobinopathies, or immunosuppression (including immunosuppression caused by medications or by human immunodeficiency virus [HIV]), requiring regular medical follow-up or hospitalization during the preceding year; women who will be pregnant during the influenza season. Occupational indications: health-care workers. Other indications: residents of nursing homes and other long-term care facilities; persons likely to transmit influenza to persons at high-risk (in-home care givers to persons with medical indications, household contacts and out-of-home caregivers of children birth to 23 months of age, or children with asthma or other indicator conditions for influenza vaccination, household members and care givers of elderly and adults with high-risk conditions); and anyone who wishes to be vaccinated. For healthy persons aged 5–49 years without high risk conditions, either the inactivated vaccine or the intranasally administered influenza vaccine (Flumist) may be given. *MMWR* 2003;52 (RR-8):1–36; *MMWR* 2003;53 (RR-13): 1–8.

3. Pneumococcal polysaccharide vaccination—Medical indications: chronic disorders of the pulmonary system (excluding asthma), cardiovascular diseases, diabetes mellitus, chronic liver diseases including liver disease as a result of alcohol abuse (e.g., cirrhosis), chronic renal failure or nephrotic syndrome, functional or anatomic asplenia (e.g., sickle cell disease or splenectomy), immunosuppressive conditions (e.g., congenital immunodeficiency, HIV infection, leukemia, lymphoma, multiple myeloma, Hodgkin's disease, generalized malignancy, organ or bone marrow transplantation), chemotherapy with alkylating agents, anti-metabolites, or long-term systemic corticosteroids. Geographic/other indications: Alaskan Natives and certain American Indian populations. Other indications: residents of nursing homes and other long-term care facilities. *MMWR* 1997;46 (RR-8):1–24.

4. Revaccination with pneumococcal polysaccharide vaccine—One-time revaccination after 5 years for persons with chronic renal failure or nephrotic syndrome, functional or anatomic asplenia (e.g., sickle cell disease or splenectomy), immunosuppressive conditions (e.g., congenital immunodeficiency, HIV infection, leukemia, lymphoma, multiple myeloma, Hodgkin's disease, generalized malignancy, organ or bone marrow transplantation), chemotherapy with alkylating agents, anti-metabolites, or long-term systemic corticosteroids. For persons 65 and older, one-time revaccination if they were vaccinated 5 or more years previously and were aged less than 65 years at the time of primary vaccination. *MMWR* 1997;46 (RR-8):1–24.

5. Hepatitis B vaccination—Medical indications: hemodialysis patients, patients who receive clotting-factor concentrates. Occupational indications: health-care workers and public-safety workers who have exposure to blood in the workplace, persons in training in schools of medicine, dentistry, nursing, laboratory technology, and other allied health professions. Behavioral indications: injecting drug users, persons with more than one sex partner in the previous 6 months, persons with a recently acquired sexually transmitted disease (STD), all clients in STD clinics, men who have sex with men. Other indications: household contacts and sex partners of persons with chronic HBV infection, clients and staff of institutions for the developmentally disabled, international travelers who will be in countries with high or intermediate prevalence of chronic HBV infection for more than 6 months, inmates of correctional facilities. *MMWR* 1991;40 (RR-13):1–19.

6. Hepatitis A vaccination—For the combined HepA-HepB vaccine use 3 doses at 0, 1, 6 months. Medical indications: persons with clotting-factor disorders or chronic liver disease. Behavioral indications: men who have sex with men, users of injecting and noninjecting illegal drugs. Occupational indications: persons working with HAV-infected primates or with HAV in a research laboratory setting. Other indications: persons traveling to or working in countries that have high or intermediate endemicity of hepatitis A. *MMWR* 1999;48 (RR-12):1–37.

7. Measles, Mumps, Rubella vaccination (MMR)—Measles component: Adults born before 1957 may be considered immune to measles. Adults born in or after 1957 should receive at least one dose of MMR unless they have a medical contraindication, documentation of at least one dose or other acceptable evidence of immunity. A second dose of MMR is recommended for adults who:

- are recently exposed to measles or in an outbreak setting
- were previously vaccinated with killed measles vaccine
- were vaccinated with an unknown vaccine between 1963 and 1967
- are students in post-secondary educational institutions
- work in health care facilities
- plan to travel internationally

Mumps component: 1 dose of MMR should be adequate for protection. Rubella component: Give 1 dose of MMR to women whose rubella vaccination history is unreliable and counsel women to avoid becoming pregnant for 4 weeks after vaccination. For women of child-bearing age, regardless of birth year, routinely determine rubella immunity and counsel women regarding congenital rubella syndrome. Do not vaccinate pregnant women or those planning to become pregnant in the next 4 weeks. If pregnant and susceptible, vaccinate as early in postpartum period as possible. *MMWR* 1998;47 (RR-8): 1–57; *MMWR* 2001;50:1117.

8. Varicella vaccination—Recommended for all persons who do not have reliable clinical history of varicella infection, or serological evidence of varicella zoster virus (VZV) infection who may be at high risk for exposure or transmission. This includes, health-care workers and family contacts of immunocompromised persons, those who live or work in environments where transmission is likely (e.g., teachers of young children, day care employees, and residents and staff members in institutional settings), persons who live or work in environments where VZV transmission can occur (e.g., college students, inmates and staff members of correctional institutions, and military personnel), adolescents and adults living in households with children, women who are not pregnant but who may become pregnant in the future, international travelers who are not immune to infection. Note: Greater than 95% of U.S. born adults are immune to VZV. Do not vaccinate pregnant women or those planning to become pregnant in the next 4 weeks. If pregnant and susceptible, vaccinate as early in postpartum period as possible. *MMWR* 1996; 45 (RR-11): 1–36; *MMWR* 1999;48 (RR-6):1–5.

9. Meningococcal vaccine (quadrivalent polysaccharide for serogroups A, C, Y, and W-135)—Consider vaccination for persons with medical indications: adults with terminal complement component deficiencies, with anatomic or functional asplenia. Other indications: travelers to countries in which disease is hyperendemic or epidemic ("meningitis belt" of sub-Saharan Africa, Mecca, Saudi Arabia for Hajj). Revaccination at 3–5 years may be indicated for persons at high risk for infection (e.g., persons residing in areas in which disease is epidemic). Counsel college freshmen, especially those who live in dormitories, regarding meningococcal disease and the vaccine so that they can make an educated decision about receiving the vaccination. *MMWR* 2000;49 (RR-7): 1–20. Note: The AAFP recommends that colleges should take the lead in providing education on meningococcal infection and vaccination and offer it to those who are interested. Physicians need not initiate discussion of the meningococcal quadrivalent polysaccharide vaccine as part of routine medical care.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Courtney V. Fletcher and Thomas N. Kakuda

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Infection with human immunodeficiency virus (HIV) occurs through three primary modes: sexual, parenteral, and perinatal. Sexual intercourse, primarily receptive anal and vaginal intercourse, is the most common method for transmission.
- 2 Once HIV enters the human body, the outer glycoprotein (gp160) expressed on the virus allows HIV to bind to CD4 receptors, proteins present on the surfaces of T-helper lymphocytes, monocytes, macrophages, dendritic cells, and brain microglia. The gp120 subunit of gp160 has high affinity for CD4 receptors and is responsible for the initial binding of the virus to the cell.
- 3 The goal of antiretroviral therapy is to achieve maximum suppression of HIV replication, interpreted to be a plasma viral load less than the lower limit of quantitation. Another equally important outcome is an increase in CD4 lymphocytes because this determines the risk for developing opportunistic infections.
- 4 The use of potent combination antiretroviral therapy to suppress HIV replication to below the levels of detection of sensitive plasma HIV RNA assays limits the potential for selection of antiretroviral-resistant HIV variants, the major factor limiting the ability of antiretroviral drugs to inhibit virus replication and delay disease progression. Therefore, maximum achievable suppression of HIV replication should be the goal of therapy.
- 5 The clinical use of antiretroviral agents is complicated by significant drug-drug interactions. Some interactions are beneficial and used purposely; others may be harmful, leading to inadequate drug concentrations. Clinicians involved in the pharmacotherapy of HIV infection must maintain a current knowledge of drug interactions for these reasons.
- 6 Current recommendations for treating HIV infection advocate a minimum of three antiretroviral agents. The typical regimen consists of two nucleoside analogues with either a protease inhibitor (often pharmacologically enhanced with ritonavir) or a nonnucleoside.
- 7 General principles for the management of opportunistic infections include prospective immunologic monitoring, primary prophylaxis, treatment, and secondary prophylaxis.
- 8 Treatment of *Pneumocystis carinii* pneumonia with agents such as trimethoprim-sulfamethoxazole (or cotrimoxazole) or parenteral pentamidine is associated with a 60% to 100% response rate. Trimethoprim-sulfamethoxazole is the regimen of choice for the treatment and prophylaxis of PCP patients with and without HIV because it is less toxic.
- 9 The combination of pyrimethamine and sulfadiazine is the most effective regimen for acute therapy of acquired immune deficiency syndrome (AIDS)-related CNS toxoplasmosis. Therapy with this combination should be continued for at least 3 weeks, but 6 weeks of treatment is recommended for more severely ill patients.
- 10 Amphotericin B is more effective than fluconazole for treatment of cryptococcal meningitis because of its lower rates of early death and disease progression. Most patients with cryptococcal meningitis probably should receive amphotericin B in an intravenous dose of at least 0.5 mg/kg per day for a minimum of 2 weeks as acute therapy.
- 11 Treatment regimens for *Mycobacterium avium* complex infection should contain at least two antimycobacterial agents. Every regimen should contain either clarithromycin or azithromycin plus a second agent such as ethambutol.
- 12 Acyclovir is the drug of choice for treatment of herpes simplex virus (HSV) infection. Recurrent HSV disease often can be managed with low-dose suppressive oral acyclovir therapy.

The acquired immune deficiency syndrome (AIDS) was first recognized by the medical community as a distinct clinical entity in 1981. This syndrome was described initially in a cohort of young homosexual men with profound immunologic deficits, *Pneumocystis carinii* pneumonia (PCP), and Kaposi's sarcoma. A retrovirus, human immunodeficiency virus type 1 (HIV-1) is the major cause of AIDS.^{1,2} A second retrovirus, HIV-2, also has been recognized to cause AIDS,

although it is far less prevalent than HIV-1. These retroviruses are transmitted primarily by sexual contact and by contact with contaminated blood or blood products. Several risk behaviors for the acquisition of HIV infection have been identified, most notably the practice of anorectal intercourse and the sharing of blood-contaminated needles by injection-drug users. Transmission of HIV between heterosexuals and from childbearing women to their offspring is an

increasing problem worldwide. Global statistics on the prevalence and incidence of this disease remain grim, and all treatments to date have been unsuccessful in eradicating HIV. However, potent combinations of antiretroviral agents, also known as *highly active antiretroviral therapy* (HAART), have been able to suppress HIV replication, delay the onset of AIDS, and prolong patient survival.³ Unfortunately, this success is tempered by the long-term toxicities that may arise from using these agents.⁴ The purpose of this chapter is to provide a discussion of the epidemiology and manifestations of HIV disease, therapeutic strategies directed at inhibiting the virus, and management of HIV-associated opportunistic infections.

appropriate prevention, care, and treatment services. Women account for a growing proportion of those newly infected.⁷ Men who have sex with men (MSM) account for most cases. The increase in unprotected sex and recent outbreaks of syphilis among this population are growing concerns in the United States.⁸ HIV infection, however, is a worldwide epidemic. The World Health Organization (WHO) estimates that 34 to 46 million adults and children are infected with HIV worldwide—primarily in sub-Saharan Africa (25 to 28.2 million) and Southeast Asia (4.6 to 8.2 million). Children younger than 15 years of age account for 2.5 million infections worldwide. Approximately 5 million additional infections occur each year, mainly (95%) in developing countries. Most of these infections will be acquired through heterosexual transmission.⁹

THE HUMAN IMMUNODEFICIENCY VIRUS

EPIDEMIOLOGY

Persons infected with HIV and AIDS cases in the United States conform to the Centers for Disease Control and Prevention (CDC) surveillance case definition (Table 123–1) and are reported by health care providers to a public health department.⁵ The cumulative number of reported AIDS cases in the United States at the end of December 2001 was 816,149; 467,910 (more than half) have already died. The number of individuals living with HIV infection or AIDS in the United States at the end of December 2001 was 181,976 and 344,178, respectively. Reported cases in men outnumbered women by approximately 6 to 1. Compared with their distribution in the overall population, African-American and Hispanic populations are disproportionately affected by AIDS, representing 42% and 20% of AIDS cases, respectively.⁶ The estimated prevalence of HIV in the United States is 850,000 to 950,000 individuals. Each year the CDC estimates that 40,000 new cases of HIV infection occur in the United States, with approximately 70% of individuals diagnosed. Only half are linked to

ETIOLOGY

HIV is a member of the lentivirinae (*lenti*, meaning “slow”) subfamily of retroviruses. Lentiviruses are characterized by their indolent infectious cycle. There are two related but distinct types of HIV, HIV-1 and HIV-2. HIV-2, found mostly in western Africa, consists of six distinct phylogenetic lineages designated as subtypes (clades) A through F. HIV-1 also can be categorized based on phylogeny. Three groups of HIV-1 are currently recognized: M (main), N (new or non-M, non-O), and O (outlier). The nine subtypes of HIV-1 group M are identified as A through D, F through H, and J and K. Mixtures of subtypes are referred to as *circulating recombinant forms*.¹⁰ HIV-1 subtype B is primarily responsible for the epidemic in North America and western Europe.

The origin of HIV is of considerable interest. The accumulated evidence suggests that HIV in humans was the result of a cross-species transmission (zoonosis) from primates infected with simian immunodeficiency virus (SIV). Phylogenetic and geographic relationships suggest that HIV-2 arose from SIV that infects sooty mangabeys. The

TABLE 123–1. Centers for Disease Control and Prevention 1993 Revised Classification System for HIV Infection in Adults and AIDS Surveillance Case Definition

| CD4+ T-Cell Categories (Absolute Number and Percentage) | (A) Asymptomatic, Acute (Primary) HIV or PGL | (B) Symptomatic, not (A) or (C) Conditions | (C) AIDS-Indicator Conditions |
|--|---|--|-------------------------------------|
| ≥500/mcL or ≥29% | A1 | B1 | C1 |
| 200–499/mcL or 14–28% | A2 | B2 | C2 |
| <200/mcL or <14% | A3 | B3 | C3 |
| AIDS-Indicator Conditions | | | |
| Candidiasis of bronchi, trachea, or lungs | | Lymphoma, Burkitt's | |
| Candidiasis, esophageal | | Lymphoma, immunoblastic | |
| Cervical cancer, invasive | | Lymphoma, primary, or brain | |
| Coccidioidomycosis, disseminated or extrapulmonary | | <i>Mycobacterium avium</i> complex or <i>M. kansasii</i> , disseminated or extrapulmonary | |
| Cryptococcosis, extrapulmonary | | <i>Mycobacterium tuberculosis</i> , any site (pulmonary or extrapulmonary) | |
| Cryptosporidiosis, chronic intestinal (duration >1 month) | | <i>Mycobacterium</i> , other species or unidentified species, disseminated or extrapulmonary | |
| Cytomegalovirus disease (other than liver, spleen or nodes) | | <i>Pneumocystis carinii</i> pneumonia | |
| Cytomegalovirus retinitis (with loss of vision) | | Pneumonia, recurrent | |
| Encephalopathy, HIV-related | | Progressive multifocal leukoencephalopathy | |
| Herpes simplex: chronic ulcer(s) (duration >1 month); or bronchitis, pneumonitis, or esophagitis | | <i>Salmonella</i> septicemia, recurrent | |

| Isosporiasis, chronic intestinal (duration >1 month) | | Wasting syndrome due to HIV | |
| Kaposi's sarcoma | | | |

PCL = persistent generalized lymphadenopathy.

origin of HIV-1 is less clear, but similarities exist between SIVcpz, a virus that infects chimpanzees (*Pan troglodytes troglodytes*), and HIV-1. Cultural practices such as the preparation and eating of bushmeat or keeping chimpanzees as pets may have allowed the virus to jump from primate to humans. The earliest known human infection with HIV has been traced to central Africa in 1959. Modern transportation, promiscuity, and drug abuse have caused the rapid spread of the virus within the United States and throughout the world.¹¹ This chapter will focus on HIV-1 because this is the predominant strain likely to be encountered in the Western world.

DETECTION OF HIV AND SURROGATE MARKERS OF DISEASE PROGRESSION

When HIV-1 infection is suspected, whether owing to symptoms or high-risk behavior, it should be confirmed by laboratory methods. The most common method is an enzyme-linked immunosorbent assay (ELISA), which detects antibodies against HIV-1. The ELISA test is both highly sensitive (>99%) and highly specific (>99%), but false-positive results can occur in multiparous women; recent recipients of hepatitis B, HIV, influenza, or rabies vaccine; patients with multiple blood transfusion, liver disease, and renal failure; or those on chronic hemodialysis. False-negative results may occur if the patient is newly infected and the test is performed before antibody production is adequate. The minimum time to develop antibodies is 3 to 4 weeks from initial exposure, with greater than 95% of individuals developing antibodies after 6 months. Convenient methods for obtaining an ELISA sample have been developed, including an oral collection device (OraSure), an over-the-counter home fingerstick blood-collection test system (Home Access), and a urine test (Calpyte). Positive ELISAs are repeated in duplicate, and if one or both tests are reactive, a confirmatory test is performed for final diagnosis. Western blot is the most commonly used confirmatory test, although an indirect immunofluorescence assay is also available. A reactive ELISA test and a positive confirmatory test indicate an established HIV infection. If the confirmatory test is indeterminate, the dilemma can be resolved by retesting the individual after 30 days or performing a viral load assay if the patient is at high risk or symptomatic.¹²

Once diagnosed, HIV disease is monitored primarily by two surrogate markers, viral load and CD4 cell count. The viral load test quantifies the degree of viremia by measuring the amount of viral RNA (HIV RNA) in the plasma. There are several methods for determining HIV RNA, including reverse transcriptase-coupled polymerase chain reaction (RT-PCR), branched-chain DNA (bDNA), transcription-mediated amplification, and nucleic acid sequence-based assay. RT-PCR and bDNA are used more widely than the other techniques. Irrespective of the method used, viral load is reported as the number of viral RNA copies per milliliter. Each assay has its own lower limit of sensitivity to viral subtypes, and results can vary from one assay method to the other; therefore, it is recommended that the same assay method be used consistently within patients. Reductions in viral load often are reported in base 10 logarithm. For example, if a patient presents initially with a viral load of 100,000 copies/mL (10^5 copies/mL) and subsequently has a viral load of 10,000 copies/mL (10^4 copies/mL), the decrease in viral load is 1 \log_{10} . In general, a clinical response is considered sufficient if the response is greater than 0.5 \log_{10} . Viral load assays have greater than 99% specificity and can be used to detect most strains of HIV. More important, viral load can be used as a prognostic factor to monitor disease progression and the effects of treatment.¹²

Because HIV attacks and destroys cells bearing the CD4 receptor, the number of CD4 lymphocytes in the blood is a surrogate marker of

disease progression. The normal adult CD4 lymphocyte count ranges from 500 to 1600 cells/mL, or 40% to 70% of all lymphocytes. CD4 counts in children are age-dependent, with younger children having higher CD4 counts. Depletion of CD4 cells has been associated with the development of opportunistic infections and other AIDS malignancies.¹³

TRANSMISSION OF HIV

1 Infection with HIV occurs through three primary modes: sexual, parenteral, and perinatal. Sexual intercourse, primarily receptive anal and vaginal intercourse, is the most common method for transmission.⁶ HIV can be found in semen and cervical secretions, and exposure to either of these infected body fluids may transmit the virus. No sexual act between individuals can be considered absolutely safe. The probability of HIV transmission from receptive anorectal intercourse is 0.1% to 3% per sexual contact; for receptive vaginal intercourse, the risk is approximately 0.1% to 0.2%.¹⁴ In general, the probability of infection is increased when the index partner is in an advanced stage of disease. Persons at highest risk for heterosexual transmission include those with ulcerative sexually transmitted diseases, individuals with multiple sex partners, and sexual partners of injection-drug users. Risk of transmission is elevated when women experience vaginal bleeding during intercourse. Individuals with genital ulcers such as from syphilis, chancroid, or herpes are at a fourfold greater risk of contracting HIV. Gonorrhea, chlamydia, and trichomoniasis increase the risk two- to threefold. Sexual partners of circumcised males are less likely to acquire HIV infection when compared with sex partners of uncircumcised males, suggesting that the absence of the foreskin has a protective effect for the partner. Infections also can occur from artificial insemination with infected semen. The risk of acquiring HIV infection from oral intercourse is less well established. Casual contact with AIDS patients or persons with HIV infection is not a significant risk factor for HIV transmission. Prevention of sexual transmission in adults has been focused primarily on encouraging the use of condoms, reducing high-risk behavior (anal intercourse and promiscuity), and the treatment of sexually transmitted diseases. A combined approach has been advocated for successful prevention. Abstinence is encouraged among adolescents. Future interventions under development such as HIV vaccines and topical vaginal microbicides may further limit the spread of sexually transmitted HIV.

Parenteral transmission of HIV broadly encompasses infections owing to contaminated blood exposure such as from needlesticks, intravenous injection with used needles, receipt of blood products, or organ transplants. The use of contaminated needles or other injection-related paraphernalia by drug abusers has been the main cause of parenteral transmissions and currently accounts for a quarter of AIDS cases reported in the United States. Cases in which receipt of infected blood transfusion, blood components, or organ transplant was involved currently portray less than 1% of reports.⁶ This low incidence is attributable to blood- and organ-donor screening and viral inactivation procedures for many clotting factors. These preventative measures have reduced the estimated risk for receiving tainted blood or blood products to 1 in 493,000.¹⁵ Health care workers have a small but definite occupational risk of contracting HIV through accidental injury. Most cases of occupationally acquired HIV have been the result of a percutaneous needle stick injury. Studies indicate that the risk of HIV infection following this route is approximately 0.3%. Significant risk factors for seroconversion include deep injury, injury with a device visibly contaminated with blood, and exposure from a source who later died of AIDS. Guidelines for health care and public safety

workers have been developed to minimize the hazard of occupational exposure.¹⁶

Perinatal infection, or vertical transmission, is the most common cause of pediatric HIV infection. Most infections occur during or near to the time of birth, and therefore, treatment of the infected mother is important. The risk of mother-to-child transmission is approximately 25% in the absence of breast-feeding and antiretroviral therapy. Factors that increase the likelihood of vertical transmission include prolonged rupture of membranes, chorioamnionitis, genital infections during pregnancy, preterm delivery, vaginal delivery, birth weight below 2500 g, illicit drug use during pregnancy, and a high maternal viral load.¹⁷ Breast-feeding also can transmit HIV. The estimated frequency of breast milk transmission in one study was 16.2%, with the majority of infections developing within the first 6 months. Formula feeding prevented 44% of infections and was associated with a higher HIV-free survival rate after 2 years.¹⁸ In countries where safe and available alternatives to breast-feeding exist, HIV-infected mothers are strongly recommended not to breast-feed.

PATHOGENESIS

2 The life cycle of HIV (Fig. 123–1) is complicated but necessary to understand because the current strategies employed in the treatment of HIV target various points in this cycle. Once HIV enters the human body, the outer glycoprotein (gp160) expressed on the virus allows HIV to bind to CD4 (cluster designation 4) receptors, proteins present on the surface of T-helper lymphocytes, monocytes, macrophages, dendritic cells, and brain microglia. The glycoprotein

consists of two subunits, gp120 and gp41. The gp120 subunit has high affinity for CD4 receptors and is responsible for the initial binding of the virus to the cell. Once initial binding occurs, the intimate association of HIV with the cell is further enhanced by chemokine coreceptors. The two major chemokine receptors used by HIV are CCR5 and CXCR4. HIV that preferentially use CCR5, R5 viruses, are macrophage-tropic and non-syncytium-inducing. The R5 virus is typically implicated in most cases of sexually transmitted HIV. The X4 virus preferentially uses CXCR4 as a coreceptor and is T-cell-tropic—this virus is often predominant in the later stage of disease and is syncytium-inducing. Clinical isolates may contain a mixture of R5 and X4 viruses, and some viral strains, designated R5X4, may be dual-tropic (i.e., can use both coreceptors). Genetic defects in the expression of chemokine receptors appear to protect some individuals from developing AIDS despite their being exposed to the virus.¹⁹ Attachment of HIV to the cell promotes fusion and internalization (adsorption) of the virus—a process mediated by the gp41 subunit.

After internalization, the virus is uncoated in preparation for replication. The genetic material of HIV is positive-sense single-strand RNA (ssRNA); the virus must transcribe this RNA into DNA to optimally replicate in human cells (transcription normally occurs from DNA to RNA—HIV works backward, hence the name *retrovirus*). To do so, HIV is equipped with a unique enzyme, RNA-dependent DNA polymerase (reverse transcriptase). Reverse transcriptase first synthesizes a complementary strand of DNA using the viral RNA as a template. The RNA portion of this DNA-RNA hybrid is then partially removed by ribonuclease H (RNase H), allowing reverse transcriptase to complete the synthesis of a double-stranded DNA (dsDNA) molecule. Unfortunately, the fidelity of reverse transcriptase is poor,

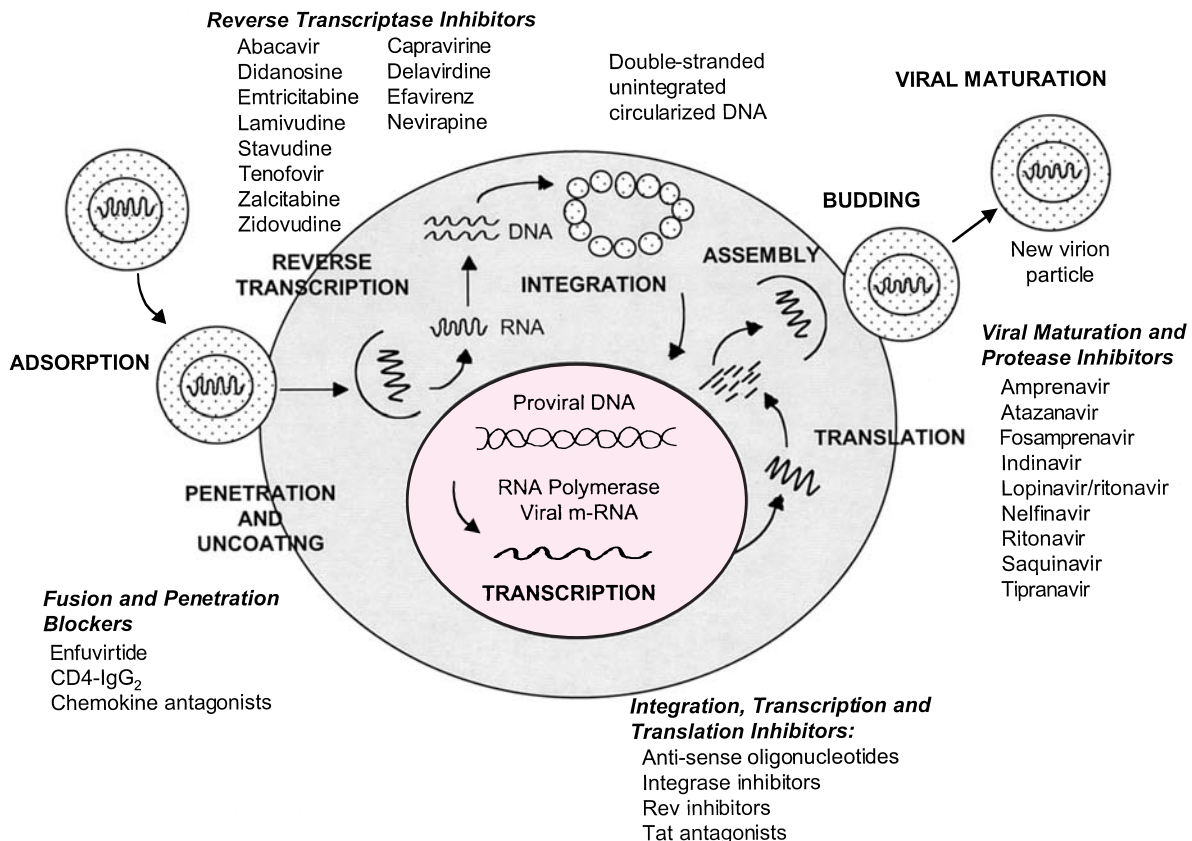

FIGURE 123–1. Life cycle of HIV with potential targets where replication may be interrupted and known or putative antiretroviral agents. (Reprinted with permission, © Courtney V. Fletcher, 2004.)

and many mistakes are made during the process. These errors in the final DNA product contribute to the rapid mutation of the virus and allow drug resistance to evolve. Following reverse transcription, the final dsDNA product migrates into the nucleus and is integrated into the host cell chromosome by integrase, another enzyme unique to HIV.

The integration of HIV into the host chromosome is troublesome for several reasons. First, HIV can establish a chronic and persistent infection, particularly in long-lived cells of the immune system such as memory T-lymphocytes.²⁰ Second, integration is random, thus making it difficult to target and extract integrated HIV. Last, random integration of HIV may cause cellular abnormalities and induce apoptosis.

Activation of the infected cell by antigens, cytokines, or other factors stimulates the cell to produce nuclear factor κ B (NF- κ B), an enhancer-binding protein. NF- κ B normally regulates the expression of T-lymphocyte genes involved in growth but also can inadvertently activate replication of HIV. When HIV replication is induced, the host DNA polymerase transcribes the integrated proviral DNA into messenger RNA (mRNA) with subsequent translation of the mRNA into viral proteins. At first, transcription and translation are done at a low level, yielding various regulatory HIV proteins such as Tat, Nef, and Rev. The Tat protein is a potent amplifier of HIV gene expression; it binds to a specific RNA sequence of HIV that initiates and stabilizes transcription elongation. There is no evident function for Nef, although it appears to downregulate class I molecules and protect infected cells from cytotoxic T-lymphocytes.²¹ Deletion of the *Nef* gene has been noted in HIV strains that have infected a cohort of long-term nonprogressors.²² The Rev protein regulates posttranscriptional activity and, like Tat, is essential for HIV replication. Rev essentially shifts synthesis of HIV regulatory proteins to structural proteins (e.g., gp120) by inhibiting viral mRNA splicing and exporting the mRNA outside the nucleus.²¹

Assembly of new virion particles occurs in a stepwise manner beginning with the coalescence of HIV proteins beneath the host cell lipid bilayer. The nucleocapsid subsequently is formed with viral ssRNA and other components packaged inside. Once packaged, the virion then buds through the plasma membrane, acquiring the characteristics of the host lipid bilayer. After the virus buds, the maturation process begins. Within the virion, HIV protease begins cleaving a large precursor polypeptide into functional proteins that are necessary to produce a complete virus. Without this enzyme, the virion is immature and unable to adequately infect cells.²³

HIV-1 exhibits a very high turnover rate, with an estimated 10 billion new viruses produced each day. More than 99% of these viruses are produced in newly infected cells. Ultimately, most infected cells will be destroyed from a number of mechanisms, including cell lysis by newly budding virions, cytotoxic T-lymphocyte-induced cell killing, syncytia formation, or apoptosis. Syncytia formation occurs when viral proteins expressed on the surface of the infected cell act as ligands for receptors expressed on uninfected cells. Uninfected cells clump onto the infected cell and fuse into a giant multinucleated cell. The syncytium-inducing X4 virus phenotype may develop later in disease and is associated with more rapid disease progression. Destruction of the CD4 cells leads to compromised immune function and consequently AIDS.

CLINICAL PRESENTATION

Clinical presentation of primary HIV infection may vary, but patients often have an acute retroviral syndrome or mononucleosis-like illness^{24,25} (Table 123–2). Symptoms often last 2 weeks, and hospi-

TABLE 123–2. Clinical Presentation of Primary HIV Infection in Adults

Symptoms

Fever, sore throat, fatigue, weight loss, and myalgia
40% to 80% of patients will also exhibit a morbilliform or maculopapular rash usually involving the trunk
Diarrhea, nausea, and vomiting
Lymphadenopathy, night sweats
Aseptic meningitis (fever, headache, photophobia, and stiff neck) may be present in a quarter of presenting cases

Other

High viral load (exceeding 50,000 copies/mL in the adult or 500,000 copies/mL in the child)
Persistent decrease in CD4 lymphocytes

talization may be required for 15% of patients.²⁴ Primary infection is often associated with a high viral load and development of an immune response that for a period of time suppresses, but does not eliminate, viral replication. During this period, HIV is trapped by follicular dendritic cells in lymphoid tissue and replicates in the germinal center. The amount of HIV RNA in plasma falls substantially at this point, and symptoms resolve gradually. This decline coincides with the development of an immune response to HIV. The clinically latent period, however, is not virologically latent because HIV replication and immune system deterioration are ongoing. A persistent decrease in CD4 cells is the most measurable aspect of this immune system destruction.²⁰ Plasma viral load, on the other hand, will appear to have stabilized at a particular level or “set point.” The set point that is established correlates directly with progression to AIDS and morbidity. The Multicenter AIDS Cohort Study (MACS) measured viral load in 181 HIV-positive men and followed them for as long as 11 years. Only 8% of patients with viral loads of less than 4530 copies/mL progressed to AIDS within 5 years, whereas the 5-year progression rate for those with initial viral loads above 36,270 copies/mL was 62%. The mortality rates within 5 years were 5% and 49%, respectively. Those with viral loads between 4531 and 13,020 progressed to AIDS at a rate of 26%, with a mortality rate of 10%, and those with viral loads from 13,021 to 36,270 progressed to AIDS at a rate of 49%, with a mortality rate of 25%. Clearly, a higher level of viremia at the onset is associated with poorer prognosis.²⁶

Most children born with HIV are asymptomatic. On physical examination, children often present with unexplained physical signs such as lymphadenopathy, hepatomegaly, splenomegaly, failure to thrive, weight loss or unexplained low birth weight (in prenatally exposed infants), and fever of unknown origin. Laboratory findings include anemia, hypergammaglobulinemia (primarily IgA and IgM), altered mononuclear cell function, and altered T-cell subset ratios.²⁷ Of note, the normal range for CD4 cell counts in young children is much different from that in adults (Table 123–3). Bacterial infections, including *Streptococcus pneumoniae*, *Salmonella* spp., and *Mycobacterium tuberculosis*, may be more prevalent in children with AIDS than in adults with the disease. Kaposi’s sarcoma is rare in children. Children with HIV infection may develop lymphocytic interstitial pneumonitis without evidence of *Pneumocystis carinii* or other pathogens on lung biopsy. Some children present with progressive, unexplained neurologic deterioration, including late-onset seizures, loss of developmental milestones, cessation of brain growth, and diffuse, unexplained encephalopathy. A history of recurrent or persistent bacterial, fungal, or viral infections, which may be chronic and initially subclinical or slowly progressive, has been observed. Included in this group are children with recurrent bacterial sepsis, meningitis,

and chronic otitis media and children with chronic oral candidiasis and presumed disseminated histoplasmosis. The current CDC pediatric AIDS surveillance definition (see Table 123–3) excludes children with congenital or perinatally acquired cytomegalovirus or other iden-

tified causes of congenital immunodeficiency.²⁸ Management of the HIV-infected child involves similar principles as the adult: antiretroviral therapy, treatment and prophylaxis of opportunistic infections, and supportive care.²⁹

▶ TREATMENT: Human Immunodeficiency Virus Infection

■ DESIRED OUTCOME

3 The goal of antiretroviral therapy is to achieve maximum suppression of HIV replication. This is commonly interpreted to be a plasma viral load less than the lower limit of quantitation (i.e., undetectable). Long-term response to therapy (i.e., durability) is determined by the viral load nadir achieved.^{30,31} Another equally important outcome is an increase in CD4 lymphocytes because this determines the risk for developing opportunistic infections.³² Occasionally, patients may respond virologically or immunologically without the other—the reasons for this discordance are unclear. The ultimate goal of antiretroviral therapy, however, is decreased morbidity and mortality.

■ GENERAL APPROACH TO TREATMENT

In mid-1997, the National Institutes of Health Office of AIDS Research convened a panel to define the scientific principles that might serve as a guide for the clinical use of antiretroviral agents.³³ The 11 principles presented below are an amalgamation of knowledge of the life cycle of HIV, the consequences of HIV replication, clinical trials of antiretroviral agents, and scientific opinion.

1. Ongoing HIV replication leads to immune system damage and progression to AIDS. HIV infection is always harmful, and true long-term survival free of clinically significant immune dysfunction is unusual.
2. Plasma HIV RNA levels indicate the magnitude of HIV replication and its associated rate of CD4 cell destruction, whereas CD4 cell counts indicate the extent of HIV-induced immune damage already suffered. Regular, periodic measurement of plasma HIV RNA levels and CD4 cell counts is necessary to determine the risk of disease progression in an HIV-infected individual and to determine when to initiate or modify antiretroviral treatment regimens.

3. Because rates of disease progression differ among individuals, treatment decisions should be individualized by level of risk indicated by plasma HIV RNA levels and CD4 cell counts.

4. The use of potent combination antiretroviral therapy to suppress HIV replication to below the levels of detection of sensitive plasma HIV RNA assays limits the potential for selection of antiretroviral-resistant HIV variants, the major factor limiting the ability of antiretroviral drugs to inhibit virus replication and delay disease progression. Therefore, maximum achievable suppression of HIV replication should be the goal of therapy.
5. The most effective means to accomplish durable suppression of HIV replication is the simultaneous initiation of combinations of effective anti-HIV drugs with which the patient has not been treated previously and that are not cross-resistant with antiretroviral agents with which the patient has been treated previously.
6. Each of the antiretroviral drugs used in combination therapy regimens always should be used according to optimal schedules and dosages.
7. The available effective antiretroviral drugs are limited in number and mechanism of action, and cross-resistance between specific drugs has been documented. Therefore, any change in antiretroviral therapy increases future therapeutic constraints.
8. Women should receive optimal antiretroviral therapy regardless of pregnancy status.
9. The same principles of antiretroviral therapy apply to both HIV-infected children and adults, although the treatment of HIV-infected children involves unique pharmacologic, virologic, and immunologic considerations.
10. Persons with acute primary HIV infections should be treated with combination antiretroviral therapy to suppress virus replication to levels below the limit of detection of sensitive plasma HIV RNA assays.

TABLE 123–4. Treatment of HIV Infection: Antiretroviral Regimens Recommended in Antiretroviral-Naive Persons**Nonnucleoside Reverse Transcriptase Inhibitor (NNRTI)-Based Regimens**

Preferred Efavirenz *plus* lamivudine *plus* zidovudine (or tenofovir DF or stavudine) except for pregnant women or women with pregnancy potential

Alternatives Efavirenz *plus* emtricitabine *plus* zidovudine (or tenofovir DF or stavudine) except for pregnant women or women with pregnancy potential

or

Efavirenz *plus* (lamivudine or emtricitabine) *plus* didanosine except for pregnant women or women with pregnancy potential

or

Nevirapine *plus* (lamivudine or emtricitabine) *plus* zidovudine (or stavudine or didanosine)

Protease Inhibitor (PI)-Based Regimens

Preferred Lopinavir/ritonavir *plus* lamivudine *plus* zidovudine (or stavudine)

Alternatives Amprenavir/ritonavir *plus* lamivudine (or emtricitabine) *plus* zidovudine (or stavudine)

Atazanavir *plus* lamivudine (or emtricitabine) *plus* zidovudine (or stavudine)

Indinavir-ritonavir *plus* lamivudine (or emtricitabine) *plus* zidovudine (or stavudine)

Lopinavir-ritonavir *plus* emtricitabine *plus* zidovudine (or stavudine)

Nelfinavir *plus* lamivudine (or emtricitabine) *plus* zidovudine (or stavudine)

Saquinavir-ritonavir *plus* lamivudine (or emtricitabine) *plus* zidovudine (or stavudine)

Triple Nucleoside Reverse Transcriptase Inhibitor-Based Regimen

(Only as an alternative to NNRTI- or PI-based regimens when these cannot be used as preferred therapy)

Abacavir *plus* lamivudine *plus* zidovudine

Abacavir *plus* lamivudine *plus* stavudine

NRTI = nucleoside reverse transcriptase inhibitor; NNRTI = nonnucleoside reverse transcriptase inhibitor; PI = protease inhibitor.

From Panel on Clinical Practice for Treatment of HIV Infection. Guidelines for the use of antiretroviral agents in HIV-infected adults and adolescents. November 3, 2003, <http://AIDSinfo.NIH.gov>; accessed, January 5, 2004.

- HIV-infected persons, even those with viral loads below detectable limits, should be considered infectious and should be counseled to avoid sexual and drug-use behaviors that are associated with transmission or acquisition of HIV and other infectious pathogens.

The extent to which these principles will stand the test of time is unknown; new information on the pathogenesis of HIV accrues constantly. The field of antiretroviral therapy is also evolving rapidly. Twenty antiretroviral agents are now approved by the Food and Drug Administration (FDA), and more are certain to come. Health care professionals involved in care of the HIV-infected person always must consult the most current literature with respect to the principles and strategies for therapy. At this time, a particularly excellent source for information on treatment guidelines can be found at: www.AIDSinfo.NIH.gov. With these caveats, Table 123–4 presents the state of the art for treatment of the HIV-infected individual as of November 2003. Treatment is recommended for all HIV-infected persons with symptomatic disease, CD4 lymphocyte counts below 350 cells/mcL, or plasma HIV RNA greater than 55,000 copies/mL regardless of the CD4 count.³⁴

■ PHARMACOLOGIC THERAPY

Conceptually, there are three primary methods of therapeutic intervention against HIV: inhibition of viral replication, vaccination to stimulate a more effective immune response, and restoration of the immune system with immunomodulators. Several approaches for an

HIV vaccine are in development, including whole killed virus, subunit and peptide vaccination, recombinant live vector, and naked DNA delivery. While clinical studies of vaccines have been done, at this point, optimal vaccine strategies are still being explored. Genetic variability in HIV and a nascent understanding of the role of the immune system in suppressing viral replication are significant barriers to the development of an effective HIV vaccine with long-lasting and protective immunity.³⁵ Among immunomodulators, interleukin 2 (aldesleukin or IL-2) appears to be the most promising. Several methods of dosing and administration have been attempted—the most common is subcutaneous administration for 5 consecutive days in 2-month cycles. The main benefit of IL-2 is increased CD4 cells; unfortunately, it is also associated with significant toxicities. Studies to assess clinical end points are underway.³⁶

■ ANTIRETROVIRAL AGENTS

Inhibiting viral replication with combinations of potent antiretroviral agents has been the most clinically successful strategy. Thus far there are three primary groups of drugs used: entry inhibition, reverse transcriptase inhibitors, and protease inhibitors (Table 123–5). Reverse transcriptase inhibitors are of two types, those which are chemical derivatives of purine- and pyrimidine-based nucleosides and nucleotides (nucleoside/nucleotide reverse transcriptase inhibitors [NRTIs]) and those which are not (nonnucleoside reverse transcriptase inhibitors [NNRTIs]). NRTIs include thymidine analogues such as stavudine (d4T) and zidovudine (AZT or ZDV); cytosine analogues such as emtricitabine (FTC), lamivudine (3TC), and zalcitabine (ddC); the inosine derivative didanosine (ddI); and the guanosine analogue abacavir sulfate (ABC). Tenofovir disoproxil

^gUsing PMPA molecular weight, not prodrug.

IND = indeterminate with standard analytical techniques; F = bioavailability; V_d = distribution volume; t_{1/2} = elimination half-life; CL = total-body clearance; C_{max} = maximum plasma concentration; C_{min} = minimum plasma concentration; CSF = cerebrospinal fluid; IC₅₀₋₉₀ = concentration required to produce 50% or 90% inhibition of HIV strains in vitro.

fumarate (TDF or PMPA) is an adenosine-derived nucleotide reverse transcriptase inhibitor. Several nucleoside analogues in various stages of development include alovudine (FLT), dOTC, and β-L-d4FC. As a class, the NRTIs require phosphorylation to the 5'-triphosphate moiety to be active. Intracellular phosphorylation occurs by cytoplasmic or mitochondrial kinases and phosphotransferases. Following prodrug activation, the 5'-triphosphate moiety acts in two ways: (1) It competes with endogenous deoxynucleotides for reverse transcriptase, and (2) it prematurely terminates DNA elongation owing to the modified 3'-hydroxyl group.³⁷ Hydroxyurea, a ribonucleotide reductase inhibitor, depletes intracellular deoxynucleotides and has been used in combination with NRTIs. Presumably, the reduction of endogenous triphosphates by hydroxyurea shifts the competition for reverse transcriptase in favor of the exogenous triphosphate (i.e., NRTI). In doing so, however, hydroxyurea may accentuate adverse effects such as pancreatitis from didanosine and peripheral neuropathy from stavudine-didanosine combinations.³⁸ Mycophenolic acid, an inosine monophosphate dehydrogenase inhibitor, can cause similar shifts in endogenous nucleotide pools. Although NRTIs are specific for HIV reverse transcriptase, their adverse effects in part may be owing to some inhibition of human DNA polymerases, particularly mitochondrial DNA polymerase γ.³⁹

NNRTIs are a chemically heterogeneous group of agents that bind noncompetitively to reverse transcriptase close to the catalytic

site. Unlike NRTIs, NNRTIs do not require intracellular activation, do not compete against endogenous deoxynucleotides, and do not have strong antiviral activity against HIV-2. Available NNRTIs include efavirenz, delavirdine, and nevirapine.⁴⁰ Capravirine and calanotide A are two agents in clinical development under this class.

The protease inhibitors (PIs) are a potent class of antiretrovirals that includes amprenavir, atazanavir, fosamprenavir, indinavir, lopinavir, nelfinavir, ritonavir, and saquinavir. Tipranavir is an investigational PI at the time of this writing. The pharmacology, safety, and efficacy of these drugs are reviewed elsewhere.⁴¹ Briefly, PIs block the maturation process, thereby resulting in the production of immature, noninfectious virions.²³

Enfuvirtide (T-20, or pentafuside) is the only entry inhibitor available at this time. An inhibitor of fusion, enfuvirtide is a synthetic 36-amino-acid peptide derived from the second heptad repeat (HR2) domain of gp41. It prevents fusion of HIV with the target cell by binding to the first heptad repeat (HR1) domain of gp41, thereby interfering with the “zipping” process of HR1 and HR2. Because of the peptide nature of enfuvirtide, oral delivery is impossible, and subcutaneous injection is the preferred route of administration.⁴² A derivative of enfuvirtide designated T-1249 is currently under investigation—this too must be administered by subcutaneous injection.

Novel antiviral agents are currently in development and exploit other areas of HIV replication. Entry can be aborted by chemokine

receptor antagonists and integrase, which represents another HIV-specific enzyme that can be targeted for inhibition. Drugs that block the assembly of HIV are also in development.⁴³

■ DRUG INTERACTIONS

5 The clinical use of antiretroviral agents is complicated by the significant drug-drug interactions that can occur with many of these agents. Some interactions are beneficial and used purposely; others may be harmful, leading to inadequate drug concentrations. Clinicians involved in the pharmacotherapy of HIV must maintain a current knowledge of drug interactions for these reasons. The Internet provides a useful resource for updated information on antiretroviral drug interaction—recommended Web sites can be found in the ref. 44. In general, amprenavir, efavirenz, nevirapine, and tipranavir are inducers of drug metabolism, whereas delavirdine and the PIs inhibit drug metabolism.⁴⁴ Ritonavir is a potent inhibitor of cytochrome P450 3A-mediated metabolism and is now used primarily as a pharmacokinetic enhancer of other PIs. Lopinavir is coformulated with ritonavir (LPV/r) for this reason.⁴⁵ NRTIs also may have interactions among themselves. Zidovudine and stavudine, for example, are phosphorylated by the same kinases; antagonism occurs between these two drugs both in vitro and in vivo; thus the two should never be given together.⁴⁶ Complicating matters is the drug interaction potential of antituberculosis agents, particularly rifamycins. Rifampin is contraindicated with most PIs because drug concentrations of the PIs are reduced substantially. If patients require simultaneous treatment for both HIV and tuberculosis, a regimen consisting of efavirenz, ritonavir, or saquinavir-ritonavir should be considered.⁴⁷ The herbal product Saint John's wort (*Hypericum perforatum*) is a potent inducer of metabolism and is contraindicated with PIs and NNRTIs. Among health volunteers, St. John's wort decreased indinavir area under the curve on average 57%.⁴⁸

■ PIVOTAL DEVELOPMENTS IN TREATMENT STRATEGIES

The pharmacotherapy of HIV infection has changed rapidly over the years as newer agents have become available and treatment paradigms have evolved. Highlights of the development of antiretroviral therapeutics are

- The demonstration that zidovudine monotherapy confers a survival benefit in persons who have AIDS.⁴⁹
- The demonstration that combination regimens of two NRTIs (e.g., zidovudine and didanosine or zalcitabine) are superior to zidovudine monotherapy in immunologic and virologic parameters, particularly in patients with no previous antiretroviral therapy, and confer a superior survival benefit (ACTG 175).⁵⁰
- The use of triple therapy with combinations of two NRTIs with NNRTIs or PIs, which has been clearly associated with a reduced incidence of opportunistic infections and improved survival.³

6 Current recommendations for treating HIV infection advocate a minimum of three antiretroviral agents. The typical regimen consists of two nucleoside analogues with either a PI (often pharmacologically enhanced with ritonavir) or an NNRTI, e.g., tenofovir, emtricitabine, lopinavir-ritonavir and zidovudine, lamivudine, efavirenz, respectively. Other combinations may include triple nucleoside analogues, dual PIs (two PIs both at active doses), dual boosted

PIs (two PIs pharmacologically enhanced with ritonavir), or a PI with a NNRTI. The initial choice in drugs is critical to long-term success, and factors such as adherence, efficacy (virologic and immunologic), durability, which drugs to start with and what to change to (i.e., sequencing), and tolerability are paramount to success.³⁴ Brief comments on these factors follow.

The simplest definition of adherence is the patient's ability to take medication as directed. Antiretroviral therapy is complex and long term, and the risk for virologic failure increases as adherence decreases. Patients with greater than 95% adherence on a PI regimen had better virologic and immunologic outcomes and a lower hospitalization rate than those with adherence below this threshold.⁵¹ As clinicians, it is important to communicate to the patient the importance of proper medication taking with specific education aimed at understanding the disease process, monitoring, and goals of therapy. An individual's "readiness" to take medications should be clearly established before any treatment is initiated.³⁴ Caregivers, friends, and/or family members should be included in this process because social and psychological support are among the most important factors that influence adherence in this patient population.⁵²

Several clinical trials have demonstrated the virologic and immunologic efficacy of antiretrovirals—the results are summarized succinctly elsewhere.^{53–55} Unfortunately, only a few have been large, randomized, comparative (head-to-head) trials. Nevertheless, these trials provide insight on the subtle differences in efficacy among antiretrovirals. Superior virologic efficacy was seen with lopinavir-ritonavir 400/100 mg twice daily compared with nelfinavir 750 mg three times daily in antiretroviral-naïve patients concomitantly treated with 40 mg twice daily of stavudine and lamivudine 150 mg twice daily. This double-blind, randomized, placebo-controlled trial involving 637 patients resulted in 75% of patients treated with lopinavir-ritonavir achieving viral loads of less than 400 copies/mL versus 63% of nelfinavir-treated patients after 48 weeks. The mean increases in CD4 cell counts were similar for both agents, 195 cells/mL with nelfinavir and 207 cells/mL with lopinavir-ritonavir. Overall tolerability was similar between the two agents.⁵⁶ Significantly more patients achieved viral suppression after 48 weeks with the NNRTI efavirenz given in combination with zidovudine-lamivudine when compared with a regimen of indinavir-zidovudine-lamivudine or indinavir-efavirenz in a multicenter, randomized, open-label study involving 432 patients. Both zidovudine and lamivudine were dosed twice daily, 300 and 150 mg, respectively. The administered dose for efavirenz was 600 mg once daily and that for indinavir was 800 mg every 8 hours. For the indinavir-efavirenz arm, efavirenz was given 600 mg once daily with indinavir 1000 mg every 8 hours to account for the drug interaction. The proportion of patients achieving HIV RNA of less than 400 copies/mL was 70% for those receiving treatment with efavirenz-zidovudine-lamivudine and 53% and 48% for indinavir-efavirenz and indinavir-zidovudine-lamivudine, respectively; mean increases in CD4 cell counts were 201, 180, and 185 cells/mL, respectively.⁵⁷

The durability and sequencing of a regimen are equally important as its efficacy. Since the advent of HAART, patients have been living longer with improved quality of life. The consequence of this is that patients will have to rely on their treatment for years to come, not months. Data on the long-term durability of HAART are scarce. The initiation of antiretroviral therapy in a treatment-naïve person must come with consideration for what agents will be available should the first regimen fail. Antiretroviral resistance testing is a useful tool in this regard. There are two types of resistance tests: phenotype and genotype. A phenotype test determines the concentration of antiretroviral necessary to inhibit 50% of viral replication

(IC₅₀) in a recombinant viral assay. Results usually are expressed as a fold-change in susceptibility compared with wild-type virus. While an increase in the fold-change suggests reduced susceptibility to that antiretroviral, resistance is never absolute, and partial susceptibility may remain. Alternatively, drug levels may be increased to overcome reduced susceptibility—this strategy is currently under evaluation. Genotyping assesses the codon changes in gp41, reverse transcriptase, or protease in the patient and compares it to the wild-type sequence. Mutations, when present, are listed by the wild-type amino acid followed by the position in the genetic sequence of the protein or enzyme and end with the mutation found in the patient. For example, a common mutation caused by lamivudine and emtricitabine is the M184V mutation—a substitution of valine (V) for methionine (M) at the 184 position of reverse transcriptase. Interpretation of genotypes is complex, and the reader is encouraged to consult the most recent guidelines on HIV resistance testing.⁵⁸

As with any medication, adverse effects occur with antiretroviral agents that may limit the patient's ability to tolerate medication. Several important adverse effects have been recognized with the currently available antiretrovirals. These include mitochondrial toxicity with NRTIs, rash with NNRTIs, and metabolic perturbations with PIs. A discussion on the specific presentation and management of these adverse effects is beyond the scope of this chapter but can be found elsewhere.^{4,39,59–61}

■ TREATMENT IN SPECIAL POPULATIONS

■ PREGNANCY

Treatment recommendations have been made to address the specific requirements for HIV-infected pregnant women and the prevention of vertical transmission.⁶² Therapy is warranted particularly in light of the dramatic reduction in transmission seen with zidovudine monotherapy (ACTG protocol 076). ACTG protocol 076 randomized 477 HIV-infected pregnant women (14 to 34 weeks' gestation) to either zidovudine or placebo. The zidovudine regimen consisted of antepartum zidovudine (100 mg five times daily) plus a continuous infusion of zidovudine during labor (2 mg/kg intravenously over 1 hour followed by 1 mg/kg per hour), and zidovudine for the newborn (2 mg/kg orally every 6 hours for 6 weeks). The HIV transmission rate was

25.5% among those who received placebo but was 8.3% when the mothers and their babies received zidovudine. This difference corresponds to a two-thirds reduction in the risk of maternal-to-infant HIV transmission. Adverse reactions associated with zidovudine therapy in the study were minimal: Hemoglobin concentrations were significantly lower at birth in infants whose mothers received zidovudine, but this difference disappeared by 12 weeks of age; there was no difference in minor or major structural abnormalities in the two groups.⁶³

CLINICAL CONTROVERSY

Unfortunately, little is known about the use of other antiretrovirals in pregnant women and the effect these drugs may have on the developing fetus. PI use among 89 pregnant women appeared generally safe to both mother and baby in a retrospective multicenter survey.⁶⁶ In general, pregnant women should be treated similarly as nonpregnant adults; if possible, zidovudine should be used for both mother and infant.⁶²

An abbreviated course of zidovudine (i.e., given during labor or in the first 48 hours of life) also can reduce transmission substantially and may be easier for the patient to take.⁶⁴ Alternatively, single-dose nevirapine given to the mother during labor and to the baby within 3 days of birth also can reduce transmission of HIV.⁶⁵

■ POSTEXPOSURE PROPHYLAXIS

Protection of health care workers from accidental exposure to HIV is an important concern. The CDC has issued guidelines governing treatment for occupational HIV exposure. Postexposure prophylaxis (PEP) with a triple-drug regimen consisting of two NRTIs and a PI is recommended for percutaneous blood exposure involving significant risk (large volume of blood or blood from patients with advanced AIDS). Two NRTIs may be offered to the health care worker with lower risk of exposure, such as those involving the mucous membrane or skin. Treatment is not necessary if the source of exposure is urine or saliva. The optimal duration of treatment is unknown, but at least 4 weeks of therapy is advocated. Treatment ideally should be initiated within 1 to 2 hours of exposure.¹⁶ Guidelines also have been developed for postcoital and postinjection-drug-use prophylaxis.⁶⁷

EVALUATION OF THERAPEUTIC OUTCOMES

Following the initiation of therapy, patients usually are monitored at 3-month intervals with immunologic (CD4 count), virologic (HIV RNA), and clinical assessments. There are two general indications to change therapy: significant toxicity or treatment failure. Each of the available antiretroviral agents has its own set of drug-limiting adverse reactions⁴; fortunately, alternatives with nonoverlapping adverse effects are available. For example, the patient who experiences significant peripheral neuropathy on the combination of didanosine and stavudine could be changed to a combination of zidovudine and lamivudine. Specific criteria to indicate treatment failure have not been established through controlled clinical trials. As a general guide, the following events should prompt consideration for changing therapy:

1. Less than 1 log₁₀ reduction in HIV RNA 1 month after the initiation of therapy or a failure to achieve maximal suppression of HIV replication within 4 to 6 months
2. A persistent decline in the CD4 cell count or a return to pretreatment value or an increase in HIV RNA of 0.3 to 0.5 log₁₀ copies per milliliter from nadir
3. Clinical disease progression, usually the development of a new opportunistic infection

THERAPEUTIC FAILURE

Therapeutic failure in HIV therapy may be the result of nonadherence to medication, development of drug resistance, intolerance to one or more medications, adverse drug-drug interactions, or pharmacokinetic-pharmacodynamic variability. Few clinical data are available to indicate what alternative strategies should be employed for patients who fail their initial regimen. Moreover, the data that are available are confounded by the heterogeneity in the patients and their infecting viruses, which makes the results difficult to interpret. In general, patients failing their first regimen should be treated with a drug representing a new class (e.g., if the patient was treated initially

with a PI, the PI can be switched to an NNRTI). The guiding principles (numbers 5 and 7) recommend changing to at least two new antiretroviral drugs that are not cross-resistant with agents the patient has received previously. Table 123–4 presents some examples of alternative regimens. Virologic resistance testing may help to guide the health care provider in selecting appropriate agents.⁵⁸ In addition to an alternative antiretroviral regimen, other investigational strategies suggested for therapeutic failure include drug holidays, structured or strategic treatment interruptions (STIs), and structured intermittent therapy (SIT). While there are subtle differences between these strategies, the overall premise is similar—stop all antiretrovirals and allow the patient time off medication. Undoubtedly, any strategy that discontinues antiretroviral therapy will allow viral replication to occur with subsequent declines in CD4 lymphocytes. Reinitiation of therapy then is intended to reestablish control of the disease. There remain numerous uncertainties about these discontinuation strategies, including how long the patient can remain off medications, how often this cycle can be done, and most important, the ability of the strategy to reduce morbidity and mortality, as has conventional HAART. Prospective studies are necessary to answer these questions.

INFECTIOUS COMPLICATIONS OF AIDS

The consequence of uncontrolled HIV replication is a steady decline in CD4 cells. Ironically, these are the cells that coordinate the immune system—the system designed to prevent infections from occurring in the first place. HIV is an insidious disease in that persons infected often present with opportunistic infections (OIs), a consequence of the weakened immune system rather than HIV per se. Most OIs are caused by organisms that are common in the environment and often represent the reactivation of quiescent infections. The development of certain OIs is related directly or indirectly to the level of CD4 lymphocytes and can be predicted with some degree of accuracy¹⁶ (Fig. 123–2). Until the immunosuppression induced by HIV can be prevented, the prevention and management of OIs will remain an essential component of the comprehensive care of HIV-infected individuals.

Surveillance data indicate that the incidence of certain OIs in HIV-infected persons in the United States continues to change. The three major OIs—*Pneumocystis carinii* pneumonia (PCP), *Mycobacterium avium* complex (MAC) disease, and cytomegalovirus (CMV) retinitis—all have decreased in incidence.^{3,68} Potent antiretroviral reg-

FIGURE 123–2. Natural history of opportunistic infections associated with HIV infection. (Reprinted with permission, © Courtney V. Fletcher, 1995.)

imens and prophylactic strategies for OIs are major factors associated with these decreases. Nevertheless, opportunistic diseases continue to be complications of HIV disease and occur at low CD4 lymphocyte counts. For example, the risk of an OI was almost sixfold higher in persons receiving HAART with a baseline CD4 count of fewer than 50 cells/mcL compared with more than 200 cells/mcL.⁶⁹

The spectrum of infectious diseases observed in HIV-infected individuals and recommended first-line regimens for treatment are shown in Table 123–6, and recommended therapies for primary prophylaxis are shown in Table 123–7. An exhaustive review of all OIs associated with HIV infection is beyond the scope of this chapter. The major OIs include: PCP, candidal esophagitis (discussed elsewhere in this text), central nervous system toxoplasmosis, cryptococcosis, mycobacterial disease, and herpes group virus infections. The following discussion will emphasize these pathogens and will provide an overview of the epidemiology, diagnosis, clinical manifestations, and results of treatment for these infections. Readers desiring more specific information, either for the diseases or agents mentioned, will need to consult additional references.

PNEUMOCYSTIS CARINII

P. carinii pneumonia (PCP) is the most common life-threatening opportunistic infection in patients with AIDS. Early in the AIDS epidemic, approximately 60% of patients with AIDS had PCP as their AIDS-defining event, and 80% experienced PCP at some point during their lifetime.⁷⁰ The advent of effective prophylaxis for PCP has decreased the relative incidence of PCP. However, PCP prophylaxis has not eliminated the disease because of persons unaware of their HIV infection, breakthrough PCP in those receiving prophylaxis, and variable compliance with prophylaxis. The taxonomy of the organism is unclear, having been classified as both protozoan and fungal, but genomic sequences suggests that *P. carinii* is a fungus.⁷¹ Exposure to *P. carinii* is widespread because 80% of the population has developed serum antibodies by age 2 or 3 years.⁷² The organism appears to reside without consequence in the human unless the host becomes immunologically compromised; immunosuppression allows the organism to multiply, giving rise to clinical disease.

PCP in patients with AIDS differs in clinical presentation from that in patients with other immunosuppressive conditions, such as malignant neoplasms. In AIDS patients, the presentation is often more subacute. Characteristic symptoms include fever and dyspnea; clinical signs are tachypnea with or without rales or rhonchi, and a non-productive or mildly productive cough. Chest radiographs may show florid or subtle infiltrates or occasionally be normal. Infiltrates are usually interstitial and bilateral, however. Arterial blood gases may show minimal hypoxia (PaO₂ 80 to 95 mm Hg), but in more advanced disease they may be markedly abnormal. The onset of PCP is often insidious, occurring over a period of weeks, although more fulminant presentations can occur. The diagnosis of PCP is usually made by identification of the organism in induced sputum or in specimens obtained from bronchoalveolar lavage. Less commonly, transbronchial biopsy is used for diagnosis.

Untreated PCP has a mortality of nearly 100%. Treatment with agents such as trimethoprim-sulfamethoxazole (or cotrimoxazole) or parenteral pentamidine is associated with a 60% to 100% response rate. Both agents appear to be equally efficacious, but trimethoprim-sulfamethoxazole was less toxic. Trimethoprim-sulfamethoxazole is the regimen of choice for treatment and prophylaxis of PCP in patients with and without HIV.^{73,74}

Trimethoprim-sulfamethoxazole, when used for the treatment of PCP, usually is given in doses of 15 to 20 mg/kg per day (based on

TABLE 123–6. Therapies for Common Opportunistic Pathogens in HIV-Infected Individuals

| Clinical Disease | Selected Initial Therapies for Acute Infection in Adults | Common Drug- or Dose-Limiting Adverse Reactions |
|---|--|--|
| Fungi | | |
| Candidiasis, oral | Fluconazole 200 mg orally single dose or 100 mg orally for 5 days <i>or</i> Nystatin 500,000 units oral swish 4–6 times daily for 7–10 days <i>or</i> Clotrimazole 10 mg (1 troche) orally 5 times daily for 7–10 days | Taste, patient acceptance |
| Candidiasis, esophageal | Fluconazole 200 mg orally or intravenously on the first day then 100 mg/d for 10–14 days <i>or</i> Ketoconazole 400 mg/d orally for 10–14 days | Elevated liver function tests, hepatotoxicity, nausea and vomiting Elevated liver function tests, hepatotoxicity, rash, nausea and vomiting |
| <i>Pneumocystis carinii</i> pneumonia | Trimethoprim-sulfamethoxazole intravenously or orally 12–20 mg/kg/day as TMP component in 3–4 divided doses for 21 days ^a <i>or</i> Pentamidine intravenously 3–4 mg/kg/day for 21 days ^a | Skin rash, fever, leukopenia Thrombocytopenia Azotemia, hypoglycemia, hyperglycemia |
| | <i>Mild episodes</i> Atovaquone suspension 750 mg (5 mL) orally twice daily with meals for 21 days ^a | Rash, elevated liver enzymes, diarrhea |
| Cryptococcal meningitis | Amphotericin B 0.5–1.0 mg/kg/day intravenously for a minimum of 2 weeks <i>with or without</i> flucytosine 100–150 mg/kg/day orally in 4 divided doses <i>followed by</i> Fluconazole 100 to 200 mg/day, orally ^a | Nephrotoxicity, hypokalemia, anemia, fever, chills Bone marrow suppression Elevated liver enzymes Same as above |
| Histoplasmosis | Amphotericin B 0.5–1 mg/kg/day intravenously for 6–8 weeks ^a <i>or</i> Itraconazole 200–400 mg/day orally for 3 months ^a | Same as above Elevated liver function tests, hepatotoxicity, nausea and vomiting, hypertension |
| Coccidioidomycosis | Amphotericin B 0.5–1 mg/kg/day intravenously for ≥6–8 weeks ^a | Same as above |
| Protozoa | | |
| Toxoplasmic encephalitis | Pyrimethamine 200 mg orally once then 50–100 mg/day <i>plus</i> Sulfadiazine 1–1.5 g orally four times daily <i>and</i> Folinic acid 10–20 mg orally daily for a minimum of 28 days ^a | Bone marrow suppression Allergy, rash, drug fever |
| Isosporiasis | Trimethoprim and sulfamethoxazole 1–2 double-strength tablets (160 mg trimethoprim and 800 mg sulfamethoxazole) orally twice daily for 2–4 weeks | Same as above |
| Bacteria | | |
| Organisms associated with T-cell defects: | | |
| <i>Mycobacterium avium</i> complex | Clarithromycin 500 mg orally twice daily, <i>plus</i> ethambutol 15 mg/kg/day orally to a maximum of 1000 mg/day, <i>and</i> Rifabutin 300 mg/day ^a | Gastrointestinal intolerance Optic neuritis, peripheral neuritis |
| <i>Salmonella</i> enterocolitis or bacteremia | Ciprofloxacin 500–750 mg orally twice daily for 14 days <i>or</i> Trimethoprim (160 mg)–sulfamethoxazole (800 mg) 1 tablet orally twice daily for 14 days | Rash, gastrointestinal intolerance Neutropenia, discolored urine, uveitis Gastrointestinal intolerance Same as above |
| Organisms associated with B-cell defects: | | |
| <i>Campylobacter</i> enterocolitis | Ciprofloxacin 500 mg orally twice daily for 7 days <i>or</i> Erythromycin 250–500 mg orally four times daily for 7 days | Same as above Gastrointestinal intolerance, colitis ototoxicity |
| <i>Shigella</i> enterocolitis | Ciprofloxacin 500 mg orally twice daily for 5 days | Same as above |

(continued)

TABLE 123–6. (Continued)

| Clinical Disease | Selected Initial Therapies for Acute Infection in Adults | Common Drug- or Dose-Limiting Adverse Reactions |
|------------------------------|--|--|
| Viruses | | |
| Mucocutaneous herpes simplex | Acyclovir 1–2 g/day orally in 3–5 divided doses for 7–10 days <i>or</i> Valacyclovir 500 mg orally every 12 hours for 7–10 days <i>or</i> Famciclovir 500 mg orally every 12 hours for 7–10 days | Gastrointestinal intolerance |
| Varicella-zoster | Acyclovir 30 mg/kg/day intravenously in 3 divided doses <i>or</i> 4 g/day orally for 7–10 days <i>or</i> Valacyclovir, 1 g orally every 8 hours for 7–10 days <i>or</i> Famciclovir 500 mg orally every 8 hours for 7–10 days | Obstructive nephropathy, CNS symptomatology |
| Cytomegalovirus | Ganciclovir 7.5–10 mg/kg/day in 2–3 divided doses intravenously for 14 days ^a <i>or</i> Foscarnet 180 mg/kg/day in 2 or 3 divided doses intravenously for 14 days ^a | Neutropenia, thrombocytopenia |
| Cytomegalovirus retinitis | Ganciclovir intraocular implant | Nephrotoxicity, hypohypercalcemia, hypohyperphosphatemia, anemia |

^aMaintenance therapy is recommended.

the trimethoprim component) as three to four divided doses. Doses of 12 to 15 mg/kg per day may be as effective and perhaps reduce the incidence of toxicity. Trimethoprim-sulfamethoxazole usually is initiated by the intravenous route, although oral therapy (since oral absorption is high) may suffice in mildly ill and reliable patients or to complete a course of therapy after a response has been achieved with intravenous administration. If oral therapy is used, it may be prudent to document absorption with serum concentrations of trimethoprim or sulfamethoxazole because gastrointestinal disturbances or a malabsorption syndrome is known to alter drug absorption in patients with AIDS. Target concentrations for trimethoprim are between 5 and 8 mcg/mL.

For treatment of HIV-associated PCP, pentamidine isethionate is administered intravenously usually in doses of 4 mg/kg per day, although a pilot study has reported successful treatment with 3 mg/kg per day.^{75,76} Aerosolized pentamidine should not be used for treatment of PCP because comparative studies with intravenous pentamidine indicate that aerosolized treatment is associated with a slower clinical response and higher rates of therapeutic failure and PCP relapse.^{76,77}

The efficacy of trimethoprim-sulfamethoxazole or pentamidine for treatment of an initial episode of PCP in HIV-infected individuals is similar, with published response rates between 60% to 80%. While comparative studies between the two regimens are few, one prospective, randomized trial found that oxygenation improved more quickly and survival was better in those who received trimethoprim-sulfamethoxazole.⁷⁸

CLINICAL CONTROVERSY

The optimal length of therapy for treatment of PCP with either agent is not known, but 21 days is commonly recommended. Clinical improvement in patients with AIDS is often slower than in non-AIDS patients. One study demonstrated improvement in chest radiograph or gallium scan in only two-thirds of patients at the end of treatment.⁷⁹ Thus the lack of prompt clinical improvement is not necessarily an indication of no response. In fact, patients frequently may worsen before they

improve. However, continued worsening after 4 days or lack of improvement after 7 to 10 days is an indication for a change in therapy regardless which agent was started initially. There are no data regarding the utility of concurrent therapy with both trimethoprim-sulfamethoxazole and pentamidine, and this approach is not recommended

Adverse reactions to both trimethoprim-sulfamethoxazole and pentamidine are common and range between 20% to 85% in this setting. The more common adverse reactions seen with trimethoprim-sulfamethoxazole are rash, fever, leukopenia, elevated serum transaminases, and thrombocytopenia. Mild rashes should be watched closely for progression to more severe reactions but are not an absolute contraindication to continuing therapy. The incidence of these adverse reactions is higher in HIV-infected individuals than in those not infected with HIV.⁸⁰ For pentamidine, side effects include hypotension, tachycardia, nausea, vomiting, severe hypoglycemia or hyperglycemia, pancreatitis, irreversible diabetes mellitus, elevated serum transaminases, nephrotoxicity, leukopenia, and cardiac arrhythmias. Some of these reactions appear to be infusion-rate-related (e.g., hypotension and tachycardia) and can be minimized by infusing pentamidine over 1 hour or more. The overall incidence of adverse reactions to pentamidine appears to be similar between individuals infected with HIV and those not infected. Dosage modification or pharmacokinetic monitoring can reduce somewhat the toxicity of both pentamidine and trimethoprim-sulfamethoxazole.⁷⁹ Dose reduction of pentamidine from 4 to 3 mg/kg per day appears to be successful in minimizing further rises in serum creatinine. Maintenance of serum trimethoprim concentrations between 5 and 8 mcg/mL may help to prevent severe myelosuppression.

The early addition of adjunctive corticosteroid therapy to anti-PCP regimens decreases the risk of respiratory failure and improves survival in patients with AIDS and moderate to severe PCP ($\text{PaO}_2 \leq 70$ mm Hg or A–a gradient ≥ 35 mm Hg).^{81,82} The adverse effects associated with corticosteroid therapy in these patients were minimal, primarily an increased incidence of herpetic lesions, although some

TABLE 123–7. Therapies for Prophylaxis of First Episode Opportunistic Diseases in Adults and Adolescents

| Pathogen | Indication | First Choice |
|--|--|---|
| I. Standard of Care | | |
| <i>Pneumocystis carinii</i> | CD4+ count <200/mcL or oropharyngeal candidiasis | Trimethoprim-sulfamethoxazole, 1 double-strength tablet orally once daily or 1 single-strength tablet orally once daily |
| <i>Mycobacterium tuberculosis</i> | | |
| Isoniazid-sensitive | TST reaction ≥ 5 mm or prior positive TST result without treatment or contact with case of active tuberculosis | Isoniazid 300 mg orally plus pyridoxine, 50 mg orally once daily for qmo or isoniazid 900 mg orally plus pyridoxine 50 mg orally twice weekly $\times 12$ mo 5 |
| Isoniazid-resistant | Same as isoniazid-sensitive; high probability of exposure to isoniazid-resistant tuberculosis | Rifampin 600 mg orally once daily plus pyrazinamide 200 mg/kg orally once daily for 2 mo |
| <i>Toxoplasma gondii</i> | IgG antibody to <i>Toxoplasma</i> and CD4+ count <100/mcL | Trimethoprim-sulfamethoxazole 1 double-strength tablet orally once daily |
| <i>Mycobacterium avium</i> complex | CD4+ count <50/mcL | Azithromycin, 1200 mg orally once weekly or clarithromycin, 500 mg orally twice daily |
| Varicella zoster virus (VZV) | Significant exposure to chickenpox or shingles for patients who have no history of either condition or, if available, negative antibody to VZV | Varicella zoster immune globulin (VZIG), 5 vials (1.25 mL each) intramuscularly administered ideally within 48 h of exposure but ≤ 96 h |
| II. Usually Recommended | | |
| <i>Streptococcus pneumoniae</i> | CD4 count of ≥ 200 cells/mcL | 23-valent polysaccharide vaccine, 0.5 mL intramuscularly |
| Hepatitis B virus | All susceptible (antihepatitis B core antigen negative) patients | Hepatitis B vaccine, 3 doses |
| Influenza virus | All patients (annually, before influenza season) | Inactivated trivalent influenza virus vaccine: 0.5 mL intramuscularly |
| Hepatitis A virus | All susceptible (anti-HAV-negative) patients at increased risk for hepatitis A infection (e.g., illegal drug users, men who have sex with men, hemophiliacs) or patients with chronic liver disease including chronic hepatitis B or C | Hepatitis A vaccine: 2 doses |
| III. Indicated for Use Only in Selected Circumstances | | |
| Bacteria | Neutropenia | Granulocyte-colony-stimulating factor (G-CSF), 5–10 mcg/kg subcutaneously once daily for 2–4 weeks; or granulocyte-macrophage colony-stimulating factor (GM-CSF), 250 mcg/m ² subcutaneously for 2–4 weeks |
| <i>Cryptococcus neoformans</i> | CD4+ count <50/mcL | Fluconazole, 100–200 mg orally once daily |
| <i>Histoplasma capsulatum</i> | CD4+ count < 100/mcL, endemic geographic area | Itraconazole capsule, 200 mg orally once daily |
| Cytomegalovirus | CD4+ count < 50/ μ L and CMV antibody positivity | Oral ganciclovir, 1 g po three times daily |

From Centers for Disease Control and Prevention. Guidelines for Preventing Opportunistic Infections Among HIV-Infected Persons—2002 Recommendations of the USPHS/IDSA. *MMWR* 2002;51:1–52.

concerns exist about the potential for reactivation of tuberculosis. The optimal dose and duration of corticosteroid therapy have not been identified. The regimen currently recommended is 40 mg prednisone orally twice daily during days 1 through 5, 40 mg once daily on days 6 through 10, and 20 mg once daily on days 11 through 21 or for the duration of therapy.⁸³ Methylprednisolone at 75% of the prednisone dose can be used if parenteral therapy is necessary. In general, adjunctive corticosteroid therapy should be initiated when antipneumocystis therapy is started because the data supporting the use of corticosteroids are based on initiation within the first 24 to 72 hours of the start of antipneumocystis therapy.

HIV-infected individuals who have had PCP are at high risk for recurrent PCP if no prophylactic measures are taken. Even though the treatment of PCP is becoming increasingly successful, the mortality

rate from first-episode PCP is still between 5% and 20%, and therapy frequently is complicated by adverse reactions. Prevention of PCP is clearly a preferable strategy to treatment. The relative risk of PCP in 1665 HIV-infected participants who did not have AIDS was 4.9 in those with CD4 lymphocyte counts of fewer than 200 cells/mcL.⁸⁴ Currently in the United States, PCP prophylaxis is recommended for all HIV-infected individuals who have already had previous PCP. Prophylaxis is also recommended for any HIV-infected person who has a CD4 lymphocyte count of fewer than 200 cells/mcL or in whom the CD4 cells are less than 20% of total lymphocytes or who has oropharyngeal candidiasis.¹⁶

Trimethoprim-sulfamethoxazole is the preferred therapy for both primary and secondary prophylaxis of PCP in adults and adolescents. Trimethoprim-sulfamethoxazole is the most effective and least

expensive agent for prophylaxis; it also appears to confer cross-protection against toxoplasmosis and many bacterial infections. The recommended dose in adults and adolescents is one double-strength tablet daily, although other regimens, such as one double-strength tablet thrice weekly or one single-strength tablet daily and gradual dose escalation using liquid trimethoprim-sulfamethoxazole, have been used in an attempt to reduce the incidence of adverse reactions and improve compliance. Alternative prophylactic regimens if trimethoprim-sulfamethoxazole cannot be tolerated include dapsone, dapsone plus pyrimethamine and leucovorin, aerosolized pentamidine, and atovaquone.⁸⁵

Trimethoprim-sulfamethoxazole is also the recommended drug of choice for PCP prophylaxis in children. As described previously, the normal range for CD4 lymphocytes is very different for children than for adults. Both the absolute CD4 count and CD4 cells as a percentage of the total should be determined. A CD4 percentage of less than 25% is an indication of immunosuppression. The utility of trimethoprim-sulfamethoxazole for prophylaxis is well established for children not HIV-infected receiving myelosuppressive therapy.⁸⁶ The trimethoprim-sulfamethoxazole regimen recommended (although other acceptable alternatives exist) is 150 mg/m² per day of trimethoprim and 750 mg/m² per day of sulfamethoxazole given in divided doses twice daily three times weekly on consecutive days (e.g., Monday, Tuesday, and Wednesday). The total daily dose of trimethoprim-sulfamethoxazole in children should not exceed 320 mg trimethoprim and 1600 mg sulfamethoxazole. PCP prophylaxis in HIV-exposed/infected children is strongly recommended as follows: (1) all HIV-exposed infants beginning between 4 to 6 weeks of age and continuing to 12 months of age if infection status is unknown, (2) all HIV-infected infants beginning at 4 to 6 weeks of age and continuing to 12 months of age, and (3) all HIV-infected children older than 1 year of age with severe immunosuppression.⁶⁸

TOXOPLASMA GONDII

The seroprevalence of *T. gondii* in HIV-infected individuals from major urban areas of the United States varies from 10% to 45%. The parasite is passed to humans from raw or undercooked meat and contact with feces from infected cats. *T. gondii* can infect any organ of the body and cause an acute infection; it has a predilection for the brain and the eye. Once an individual is infected, the organism can replicate, forming tissue cysts that persist for the life of the host. Many individuals will not have symptoms of disease. Immunosuppression, however, allows the release of tachyzoites from tissue cysts that produce a necrotic foci of infection, most often in the brain. In the patient with AIDS, *T. gondii* is an important opportunistic pathogen that is responsible for most focal intracerebral lesions.⁸⁷

The clinical signs and symptoms of toxoplasmosis are associated most frequently with involvement of the CNS and less commonly the lungs and eyes, although any organ can be affected. Clinical presentation often includes: fever, headache, seizures (in approximately 10% to 25% of patients), focal neurologic abnormalities (in approximately 60% to 90%), and mental status changes. Brain biopsy is required to make a definitive diagnosis of toxoplasmic encephalitis, although presumptive diagnosis is made commonly in *T. gondii*-seropositive patients with typical CNS lesions. Characteristic radiographic abnormalities found by computed tomographic (CT) scan or magnetic resonance imaging (MRI) also have been useful in the diagnosis of CNS toxoplasmosis.

The initial treatment of CNS toxoplasmosis is usually empirical. Brain biopsy in patients with AIDS may be complicated by

potential morbidity, location of the lesion(s), or thrombocytopenia. Anti-*Toxoplasma* therapy usually is initiated in patients with AIDS who are seropositive for *Toxoplasma* and have clinical symptoms suspicious for toxoplasmosis and characteristic findings on neuro-radiographic studies (multiple ring-enhancing lesions). In this setting, brain biopsy usually is not undertaken unless the patient fails to respond clinically or radiologically to 10 to 14 days of therapy or deteriorates clinically. Brain biopsy is an initial consideration in the *T. gondii*-seronegative patient or in patients with atypical lesions.

9 The combination of pyrimethamine and sulfadiazine is considered the most effective regimen for acute therapy of AIDS-related CNS toxoplasmosis.⁸⁸ This regimen works synergistically by sequentially inhibiting two steps in folic acid synthesis of the proliferative form of *T. gondii*. There is no widespread agreement on the optimal doses of pyrimethamine and sulfadiazine. Pyrimethamine loading doses of 75 mg orally on the first day, followed by 25 mg/day thereafter, have been used commonly. The erratic concentrations of pyrimethamine found in patients with AIDS and toxoplasmic encephalitis at lower doses (25 mg/day) have prompted some investigators to use larger doses.⁸⁹ Loading doses of 100 to 200 mg followed by daily oral doses of 1 to 1.5 mg/kg per day (50 to 100 mg/day) have been recommended.⁹⁰ The usual dose of sulfadiazine is 1 to 1.5 g every 6 hours (4 to 8 g/day). Folinic acid, in doses of 10–20 mg/day (although doses as high as 50 mg/day have been used), usually is added to the combination to reduce the pyrimethamine-induced bone marrow toxicity. Acute therapy with this combination should be continued for at least 3 weeks, but 6 weeks of treatment is recommended for more severely ill patients. Response rates (combined partial and complete) of approximately 85% have been observed following a minimum of 4 weeks of therapy. Adverse reactions, primarily bone marrow suppression associated with pyrimethamine and sulfadiazine hypersensitivity reactions, may limit therapy in as many as 40% of AIDS patients.⁸⁹ A regimen of pyrimethamine (50 mg/day) plus clindamycin (2400 mg/day) for 6 weeks, followed by reduced-dose maintenance therapy, was less effective (disease progression risk 1.8 times higher) than pyrimethamine-sulfadiazine.⁸⁸ The combination of pyrimethamine plus clindamycin does appear to be less toxic than pyrimethamine plus sulfadiazine. Other investigational alternative regimens include trimethoprim-sulfamethoxazole and pyrimethamine and leucovorin plus either clarithromycin, azithromycin, atovaquone, or dapsone.

The discontinuation of pyrimethamine-sulfadiazine after successful initial therapy may be considered in persons who have a sustained CD4 cell count of greater than 200 cells/mL for at least 6 months and have completed initial therapy and are asymptomatic.⁶⁸ A regimen of sulfadiazine 500 to 1000 mg orally 4 times daily plus pyrimethamine 25 to 50 mg orally and leucovorin 10 to 25 mg orally once daily is recommended for maintenance therapy. Pyrimethamine plus clindamycin also can be considered for maintenance therapy, but this regimen may be associated with a higher relapse rate. A further advantage to the combination of pyrimethamine plus sulfadiazine is that an additional agent for prophylaxis of PCP is unnecessary, which is not the case with the pyrimethamine plus clindamycin combination.⁹¹

Only limited information about primary prophylaxis of *T. gondii* in the HIV-infected person is available from carefully controlled prospective studies. Primary prophylaxis is recommended, but in HIV-infected persons who have immunoglobulin G antibody to *T. gondii* and a CD4 cell count of fewer than 100 cells/mL, the preferred regimen is trimethoprim-sulfamethoxazole one double-strength tablet orally once daily.⁶⁸

CRYPTOCOCCUS NEOFORMANS

Infection with *C. neoformans* is now uncommon in the HAART era and occurs primarily in those with limited access to health care.⁹² Infections probably are contracted originally through inhalation, and the respiratory tract is believed to be the first infected site. The usual clinical presentation of cryptococcal infection is meningitis, although pneumonia and disseminated disease also occur. The clinical features of cryptococcal meningitis may be subtle, nonspecific, and not localize to the CNS.⁹³ Fever, headache, and malaise are the most frequent symptoms. Meningeal features, mental status changes, and other focal neurologic signs occur only in a minority of patients. The diagnosis of cryptococcal meningitis always should be considered when HIV-infected individuals with advanced disease or low CD4 lymphocyte counts present with nonspecific symptoms or pulmonary or CNS findings.

Methods for diagnosis of cryptococcal infection includes serum and cerebrospinal fluid (CSF) testing for cryptococcal antigen and fungal cultures. Detection of cryptococcal antigen in serum and CSF is the most sensitive and specific test; an antigen titer of greater than 1:8 should be regarded as evidence for infection. Identification of *C. neoformans* on india ink examination of the CSF or from culture also may be used to confirm the diagnosis when antigen is unavailable. Factors suggestive of a poor prognosis in patients with cryptococcal meningitis include alteration in mental status, CSF antigen greater than 1:1024, a low CSF leukocyte count, and age younger than 35 years.

10 The goals of therapy for cryptococcal meningitis in patients with AIDS are to induce a remission and maintain a high quality of life. The standard therapeutic approach has been amphotericin B for both acute and maintenance therapy, although the introduction of azole compounds has changed the therapeutic approach for clinically stable patients. The largest controlled clinical trial of amphotericin B (mean daily dose \approx 0.4 mg/kg) plus flucytosine versus fluconazole for cryptococcal meningitis in 194 patients with AIDS found that treatment was successful in 40% of the amphotericin recipients and in 34% of fluconazole recipients.⁹⁴ The death rate in the first 2 weeks of treatment was 18% in the fluconazole arm and 14% in the amphotericin arm. The death rate after 2 weeks was 4% and 6%, respectively, in the fluconazole and amphotericin groups. The median time to sterilization of CSF cultures was 42 days in amphotericin B recipients and 64 days in those who received fluconazole. These data suggest that while fluconazole is effective for treatment of cryptococcal meningitis, amphotericin B is more effective because of its lower rates of early death and disease progression. Most patients with cryptococcal meningitis probably should receive amphotericin B in an intravenous dose of at least 0.5 mg/kg per day for a minimum of 2 weeks as acute therapy. Flucytosine in doses of 100 to 150 mg/kg per day can be considered for combination with amphotericin B; serum concentrations should be monitored and peak levels kept below 100 mcg/mL to minimize hematologic adverse reactions. The addition of flucytosine to an amphotericin B regimen of 0.7 mg/kg per day for 2 weeks significantly improved mortality, clinical course, or CSF culture status at 2 weeks.⁹⁵

Once the acute treatment of cryptococcal meningitis is completed, maintenance therapy is necessary to prevent relapse. Placebo-controlled trials of 100 to 200 mg/day fluconazole, as well as controlled trials versus 1 mg/kg per week of amphotericin B, have been conducted to prevent recurrence of cryptococcal disease in patients who completed acute therapy.^{96,97} Compared with patients receiving amphotericin B maintenance therapy, the probability of remaining relapse-free at 1 year was higher for fluconazole recipients (97% ver-

sus 78%), and the rate of serious drug toxicity was lower (7% versus 31%). Fluconazole is superior to either placebo, amphotericin, or itraconazole for maintenance therapy and is the drug of choice to prevent relapse of cryptococcal meningitis.

In addition to treatment strategies, investigations are underway to determine whether fungal infections can be prevented. Results of a controlled trial of fluconazole (200 mg/day) versus clotrimazole troches (10 mg five times daily) suggest that after a median follow-up of 35 months, fluconazole recipients had a significant benefit in terms of reduced rate of invasive fungal infection (primarily cryptococcosis) and esophageal candidiasis.⁹⁸ The benefit of fluconazole therapy was greater for patients with fewer than 50 CD4 cells/mcL. The 2-year cumulative risk of cryptococcosis was 1.6% in the fluconazole group and 9.9% in the clotrimazole group ($p = 0.02$) in contrast to risks of 0.8% and 4.3%, respectively, in patients with higher CD4 counts. There was, however, no survival difference between the two groups. Despite fluconazole therapy, 10.6% of recipients developed proved or presumed candidiasis, raising the possibility of emergence of resistance to fluconazole. Drug-resistant candidiasis caused by *Candida albicans* and *C. krusei* has been observed in patients infected with HIV who are receiving fluconazole. The central question of whether the benefit of fluconazole and other agents for prophylaxis of fungal infections outweighs the risks, including resistance, remains to be clearly delineated. Presently, routine antifungal prophylaxis of cryptococcosis is not recommended.

MYCOBACTERIUM INFECTIONS

M. tuberculosis infection is a well-recognized and treatable complication of HIV infection and AIDS.⁴⁷ A discussion of the clinical presentation and treatment is found elsewhere in this book (Chap. 110).

Infections with non-tuberculous mycobacterial organisms, especially *M. avium* complex (MAC), were recognized early in the AIDS epidemic. Disseminated MAC is now uncommon, occurring in 1% to 3% of HIV-infected individuals. The major risk factor for MAC is advanced immunosuppression; the mean CD4 lymphocyte count in patients with disseminated MAC is usually fewer than 50 cells/mcL, and infection is rare in individuals with more than 100 cells/mcL. The organism is a common water and soil saprophyte; the routes of acquisition in patients with AIDS are thought to be gastrointestinal and/or respiratory. In patients with advanced HIV disease, MAC causes a widely disseminated infection. Local colonization also can occur and precede disseminated disease, although cultures of sputum or the gastrointestinal tract have a poor predictive value for subsequent disseminated MAC. The clinical syndrome associated with MAC includes high spiking fevers, diarrhea, night sweats, malaise, weight loss, anemia, and neutropenia. Persistent diarrhea and abdominal pain, a malabsorption syndrome, and extrahepatic biliary obstruction are manifestations associated with MAC gastrointestinal infection. Diagnosis of MAC infection usually is based on culture of the organisms from the blood, although biopsies of the liver, bone marrow, and lymph nodes are also highly sensitive and specific. Diagnosis of disseminated MAC in advanced HIV disease suggests a poor long-term prognosis without therapy.

Unfortunately, MAC is resistant to the standard drugs used for tuberculosis, such as isoniazid and pyrazinamide. Multiple agents such as rifampin, rifabutin (ansamycin), clofazimine, imipenem, amikacin, ethambutol, ciprofloxacin, clarithromycin, and azithromycin have varying degrees of in vitro anti-MAC activity.⁹⁹ Controversy formerly existed as to whether treatment for MAC is beneficial, but data indicate that an aggressive therapeutic approach decreases symptoms

and prolongs survival. The largest randomized comparison of MAC treatment regimens evaluated clarithromycin with either ethambutol (C + E), rifabutin (C + R), or both (C + E + R) in 160 HIV-infected persons with MAC bacteremia. The proportion of subjects with a complete microbiologic response at week 12 was 40% in the C + E group, 42% in the C + R group, and 51% in the C + E + R group (no statistical differences). Relapse while receiving C + R (24%) was significantly higher than the other two arms (6% to 7%).¹⁰⁰

There are several important issues regarding therapy of MAC, most notably who to treat, which drugs to use and for how long, and how to assess response to therapy. First, treatment regimens should contain at least two antimycobacterial agents. Second, every regimen should contain either clarithromycin or azithromycin because both have excellent activity against MAC. Of these agents, clarithromycin (500 mg twice daily) is the preferred agent for MAC treatment based on greater clinical experience and data that indicate that clarithromycin and ethambutol versus azithromycin and ethambutol produced a more rapid resolution of MAC bacteremia.¹⁰¹ For the second agent, numerous choices are available, although ethambutol (15 mg/kg per day) is preferred by many experts. Many clinicians would add a third and some a fourth drug to this regimen. Among the alternatives available for the third drug, only rifabutin (300 mg/day) adds a significant microbiologic benefit. Clofazimine appears to be associated with an increase in mortality when used for therapy of MAC and should not be used.¹⁰² Clinical responses usually occur within 2 to 8 weeks of the start of therapy. If a clinical and microbiologic response is observed, therapy should continue for the duration of the patient's life. The recommended regimen for secondary prophylaxis is clarithromycin 500 mg orally twice daily plus ethambutol 15 mg/kg orally once daily with or without rifabutin 300 mg orally once daily.

Disseminated MAC infection contributes significantly to morbidity and mortality in the HIV-infected person, therapy is not uniformly successful, and a high-risk population can be identified. Therefore, a strong basis for prophylaxis of MAC exists. Clarithromycin and azithromycin both reduce the risk of disseminated MAC. In a double-blind, placebo-controlled study, 682 persons with AIDS and CD4 lymphocyte counts of fewer than 100 cells/mL were randomized to receive clarithromycin 500 mg twice daily or placebo.¹⁰³ MAC bacteremia developed nearly three times as often in placebo recipients as in clarithromycin recipients. There were 19 (6%) breakthrough MAC infections in the clarithromycin group versus 53 (16%) in the placebo arm ($p < 0.001$). Clarithromycin-resistant strains of MAC were detected in some patients. During about 10 months of follow-up, 32% of the patients who received clarithromycin died compared with 41% ($p = 0.026$) in the placebo group. Azithromycin also has been shown to have a protective benefit against MAC infection. A three-arm trial evaluated azithromycin (1200 mg weekly), rifabutin (300 mg/day), and the combination in 693 HIV-infected persons with fewer than 100 CD4 cells/mL.¹⁰⁴ The incidence of disseminated MAC infection at 1 year was 7.6% for azithromycin, 15.3% for rifabutin, and 2.6% for the combination. MAC isolates resistant to azithromycin were found in 11% of the patients who failed azithromycin prophylaxis. Dose-limiting adverse reactions, primarily gastrointestinal, were more common in the azithromycin plus rifabutin group. There was no difference in survival among the three regimens.

MAC prophylaxis is now strongly recommended for all HIV-infected adults and adolescents with CD4 counts of fewer than 50 cells/mL.¹⁶ The first-line choices are either azithromycin (1200 mg once weekly) or clarithromycin (500 mg twice daily); rifabutin is an alternative. Persons considered for prophylaxis should be evaluated to be sure that they do not have active disease owing to MAC or *M. tuberculosis*.

HERPESVIRUS INFECTIONS

HERPES SIMPLEX VIRUS

Herpes simplex viruses (HSV) types 1 and 2 cause significant morbidity in patients with AIDS. Seropositivity for HSV is widespread among adults with AIDS, and clinical disease usually is the result of reactivation of latent virus. The manifestations of HSV disease observed in persons with AIDS include orolabial, genital, and anorectal mucocutaneous disease; esophagitis; and less commonly, encephalitis. Ulcerative HSV lesions present for longer than 1 month in an individual with laboratory evidence for HIV infection or no other apparent cause for immunodeficiency are considered an AIDS-defining condition.

Anorectal lesions are common clinically evident HSV disease causing morbidity in homosexual men with AIDS and likely reflect the common risk factors for acquisition (sexual contact) of both HSV and HIV. Chronic perianal HSV lesions were among the first opportunistic infections associated with AIDS.¹⁰⁵ Symptoms include pain, itching, and painful defecation. The clinical presentation of anal, orolabial, and genital herpes in the patient with AIDS is similar to that in other immunosuppressed individuals. The severity of the episode can range from mild to severely destructive. The severity of mucocutaneous HSV disease increases with progressive immunosuppression. Other HSV manifestations, such as encephalitis, are rare in the patient with AIDS but are life-threatening. Differentiation from other CNS infections such as those caused by *C. neoformans* or *T. gondii* is important, and prompt treatment is essential.

Acyclovir is the drug of choice for the treatment of HSV disease.

For mild to moderate mucocutaneous disease, oral acyclovir in doses of 200 mg five times daily or 400 mg three times daily are used, although regimens of 400 mg five times daily have been described occasionally as clinically necessary. Intravenous acyclovir (15 mg/kg per day) should be used in settings where absorption of oral drug is questionable or oral tolerance is unlikely (HSV esophagitis) or perhaps when severe mucocutaneous disease is present. Treatment of mucocutaneous disease should be continued until all lesions have crusted. Intravenous acyclovir (30 mg/kg per day) also should be used for viscerally disseminated disease and for HSV encephalitis. Famciclovir and the oral prodrug of acyclovir, valacyclovir, are alternatives to oral acyclovir.

Recurrent HSV disease is common in many patients with AIDS following discontinuation of therapy. These individuals often can be managed with low-dose suppressive oral acyclovir therapy, as have other immunosuppressed patients at risk for frequently recurring HSV diseases.¹⁰⁶ Regimens commonly used include acyclovir 200 mg four times daily, 400 mg twice daily, and 800 mg once daily.

Acyclovir-resistant HSV has been isolated from patients with AIDS.¹⁰⁷ The primary mechanism of resistance appears to be a deficiency in viral thymidine kinase. Strategies that have been employed for management of severe acyclovir-resistant HSV infections include increasing the dose of acyclovir, discontinuing acyclovir, and use of an alternative antiviral agent. Vidarabine and foscarnet, because they do not require phosphorylation by thymidine kinase, are examples of potential alternative agents.^{108,109} A randomized comparison of foscarnet and vidarabine indicated that foscarnet is more effective and associated with fewer adverse reactions than vidarabine.¹¹⁰

VARICELLA-ZOSTER VIRUS

Most adults with AIDS have been infected previously with varicella-zoster virus (VZV) and thus are not susceptible to primary infection

(chickenpox) but may develop recurrent infection (zoster). The prevalence of zoster in HIV-infected individuals appears higher than in other age-matched immunocompetent persons and seems to reliably herald the loss of cell-mediated immunity and progression to AIDS.¹¹¹

Zoster usually begins as radicular pain followed by localized erythematous rash and characteristic vesicles. Zoster usually remains confined to a limited number of dermatomes, but complications such as widespread cutaneous involvement and disseminated visceral zoster may occur. As in the treatment of HSV infections, acyclovir is the drug of choice for VZV infections. While an oral acyclovir regimen of 4 g/day is effective for the treatment of zoster in immunocompetent adults, the drug has not been fully evaluated in immunocompromised patients such as those with AIDS.¹¹² For practical reasons, oral acyclovir, famciclovir, or valacyclovir is often used for localized zoster. However, careful monitoring for signs of progression of zoster is essential. AIDS patients with disseminated cutaneous or visceral zoster should receive treatment with intravenous acyclovir in doses of 30 mg/kg per day for at least 7 days or until all lesions are crusted. Acyclovir-resistant VZV infections have been reported in patients with AIDS.¹¹³

CYTOMEGALOVIRUS

Cytomegalovirus (CMV) is the most common life-threatening viral infection in patients with AIDS. As with infection with other herpes group viruses, infection with CMV is ubiquitous; seropositivity among homosexual men with AIDS approaches 100%.¹¹⁴ There are numerous manifestations of CMV infection, including retinitis, esophagitis, hepatitis, gastrointestinal involvement, and less commonly, radiculopathy, encephalitis, and pneumonitis. CMV end-organ disease occurs in up to 44.9% of AIDS patients, particularly when their CD4 count is below 50 cells/mL. The incidence, however, has decreased in the era of HAART.¹¹⁵

CMV retinitis, the most commonly recognized CMV disease associated with AIDS, usually is associated with a painless progressive loss of vision. Patients initially may complain of blurry vision, loss of visual acuity, or "floaters." CMV retinitis usually begins unilaterally, but bilateral involvement may occur. Untreated, CMV retinitis invariably leads to blindness. The diagnosis of CMV retinitis is made by funduscopic examination and identification of characteristic findings. Lesions characteristic of CMV retinitis include a fluffy white perivascular exudate frequently associated with hemorrhage. Early diagnosis and treatment are crucial to prevent further visual deterioration.

The first approved agent of treatment for CMV diseases was ganciclovir. Structurally, ganciclovir differs from acyclovir only by a single hydroxyl side chain, but it is 30 to 50 times more active in vitro against CMV. The use of ganciclovir therapy traditionally has been divided into two phases, induction and maintenance, because high relapse rates are found after discontinuation of the drug following successful completion of a 2- to 3-week course of initial therapy. Induction regimens with ganciclovir are typically 7.5–10 mg/kg per day intravenously in two or three equally divided doses for 14 days or longer if there is a slow clinical response. Maintenance therapy is usually 5 to 6 mg/kg once daily, although doses of 10 mg/kg have been used 5 to 7 days per week for an indefinite period of time. Initial response rates for retinal CMV disease range from 60% to 90%.¹¹⁶ Unfortunately, even with intravenous maintenance therapy, relapse of CMV retinitis is common and occurs at a median of approximately 55 to 80 days. Valganciclovir, an orally administered prodrug of ganciclovir, also can be used for induction therapy. A randomized trial of valganciclovir [900 mg twice daily for 3 weeks (induction), followed by 900 mg once daily for 1 week (maintenance)] versus intravenous ganciclovir [5 mg/kg twice daily (induction), followed by 5 mg/kg

once daily (maintenance)] resulted in a faster median time to progression of retinitis for the group assigned to intravenous ganciclovir (125 days) compared with the group assigned to oral valganciclovir (160 days).¹¹⁷

Neutropenia and thrombocytopenia are the most common drug- or dose-limiting adverse reactions associated with use of intravenous ganciclovir. Up to 50% of patients with AIDS receiving ganciclovir (alone) may need a dose reduction or interruption of therapy as a result of hematologic toxicity. Filgrastim (granulocyte-CSF), erythropoietin, or sargramostim (granulocyte-monocyte-CSF) offers some potential amelioration of the adverse hematologic effects of ganciclovir. Intravitreal administration also has been used as salvage therapy in an attempt to circumvent these adverse reactions.¹¹⁸ Sustained-release intraocular ganciclovir implants represent another strategy developed not only to overcome systemic toxicity but also to avoid the need for intravitreal injections. One-hundred and seventy three patients representing 222 eyes were randomized to receive either ganciclovir implant 1 mcg/h (75 eyes), 2 mcg/h (71 eyes), or intravenous ganciclovir (76 eyes). Median progression to CMV retinitis was similar in the 1 and 2 mcg/h implant groups, 221 days and 191 days, respectively, but median time to progression in the patients treated with intravenous ganciclovir was 71 days ($p < 0.001$). Intravenous ganciclovir was associated with an almost threefold risk of progression compared with ganciclovir implants.¹¹⁹ Ganciclovir implants, however, do not protect patients from CMV occurring elsewhere, including the initially uninvolved eye. Intravenous ganciclovir cuts the risk of CMV retinitis in the initially uninvolved eye by half. Extraocular involvement of CMV did not occur in patients receiving intravenous ganciclovir compared with 10.3% of patients who received an implant only. Therefore, patients having an implant also should receive systemic therapy, such as oral ganciclovir.

Foscarnet is a pyrophosphate analogue with both anti-HIV and anti-CMV activity. Controlled trials to evaluate immediate versus delayed foscarnet therapy of CMV retinitis in HIV-infected individuals found immediate foscarnet therapy more effective than delayed therapy in preventing progression of CMV disease.¹²⁰ Furthermore, prolonged survival and an anti-HIV effect (as assessed by a decline in HIV or p24 antigen) were observed.¹²¹ An unblinded, randomized trial comparing ganciclovir with foscarnet therapy of CMV retinitis was conducted in 234 patients with AIDS.¹²² Both drugs were administered in standard 14-day induction regimens, followed by maintenance therapy. Ganciclovir and foscarnet were equally effective in delaying the progression of CMV disease. The median time to progression of retinitis was 56 days in the ganciclovir groups and 59 days in the foscarnet group. There was a difference, however, in survival between these two groups. Median survival was 8.5 months for ganciclovir recipients, whereas it was 12.6 months for those who received foscarnet. The explanation for this survival difference is unknown. It is conceivable that the difference in mortality was due to the anti-HIV effect of foscarnet. Adverse reactions that necessitated a switch in therapy were more common among the foscarnet recipients. The choice of therapy for CMV retinitis is largely dictated by the adverse-reaction profiles of the two agents, convenience, concomitant medications being taken by the patient, and underlying disease states.

While foscarnet appears less likely to cause neutropenia than ganciclovir, it has a variety of potential adverse effects. The most common side effects are renal insufficiency and metabolic disturbances (both increases and decreases in calcium and phosphorus). Other adverse reactions include anemia, thrombocytopenia, infusion-site reactions, nausea and vomiting, penile ulcerations, and seizures. Hydration reduces the incidence of serum creatinine elevations from 66% in a nonhydrated control group to 13% in hydrated individuals.¹²³ Foscarnet, like ganciclovir, is currently administered in two phases,

induction and maintenance. Induction doses are 180 mg/kg per day intravenously in two or three divided doses for 14 days, followed by maintenance therapy in doses of 90 to 120 mg/kg intravenously once daily; foscarnet doses must be adjusted in individuals with renal insufficiency.

Other approaches to the treatment of CMV disease include the combination of ganciclovir and foscarnet and cidofovir. In patients who have relapsed CMV retinitis, the ganciclovir-foscarnet combination was compared with retreatment with either drug alone.¹²⁴ The median times to retinitis progression were foscarnet 1.3 months, ganciclovir 2.0 months, and ganciclovir-foscarnet 4.3 months. Adverse events among the three groups were similar. However, the combined use of ganciclovir-foscarnet had the greatest negative impact on quality of life most likely because of the time-intensive and complex administration requirements. Cidofovir is a nucleotide analogue shown to delay the progression of CMV retinitis. In a study of 64 patients with AIDS and previously untreated CMV retinitis, the median time to progression was 21 days in the deferred-therapy group versus 64 days in those who received low-dose cidofovir.¹²⁵ While cidofovir has certain advantages over ganciclovir and foscarnet, including a less frequent dosing schedule, the drug is nephrotoxic and can cause irreversible damage to the proximal renal tubules. Cidofovir must be given with aggressive intravenous hydration and concomitant probenecid, although these efforts only reduce, not prevent, nephrotoxicity. Also concerning is the finding that cidofovir did not show a significant effect on CMV viremia at the 3-week assessment point in the trial previously mentioned; this finding is in contrast to ganciclovir or foscarnet, which both suppress CMV viremia.

CMV infection of the gastrointestinal tract can involve sites ranging from the esophagus and stomach to the colon and rectum. In one series of AIDS patients with gastrointestinal tract infection, the colon was the most common site of infection, followed by the stomach or esophagus.¹²⁶ CMV colitis may be characterized by abdominal pain, fever, weight loss, and diarrhea, symptoms quite common among patients with HIV disease even in the absence of CMV infection. Characteristic symptoms of CMV esophagitis are dysphagia and substernal chest pain. Barium contrast studies may demonstrate abnormalities but will not distinguish among other etiologic agents, such as *Candida* and HSV, both of which are more common. The definitive diagnosis of CMV gastrointestinal infection requires endoscopy and biopsy with histologic identification of CMV inclusions or in situ antigen detection.

The therapy of CMV gastrointestinal disease has been more controversial. Few randomized, controlled trials have been conducted. A small randomized comparison of ganciclovir and foscarnet for AIDS-associated gastrointestinal disease found both therapies to be equally effective.¹²⁷ Judged by endoscopy, 83% of foscarnet recipients and 85% of ganciclovir recipients showed a response. Survival, however, was poor at less than 40 weeks for both groups. Although patients were not randomized to receive maintenance therapy or not, it is interesting that there was no difference in the time to progression of disease between those who did and those who did not. Symptomatic CMV gastrointestinal disease warrants treatment, and it appears that ganciclovir and foscarnet are equivalent. The role of maintenance therapy is less clear.

Various strategies have been evaluated to determine whether CMV disease in HIV-infected individuals can be prevented. A randomized, double-blind, placebo-controlled study of oral ganciclovir (1000 mg every 8 hours) in CMV-seropositive patients with AIDS found that oral ganciclovir significantly reduced the incidence of CMV disease.¹²⁸ CMV disease occurred in 26% of placebo recipients versus 14% of ganciclovir recipients ($p < 0.001$). However, there was no difference in survival between the two groups; the 1-year

mortality rate was 26% for placebo recipients versus 21% for ganciclovir recipients. A study of oral ganciclovir for prevention in patients with a slightly higher CD4 lymphocyte count did not find any protective benefit. Currently, prophylaxis with oral ganciclovir may be considered in HIV-infected adults and adolescents who have a CD4 cell count of fewer than 50 cells/mL and are CMV antibody-positive, but it is not a recommended standard of care.

DISCONTINUATION OF PROPHYLAXIS FOR OPPORTUNISTIC INFECTIONS

The ability of HAART regimens to restore the CD4 cell count to levels rarely associated with the development of OIs provides a basis for the discontinuation of primary and secondary prophylaxis for certain patients. The current recommendations are found in ref. 68; select examples are as follows.⁶⁸ For PCP, primary prophylaxis can be discontinued in patients receiving and responding to HAART who have a CD4 cell count of more than 200 cells/mL sustained for 3 months or more. Prophylaxis should be reinstated if the CD4 count drops to fewer than 200 cells/mL. These same criteria apply for both the discontinuation and the reinitiation of secondary prophylaxis of PCP. Primary prophylaxis for MAC disease can be discontinued in patients who have had CD4 counts of more than 100 cells/mL for a period of 3 months. Prophylaxis should be restarted if the CD4 count returns to fewer than 50 to 100 cells/mL. Secondary prophylaxis for MAC can be considered for discontinuation in persons who have had a CD4 count sustained above 100 cells/mL for at least 6 months and have completed 12 months of MAC therapy and are asymptomatic for MAC. Maintenance therapy (secondary prophylaxis) for CMV retinitis can be discontinued in patients whose CD4 cells have increased to more than 100 to 150 cells/mL for 6 months or more and who have no evidence of active disease. Additional considerations should include the anatomic location of the CMV lesion (sight-threatening or not), adequate vision in the other eye, and the availability of regular eye examinations. Readers are advised that data continue to emerge on the safety of stopping primary and secondary prophylaxis, as well as criteria for when to restart secondary prophylaxis, and the most current guidelines always should be consulted.

CONCLUSION

Irrefutable progress has been made in the management of HIV: Disease progression can be delayed, survival can be prolonged, and the risk of maternal-to-fetal HIV transmission can be reduced. Twenty antiretroviral agents are now available for clinical use, and additional compounds are likely to follow. However, therapy is still suboptimal in that complete suppression of viral replication has not been achieved. There remain significant deficits in our understanding of the virologic and immunologic processes associated with HIV infection and the clinical pharmacology of anti-HIV compounds. Critical issues include the need for simpler and more potent regimens, emergence of drug-resistant viral isolates, and the inexorably progressive nature of HIV infection in some patients despite antiretroviral therapy. There is a clear need for more selective and potent inhibitors of HIV. The medical management of opportunistic infections associated with HIV disease also has changed dramatically since the recognition of AIDS early in the 1980s and has improved survival. The approach to PCP is most illustrative. The transition from an era marked by treatment of only established disease to one where primary and secondary prophylaxis based on CD4 lymphocyte count are standards of care reflects both progress in understanding the risk factors for OIs and in

pharmacologic therapy. Collectively, three important lessons have been learned from the treatment of HIV and associated OIs: the need for prospective immunologic and virologic monitoring and early recognition of HIV infection, the use of potent combinations of antiretroviral agents to maximally inhibit viral replication and restore immune function, and primary and secondary prophylaxis of OIs. Emphasis on these principles, coupled with carefully controlled investigations of novel agents and therapeutic strategies, will continue to offer definite benefit and improve the quality of life for HIV-infected individuals and yield an advantage over this pernicious virus that causes AIDS.

CANCER TREATMENT AND CHEMOTHERAPY

Carol McManus Balmer, Amy Wells Valley, and Andrea Iannucci

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Carcinogenesis is a multi-step process that includes initiation, promotion, conversion, and progression. The growth of both normal and cancerous cells is genetically controlled by the balance or imbalance of oncogene, protooncogene, and tumor suppressor gene protein products. Multiple genetic mutations are required to convert normal cells to cancerous cells. Apoptosis and cellular senescence (aging) are normal mechanisms for cell death.
- 2 Tumor growth patterns can be described mathematically by the Gompertzian growth curve. Most of the life span of an individual's cancer takes place before the cancer is clinically evident. The growth curve illustrates concepts of exponential tumor growth, growth fraction, tumor burden, and doubling time.
- 3 Because patients with clinically evident metastatic cancer can rarely be cured, early detection is critical. Screening programs are designed to detect cancers in asymptomatic people who are at risk of a specific type of cancer. Knowing the early warning signs of cancer is also important in early detection, when cancers are most likely to be localized.
- 4 Treatment for cancer should not begin until the presence of cancer is confirmed by a tissue (i.e., histologic) diagnosis. Clinical cancer staging provides prognostic information, and in conjunction with the patient's treatment goals, guides the selection of cancer treatment. The goals of cancer treatment include cure, prolongation of life, and relief of symptoms. Surgery and radiation therapy provide the best chance of cure for patients with localized cancers, but systemic treatment methods are required for systemic cancers.
- 5 Adjuvant therapy is usually systemic therapy that is administered to treat any existing micrometastases remaining after treatment of localized disease. Because adjuvant therapy is given to patients with no clinical evidence of cancer, the benefit of the treatment cannot be proven for an individual patient, but only for patient populations. Treatment decisions are based largely on an assessment of the presence of risk factors in an individual patient and the patient's estimated risk for cancer recurrence. The effectiveness of adjuvant therapies is measured statistically, by the relative and absolute reduction in the risk of recurrence. In contrast, outcomes can be assessed for individual patients with metastatic disease with carefully defined response criteria. Response criteria are disease-specific and usually include complete response, partial response, stable disease, progression, and clinical benefit.
- 6 Cancer cells are genetically unstable, which results in tumor masses of heterogeneous cells, and makes the cancer a "moving target" for drug therapy. Existence of many different clones of cancer cells in most patients provides the rationale for use of cancer drugs in combination, and is the likely reason for failure of cancer drug therapy to cure most patients with advanced cancer.
- 7 Compromising dose intensity of cancer drug therapy by delaying or reducing doses can compromise outcomes of therapy. Dose regimen and method of administration of some anticancer drugs can greatly affect their efficacy and toxicity. Rescue agents, antidotes, or other chemoprotectants are available for a few cancer drugs, and can be used to minimize toxicity to normal cells. Understanding the pathophysiology of chemotherapy drug toxicities can lead to more effective prevention and treatment of these toxicities. Prospective dose modification of some cancer drugs is essential in patients with impaired renal or hepatic function, to reduce the risk of severe toxicities. Identification of genetic variations that affect drug activation and metabolism may permit the development of individualized drug therapy regimens that optimize effectiveness and minimize toxicity.
- 8 The immune system is a natural defense against cancer, and can be utilized to treat existing cancers.
- 9 Development of biologically targeted agents that exploit differences between cancerous and normal cells permits greater specificity for cancer cells with less damage to normal cells. Monoclonal antibodies in cancer treatment recognize an antigen that is expressed preferentially on cancer cells, and can be used to target drugs or radioisotopes to the antigen-expressing cells.
- 10 The growth of some breast and prostate cancers is fed by gonadal hormones. Elimination of the effects of the feeding hormone can result in regression of the cancer.

- ▶11 Tumors must develop new blood vessels in order to grow.
- ▶12 Myelosuppression, which creates risk of infection and bleeding, is the acute dose-limiting toxicity for most non-specific cancer drugs. The risk of infection in neutropenic patients is related to the depth and duration of neutropenia. The only reliable indicator of infection in neutropenic patients is fever. Unexplained fever in neutropenic patients requires prompt initiation of empiric antibiotic therapy. Colony-stimulating factors may reduce the risk of febrile neutropenia. Evidence-based clinical guidelines should direct the use of costly supportive care resources such as hematopoietic growth factors.

- ▶13 Fatigue in cancer patients is multifactorial and can greatly compromise quality of life. Correctable causes of fatigue such as anemia should be identified and addressed.
- ▶14 Long-term complications of cancer treatment, such as infertility, secondary malignancies, effects on physical or intellectual development, and major organ damage, can negatively affect health and quality of life for cancer survivors.
- ▶15 The risk of developing some cancers may be modified prospectively by changes in lifestyle, diet, exposure to known carcinogens, and by other interventions.

Cancer is a group of more than 100 different diseases, characterized by uncontrolled cellular growth, local tissue invasion, and distant metastases.¹ It is second only to cardiovascular disease as a cause of mortality in Americans. More than 1.3 million cases of cancer are diagnosed annually, and cancer claims an estimated 570,280 lives in the United States each year.² The estimated incidence of common cancers and cancer-related deaths is illustrated in Fig. 124–1. The four most common cancers are prostate, breast, lung, and colorectal cancer. The most common cause of cancer-related deaths in the United States is lung cancer, which accounts for about 160,000 deaths each year. These cancers are discussed in further detail in the chapters that follow.

The roles of health professionals in the management of cancer patients can be very diverse. Thorough knowledge of antineoplastic drug pharmacology and pharmacokinetics is essential to prevent and to manage many drug-induced toxicities. Supportive-care issues such as nutritional support, pain management, infection, and nausea and vomiting require application of both clinical and pharmacologic principles. Provision of drug information to other health professionals and to patients and their families is another critical role. Experienced

health professionals are able to fulfill these roles and to make valuable contributions to patient care in the oncology setting.

This chapter introduces the basic concepts of carcinogenesis, tumor growth, and cancer treatment, provides general information on the pharmacology and clinical use of the antineoplastic agents, and presents an overview of supportive care issues in the oncology patient.

ETIOLOGY OF CANCER

CARCINOGENESIS

- ▶1 The mechanism by which cancers occur is incompletely understood. A cancer, or neoplasm, is thought to develop from a cell in which the normal mechanisms for control of growth and proliferation are altered. Current evidence supports the concept of carcinogenesis as a multistage process that is genetically regulated (Fig. 124–2).^{3–6} The first step in this process is *initiation*, which requires exposure of normal cells to carcinogenic substances. These carcinogens produce genetic damage that, if not repaired, results in irreversible cellular

* Excludes basal and squamous cell skin cancers in situ carcinomas, except urinary bladder, American Cancer Society, Inc., Surveillance Research, 2005.

mutations. This mutated cell has an altered response to its environment and a selective growth advantage, giving it the potential to develop into a clonal population of neoplastic cells. During the second phase, known as *promotion*, carcinogens or other factors alter the environment to favor growth of the mutated cell population over normal cells. The primary difference between initiation and promotion is that promotion is a reversible process. In fact, because it is reversible, the promotion phase may be the target of future chemoprevention strategies, including changes in lifestyle and diet. At some point, however, the mutated cell becomes cancerous (*conversion* or *transformation*). Depending on the type of cancer, 5 to 20 years may elapse between the carcinogenic phases and the development of a clinically detectable cancer. The final stage of neoplastic growth, called *progression*, involves further genetic changes leading to increased cell proliferation. The critical elements of this phase include tumor invasion into local tissues and the development of metastases.

Substances that may act as carcinogens or initiators include chemical, physical, and biologic agents.^{5,6} Exposure to chemicals may occur by virtue of occupational and environmental means, as well as lifestyle habits. The association of aniline dye exposure and bladder cancer is one such example. Benzene is known to cause some leukemias. Some drugs and hormones used for therapeutic purposes are also classified as carcinogenic chemicals (Table 124-1). Physical agents that act as carcinogens include ionizing radiation and ultraviolet light. These types of radiation induce mutations by forming free radicals that damage DNA and other cellular components. Viruses are biologic agents that are associated with certain cancers. The Epstein-Barr virus is believed to be an important factor in the initiation of African Burkitt’s lymphoma. Likewise, infection with hepatitis B virus is known to be a major cause of hepatocellular cancer. All the previously mentioned carcinogens, as well as age, gender, diet, growth factors, and chronic irritation, are among the factors considered to be promoters of carcinogenesis.

either expression or biochemical function of genes.”⁷ In recent years, there has been marked progress in the understanding of the genetic changes that lead to the development of cancer, largely because of improvements in research techniques and new information generated as part of the human genome project.^{3,5,6,8,9} There are two major classes of genes involved in carcinogenesis: oncogenes and tumor-suppressor genes. Figure 124-3 illustrates the effects of oncogenes and tumor-suppressor genes on normal cellular function. Oncogenes develop from normal genes, called protooncogenes, and may have important roles in all phases of carcinogenesis. Protooncogenes are present in all cells and are essential regulators of normal cellular functions, including the cell cycle. Genetic alteration of the protooncogene through point mutation, chromosomal rearrangement, or gene amplification

GENETIC BASIS OF CANCER

1 Cancer has been described as “a malady of genes, arising from genetic damage of diverse sorts and leading to distortions of

TABLE 124-1. Selected Drugs and Hormones Known to Cause Cancer in Humans

| Drug or Hormone | Type of Cancer Caused |
|--|--|
| Alkylating agents (e.g., chlorambucil, mechlorethamine, melphalan, nitrosoureas) | Leukemia |
| Anabolic steroids | Liver |
| Analgesics containing phenacetin | Renal, urinary bladder |
| Anthracyclines (e.g., doxorubicin) | Leukemia |
| Antiestrogens (tamoxifen) | Endometrium |
| Coal tars (topical) | Skin |
| Estrogens | |
| Nonsteroidal (diethylstilbestrol) | Vagina/cervix, endometrium, breast, testes |
| Steroidal (estrogen replacement therapy, oral contraceptives) | Endometrium, breast, liver |
| Epipodophyllotoxins (etoposide, teniposide) | Leukemia |
| Immunosuppressive drugs (cyclosporine, azathioprine) | Lymphoma, skin |
| Oxazaphosphorines (cyclophosphamide, ifosfamide) | Urinary bladder, leukemia |

FIGURE 124-3. The effects of oncogenes and tumor-suppressor genes on cellular function. Signaling pathways in normal cells relay growth-controlling messages from the outer surface to the nucleus, where the cell-cycle clock receives these messages and decides whether the cell should divide. In cancer cells, genetic mutations can either activate oncogenes, resulting in excessive stimulation (too many “go” signals) or inactivate tumor-suppressor genes, resulting in loss of cell-cycle inhibition (no “stop” signals). Examples of abnormal stimulatory or inhibitory processes are provided in the boxes. (Adapted with permission from Weinberg.⁹)

activates the oncogene. These genetic alterations may be caused by carcinogenic agents such as radiation, chemicals, or viruses (somatic mutations), or they may be inherited (germ-line mutations). Once activated, the oncogene produces either excessive amounts of the normal gene product or an abnormal gene product. The result is dysregulation of normal cell growth and proliferation, which imparts a distinct growth advantage to the cell and increases the probability of neoplastic transformation. An example is the *myc* family of oncogenes. The normal gene product of *myc* acts as a signal for cellular proliferation. As an oncogene, the gene product is overexpressed or amplified, resulting in excessive cellular proliferation. Table 124-2 lists examples of other oncogenes and their classification by mechanism.

In contrast, tumor-suppressor genes regulate and inhibit inappropriate cellular growth and proliferation.^{3,6,8,9} Gene loss or mutation results in loss of control over normal cell growth (see Fig. 124-3). Two common examples of tumor-suppressor genes are the retinoblastoma and *p53* genes. Mutation of *p53* is one of the most common genetic changes associated with cancer, and is estimated to occur in half of all malignancies.⁹ The normal gene product of *p53* is responsible for negative regulation of the cell cycle, allowing the cell cycle to halt for repairs, corrections, and responses to other external signals. Inactivation of *p53* removes this checkpoint, allowing mutations to occur. Mutation of *p53* has been linked to a variety of malignancies, including brain tumors (astrocytoma); carcinomas of the breast, colon, lung, cervix, and anus; and osteosarcoma. Another important function of *p53* may be modulation of cytotoxic drug effects. Loss of *p53* has been associated with antineoplastic drug resistance.

Another group of genes important in carcinogenesis is the DNA repair genes.⁶ The normal function of these genes is to repair DNA that is damaged by environmental factors, or errors in DNA that occur during replication. If not corrected, these errors can result in mutations that activate oncogenes or inactivate tumor suppressor genes. As more mutations in the genome occur, the risk for malignant transformation increases. The DNA repair genes have been classified as tumor suppressor genes, because a loss in their function results in increased risk for carcinogenesis. Deficiencies in DNA repair genes have been discovered in familial colon cancer (hereditary nonpolyposis colon cancer) and breast cancer syndromes.

Oncogenes and tumor-suppressor genes provide the stimulatory and inhibitory signals that ultimately regulate the cell cycle.⁹⁻¹¹ These signals converge on a molecular system in the nucleus known as the cell cycle clock (see Fig. 124-3). The function of the clock in normal tissue is to integrate the signal input and to determine if the cell cycle should proceed. The clock is composed of a series of interacting proteins, the most important of which are cyclins and cyclin-dependent kinases (CDKs). Cyclins (especially cyclin D1) and CDKs promote entry into the cell cycle and are overexpressed in several cancers, including breast cancer. CDK inhibitors have been identified as important negative regulators of the cell cycle.

▲ When the normal regulatory mechanisms for cellular growth fail, back-up defense systems may be activated. The secondary defenses include apoptosis (programmed cell death or suicide) and cellular senescence (aging). Apoptosis is a normal mechanism of cell death required for tissue homeostasis.⁹⁻¹² This process is regulated by oncogenes and tumor-suppressor genes and is also a mechanism of cellular death after exposure to cytotoxic agents. Overexpression of oncogenes responsible for apoptosis may produce an “immortal” cell, which has increased potential for malignancy. The *bcl-2* oncogene is an example. The most common chromosomal abnormality found in lymphoid malignancies is the t(14;18) translocation. The *bcl-2* protooncogene is normally located on chromosome 18. Translocation of this protooncogene to chromosome 14 in proximity to the immunoglobulin heavy chain gene leads to overexpression of *bcl-2*, which decreases apoptosis and confers a survival advantage to the cell. Studies show that *p53* is also a regulator of apoptosis. Loss of *p53* disrupts normal apoptotic pathways, imparting a survival advantage to the cell. Recent evidence also has revealed an important role for apoptosis as a mechanism of inherent resistance to chemotherapy.¹²

Cellular senescence is another important defense mechanism.^{6,8-10} Laboratory studies demonstrate that once a cell population has undergone a preset number of doublings, growth stops and cells die. This is known as senescence, a process that is regulated by telomeres. Telomeres are the DNA segments or caps at the ends of chromosomes. They are responsible for protecting the end of the DNA from damage. With each replication, the length of the telomeres is shortened. After the telomeres are shortened to a critical

TABLE 124–2. Examples of Oncogenes and Tumor Suppressor Genes

| Gene | Function | Associated Human Cancer |
|---|--|---|
| Oncogenes | | |
| <i>Genes for growth factors or their receptors</i> | | |
| <i>EGFR</i> or <i>ERB-B1</i> | Codes for epidermal growth factor (EGFR) receptor | Glioblastoma, breast cancer, squamous carcinoma |
| <i>HER-2/neu</i> or <i>ERB-B2</i> | Codes for a growth factor receptor | Breast, salivary gland, prostate, bladder and ovarian cancers |
| <i>RET</i> | Codes for a growth factor receptor | Thyroid cancer |
| <i>Genes for cytoplasmic relays in stimulatory signaling pathways</i> | | |
| <i>K-RAS</i> | Code for guanine nucleotide-proteins with GTPase activity | Lung, ovarian, colon, pancreatic binding cancers |
| <i>N-RAS</i> | | |
| <i>Genes for transcription factors that activate growth-promoting genes</i> | | |
| <i>c-MYC</i> | | Leukemia and breast, colon, gastric, and lung cancers |
| <i>N-MYC</i> | | Neuroblastoma, small cell lung cancer, and glioblastoma |
| <i>Genes for cytoplasmic kinases</i> | | |
| <i>BCR-ABL</i> | Codes for a nonreceptor tyrosine kinase | Chronic myelogenous leukemia |
| <i>Genes for other molecules</i> | | |
| <i>BCL-2</i> | Codes for a protein that blocks apoptosis | Indolent B-cell lymphomas |
| <i>BCL-1</i> or <i>PRAD1</i> | Codes for cyclin D1, a cell cycle clock stimulator | Breast, head and neck cancers |
| <i>MDM2</i> | Protein antagonist of p53 tumor suppressor protein | Sarcomas |
| Tumor suppressor genes | | |
| <i>Genes for proteins in the cytoplasm</i> | | |
| <i>APC</i> | Step in a signaling pathway | Colon and gastric cancer |
| <i>NF-1</i> | Codes for a protein that inhibits the stimulatory Ras protein | Neurofibroma, leukemia, and pheochromocytoma |
| <i>NF-2</i> | Codes for a protein that inhibits the stimulatory Ras protein | Meningioma, ependymoma, and schwannoma |
| <i>Genes for proteins in the nucleus</i> | | |
| <i>MTS1</i> | Codes for p16 protein, a cyclin-dependent kinase inhibitor | Involved in a wide range of cancers |
| <i>RB1</i> | Codes for the pRB protein, a master brake of the cell cycle | Retinoblastoma, osteosarcoma, and bladder, small cell lung, prostate and breast cancers |
| <i>p53</i> | Codes for the p53 protein, which can halt cell division and induce apoptosis | Involved in a wide range of cancers |
| <i>Genes for protein whose cellular location is unclear</i> | | |
| <i>BRCA1</i> | DNA repair, transcriptional regulation | Breast and ovarian cancers |
| <i>BRCA2</i> | DNA repair | Breast cancer |
| <i>VHL</i> | Regulator of protein stability | Renal cell cancer |
| <i>MSH2, MLH1, PMS1, PMS2, MSH6</i> | DNA mismatch repair enzymes | Hereditary nonpolyposis colorectal cancer |

length, senescence is triggered. In this way, telomeres tally and limit the number of cell doublings. In cancer cells, the function of telomeres is overcome by overexpression of an enzyme known as telomerase. Telomerase replaces the portion of the telomeres that is lost with each cell division, thereby avoiding senescence and permitting an infinite number of cell doublings. Telomerase is a target for antineoplastic drug development.

1 As information regarding the role of oncogenes and tumor-suppressor genes accumulated, it became evident that a single mutation is probably not sufficient to initiate cancer.^{4–9} Scientists postulate that combinations of mutations are required for carcinogenesis and that each mutation is inherited by the next generation of cells

(Fig. 124–4). Thus, several detectable genetic mutations may be present in an established tumor. Early mutations are found in both premalignant lesions and in established tumors, whereas later mutations are found only in the established tumor. This theory of sequential genetic mutations resulting in cancer has been demonstrated in colon cancer and in brain tumors. In colon cancer, the initial genetic mutation is believed to be loss of the adenomatous polyposis coli gene, which results in formation of a small benign polyp. Oncogenic mutation of the *ras* gene is often the next step, leading to enlargement of the polyp. Loss of function of DNA mismatch repair enzymes may occur at many points in the progression of malignant transformation. Loss of the *p53* gene and another gene, believed to be the “deleted in

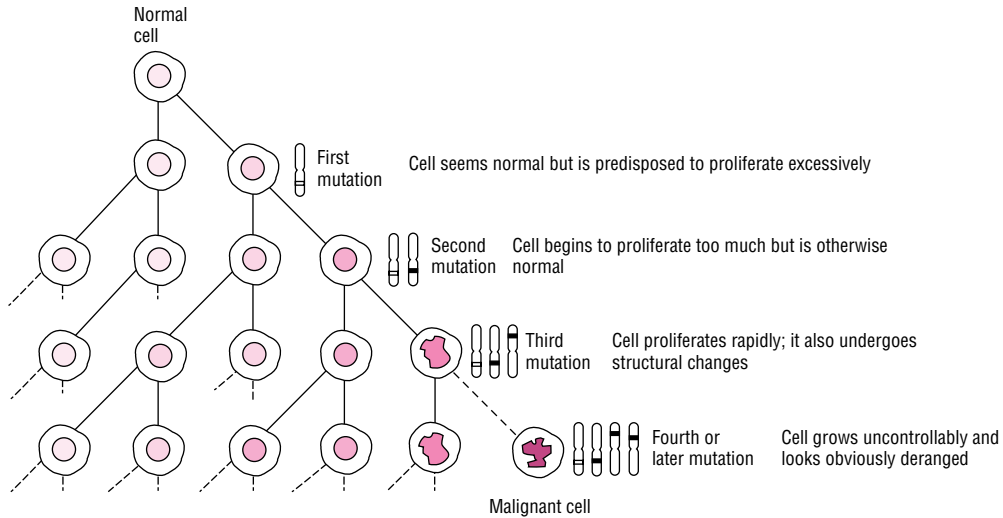

FIGURE 124-4. Emergence of a cancer cell from a normal cell is thought to occur through a process known as clonal evolution. First, one daughter cell inherits or acquires a cancer-promoting mutation and passes the defect to its progeny and all future generations. At some point, one of the descendants acquires a second mutation, and a later descendant acquires a third, and so on. Eventually, some cell accumulates enough mutations to cross the threshold to cancer. (Reproduced with permission from Cotran et al.⁶)

colorectal cancer” gene, complete the transformation into a malignant lesion. Loss of *p53* is thought to be a late event in the development and progression of the malignancy.

Identification of genes and other proteins involved in carcinogenesis has several important clinical implications. In the future, they may be used in cancer screening to identify individuals at increased risk for cancer, and in cancer treatment to design new anticancer agents and gene therapies. Specific genetic abnormalities are so commonly associated with some types of cancers that the presence of that abnormality aids in the diagnosis of that cancer. If the presence of these genes (i.e., gene expression profile) can reliably predict the clinical course of a cancer or response to certain cancer therapies,

then genetic analysis may also become an important prognostic and treatment decision tool.¹³

PRINCIPLES OF TUMOR GROWTH

The study of tumor growth forms the foundation for many of the basic principles of modern cancer chemotherapy. The growth of most tumors is illustrated by the Gompertzian tumor growth curve (Fig. 124-5).^{6,11,14} Gompertz was a German insurance actuary who described the relationship between age and expected death. This mathematical model also approximates tumor-cell proliferation. In the

FIGURE 124-5. Gompertzian kinetics tumor-growth curve; relationship to symptoms, diagnosis, and various treatment regimens. (Reproduced with permission from Buick.¹⁴)

early stages, tumor growth is exponential, which means that the tumor takes a constant amount of time to double its size. During this early phase, a large portion of the tumor cells is actively dividing. This population of cells is called the *growth fraction*. The doubling time, or time required for the tumor to double in size, is very short. Because most anticancer drugs have greater effect on rapidly dividing cells, tumors are most sensitive to the effects of chemotherapy when the tumor is small and the growth fraction is high. However, as the tumor grows, the doubling time is slowed.^{11,14} The growth fraction is decreased, probably owing to the tumor outgrowing its blood and nutrient supply or the inability of blood and nutrients to diffuse throughout the tumor mass. Wide variability exists in measured doubling times for different cancers. The doubling time of most solid tumors is about 2 to 3 months. However, some tumors have doubling times of only days (e.g., aggressive lymphomas) and others have even longer doubling times (e.g., some salivary gland tumors).⁶

Figure 124-5 also illustrates the impact of tumor burden. It takes about 10^9 cancer cells (1-g mass, 1 cm in diameter) for a tumor to be clinically detectable by palpation or radiography. Such a tumor has undergone approximately 30 doublings in cell number. It only takes 10 additional doublings for this 1-g mass to reach 1 kg in size. A tumor possessing 10^{12} cancer cells (1-kg mass) is considered lethal. Thus a tumor is clinically undetectable for most of its life span. Tumor burden also impacts response to chemotherapy. The cell kill hypothesis states that a certain percentage of cancer cells (not a certain number of cells) will be killed with each course of chemotherapy. For example, if a tumor consists of 1,000 cancer cells and the chemotherapy regimen kills 90% of the cells, then 10% or 100 cancer cells would remain. The second chemotherapy course kills another 90% of cells, and again only 10% or 10 cells remain. According to this hypothesis, the tumor burden will never reach zero. Tumors consisting of less than 10^4 cells are believed to be small enough for elimination by host factors, including immunologic mechanisms, and these factors must be in place for a cure to be possible. The limitations of this theory are that it assumes all cancers are equally responsive and that drug resistance and metastases do not occur.^{1,6,11,14}

INVASION AND METASTASIS

3 Metastasis is the spread of neoplastic cells from the primary tumor site to distant sites.^{6,15} Despite advances in diagnostic techniques and screening for cancer, many patients have detectable metastatic disease at diagnosis. Once clinically evident distant metastases are present, cancers are seldom curable. Newly diagnosed cancer patients may also have microscopic cancer metastases. Although clinically undetectable, these small clusters of diseased cells must be present, because many patients subsequently relapse at distant sites despite removal of the primary tumor. Some patients with micrometastatic disease may be cured with systemic chemotherapy.

The two primary pathways of metastasis are hematogenous and lymphatic. Other, less-common modes of disease spread include dissemination via cerebrospinal fluid and transabdominal spread within the peritoneal cavity. Tumors are constantly shedding neoplastic cells into the systemic circulation or surrounding lymphatics. This process may begin early in the life of the tumor and often increases with time. The time course for metastasis depends largely on the biology of the tumor. Breast cancer, for example, tends to metastasize very early. Not all of the shed cancer cells, or “seeds,” result in a metastatic lesion. The “seed” must first find the appropriate “soil,” or an environment suitable for growth.¹⁵ This process is illustrated in the diverse patterns

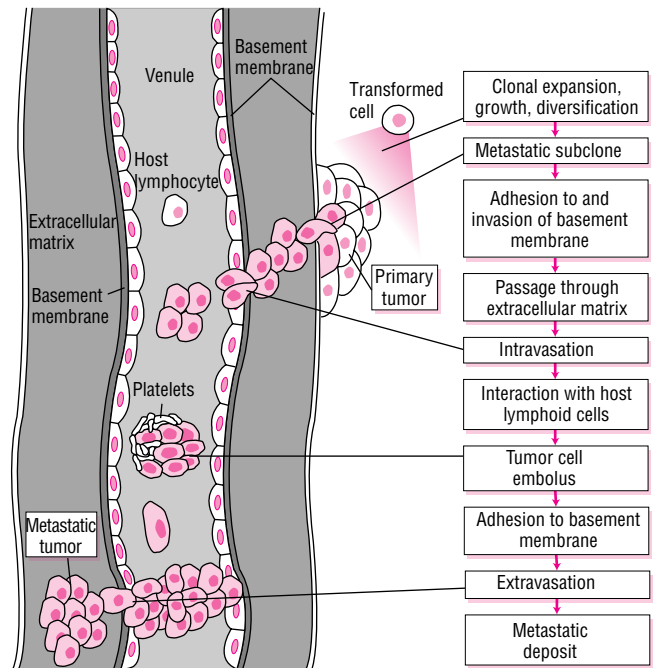

FIGURE 124-6. The process of developing a cancer metastasis. (Reproduced with permission from Cotran et al.⁶)

of metastasis that are characteristic of individual types of cancer. An example is prostate cancer, which commonly metastasizes to bone, but rarely to the brain.

The process of invasion and metastasis involves several essential steps (Fig. 124-6). After neoplastic transformation, the malignant cells and surrounding host tissue secrete substances that stimulate the formation of new blood vessels to provide oxygen and nutrients. This process is known as *angiogenesis* or *neovascularization*.¹⁶ Tumor cells must then detach from the primary mass and invade surrounding blood and lymph vessels. The tumor cells or cell aggregates detach and embolize through these vessels, but most do not survive circulation. The disseminated cells must then attach to the vascular endothelium. The cells may proliferate within the lumen of the vessel, but most commonly extravasate into the surrounding tissue. The local microenvironment may provide growth factors that can serve as “fertilizer” to potentiate the proliferation of the metastasis. At every step of the way, the potential metastatic cell must fight the host immune system. Last, the metastasis must again initiate angiogenesis to ensure continued growth and proliferation. Because angiogenesis has been recognized as a critical element in primary tumor growth as well as metastasis, it has become a target for development of new anticancer agents.

PATHOLOGY OF CANCER

TUMOR CHARACTERISTICS

Tumors may be either benign or malignant. Benign tumors are non-cancerous growths that are often encapsulated, localized, and indolent. Cells of benign tumors resemble the cells from which they developed. These masses seldom metastasize, and once removed they rarely recur. In contrast, malignant tumors invade and destroy the surrounding tissue. The cells of malignant tumors are genetically unstable, and

TABLE 124–3. Tumor Classification by Tissue Type

| Tissue of Origin | Benign | Malignant |
|---|------------------------|--------------------------------------|
| Epithelial | | |
| Surface epithelium | Papilloma | Carcinoma (squamous, epidermoid) |
| Glandular tissue | Adenoma | Adenocarcinoma |
| Connective tissue | | |
| Fibrous tissue | Fibroma | Fibrosarcoma |
| Bone | Osteoma | Osteosarcoma |
| Smooth muscle | Leiomyoma | Leiomyosarcoma |
| Striated muscle | Rhabdomyoma | Rhabdomyosarcoma |
| Fat | Lipoma | Liposarcoma |
| Lymphoid tissue and hematopoietic cells | | |
| Bone marrow elements | | Leukemias |
| Lymphoid tissue | | Hodgkin's and non-Hodgkin's lymphoma |
| Plasma cell | | Multiple myeloma |
| Neural tissue | | |
| Glial tissue | "Benign" gliomas | Glioblastoma multiforme, astrocytoma |
| Nerve sheath | Neurofibroma | Neurofibrosarcoma |
| Melanocytes | Pigmented nevus (mole) | Malignant melanoma |
| Mixed tumors | | |
| Gonadal tissue | Teratoma | Teratocarcinoma |

Adapted from Cotran.⁶

loss of normal cell architecture results in cells that are atypical of their tissue or cell of origin. These cells lose the ability to perform their usual functions. This loss of structure and function is defined as anaplasia. In contrast to benign tumors, malignant tumors tend to metastasize, and consequently recurrences are common after removal or destruction of the primary tumor.

TUMOR ORIGIN

Tumors may arise from any of four basic tissue types: epithelial tissue, connective tissue (i.e., muscle, bone, and cartilage), lymphoid tissue, and nerve tissue. Although some malignant cells are atypical of their cells of origin, the involved cells usually retain enough of their parent's traits to identify their origin. Benign tumors are named by adding the suffix *-oma* to the name of the cell type. Hence, adenomas are benign growths of glandular origin, or growths that exhibit a glandular pattern. Table 124–3 lists common tumor nomenclature by tissue type.⁶

Some cancers are preceded by cellular changes that are abnormal, but not yet malignant. Correction of these early changes could potentially prevent the occurrence of a cancer. Precancerous lesions may be described as consisting of either hyperplastic or dysplastic cells. Hyperplasia is an increase in the number of cells in a particular tissue or organ, which results in an increased size of the organ. It should not be confused with hypertrophy, which is an increase in the size of the individual cells. Hyperplasia occurs in response to a stimulus and reverses when the stimulus is removed. Dysplasia is defined as an abnormal change in the size, shape, or organization of cells or tissues. Hyperplasia and dysplasia may precede the appearance of a cancer by several months or years.

Malignant cells are divided into those of epithelial origin or the other tissue types. Carcinomas are malignant growths arising from epithelial cells. Malignant growths of muscle or connective tissue are called sarcomas. Therefore an adenocarcinoma is a malignant tumor arising from glandular tissue. Another term used frequently in the description of malignancy is *carcinoma in situ*. In this instance, the cancer is limited to the epithelial cells of origin; it has not yet invaded

the basement membrane. Carcinoma in situ is a preinvasive stage of malignancy, and most tumors have progressed well beyond this stage at diagnosis. Like all classification systems, there are exceptions to these rules. Malignancies of hematologic origin, such as leukemias and lymphomas, are classified separately. Leukemias and lymphomas are discussed in later chapters.

DIAGNOSIS AND STAGING

SCREENING

3 Because cancers are most curable with surgery or radiation before they have metastasized, early detection and treatment have obvious potential benefits. In addition, small tumors are more responsive to chemotherapy, as discussed previously. Early diagnosis is difficult for many cancers because they do not produce clinical signs or symptoms until they have become large or have metastasized. Cancer screening programs are designed to detect signs of cancer in people who have not yet developed symptoms from cancer. Lack of effective screening methods for some cancers and inaccessibility of some anatomic sites further complicate the process. Education of the public on the early warning signs of common cancers is extremely important for facilitating early detection. For some cancers, effective screening procedures do exist. The Papanicolaou (Pap) smear test, for example, is an effective tool to detect cervical cancer in its early stages. Self-examination of the breasts in women and of the testicles in men may lead to early diagnosis of cancers in these organs. The American Cancer Society has published guidelines for routine screening examinations (Table 124–4).¹⁷

DIAGNOSIS

4 The presenting signs and symptoms of cancer vary widely and depend on the type of cancer. The presentation in adults may include any of cancer's seven warning signs (Table 124–5), as well as pain or loss of appetite.¹⁸ The warning signs of cancer in

TABLE 124–4. Screening Guidelines for Early Detection of Cancer in Asymptomatic People

| Disease | Test or Procedure | Sex | Age (y) | Frequency |
|-------------------------|--|------------|---|-------------------------|
| Breast cancer | Breast self-examination | F | 20 and over | Monthly |
| | Clinical breast examination | F | 20–39 | Every 3 years |
| | 40 and over | Every year | | |
| | Mammography | F | 40 and over | Every year ^a |
| Colon and rectal cancer | One of the following examination schedules should be followed: | | | |
| | Fecal occult blood test (FOBT) or fecal immunochemical test (FIT) | M and F | 50 and over | Every year |
| | Flexible sigmoidoscopy | M and F | 50 and over | Every 5 years |
| | Annual FOBT or FIT and flexible sigmoidoscopy ^b | M and F | 50 and over | Every 5 years |
| | Colonoscopy | M and F | 50 and over | Every 10 years |
| | Double contrast barium enema | M and F | 50 and over | Every 5 years |
| Prostate cancer | Digital rectal exam and prostate-specific antigen (PSA) blood test | M | 50 and over | Every year ^c |
| | | M | 50 and over | Every year ^c |
| Cervical cancer | Pap test or liquid-based test | F | 3 years after beginning vaginal intercourse | Every year ^d |
| | | | | Every 2 years |
| Endometrial cancer | Information on risks and symptoms | F | Menopause | Once ^e |
| Cancer-related check-up | Health counseling and physical exam ^f | M and F | 20–40 | Every 3 years |
| | | | 40 and over | Every year |

^aWomen at increased risk (e.g., family history, genetic tendency, or past breast cancer) should talk with their physician about benefits and limitations of starting earlier, having additional tests, or more frequent examinations.

^bFlexible sigmoidoscopy together with FOBT or FIT is preferable to either test alone, although annual FOBT/FIT alone and flexible sigmoidoscopy every 5 years without FOBT/FIT has some benefit. People at moderate to high risk for colorectal cancer should discuss a different testing schedule with their physician.

^cDigital rectal examination and PSA testing should be offered annually to men with a life expectancy of at least 10 years. Men at high risk (e.g., African-American men and men with a strong family history) should begin testing at age 45. Information should be provided regarding benefits and limitations of prostate cancer screening.

^dAt or after age 30, women with three consecutive normal tests may be screened at less frequent intervals (every 2–3 years). Alternatively, HPV DNA testing and conventional or liquid-based testing could be performed every 3 years. Women at high risk (e.g., human immunodeficiency virus infection or weak immune system) may be screened more frequently. Women over the age of 70 years may stop screening if they have three normal tests in the last 10 years.

^eWomen with or at risk for hereditary nonpolyposis colon cancer should begin annual endometrial biopsy starting at age 35.

^fTo include examination for cancers of the mouth, thyroid, testicles, skin, lymph nodes, and ovaries, as well as health counseling about tobacco, sun exposure, diet and nutrition, risk factors, sexual practices, and environmental and occupational exposures. From The American Cancer Society.¹⁷

children are different, and reflect the types of tumors more common in this patient population (Table 124–6).¹⁸ Even with increased public awareness, the fear of a cancer diagnosis can deter patients from seeking medical attention. The definitive diagnosis of cancer relies on the procurement of a sample of the tissue or cells suspected of malignancy and pathologic assessment of this sample. This sample can be obtained by numerous methods, including biopsy, exfoliative cytology, or fine-needle aspiration. A tissue diagnosis is essential, because many benign conditions can masquerade as cancer. Definitive treatment should not begin without a pathologic diagnosis.

TABLE 124–5. Cancer’s Seven Warning Signs

- Change in bowel or bladder habits
- A sore that does not heal
- Unusual bleeding or discharge
- Thickening or lump in breast or elsewhere
- Indigestion or difficulty in swallowing
- Obvious change in wart or mole
- Nagging cough or hoarseness
- If YOU have a warning signal, see your doctor!

From American Cancer Society. Seven warning signs of cancer. Atlanta, American Cancer Society.

TABLE 124–6. Cancer’s Warning Signs in Children

- Continued, unexplained weight loss
- Headaches with vomiting in the morning
- Increased swelling or persistent pain in bones or joints
- Lump or mass in abdomen, neck, or elsewhere
- Development of a whitish appearance in the pupil of the eye
- Recurrent fevers not caused by infections
- Excessive bruising or bleeding
- Noticeable paleness or prolonged tiredness

From American Cancer Society. Eight warning signs of cancer in children. Atlanta, American Cancer Society.

TABLE 124–7. TNM Staging Classification System for Colorectal Cancer

Primary tumor (T)
 T_x Primary tumor cannot be assessed
 T₀ No evidence of primary tumor
 T_{is} Carcinoma in situ: intraepithelial or invasion of lamina propria
 T₁ Tumor invades submucosa
 T₂ Tumor invades muscularis propria
 T₃ Tumor invades through the muscularis propria into the subserosa, or into nonperitonealized pericolic or perirectal tissues
 T₄ Tumor perforates the visceral peritoneum, and/or directly invades other organs or structures

Regional lymph nodes (N)
 N_x Regional lymph nodes cannot be assessed
 N₀ No regional lymph node metastasis
 N₁ Metastasis in one to three pericolic or perirectal lymph nodes
 N₂ Metastasis in four or more pericolic or perirectal lymph nodes

Distant metastasis (M)
 M_x Presence of distant metastasis cannot be assessed
 M₀ No distant metastasis
 M₁ Distant metastasis

| Stage | Grouping | Dukes | Modified Astler-Collier |
|------------|------------------|----------------|-------------------------|
| Stage 0 | T _{is} | N ₀ | M ₀ |

STAGING

4 In addition to tissue diagnosis, tumors should be staged to determine the extent of disease before any definitive treatment is initiated.¹⁸ The process is dictated by knowledge of the biology of the tumor and by the signs and symptoms elicited in the history and physical examination. Staging provides information on prognosis and guides treatment selection. After treatment is implemented, the staging work-up is usually repeated to evaluate the effectiveness of the treatment. Uniform staging criteria are imperative in clinical research aimed at evaluating cancer treatment regimens. Staging has been valuable in learning more about the biology of various tumor types. A staging work-up may involve x-rays, computed tomography scans, magnetic resonance imaging, ultrasounds, bone-marrow biopsies, bone scans, lumbar puncture, and a variety of laboratory tests, including appropriate tumor markers. Some cancers produce antigens or other substances that are characteristic of that particular cancer. These so-called tumor markers are often nonspecific and may be elevated in many different cancer types, or in patients with nonmalignant diseases. As a result, tumor markers are generally more useful for monitoring response and detecting recurrence than as diagnostic tools. Examples are the measure of human chorionic gonadotropin and

α-fetoprotein in patients with testicular cancer, or prostate-specific antigen in prostate cancer.⁶

The most commonly applied staging system for solid tumors is the TNM classification, where T = tumor, N = node, and M = metastases. A numerical value is assigned to each letter to indicate the size or extent of disease. The designated rating for tumor describes the size of the primary mass and ranges from T₁ to T₄. Carcinoma in situ is designated T_{is}. Nodes are described in terms of the extent and quality of nodal involvement (N₀ to N₃). Metastases are generally scored depending on their presence or absence (M₀ or M₁). To simplify the staging process, most cancers are classified according to the extent of disease by a numerical system involving stages I through IV. Stage I usually indicates localized tumor, stages II and III represent local and regional extension of disease, and stage IV denotes the presence of distant metastases. The assigned TNM rating translates into a particular stage classification. For example, T₃N₁M₀ describes a moderate- to large-sized primary mass, with regional lymph node involvement and no distant metastases, and for most cancers is stage III. The criteria for classifying disease extent are quite specific for each different type of cancer. For some tumors, alternative alphabetical systems (stage A, B, C, or D) are used in clinical practice. Table 124–7 provides an example of the staging system for colorectal cancer.¹⁹

► TREATMENT: Modalities of Cancer Treatment

4 Four primary modalities are employed in the approach to cancer treatment: surgery, radiation, chemotherapy, and biologic therapy.²⁰ The oldest of these is surgery, which plays a major role in the diagnosis and treatment of cancer. Surgery remains the treatment

of choice for most solid tumors diagnosed in the early stages. Radiation therapy was first used for cancer treatment in the late 1800s and remains a mainstay in the management of cancer. Although very effective for treating many types of cancer, surgery and radiation are local

treatments. These modalities are likely to produce a cure in patients with truly localized disease. But because most patients with cancer have metastatic disease at diagnosis, localized therapies often fail to completely eliminate the cancer. In addition, systemic diseases such as leukemia cannot be treated with a localized modality. Chemotherapy (including hormonal therapy) accesses the systemic circulation and can theoretically treat the primary tumor and any metastatic disease. Biologic therapies are currently considered in the broader sense of “biologically directed” therapies. Immunotherapy, the earliest important form of biologic therapy, usually involves stimulating the host’s immune system to fight the cancer. The agents used in immunotherapy are usually naturally occurring cytokines, which have been produced with recombinant DNA technology. Examples of agents used in immunotherapy include interferons (IFNs) and interleukins (ILs). Biologically directed therapies include monoclonal antibodies, other targeted therapies such as tyrosine kinase inhibitors or proteasome inhibitors, and tumor vaccines.

5 Many cancers appear to be eliminated by surgery or radiation. However, the high incidence of later recurrence implies that the primary tumor began to metastasize before it was removed. These early metastases are too small to detect with currently available diagnostic tests and are known as micrometastases. Adjuvant therapy is defined as the use of systemic agents to eradicate micrometastatic

disease following localized modalities such as surgery or radiation or both. The goal of systemic therapy given in this setting is to reduce subsequent recurrence rates and prolong long-term survival. Thus adjuvant therapy is given to patients with potentially curable malignancies who have no clinically detectable disease after surgery or radiation. Because adjuvant therapy is given at a time that the cancer is undetectable, its effectiveness cannot be measured by response rates; instead it is evaluated by recurrence rates and survival. The value of adjuvant therapy is best established in colorectal and breast cancers. Chemotherapy may also be given in the neoadjuvant or preoperative setting. The goals in this instance are to make other treatment modalities more effective by reducing tumor burden and to destroy micrometastases. For example, in head and neck cancer, neoadjuvant chemotherapy is employed in an attempt to shrink large tumors and to make them more amenable to later surgical resection, and possibly spare critical organs, such as the larynx.

The management of most types of cancer involves the use of combined modalities. Early stage breast cancer is a good example of the use of a combined-modality approach. The primary tumor is removed surgically, and radiation therapy is delivered to the remaining breast (after lumpectomy) or to the axilla (if there is marked lymph node involvement). Adjuvant chemotherapy and/or hormonal therapy is then administered to eradicate any micrometastatic disease.

► TREATMENT: Principles of Chemotherapy

■ PURPOSES OF CHEMOTHERAPY

4 The era of modern cancer chemotherapy was born in 1941, when Goodman and Gilman first administered nitrogen mustard to patients with lymphoma.²¹ Since that time, numerous antineoplastic agents have been developed, and a variety of chemotherapy regimens have been investigated in every type of cancer. Table 124–8 lists tumors and their responsiveness to chemotherapy.^{14,22} Cancer chemotherapy may be indicated as a primary, palliative, adjuvant, or neoadjuvant treatment modality. Treatment with cytotoxic drugs is the primary curative modality for a few diseases, including leukemias, lymphomas, choriocarcinomas, and testicular cancer. Most solid tumors are not curable with chemotherapy alone, either because of the biology of the tumor or because of advanced disease at presentation. Chemotherapy in this setting is often initiated for palliative purposes. It is often possible to decrease tumor size or to retard growth enough to reduce untoward symptoms caused by the tumor. Adjuvant and neoadjuvant chemotherapy are defined in the previous section.

■ RESPONSE CRITERIA

5 The response to chemotherapy and other treatment modalities may be described as a cure, complete response, partial response, stable disease, or progression.^{22,23} These terms are used routinely in oncology to define the response to chemotherapy and other treatment modalities. A cure implies that the patient is entirely free of disease and has the same life expectancy as a cancer-free individual. Although there is no way to be absolutely certain that an individual patient is cured, a stable plateau in the survival curve after cancer treatment is taken as evidence of cure. For most cancers, the survival curves have plateaued by about 5 years. Thus 5 years of survival without

disease recurrence is often equated with a cure. However, there are some malignancies, such as breast cancer and melanoma for example, in which patients are still at significant risk for relapse after 5 years.

Complete response (CR) means complete disappearance of all cancer without evidence of new disease for at least 1 month after treatment. The terms “cure” and “CR” are not synonymous. Although an individual must have a CR to be cured, many individuals who achieve a CR will eventually relapse. A *partial response* (PR) is defined as a 50% or greater decrease in the tumor size or other objective disease markers, and no evidence of any new disease for at least 1 month. Overall objective response rates for a given treatment are determined by adding the CR and PR rates. Despite the small changes in tumor size, some patients may experience subjective improvement in the symptoms caused by their cancer. Although clinically important, this does not indicate an objective response. The term *clinical benefit response* was recently coined; it refers to patients who have clinical benefit as measured by decreases in pain or analgesic consumption, or improved quality of life or performance status. A patient whose tumor size neither grows nor shrinks by more than 25% has stable disease. Progression of disease is defined as a 25% increase in the tumor size or the development of any new lesions while receiving treatment. These response definitions are applicable to solid tumors, but diseases such as leukemias and multiple myeloma are not characterized by discrete, measurable masses. Responses in these diseases are measured by elimination of abnormal cells (e.g., return to normal hematology parameters and normal bone marrow in leukemia), return of tumor markers to normal levels (e.g., normal serum protein electrophoresis in multiple myeloma), disappearance of pleural or peritoneal effusions, or improved function of affected organs (e.g., improved renal function after obstructive uropathy). Cytogenetic markers and molecular techniques have an increasingly important role in determining whether all cancer has been truly eliminated. For example, in chronic myelogenous leukemia, the Philadelphia chromosome [a (9:22) chromosomal translocation resulting in the *bcr-abl* gene] can be detected

TABLE 124–8. The Role of Chemotherapy in the Treatment of Cancer

| | |
|---|---|
| Chemotherapy used alone with curative intent | |
| Acute lymphocytic leukemia | Acute nonlymphocytic (myelogenous) leukemia |
| Burkitt's lymphoma | Diffuse large cell lymphoma |
| Hodgkin's lymphoma | Testicular cancer |
| Choriocarcinoma (gestational trophoblastic neoplasm) | |

by polymerase chain reaction techniques, even when no leukemia is evident in the bone marrow or bloodstream. Patients without evidence of the Philadelphia chromosome are classified as a complete cytogenetic response.

FACTORS AFFECTING RESPONSE TO CHEMOTHERAPY

6 These include tumor burden, tumor-cell heterogeneity, drug resistance, dose intensity, and patient-specific factors. The significance of tumor burden has been discussed earlier. Tumors consist of a heterogeneous population of cell types. Because of the genetic instability of cancer cells compared to normal cells, mutations commonly occur during cell division. Large tumors have undergone many cell divisions and express multiple cell mutations resulting in genetically varied cell populations.^{6,14,22} In 1979, Goldie and Coldman proposed that these cytogenetic changes were not completely random and were highly associated with the development of the ability of tumors to resist drug action.^{1,6,14} The probability of developing resistant cell populations increases as tumor size increases. It is believed that a small percentage of resistant cancer cells may survive initial chemotherapy. Resistant populations later proliferate and eventually become the dominant cell types. This explains the common pattern of an initial response to chemotherapy, followed by progressive tumor regrowth despite continuing the same treatment regimen.

Drug resistance may be either an acquired or inherited property of a neoplastic cell. Mechanisms of drug resistance include decreased activation of prodrugs, decreased uptake of drugs secondary to alterations in drug transport systems, changes in target enzymes, alterations in the cell's ability to repair drug-induced damage, increased drug inactivation, and decreased apoptosis.^{6,12,14,20} One focus of research in this area is pleiotropic drug resistance or multidrug resistance.^{14,20,24,25} When some cancer cells are exposed to increasing concentrations of a specific antineoplastic agent in vitro, they become resistant to that agent. Surprisingly, these same cells also become resistant to other structurally unrelated antineoplastic agents; that is, they are multidrug resistant. Cytotoxic agents derived from natural products, such as the anthracyclines, actinomycin D, mitomycin C, the vinca alkaloids, the epipodophyllotoxins, and the taxanes, produce multidrug resistance. The resistant cancer cells possess a membrane-associated protein known as P170 or P-glycoprotein, which appears to enhance the export of toxins, such as chemotherapy agents, out of the cell (Fig. 124–7). The gene that encodes for P-glycoprotein is known as the *mdr-1* gene. Expression of this gene is amplified in cells that are resistant to the natural products listed previously. P-glycoprotein is also found in high concentrations in tumors that are traditionally resistant to chemotherapy (e.g., renal cell and non-small-cell lung cancers) and thus may also be an important mechanism of intrinsic or inherited drug resistance. Several drugs have been investigated as possible inhibitors of this efflux pump, such as the calcium channel blockers, quinidine, cyclosporine, and the phenothiazines. Another

FIGURE 124–7. P-glycoprotein (P-gp) is a membrane-associated protein that acts as a drug efflux pump. Anticancer agents enter the cell, bind to the P-gp receptor, and are ejected. Some agents that modify multidrug resistance, like verapamil, block the P-gp receptor, allowing the anticancer agent to remain in the cell.

efflux pump, known as the multidrug resistance–associated protein, was also recently identified. Other potential mechanisms of drug resistance include inactivation of chemotherapy agents by glutathione metabolism, upregulation of target enzymes such as topoisomerases or dihydrofolate reductase, and decreased apoptosis after exposure to chemotherapy.²⁴ The last mechanism can be mediated by *bcl-2* oncogene overexpression or loss of the *p53* gene, as discussed in the oncogene section. The interplay between apoptosis and drug resistance is an area of intense research.¹²

7 The relationship between dose and response has been extensively explored in cancer chemotherapy. Dose is believed to be a critical factor in determining response for many types of cancers. Dose intensity is defined as the dose delivered to the patient over a specified period of time.^{1,26,27} The three main variables that determine delivered dose intensity are the dose per course, the interval between doses, and the total cumulative dose. Dose density refers to shortening of the usual interval between doses (e.g., every 2 weeks instead of every 3 weeks) and is designed to maximize the drugs' effects on tumor growth kinetics. This strategy has been most extensively studied in breast cancer, with positive results in adjuvant therapy of patients with high-risk node-positive disease. The delivery of optimal dose intensity is often compromised by the toxicities of the oncologic drugs. Treatment cycles are commonly delayed because of inadequate recovery from drug toxicity, especially myelosuppression. Subsequent doses of chemotherapy are often reduced to prevent or reduce the severity of these toxicities. The impact of this issue on patient outcome has been proven in studies showing reduced rates of response and survival in individuals receiving less-than-optimal chemotherapy doses.²⁶ Understanding the pathophysiology of drug-induced toxicities has led to the development of more effective agents for prevention and management of these toxicities. The development of drug- and toxicity-specific chemoprotective agents has facilitated application of dose-intensity principles.²⁸ The colony-stimulating factors avert neutropenia and permit delivery of dose-intensive or dose-dense regimens that are usually dose-compromised by neutropenia. The issue of dose intensity is brought into a new light in the era of high-dose chemotherapy with autologous hematopoietic stem cell support. Although lethal myelosuppression is avoided by administering hematopoietic stem cells, other severe end-organ toxicities emerge as antineoplastic doses are increased.

Patient-specific factors create unpredictable variability in response to chemotherapy. The biology of cancer is strongly affected by host characteristics and genetics. The pathway of genetic mutations that resulted in malignancy can also affect response to therapy. For example, breast cancers that overexpress the *HER-2/neu* (*EGFR-2*) oncogene are often refractory to regimens like CMF (cyclophosphamide, methotrexate, and 5-fluorouracil), but sensitive to anthracycline-based regimens.²⁹ Likewise, patients with *EGFR* mutations that result in enhanced tyrosine kinase activity are more likely to respond to the tyrosine kinase inhibitor gefitinib.³⁰ Interindividual variations in drug absorption, disposition, elimination, or metabolism may lead to sub- or supratherapeutic levels of antineoplastic agents and their metabolites.^{31,32} As a result, both drug efficacy and drug toxicity can be affected. Until recently, health professionals in oncology have focused on dose modification based on variation in body size, blood counts, and renal and hepatic function. Prospective dose modifications based on these parameters are still very important to optimize the effectiveness of therapy and minimize toxicity. But recently, more specific tools are becoming available, as we learn how to identify and apply differences in people's genetic make-up to their cancer drug therapy. The study of the role of inheritance in individual variation in drug response is known as *pharmacogenomics*. In oncology, several clinically relevant genetic polymorphisms, or variations, have been identified that can affect drug pharmacokinetics and pharmacodynamics. Examples include polymorphisms in genes responsible for production of the enzymes dihydropyrimidine dehydrogenase (responsible for 5-fluorouracil metabolism), thiopurine S-methyltransferase (responsible for thiopurine metabolism), and uridine diphosphate-glucuronosyltransferase 1A1 (responsible for irinotecan metabolism). Patients with deficiencies in these enzymes can experience significant and possibly life-threatening toxicity. Screening for these genetic abnormalities will permit individualization of regimens to avoid toxicity and maximize antitumor effects. Monitoring of antineoplastic drug concentrations may also improve the therapeutic index.³³ Pharmacokinetic and pharmacodynamic modeling is associated with improved responses and decreased toxicity in children with acute lymphoblastic leukemia.³⁴

The presence of other disease states may also affect response to treatment by limiting treatment options. The overall functional status of a patient may be assessed using performance status scales, such as the Karnofsky and Eastern Cooperative Oncology Group scales (Table 124–9).²³ These scales can be used to predict patient tolerance of chemotherapy, as well as to assess the effects of chemotherapy on the patient's level of activity and quality of life. In many cancers, performance status at diagnosis is the most important prognostic indicator.

Today's oncology clinician has a wealth of information to consider when designing a treatment approach for an individual patient. Patient-specific factors (e.g., performance status, comorbidities, renal and hepatic function, and pharmacogenomics), tumor-specific factors (e.g., pathology, stage, and molecular profile), and treatment goals (e.g., palliation and cure) are all considered when determining the best treatment option.

COMBINATION CHEMOTHERAPY

Although single-agent therapy is sometimes employed, the more common approach to chemotherapy involves administration of multiple agents.^{1,21,23} This approach is based on the Goldie-Coldman hypothesis, which addresses the issue of tumor cell heterogeneity and the inevitable development of drug resistance. Combination chemotherapy is employed to target as many types of cells in the tumor as possible.

TABLE 124–9. Performance Status Scales

| Description: Karnofsky Scale | Karnofsky Scale (%) | Zubrod Scale (ECOG) | Description: ECOG Scale |
|--|---------------------|---------------------|--|
| No complaints; no evidence of disease | 100 | 0 | Fully active, able to carry on all predisease activity |
| Able to carry on normal activity; minor signs or symptoms of disease | 90 | | |
| Normal activity with effort, some signs or symptoms of disease | 80 | 1 | Restricted in strenuous activity, but ambulatory and able to carry out work of a light or sedentary nature |
| Cares for self; unable to carry on normal activity or to do active work | 70 | | |
| Requires occasional assistance but is able to care for most personal needs | 60 | 2 | Out of bed more than 50% of time; ambulatory and capable of self-care, but unable to carry out any work activities |
| Requires considerable assistance and frequent medical care | 50 | | |
| Disabled; requires special care and assistance | 40 | 3 | In bed more than 50% of time; capable of only limited self-care |
| Severely disabled; hospitalization indicated, although death not imminent | 30 | | |
| Very sick; hospitalization necessary; requires active supportive treatment | 20 | 4 | Bedridden; cannot carry out any self-care; completely disabled |
| Moribund; fatal processes progressing rapidly | 10 | | |
| Dead | 0 | | |

ECOG, Eastern Cooperative Oncology Group.

Selection of agents for combination chemotherapy regimens involves consideration of drug-specific factors such as mechanism of action, antitumor activity, and toxicity profile. Drugs that possess minimally overlapping mechanisms of action and toxicities are combined, when possible. Myelosuppressive combinations are sometimes alternated with nonmyelosuppressive combinations to allow bone marrow re-

covery, while gaining additive antitumor effects. The selected agents should each have significant activity against the tumor that is to be treated. If a synergistic reaction is known to exist for two agents, they may be combined in various treatment regimens. Development of more specifically targeted agents may decrease the need for combining multiple agents.

CELL CYCLE

Both cancer cells and normal cells reproduce in a series of steps known as the cell cycle. Figure 124–8 depicts the cell cycle and the phases of activity for commonly used antineoplastic agents.^{11,14} The first phase is mitosis (M). Mitosis lasts for approximately 30 to 60 minutes and during this phase, cell division occurs. After mitosis, the cell might enter a dormant phase (G_0), or might proceed to the first gap phase (G_1). G_0 is the largest variable in the cell cycle, and during this resting phase, the cell is not actively committed to cell division. Some stimulus results in the cell entering the first gap phase (G_1). During G_1 , the cell prepares for DNA synthesis by manufacturing necessary enzymes. DNA synthesis (S) occurs next, and this phase lasts 10 to 20 hours. The percentage of cells in the S phase can be measured by flow cytometry and is an indicator of the rate of tumor-cell proliferation. Tumors with a high percentage of S-phase cells are aggressively growing. The synthesis phase is followed by a second gap or premitotic phase (G_2), lasting 2 to 10 hours. During this second gap, the cell prepares for mitosis by producing ribonucleic acid (RNA) and specialized proteins, as well as the mitotic spindle apparatus. The cycle then begins again with the M phase. Most normal human cells exist in the G_0 phase, and most cancer cells are not sensitive to the effects of chemotherapy when in this stage. The cell cycle is regulated by external mitogens, including cytokines, hormones, and

growth factors. As mentioned earlier, some of the genes that regulate the cell cycle are known to be protooncogenes and tumor-suppressor genes.

All cancer cells do not proliferate faster than normal cells; some cancer cells reproduce more rapidly, and others are more indolent. Many anticancer drugs target rapidly-proliferating cells (both normal and cancerous cells), and these agents may act at selective or multiple sites of the cell cycle. Agents with major activity in a particular phase of the cell cycle are known as cell-cycle phase-specific agents. The antimetabolites exert their major effect during the S phase. Cell-cycle phase-specific agents may also be active to a lesser extent in other phases of the cycle. Cell-cycle phase-nonspecific agents are those with significant activity in multiple phases. The alkylating agents such as nitrogen mustard are examples. In many cases, the cytotoxic effects of a drug may result from interactions with other intracellular activities and are not related to specific cell-cycle events. Hormones are an example of this type of drug.

Knowledge of cell-cycle specificity has been applied to the scheduling of chemotherapy administration. By definition, phase-specific agents exert their major activity when cells are in a particular phase of the cell cycle. At any given time, the heterogeneous cell populations within a tumor are at various phases in the cell cycle. By giving phase-specific agents as a continuous infusion or in multiple repeated fractions, it is theoretically possible to target more cells as they progress into the drug-sensitive phase. Thus phase-specific

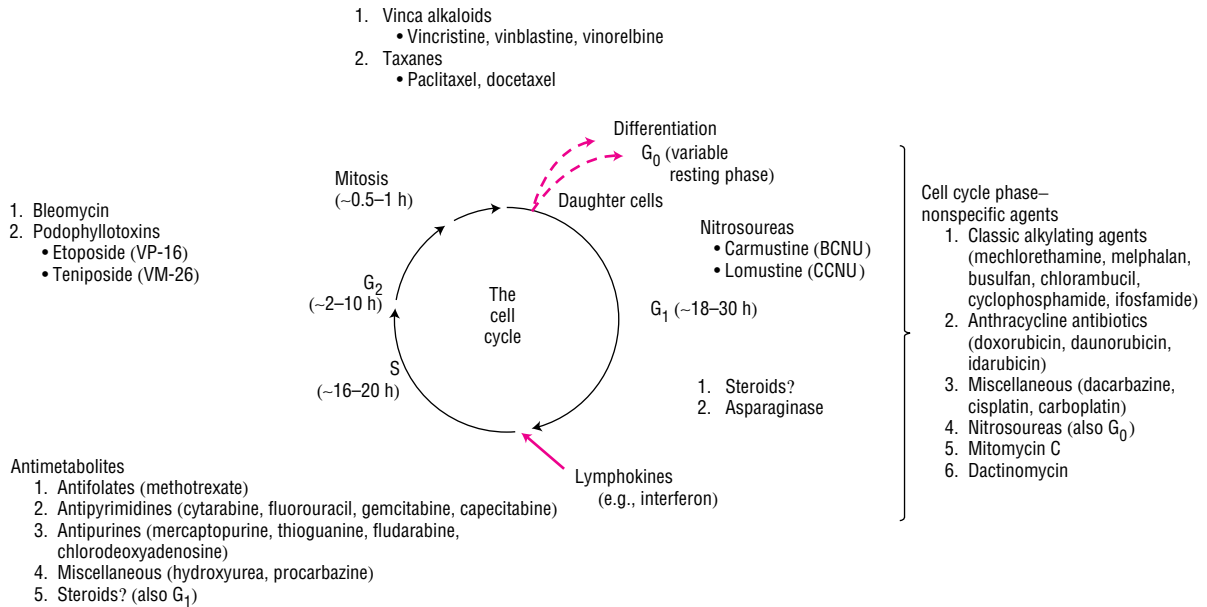

FIGURE 124–8. Cell cycle activity for anticancer drugs. Cell cycle phase-specific agents appear to be most active during a particular phase, but may also be active in another phase. Cell cycle phase-nonspecific agents may have greater activity in one phase than another, but not to the degree of cell cycle (phase)-specific agents. In many cases, it is likely that drug cytotoxicity involves multiple intracellular sites of action and may not be linked to specific cell-cycle events.

agents are also termed *schedule dependent*. In contrast, cell-cycle phase-nonspecific drugs are active in many phases, and consequently are not schedule dependent. The activity of this group of drugs is dependent on the magnitude of the dose, and these drugs are termed *dose dependent*.

MOLECULAR BIOLOGY

Because many antineoplastic agents interfere with the cellular synthesis of DNA, RNA, and proteins, it is important to review the basic principles of molecular biology.^{3,35} Each normal human cell contains 46 chromosomes, which are composed of DNA (deoxyribonucleic acid; Fig. 124–9). DNA carries hereditary information in units called genes. A single chromosome can contain 20,000 or more genes. Genes code for specific proteins that regulate cellular activity and inherited traits (some of which affect carcinogenesis and cancer growth, as well as the efficacy and metabolism of anticancer drugs). The genetic information is encoded in DNA by precise sequencing of subunits known as nucleotides. Each nucleotide consists of a sugar (deoxyribose), phosphoric acid, and a base. Four bases exist in DNA: adenine, thymine, guanine, and cytosine. Adenine and guanine are purine-type bases; thymine and cytosine are pyrimidine-type bases (Fig. 124–10). These nucleotides are connected linearly to form a chain. Each DNA molecule is made up of two chains of nucleotides, which wind around each other to form a double helix (see Fig. 124–9). The two strands are held together by chemical bonding between the bases. The bonding process is very specific; adenine binds only with thymine, and guanine binds only with cytosine. This is known as complementary base pairing. RNA (ribonucleic acid) is important in the DNA-directed synthesis of proteins or enzymes. RNA differs from DNA in that it is composed of a single strand of nucleotides, the sugar is ribose, and the base uracil is substituted for thymine. There are three known

types of RNA: messenger RNA (mRNA), transfer RNA (tRNA), and ribosomal RNA (rRNA).

DNA SYNTHESIS

During the DNA synthesis phase, which takes place in the cell nucleus, the DNA unwinds and exposes its nucleotides. When DNA unwinds for replication or protein synthesis, only the portion of the molecule containing the needed nucleotides needs to be exposed. Rather than unwinding the entire strand, topoisomerase I and II enzymes cleave the DNA strands to facilitate unwinding of the section that is needed. The enzyme DNA polymerase matches free complementary nucleotides from the environment to the exposed nucleotides of the DNA (see Fig. 124–9). The newly created strands rewind, resulting in two complete double helices. The topoisomerase enzymes are also responsible for resealing the cleaved DNA strands.

PROTEIN SYNTHESIS

The synthesis of proteins is a more complex process (Fig. 124–11). Proteins consist of chains of amino acids in very specific sequences. As in DNA synthesis, the double helix must unwind. However, in protein synthesis, only the portion of the DNA molecule that codes for the desired protein is exposed. The enzyme RNA polymerase matches free complementary RNA nucleotides to the exposed DNA nucleotides, and the resultant chain of nucleotides is called mRNA. This process is called transcription. The mRNA travels to ribosomes in the cytoplasm, where protein synthesis occurs. Each three nucleotides of the mRNA chain compose a codon, whose sequence is specific for a particular amino acid. The codon is recognized by tRNA, which then carries the amino acid to the ribosome, where it is added to the growing peptide chain. This process is known as translation. The

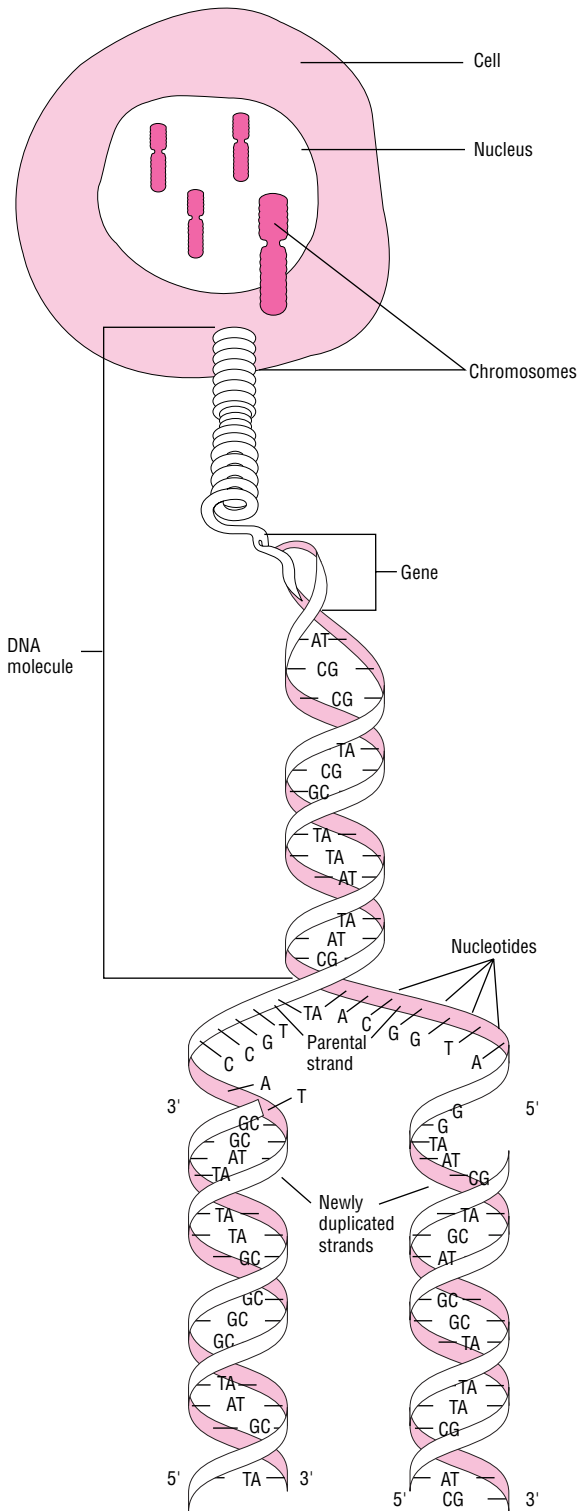

FIGURE 124-9. Structure and function of DNA. Within the cellular nucleus, tightly coiled strands of DNA are packaged in units called chromosomes. Working subunits of chromosomes are called genes. During DNA replication, the double-stranded DNA helix unwinds, exposing individual nucleotides. Complementary nucleotides are retrieved and assembled by DNA polymerases to form new strands of DNA.

FIGURE 124-10. Structures of DNA constituents.

completed protein is then ready for its intended use as an enzyme or as a structural component.

CLINICAL PHARMACOLOGY OF ANTICANCER AGENTS

Agents used in cancer chemotherapy are commonly categorized by their mechanism of action or by their origin. The alkylating agents exert their effects on DNA and protein synthesis by binding to DNA and preventing the unwinding of the DNA molecule. The antimetabolites resemble naturally occurring nuclear structural components (“metabolites”), such as the nucleotide bases, or inhibit enzymes involved in the synthesis of DNA and proteins. Antitumor antibiotics gain their name from their source; they are fermentation products of *Streptomyces* species. Figure 124-12 shows the sites of action of common categories of antineoplastic agents. The following section addresses these and other classes of agents used in the treatment of cancer. The clinical uses, mechanisms, side effects, and practical patient management suggestions for commonly used agents in each class are detailed in the accompanying tables. Unless otherwise indicated, information included in the tables is derived from FDA-approved drug labeling for individual agents. Dose modifications of individual agents are summarized in Table 124-10.

ANTIMETABOLITES

FLUORINATED PYRIMIDINES

Fluorouracil
 Fluorouracil (5-FU) is a fluorinated analog of the naturally occurring pyrimidine uracil, originally synthesized in the late 1950s (Table 124-11). It is a prodrug and must be metabolized to the nucleotide form, fluorodeoxyuridine monophosphate (FdUMP), to be active. In the presence of folates, FdUMP binds tightly to and interferes with

FIGURE 124–11. Protein synthesis. When a specific protein is needed, the portion of DNA responsible for that protein unwinds, exposing the necessary nucleotide sequence. Complementary nucleotides are assembled to form messenger RNA (mRNA), which travels to ribosomes in the cytoplasm. There, transfer RNA (tRNA) matches amino acids to the nucleotide sequence on the mRNA. The amino acids are assembled to form proteins.

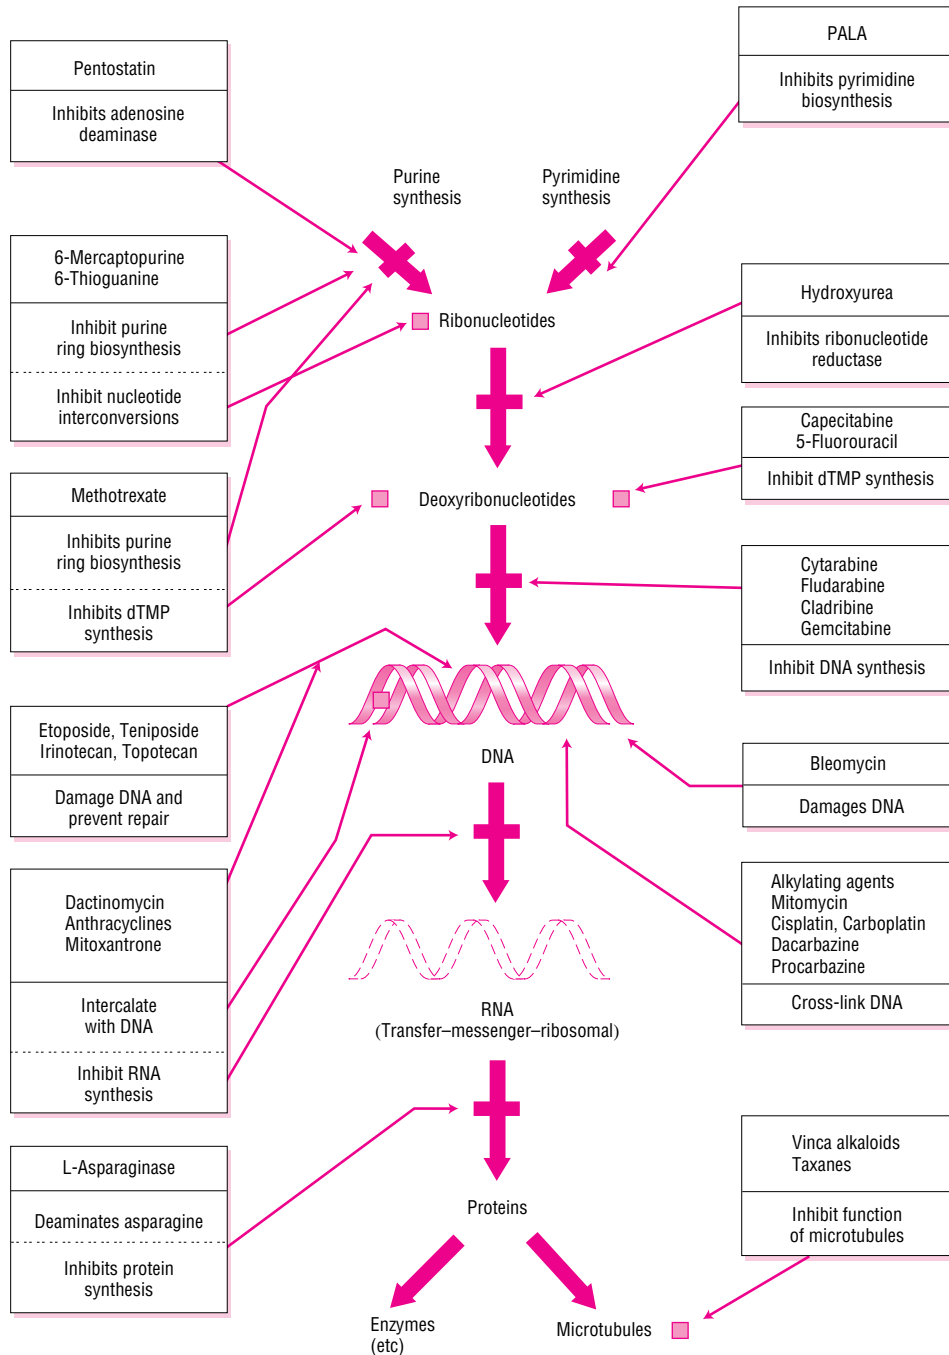

FIGURE 124–12. Mechanisms of action of commonly used antineoplastic agents. (From Chabner BA, Ryan DP, Paz-Ares L, Garcia-Carbonero R, Calabresi P. Antineoplastic agents. TABLE 124–10. Empiric Dose Modifications in Patients with Renal and Hepatic Disease^a

| Agent | Organ Dysfunction | Suggested Dose Modification |
|--|---------------------|---|
| Methotrexate, cisplatin | Renal impairment | In proportion to lowered creatinine clearance (normal = 60 mL/min per m ²) Cl _{cr} <10 mL/min, contraindicated |
| Carboplatin | Renal impairment | See Table 124–14 for dosing guideline |
| Cyclophosphamide | Renal failure | Cl _{cr} <25 mL/min; reduce dose by 50% |
| Bleomycin | Renal failure | Cl _{cr} <25 mL/min; reduce dose by 50% to 75% |
| Capecitabine | Renal impairment | Cl _{cr} 30–50 mL/min; reduce dose by 25% Cl _{cr} <30 mL/min, contraindicated |
| Cytarabine (high dose: >1 g/m ²) | Renal impairment | For creatinine 1.5–1.9 mg/dL, reduce dose by 50% For creatinine >2.0 mg/dL, reduce dose by 95% |
| Topotecan | Renal impairment | Cl _{cr} 20–39 mL/min; reduce dose by 25% |
| Cladribine | Renal impairment | In proportion to lowered creatinine clearance |
| Fludarabine | | |
| Hydroxyurea, doxorubicin, daunorubicin, vincristine, vinblastine | Hepatic dysfunction | For bilirubin >1.5 mg/dL, reduce dose by 50% For bilirubin >3.0 mg/dL, reduce dose by 75% |
| Vinorelbine | Hepatic dysfunction | For bilirubin >2.0 mg/dL, reduce dose by 50% For bilirubin >3.0 mg/dL, reduce dose by 75% |
| Gemcitabine | Hepatic dysfunction | For bilirubin >1.6 mg/dL, reduce dose by 20% |
| Idarubicin, mitoxantrone | Hepatic dysfunction | Consider dose reductions; no published guidelines available |
| Docetaxel | Hepatic dysfunction | Contraindicated in patient with bilirubin >1.5 × ULN or transaminases >1.5 × ULN or alkaline phosphatases >2.5 × ULN |
| Irinotecan | Hepatic dysfunction | Contraindicated in patients with bilirubin >2 mg/dL, or transaminases >3 × ULN (without liver metastases), >5 × ULN (with liver metastases) |
| Paclitaxel | Hepatic dysfunction | Reduce dose by ≥50% for moderate to severe increases in bilirubin or transaminases |

^aOnly approximate guidelines can be given. See text for explanations and limitations. Cl_{cr}, creatinine clearance; ULN, upper limit of normal laboratory values.

Adapted from ref. 1 and package inserts.

the function of thymidylate synthase. This enzyme is required for synthesis of thymidine, one of the four essential building blocks of DNA. Another metabolite of 5-FU, the triphosphate nucleotide, is incorporated into RNA as a false base, and interferes with its function. Interference with both thymidine formation and RNA function is important in producing the cytotoxic effects of 5-FU. Although 5-FU nucleotides can also be incorporated directly into DNA and affect its stability, the contribution to cell damage remains unclear. The method of administration influences the mechanism of action, with thymidylate synthesis inhibition playing a greater role in continuous-infusion regimens, and incorporation into RNA being more important for intermittent-bolus schedules.³⁶

Several pharmacologic strategies have been attempted to increase the cytotoxicity of 5-FU against tumor cells and to decrease its toxicity to normal cells. The most successful of these attempts at biochemical modulation are combinations of fluorouracil and the reduced folate leucovorin. Folates increase the stability of the FdUMP-thymidylate synthase complex, thereby increasing the cytotoxicity and clinical usefulness of the drug.^{36–40}

Oral Fluoropyrimidines

Capecitabine is an orally active pyrimidine analog. Despite the similarity of its name to cytidine derivatives such as cytarabine and

gemcitabine, capecitabine is an analog of uracil and is a prodrug of 5-FU. Because capecitabine is converted to 5-FU, it shares the same mechanisms of action. It generates higher levels of 5-FU selectively within some tumors compared with healthy tissues. Because chronic twice-daily oral dosing of capecitabine produces sustained 5-FU levels similar to continuous intravenous infusions of 5-FU, the toxicity pattern is similar to that of 5-FU infusions.^{36,41–43} Several other oral fluoropyrimidine products are under investigation.⁴⁴

CYTIDINE ANALOGS

Cytarabine

Cytarabine (ara-C) is an arabinose analog of cytosine. Cytarabine was originally isolated from sponges, but is now produced synthetically. Ara-C is phosphorylated to its active triphosphate form (ara-CTP) within tumor cells. Ara-CTP inhibits DNA polymerase, an enzyme responsible for strand elongation. It is also incorporated directly into DNA, where it inhibits the replication of DNA and acts as a chain terminator to prevent DNA elongation. Activation of ara-C is opposed by deaminase enzymes, particularly cytidine deaminase, which degrades ara-C to an inactive form, ara-U.^{36,45,46}

TABLE 124–11. Antimetabolites

| Agent/Major Uses | Class/Mechanism | Major Side Effects | Comments |
|---|--|---|---|
| Azacitidine [5-azacytidine, 5-AC, Ara C, Vidaza] ^a MDS Sickle cell anemia; thalassemia | Pyrimidine [cytidine] nucleoside analog antimetabolite; induces differentiation in malignant cells; causes demethylation or hypomethylation of DNA; this can alter gene transcription and expression, restoring normal function to tumor suppressor genes responsible for cell differentiation and growth | Myelosuppression; low emetogenic potential; constitutional symptoms (fatigue, weakness, fever, rigors); musculoskeletal symptoms (arthralgias, pain in limbs); pulmonary (cough, dyspnea) | Suspension for subcutaneous injection; approved for treatment of all MDS subtypes; onset of response usually requires 3–4 months; myelosuppression decreases with onset of response in MDS patients; drug toxicity may be difficult to distinguish from symptoms of MDS |
| Capecitabine (Xeloda) ^b Breast cancer; colorectal cancer; GI tract cancers | Similar to 5-fluorouracil: converted to 5-FU in three-step process; greater activation in tumor cells than in normal cells | Diarrhea may require fluid and electrolyte replacement; warn patients to stop drug if they experience an increase of 4–6 or more stools per day or nocturnal stools; hand-foot syndrome (palmar-plantar erythema): numbness, dysesthesia, tingling, swelling, redness, pain, sometimes blistering, ulceration in hands and feet; stop drug and restart at lower dose when resolved; topical emollients may be helpful; nausea common but mild; low risk of myelosuppression | Pharmacokinetics and toxicity mimic continuous-infusion 5-FU; drug interactions: Warfarin—(<i>major interaction</i>), results in increased anticoagulant effects, increased risk of bleeding; monitor coagulation parameters closely; phenytoin—may require phenytoin dose reduction; monitor phenytoin levels closely; leucovorin increases the activity and toxicity of capecitabine Dose adjustment for renal dysfunction: reduce dose by 25% for Cl_{cr} 30–50 mL/min; avoid with $Cl_{cr} < 30$ mL/min Usually administered by continuous infusion for 7 days |
| Cladribine [2-chlorodeoxyadenosine, 2-CDA, Leustatin] ^c Hairy cell leukemia; CLL; NHL | Purine [adenosine] nucleoside antimetabolite; active triphosphate form can prevent elongation of DNA chain; also inhibits ribonucleotide reductase, depleting intracellular deoxynucleotides and impairing DNA synthesis | Myelosuppression; fever (onset by day 6, persisting for about 3 days); immunosuppressive; severe opportunistic infections occur; low emetogenic potential | Usually administered by continuous infusion for 7 days |
| Cytarabine (ara-C; cytosine arabinoside; Cytosar U) ^d ANLL; ALL; lymphomatous meningitis; NHL; MDS High-dose ara-C (HDAC) Liposomal cytarabine (Depocyt) for intrathecal use for lymphomatous meningitis | Antipyrimidine antimetabolite; inhibits DNA polymerase with inhibition of DNA strand elongation and replication; activated in tumor cells to triphosphate form; competes with conversion of cytidine to deoxycytidine nucleotides, further blocking polymerization of DNA; leads to production of short DNA strands; cell-cycle specific (S phase): acts only on proliferating cells | Myelosuppression; alopecia; moderate emetogen; worse with high dose (> 1 g/m ²) or IT administration; diarrhea; mucositis; flu-like syndrome with fever and arthralgias; rash often followed by desquamation on palms and soles <i>HDAC toxicities:</i> Cerebellar toxicity; direct neurotoxicity: ataxia, slurred speech, nystagmus; conjunctivitis (drug is excreted into tears and blocks corneal DNA synthesis) | HDAC infusions should be administered over 2–3 hours to decrease risk of CNS toxicity; use steroid eyedrops during treatment and for 48 hours posttreatment to prevent conjunctivitis with HDAC Increased HDAC neurotoxicity in patients with impaired renal function; dose reduction recommended; frequent neurologic exams; monitor creatinine; avoid concurrent administration of nephrotoxic drugs Rapid cell kill: may see tumor lysis syndrome with large tumor burden ($WBC > 100,000/mm^3$) |
| Fludarabine (FAMP; Fludara) ^e CLL; low-grade NHL; ANLL; Waldenstrom's macroglobulinemia | Inhibits ribonucleotide reductase via inhibition of DNA synthesis; inhibits DNA polymerase via inhibition of DNA repair | Myelosuppression, including decreased T cells; low emetogenic potential; diarrhea; rare CNS toxicity: somnolence, peripheral neuropathies, hearing loss that is dose related, may be severe with high cumulative doses; may induce altered mental status, seizures; pulmonary toxicity: interstitial pneumonitis | Risk of opportunistic infections associated with decreased T-cell function for several months after treatment (PCP, mycobacterial infections); prophylactic antibiotics for PCP and HSV should be considered, particularly when fludarabine is used in combination with corticosteroids Rapid cell kill: tumor lysis syndrome precautions needed; reduce dose with impaired renal function |

(continued)

TABLE 124–11. (Continued)

| Agent/Major Uses | Class/Mechanism | Major Side Effects | Comments |
|---|--|--|--|
| Fluorouracil (5-FU)^f Breast cancer; colorectal cancer; gastric and pancreatic cancers; esophageal, head, and neck cancer; cervical cancer Radiosensitizer Cataract surgery | Fluorinated antiprimidine analog of uracil; prodrug fluorodeoxyuridine monophosphate (FdUMP) is active form; thymidylate synthase (TS) inhibitor; interferes with RNA/DNA function; “false” pyrimidine; leucovorin enhances binding of FdUMP to TS; potentiates cytotoxicity as well as toxicity; cell-cycle specific: S phase | Mucositis and diarrhea resulting from damage to normally rapidly proliferating cells of GI tract (worse with continuous infusion, concurrent leucovorin regimens); mild emetogen; myelosuppression (worse with bolus administration); rash, hyperpigmentation, photosensitivity; hand-foot syndrome (palmar-plantar erythema) with continuous-infusion regimens; alopecia uncommon; ocular toxicity (excess tearing, itching, burning); myocardial ischemic symptoms (especially high-dose continuous infusions) | Various routes of administration: IV bolus or short or continuous infusion; dose, schedule, and inclusion of leucovorin affect toxicity pattern <i>Diarrhea can be severe and life threatening</i> ; treat aggressively with antimotility agents; leucovorin can worsen 5-FU diarrhea; special caution in elderly females Deficiency of dihydropyrimidine dehydrogenase (DPD) correlates with increased toxicity; DPD required to metabolize 5-FU <i>Drug interaction with warfarin</i> : increased anticoagulant effect; monitor closely |
| Gemcitabine (Gemzar)^g Pancreatic cancer; NSCLC; breast cancer; head and neck cancer; bladder cancer; testicular cancer; ovarian cancers, HD | Related to cytarabine, incorporated into DNA, inhibits DNA synthesis; ribonucleotide reductase inhibitor; interferes with DNA chain elongation | Myelosuppression; neutropenia, thrombocytopenia; may be more severe with infusions >1 hour; myelosuppression may necessitate dose reduction and/or delay in therapy; flu-like syndrome: fever, myalgias; rash: typically erythematous, pruritic, starts 48–72 hours after dose; elevations in liver transaminases; low emetogenic potential; rare pulmonary toxicity: dyspnea, bronchospasm; radiation-recall reactions | Generally very well-tolerated; rash may respond to topical steroids, dose reduction; fevers may respond to acetaminophen Dose reduction recommended for patients with elevated total bilirubin (>1.5 mg/dL) Breast cancer indication is in combination with paclitaxel |
| Hydroxyurea (Hydrea)^c CML; sickle cell disease; melanoma; ^h head and neck cancers; ^h ovarian cancer; ^h cervical cancer | Inhibits ribonucleotide reductase; inhibits DNA synthesis (does not interfere with RNA or protein synthesis) | Myelosuppression; low emetogenic potential; rash, pruritus, skin hyperpigmentation; hyperuricemia may occur with rapid cytoreduction; secondary leukemias may occur with long-term use | Drug is degraded by moisture; keep capsules in a tightly sealed container with a desiccant |
| 6-Mercaptopurine (Purinethol; 6-MP)^c ALL | Antipurine antimetabolite; purine analog; inhibits DNA, RNA, protein synthesis; metabolized by xanthine oxidase | Myelosuppression: mild; anorexia, low emetogenic potential; dry skin rash, photosensitivity; hepatotoxicity: jaundice and hyperbilirubinemia occur after 1–2 months of therapy and may be dose-limiting | Drug interactions: allopurinol increases the toxicity of 6-MP by interfering with metabolism: 75% <i>dose reduction</i> of 6-MP is required if used with allopurinol; 6-MP reduces anticoagulant effects of warfarin; concurrent use of 6-MP with other hepatotoxic drugs increases the risk of hepatotoxicity |
| Methotrexate [MTX] ALL CNS leukemia [IT] Breast cancer NHL Osteosarcoma Head and neck cancer Bladder cancer Rheumatoid arthritis | Folic acid antagonist ; inhibits dihydrofolate reductase (DHFR); blocks reduction of folate to tetrahydrofolate; inhibits <i>de novo</i> purine synthesis; results in arrest of DNA, RNA, and protein synthesis Leucovorin provides reduced folate to bypass the metabolic block. | Myelosuppression: can be prevented with leucovorin rescue Mucositis: can be prevented with leucovorin Renal dysfunction: (high dose regimens) caused by precipitation of drug in renal tubules; hydration (3 L/m ² /day) and alkalinization of urine (to | Avoid drugs that decrease renal excretion of cisplatin, salicylates, sulfas, probenecid, penicillins Methotrexate distributes readily into third space fluids (ascites, pleural effusions), prolonging exposure and increasing toxicity. May be contraindication for use. |

TABLE 124–11. (Continued)

| Agent/Major Uses | Class/Mechanism | Major Side Effects | Comments |
|---|--|--|--|
| SLE and other autoimmune disorders Ectopic pregnancy | | increase drug solubility; keep urine pH >7) minimize nephrotoxicity. Reduce dose for renal dysfunction; avoid use in severe renal impairment Emetogenic potential generally low, but higher emetogenicity with high-dose therapy CNS toxicity: malaise, dizziness; may be more severe with IT administration (nausea, vomiting, seizures, headache) Hepatotoxicity: cirrhosis/portal fibrosis (more common with chronic administration) Photosensitivity | Monitor methotrexate levels with high-dose administration Toxicities (mucositis, BM suppression) correlate with MTX levels >1 μM ($1 \times 10^{-6}\text{M}$) for >48 hours. High-dose regimens must include leucovorin (LCV) rescue to prevent irreversible BM toxicity. LCV continued until MTX level <0.1 μM to 0.01 μM . Use preservative-free preparations for IT and high-dose administration. |
| Pemetrexed [Allmeta] Mesothelioma NSCLC | Multitargeted antifolate; disrupts folate-dependent processes essential for cell reproduction. Inhibits thymidylate synthase, dihydrofolate reductase [DHFR], and glycinamide ribonucleotide formyltransferase [GARFT], all involved in synthesis of thymidine and purine nucleotides. | Myelosuppression: increased in patients with elevated cystathionine or homocysteine concentrations. Folic acid and vitamin B ₁₂ supplementation decrease myelosuppression by decreasing elevated cystathionine and homocysteine levels. Stomatitis, pharyngitis Rash, desquamation. Premedicate with dexamethasone 4 mg twice daily the day before, day of, and day after administration. | Approved for use in combination with cisplatin Renally eliminated. No dose changes require creatinine clearance ≥ 45 mL/min. Not recommended in patients with lower creatinine clearances. Avoid short-acting NSAIDs [eg ibuprofen] for before and after pemetrexed administration. Avoid longer acting NSAIDs for 5 days prior to and 2 days after pemetrexed administration. Supplementation with folic acid [400 mcg daily starting 1 week before first dose; continued days after last dose] and vitamin B ₁₂ [1000 mcg IM during week prior to first dose and even cycles thereafter] is required during administration to reduce toxicity. Leucovorin rescue is indicated for Grade 4 toxicities. |

Cytidine deaminase levels are very low in the CNS. Cytotoxic concentrations are maintained in the CNS for several hours after CNS administration of traditional cytarabine formulations, and for more than 2 weeks following CNS administration of depot formulated cytarabine.

The toxicity of cytarabine is dose dependent. The most characteristic toxicity of high-dose ara-C (HDAC; >1 g/m² per dose) regimens is a cerebellar syndrome of dysarthria, nystagmus, and ataxia. Risk of CNS toxicity is strongly correlated with advanced age and renal dysfunction. Renal insufficiency permits accumulation

of high levels of ara-CTP, which is believed to be neurotoxic. Hepatic dysfunction, high cumulative doses, and bolus dosing may also increase the risks of neurotoxicity.^{36,45,46}

Gemcitabine

Gemcitabine is a fluorine-substituted deoxycytidine analog related structurally to cytarabine (see Table 124–11). Its activation and mechanism of action are similar to those of cytarabine. Gemcitabine is incorporated into DNA, where it inhibits DNA polymerase activity. It also inhibits ribonucleotide reductase. Compared with cytarabine,

gemcitabine achieves intracellular concentrations about 20 times higher than does ara-C, secondary to increased penetration of cell membranes, and greater affinity for the activating enzyme deoxycytidine kinase. Gemcitabine that is incorporated into DNA has a prolonged intracellular half-life. Its stereoconfiguration causes another normal base pair to be added next to the fraudulent gemcitabine base pair in the DNA strand. This “masked chain termination” protects the gemcitabine from excision and elimination.^{36,45,47,48}

Azacytidine

Azacytidine was approved in 2004 for the treatment of patients with myelodysplastic syndrome, a disorder of hematopoietic cell maturation that can progress to acute leukemia. Azacytidine, a cytidine nucleoside analog, causes hypomethylation of DNA. Hypomethylation may normalize the function of genes that control cell differentiation and proliferation, promoting normal cell maturation.⁴⁹

PURINES AND PURINE ANTIMETABOLITES

6-Mercaptopurine and 6-Thioguanine

Some of the oldest and newest anticancer agents are synthetic analogs of the naturally occurring purines guanine and adenine (see Table 124–11). 6-Mercaptopurine (6-MP) was the first purine analog to be used in cancer chemotherapy. Thioguanine (6-TG) is the two-amino analog of 6-MP. Both drugs are rapidly converted to ribonucleotides that inhibit purine biosynthesis. They also undergo purine interconversion reactions needed to supply purine precursors for synthesis of nucleic acids. Clinical cross-resistance is generally observed.³⁶

6-MP depends on xanthine oxidase for an initial oxidation step. Its metabolism is markedly decreased by concomitant administration of the xanthine oxidase inhibitor allopurinol, and serious toxicity may result. Oral 6-MP doses must be reduced when allopurinol is administered together with 6-MP.³⁶

Fludarabine Monophosphate

Fludarabine monophosphate (FAMP) is an analog of the purine adenine. Like cytarabine, fludarabine interferes with DNA polymerase, causing chain termination. Unlike ara-C, fludarabine is also incorporated into RNA, resulting in inhibited transcription. The usual dose-limiting toxicity is myelosuppression. Fludarabine is also immunosuppressive, with associated opportunistic infections.^{36,50,51}

Cladribine

Cladribine (2-chlorodeoxyadenosine; 2-CDA) is a purine nucleoside analog that is resistant to inactivation by adenosine deaminase. The triphosphate form of this agent is incorporated into DNA, resulting in inhibition of DNA synthesis and early chain termination. Cladribine’s antitumor activity is unusual for an antimetabolite in that it affects both actively dividing and resting cancer cells. Like fludarabine, cladribine possesses immunosuppressive effects that place patients at risk for serious opportunistic infections.^{36,45}

ANTIFOLATES

Folate vitamins are essential cofactors in DNA synthesis. They carry one-carbon groups in transfer reactions that are required for purine and thymidyl acid synthesis, and in turn for formation of DNA and for cell division. Natural folates circulating in the blood have a single glutamic acid group, but within cells they are converted to polyglutamates, which are more efficient cofactors and which are preferentially retained inside the cells.⁵²

Dietary folates must be chemically reduced to their tetrahydro forms, with four hydrogens on the perididine ring, to be active. The enzyme responsible for this reduction is dihydrofolate reductase (DHFR), a key enzyme whose actions are inhibited by methotrexate and other antifolates. The result of this inhibition is depletion of intracellular pools of reduced folates (tetrahydrofolates) essential for thymidylate and purine synthesis. Lack of either thymidine or purines prevents synthesis of DNA. The DHFR-mediated effects of antifolate drugs on normal and probably also on cancerous cells may be neutralized by supplying reduced folates exogenously. The reduced folate used clinically for “rescue” is leucovorin (folinic acid), which bypasses the metabolic block induced by DHFR inhibitors.⁵²

Methotrexate

The folic acid analog methotrexate (MTX) is the best understood of all drugs in the broad category of antimetabolites (see Table 124–11). It has been in clinical use for about 50 years. Like physiologic folates, methotrexate is transported intracellularly by an active transport system. In high doses, passive diffusion may overcome tumor cell resistance caused by saturated active transport systems. Resistance to the antifolates can also be caused by increased production of DHFR. Other potential causes of resistance are slow rates of thymidylate synthesis, decreased affinity of DHFR for methotrexate, and lack of polyglutamation within tumor cells. Polyglutamated forms of folates are better retained within cells. Malignant cells may achieve greater MTX polyglutamate levels than normal cells, which may in part explain the selective effects of MTX on malignant versus normal cells.⁵²

Accurate and readily available assays for serum MTX levels have made therapeutic drug monitoring of MTX a valuable clinical tool. The threshold for cytotoxic effects of MTX is approximately 5×10^{-8} M. Toxicity and efficacy are related not only to peak concentrations, but more importantly, to time that concentrations remain above this threshold level. For MTX doses requiring leucovorin rescue (generally doses greater than 100 mg/m²), leucovorin must be administered until levels fall below 5×10^{-8} M. Therapeutic drug monitoring is also an effective means of increasing the likelihood of therapeutic success, by individualizing doses based on target parameters.⁵²

Pemetrexed

Pemetrexed is a multitargeted antifolate that inhibits at least three biosynthetic pathways in thymidine and purine synthesis (see Table 124–11). In addition to inhibition of DHFR, it also inhibits thymidine synthase and glycinamide ribonucleotide formyltransferase, decreasing the risk of development of drug resistance. Supplementation of folic acid and vitamin B₁₂ is required to decrease myelosuppression.^{52,53}

MICROTUBULE-TARGETING DRUGS

VINCA ALKALOIDS

Vincristine, vinblastine, and vinorelbine are natural alkaloids derived from the periwinkle (vinca) plant. They act as mitotic inhibitors, or “spindle poisons.” Although the alkaloids are very similar structurally, they have different activities and patterns of toxicity (Table 124–12).

Vinca alkaloids bind to tubulin, the structural protein that polymerizes to form microtubules. These are the hollow tubes that make up the mitotic spindle and that are also important in nerve conduction and neurotransmission. Vinca alkaloids disrupt the normal balance between polymerization and depolymerization of microtubules, inhibiting assembly of microtubules and disrupting microtubule dynamics. This interferes with formation of the mitotic spindle and

TABLE 124–12. Antimicrotubule Agents

| Agent/Major Uses | Mechanism | Adverse Effects | Comments |
|---|--|--|---|
| <i>Taxanes</i> | | | |
| Docetaxel (Taxotere) ^a Breast cancer; NSCLC; prostate cancer; ovarian cancer; SCLC; bladder cancer; gastric cancer; head and neck cancers; melanoma; soft tissue sarcomas | Similar to paclitaxel, promotes microtubule assembly; inhibits depolymerization of tubulin; inhibits cell division | Myelosuppression; fluid retention syndrome: edema, weight gain, pleural effusions, ascites; typically occurs when cumulative dose exceeds 400 mg/m ² ; alopecia; rash: forearms, hands; nail disorders: onycholysis, banding, hypo- or hyperpigmentation; mild peripheral neuropathy; mildly emetogen; hypersensitivity reactions | Dexamethasone 8 mg orally twice daily for 3 days (starting 1 day prior to docetaxel) is recommended to lower risk of fluid retention syndrome; shorter dexamethasone regimens used for weekly docetaxel dosing Requires dose reduction for liver dysfunction (elevated total bilirubin, elevated transaminases and/or alkaline phosphatase) Prepare and administer using glass or non-PVC IV bags and tubing |
| Paclitaxel (Taxol) ^c Ovarian cancer; breast cancer; KS; NSCLC; SCLC; esophageal and head and neck cancers; testicular cancer; bladder cancer; cervical and endometrial cancers | Induces polymerization of microtubules, stabilizing the microtubules to make them nonfunctional; derived from the Pacific yew tree (<i>Taxus brevifolia</i>) | Myelosuppression may be dose-limiting; hypersensitivity reactions (preventable with appropriate premedications); peripheral neuropathy: paresthesias may be cumulative, dose-related; myalgias/arthralgias typically occur 3–5 days after administration and persist for 3–5 days; mucositis: more common with high doses; mildly emetogen; cardiac: asymptomatic bradycardia most common; ventricular arrhythmias, third-degree heart block, and MI rarely reported; alopecia: total body | Premedicate patients to prevent hypersensitivity reactions: dexamethasone 20 mg IV or orally 12 hours and 6 hours prior to paclitaxel, and diphenhydramine 50 mg IV 30 minutes prior to paclitaxel, and ranitidine 50 mg IV or cimetidine 300 mg IV 30 minutes prior to paclitaxel Reduce dose in patients with elevated total bilirubin (>1.5 mg/dL) and/or elevated transaminases (guidelines not well established) Neurotoxicity may be severe enough to require discontinuation; treat myalgias/arthralgias with NSAIDs, narcotic analgesics In paclitaxel-cisplatin combination regimens, give paclitaxel first to decrease neutropenia |
| <i>Nitrogen-mustard type alkylating agent</i> | | | |
| Estramustine (Emcyt) ^b Prostate cancer | Structurally is a combined estrogen and alkylating agent, but functions mainly as an antimicrotubule agent; interferes with microtubule associated proteins (MAPs) | Nausea and vomiting (may be dose-limiting); diarrhea; cardiovascular: lowers arterial circulation; ischemic heart disease patients with CHF may develop increased symptoms of heart failure; thromboembolic events; gynecomastia, nipple tenderness; increased liver function tests | Patients with pre-existing heart disease, cerebrovascular disease, and hypertension should be closely monitored during treatment; most cardiovascular complications occur within the first 2 months to 1 year of treatment; low-dose warfarin (1–2 mg/day) is commonly used to decrease risk of thromboembolic events, but its value is not proven Doses should be taken on an empty stomach (1 hour before or 2 hours after a meal); avoid concurrent administration with dairy products or calcium compounds; refrigerate |
| <i>Vinca alkaloids</i> | | | |
| Vinblastine (Velban) ^b Testicular cancer; NHL; HD; KS; bladder cancer; breast cancer; NSCLC; melanoma; prostate cancer; renal cell carcinoma | Antimicrotubule agent/vinca alkaloid; derived from the periwinkle plant; disrupts formation of microtubules | Myelosuppression may be dose-limiting; mucositis; mildly emetogen; neurotoxicity: less common than with vincristine; myalgias; SIADH (rarely); vesicant: extravasation injury | Treat extravasation injury with warm soaks, and injection of hyaluronidase Reduce dose by 50% for total bilirubin 1.5–3 mg/dL; by 75% for total bilirubin >3 mg/dL |

(continued)

TABLE 124–12. (Continued)

| Agent/Major Uses | Mechanism | Adverse Effects | Comments |
|---|--|--|--|
| Vincristine (VCR, Oncovin) ^b ALL; HD; NHL; multiple myeloma; breast cancer; SCLC; KS; brain tumors; soft tissue sarcomas; osteosarcomas; neuroblastoma; Wilms' tumor | Antimicrotubule agent/vinca alkaloid; derived from the periwinkle plant; disrupts formation of microtubules | Peripheral neuropathy; primary dose-limiting toxicity; motor, sensory, autonomic, and cranial nerves may all be affected (paresthesias, ileus, urinary retention, facial palsies); may be irreversible; mild emetogen; SIADH; vesicant: extravasation injury | <i>Prevent ileus</i> : treat constipation aggressively; doses range from 1–1.4 mg/m ² (max); doses are traditionally capped at 2 mg to minimize neurotoxicity, but capping is controversial Reduce dose by 50% for total bilirubin 1.5–3 mg/dL; by 75% for total bilirubin >3 mg/dL; treat extravasation injury with warm soaks, and injection of hyaluronidase LETHAL if administered intrathecally! |
| Vinorelbine (Navelbine) ^b NSCLC; breast cancer; HD; cervical cancer; ovarian cancer; prostate cancer | Antimicrotubule agent/synthetic vinca alkaloid; disrupts formation of microtubules | Myelosuppression (neutropenia); neurotoxicity: peripheral neuropathy (less common than with vincristine); constipation; low back pain; mild emetogen; vesicant: causes painful phlebitis with administration; alopecia is uncommon | Eliminated primarily by metabolism and biliary excretion: follow package insert for dose adjustments Drug interaction with phenytoin: decreases phenytoin levels; drug interaction with erythromycin (may inhibit vinorelbine metabolism): increased risk of vinorelbine toxicity |

^aFrom Rowinsky et al.⁵⁴ Hainsworth et al.⁵⁵ and Krieger et al.⁵⁶

^bFrom Kitamura et al.³⁶

^cFrom Rowinsky et al.⁵⁴ and Krieger et al.⁵⁶

All, acute lymphocytic leukemia; CHF, congestive heart failure; HD, Hodgkin's disease; KS, Kaposi's sarcoma; MI, myocardial infarction; NHL, non-Hodgkin's lymphoma; NSAID, nonsteroidal anti-inflammatory drug; NSCLC, non-small-cell lung cancer; PVC, polyvinyl chloride; SIADH, syndrome of inappropriate secretion of antidiuretic hormone; SCLC, small cell lung cancer.

causes cells to accumulate in mitosis. They also disturb a variety of microtubule-related processes in cells, and induce apoptosis. Resistance to the vinca alkaloids develops primarily from P-glycoprotein-mediated multidrug resistance, which decreases drug accumulation and retention within tumor cells.⁵⁴

TAXANES

Paclitaxel and docetaxel are taxane plant alkaloids with antimetabolic activity (see Table 124–12). Paclitaxel was isolated from the bark of the Pacific yew tree, *Taxus brevifolia*, but is now produced semisynthetically from the needles of the European yew, *Taxus baccata*. Docetaxel is a semisynthetic taxoid extracted from 10-deacetyl baccatin III, a nontoxic precursor found in the renewable needle biomass of yew plants.⁵⁴

Paclitaxel and docetaxel both act by binding to tubulin, but unlike the vincas do not interfere with tubulin assembly. Instead, the taxanes promote microtubule assembly and interfere with microtubule disassembly. They induce tubulin polymerization, resulting in formation of inappropriately stable, nonfunctional microtubules. The stability of the microtubules damages cells, because the dynamics of microtubule-dependent structures required for mitosis and other cellular functions are disrupted. Taxanes also have some nonmitotic actions that can promote cancer cell death, such as inhibition of angiogenesis. Resistance to the antitumor effects of the taxanes is attributable to alterations in tubulin or tubulin binding sites, or to P-glycoprotein-mediated multidrug resistance. Although paclitaxel and docetaxel have very similar mechanisms of action, cross-resistance between the two agents is incomplete.^{54–56}

ESTRAMUSTINE

Estramustine is an unusual drug in that it structurally combines the alkylating agent nor-nitrogen mustard with the hormone estradiol. It was designed with the intent that the estradiol portion of the molecule would facilitate uptake of the alkylating agent into hormone-sensitive prostate cancer cells. Despite the inclusion of an alkylator, estramustine does not function in vivo as an alkylating agent. Estrogens are released after its administration and are responsible for much of the toxicity of estramustine, but are not believed to contribute to its cytotoxic effect. In the mid-1980s, estramustine was redefined as an antimicrotubule agent. It binds covalently to microtubule-associated proteins that are part of the structural support for microtubules. The binding causes the separation of microtubule-associated proteins from the microtubules, inhibiting microtubule assembly and eventually causing their disassembly.⁵⁷

TOPOISOMERASE INHIBITORS

Topoisomerases are essential enzymes involved in maintaining DNA topologic structure during replication and transcription. DNA topoisomerase enzymes relieve torsional strain during DNA unwinding by producing strand breaks. They cleave DNA strands and form intermediates with the strands, producing a gap through which DNA strands can pass, then reseal the strand breaks. Topoisomerase I produces single-strand breaks; topoisomerase II produces double-strand breaks.⁵⁸ Several important anticancer agents target topoisomerase enzymes: anthracyclines, camptothecins, and the epipodophyllotoxins (Table 124–13).

TABLE 124–13. Topoisomerase-Active Agents

|---|--|---|--|
| <i>Topoisomerase I inhibitors</i> | | | |
| Irinotecan (CPT-11; Camptosar) ^a Colon cancer; NSCLC; SCLC; cervical and ovarian cancers; gastric cancer; pancreatic cancer | Topoisomerase I inhibitor; inhibits DNA binding activity of topoisomerase I, resulting in multiple DNA single-strand breaks; ultimately interferes with DNA synthesis | Diarrhea: acute (cramping, flushing, vomiting, diaphoresis within 1 hour of completion; related to cholinergic effects) and delayed (>12 hours after administration; usually after the second or third dose); may be severe; moderately high emetogenic potential; myelosuppression: neutropenia; alopecia; fatigue; increased liver function tests; pulmonary toxicity: diffuse infiltrates, fever, dyspnea | Acute diarrhea is best treated or prevented with atropine; delayed diarrhea managed with antimotility agents (loperamide 4 mg at first sign of diarrhea then 2 mg every 2 hours until no diarrhea for 12 hours); octreotide is not usually effective; ensure that patients have a supply of antimotility agents to take with the first symptoms of diarrhea; ensure fluid and electrolyte replacement in patients with severe diarrhea Dose should be reduced in patients with elevated total bilirubin, no specific guidelines available Drug administration sequence affects pharmacokinetics and tolerability of irinotecan in 5-FU + irinotecan regimens Dose adjustments may be necessary for Cl _{Cr} <60 mL/min |
| Topotecan (Hycamtin) ^b Ovarian cancer; SCLC; MDS | Topoisomerase I inhibitor; inhibits DNA binding activity of topoisomerase I, resulting in multiple DNA single-strand breaks; ultimately interferes with DNA synthesis | Myelosuppression (neutropenia); mucositis (dose-related; worse with continuous infusion); very low to low emetogenic potential; diarrhea (mild); reversible elevations in transaminases | |
| <i>Topoisomerase II inhibitors</i> | | | |
| Daunorubicin (Daunomycin, Dauno, Cerubidine) ^c Liposomal daunorubicin (DaunoXome) ANLL; ALL; KS (liposomal) | Antitumor antibiotic; topoisomerase II inhibitor; DNA intercalator; free-radical formation (thought to be related to cardiac toxicity and tissue injury) | Myelosuppression (dose-related); mucositis (worse with continuous infusion); moderate emetogenic potential; alopecia; vesicant: severe extravasation injury; cardiac toxicities: <i>acute</i> —not related to cumulative dose; arrhythmias, pericarditis; <i>chronic</i> —cumulative injury to myocardium (total dose >550 mg/m ² ; lower total cumulative doses cause damage to myocardium in children (e.g., 350 mg/m ²) | Apply ice to areas of extravasation to lessen extent of injury Dose reduction required for total bilirubin >1.5 mg/dL (50% of full dose) and >3 mg/dL (25% of full dose) May discolor urine (red-orange) Liposomal form: decreased risk of cardiac and vesicant toxicity |
| Doxorubicin (Adriamycin, Adria, Doxo, hydroxydaunorubicin) ^c Liposomal doxorubicin (Doxil) Breast cancer; osteosarcoma and soft tissue sarcomas; NHL; HD; ALL; ANLL; bladder cancer; ovarian cancer; thyroid cancer; Wilms' tumor; neuroblastoma; SCLC; KS (liposomal); gastric cancer; multiple myeloma; NSCLC; endometrial cancer | Antitumor antibiotic; topoisomerase II inhibitor; DNA intercalator; free-radical formation (thought to be related to cardiac toxicity and tissue injury) | Myelosuppression; mucositis: worse with continuous infusion; moderate emetogenic potential: may cause acute and delayed (by 24–48 hours) emesis; vesicant: severe extravasation injury; cardiac toxicities: <i>acute</i> —not related to cumulative dose; arrhythmias, pericarditis; <i>chronic</i> —cumulative injury to myocardium (total dose >550 mg/m ²); lower total cumulative doses cause damage to myocardium in children (e.g. 350 mg/m ²); radiation recall reactions | Apply ice to areas of extravasation to lessen extent of injury; dose reduction required for total bilirubin >1.5 mg/dL (50% of full dose) and >3 mg/dL (25% of full dose) May discolor urine (red-orange) Dexrazoxane (Zinecard), a cardioprotectant, decreases risk of cardiotoxicity; approved for use in breast cancer patients with >300 mg/m ² doxorubicin; concerns over possible tumor protection limit its use Liposomal form: decreased risk of cardiac and vesicant toxicities |

(continued)

TABLE 124–13. (Continued)

| Agent/Major Uses | Mechanism | Adverse Effects | Comments |
|---|---|--|---|
| Epirubicin (Ellence) ^e Breast cancer; gastric cancer | Antitumor antibiotic (see daunorubicin and doxorubicin) | Myelosuppression; mucositis: worse with continuous infusion; moderately emetogenic: may cause acute and delayed (by 24–48 hours) emesis; vesicant: severe extravasation injury; cardiotoxicity (similar to other anthracyclines); may be less cardiotoxic than doxorubicin; controversy about equivalent doses; cardiac toxicity associated with cumulative doses >900 mg/m ² | Apply ice to areas of extravasation to lessen extent of injury; dose reduction required for total bilirubin >1.5 mg/dL (50% of full dose) and >3 mg/dL (25% of full dose) May discolor urine (red-orange) |
| Etoposide (VP-16; Vepesid), Etoposide phosphate (Etopophos) ^d Testicular cancer; SCLC; NSCLC; ANLL; KS; HD; NHL; BMT preparative chemotherapy; gastric cancer | Plant alkaloid, epipodophyllotoxin; inhibits DNA binding activity of topoisomerase II, resulting in multiple DNA double-strand breaks | Myelosuppression; moderately emetogenic: may be worse with oral and high-dose regimens; alopecia; mucositis; hypotension: infusion rate–related; etoposide phosphate can be given IV push without hypotension risk; hypersensitivity reactions: especially common in children | Requires large volumes of fluid for IV administration due to limited solubility (max concentration 0.4 mg/mL); if hypotension occurs, stop infusion until BP stable, then resume at decreased rate Available orally in liquid-filled gelatin capsules; approximately 50% bioavailability, but absorption is variable and greater at lower oral doses |
| Idarubicin (Idamycin) ^e ANLL; oral preparation investigational | Antitumor antibiotic (similar to daunorubicin and doxorubicin, but more potent); topoisomerase II inhibition; DNA intercalation; free-radical formation | Myelosuppression; mucositis; moderately emetogenic; vesicant: extravasation; alopecia; cardiac toxicities: <i>acute</i> and <i>chronic</i> , as with daunorubicin and doxorubicin (total cumulative dose not well established; >150 mg/m ² reported to be associated with decreased LVEF | Apply ice to areas of extravasation to lessen extent of injury Dose reduction required for total bilirubin >1.5 mg/dL (50% of full dose) and >3 mg/dL (25% of full dose) May discolor urine red-orange Produces cumulative cardiotoxicity with other anthracyclines |
| Mitoxantrone (Novantrone) ^f ANLL; prostate cancer; NHL; HD; breast cancer Multiple sclerosis | Anthracenedione (not an anthracycline); topoisomerase II inhibitor; DNA intercalator; low potential compared with anthracyclines for formation of free radicals | Myelosuppression; low emetogenic potential; mucositis; alopecia; less cardiotoxic than the anthracyclines | Not a vesicant (may cause vein irritation, but not associated with severe tissue injury like anthracyclines) May discolor urine blue-green |

ALL, acute lymphocytic leukemia; ANLL, acute nonlymphocytic leukemia; BMT, bone marrow transplantation; BP, blood pressure; Cl_{cr}, creatinine clearance; HD, Hodgkin's disease; KS, Kaposi's sarcoma; LVEF, left ventricular ejection fraction; MDS, myelodysplastic syndrome; NHL, non-Hodgkin's lymphoma; NSCLC, non-small-cell lung cancer; SCLC, small cell lung cancer.

ETOPOSIDE AND TENIPOSIDE

Etoposide and teniposide are semisynthetic podophyllotoxin derivatives (see Table 124–13). Podophyllin is extracted from the mayapple or mandrake plant. Like the vinca alkaloids, podophyllin itself binds to tubulin and interferes with microtubule formation. Unlike the parent compound, however, etoposide and teniposide damage tumor cells by causing strand breakage through inhibiting topoisomerase II.^{58,59} Resistance may be caused by differences in topoisomerase II levels, by increased cell ability to repair strand breaks, or by increased levels of P-glycoproteins. Etoposide and teniposide are usually clinically cross-resistant. They are cell-cycle phase–specific and arrest cells in

the S or early G₂ phase. As a result, activity is much greater when they are administered in divided doses over several days, rather than in large single doses.^{58,59}

CAMPTOTHECIN DERIVATIVES

Camptothecin, a plant alkaloid derived from *Camptotheca acuminata*, is a potent inhibitor of DNA topoisomerase I. Clinical trials failed to show expected antitumor activity, and the drug produced severe, unpredictable toxicity. The camptothecin analogs irinotecan and topotecan were synthesized to reduce toxicity and improve therapeutic

effects. Both irinotecan and topotecan, through its active metabolite SN-38, poison the actions of the topoisomerase I enzymes. Topoisomerase I enzymes stabilize DNA single-strand breaks and inhibit strand resealing (see Table 124–13).^{58,60–64}

ANTHRACENE DERIVATIVES

The most widely used and best understood anthracene derivative is doxorubicin, also commonly known by its earliest trade name, Adriamycin or “Adria.” Other members of the anthracene group include daunorubicin (daunomycin), idarubicin, epirubicin, and mitoxantrone (see Table 124–13). All of these agents except mitoxantrone are anthracyclines and share a common, four-membered anthracene ring complex with an attached aglycone or sugar portion. The ring complex is a chromophore and accounts for the intense colors of these compounds. Doxorubicin differs from its parent compound daunorubicin by the addition of a hydroxyl group on the attached sugar, and it is sometimes referred to as hydroxydaunorubicin. A hydroxyl group on epirubicin is in the *epi* conformation compared with doxorubicin (epidoxorubicin), and idarubicin is demethoxydaunorubicin. Mitoxantrone is an anthracenedione rather than an anthracycline, and has no sugar group attached to the three-membered anthracene ring complex.^{58,65}

Doxorubicin, Daunorubicin, Idarubicin, and Epirubicin

Anthracyclines have been classified as antitumor antibiotics, but it is more accurate to refer to them as intercalating topoisomerase inhibitors (see Table 124–13). Intercalating agents are compounds that insert or stack between base pairs of DNA. Although it is well established that the planar groups of the anthracene ring complex do intercalate with DNA, causing structural changes that interfere with DNA and RNA synthesis, this is not their primary mechanism of cytotoxicity. The anthracyclines are primarily topoisomerase II poisons, producing double-strand DNA breaks.^{58,65}

The anthracyclines also undergo electron reductions to reactive compounds that can damage DNA and cell membranes. Free radicals formed from reduction of the anthracyclines first donate electrons to oxygen to make superoxide, which can react with itself to make hydrogen peroxide. Cleavage of hydrogen peroxide produces the highly reactive and destructive hydroxyl radical. This last step requires iron, and the anthracyclines are potent iron binders. Iron-anthracycline complexes can bind to DNA and react rapidly with hydrogen peroxide to produce the hydroxyl radicals that actually cleave DNA. Human cells have natural defenses against oxygen radical damage, in the form of enzymes that can convert the radicals to less reactive compounds, or that can repair DNA damage. Differences in distribution of these defensive enzymes may account for characteristic sites of toxicities of the anthracyclines. For example, cardiac muscle has low levels of defensive enzymes and high levels of enzymes that activate anthracyclines. Oxygen free-radical formation is firmly established as a cause of cardiac damage and extravasation injury, but is not a major mechanism of tumor-cell killing. Resistance to the anthracyclines is usually secondary to P-glycoprotein–dependent multidrug resistance, causing the anthracyclines to be actively pumped out of tumor cells. Altered topoisomerase II activity may also be clinically important.^{58,65}

Mitoxantrone

The anthracenedione mitoxantrone was synthesized in an attempt to develop agents with comparable antitumor activity to doxorubicin, but with an improved safety profile (see Table 124–13). Like the anthracyclines, mitoxantrone is an intercalating topoisomerase II inhibitor,

but its potential for free-radical formation is much less than that of the anthracyclines. Perhaps because of the decreased tendency for free-radical formation, the risks of cardiac toxicity and ulceration after extravasation, although still present, are markedly reduced.^{57,65}

ALKYLATING AGENTS

The alkylating agents are among the oldest and most useful of antineoplastic drugs. Their clinical use evolved from the observation of bone marrow suppression and lymph node shrinkage in soldiers exposed to sulfur mustard gas warfare during World War I. In an effort to develop similar agents that might be useful in treating cancerous overgrowths of lymphoid tissues, less reactive derivatives were synthesized. Their effectiveness as anticancer agents was confirmed by clinical trials in the middle 1940s.⁶⁶

All of the alkylating agents work through the covalent bonding of highly reactive alkyl groups or substituted alkyl groups with nucleophilic groups of proteins and nucleic acids. Some alkylating agents react directly with biologic molecules; others form an intermediate compound that reacts with the targets. The most common binding site for alkylating agents is the seven-nitrogen group of guanine. These covalent interactions result in cross-linking between two DNA strands or between two bases in the same strand of DNA. Reactions between DNA and RNA and between drug and proteins may also occur, but the main insult that results in cell death is inhibition of DNA replication, because the interlinked strands do not separate as required. Because the alkylating agents can damage DNA during any phase of the cell cycle, they are not cell-cycle–phase specific. However, their greatest effect is seen in rapidly dividing cells.

As a class, alkylators are cytotoxic, mutagenic, teratogenic, carcinogenic, and myelosuppressive. Resistance to these agents can occur from increased DNA repair capabilities, from decreased entry into or accelerated exit from cells, from increased inactivation of the agents inside cells, or from lack of cellular mechanisms to result in cell death following DNA damage. They react with water and are inactivated by hydrolysis, making spontaneous degradation an important component of their elimination.⁶⁷

CYCLOPHOSPHAMIDE AND IFOSFAMIDE

Cyclophosphamide and ifosfamide are nitrogen mustard derivatives, and are widely used alkylating agents (Table 124–14). They are closely related in structure, clinical use, and toxicity. Neither agent is active in its parent form and must be activated by mixed hepatic oxidase enzymes. The active metabolite of cyclophosphamide is phosphoramidate mustard. Another metabolite, 4-hydroxycyclophosphamide is cytotoxic, but is not an alkylating agent. Ifosfamide is hepatically activated to ifosfamide mustard. Acrolein, a metabolite of both cyclophosphamide and ifosfamide, has little antitumor activity, but is responsible for some of their toxicity.^{67,68}

NITROSOUREAS

The nitrosoureas are alkylating agents characterized by lipophilicity and ability to cross the blood-brain barrier. Carmustine or bischloroethylnitrosourea (BCNU) and lomustine (CCNU) are commercially available. BCNU is available as an intravenous preparation and as a drug-impregnated biodegradable wafer (Gliadel) for direct application to residual tumor tissue following surgical resection of brain tumors. The nitrosoureas decompose to reactive alkylating metabolites and to isocyanate compounds that have several effects on reproducing cells (see Table 124–14).⁶⁷

TABLE 124–14. Alkylating Agents

| Agent/Major Uses | Class/Mechanism | Major Side Effects | Comments |
|---|---|---|--|
| Busulfan (Myleran tablets, Busulfex injection) ^a CML; BMT preparative regimens | DNA-DNA and DNA-protein cross-links; inhibition of DNA replication; selective cytotoxicity for myeloid cells; crosses blood-brain barrier | Myelosuppression; skin hyperpigmentation; pulmonary fibrosis; low emetogenic potential (in standard doses); endocrine: gynecomastia, adrenal insufficiency; <i>high- and BMT-dose toxicities</i> : seizures (generalized tonic-clonic); hepatic veno-occlusive disease; highly emetogenic in BMT doses | Bone marrow recovery may be delayed (3–6 weeks); pulmonary fibrosis associated with >3 years exposure, prior chest radiation; seizure prophylaxis (phenytoin 300 mg/day with BMT doses) Pharmacokinetic monitoring is required with IV busulfan, preferably in an experienced BMT setting <i>IV and oral preparations are not interchangeable</i> ; put tablets in gelatin capsules for easier administration with high-dose administration |
| Carboplatin (Paraplatin) ^b Ovarian cancer; NSCLC; SCLC; head and neck cancer; testicular cancer; bladder cancer; breast cancer | Platinum agent; forms inter- and intrastrand DNA cross-links; inhibition of DNA synthesis | Myelosuppression: thrombocytopenia, neutropenia, anemia; moderately emetogenic; risk of hypersensitivity reactions, frequently delayed, after 5+ doses; may necessitate discontinuation of carboplatin; frequently results in cross-hypersensitivity to cisplatin | Reduce dose for $Cl_{Cr} < 60$ mL/min; platelet recovery may be delayed (4–5 weeks) Calvert formula for dose modifications: Dose (mg) = target AUC × ($Cl_{Cr} + 25$); Cl_{Cr} calculated using Cockcroft-Gault equation; note that the calculated dose is <i>total</i> dose, <i>not</i> dose per m ² body surface area |
| Carmustine (BCNU, bischloro-nitrosourea; BiCNU) ^a Brain tumors; myeloma; NHL; HD; BMT preparative regimens; melanoma; also available in wafer form for implantation into brain tumor cavities after resection (Gliadel) | Nitrosourea; cross-links DNA strands; inhibits DNA replication; highly lipophilic; penetrates CNS | Myelosuppression (may be delayed, nadir at 3–4 weeks); highly emetogenic; cumulative nephrotoxicity; pulmonary fibrosis; facial flushing during infusion | Bone marrow recovery may require 6–8 weeks postadministration; not a vesicant; vein irritation and facial flushing may be related to alcohol vehicle Prepare in glass bottles or non-PVC bags and non-PVC (such as nitroglycerin-designated) tubing to avoid adsorption of drug to PVC plastics |
| Chlorambucil (Leukeran) ^a CLL; NHL; HD Available only as 2-mg tablets | Nitrogen mustard derivative; forms interstrand DNA cross-links; selective cytotoxicity for lymphocytes | Myelosuppression (dose-limiting); increased liver function tests; skin rash; low emetogenic potential; menstrual irregularities; pulmonary toxicity: interstitial pneumonitis/fibrosis; carcinogenic: risk of secondary malignancies; causes infertility and sterility; teratogenic | Should be taken on an empty stomach; food decreases absorption May be dosed in low daily-dosing regimens or in higher dose, “pulse” or intermittent dosing schedules administered biweekly or monthly; <i>note: pulse dosing may require patients to take several tablets (e.g., 10–20 tablets) per dose</i> |
| Cisplatin (CDDP; cis-diaminodichloro-platinum; Platinol) ^c Ovarian cancer; bladder cancer; testicular cancer; cervical cancer; NSCLC; SCLC; esophageal and head and neck cancers; NHL; sarcomas; melanoma; endometrial cancer; gastric cancer Radiosensitizer | Platinum agent; forms inter- and intrastrand DNA cross-links; inhibition of DNA synthesis; aquated species is cytotoxic | Nephrotoxic! Direct toxicity to renal tubules; severe and prolonged potassium and magnesium wasting; highly emetogenic (acute and/or delayed onset); neurotoxicity: peripheral neuropathy that is cumulative and dose-related in stocking-glove pattern; may be reversible; ototoxicity: may cause permanent hearing loss; may require dose reduction or drug discontinuation; anemia with chronic dosing; may respond to epoetin; generally not myelosuppressive; doses should not exceed 100 mg/m ² (maximum single dose <i>and</i> per-cycle dose); inactivated by contact with aluminum needles | Hydration required! 1–2 liters of 0.9% sodium chloride minimum pre- and post cisplatin administration; ensure good urine output (>100 mL/hour); potassium chloride and magnesium sulfate in IV fluid to replace losses; with or without mannitol 12.5–50 g to increase urine flow; dose reductions with $Cl_{Cr} < 60$ mL/min; carboplatin may be an alternative agent for patients with impaired renal function; aggressive antiemetics required pretreatment and for 3–5 days after to prevent delayed nausea/vomiting Amifostine chemoprotective agent; may reduce cisplatin renal toxicity; little impact on neurotoxicity or myelosuppression; adds to nausea and causes hypotension; limited evidence of efficacy of vitamin E for prevention of neurotoxicity |

TABLE 124–14. (Continued)

| Agent/Major Uses | Class/Mechanism | Major Side Effects | Comments |
|--|---|--|--|
| Cyclophosphamide (Cytosan) ^d Breast cancer; NHL; ALL; ANLL; CLL; ovarian cancer; myeloma; retinoblastoma; neuroblastoma; HD; NSCLC; SCLC; endometrial cancer; soft-tissue sarcomas; BMT-preparative (high-dose); bladder cancer SLE; autoimmune disorders | Alkylating agent; nitrogen mustard derivative; cross-links DNA-DNA or DNA-protein; inhibits DNA synthesis; activated by hepatic microsomal (CYP450) mixed function oxidases; acrolein metabolite (no antitumor activity) associated with hemorrhagic cystitis | Hemorrhagic cystitis Moderately emetogenic: worse with high doses; nausea may be delayed 12–24 hours; myelosuppression; alopecia; SIADH, typically with high doses (>2 g/m ²); secondary malignancies (bladder cancers, acute leukemia); infertility, sterility | Hydration needed to prevent hemorrhagic cystitis (oral/IV ~3 L/ day × 72h); mesna may be required with high-dose regimens (see ifosfamide) Instruct patients to take oral tablets in the morning to allow for elimination of toxic metabolite; absorbed through skin: <i>avoid spills</i> Drug interactions: CYP450 inducers (e.g., barbiturates) may increase formation of toxic metabolites; CYP450 inhibitors (e.g., cimetidine) may increase myelosuppression |
| Dacarbazine (DTIC; <i>dimethyltriazeno-imidazole- carboxamide</i>) ^a Melanoma; HD; soft-tissue sarcomas; brain tumors | Exact mechanism unclear; alkylation most likely mechanism, but does not cause DNA cross-linking; also appears to inhibit DNA, RNA, and protein synthesis; activated by hepatic microsomal mixed function oxidases (CYP450 enzymes) | Myelosuppression; highly emetogenic; flu-like syndrome: fever, myalgia, malaise (may last for several days after dacarbazine administration); facial flushing; photosensitivity: use caution with sun exposure | Not a vesicant, but may cause burning pain at injection site Light-sensitive: dispense in lightproof bags; pink color indicates decomposition |
| Ifosfamide (Ifex) ^d Testicular cancer; soft-tissue sarcomas; NHL; NSCLC; cervical cancer; head and neck cancers | Alkylating agent; cross-links DNA strands; activated in the liver by microsomal (CYP450) mixed function oxidases | Hemorrhagic cystitis: <i>always</i> given with mesna and hydration; nephrotoxicity: renal tubular acidosis; potassium, magnesium, and phosphate wasting, especially in high-dose regimens; myelosuppression; CNS effects: somnia, confusion, disorientation, cerebellar symptoms that are dose-related; moderately emetogenic; alopecia | 3–4 L/day fluid for hydration; potassium, magnesium, and phosphate may be required to replace losses Mesna dose is typically 60–100% of ifosfamide dose (1:1 for continuous infusion ifosfamide); ifosfamide and mesna are physically compatible and may be delivered in same IV bag CNS toxicity and nausea and vomiting may be more severe with rapid infusion; case reports suggest methylene blue may be effective treatment for CNS toxicity |
| Mechlorethamine (nitrogen mustard; H ₂ N; Mustargen) ^a HD; NHL; Mycosis fungoides (topical) | Bifunctional alkylating agent (two reactive groups); forms inter- and intrastrand DNA cross-links; inhibits DNA, RNA, and protein synthesis | Myelosuppression; highly emetogenic: rapid onset, within 1–2 hours of dose; vesicant: extravasation injury; secondary malignancies; sterility and infertility | Antidote for extravasation: sodium thiosulfate; very short stability in aqueous solutions, about 1 hour Used as topical solution or in compounded ointments for mycosis fungoides |
| Oxaliplatin (Eloxatin) ^d Colorectal cancer; ovarian cancer; gastric cancer | Platinum agent (see cisplatin, carboplatin) | Peripheral neuropathy >50% patients: <i>acute form</i> : <14 days, rapid onset, reversible, exacerbated by cold, affects hands, feet, perioral area, and throat; <i>persistent form</i> : onset >14 days, mainly hands and feet; may affect proprioception; may be permanent; pharyngolaryngeal dysesthesias in 1–2%; nausea, vomiting: moderately emetogenic; abdominal pain, diarrhea; anaphylaxis risk | Renally eliminated; reduce dose in patients with impaired renal function Glutathione, magnesium, and calcium supplementation being evaluated for prevention of neuropathies Avoid exposure to cold |
| Procarbazine (Matulane) ^a HD; brain tumors; NSCLC Only available orally | Exact mechanism unclear; alkylation most likely mechanism of action; also appears to inhibit DNA, RNA, and protein synthesis; activated by hepatic microsomal mixed function oxidases (CYP450 enzymes); good CNS penetration | Myelosuppression: thrombocytopenia, neutropenia (may be prolonged 4–6 weeks); low emetogenic potential may be more severe initially; diarrhea; neurotoxicity: paresthesias, neuropathy; flu-like syndrome; infertility and sterility; secondary malignancies | Administered as a single, daily dose on an empty stomach Monoamine oxidase inhibitors: drug-food interactions with tyramine-rich foods such as red wines, dark beers, aged cheeses, yogurt; may precipitate hypertensive crisis; drug interactions: tricyclic antidepres- sants and SSRIs, sympathomimetics; disulfiram-like reaction with alcohol |

(continued)

TABLE 124–14. (Continued)

| Agent/Major Uses | Class/Mechanism | Major Side Effects | Comments |
|---|---|--|--|
| Temozolomide (Temodar) ^f Brain tumors; brain metastases; melanoma | Similar to dacarbazine; same reactive metabolite as dacarbazine (MTIC); does not require liver for activation; well absorbed orally; achieves therapeutic levels in CNS | Headache and fatigue; moderately emetogenic; myelosuppression: neutropenia, thrombocytopenia; myalgias, back pain; diplopia; lymphopenia, especially in chronic dosing | Crosses blood-brain barrier in therapeutic concentrations Administer on an empty stomach; capsules should not be opened or chewed Drug interaction: valproic acid may decrease clearance of temozolomide slightly PCP prophylaxis should be considered for patients who develop lymphopenia |
| Thiotepa (thiethylene thiophosphoramidate; ThioTEPA) ^a Breast cancer; bladder cancer (instillation); BMT preparation | Trifunctional alkylating agent; active metabolite TEPA; crosses blood-brain barrier | Myelosuppression (dose-limiting); nausea and vomiting; severe at high doses for BMT preparation; mucositis; pruritus and dermatitis | Very old drug, now most commonly used as preparative regimen for stem cell transplants |

ALL, acute lymphocytic leukemia; ANLL, acute nonlymphocytic leukemia; AUC, area under the curve; BMT, bone marrow transplantation; Cl_{cr}, creatinine clearance; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; CNS, central nervous system; CYP450, cytochrome P450 isoenzyme; HD, Hodgkin's disease; NHL, non-Hodgkin's lymphoma; NSCLC, non-small-cell lung cancer; PCP, *Pneumocystis carinii* pneumonia; PVC, polyvinyl chloride; SCLC, small cell lung cancer; SIADH, syndrome of inappropriate secretion of antidiuretic hormone; SLE, systemic lupus erythematosus; SSRI, selective serotonin reuptake inhibitor; TEPA, thiethylene phosphoramidate.

NONCLASSIC ALKYLATING AGENTS

Several other cytotoxic agents appear to act as alkylators, although their structures do not include the classic alkylating groups. They are capable of binding covalently to cellular components and include procarbazine, dacarbazine, temozolamide, the heavy metal compounds, and some antitumor antibiotics (see Table 124–14).⁶⁷

Dacarbazine and Temozolomide

Dacarbazine, or dimethyl triazeno-imidazole-carboxamide (DTIC), and temozolomide (dihydro methyl oxoimidazo tetrazino carboxamide) are nonclassic alkylating agents (see Table 124–14). Both compounds undergo demethylation to the same active intermediate (monomethyl triazeno imidazole carboxamide [MTIC]) that interrupts DNA replication by causing methylation of guanine. Unlike dacarbazine, temozolomide does not require the liver for activation, and is chemically degraded to MTIC at physiologic pH. Both drugs inhibit DNA, RNA, and protein synthesis.^{67,69,70}

Important pharmacokinetic differences exist between the two drugs. Dacarbazine is poorly absorbed, and must be administered by intravenous infusion. Temozolomide is rapidly absorbed after oral administration, and is approximately 100% bioavailable when given on a completely empty stomach. Dacarbazine penetrates the CNS poorly, but temozolomide readily crosses the blood-brain barrier, achieving therapeutically active concentrations in cerebrospinal fluid and brain tumor tissues.^{67,69,70}

HEAVY METAL COMPOUNDS

CISPLATIN, CARBOPLATIN, AND OXALIPLATIN

The platinum derivatives, cisplatin, carboplatin, and oxaliplatin are anticancer agents with remarkable usefulness in cancer treatment (see Table 124–14). Recognition of cisplatin's cytotoxic activity was

the result of a serendipitous observation that bacterial growth in culture was altered when an electric current was delivered to the media through platinum electrodes. The growth change was noted to be similar to that produced by alkylating agents and radiation. It was found that a platinum-chloride complex, now known as cisplatin, generated by the current was responsible for the changes. Carboplatin is a structural analog of cisplatin in which the chloride groups of the parent compound are replaced by a carboxycyclobutane moiety. It shares a similar spectrum of clinical activity with cisplatin, and cross-resistance is common. Oxaliplatin is an organoplatinum compound in which the platinum is complexed with an oxalate ligand as the leaving group and to diaminocyclohexane. Its spectrum of activity differs substantially from the other platinum compounds, and includes notable activity against colorectal cancers.^{67,71}

The cytotoxicity of the platinum derivatives depends on platinum binding to DNA and the formation of intrastrand cross-links or adducts between neighboring guanines. These intrastrand links cause a major bending of the DNA. They may cause cellular damage by distorting the normal DNA conformation and preventing bases that are normally paired from lining up with each other. Interstrand cross-links also occur.^{67,71}

The cytotoxic form of cisplatin is the aquated species, in which hydroxyl groups or water molecules replace the two chloride groups. This reaction occurs readily in low concentrations of chloride, such as the concentrations present within cells, and produces a positively charged compound that can react with DNA. The aquated species is responsible for both the efficacy and toxicity of cisplatin. Carboplatin also undergoes aquation, but at a slower rate. Oxaliplatin becomes active when the oxalate ligand is displaced in physiologic solutions.^{67,71}

Resistance to the therapeutic effects of platinum compounds may occur through several mechanisms. The ability to repair platinum-induced DNA damage may be increased, or the agents may be inactivated by increased levels of intracellular glutathione,

metallothioneins, or other thiol-containing proteins. Altered uptake into cells may also affect sensitivity to platinum compounds.^{67,71,72}

Cisplatin is a highly toxic antineoplastic agent, with potential for producing serious nephrotoxicity, ototoxicity, peripheral neuropathy, emesis, and anemia. The significant efficacy of cisplatin against many tumor types makes it a valuable agent despite these toxicities, most of which can be prevented or managed with aggressive supportive care measures.^{67,72,73} In contrast, carboplatin administration is limited by hematologic toxicity. Patients with compromised renal function require dose reductions to limit myelosuppressive toxicity. The most widely used dosage schema, the Calvert formula (see Table 124–14), uses a target area under the curve and renal function parameters to estimate the carboplatin dose.^{67,71} Carboplatin's potential to cause renal damage, peripheral neuropathy, ototoxicity, and nausea and vomiting is much less than that of comparable cisplatin doses.⁶⁷ Oxaliplatin is not nephrotoxic, ototoxic, or highly emetogenic, but produces peripheral neuropathies and unique cold-induced neuropathies.⁷⁴ All of the platinum derivatives have significant potential to cause hypersensitivity reactions, including anaphylaxis.

MISCELLANEOUS AGENTS

BLEOMYCIN

Bleomycin or “bleo” is an antitumor antibiotic (Table 124–15). It is a mixture of peptides from fungal *Streptomyces* species, and as such its strength is expressed in units of drug activity. One unit is roughly equal to 1 mg of polypeptide protein. The predominant peptide is bleomycin A2, which makes up approximately 70% of the commercial product. Bleomycin's cytotoxicity is secondary to DNA strand breakage, or scission, which it produces via free-radical formation. Cytotoxicity depends on binding of an iron-bleomycin complex to DNA. The bleomycin-iron complex then reduces molecular oxygen to free oxygen radicals that cause primarily single-strand breaks in DNA. Bleomycin has greatest effect on cells in the G₂ phase of the cell cycle and in mitosis.⁷⁵

Bleomycin is inactivated within cells by the enzyme aminohydrolase. This enzyme is widely distributed, but is present in only low concentrations in the skin and the lungs, explaining the predominant toxicities of bleomycin to those sites. The presence of hydrolase enzymes in tumor cells is the primary mechanism of resistance to bleomycin. Cells can also become resistant by repairing the DNA breaks produced by bleomycin.⁷⁵

HYDROXYUREA

Hydroxyurea is a unique drug that inhibits ribonucleotide reductase, the enzyme required to convert ribonucleotides into the deoxyribonucleotide forms required for both DNA synthesis and repair (see Table 124–15). Cells accumulate in the S phase because DNA synthesis is inhibited, and only abnormally short DNA strands are produced.³⁶

L-ASPARAGINASE

L-Asparaginase is unique among cytotoxic drugs in its unusual mechanism of action, patterns of toxicity, and source (see Table 124–15). It is an enzyme produced by *Escherichia coli* and other bacteria.

L-Asparagine is a nonessential amino acid that can be synthesized by most mammalian cells, except for those of certain lymphoid human malignancies, which lack or have very low levels of the synthetase enzyme required for L-asparagine formation. L-Asparagine is degraded by the enzyme L-asparaginase, which depletes existing

supplies and inhibits protein synthesis. Increased L-asparagine synthetase activity within tumor cells causes resistance to L-asparaginase treatment.⁷⁶

ARSENIC TRIOXIDE

Arsenic is an organic element and a well-known poison that is an effective treatment for acute promyelocytic leukemia (see Table 124–15).⁷⁷ As an antineoplastic, arsenic trioxide acts as a differentiating agent, inducing the growth progression of cancerous cells into mature, more normal cells. It also induces programmed cell death or apoptosis.

MITOMYCIN C

Mitomycin C is a natural product sometimes classified as an antitumor antibiotic (see Table 124–15).^{67,78} It has functional similarities to nitrogen mustard compounds and may function as an alkylating agent, although its toxicity pattern differs from conventional alkylators.

IMMUNE THERAPIES

8 An intact immune system is believed to play an important role in the control of cancer growth, as evidenced by the high incidence of cancers in immunosuppressed patients such as solid organ transplant recipients or those with human immunodeficiency virus infections. There are also rare but well documented spontaneous remissions of immunologically-linked cancers, particularly melanoma and renal cell carcinoma. Immune therapies attempt to harness the immune system to treat cancer (Table 124–16).^{79–81}

INTERFERONS

The interferons (IFNs) are a family of proteins produced by nucleated cells and by recombinant DNA technology, with antiviral, antiproliferative, and immunoregulatory activities. They are classified as α , β , or γ interferons based on antigenic, biologic, and pharmacologic properties. Many subtypes of IFN α are known. IFN α -2a and IFN α -2b, approved for anticancer indications, are very similar single-species recombinant products.

The mechanisms of IFN α 's antitumor action are complex. IFN increases the activity of cytotoxic cells within the immune system, but direct antiproliferative effects also play a role. IFNs prolong the cell cycle, which results in cytostasis, an increase in cell size, and apoptosis. They can inhibit new blood vessel formation in tumors and can increase the expression of antigens on tumor cell surfaces, making the cancerous cells more easily recognized by the cells of the immune system. They also inhibit or block certain oncogenes that can direct the unregulated cell growth that is characteristic of cancerous cells. Alterations in gene expression may change the levels of receptors for other cytokines, or the concentration of regulatory proteins on immune cells, or may activate enzymes that alter cellular growth and function.^{79,80}

INTERLEUKIN-2 (ALDESLEUKIN)

Interleukin-2 (aldesleukin; IL-2) is a lymphokine produced by recombinant DNA technology that promotes B- and T-cell proliferation and differentiation and initiates a cytokine cascade with multiple interacting immunologic effects. The IL-2 receptor is expressed in increased amounts on activated T cells and mediates most of the effects of IL-2. Antitumor effects depend on proliferation of

TABLE 124–15. Miscellaneous Agents

| Agent/Major Uses | Class/Mechanism | Major Side Effects | Comments |
|---|--|--|--|
| Arsenic trioxide (Trisenox) ^a APL | Differentiating agent; exact mechanism unclear; causes morphologic changes and DNA fragmentation characteristic of apoptosis | Retinoic acid syndrome: pulmonary infiltrates, respiratory distress, and hypotension; cardiovascular: tachycardia, edema, QT prolongation, chest pain, hypotension; low to moderate emetogenic potential; electrolyte abnormalities: hypokalemia or hyperkalemia, hypomagnesemia, hyperglycemia; rash; light-headedness or vasomotor symptoms; fatigue; musculoskeletal pain | Retinoic acid syndrome must be treated promptly with corticosteroids; weight gain secondary to fluid retention may be dose limiting |
| Asparaginase (L-asparaginase, Elspar) Pegaspargase (Oncospar) ^b ALL | Antitumor enzyme, hydrolyzes L-asparagine in bloodstream, depriving tumor cells of the essential amino acid; results in inhibition of protein, DNA, and RNA synthesis and cell proliferation; derived from <i>Escherichia coli</i> | Hypersensitivity reactions (fever, hypotension, rash, dyspnea in 25%), much lower risk with polyethylene glycol form; low emetogenic potential; pancreatitis; decreased synthesis of proteins, clotting factors; CNS: lethargy | Skin test prior to administration; anaphylaxis precautions; Pegaspargase complexed with polyethylene glycol to decrease immunogenicity and prolong duration of action (dose every 2 weeks vs. 2–5 times/week); more costly, may be difficult to obtain Monitor clotting function Test dose (1 unit) is recommended, but controversial: premedicate for subsequent doses with acetaminophen Dose reduction for CL _{Cr} <60 mL/min Pulmonary toxicity associated with: single doses >30 units, cumulative dose >400 units, bolus administration; risk factors: age >70, pre-existing pulmonary disease, prior chest radiation, exposure to high oxygen concentrations |
| Bleomycin (Bleo, Blenoxane) ^c NHL, HD; testicular cancer; squamous cell cancers of the head and neck, cervix, skin, penis, or vulva; malignant pleural effusions; KS | Antitumor antibiotic, causes single- and double-strand DNA scission (free-radical mediated); inhibition of protein, DNA, and RNA synthesis | Anaphylaxis and hypersensitivity reactions; fever and flu-like symptoms; mucositis; pulmonary fibrosis secondary to oxygen free-radical formation; low emetogenic potential; alopecia; not myelosuppressive | Apply ice or cold packs to site for extravasation; tissue damage may be delayed for 3–4 months after extravasation Sometimes administered intra-arterially, but systemic side effects may still occur |
| Mitomycin C (Mutamycin) ^d Gastric cancer, breast cancer; bladder cancer (instillation); esophageal cancer; cervical cancer; colorectal cancer; NSCLC | Antitumor antibiotic activated to an alkylating agent; cross-links DNA; inhibits DNA and RNA synthesis; superoxide free radicals may produce DNA strand breaks | Myelosuppression: may be delayed and prolonged (up to 8 weeks); mucositis; moderately emetogenic; extravasation: severe vesicant; pulmonary toxicity: pneumonitis, fibrosis (worse with concurrent vincristine or vinblastine); hemolytic anemia and uremic syndrome | |

^aFrom Kurtzberg et al.⁷⁶^bFrom Laxo et al.⁷⁵^cFrom Andre et al.⁷⁴^dFrom Bast et al,⁶⁶ Soignet et al.⁷⁷ALL, acute lymphocytic leukemia; APL, acute promyelocytic leukemia; CL_{Cr}, creatinine clearance; CNS, central nervous system; HD, Hodgkin's disease; KS, Kaposi's sarcoma; NHL, non-Hodgkin's lymphoma; NSCLC, non-small-cell lung cancer.

cytotoxic immune cells that can recognize and destroy tumor cells without damaging normal cells. Some of these cytotoxic cells are natural killer cells, lymphokine-activated killer cells, and tumor-infiltrating lymphocytes.⁸¹

The toxicity of IL-2 is related to dose, route, and duration of therapy, but in general, IL-2 is toxic therapy that requires vigorous supportive care. The most common dose-limiting toxicities are hypotension, fluid retention, and renal dysfunction. IL-2 decreases peripheral vascular resistance, producing peripheral vasodilation, tachycardia, and hypotension. A characteristic vascular- or

capillary-leak syndrome produces fluid retention, which in turn can cause respiratory compromise. These toxicities require administration of vasopressors in most patients, judicious use of fluid support and diuretics, and supplemental oxygen. Patients with underlying cardiovascular or renal abnormalities are more susceptible to these adverse effects, making careful patient selection important.⁸¹ Most patients treated with IL-2 in full doses experience thrombocytopenia, anemia, eosinophilia, reversible cholestasis, and skin erythema with burning and pruritus, and some have neuropsychiatric changes, hypothyroidism, and bacterial infections.^{82–85} In general, the

TABLE 124–16. Immune Therapies

| Agent/Major Uses | Mechanism | Adverse Effects | Comments |
|--|--|---|--|
| Interferon alfa (interferon α -2b; Intron A and Interferon α -2a; Roferon-A, IFN) ^a KS; CML; melanoma; hairy cell leukemia; renal cell carcinoma; NHL; multiple myeloma Hepatitis B and C; condyloma acuminata | Stimulates the immune system against tumor cells; direct and indirect cytotoxic activity; increases expression of tumor-associated antigens | Flu-like syndrome: fever, malaise, chills, headaches; fatigue: often dose-limiting; anorexia and altered taste; increased liver function tests (transient); myelosuppression: mild leukopenia, thrombocytopenia; depression; vivid dreams or nightmares | Patients should be advised to administer interferon in the evening to reduce excessive daytime sedation; premedication and scheduled dosing with acetaminophen or an NSAID may alleviate flu-like symptoms Flu-like symptoms typically subside with chronic use; no tolerance to fatigue, may necessitate dose reduction; antidepressants valuable for depressive symptoms Polyethylene glycol interferon forms have sustained duration of effect |
| Aldesleukin (interleukin-2, IL-2; Proleukin) ^b Renal cell cancer; melanoma | Stimulates growth, differentiation, and proliferation of activated T cells; generates lymphokine-activated killer cell activity and other killer cells; stimulates the immune system against tumor cells | Flu-like syndrome: fevers, chills, malaise; vascular or capillary leak syndrome: hypotension, pulmonary and peripheral edema; GI: moderately emetogenic, diarrhea; nephrotoxicity: partially due to hypotension or decreased renal perfusion; myelosuppression: thrombocytopenia, leukopenia, generally transient; cardiac: arrhythmias, reflex tachycardia; skin rash, flushing, itching, peeling, dryness; CNS: somnolence, confusion; bacterial infections common, especially staphylococcal | Addition of dopamine in “renal” doses (1–5 mcg/kg per minute) may help maintain good renal blood flow and blood pressure Pulmonary edema can be managed with cautious use of diuretics; short courses of albumin may also be beneficial Patients with history of cardiac arrhythmias may require cardiac monitoring during IL-2 administration Itching may respond to treatment with antihistamines (hydroxyzine or diphenhydramine); emollient skin creams or occlusive agents are effective for dry, peeling skin; avoid corticosteroids: may counteract the antitumor effects of IL-2. |

CML, chronic myelogenous leukemia; CNS, central nervous system; KS, Kaposi’s sarcoma; NHL, non-Hodgkin’s lymphoma; NSAID, nonsteroidal anti-inflammatory drug.

toxicities from IL-2 therapy reverse quickly once therapy is stopped, and can be managed or prevented by careful prospective monitoring and pharmacologic supportive care.⁸¹

BIOLOGICALLY DIRECTED THERAPIES

9 Most anticancer drugs are relatively indiscriminant cellular poisons. Although a few, such as methotrexate, capecitabine, L-asparaginase, and the immune therapies demonstrate some degree of selectivity for malignant cells, the selectivity is incomplete, and dose-limiting damage to normal cells also occurs. Recently anticancer research has focused on development of anticancer agents that target malignant cells more specifically, or the biochemical processes that control cancerous cell growth.

DENILEUKIN DIFTITOX

Denileukin diftotox (Ontak) is a recombinant fusion protein that combines the active sections of both IL-2 and diphtheria toxin. Unconjugated diphtheria toxin is much too toxic to administer to humans. As

the “payload” of the fusion protein, however, its cytotoxic effects are directed toward cells that express the high-affinity form of the IL-2 receptor, such as cancer cells of some patients with cutaneous T-cell lymphoma. Once denileukin diftotox interacts with the IL-2 receptors, the toxin inhibits protein synthesis in the cancer cells and causes cell death.⁶⁶

Although denileukin diftotox is directed therapy, its targeting of cells that express high-affinity IL-2 receptors is not specific; that is, these receptors are expressed on cells other than cancer cells. Denileukin diftotox produces acute hypersensitivity reactions, flu-like symptoms, sometimes with prominent diarrhea, and vascular-leak syndrome. It differs from the vascular-leak syndrome produced by high-dose IL-2 in that it occurs in fewer patients, is delayed in onset, is usually self-limited, and does not consistently recur on retreatment.⁸¹

ENDOCRINE THERAPIES

10 Perhaps the earliest successful approach to target the growth processes of cancerous cells was the use of endocrine therapies. Endocrine manipulation is an option for management of

cancers from tissues whose growth is under gonadal hormonal control, especially breast, prostate, and endometrial cancers. These cancers may regress if the “feeding” hormone is eliminated or antagonized. Major organ system toxicity is uncommon from hormonal treatment, making it the least toxic of systemic anticancer therapies. Increasingly specific agents such as the selective estrogen receptor modulators (SERMs) and aromatase inhibitors have increased the utility of

hormonal therapies in the treatment of cancer. Individual agents are described in Table 124–17.^{86–93}

Corticosteroid hormones are also useful anticancer agents because of their lymphotoxic effects. Their primary use is in management of hematologic malignancies, especially lymphomas, lymphocytic leukemias, and multiple myeloma. In addition to their cytotoxic effects, corticosteroids have many other applications in

TABLE 124–17. Endocrine Agents Commonly Used in Cancer Treatment

| Agent/Major Uses | Class/Mechanism | Major Side Effects | Comments |
|--|---|--|---|
| <i>Antiandrogens</i> | | | |
| Bicalutamide (Casodex) ^a Prostate cancer | Nonsteroidal antiandrogen; androgen receptor antagonist; inhibits testosterone and dihydrotestosterone uptake and binding in prostate cells | Hot flashes; gynecomastia, breast tenderness; decreased libido; hepatotoxicity, elevated transaminases; diarrhea | Monitor serum transaminases Drug interactions: may displace warfarin from protein binding sites, increasing anticoagulant effects Often used in combination with an LHRH agonist at initiation of therapy to prevent symptoms of tumor flare |
| Flutamide (Eulexin) ^a Prostate cancer | Nonsteroidal antiandrogen; androgen receptor antagonist; inhibits testosterone and dihydrotestosterone uptake and binding in prostate cells | Hot flashes; gynecomastia, breast tenderness, nipple pain; decreased libido; diarrhea; low emetogenic potential; mild transient elevations in liver transaminases | Use with caution in G6PD deficiency: may lead to methemoglobinemia Monitor serum transaminases Drug interactions: substrate of CYP450 1A2, CYP450 3A4; inhibits CYP450 1A2; may lead to increased warfarin anticoagulant effects Often used in combination with LHRH agonist at initiation of therapy to prevent symptoms of tumor flare |
| Nilutamide (Nilandron) ^a Prostate cancer | Nonsteroidal antiandrogen; androgen receptor antagonist; inhibits testosterone and dihydrotestosterone uptake and binding in prostate cells | Pulmonary: dyspnea; may cause interstitial pneumonitis (dyspnea on exertion, chest pain, fever) symptom onset in the first 3 months; hot flashes; gynecomastia; low emetogenic potential; testicular atrophy, decreased libido; hepatic toxicity: elevated transaminases; rare fatal hepatitis; visual disturbances: delayed adaptation to darkness, photophobia, cataracts; isolated cases of aplastic anemia reported; disulfiram-like reaction with alcohol | Visual disturbances (impaired adaptation to darkness) may reverse with dose reduction; monitor serum transaminases; obtain chest x-ray if patient reports dyspnea; evidence of interstitial pneumonitis necessitates discontinuation of treatment Often used in combination with an LHRH agonist at initiation of therapy to prevent symptoms of tumor flare |
| <i>Antiestrogens</i> | | | |
| Aminoglutethimide (Cytadren) ^b Breast cancer; prostate cancer | Nonsteroidal aromatase inhibitor; inhibits conversion of cholesterol to delta-5-pregnenolone; results in decreased synthesis of corticosteroid hormones (glucocorticoids, estrogens, and androgens); also blocks conversion of androgens to estrogens | Adrenocorticoid suppression and insufficiency; skin rash, typically within the first week, usually self-limiting, disappears after 5–8 days, but may require discontinuation of therapy; lethargy, somnolence, dizziness; mild nausea, anorexia; leukopenia and agranulocytosis have been rarely reported | Mineralocorticoid (fludrocortisone) and glucocorticoid (e.g., hydrocortisone 20–30 mg/day) replacement therapy may be required in as many as 50% of patients Salvage therapy for breast cancer and prostate cancer |
| Anastrozole (Arimidex) ^c Breast cancer | Selective, nonsteroidal aromatase inhibitor; inhibits conversion of androgens to estrogens | Hot flashes; vasodilation, peripheral edema; weakness; arthralgias; elevated transaminases; hyperlipidemia; thrombosis less common than with tamoxifen | Should not be used concurrently with tamoxifen; not indicated for premenopausal women or women with ER-negative tumors; used in postmenopausal women because peripheral conversion of adrenal androgens to estrogens is the primary source of estrogen; not used in premenopausal women because it does not interfere with production of ovarian estrogens |

TABLE 124–17. (Continued)

| Agent/Major Uses | Class/Mechanism | Major Side Effects | Comments |
|--|--|---|---|
| Exemestane (Aromasin) ^c Breast cancer | Irreversible steroidal aromatase inactivator; prevents conversion of androgens to estrogens by inhibiting the aromatase enzyme | Hot flashes; fatigue; depression, anxiety, insomnia; mild nausea, anorexia; edema; dyspnea; elevated transaminases | Not indicated for premenopausal women Drug interactions: CYP450 3A4 substrate, but no significant interactions yet reported; St. John's wort may decrease exemestane levels Food interactions: plasma levels increase when taken with a fatty meal; recommended to be taken after a meal |
| Fulvestrant (Faslodex) ^d Breast cancer | Antiestrogen; estrogen receptor antagonist; downregulates estrogen receptor protein in human breast cancer cells; no estrogen agonist properties | Hot flashes; low emetogenic potential; diarrhea, constipation, abdominal pain; headache; back pain and myalgia; pharyngitis; dizziness; insomnia; depression | Available in prefilled syringes for IM injection once a month IM injection should be administered into buttocks; should not be used in patients with thrombocytopenia or on anticoagulant therapy Not indicated for premenopausal or women with ER-negative tumors |
| Letrozole (Femara) ^e Breast cancer | Selective, nonsteroidal aromatase inhibitor; inhibits conversion of androgens | Hot flashes; arthralgias, myalgias; headache; fatigue; low emetogenic potential; dyspnea, cough; breast pain; hyperlipidemia; elevated transaminases | Not indicated for premenopausal women; emerging evidence supports the use of letrozole for 5 years following completion of 5 years of adjuvant tamoxifen to further prolong survival in postmenopausal women Drug interactions: substrate of CYP450 2A6 and 3A4; inhibits CYP450 2A6 and C19; potential for interactions with inhibitors or inducers of these enzymes as well as other substrates, but specific drug interactions have not been identified |
| Megestrol acetate (Megace) ^f Breast cancer; endometrial cancer; cancer cachexia and anorexia; prostate cancer | Synthetic progestin with antiestrogen properties; interferes with normal estrogen cycle; may also have direct effects on the endometrium | Fluid retention and edema; weight gain; hot flashes; vaginal bleeding and spotting, amenorrhea and menstrual irregularities; decreased libido; breast tenderness; adrenal corticoid suppression and adrenal insufficiency; hepatotoxicity; thrombosis; photosensitivity | Suspension is compatible with water, apple juice, and orange juice High doses required for appetite stimulation |
| Tamoxifen (Nolvadex) ^e Breast cancer | Nonsteroidal estrogen receptor antagonist; competitively binds to estrogen receptors on estrogen-dependent breast cells | Hot flashes; fluid retention; weight loss; mood swings, depression; bone pain, tumor pain; thrombosis; vaginal bleeding and spotting, vaginal discharge, menstrual irregularities, decreased libido; endometrial and uterine cancer; low emetogenic potential; hyperlipidemia; decreased visual acuity, retinopathy, corneal changes, cataracts; rash, photosensitivity; hepatotoxicity, elevated transaminases; thrombocytopenia | Breast cancer treatment or adjuvant therapy in ER-positive patients; preventive therapy in women at high risk for breast cancer Monitor patients closely for endometrial hyperplasia or cancer; monitor serum transaminases CYP450 substrate (CYP450 2A6, 2B6, 2C8/9, 2D6, 2E1, 3A4) and inhibitor (CYP450 3A4, 2B6, 2C8/9); significantly increases anticoagulant effects of warfarin |
| Toremifene (Fareston) ^e Breast cancer; endometrial cancer; desmoid tumors | Nonsteroidal antiestrogen; estrogen receptor antagonist | Hot flashes; vaginal discharge or bleeding; low emetogenic potential; diaphoresis; thromboembolism; dizziness; hypercalcemia; dry eyes, visual acuity changes | Hypercalcemia and tumor flare have been reported during the first weeks of treatment Drug interactions: substrate of CYP450 1A2, 3A4; enzyme inhibitors may increase toremifene blood levels; toremifene can increase anticoagulant effects of warfarin; anticonvulsants can decrease toremifene blood levels |

TABLE 124–17. (Continued)

| Agent/Major Uses | Class/Mechanism | Major Side Effects | Comments |
|--|---|---|--|
| <i>LHRH Agonists</i> | | | |
| Goserelin (Zoladex) ^g Prostate cancer; breast cancer | LHRH agonist; initially stimulates steroidogenesis by increasing levels of LH and FSH, but ultimately inhibits gonadotropin secretion with continuous administration by negative feedback mechanism; results in decreased testosterone and estrogen levels | Testicular atrophy, decreased libido, impotence; gynecomastia, breast tenderness; hot flashes; low emetogenic potential; depression, confusion; angina, CHF; thrombosis; elevated liver function tests; injection site reactions or abscess; hyperlipidemia; decreased bone density | Antiandrogens are coadministered during initial therapy to decrease symptoms of tumor flare (bone pain, urinary tract obstruction, or spinal cord compression) associated with the initial increase in serum testosterone levels Administered as a subcutaneous injection of implanted pellets every 1–3 months |
| Leuprolide (Lupron, Lupron Depot, Eligard) ^g Prostate cancer; breast cancer | LHRH agonist; initially stimulates steroidogenesis by increasing levels of LH and FSH, but ultimately inhibits gonadotropin secretion with continuous administration by negative feedback mechanism; ultimately results in decreased testosterone and estrogen levels | Testicular atrophy, decreased libido, impotence; gynecomastia, breast tenderness; hot flashes; low emetogenic potential; depression, confusion; angina, CHF, thrombosis; elevated liver function tests; pain at injection site; hyperlipidemia; decreased bone density | Antiandrogens are coadministered during initial therapy to decrease symptoms of tumor flare (bone pain, urinary tract obstruction, or spinal cord compression) associated with the initial increase in serum testosterone levels Administered as IM injection every 1–4 months |
| <i>LHRH Antagonists</i> | | | |
| Abarelix (Plenaxis) ^h Prostate cancer | GnRH antagonist; directly competes with GnRH receptors in pituitary, suppressing LH and FSH production, and reducing testosterone secretion by testes | <i>Life-threatening hypersensitivity reactions, sometimes severe and immediate, limit use:</i> urticaria, hypotension, syncope; reactions may occur after any dose; risk increases with cumulative dosing; hot flashes; breast enlargement or pain; can prolong QT interval | No initial surge in testosterone production, therefore no risk of tumor flare Observe patients for allergic reactions for at least 30 minutes after each dose Patients must sign consent before drug administration to confirm understanding of risks and benefits; risks limit use to men who require androgen suppression, cannot risk tumor flare, and refuse orchiectomy |

CBC, complete blood cell count; CHF, congestive heart failure; CYP450, cytochrome P450 isoenzyme; G6PD, glucose-6-phosphate dehydrogenase; ER, estrogen receptor; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; IM, intramuscular; LH, luteinizing hormone; LHRH, luteinizing-hormone releasing hormone.

supportive care of cancer patients. Corticosteroids have diverse toxicities in chronic or high-dose use, but are generally well tolerated in the short-term therapies usually used in cancer patient care.⁹⁴

RETINOIDS

Vitamin A and its metabolites, collectively referred to as the retinoids, play important roles in numerous biologic processes, including normal cellular differentiation. Because cancerous growth is characterized by abnormal cellular differentiation, retinoids are proving to have important therapeutic roles in the treatment and perhaps in the prevention of cancers. Tretinoin (all-*trans*-retinoic acid) is a naturally occurring derivative of vitamin A (retinol). Other retinoids indicated for treatment of cancers include alitretinoin (9-*cis*-retinoic acid), available in gel form for topical management of Kaposi's sarcoma lesions and bexarotene (Targretin) gel or capsules for treatment of cutaneous T-cell lymphoma (Table 124–18).^{95,96}

Retinoids are classed as morphogens, small molecules released from one type of cells that can affect the growth and differentiation of neighboring cells. Their normal roles in the human body are to induce differentiation of some cells, stop the differentiation of others, and both suppress and induce apoptosis in different cell types. Their diverse actions come from the diversity of their receptors. The two classes of retinoid receptors are retinoid X receptors (RXRs) and retinoic acid receptors (RARs), each with α , β , and γ subclasses. RXRs are versatile; they bind to RARs and to other nuclear receptors such as thyroid hormone receptors. Once activated, the receptors act as transcription factors that in turn regulate the expression of genes that control cellular growth and differentiation.⁹⁵

Tretinoin binds primarily to the RAR- α receptors. Alitretinoin is considered a panagonist; that is, it binds to all known retinoid receptors, producing diverse regulatory effects. Bexarotene is synthetic and is classed as a rexinoid. It is the first RXR-selective retinoid agonist. The exact mechanism of action of alitretinoin and bexarotene as anticancer agents is unknown.^{95,96}

TABLE 124–18. Biologically-Directed Therapies

| Agent/Major Uses | Class/Mechanism | Major Side Effects | Comments |
|---|--|---|--|
| <i>Molecular targets</i> | | | |
| Bexarotene (Targretin) ^a Cutaneous T-cell lymphoma | Retinoid analog that may activate retinoid receptors | Peripheral edema; insomnia, headache; fever, chills; lipid abnormalities, increased triglycerides, cholesterol, reduced high-density lipoproteins; hypothyroidism (reduced thyroxine, thyroid-stimulating hormone); diarrhea; low emetogenic potential; leukopenia and anemia; dry skin; increased liver function tests; pancreatitis | Drug interactions: metabolized by CYP450 3A4, may interact with drugs that inhibit or induce this enzyme May cause hypoglycemia in patients receiving insulin, sulfonylureas, or metformin; contraindicated in pregnant women Limit vitamin A supplements |
| Bortezomib (PA-341, Velcade) ^b Multiple myeloma; prostate cancer | Boronic acid dipeptide that reversibly inhibits the proteasome; proteasomes are enzyme complexes in cells that degrade proteins that regulate cell-cycle progression; actions are mediated through inhibition of the degradation of NF- κ B | Fatigue or malaise; nausea, diarrhea, anorexia, constipation, vomiting; low to moderate GI effects; myelosuppression, especially thrombocytopenia; hyponatremia, hypokalemia; peripheral neuropathy may be dose-limiting, cumulative, and dose-related, but reversible; fever | First proteasome inhibitor; administered as rapid IV bolus twice weekly for 2 weeks in 21-day cycle Increased risk of severe neuropathy in patients with pre-existing neuropathy |
| Gefitinib (Iressa) ^c NSCLC | EGFR tyrosine kinase inhibitor; inhibits signal transduction pathways essential for tumor cell proliferation, differentiation, angiogenesis, and metastasis | Pulmonary toxicity: interstitial lung disease (ILD), symptoms of cough, dyspnea, and fever (~1% overall incidence, but 1/3 of cases have been fatal); diarrhea; skin reactions: acne-like rash, dry skin, may require interruption of treatment; low emetogenic potential; hepatotoxicity; eye pain | Therapy should be interrupted if patients develop symptoms of ILD and drug should be discontinued if ILD is confirmed Patients with symptoms of eye pain should be evaluated for aberrant eyelash growth Drug interactions: metabolized by CYP450 3A4, gefitinib effects may be decreased by CYP450 3A4 inducers (e.g., rifampin, phenytoin) and increased by CYP450 3A4 inhibitors (e.g., ketoconazole, voriconazole); major interaction with warfarin leading to increased anticoagulant effects and increased bleeding risk; histamine-2 blockers may decrease gefitinib levels |
| Imatinib mesylate (Gleevec, STI 571) ^d CML (adults and pediatrics); GIST; Ph + ALL | Tyrosine kinase inhibitor; relatively specific for the tyrosine kinase coded for by the <i>bcr-abl</i> translocation in CML patients | Moderate emetogenic potential: take with meals and a full glass of water; edema: periorbital edema is characteristic; pleural effusions, ascites, or pulmonary edema also occur; rash; diarrhea; neutropenia, thrombocytopenia (sometimes difficult to distinguish from CML-induced cytopenias); increased liver function tests | Metabolized primarily by CYP450 3A4; competitive inhibitor of CYP450 3A4, 2C9, and 2D6, so beware of drug interactions; may increase warfarin effects Dose reductions should be considered for liver dysfunction and myelosuppression per manufacturer recommendations Usual dose: 400 mg orally per day; cost ~\$2,400 per month |
| Tretinoin (All- <i>trans</i> -retinoic acid [ATRA], Vesanoid) ^e APL | Vitamin A derivative (retinoid); induces differentiation, maturation of immature promyelocytic cells | Headache is most common side effect; severe headache may be sign of pseudotumor cerebri (intracranial hypertension); "ATRA syndrome": pulmonary symptoms (dyspnea, respiratory distress, fever, pleural effusions); low emetogenic potential; dry skin and mucous membranes, mucositis; bone pain; transient elevations in transaminases, bilirubin | Headaches are usually manageable with mild analgesics; ATRA syndrome treated with corticosteroid administration (initiate when WBC $\geq 10,000$) and/or holding ATRA until symptoms resolve; bone pain typically responds to mild analgesics; teratogenic: contraindicated in pregnancy; female patients should be educated about proper contraceptive measures Give daily dose orally in two divided doses; round to nearest 10 mg (available only as 10 mg capsules) |

(continued)

TABLE 124–18. (Continued)

| Agent/Major Uses | Class/Mechanism | Major Side Effects | Comments |
|--|---|---|---|
| <i>Monoclonal antibodies</i> Alemtuzumab (Campath) ^f B-cell CLL | Anti-CD52 monoclonal antibody, results in antibody-dependent lysis of CD52 ⁺ B and T lymphocytes | Myelosuppression and immunosuppression; infection; infusion-related nausea and vomiting; fever; hypotension; rash; headache; fatigue | Patients should be started on antiviral and PCP prophylaxis during and 6 months posttreatment; some evidence suggests that subcutaneous administration may be associated with less acute toxicity |
| Bevacizumab (Avastin) ^g Colorectal cancer; renal cell carcinoma | Recombinant humanized MoAB; binds to vascular endothelial growth factor to prevent it from binding to its receptors; this inhibits new vessel formation (angiogenesis) | Most serious adverse effect (2% incidence, idiosyncratic) is GI bleeding or perforation, sometimes with intra-abdominal abscess formation; impaired wound healing; hypertension; proteinuria; rare severe pulmonary hemorrhage | Presenting symptoms of GI bleeding or perforation: abdominal pain, nausea, vomiting, and constipation; risk not correlated with duration of therapy; treat hypertension with standard antihypertensives; avoid within 28 days after major surgery; suspend treatment before elective surgery |
| Cetuximab (Erbix) ^h Colorectal cancer | Recombinant human/mouse MoAB that binds to the EGFR and inhibits the binding of EGFR and other growth factors; EGFR is overexpressed in some solid tumors such as colorectal cancer; cetuximab inhibits cell cycle progression; induces apoptosis; may enhance the effects of some chemotherapy agents and radiation | Acne-like rash in most patients, sometimes severe, on face and upper torso, onset in 1–3 weeks, may improve with continued treatment, reversible; paronychia cracking in fingers or toes, may take several months to heal; asthenia; abdominal pain, nausea, constipation, diarrhea; infusion and hypersensitivity reactions | Acne-like rash is poorly responsive to standard acne treatments; dose reductions may be required; skin rash may correlate with response; premedicate with antihistamine; medical resources for the treatment of severe infusion reactions should be available; reduce infusion rate for mild to moderate infusion reactions, discontinue infusion for severe toxicity |
| Gemtuzumab ozogamicin (Mylotarg) ⁱ CD33 ⁺ ANLL | Humanized anti-CD33 antibody linked to calicheamicin, a potent toxin; binding to the CD33 receptor results in internalization of the antibody-antigen complex; calicheamicin is then released intracellularly and exerts cytotoxicity by causing DNA double-strand breaks, resulting in cell death | Infusion reactions: fevers, chills, nausea, vomiting, hypotension, dyspnea; myelosuppression may be severe and prolonged; tumor lysis syndrome: WBCs should be reduced to <30,000/mm ³ prior to administration if possible, to decrease risk; increased liver function tests and bilirubin, hepatic veno-occlusive disease | Premedicate with acetaminophen 1000 mg and diphenhydramine 50 mg; requires 4–8 hours of observation postinfusion; light-sensitive Requires preparation in darkened hood and light protective bag for administration |
| Ibritumomab tiuxetan (Zevalin) ^j NHL (low-grade CD20 ⁺) | Anti-CD20 MoAB linked to radioactive yttrium (Y ⁹⁰); murine version of the rituximab antibody; monoclonal antibody to CD20 (a B-lymphocyte surface antigen)-positive cells; binds complement and increases antibody dependent cellular cytotoxicity; radioactive linkage delivers radiation dose directly to tumor cells to decrease damage to normal cells | Must consider toxicities of rituximab also, since always given in combination; hematologic toxicity very delayed in onset, occurring 7 ± 9 weeks after drug administration with 2–4 weeks for recovery; infusion reactions: asthenia, nausea, chills, fever; tumor pain | Rituximab administered prior to ibritumomab to decrease circulating B-cells, improves targeting of the radiation (see rituximab); imaging dose of ibritumomab chelated to indium-111 to map the expected distribution of the radioisotope is administered ~1 week prior to treatment dose; repeated treatment not usually required |
| Rituximab (Rituxan) ^k Low-grade NHL; CLL; intermediate-grade NHL Idiopathic thrombocytopenic purpura; rheumatoid arthritis | Monoclonal antibody that reacts with CD20 (a B-lymphocyte surface antigen)-positive cells; binds complement and increases antibody dependent cellular cytotoxicity | Hypersensitivity reactions, infusion rate-related; infusion-related side effects: flushing, chills, fever, rigors, hypotension; bronchospasm, dyspnea, angioedema; tumor lysis syndrome, especially with large tumor burden (e.g., CLL with a high WBC); low emetogenic potential; thrombocytopenia; myalgias; tachycardia | Infusion-related reactions may be severe; increase rate of infusion gradually (e.g., start at 25–50 mg/min increasing by 25–50 mg/min at 30-minute intervals; maximum infusion rate = 400 mg/h); premedicate with 650–1000 mg acetaminophen, 50 mg diphenhydramine with or without dexamethasone; use meperidine 25 mg IV as needed for rigors; consider hospitalization for first dose |

TABLE 124–18. (Continued)

| Agent/Major Uses | Class/Mechanism | Major Side Effects | Comments |
|---|--|--|--|
| Tositumomab (Bexxar) ^f NHL (low-grade CD20 ⁺) | Anti-CD20 MoAB linked to radioactive iodine (¹³¹ I); monoclonal antibody to CD20 (a B-lymphocyte surface antigen)-positive cells; binds complement and increases antibody dependent cellular cytotoxicity; radioactive linkage delivers radiation dose directly to tumor cells, resulting in additional cytotoxicity | Cytopenias (especially thrombocytopenia and neutropenia): severe and prolonged; late onset 4–7 weeks after treatment, persisting >3 months; nausea, vomiting, abdominal pain (within days), diarrhea (within days to weeks after infusion); infusion reactions: fever, rigors, chills, sweating, hypotension, dyspnea, bronchospasm; anaphylaxis may occur; premedicate; hypothyroidism: all patients must receive thyroid-blocking agents; asthenia, myalgias, arthralgias; cough; rash | Radiopharmaceutical, to be prepared and administered only by personnel trained in radiopharmaceuticals; premedicate with acetaminophen and antihistamines; slow infusion rate or interrupt infusion for infusion reactions; medications for treatment of hypersensitivity reactions should be available for immediate use; avoid in pregnant females; may cause hypothyroidism in fetus; two-step administration; MoAB and low radioisotope dose is followed after 1–2 weeks by MoAB and therapeutic radioisotope dose; renally excreted; impaired renal function may increase exposure to radioactive components; patients must be trained in precautions to decrease radiation exposure to family, friends, and general public |
| Trastuzumab (Herceptin) ^m Breast cancer; prostate cancer; pancreatic cancer; lung cancer; ovarian cancer | MoAB directed against <i>HER2</i> receptors, overexpressed in some breast cancer patients and related to epidermal growth factor | Cardiac toxicity: congestive cardiomyopathy, usually reversible with medical management; infusion reactions | Do not administer with anthracyclines; best response seen in patients highly positive for <i>HER2</i> overexpression |

ANLL, acute nonlymphocytic leukemia; APL, acute promyelocytic leukemia; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; EGFR, epidermal growth factor receptor; GIST, gastrointestinal stromal tumor; MoAB, monoclonal antibody; NF- κ B, nuclear factor- κ B; Ph+ ALL, Philadelphia chromosome-positive acute lymphocytic leukemia; PCP, *Pneumocystis carinii* pneumonia; WBC, white blood cell.

TYROSINE KINASE INHIBITORS

Imatinib

Imatinib mesylate was the first tyrosine kinase inhibitor to be approved for treatment of cancer (see Table 124–18). It inhibits deregulated *bcr-abl* tyrosine kinase, the molecular abnormality in patients with chronic myelogenous leukemia that results from the characteristic “Philadelphia chromosome” translocation. The deregulated tyrosine kinase constantly drives leukemic cell proliferation. Imatinib inhibits cell proliferation and induces apoptosis in the Philadelphia chromosome-positive cells. It is relatively, but not completely, selective for these cells.^{97–100}

Gefitinib

Gefitinib is a selective inhibitor of epidermal growth factor receptor [EGFR] tyrosine kinase (see Table 124–18). EGFR is a cell surface receptor expressed or overexpressed in many solid tumors. When ligand binds to the EGFR receptor, tyrosine kinase activity initiates a cascade of signaling events within the cancer cells that stimulates their proliferation and promotes their survival. Gefitinib inhibits EGFR ac-

tivity by competing with adenosine triphosphate for its binding site on the EGFR tyrosine kinase. This blocks the tyrosine kinase cascade of downstream signaling, and ultimately interferes with the proliferation and growth of cancer cells. It is orally administered and well tolerated, most commonly producing diarrhea and mild skin rashes.^{97,101,102}

PROTEOSOME INHIBITORS

Proteosomes are protein complexes within cells that are responsible for degrading and eliminating cellular proteins. Some of the proteins that are degraded by proteosomes are proteins that regulate critical functions for successful cancer growth, such as regulation of the cell cycle, transcription factors, apoptosis, angiogenesis, and cell adhesion.^{103,104} One proteosome inhibitor, bortezomib, is commercially available (see Table 124–18). Bortezomib has very specific affinity for the catalytic portion of the proteosome. It can induce apoptosis in cancer cells indirectly. Although many actions may contribute to its effects, one pathway of action is well established. Bortezomib interferes with degradation of the inhibitory partner protein of a transcription factor, nuclear factor- κ B [NF- κ B]. NF- κ B induces

transcription of genes that block cell death pathways and promote cell proliferation, but in order for it to do so, NF- κ B must be released from its inhibitory partner protein in the cytoplasm and move to the nucleus. When NF- κ B's partner protein fails to degrade, through the actions of bortezomib, NF- κ B is held in the cytoplasm and prevented from transcribing the genes that promote cancer growth. Bortezomib is approved for the treatment of patients with multiple myeloma.^{103,104}

MONOCLONAL ANTIBODIES

9 The monoclonal antibodies have become established agents in the treatment of cancer. Monoclonal antibodies (MoABs) consist of immunoglobulin sequences that are known to recognize a specific antigen or protein on the surface of cells. There are several mechanisms by which monoclonal antibodies may induce death of cancer cells. Direct mechanisms include induction of apoptosis, blockade of growth factor receptors, or induction of anti-idiotypic antibodies. Important indirect mechanisms include antibody-dependent cellular toxicity and complement-mediated cellular toxicity.^{66,105} Antibodies may also be carriers for cytotoxic drugs or toxins (i.e., immunoconjugates) that are targeted by the antibody directly to the antigen-bearing cancer cells. Once the antibody binds to its cellular surface receptor, the complex can be internalized, and the toxic "payload" liberated into the cytoplasm to cause cell damage. MoABs can also serve as carriers for radioisotopes. Delivery of radiation therapy in this manner is called radioimmunotherapy. Drug and toxin conjugates kill only the targeted cell, but radiation delivered via MoAB is less narrowly targeted. Depending on the penetration of the radioisotope through tissue, the radiation can also damage nearby cells that do not express the targeted antigen.^{66,105} Table 124–18 summarizes the characteristics and clinical uses of monoclonal antibodies.^{82–85,106–115}

Several limitations affect the success and specificity of treatment with MoABs. Although monoclonal antibodies are designed to be specific to a particular target antigen, that target antigen may also be expressed on normal tissues to some degree, decreasing their selectivity. Thus toxicity often occurs when the monoclonal antibodies bind to normal cells, or are recognized by the immune system. All of the monoclonal antibodies are also associated with some degree of infusion-related reactions. The severity of these reactions can range from mild (e.g., fever, chills, nausea, and rash) to severe, life-threatening anaphylaxis with cardiopulmonary collapse. Many patients also experience chest or back pain during the infusion. Patients with circulating tumor cells in the bloodstream are at highest risk for more severe reactions. For these reasons, patients must be monitored closely during drug infusion. The reactions tend to be more severe with the initial infusion, and subside with subsequent treatment. Most agents require premedication with antihistamines and acetaminophen. Recommended infusion rates are usually lower for the initial dose, with incremental increases as tolerated by the patient. For patients experiencing signs or symptoms of infusion-related reactions, the infusion should be interrupted and prompt treatment with antihistamines, corticosteroids, and other supportive measures should be initiated. Pulmonary toxicity may occur as part of the infusion-related reaction or may occur as a distinct entity.^{66,82–86,105–115}

ANGIOGENESIS INHIBITORS

11 Angiogenesis refers to the development of new capillaries to increase vascular supply of tissue. Although angiogenesis is a normal function, and is essential to wound healing, reproduction, and growth, it is also central to the successful growth of tumor masses. Tumors need blood supply to grow. Interference with their ability to

develop new blood vessels by means of antiangiogenic drugs can limit or prevent tumor growth.¹⁰⁷

There are many potential means of interfering with angiogenesis. Examples are targeting vascular growth factors, or the production and control of the endothelial cells that make up the vessel linings. Most antiangiogenic drugs are cytostatic rather than truly cytotoxic, since they prevent new vessel growth and thus cause growth delay of the tumors. Some vascular targeting agents, however, can destroy existing blood vessels. These could be cytotoxic.^{107,116}

Bevacizumab is a humanized monoclonal antibody directed against vascular endothelial growth factor (VEGF), a growth factor that regulates proliferation and permeability of blood vessels (see Table 124–18). VEGF acts through two receptors. Bevacizumab inhibits the signaling process for new blood vessels by binding VEGF ligand to prevent it from interacting with its receptors. It was approved in 2004 for treatment of patients with colorectal cancer.^{107–109}

THALIDOMIDE

Thalidomide, the infamous drug that caused severe limb deformities (phocomelia or "seal limbs") when used by pregnant women as an over-the-counter sedative in the 1960s, is approved for treatment of leprosy and has orphan drug status for multiple myeloma. It also has documented clinical activity in several other types of cancer. Thalidomide is a glutamic acid derivative, and is broadly classed as an immunomodulatory agent. It has many potential mechanisms of action as an anticancer agent. It is an angiogenesis inhibitor, interfering with the growth of new blood vessels needed for tumor growth. This action is also linked to its teratogenic effects. Other possible mechanisms include: direct inhibition of cancer cells, free-radical oxidative damage to DNA, interfering with adhesion of cancer cells, inhibiting tumor necrosis factor- α production, or altering secretion of cytokines that affect the growth of cancer cells. Great care must be taken to prevent thalidomide's use during pregnancy.^{107,116,117}

GENERAL SUPPORTIVE CARE ISSUES

The treatment of cancer with most antineoplastic drugs is complicated by the risk of multiple serious toxicities, many of which are life threatening. Drug-specific toxicities, such as doxorubicin-induced cardiotoxicity and bleomycin-related pulmonary toxicity, were summarized in the previous section (see Tables 124–11 through 124–18). Several adverse effects are common to many antineoplastic agents. These include nausea and vomiting, myelosuppression, mucositis, alopecia, infertility, and carcinogenesis. Nutritional support and pain management are also important supportive care issues, although malnutrition and pain are not usually direct results of drug toxicity. The management of chemotherapy-induced nausea and vomiting and the basic principles of nutritional support and pain management are discussed in detail in other sections of this text.

Because many antineoplastic drugs affect DNA synthesis, any cell with a high turnover rate will be more sensitive to the toxic effects of chemotherapy. Cancer cells do not necessarily proliferate faster than normal cells. Normal tissues that consist of rapidly proliferating cells are targets for the toxicities of many anticancer drugs.¹⁴ The bone marrow, intestinal mucosa, and hair follicles are such tissue sites where drug effects are manifested.

MYELOSUPPRESSION

12 Although not seen with all antineoplastic agents, myelosuppression is the most common dose-limiting side effect of cytotoxic

agents. Bone marrow suppression does not usually occur immediately after chemotherapy administration. Blood components that have already been produced must be consumed before the effect is evident. White blood cells (WBCs), especially neutrophil precursors, are most significantly affected because of their rapid proliferation and short life-span (6 to 12 hours). Platelets (5- to 10-day life-span) are also affected, but to a much less degree than neutrophils. Erythrocytes, with a 120-day life-span, are affected the least. Usual nadirs, or lowest blood cell counts, occur at 10 to 14 days following chemotherapy administration, with recovery by 3 to 4 weeks. There are some exceptions to this general rule. The nitrosoureas and mitomycin C exhibit a delayed pattern of nadir (4 to 6 weeks) and recovery (6 to 8 weeks). Planned courses of chemotherapy may have to be delayed while waiting for the granulocyte count to return to normal. For a patient to safely receive another cycle of myelosuppressive chemotherapy, a WBC count $\geq 3,000/\text{mm}^3$ or an absolute neutrophil count (ANC) of $\geq 1,500/\text{mm}^3$ and a platelet count of $\geq 100,000/\text{mm}^3$ are usually required.

Myelotoxicity is a desired therapeutic effect in leukemia patients during induction chemotherapy. However, myelosuppression is an undesirable side effect during chemotherapy for other malignancies. If significant myelosuppression has occurred with prior courses of chemotherapy, the doses of the offending agent(s) in subsequent courses may be reduced. The magnitude of dose reduction is dictated by the degree of myelosuppression incurred and the incidence and severity of infection or bleeding. Empiric dosage reductions may be made for the first chemotherapy treatment if the patient has a low baseline WBC or platelet count, has diminished bone marrow reserve, has impaired drug-elimination capabilities, or is to receive a combination of several drugs that cause myelosuppression. Patients who have received multiple prior courses of other myelotoxic chemotherapy regimens or extensive radiation therapy, especially to the pelvis, may have a decreased bone marrow reserve. They are more sensitive to the myelosuppressive effects of chemotherapy, and normal doses may produce profound marrow toxicity. The pharmacokinetic profile of a myelosuppressive agent is also important in determining the appropriate dose. For example, the anthracyclines produce bone marrow suppression as an acute dose-limiting toxicity, and these agents depend on biliary excretion as their primary route of elimination. A patient with biliary obstruction may have compromised elimination of anthracyclines and is at increased risk for severe bone marrow suppression. Although dosage reduction can prevent myelotoxicity, it may also compromise antitumor response for some tumors (e.g., breast cancer or lymphoma). For such tumors, empiric use of hematopoietic growth factors provides an alternative to dose reduction in patients at high risk for toxicity.

NEUTROPENIA

◀² When the ANC falls below $500/\text{mm}^3$, infection risk increases.^{118–120} The ANC may be calculated by multiplying the percentage of neutrophils (segmented plus banded neutrophils) by the total WBC count. The risk of infection is also directly proportional to the duration of neutropenia. Other risk factors for infection include alteration in the integrity of physical defense barriers and the functional integrity of WBCs. The patient's underlying cancer, as well as treatment with cytotoxic drugs and radiation, can affect neutrophil function. The diagnosis of infection in the neutropenic patient is complicated by the lack of WBCs. Usual signs and symptoms of infection, such as pus, abscesses, and infiltrates on chest x-ray, depend on the presence of WBCs. The only reliable indication of infection in these patients is fever. Definitive culture results may take days, and a septic neutropenic cancer patient can die within hours if not treated. Therefore the basic approach to the manage-

ment of the febrile neutropenic cancer patient is prompt initiation of empiric antibiotics. The antibiotics are chosen based on reliable coverage of the most likely organisms, antibiotic sensitivities at the institution, the patient's signs and symptoms (if present), side-effect profiles, and cost.¹²⁰ The most common source of infection in these patients is self-infection with body flora, which includes both gram-positive and gram-negative bacteria. Although bacteria cause most early infections, fungi become important pathogens as the course of neutropenia is prolonged. Traditionally, all febrile neutropenic cancer patients have received intravenous antibiotics in the hospital setting until full recovery of neutrophils. However, it is possible to identify patients at low risk for infectious complications who are candidates for alternative treatment strategies, including early discharge from the hospital and outpatient oral or intravenous antibiotics.^{120,121} Specific treatment of infections in immunocompromised hosts is discussed elsewhere in this text.

Numerous methods have been explored to prevent infections in cancer patients.^{120,122} Colony-stimulating factors (CSFs) are commonly employed for this purpose.^{122–124} These hormones are naturally occurring proteins that are essential for the normal growth and maturation of blood cell components (Fig. 124–13). The CSFs have the ability to enhance the production and also the function of their target cells. Two agents, G-CSF (granulocyte colony-stimulating factor) and GM-CSF (granulocyte-macrophage colony-stimulating factor) are commercially available in the United States. G-CSF (filgrastim) specifically stimulates the production of neutrophilic granulocytes. GM-CSF (sargramostim) promotes the proliferation of granulocytes (neutrophils and eosinophils) and monocytes/macrophages. Although GM-CSF stimulates megakaryocytes, no consistent effect on platelet production has been observed in clinical trials. Both agents initially enhance demargination and mobilization of mature cells from the marrow and then provide constant stimulation of stem cell progenitors. Colony-stimulating factors are produced by recombinant DNA technology, and several host cells are used to produce CSFs, including bacteria (*Escherichia coli*), yeast, and mammalian cells (Chinese hamster ovary cells) (Table 124–19). Products derived from yeast or mammalian sources are glycosylated to varying degrees, as are naturally occurring CSFs, whereas those derived from *E. coli* are nonglycosylated. This difference does not result in any clinically significant effects on neutrophil production. Pegfilgrastim is a long-acting CSF, created by addition of a polyethylene glycol molecule to G-CSF. Clinical trials have demonstrated that a single dose of pegfilgrastim provides equivalent effects to 10 to 11 days of daily G-CSF, with similar side-effect profiles.

The CSFs reduce the incidence, magnitude, and duration of neutropenia when used as preventive therapy following a variety of myelosuppressive chemotherapy regimens.^{122–124} These effects have been accompanied by a modest decrease in febrile days, fewer infections, and fewer days on antibiotics. In some studies, use of CSFs also resulted in a decrease in the incidence of mucositis. Growth factors have also permitted the administration of subsequent chemotherapy courses on schedule, resulting in enhanced dose intensity. However, the increased dose intensity provided by the CSFs has not yet been found to translate into improved tumor response or survival. Because of lack of impact on response rates and survival, decisions regarding appropriate use of growth factors are based on weighing proven clinical benefits against economic considerations. The American Society of Clinical Oncology has developed evidence-based clinical practice guidelines to promote appropriate use of the CSFs.^{123–124}

Growth factors may be used in either the primary or secondary prophylaxis of neutropenia. Primary prophylaxis refers to the use of CSFs to prevent neutropenia with the first cycle of chemotherapy. This strategy is only clinically and economically appropriate for

FIGURE 124-13. Sites of action of hematopoietic growth factors in the differentiation and maturation of marrow cell lines. A self-sustaining pool of marrow stem cells differentiates under the influence of specific hematopoietic growth factors to form a variety of hematopoietic and lymphopoietic cells. Stem cell factor (SCF), FTL-3 ligand (FL), interleukin-3 (IL-3), and granulocyte/macrophage colony-stimulating factor (GM-CSF), together with cell-cell interactions in the marrow, stimulate stem cells to form a series of burst-forming units (BFU) and colony-forming units (CFU): CFU-GEMM, granulocyte, erythrocyte, monocyte, and megakaryocytes; GM, granulocyte and macrophage; Meg, megakaryocyte; E, erythrocyte). After considerable proliferation, further differentiation is stimulated by synergistic interactions with growth factors for each of the major cell lines—granulocyte colony-stimulating factor (G-CSF), monocyte/macrophage-stimulating factor (M-CSF), thrombopoietin, and erythropoietin. Each of these factors also influences the proliferation, maturation, and, in some cases, the function of the derivative cell line. (Adapted from Hillman RS. Hematopoietic agents: Growth factors, minerals and vitamins. In: Hardman JG, Limbird LE, Gilman AG, eds. Goodman & Gilman's The Pharmacologic Basis of Therapeutics, 10th ed. New York, McGraw-Hill, 2001:1489.)

patients who are receiving a chemotherapy regimen associated with febrile neutropenia in more than 40% of patients.¹²⁴ Models to predict the likelihood of developing neutropenia after chemotherapy are under development, and if validated, may serve to identify patients most likely to benefit from primary prophylaxis.¹²⁵ Secondary prophylaxis refers to the use of growth factors to prevent recurrent neutropenia in patients who experienced neutropenia with the prior cycle of chemotherapy. Because this method of using CSFs has not been demonstrated to improve disease-free or overall survival, it is recommended that secondary prophylaxis be reserved for patients with curable malignancies where dose should not be compromised.¹²⁴

Although both G-CSF and GM-CSF are used clinically to prevent febrile neutropenia after administration of standard doses of chemotherapy, only G-CSF is FDA-approved for this indication. One exception is in the induction treatment of acute myelogenous leukemia, in which both G-CSF and GM-CSF have been demonstrated to reduce the duration of neutropenia, often accompanied by modest decreases in hospitalization and infectious complications. Benefits

have been most clearly documented in patients older than age 55 years. Similar data are available for G-CSF in the treatment of patients with acute lymphoblastic leukemia. These beneficial effects, however, have not resulted in improved response rates or overall survival.¹²⁴

Only a few studies have addressed the role of CSFs in the treatment of established neutropenia.^{123,124} These studies suggest no or only minimal clinical benefit from use of CSFs. At this time, the CSFs should not be routinely employed in patients with established neutropenia, regardless of the presence of fever. Both CSFs have also proven effective in acceleration of hematopoietic engraftment and in treatment of graft failure following hematopoietic stem cell transplantation. Other uses for the CSFs include peripheral blood stem cell mobilization, neutropenia in patients with acquired immune deficiency syndrome, myelodysplastic syndromes, congenital neutropenia, and aplastic anemia. Growth factors should not be used in patients receiving concomitant chemotherapy and radiotherapy, especially if the radiation involves the mediastinum. These patients appear to experience more significant thrombocytopenia when administered CSFs.

TABLE 124-19. Granulocyte Colony-Stimulating Factor (G-CSF) and Granulocyte-Macrophage Colony-Stimulating Factor (GM-CSF) Products and Sources

| CSF | Generic Name | Brand Name | Manufacturer | Recombinant DNA Source |
|--------|---------------|------------------------|--------------------------|---|
| G-CSF | Filgrastim | Neupogen | Amgen | <i>Escherichia coli</i> |
| | Pegfilgrastim | Neulasta | Amgen | |
| | Lenograstim | Granocyte ^a | Chugai/Rhone Poulenc | Chinese hamster ovary cells |
| GM-CSF | Sargramostim | Leukine | Berlex | <i>Saccharomyces cerevisiae</i> (yeast) |
| | Molgramostim | Leucomax ^a | Novartis/Schering-Plough | <i>E. coli</i> |

^aNot approved by the FDA; available outside the U.S.

At currently recommended doses, the CSFs are well tolerated. Side effects are more commonly seen with GM-CSF and may be related to the drug's ability to enhance binding of neutrophils to endothelial cells or to activation of monocytes/macrophages, which may stimulate the release of cytokines such as IL-1 and tumor necrosis factor.¹²² The most common toxicity of the CSFs is bone pain (20% to 25% of patients), which can be treated with acetaminophen or nonsteroidal anti-inflammatory drugs. Bone pain was the most significant toxicity seen in clinical trials with G-CSF. Other side effects of G-CSF include an increase in lactate dehydrogenase, alkaline phosphatase, and uric acid levels. Additional toxicities of GM-CSF include constitutional symptoms, such as low-grade fever, myalgias, arthralgias, lethargy, and mild headache. GM-CSF may also produce an elevation in liver transaminases. At higher doses of GM-CSF, pleural and pericardial effusions, capillary-leak syndrome, and thrombus formation may occur. A first-dose reaction described after GM-CSF administration has been reported more commonly with the *E. coli*-derived product (molgramostim), which is not commercially available in the United States. This reaction is more common after intravenous infusion and consists of dyspnea, facial flushing, hypotension, hypoxia, and tachycardia. Both G-CSF and GM-CSF may produce mild erythema at subcutaneous injection sites, as well as a generalized maculopapular rash with either subcutaneous or intravenous administration.

For prophylaxis of chemotherapy-induced neutropenia, CSF therapy should not begin sooner than 24 hours after the last dose of chemotherapy and should be continued until the ANC exceeds a safe level following the expected chemotherapy nadir. In the setting of bone marrow transplantation, CSFs should not begin sooner than 24 hours after the last dose of chemotherapy or 12 hours after the last radiotherapy treatment. The recommended starting dose of G-CSF is 5 mcg/kg per day in all settings except for peripheral blood stem cell mobilization, where doses of 10 mcg/kg per day are usually used. For pegfilgrastim, a single dose of 6 mg administered 24 hours after chemotherapy is used. The recommended dose of yeast-derived GM-CSF is 250 mcg/m² per day. Pharmacokinetic data favor subcutaneous injection as the most effective route. However, in patients in whom subcutaneous injections are not feasible (e.g., where there is anasarca), G-CSF and GM-CSF may be given intravenously. Pegfilgrastim should not be given intravenously. Because of the high cost associated with CSF use, alternative dosing regimens have been explored. These regimens attempt to decrease the total amount of CSF used by either delaying the start of CSFs (e.g., to day 3 after chemotherapy), decreasing the dose (e.g., to 3 mcg/kg per day of G-CSF), or decreasing the duration of CSF therapy. Specifically, the posttreatment target ANC of 10,000/mm³ recommended by product information is often reduced to an ANC of greater than 2,000 or 5,000/mm³ in clinical practice. Standardized doses of 300 mcg or 480 mcg of G-CSF and 500 mcg of GM-CSF, based on product vial sizes, are often used to minimize waste. For patients receiving pegfilgrastim, it is important that additional CSF not be administered for the 10 days following administration, as additional benefit is not realized.

THROMBOCYTOPENIA

Chemotherapy-induced thrombocytopenia puts the patient at risk for significant bleeding. To date, platelet transfusions remain the mainstay of management.¹²⁶ At most centers, platelet transfusion is indicated for patients with a platelet count of <10,000/mm³, or for patients with lesser degrees of thrombocytopenia with signs or symptoms of hemorrhage. Patients with thrombocytopenia who must undergo a surgical procedure are also appropriate candidates for transfusion. For patients with nonmyeloid malignancies who experienced significant

thrombocytopenia with a prior cycle of chemotherapy, oprelvekin (IL-11) may be considered as secondary prophylaxis. When used after chemotherapy regimens associated with a high risk of thrombocytopenia, oprelvekin decreased the need for platelet transfusions, as well as the numbers of platelets required for transfusion.¹²⁷ Unfortunately, oprelvekin is associated with some significant adverse effects, mostly related to fluid retention (e.g., edema, dilutional anemia, dyspnea, and pleural effusions). Cardiac toxicity, especially tachycardia, and atrial fibrillation and flutter have also been observed. Prophylactic oprelvekin is also significantly more expensive than platelet transfusions.¹²⁸ Considering the modest clinical benefit, the adverse effects, and the high cost, oprelvekin use should be reserved for patients at high risk for severe thrombocytopenia from chemotherapy where dose reduction is known to compromise disease response. Other CSFs such as interleukins-1, -3, and -6, have also been studied, but significant impact on platelet counts with an acceptable adverse-effect profile has not been demonstrated. The discovery and development of thrombopoietin, a megakaryocyte-stimulating factor, may represent the most significant factor in the future of thrombocytopenia treatment.

ANEMIA

13 Anemia is a common hematologic complication of cancer chemotherapy.¹²⁹ The incidence of anemia depends on several factors, including the type and duration of therapy, and the type and stage of the underlying malignancy. For example, cisplatin and carboplatin are more commonly associated with anemia than many other chemotherapeutic agents. Multiple conditions are known to cause anemia in cancer patients, including chronic gastrointestinal blood loss, nutrient deficiency (e.g., iron and folate), chemotherapy and radiation therapy, bone marrow invasion by the tumor, hemolysis, renal dysfunction, and anemia of chronic disease. Of all the signs and symptoms of anemia, fatigue is most common in cancer patients.^{129,130} In fact, fatigue is the most commonly reported symptom overall in patients undergoing chemotherapy. The presence of fatigue is correlated with the severity of anemia; treatment of anemia results in improvement in fatigue and quality of life. Anemia is only one of many possible causes of fatigue in patients with cancer. Other common causes of fatigue include insomnia, depression, unrelieved pain, and the underlying malignancy.

Previously, the only option for the treatment of chemotherapy-related anemia was red blood cell transfusions. This intervention is still the mainstay of acute management, but the availability of the recombinant human erythropoietic products—epoetin alfa and darbepoetin alfa—has provided another therapeutic tool.¹²⁹ Several studies have documented the efficacy of these agents in the anemia associated with chemotherapy. Both epoetin alfa and darbepoetin alfa increase hemoglobin and hematocrit, decrease transfusion requirements, and improve quality of life. Several early indicators of response have been derived, including an increase in hemoglobin of 0.5 to 1 g/dL above baseline, a decline in ferritin, or an increase in the absolute reticulocyte count after 2 to 4 weeks of therapy. These surrogate end points can be used to identify nonresponders early, so that therapy may be modified or discontinued, as indicated. Serum erythropoietin levels have minimal utility in predicting response or monitoring therapy.

Clinical practice guidelines to guide the appropriate use of erythropoietic agents have been developed (Fig. 124–14).¹³¹ The first step is to evaluate the underlying cause of the anemia and initiate specific therapy as indicated. For example, patients with iron deficiency anemia should receive iron supplementation. Patients with chronic bleeding or hemolysis should not receive erythropoietic therapy, as

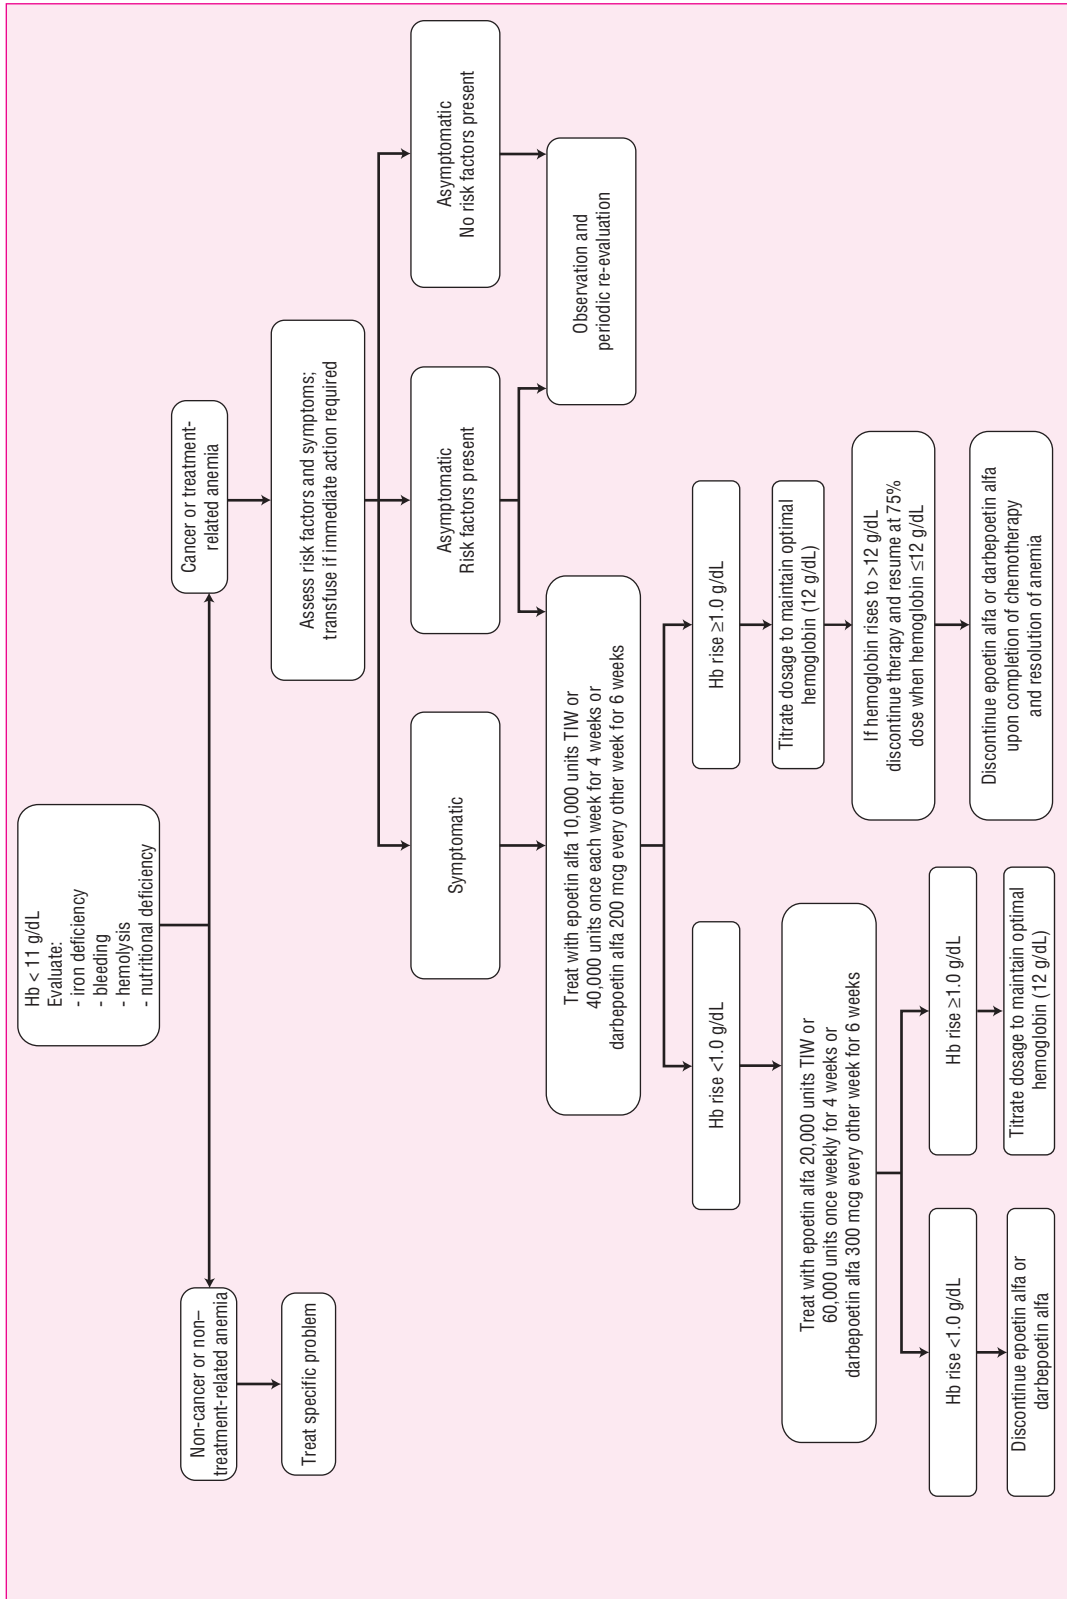

FIGURE 124-14. 2004 National Comprehensive Cancer Network clinical practice guidelines for cancer and treatment-related anemia.

this does not target the underlying cause of their anemia. Epoetin alfa and darbepoetin alfa should be considered for chemotherapy- or cancer-related anemia only after otherwise treated causes of anemia have been ruled out. These patients can be started on either epoetin alfa at a dose of 10,000 units three times a week or 40,000 units once each week, or darbepoetin alfa at a dose of 200 mcg every other week. After 4 to 6 weeks, the hemoglobin should be reassessed. In patients who do not achieve at least a 1-g/dL rise in hemoglobin, the dose should be increased as shown in Fig. 124–14. Treatment should be discontinued in patients who do not respond after 4 to 6 weeks at the higher dose. Iron deficiency should be ruled out as a cause of treatment failure prior to discontinuing therapy. Erythropoietic therapy should also be discontinued in patients who complete planned chemotherapy or in those who have resolution of their anemia (hemoglobin level 12 to 13 g/dL).

MUCOSITIS

The gastrointestinal mucosa is composed of epithelial cells with a high mitotic index and rapid turnover rate, making it a common site of chemotherapy-induced toxicity.^{132,133} The subsequent inflammation, or mucositis, can lead to painful ulcerations, local infection, and inability to eat, drink, or swallow. Disruption of the GI mucosal barrier may also provide an avenue for systemic microbial invasion. The time course for development and resolution of mucositis often parallels that of neutropenia. Agents most commonly associated with mucositis include 5-FU, doxorubicin, and methotrexate. Currently, the most effective means of preventing mucositis is through good oral hygiene. Patients at high risk for this toxicity (those with poor dentition, high-dose chemotherapy, or radiation therapy involving the oropharynx) should be evaluated by a dentist prior to chemotherapy and should be instructed to rinse their mouths frequently with baking soda and salt water or plain saline rinses during and between courses of chemotherapy. Clinical practice guidelines for the prevention and treatment of cancer therapy-induced mucositis have recently been published.¹³⁴ The benefit of chlorhexidine rinses over saline rinses is unclear. In patients undergoing radiation therapy to the head and neck region, chlorhexidine rinses have detrimental effects on the oral mucosa. For patients receiving 5-FU treatment, the use of ice (oral cryotherapy) may decrease the risk for mucositis by decreasing drug delivery to the oral mucosa. A better understanding of the pathobiology of mucositis has resulted in identification of promising new agents to better prevent mucositis. The keratinocyte growth factors palifermin and repifermin are in clinical trials for prevention of chemotherapy-induced mucositis, and one of these agents (i.e., palifermin) was approved by the FDA in December 2004 for use in patients receiving high-dose chemoradiotherapy prior to hematopoietic stem cell transplantation.

After mucositis has developed, treatment is mainly supportive, including use of topical or systemic analgesics and oral hygiene (including the rinses described).^{132,134} Viscous lidocaine, diphenhydramine liquid, and dyclonine are topical anesthetics commonly employed. Severe cases of mucositis may lead to dehydration and require intravenous hydration. Local infections caused by *Candida* species and reactivation of herpes simplex viruses are common in these patients. Suspicious lesions should be cultured, and appropriate antifungal and/or antiviral treatment should then be instituted. Antifungal therapy may be delivered topically for mild infections (thrush) using clotrimazole troches or nystatin oral suspension. For more severe oral or esophageal fungal infections, systemic treatment with oral fluconazole or intravenous amphotericin B is indicated.

Mucosal damage can occur at any point along the entire length of the GI tract. In the lower portion of the GI tract, this damage is

usually manifested as diarrhea (mild to life-threatening in nature) and abdominal pain. Support with intravenous fluids and electrolyte supplementation should be initiated promptly in severe cases. After infectious causes have been ruled out, diarrhea can safely be treated with antispasmodics such as Lomotil or loperamide. The somatostatin analog octreotide has also been used successfully to treat severe cases of chemotherapy-induced diarrhea. The specific treatment of early and late diarrhea from irinotecan is summarized in Table 124–13.

ALOPECIA

Although not a life-threatening side effect of chemotherapy, the toxicity that many patients find most distressing is alopecia. Alopecia from chemotherapy is usually temporary, and the degree of hair loss varies widely.¹³⁵ Loss of hair is not limited to the scalp; any area of the body may be affected. Patients receiving a taxane as part of their chemotherapy regimen are especially prone to total body alopecia. Hair loss usually begins 1 to 2 weeks after chemotherapy, and regrowth may begin before the chemotherapy courses are completed. Cryotherapy (local application of ice) and scalp tourniquets have both been investigated as methods of preventing alopecia. Both techniques produce vasoconstriction, resulting in decreased exposure of hair follicles to the chemotherapy agents. These techniques are not uniformly effective and are contraindicated in patients with cancers that may metastasize to the scalp, such as leukemia and lymphoma.

EXTRAVASATION

Vesicants are antineoplastic agents that may cause severe tissue damage if they escape from the vasculature.^{136,137} These agents include the anthracyclines, actinomycin D, the vinca alkaloids, mitomycin C, nitrogen mustard, and the taxanes. The anthracyclines are the most notorious agents, and the most extensively investigated. The tissue damage may result in prolonged pain, tissue sloughing, infection, and loss of mobility. Prompt initiation of the appropriate interventions is important to minimize morbidity. Unfortunately, most information on extravasation management is anecdotal; few controlled clinical studies have been conducted to determine optimal intervention strategies. Therefore prevention has become the focus of extravasation management. The most important method of prevention is good administration technique,¹³⁶ but even then, extravasations may occur. The vein selected for administration should be on the distal portion of the arm. The large veins of the forearm are desirable because if a drug does extravasate, there is adequate soft-tissue coverage to protect crucial structures like nerves and tendons, and joint function is not put at risk. Peripherally administered vesicants should be given slowly via intravenous injection (IV push) through the side arm of a running IV. The person administering the vesicant should verify needle stability and adequate blood return after each 1 to 2 mL of drug is injected. Vesicants should not be administered by intravenous infusion unless the patient has a central venous catheter. For extravasation of vesicants, one of the most important interventions is the application of ice packs to the affected area. One exception to this rule is the vinca alkaloids, which are better managed with application of heat. Only a few antidotes to vesicant agents are employed clinically. Sodium thiosulfate is used to neutralize nitrogen mustard extravasations, and hyaluronidase (if available) can improve the outcome after extravasation of vinca alkaloids, etoposide, and taxanes. Topical application of dimethyl sulfoxide may be an effective method for managing anthracycline and mitomycin C extravasations.¹³⁷

INFERTILITY

14 Advances in the treatment of some cancers, such as Hodgkin's disease and testicular cancer, have produced long-term survivors and the opportunity to examine the late consequences of chemotherapy administration. Infertility and secondary cancers have emerged as important late effects. The gonadal toxicities of chemotherapy have not received much attention in the past because they are not life threatening. High rates of fertility deficits and sexual dysfunction have been noted for both men and women.^{138,139} In men the antitumor drugs have been shown to produce severe oligospermia or azoospermia as well as infertility. Serum testosterone levels are only rarely altered. The recovery of spermatogenesis after completion of chemotherapy is unpredictable. Men receiving combination chemotherapy appear to sustain more long-lasting adverse effects on fertility than men receiving single-agent therapy. Age, total dose, duration of therapy, and type of drug are other important variables. In women, toxic effects on the ovaries result clinically in amenorrhea, vaginal epithelial atrophy, and menopausal symptoms. These effects are related to dose and age. Younger patients are more resistant to the effects on the ovaries. As with men, the recovery of fertility is unpredictable, but women younger than 25 years of age appear to have the best outcomes. The effects of the alkylating agents on fertility have been extensively studied. This group of drugs exerts profound and consistently detrimental effects on reproductive function. Less is known about commonly used agents such as doxorubicin, taxanes, and platinum compounds. Patients with potentially curable tumors who desire to have children in the future should be informed about the risk for infertility and sperm or oocyte banking options.

SECONDARY MALIGNANCIES

Secondary cancers induced by chemotherapy and radiation are a serious long-term complication.¹⁴⁰ Although many types of solid tumors have been reported as chemotherapy-induced malignancies, acute nonlymphocytic leukemia (ANLL) or myelodysplastic syndrome is the most common secondary cancer. ANLL or myelodysplastic syndrome has been reported following successful treatment of Hodgkin's lymphoma, acute leukemias, non-Hodgkin's lymphomas, multiple myeloma, breast cancer, and advanced ovarian cancer. For curable cancers, the relatively small risk for occurrence of secondary malignancies is far outweighed by the benefits of survival in large numbers of patients. However, for cancers such as ovarian cancer, the risk of leukemia is not offset by improved survival in chemotherapy recipients. The issue of secondary malignancies is of particular concern in patients receiving adjuvant chemotherapy. As with the late complication of infertility, the antineoplastic agents primarily associated with secondary cancers are the alkylating agents. Etoposide, teniposide, and the anthracyclines have also been linked to secondary leukemias. Solid tumors as secondary malignancies occur more commonly after treatment with radiation than with chemotherapy.

SAFETY AND HANDLING ISSUES

As discussed previously, the cytotoxic drugs used to treat cancer are carcinogenic, mutagenic, and teratogenic. Consequently, these drugs should be handled with care to avoid inadvertent exposure of health care professionals.¹⁴¹ All pharmacies should have written procedures for handling these drugs safely, and all personnel should be oriented to these procedures. The most common avenue of exposure is via inhalation of aerosolized drug. Individuals preparing chemotherapy should work in a class II biologic safety cabinet and wear gowns and powder-free disposable latex gloves. The gowns should be made

of lint-free, low-permeability fabric with a solid front, long sleeves, and tight-fitting elastic cuffs. Negative-pressure techniques should be employed in drug preparation to minimize aerosolization. Health care workers administering these agents should take similar precautions to avoid exposure. Kits for cleaning up chemotherapy spills should be located in all areas of the institution in which chemotherapy is handled. Cytotoxic waste should be disposed of properly, and patients should be informed of proper methods of disposing of potentially contaminated body excreta and cytotoxic waste.

CANCER PREVENTION

15 Since many cancers are difficult to treat, especially in the advanced stages, cancer prevention has become an intense focus of cancer research. For some cancers, effective pharmacologic means of cancer prevention have been identified, such as tamoxifen for breast cancer prevention. Specific chemoprevention strategies will be discussed in disease-specific cancer chapters of this text. There are also general strategies known to prevent or reduce the risk of many malignancies, including modification of nutritional factors, increased physical activity, and reductions in exposure to known carcinogens, such as tobacco and the sun.

NUTRITION AND PHYSICAL ACTIVITY

The relationship between diet and cancer is the subject of intense investigation. There is evidence that suggests that up to one-third of cancer deaths in the United States are attributable to dietary factors.¹⁷ Although controversy exists over the true role of diet in carcinogenesis, some general recommendations have been developed by the American Cancer Society (Table 124–20).¹⁷ There is strong evidence that increased consumption of fruits and vegetables lowers the risk for many cancers, especially those of the gastrointestinal and respiratory tracts. Consumption of a high-fat diet appears to increase the risk for breast, colorectal, and prostate cancers. The average American consumes 36% to 38% of daily calories as fat. A decrease in fat intake to less than 30% of daily calories may decrease the risk for developing cancer, as well as heart disease. Obese individuals have increased risk of several cancers, including colorectal, breast, biliary, and uterine cancers. The inverse relationship between dietary fiber and colon cancer has received much attention. The American diet is typically low in fiber (11 g/day). High fiber intake (20 to 30 g/day) may decrease the risk of colon cancer. A high alcohol intake has been shown to increase the risk for many upper aerodigestive tract malignancies, especially in smokers.

Obesity and inactivity are also an important determinant of cancer risk. Increased physical activity is known to decrease the risk for breast, colon, endometrial, and prostate cancers.¹⁷ Recommendations to increase physical activity and maintain a healthful weight are included in the American Cancer Society Cancer Prevention Guidelines.

TOBACCO

Cigarette smoking remains the most preventable cause of premature death in the United States. More than 400,000 deaths per year and 30% of all cancers in the United States are due to smoking.¹⁴² For many types of cancer, the underlying etiology is unknown. One notable exception is lung cancer; cigarette smoking is the major cause of this disease. More than 90% of all cases of lung cancer are diagnosed in smokers. Tobacco smoking also increases the relative risk for development of many other types of cancer, including cancers of

TABLE 124–20. American Cancer Society Guidelines on Nutrition and Physical Activity for Cancer Prevention**Recommendations for individuals**

1. *Eat a variety of healthful foods, with an emphasis on plant sources.*
 - Eat five or more servings of a variety of vegetables and fruits each day.
 - Choose whole grains in preference to processed (refined) grains and sugars.
 - Limit consumption of red meats, especially high-fat and processed meats.
 - Choose foods that help maintain a healthful weight.
2. *Adopt a physically active lifestyle.*
 - Adults should engage in at least moderate activity for 30 minutes or more on five or more days of the week; 45 minutes or more of moderate to vigorous activity on five or more days per week may further enhance reductions in risk of breast and colon cancer.
3. *Maintain a healthful weight throughout life.*
 - Balance caloric intake with physical activity.
 - Lose weight if currently overweight or obese.
4. *If you drink alcoholic beverages, limit consumption.*

Recommendations for community action

Public, private, and community organizations should work to create social and physical environments that support the adoption and maintenance of healthy nutrition and physical activity behaviors.

- Increase access to healthful foods in schools, worksites, and communities.
- Provide safe, enjoyable, and accessible environments for physical activity in schools and for transportation and recreation in communities.

From American Cancer Society.¹⁷

the mouth, pharynx, larynx, esophagus, and bladder. Passive inhalation of exhaled tobacco by-products and cigarette smoke represents a significant risk factor for lung cancer in the nonsmoking population. Smokeless tobacco has been connected to the development of oral cancers. Abstinence from chewing and smoking tobacco is believed to be a major factor in the prevention of these malignancies.

SUN EXPOSURE

The association between sun exposure and skin neoplasms is also well established. The incidence of both nonmelanomatous skin cancer and melanoma has steadily increased in past decades, paralleling the increase in recreational sun exposure.¹⁴³ During this same time period, protection from ultraviolet light exposure normally provided by the ozone layer has been compromised. Fair-skinned individuals who sunburn easily are particularly at high risk. Melanoma and skin cancers can be largely prevented by minimizing exposure to the sun and by applying strong sunscreens and sunblocks to sun-exposed areas (SPF-15 or greater).

ABBREVIATIONS

ANC: absolute neutrophil count
 ANLL: acute nonlymphocytic leukemia
 ara-C: cytarabine
 ara-CTP: active triphosphate form of cytarabine
 BCNU: carmustine
 CCNU: lomustine
 2-CDA: cladribine (2-chlorodeoxyadenosine)
 CDK: cyclin-dependent kinase
 CMF: cyclophosphamide, methotrexate, and 5-fluorouracil
 CR: complete response
 CSF: colony-stimulating factor
 DHFR: dihydrofolate reductase
 DNA: deoxyribonucleic acid
 EGFR: epidermal growth factor receptor
 FAMP: fludarabine monophosphate

FdUMP: fluorodeoxyuridine monophosphate
 5-FU: fluorouracil
 G₀: dormant phase of the cell cycle
 G₁: first gap phase of the cell cycle
 G₂: second gap or premitotic phase of the cell cycle
 G-CSF: granulocyte colony-stimulating factor
 GM-CSF: granulocyte-macrophage colony-stimulating factor
 HDAC: high-dose ara-C
 IFN: interferon
 IL: interleukin
 M: mitosis
 MoAB: monoclonal antibody
 6-MP: 6-mercaptopurine
 mRNA: messenger RNA
 MTIC: monomethyl triazeno imidazole carboxamide
 MTX: methotrexate
 NF- κ B: nuclear factor- κ B
 PR: partial response
 RAR: retinoic acid receptor
 RNA: ribonucleic acid
 rRNA: ribosomal RNA
 RXR: retinoid X receptor
 S: DNA synthesis phase of the cell cycle
 6-TG: thioguanine
 tRNA: transfer RNA
 VEGF: vascular endothelial growth factor
 WBC: white blood cell

BREAST CANCER

Celeste Lindley and Laura Boehnke Michaud

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Breast cancer is most commonly diagnosed in early stages, when it is a highly curable malignancy.
- 2 Local therapy of early stage breast cancer consists of modified radical mastectomy or lumpectomy plus external beam radiation therapy. The surgical approach to the ipsilateral axilla may consist of a full level I/II axillary lymph node dissection or a lymph node mapping procedure with sentinel lymph node biopsy.
- 3 Adjuvant endocrine therapy reduces the rates of relapse and death in patients with hormone-receptor positive early breast cancer tumors. Adjuvant chemotherapy reduces the rates of relapse and death in all patients with early stage breast cancer.
- 4 The choice of chemotherapy regimen, dose, schedule and duration of therapy, and the choice of endocrine therapy are controversial and rapidly changing as results from ongoing randomized clinical trials are reported.
- 5 Neoadjuvant chemotherapy is appropriate for patients with locally advanced or inflammatory breast cancer, followed by local therapy and further adjuvant systemic therapy.
- 6 Initial therapy of metastatic breast cancer in women with hormone receptor–positive tumors should consist of hormonal therapy.
- 7 Women with metastatic breast cancer who have hormone receptor–positive tumors and respond to an initial hormonal manipulation will usually respond to a second hormonal manipulation.
- 8 Approximately 40% of women with metastatic breast cancer will respond to chemotherapy regimens; doxorubicin- and taxane-containing regimens are the most active.
- 9 The goal of adjuvant chemotherapy is curative, while the goal of chemotherapy in the metastatic setting is palliative.
- 10 Although controversial, the benefits of annual screening mammography in women younger than 50 years of age are apparent and a large number of national and international studies demonstrate a 20% to 40% reduction in breast cancer mortality from annual or biannual screening mammography in women aged 50 to 70 years.

Breast cancer is the most common site of cancer and is second only to lung cancer as a cause of cancer death in American women. It is estimated that 211,240 new cases of breast cancer will be diagnosed and that 40,410 women will die of breast cancer in 2005.¹ Whites account for the largest portion of estimated cases (82%) and deaths (80%). In addition to invasive breast cancers, it is estimated that 58,490 cases of in situ cancer will be diagnosed among women in the United States in 2005.

Female breast cancer incidence rates vary considerably across racial and ethnic groups. The average annual age-adjusted incidence rate from 1997 to 2001 was 141.7 cases per 100,000 among white females, 119.9 among blacks, 96.8 among Asian-Americans/Pacific Islanders, 89.6 in Hispanics, and 54.2 in American Indians/Alaska Natives.² Probable reasons for the higher incidence rates in whites than other racial and ethnic groups include genetic, reproductive, and lifestyle factors.³ Female breast cancer incidence rates increased for all women combined from 1980 to 2001, although the rate of increase slowed in the 1990s. The temporal trends in incidence are shown by race and ethnicity in Fig. 125–1. Incidence rates continued to increase in white women (0.4% per year, 1987–2001), but have stabilized in black women since 1992. In other racial and ethnic groups, rates increased from 1992 through 2001 in Asian-Americans/Pacific

Islanders (1.7% per year) and Hispanics (0.7% per year), but decreased among American Indians/Alaska Natives (3.7% per year).²

1 Most breast cancers diagnosed are small tumors (≤ 2 cm) and disease is localized in all racial and ethnic groups. However, blacks and other minority women have proportionally more cases of disease diagnosed at more advanced stages compared with white women. This is thought to reflect access to and use of screening mammography and timely treatment. The incidence of ductal carcinoma in situ (DCIS) increased rapidly between the early and late 1980s, stabilized between the late 1980s and early 1990s, and increased rapidly thereafter. The rapid increases in DCIS are largely attributed to increased use of screening mammography, because most cases of DCIS manifest solely as clustered microcalcifications seen on mammography.³

Figure 125–1 shows trends in female breast cancer mortality rate by race and ethnicity. From 1997 to 2001, the average breast cancer death rate was highest in blacks (35.4 cases per 100,000 women), followed by whites (26.4), Hispanics (17.3), American Indians/Alaska Natives (13.6), and Asian-Americans/Pacific Islanders (12.6).² The death rate is higher among blacks than white women despite the lower incidence. Breast cancer death rates decreased by 2.6% per year among white women and by 1.2% per year since 1992 among

FIGURE 125-1. Breast cancer incidence and mortality rates by race, 1975–2001. (From Ries et al.²)

black women. These declines in breast cancer mortality have been attributed to changes in screening practices and effectiveness of adjuvant systemic therapy following primary local regional therapy. The disparity between white and black women can be explained by differences in timely diagnosis through mammography screening and unequal access to prompt, high-quality treatment.³

EPIDEMIOLOGY AND ETIOLOGY

The two variables most strongly associated with the occurrence of breast cancer are gender and age. Although one commonly thinks of breast cancer as a disease confined to women, about 1,690 cases of male breast cancer were projected to be diagnosed in the United States in 2005.¹ Although male gender had been considered a poor prognostic factor in some investigations, it is now believed that higher mortality rates in men are attributable to more advanced disease at the time of diagnosis. When stage and other known prognostic factors are controlled for, men do not fare any differently from their female counterparts. Similarly, treatment of male breast cancer is no different from treatment of breast cancer in females.

The incidence of breast cancer increases with advancing age. Perhaps the most frequently quoted breast cancer statistic is that one in seven women will develop breast cancer during their lifetime. It should be emphasized that this is a cumulative lifetime risk of developing the disease from birth to age 110, and that the estimates are weighted by the probability of surviving through each decade of life.⁴ Women older than 90 years of age contribute very little to the overall risk statistic because their numbers are so small. The “one in seven women” figure is often misinterpreted by women who assume that it

translates into one in seven women being diagnosed with breast cancer each year. Feuer and colleagues developed a more useful method of presenting the risk data based on age intervals.⁴ As Table 125-1 demonstrates, the risk of a woman developing breast cancer before the age of 40 years is about 1 in 250. It is apparent from this table that although the cumulative probability of developing breast cancer increases with increasing age, more than half of the risk occurs after age 60 years.

An understanding of the relationship between age and the incidence of breast cancer is particularly relevant when one discusses “risk factors” or factors other than age that increase a woman’s probability of developing breast cancer. The relative risk (RR) of developing breast cancer for an individual woman in a defined risk group is usually multiplied by the probability of a woman developing breast cancer during her lifetime, and this figure is taken as the cumulative lifetime risk of that individual developing breast cancer. However, the

TABLE 125-1. Risk of Developing Breast Cancer in SEER Areas, Women, All Races 1998–2000

| Age Interval (y) | Probability (%) of Developing Invasive Breast Cancer During the Interval |
|---------------------|--|
| 30–40 | 0.40 or 1 in 250 |
| 40–50 | 1.45 or 1 in 69 |
| 50–60 | 2.78 or 1 in 36 |
| 60–70 | 3.81 or 1 in 26 |
| From birth to death | 13.51 or 1 in 7 |

From Ries LAG, Eisner MP, Kosary CL, eds. SEER Cancer Statistics Review: 1975–2001. Bethesda, MD, <http://seer.cancer.gov/csr/1975–2001/>, 2004.

risk of developing breast cancer is age dependent. Therefore a more meaningful way to counsel patients regarding their risk of developing breast cancer based on the presence of a known risk factor incorporates an age-specific incidence rate, not cumulative lifetime risk. For example, if a 40-year-old woman with a strong family history of breast cancer is thought to have a relative risk ratio of 2.0, her risk of developing breast cancer by the age of 50 is only 2.9% (2×1.45) not 27.02% (2×13.51) (see Table 125–1). It is also important to note that recognized risk factors are not additive in a simple mathematical sense and that the observed cumulative lifetime risk associated with nongenetic risk factors has rarely exceeded 30% (1 in 3) in any study, regardless of the number and significance of individual risk factors. Finally, it should be emphasized that more than 60% of women with breast cancer have no identifiable major risk factor, indicating that the search for the etiology of this disease is largely incomplete.

A number of calculators are available on the internet to estimate a patient's risk of developing breast cancer. The National Cancer Institute (NCI) has an online version of the Breast Cancer Risk Assessment Tool that is considered the most authoritative and accurate standard (<http://brca.nci.nih.gov/brc/q1.htm>). This tool used the original Gail Model, named after the author of a number of publications that described the scientific basis for risk calculations and applied it to data from the Breast Cancer Detection and Demonstration Project, a mammography screening project conducted in the 1970s. The Breast Cancer Risk Assessment Tool was designed for health professionals to project a women's individualized risk for invasive breast cancer over a 5-year period and over her lifetime.

ENDOCRINE FACTORS

A number of endocrine factors have been linked to the incidence of breast cancer.^{5,6} Many of these relate to the total duration of menstrual life. Early menarche, generally defined as menstruation beginning before age 12, has been shown by a number of investigators to increase the cumulative lifetime risk of breast cancer development compared to menarche at age 16 or greater. Conversely, early age of natural menopause has been shown to result in a reduction of risk. Similarly, investigators have reported that bilateral oophorectomy prior to age 35 reduces the relative risk of developing breast cancer.

Nulliparity and a late age at first birth (≥ 30 years) have been reported to increase the lifetime risk of developing breast cancer twofold. Women who have their first child after the age of 35 have a slightly higher risk than a nulliparous woman. It has been suggested that the period between the onset of menses and the age of first pregnancy provides a "window of initiation" for the development of breast cancer. This is a time when an unbalanced hormonal environment reacts with the abundant and highly responsive breast tissue. Investigators have postulated that international differences in age of menarche, age at menopause, and childbearing may account for a substantial part of the international differences in the incidence of breast cancer. In underdeveloped countries where the incidence of breast cancer is low compared to the United States, a late onset of menarche is the rule, and frequently there is a decreased interval between puberty and first pregnancy, followed by several pregnancies and early menopause.

Many studies have evaluated the relationship between exogenous hormones and development of breast cancer. Postmenopausal estrogen replacement therapy has been the subject of several recent meta-analyses, with conflicting results.^{7,8} The recently reported NCI-sponsored Women's Health Initiative study randomized 80,000 women to take postmenopausal estrogen replacement therapy combined with progesterone or a placebo.⁹ This study reported an

increased risk of breast cancer (38 vs. 30 cases per 10,000 person years [RR = 1.26]) when women taking combined estrogen/progesterone for an average of 5.2 years were compared to those receiving placebo. The increase in risk was observed in year three in women who had previously used menopausal hormones, but not until year four in women with no previous use. Women who had a hysterectomy, and therefore did not require progestin therapy to decrease risk of endometrial carcinoma, did not have an increased or decreased risk of breast cancer as compared to women receiving placebo. Thus long-term use of hormone replacement therapy and concurrent use of progestins appear to contribute to breast cancer risk.

The use of postmenopausal estrogen replacement therapy in women with a history of breast cancer is generally considered contraindicated. Because of the association of estrogen and risk of breast cancer, many clinicians believe that patients with a strong family history or other risk factors for breast cancer should not receive postmenopausal estrogen replacement therapy. This dogma has recently been challenged in the medical literature. Proponents of estrogen replacement therapy in patients with successfully treated operable breast cancer often state that the possible benefits of replacement therapy in terms of prevention of chronic conditions outweigh an unknown but potential increased risk of breast cancer development. However, a recent report from the Women's Health Initiative showed no reduction in the risk of coronary heart disease in women randomized to receive hormone replacement therapy.¹⁰ Women who are considering estrogen replacement therapy should carefully consider the risks versus benefits (see Chap. 80 for a detailed discussion of hormone replacement therapy).

There are more than 20 epidemiologic studies of the potential carcinogenic effect of oral contraceptives, most of which have not shown a relationship between use of birth control pills and breast cancer incidence. But results are conflicting and assessment of the studies necessitates consideration of the particular oral contraceptive products involved, daily and cumulative doses of the hormones administered, and the latency for development of breast cancer. A review and meta-analysis suggest that the risk of breast cancer is not increased in women who had ever received oral contraceptive drugs. However, women who were current oral contraceptive users did show a small but significant increase in the relative risk of breast cancer (RR = 1.24).¹¹ It should be pointed out that early use of oral contraceptives may be associated with early menarche and may result in late age of first birth, both of which are recognized risk factors for breast cancer. Reassuring data that oral contraceptives do not increase breast cancer risk later in life have recently been published.^{12,13} Although it is not entirely possible to rule out a promotional effect of oral contraceptives on breast cancer development in young patients, most experts believe that the safety and benefits of low-dose oral contraceptives currently outweigh the potential risks and that changes in the prescribing practice for the use of oral contraceptives are not warranted. Oral contraceptives are known to reduce the risk of ovarian cancer by about 40% and the risk of endometrial cancer by about 60%.

GENETIC FACTORS

Both personal and family histories influence a woman's risk of developing breast cancer. A past medical history for breast cancer is associated with about a fivefold increased risk of contralateral breast cancer. Cancer of the uterus and ovary has also been associated with an increased risk of the development of breast cancer. Breast cancer is observed as part of cancer family syndromes in association with other tumors. Only 5% of breast cancer patients are thought to have a pedigree consistent with hereditary breast cancer.

A topic that bears some discussion because of its prevalence in the general population is the relationship of fibrocystic breast disease to the development of invasive breast cancer. As many as 85% of American women have “lumpy breasts” and may have a clinical diagnosis of fibrocystic breast disease or benign breast disease. The relative risk of breast cancer in patients with a history of fibrocystic breast disease has ranged from 1.5 to 2.0 in reported studies. But fibrocystic disease involves a heterogeneous group of pathologic changes associated with various degrees of breast cancer risk. Thus a clinical diagnosis of fibrocystic or benign breast disease has little practical significance for counseling patients regarding individual risk of breast cancer. Benign breast conditions are classified as nonproliferative or proliferative. On the basis of a review of more than 10,000 breast biopsies,¹⁴ women with proliferative disease were found to have a relative risk of 1.9, and the subcategory of women with atypical hyperplasia had a relative risk of 4.4. Nonproliferative benign breast disease was not associated with an excess risk of breast cancer. About 80% of the reviewed biopsies were found to have nonproliferative benign breast disease, and of those demonstrating proliferation, only 3.6% were “atypical.” These data suggest that benign breast disease or fibrocystic disease is most often not associated with proliferation, and that women with benign breast disease or fibrocystic disease are not at an increased risk for developing breast cancer. However, it must be noted that “lumpy breasts” may lead to a delay in diagnosis of breast cancer because of inability of the patient or physician to detect a true malignant lesion.

It has been recognized for some time that a family history of breast cancer is associated rather strongly with a woman’s own risk for developing the disease. Empirical estimates of the risks associated

with particular patterns of family history of breast cancer indicate the following:¹⁵

1. Having any first-degree relative with breast cancer increases a woman’s risk of breast cancer 1.5- to 3-fold, depending on age.
2. The higher relative risk is associated with breast cancer with onset younger than age 45 years in one or more first-degree relatives.
3. Having multiple first-degree relatives affected has been inconsistently associated with elevated risks.
4. Having a second-degree relative affected increases a woman’s risk of developing breast cancer by approximately 50% (RR = 1.5).
5. Affected family members on the maternal side and the paternal side contribute similarly to the risk.

Although certain patterns of family history are associated with substantial elevations in the risk of breast cancer, these high-risk patterns occur infrequently in the general population (Table 125–2). The percentage of all breast cancers in the population that can be attributed to family history range between 6% and 12%.¹⁵ Thus it appears that genetically transmitted susceptibility contributes to their etiology of breast cancer in a sizable minority of patients.

In the early 1990s, pedigree analysis of 23 high-risk families for breast and ovarian cancer provided evidence for a rare autosomal dominant allele.^{16,17} From these families, a gene on the long arm of chromosome 17 (17q21) was identified as abnormal in a large percentage of these hereditary breast and ovarian cancer patients. Isolation of the *BRCA1* gene was initially reported in 1994. A second

TABLE 125–2. Established and Probable Risk Factors for Breast Cancer

| Risk Factor | Comparison Category | Risk Category | Typical Relative Risk |
|-------------------------------------|------------------------------------|--|-----------------------|
| Family history of breast cancer | No first-degree relatives affected | Mother affected before the age of 60 y | 2.0 |
| | | Mother affected after the age of 60 y | 1.4 |
| | | Two first-degree relatives affected | 4–6 |
| | | Breast cancer in one or more second-degree relatives | 1.36 |
| | | Ovarian cancer in one or more first-degree relatives | 1.59 |
| Age at menarche | 16 y | 11 y | 1.3 |
| Age at birth of first child | Before 20 y | 20–24 y | 1.3 |
| | | 25–29 y | 1.6 |
| | | ≥30 y | 1.9 |
| Age at menopause | 45–54 y | After 55 y | 1.5 |
| | | Before 45 y | 0.7 |
| | | Oophrectomy before 35 y | 0.4 |
| Benign breast disease | No biopsy or aspiration | Proliferation only | 1.5 |
| | | Atypical hyperplasia | 3.5 |
| | | Lobular carcinoma <i>in situ</i> | 7.2 |
| Obesity | 10th percentile | 90th percentile | |
| | | Age, 30–49 y | 0.8 |
| | | Age ≥50 y | 1.2 |
| Oral contraceptive use | Never used | Ever used | 1.0 |
| | | ≥4 y before first pregnancy | 1.7 |
| Postmenopausal estrogen replacement | Never used | Current use all ages | 1.4 |
| | | 15 + y | 1.3 |
| | | Past use | 1.0 |
| Alcohol use | Nondrinker | 1 drink/day | 1.10 |
| | | 2 drinks/day | 1.25 |
| | | 3 drinks/day | 1.50 |

breast cancer gene, called *BRCA2*, has been mapped to chromosome 13. From these data, a woman with a strong family history of breast or ovarian cancer, or both, who carries a germline mutation of *BRCA1* faces roughly an 85% lifetime risk of breast cancer and a 60% risk of ovarian cancer. Carriers of the *BRCA2* mutation have similar risks for breast cancer, but much lower risks for ovarian cancer.

It has been reported that Jewish people of Eastern European descent (Ashkenazi Jews) have an unusually high (2.5%) carrier rate of germline mutations in *BRCA1* and *BRCA2* as compared to the rest of the U.S. population. A recent study that examined 1,008 Ashkenazi Jewish women with breast cancer in the New York area found that by age 80, a woman with a mutation in either gene had an 82% risk of developing breast cancer, compared to an average woman's risk of about 13%.¹⁸ Risks were 20% by age 40 and 55% by age 60. Lifetime risks for ovarian cancer were 54% for women with *BRCA1* mutations and 23% for those with *BRCA2* mutations. Surprisingly, half of the patients with BRCA mutations had no breast or ovarian cancer among mothers, sisters, grandmothers, or aunts, which raised the question of the importance of family history and whether all Ashkenazi Jewish women should undergo genetic testing.¹⁸ The results of this study are in contrast with an earlier reported study of similar design in which Ashkenazi Jewish families were reported to have lifetime risks of 50% and 16% for breast and ovarian cancer, respectively.¹⁹

The question of who should receive screening for BRCA is unresolved. The probability of being a carrier of the gene is related to ethnicity and family history. Important factors in family history include the number of affected and unaffected family members, the age at which cancer is diagnosed, and the presence of ovarian cancer. It is currently estimated that the risk of a *BRCA1* mutation increases 20-fold if breast and ovarian cancer occur concurrently in one or more family members. However, as pointed out in the recent study in Ashkenazi Jewish women, the importance of family history appears to diminish as family size decreases.

To date, there are no clear recommendations for carriers of *BRCA1* and *BRCA2* from high-risk families. Bilateral total mastectomy does reduce the risk of breast cancer occurrence; however, both breast and ovarian cancer have been reported in patients who have had prophylactic removal of these organs. In BRCA carriers who do not opt for surgical prophylaxis, mammography every 6 months is recommended. Because no effective screening for ovarian cancer exists, most experts recommend bilateral oophorectomy at completion of childbearing and estrogen replacement therapy until the age of 50 years. Estrogen replacement therapy provides approximately one-third of physiologic estrogen concentrations, and although controversial, some experts suggest that the benefits in terms of prevention of chronic diseases outweigh the risk of cancer. The benefit of tamoxifen for chemoprevention in BRCA carriers is not clear.²⁰ In the recently reported New York study in women who were BRCA gene mutation carriers, women who exercised and maintained a healthy weight during adolescence had a later onset of breast cancer compared with inactive or overweight women. Of many potential risk modifiers examined, including smoking, alcohol, exposure to radiation and pesticides, and reproductive behavior, the only other factor to influence risk was that women who had at least one pregnancy also had later cancer onset.¹⁸

Isolation and cloning of *BRCA1* and *BRCA2* should ultimately lead to a greater understanding of the biology of malignant transformation of mammary epithelium, and to major advances in diagnostics and therapeutics benefiting all breast cancer patients. It is hoped that an improved basic understanding of the molecular mechanisms involved in breast cancer development and the discovery of novel approaches

to reverse or prevent these processes will ultimately lead to the ability to cure this extremely common and often fatal disease.

ENVIRONMENTAL AND LIFESTYLE FACTORS

The observation that breast cancer incidence rates vary 10-fold between countries suggests that environmental factors play an important role in the etiology of breast cancer. Perhaps the most compelling evidence is derived from studies of Asian women who migrated from Japan to the San Francisco Bay area. Although the incidence of breast cancer in Asian women is quite low (about 97 cases per 100,000 women), the incidence of breast cancer in Asian women who were born in the United States, or who migrated from Asia to the United States, gradually increases to equal that of the white population in the same area.

Diet is an obvious environmental factor, and possible relationships between fat or cholesterol intake and steroid hormone metabolism have led to an emphasis on dietary fat as a possible etiologic agent. International studies demonstrate a positive correlation between age-adjusted cancer mortality rate and national per capita fat intake. The correlation is stronger in postmenopausal than in premenopausal women. Studies in laboratory animals provide further evidence of a relationship between dietary fat intake and breast cancer. Despite these compelling indirect data, case control and prospective studies performed in the United States have not clearly demonstrated an association between dietary fat and breast cancer risk. In fact, the relative risk of developing breast cancer among the women with the highest quintile of total fat intake was 0.85 as compared to women in the lowest quintile. However, the difference in fat intake among women at these two extremes was only 25%.²¹ The results of this study show that women who reduce fat intake in the context of the usual American diet are not likely to reduce their breast cancer risk. The possible benefits of lowering fat intake to levels substantially below 30% of caloric intake will need to be tested in randomized trials.

Additional investigated dietary factors include micronutrients and food-derived heterocyclic amines. Many of the studies that have examined the relative risk for breast cancer for high fat intake have also examined the association between breast cancer and intake of fiber, β -carotene, and vitamins C, E, and A. The relationship between vitamin A and breast cancer risk is unclear. In contrast, most studies support some benefit from β -carotene, vitamin C, and/or dietary fiber. Experimental and epidemiologic evidence suggests an association between breast cancer and the Western diet, which typically includes a large amount of cooked meats and fat, as well as a high caloric intake. One group of compounds that may play a role in human breast cancer is the heterocyclic amines found commonly in cooked beef, fish, and chicken. At least 19 heterocyclic amines with mutagenic activity have been identified in grilled, broiled, and fried meat and fish. Among these heterocyclic amines, 10 were examined for long-term carcinogenicity and all proved to be positive.²² Experimental studies examining the interaction between heterocyclic amines and other dietary factors with respect to mammary carcinogenesis are warranted.

Both body weight and height are associated with breast cancer. Indices of obesity are related to breast cancer risks in a complex way that differs by age and menopausal status. Most studies of premenopausal women show either no relationship with body weight, or slightly declining breast cancer risks with increasing body weight. One plausible biologic mechanism to explain this phenomenon is reduced ovarian activity in obese women. Most studies in

postmenopausal women, however, show increasing breast cancer risks with increasing body weight. In addition to obesity, the distribution of body fat also may play an independent role in breast cancer. Upper body (central or abdominal) adiposity increases the risk of breast cancer independent of overall obesity. This association may be related to the excess levels of free-circulating estrogen resulting from the conversion of androstenedione to estradiol in peripheral adipose tissue, in conjunction with suppressed levels of circulating sex hormone binding globulin in women with central adiposity.²³

Exercise may provide modest protection against breast cancer, but the relationship is complex. Strenuous physical activity can delay menarche, and thereby decrease risk. Moderate levels of physical activity in premenopausal women are associated with anovulatory cycles, which also are associated with decreased risk. The reduction in breast cancer seen in postmenopausal women who exercise might be mediated through weight control,^{24–26} although some studies have not shown an influence of body mass index on the relationship between physical activity and breast cancer risk.^{27,28} At least one case-control study failed to show a protective role of physical activity in women of any age group.²⁹ Overall, excess body weight appears to result in a slightly increased risk of breast cancer, and those that do develop breast cancer are more likely to be estrogen receptor–positive. Although controlled weight loss probably leads to an overall healthier condition, the data to support a direct link between weight loss and breast cancer risk reduction do not exist. Research in this area is relatively recent; further progress is dependent on the development of accurate measurements of physical activity, past and present.

Reports of more than 50 epidemiologic investigations of the relationship between alcohol and breast cancer have appeared in the literature. A recent meta-analysis³⁰ of these studies indicates both a modest positive association between alcohol and breast cancer and a dose-response relationship. Data suggest that risk increases with consumption of alcohol in general, regardless of the beverage type. Several factors, including age, weight, and estrogen use, have been shown to modify this relation in some studies. The mechanism of the alcohol-breast cancer hypothesis may include increased levels of estradiol or other reproductive steroid hormones; altered hepatic metabolism of carcinogens; production of cytotoxic protein products; diminished immunologic surveillance; impaired DNA repair; or possibly an influencing effect of alcohol on cell membrane integrity and/or metabolism of intracellular substrates.³⁰ In addition, animal studies have yielded mixed results regarding the influence of alcohol on the incidence of breast cancer. Although a causal relationship between alcohol consumption and breast cancer has not been proven in a prospective trial, the weight of the evidence suggests that a relationship, direct or indirect, may exist.

Radiation is associated with an increased risk of breast cancer in survivors of the atomic bomb, in patients given radiation for postpartum mastitis, in women receiving multiple fluoroscopic exams during therapy for tuberculosis, and in patients who receive mediastinal radiation for malignancies. Interestingly, this risk appears to be confined to exposure to radiation prior to the age of 40, which again suggests that a “window of initiation” for breast cancer occurs at a relatively early age. Exposure to diagnostic x-rays including annual screening mammography does not impart a sufficient dose of radiation for clinical concern. A critical reassessment of benefits versus risks from screening mammography found recently that for a woman beginning annual screening mammography at age 50 years and continuing to age 75 years, the benefit exceeds the radiation risk by a factor of 100. Even for a woman who begins annual screening at age 35 years and continues until age 75 years, the benefit of reduced mortality is projected to exceed the radiation risk by a factor of more than 25.³¹

Cigarette smoking and augmentation mammoplasty do not appear to increase the risk of breast cancer. Blood pressure medications, reserpine, and other drugs that increase prolactin levels have not been shown to increase the risk of breast cancer. Caffeine also has no predisposing effect on breast cancer, but may play a role in exacerbation of benign breast disease. The role of environmental carcinogens has not been systematically evaluated.

CLINICAL PRESENTATION

A painless lump is the initial sign in more than 90% of women with breast cancer. The typical malignant mass is solitary, unilateral, solid, hard, irregular, and nonmobile. In approximately 10% of cases, stabbing or aching pain is the first symptom. Less commonly, nipple discharge, retraction, or dimpling may herald the onset of the disease. In more advanced cases, prominent skin edema, redness, warmth, and induration of the underlying tissue may be observed.

The breast is a complex organ composed of skin, subcutaneous tissue, fatty tissue, and branching ductal and glandular structures. Various diseases that affect these structures can produce a palpable mass. In addition, the physiologic changes associated with the menstrual cycle can cause abnormalities of the breast that produce a three-dimensional mass. The most common causes of breast masses in young women are fibroadenoma, fibrocystic disease, carcinoma, and fat necrosis.

About 80% of women first detect some breast abnormalities themselves, underscoring the importance of breast self-examination. In the United States, it is increasingly common for breast cancer to be detected during routine screening mammography in asymptomatic women. It is widely accepted that the smaller the mass, the higher the likelihood of cure, and the more conservative the treatment options offered to the patient. Thus as the number of breast cancer cases found by screening mammography increases, overall survival of breast cancer patients is expected to improve.

Breast cancer that is confined to a localized breast lesion is often referred to as *early, primary, localized, or curable*. Unfortunately, as is discussed shortly, breast cancer cells often spread by contiguity, lymph channels, and through the blood to distant sites. As discussed in subsequent sections, this often occurs early in the breast cancer growth, and deposits of tumor cells form in distant sites that cannot be detected with current diagnostic methods and equipment (micrometastases). When breast cancer cells can be detected clinically or radiologically in sites distant from the breast, the disease is referred to as *advanced or metastatic* breast cancer. Tissues most commonly involved with metastases are lymph nodes (other than axillary or internal mammary), skin, bone, liver, lungs, and brain. Symptoms of bone pain, difficulty breathing, abdominal enlargement, jaundice, and mental status changes may herald the clinical presentation of metastatic breast cancer. About 10% of women have signs and symptoms of distant metastases when they first seek treatment. In virtually all of them, a breast mass has been present for several months to years. In addition, about one-half of all patients who initially are treated for localized disease develop signs and symptoms of metastatic breast cancer, most commonly 3 to 5 years following local potentially curative therapy with surgery, radiation, and systemic adjuvant therapy.

DIAGNOSIS

Initial work-up for a woman presenting with a lesion or symptoms suggestive of breast cancer should include a careful history, physical

examination of the breast, three-dimensional mammography, and possibly other breast imaging techniques such as ultrasound. Most (80% to 85%) breast cancers can be visualized on a mammogram as a mass, a cluster of calcifications, or a combination of both. The detection of a mass smaller than 2 mm is considered ideal, but it is difficult in practice to detect tumors smaller than 5 mm. Large, noncalcified masses may be difficult to detect in the dense glandular breast, which is common in premenopausal women. The threshold for the detection of a cancer is variable and depends on the radiographic abnormality, the fat:glandular tissue ratio of the breast, the technical quality of the examination, and the diligence and expertise of the radiologist.

Interpretations of mammography obtained either for screening or to evaluate a new breast mass generally fall into one of three categories: (1) the radiologist notes nothing suspicious for malignancy; (2) something of concern is seen and follow-up or further testing is advised; or (3) something clearly suspicious is present and a biopsy is indicated. A detailed discussion of abnormal mammogram radiographic findings and their significance is beyond the scope of this chapter, although excellent references are available.^{32,33} It should be noted, however, that well-circumscribed x-ray masses are benign in 98% of cases; such lesions may not require a biopsy, but may be followed radiographically at 6-month intervals. Masses interpreted as “suspicious and a biopsy should be performed” have a 20% to 30% probability of malignancy. Masses interpreted as “highly suspicious radiographically” are malignant in 75% to 90% of cases. The overall probability of malignancy when a biopsy is performed on a nonpalpable mammographic abnormality ranges from 20% to 35%.

Breast biopsy is indicated for a mammographic abnormality that suggests malignancy or for a palpable mass on physical examination. Biopsy can be accomplished percutaneously in most circumstances, making excisional biopsy unnecessary. Excisional biopsy indicates the complete removal of the abnormal tissue. Excisional biopsy is performed with either a local or general anesthetic, and is usually done as an outpatient operative procedure. Needle biopsies have included both core-needle biopsy (which removes a core of tissue) and fine-needle aspiration (which removes cells from the suspicious site). These procedures are associated with minimal discomfort and anxiety, few complications, and no disfigurement, and could represent significant cost savings when compared to conventional surgical excisional biopsy. The accuracy of fine-needle aspiration is quite good in experienced hands, but its limitations include false-negatives, specimens with insufficient material for diagnosis, and the inability to distinguish invasive from in situ cancer. In the United States, stereotactic core needle biopsy is the most common initial biopsy method for mammographically detected, nonpalpable abnormalities. Core needle biopsy offers a more definitive histologic diagnosis, avoids inadequate samples, and can distinguish invasive from in situ breast cancer. It should be pointed out that biopsy is used only to establish the diagnosis. Following confirmation of malignancy, subsequent surgical procedures are performed to assure complete removal of the abnormal tissue.⁵

STAGING AND PROGNOSIS

Few malignant diseases illustrate the importance of stage (anatomic extent of disease) at the time of diagnosis and overall survival more clearly than breast cancer. Stage is defined on the basis of the primary tumor size (T_{1-4}), presence and extent of lymph node involvement (N_{1-3}), and presence or absence of distant metastases (M_{0-1}) (Table 125-3 and Fig. 125-2). Although many possible combinations of T and N are possible within a given stage, simplistically, stage 0

represents carcinoma in situ (T_{is}) or disease that has not invaded the basement membrane. Stage I represents small primary tumor without lymph node involvement, and the majority of stage II disease involves regional lymph nodes. Stages I and II are often referred to as *early breast cancer*. It is in these early stages that the disease is curable. Stage III, also referred to as *locally advanced disease*, usually represents a large tumor with extensive nodal involvement in which either node or tumor is fixed to the chest wall. Stage IV disease is characterized by the presence of metastases to organs distant from the primary tumor and is often referred to as *advanced or metastatic disease* as described earlier. Most cancer today presents in early stages where the prognosis is favorable (Table 125-4).

The American Joint Committee for Cancer (AJCC) recently published new staging criteria for breast cancer which were officially implemented in January 2003.³⁴ Tumor staging systems are periodically updated to incorporate new diagnostic and therapeutic advances that affect risk of disease recurrence and survival. Major changes included in the 2003 staging system from the 1988 version included size-based discrimination between micrometastases and isolated tumor cells, classification of lymph node status by number of involved axillary lymph nodes, and new classification for metastases to the infraclavicular, internal mammary, and supraclavicular lymph nodes. A new substage, IIIC, was also designated. The net effect of changes in the staging system appears to be a shifting of the population in each stage toward more advanced stages or substages. A recent report compared survival in 1,350 breast cancer patients according to the 1988 and 2003 staging system.³⁵ In this report, adoption of the 2003 AJCC staging system for breast cancer improved stage-specific overall survival by as much as 15%. This improvement in stage-specific overall survival applied across every disease stage except stage IV. It is important to note that comparison among patients staged with the different staging systems will likely result in the appearance of an improvement in treatment efficacy. However, this would be an inaccurate assessment because, for example, women staged as stage IIA based on the 1988 staging system would likely be considered to have a more advanced stage (i.e., IIB based on the 2003 staging system), and thus a worse prognosis.

TABLE 125–4. Estimated Stage at Presentation and 5-Year Disease-Free Survival (DFS): Breast Cancer

| | Percentage of Total Cases | 5-Year DFS ^a (%) |
|-----------|---------------------------|-----------------------------|
| Stage I | 40 | 70–90 |
| Stage II | 40 | 50–70 |
| Stage III | 15 | 20–30 |
| Stage IV | 5 | 0–10 ^b |

^aWith current conventional local and systemic therapy.

^bPatients in stage IV are rarely free of disease; however, 10% to 20% of these patients may survive with minimal disease for 5 to 10 years.

PATHOLOGY

The pathologic evaluation of breast lesions serves to establish the histologic diagnosis and to confirm the presence or absence of other factors believed to influence prognosis. These prognostic factors include the presence of necrosis, lymphatic or vascular invasion, nuclear grade, hormone receptor status, proliferative index, amount of aneuploidy, presence or absence of oncogenes, presence or absence of mutations in the tumor suppressor *p53* gene, and perhaps presence or absence of elevated growth factor levels, as well as enzymes (cathepsin D), proteins, and angiogenesis factors.

INVASIVE CARCINOMA

Invasive breast cancers are a histologically heterogeneous group of lesions. Most breast carcinomas are adenocarcinomas and are classified on the basis of their microscopic appearance as either ductal or lobular, corresponding to the ducts and lobules of the normal breast. The various histologic types of breast cancer have different prognoses, but it is unknown whether their response to therapy differs, because patients in therapeutic trials are not typically stratified according to histologic type. The five most common types of invasive breast cancer are briefly described.

Invasive or infiltrating ductal carcinoma is the most common histology. The other histologic patterns can occur alone or with infiltrating ductal carcinoma. These tumors are generally referred to as infiltrating ductal carcinoma “not otherwise specified,” and account for about 75% of all invasive breast cancers. These tumors commonly spread to the axillary lymph nodes and their prognosis is poorer than for other histologic types (specifically tubular, medullary, and mucinous/colloid). *Infiltrating lobular carcinoma* accounts for 5% to 10% of breast tumors. Typical presentation is an area of ill-defined thickening in the breast, in contrast to a prominent lump characteristic of infiltrating ductal carcinoma. A greater proportion of infiltrating lobular carcinomas are multicentric tumors, either in the same or opposite breast, as compared with infiltrating ductal carcinoma. Overall, infiltrating lobular carcinoma and infiltrating ductal carcinoma have similar likelihoods of axillary node involvement and prognosis, yet the sites of metastases tend to differ. Ductal carcinoma more frequently metastasizes to the bone or to the liver, lung, or brain, whereas lobular carcinoma more commonly metastasizes to meningeal and serosal surfaces and other unusual sites.

The three most common special types of invasive cancer are *tubular*, *medullary*, and *mucinous*. *Medullary carcinoma* is a well-defined lesion with a characteristic microscopic appearance that includes a well-circumscribed border, intense infiltration with small lymphocytes, and other factors. It accounts for 5% to 7% of all breast carcinomas and is believed to have a better prognosis than infiltrat-

ing ductal carcinoma. *Mucinous (or colloid) carcinoma* constitutes approximately 3% of all breast carcinomas and is characterized by the abundant accumulation of extracellular mucin around clusters of tumor cells. It is slow growing and can be bulky. When the tumor is predominantly mucinous, the prognosis tends to be more favorable. *Tubular carcinoma* accounts for approximately 2% of all breast cancers and is a type of carcinoma in which tubule formation is conspicuous on pathology. Axillary metastases are uncommon and the prognosis is considerably better than for infiltrating ductal carcinomas. Histologies rarely reported include adenocystic carcinoma, carcinosarcomas, and papillary carcinoma. In some pathology reports, infiltrating ductal carcinoma may include small areas containing these special tumor types.

Special situations seen clinically and histologically include Paget’s disease of the breast and inflammatory breast cancer. Paget’s disease of the breast occurs in 1% to 4% of all patients with breast cancer. Clinically, the patient presents with a relatively long history of eczematous changes in the nipple with itching, burning, oozing, bleeding, or some combination of these. The nipple changes are associated with an underlying carcinoma in the breast that is usually palpable. The histology of the tumor type is either ductal carcinoma in situ (DCIS) or invasive ductal carcinoma. Prognosis is related to the histologic type of the associated tumor.

Inflammatory breast cancer is characterized clinically by prominent skin, edema, redness and warmth, visible erysipeloid margin, and induration of the underlying tissue. Biopsies of the involved skin reveal cancer cells in the dermal lymphatics. Inflammatory breast cancer typically has a very rapid onset and although it may look somewhat similar to a neglected mass, its presentation with rapid onset and progression of local symptoms distinguishes it from other cases of locally advanced disease. Prognosis of patients with inflammatory breast cancer is poor, even if the disease is apparently localized.

NONINVASIVE CARCINOMA

As with invasive carcinoma, the noninvasive lesions may be divided broadly into ductal and lobular categories. Evidence supports that the development of malignancy is a multistep process and that invasive breast cancer has a preinvasive phase. During the carcinoma in situ phase, normal epithelial cells undergo genetic alterations that result in malignant transformation. Transformed epithelial cells proliferate and pile up within lobules or ducts, but lack the required genetic alterations that enable the cells to penetrate the basement membrane. Therefore carcinoma in situ is diagnosed when malignant transformation of cells has occurred, but the basement membrane is intact by light microscopy.

The widespread use of screening mammography and subsequent biopsy coupled with recognition of noninvasive breast carcinoma by pathologists has resulted in a significant increase in the diagnosis of in situ breast cancer during the past decade. Its incidence has risen from 1% to 5% in the early 1970s to 28% in the late 1980s; between 1988 and 1996, the incidence of in situ cancer rose steadily at a rate of 6% per year.² The natural history of these disorders is not well described in the literature, and thus the debate continues regarding carcinoma in situ: Is carcinoma in situ preinvasive cancer or simply a marker of unstable epithelium that represents an increased risk for the development of subsequent aggressive cancer? Although a detailed discussion of the biology and appropriate management of noninvasive breast cancer is beyond the scope of this chapter, some of the more salient characteristics of DCIS and lobular carcinoma in situ (LCIS) are described below and the reader is referred to a number of excellent reviews for a more comprehensive discussion.^{36,37}

DCIS is seen more frequently than LCIS at a ratio of about 6 to 3:1. Most DCIS cases diagnosed currently are small nonpalpable lesions, unlike its presentation as a palpable mass in more than half of cases in years prior to mammography. Most cases of DCIS today are found by biopsies performed for clustered microcalcifications seen on screening mammography. There are five distinct histologic patterns of DCIS: comedo, cribriform, micropapillary, papillary, and solid. The biologic characteristics are consistent with its role as a direct precursor to invasive carcinoma, which appears to develop in most, but not all, cases if left untreated within 10 years of diagnosis. The peak incidence of DCIS is 51 to 59 years, which closely parallels that of invasive carcinoma.

Treatment of DCIS depends on its presentation, size, and pathology. The patient and physician have the following options: (1) excision with negative margins, preferably 1 to 2 cm; (2) excision followed by breast irradiation; and (3) traditional total mastectomy with reconstruction. It is important to note, however, that in all cases, carcinoma in situ is treated as cancer. Mastectomy had been the standard treatment of DCIS for several decades. The combined data from 1,061 women who underwent mastectomy for DCIS, reported in 14 published studies, with follow-up ranging from 2 years to more than 15 years, show an overall local recurrence rate of only 0.75% and an overall cancer mortality rate of less than 1%. Breast conservation, that is, wide local excision followed by irradiation of breast tissue, may be an effective alternative to mastectomy. The recently completed National Surgical Adjuvant Breast and Bowel Project (NSABP) B17 trial randomized 808 women with DCIS to receive lumpectomy alone or lumpectomy with radiation.³⁸ The results of this trial demonstrated an advantage for radiation plus lumpectomy in terms of fewer local recurrences. Although radiation following lumpectomy does not appear to change the survival of patients with DCIS, it significantly reduces the incidence of local recurrences and enhances the breast preservation rate in these women. The EORTC Trial which was identical in design reported very similar results, which supports lumpectomy followed by radiation in women with DCIS.³⁹ However, if more than one area of the breast is involved with DCIS, a mastectomy is the preferred option. It has also been suggested that breast conservation may not be appropriate for younger women whose lifetime risk of breast cancer is high given a diagnosis of DCIS. Axillary dissection is generally not indicated. There is currently no proven benefit for the use of cytotoxic chemotherapy in patients who receive local therapy for DCIS. The value of tamoxifen in patients with DCIS is controversial. The NSABP B-24 trial, which randomized 1,804 women with DCIS to lumpectomy plus radiation plus either tamoxifen or placebo, showed a benefit of tamoxifen in reduction in ipsilateral invasive breast cancer (44% reduction, $p = 0.03$).⁴⁰ However, the UK/AN2 trial which was similar in design failed to show a benefit of tamoxifen in reduction in ipsilateral invasive breast cancer in women with DCIS.⁴¹ Most experts would agree that there is little evidence to support the routine use of tamoxifen in this patient population. However, there may be subgroups of patients with DCIS, such as hormone receptor–positive patients, who may benefit from the addition of tamoxifen to lumpectomy plus radiation. In fact, tamoxifen use in patients with DCIS that is hormone receptor–positive was recommended by the International Expert Consensus on Primary Therapy of Early Breast Cancer in their recently published update.⁴² Follow-up of women who have been treated for DCIS should be as comprehensive as that of a woman with invasive carcinoma to facilitate early detection of any subsequent malignancy.

LCIS is a microscopic diagnosis, not a gross abnormality. Therefore it is always nonpalpable and it is virtually impossible to make the diagnosis of LCIS by clinical examination. Unlike DCIS, LCIS does not demonstrate calcifications on mammography, and in fact is

not associated with mammographic abnormalities. LCIS is most frequently diagnosed in biopsy specimens that were obtained because of symptoms or mammography findings consistent with benign lesions. Multicentricity is common (>30%) with LCIS, and the opposite breast is affected in up to 50% of patients. It is unclear whether LCIS proceeds to invasive carcinoma or serves as a marker for a high probability of invasive carcinoma developing elsewhere in the breast. Thus the management of LCIS is very controversial. Some experts favor a program of breast examination, periodic physician examination, and mammography as management of LCIS. In selected patients who are particularly anxious about the development of cancer, bilateral total mastectomies and prompt reconstruction represent a reasonable approach. Radiation and systemic chemotherapy has no role in the management of LCIS. Patients with LCIS were included in the Tamoxifen Chemoprevention Trial and thus patients with LCIS should be offered tamoxifen as a preventive strategy.

PROGNOSTIC FACTORS

The natural history of breast cancer varies between patients, with some having an extremely aggressive disease that progresses rapidly, whereas others follow a more indolent course. The ability to predict which patients have a better disease prognosis is extremely important in designing treatment recommendations to maximize quantity and quality of life. A number of potential pathologic prognostic and predictive factors have been identified. Prognostic factors are measurements available at diagnosis or time of surgery, that in the absence of adjuvant therapy are associated with recurrence rate, death rate, or other clinical outcome. Predictive factors are measurements available at diagnosis that are associated with the response to a specific therapy. Prognostic and predictive factors fall into three categories: patient characteristics that are independent of the disease such as age; disease characteristics such as tumor size or histologic type; and biomarkers that are measurable parameters in tissues, cells, or fluids, such as hormone receptor status.

The median age for the diagnosis of breast cancer is between the ages of 60 and 65 years.² Younger women, particularly women younger than 35 years of age, have a more aggressive form of the disease, and elderly women, particularly those older than 70 years of age with breast cancer, frequently have hormone receptor protein in their malignant tissue, suggesting a more indolent tumor pattern and a higher likelihood of response to hormonal therapy. Race appears to be prognostic but not predictive. Black breast cancer patients are generally younger and often have larger tumors at diagnosis, and a smaller percentage have hormone receptors in their tumor tissue. These factors contribute to a poorer prognosis. It should be emphasized that for both age and race, in cases of similar clinical presentation, adjuvant treatment confers similar benefits to black and white women.

Tumor size and the presence and number of involved axillary lymph nodes are established primary factors in assessing the risk for breast cancer recurrence and subsequent metastatic disease. Table 125-5 shows the 5-year relapse rate according to size of the primary tumor and axillary node involvement from results of three investigations.⁴³⁻⁴⁵ These data clearly demonstrate that the major factor that influences the likelihood of recurrence is the presence of positive axillary nodes. But regardless of axillary node studies, the size of the primary tumor remains an independent prognostic factor for disease recurrence. In axillary node–negative patients, a tumor size of less than 2 cm is associated with a very favorable prognosis. However, there does not appear to be a large difference between prognosis in patients with large (>5 cm) tumors and negative nodes, as

TABLE 125–5. Five-Year Relapse Rate (%) Based on Size of Primary Tumor and Axillary Nodal Status

| Axillary Status | Size of Primary Tumor (cm) | | |
|-------------------------------|----------------------------|-----|----|
| | <2 | 2–5 | >5 |
| Axillary nodes negative | | | |
| Fisher et al ⁴³ | 12 | 24 | 27 |
| Nemoto et al ⁴⁴ | 13 | 19 | 25 |
| Valagussa et al ⁴⁵ | 8 | 24 | 19 |
| Axillary nodes positive | | | |
| Fisher et al ⁴³ | 50 | 60 | 79 |
| Nemoto et al ⁴⁴ | 39 | 50 | 65 |
| Valagussa et al ⁴⁵ | 37 | 64 | 74 |

compared to patients with 2- to 5-cm tumors and negative nodes. Thus the size of the primary tumor in patients with negative axillary lymph nodes may not provide as much information regarding prognosis as in node-positive patients.

The number of affected nodes is directly related to disease recurrence. The recently revised staging system for breast cancer differs from the 1988 version in that it recognizes the absolute number of positive nodes as a prognostic factor, with N₁ representing one to three positive nodes, N₂ representing four to nine positive nodes, and N₃ representing ten or more positive nodes in its pathologic staging system.⁴⁴ In addition, metastases to ipsilateral internal mammary and supraclavicular nodes are noted as N₂ and N₃, respectively (if detected macroscopically, but N₁ if detected only by microscopy), compared to axillary lymph node metastases alone, which are designated N₁. Although determination of the number of involved axillary nodes by hematoxylin and eosin staining is still the preferred technique, identifiers have been added to indicate the use of sentinel lymph node dissection and use of immunohistochemical and molecular techniques (microscopic vs. macroscopic) to determine presence of metastases.

Aside from the tumor-node-metastasis (TNM) stage of the disease, hormone receptor studies have received the most attention in the characterization of primary breast cancer. Hormone receptors are used clinically as indicators of prognosis and to predict response to hormone therapy. Hormone receptors are cytoplasmic proteins that transmit signals to the nucleus of the cell for growth and proliferation. The hormone receptors clinically useful in discussions of breast cancer include the estrogen receptor (ER) and the progesterone receptor (PR). The presence of these proteins in the primary tumor (or less often metastases) is routinely measured by enzyme-linked immunochromatographic assays and radioassays (enzyme-linked immunosorbent assay). Concentrations of hormone receptors less than 3 femtomoles (fmol) per milligram of cytosol protein are considered negative, 3 to 10 fmol/mg of cytosol protein are intermediate, and concentrations of hormone receptors greater than 10 fmol/mg of cytosol protein are positive. The level (i.e., quantitative) of hormone receptor and the methodology used to assess hormone receptors are important for predictive ability. Although the estrogen receptor has received the most attention to date, more recent data suggest that the presence of the progesterone receptor protein is required for the functional effects of the estrogen receptor protein to occur. This is evidenced by studies that have reported that response to hormonal manipulation and prognosis are highly correlated with the presence of both positive estrogen receptor protein and positive progesterone receptor protein. Hormone receptors are most valuable in predicting response to hormone therapy. About 70% to 80% of patients who are ER-positive and PR-positive will respond to hormonal manipulation. ER-negative patients rarely

respond to hormonal manipulation. The response rate in patients who are ER-negative and PR-positive is somewhere in between.

About 50% to 70% of patients with primary or metastatic breast cancer have hormone receptor–positive tumors. The median level and frequency of hormone receptor–positive tumors are higher in postmenopausal patients as compared to premenopausal patients. That difference is the primary reason for the different recommendations for adjuvant and metastatic treatment of breast cancer between premenopausal and postmenopausal patients that are discussed in later sections of this chapter. Many experts suggest that breast cancer in postmenopausal women is substantively different than that occurring in premenopausal women. Breast cancer is predominantly a disease of the elderly. When it occurs in younger patients, the course of the disease is more aggressive. Hormone receptor positivity, more common in postmenopausal women, is associated with a superior response to hormone therapy and a longer disease-free interval between primary and subsequent metastatic disease, and overall a more favorable prognosis. The presence of hormone receptors in tumors is associated with a favorable disease-free interval and perhaps an overall survival difference of 5% to 10% (as compared to hormone receptor–negative patients).

The rate of tumor cell proliferation also has prognostic significance in breast cancer recurrence. Rate of cell proliferation can be determined with either the tritiated thymidine-labeling index or DNA flow cytometry, which determines the percentage of tumor cells actively dividing (S-phase fraction). Both techniques have shown that patients with rapidly proliferating tumors have a decreased disease-free survival as compared to patients with slowly proliferating tumors.⁴⁶ Flow cytometry can also detect abnormal DNA content, or aneuploidy, in breast cancer cells. Although there are conflicting reports regarding the clinical significance of ploidy status, some studies report that patients with aneuploid tumors have significantly shorter relapse-free survival times than do patients with diploid tumors.⁴⁶ Newer methods of determining proliferative rate include the use of monoclonal antibodies to antigens in proliferating cells, such as Ki-67. As an example, in one report of 371 node-negative breast cancer women with a high Ki-67 labeling index, they had a 20-fold greater mortality rate than those with a labeling index of $\leq 10\%$.⁴⁷

Nuclear grade and tumor (histologic) differentiation are known, independent prognostic indicators. Several histologic grading systems have been developed and shown to have prognostic value in the evaluation of breast cancer. Fisher and associates⁴⁷ have shown a 5-year survival of 93% for patients with good nuclear grade, compared to 79% for patients with poor nuclear grade. However, lack of concordance between pathologists' grading results has thwarted the use of this prognostic indicator in clinical trials.

A number of additional potential prognostic factors have been identified in the past 5 years. These include overexpression of the *erbB-2* (or *HER-2/neu*) oncogene, cathepsin D, angiogenic growth factors, mutations in the tumor suppressor *p53* gene, and others.⁴⁸ Many of the new potential prognostic factors have been shown to be strongly correlated with established risk factors. For example, many ER-positive tumors are also *HER-2*–negative and cathepsin D–negative, which makes it difficult to discern the relative importance of potential prognostic factors. Identification of these numerous factors and correlations between these and known prognostic factors that affect clinical outcome is of interest because each correlation allows basic mechanistic insights into disease processes. Practically, they allow prediction of probable clinical outcomes that can guide therapeutic decision making. Several of these new prognostic factors, specifically the *HER-2* oncogene overexpression and *p53* mutations, have shown early promise as predictors of efficacy of adjuvant chemotherapy.

The *HER-2/neu* gene is located on 17q21 and is transcribed into a 4.5-kd mRNA, which is translated into a 185-kd glycoprotein. The *HER-2/neu* protein is expressed at low levels in the epithelial cells of normal breast tissue. *HER-2/neu* is a member of the erbB (or HER) growth factor receptor family and its overexpression is associated with transmission of growth signals that control aspects of normal cell growth and division. Preclinical and clinical studies indicate that *HER-2* overexpression may have prognostic and predictive value. In some studies, *HER-2/neu* gene amplification and protein overexpression, measured by fluorescence in situ hybridization (FISH) and immunohistochemistry (IHC), respectively, correlates with factors associated with a poor prognosis. However, not all studies have found this association. A number of reports have found that *HER-2/neu* amplification and overexpression are significant independent predictors of shorter disease-free survival and reduced overall survival in node-positive breast cancer.^{49,50} The relationship between *HER-2/neu* amplification and overexpression in node-negative patients has also been reported to confer less favorable outcomes in some, but not all, studies. The data regarding the predictive value of *HER-2/neu* and response to hormonal and chemotherapy is similarly conflicted. However, most experts would agree that women whose tumors overexpress *HER-2/neu* appear to be relatively resistant to alkylating agent–based adjuvant therapy, and they might derive greater benefit from an anthracycline-based adjuvant therapy regimen.⁵¹ It is important to note that the strength of the evidence to support anthracycline-based adjuvant regimens in women with *HER-2/neu*–overexpressing tumors is not considered adequate to warrant a recommendation by most consensus groups. Although some evidence supports that *HER-2/neu* overexpression is associated with relative resistance to adjuvant endocrine therapy, particularly tamoxifen, data are conflicting. *HER-2/neu* overexpression more likely represents a negative prognostic factor in hormone receptor–positive women. Hormone receptor–positive women who are also *HER-2/neu* positive should receive adjuvant hormonal therapy. Clearly, *HER-2/neu* positively predicts response to trastuzumab therapy, which is a monoclonal antibody directed against the *HER-2/neu* receptor. Currently, the use of trastuzumab is indicated for treatment of metastatic breast cancer in patients who have tumors that overexpress *HER-2/neu*. However, trials in the adjuvant set-

ting are ongoing. A final controversy surrounds the testing method employed to determine *HER-2/neu* status. Although there are many methods, *HER-2/neu* gene amplification measured by FISH and overexpression of the *HER-2/neu* protein product measured by IHC are the most commonly used methods. Discordant FISH and IHC assays are most commonly the result of false-positive results in patients with a 2+ screen by IHC testing, which suggests that overexpression of *HER-2/neu* in these cases should be confirmed by FISH.⁵²

Although there is a growing understanding of the prognostic significance of individual factors, it is not clear how to practically use multiple prognostic factors in concert. The development of decision-making systems for clinical applications will require improvements in the areas of (1) standardization of methodologies and interlaboratory quality control for prognostic factor determinations, (2) definition of a limited set of prognostic markers that are independently predictive, and (3) staging systems that integrate this information. The National Institutes of Health (NIH) convened an expert panel to develop a consensus statement on adjuvant therapy for breast cancer.⁵³ One question addressed by the Consensus Development Panel was which factors should be used to select systemic adjuvant therapy. The panel identified age, tumor size, axillary node status, histologic tumor type, standardized pathologic grade, and hormone receptor status as the only currently accepted prognostic and predictive factors. In addition, the updated International Expert Consensus on the Primary Therapy of Early Breast Cancer concluded that ER and PR expression of the primary tumor cells are the only tumor-related markers with clear predictive value for treatment response that has unequivocal clinical utility regarding adjuvant therapy.⁴² This central importance of the steroid hormone receptors emphasizes the absolute necessity to measure ER and PR, report results in a standardized quantitative manner (e.g., percentage of cells stained), and use quality-assured procedures in experienced laboratories. The predictive utility of *HER-2* overexpression, cell proliferation markers, and the interaction of these factors with steroid hormone receptor expression await confirmation. The prognostic usefulness of features such as expression of the components of uPA and PAI-1,^{54,55} deregulated expression of cyclin E,^{56,57} and presence of tumor cells in bone marrow and in circulating blood is not clear.^{58–60}

► TREATMENT: Early Breast Cancer

■ EARLY BREAST CANCER

■ LOCAL-REGIONAL THERAPY

Most patients presenting with breast cancer today have either an in situ tumor, a small tumor with negative lymph nodes (stage I), or a small stage II cancer. Surgery alone can cure most, if not all, patients with in situ cancers and approximately half of all patients with stage II cancers. The choice of surgical procedures has changed drastically over the past 50 years. This in part is a result of changes in our understanding of the biology of breast cancer, and is due in part to a series of well-conducted trials performed over this time period.

The Halstedian theory and concept of tumor growth, formulated at the end of the nineteenth century, held that breast cancer was a local-regional disease that spread to involve larger contiguous areas of the breast, chest wall, and adjacent lymph nodes. This hypothesis gave rise to emphasis throughout most of the twentieth century on the Halsted radical mastectomy, the hallmark of an approach maintain-

ing that cure of early disease could best be achieved with expansive, meticulously performed surgical procedures. The *radical mastectomy* involves removal of the breast and both major and minor pectoralis muscles. The axillary nodes on the same side (ipsilateral) as the breast lesion are also removed. Substantial morbidity is associated with this procedure. Muscle resection decreases strength and range of motion, and removal of axillary lymph nodes can produce edema of the arm and resected breast area. This procedure was often followed by external beam radiation therapy to the involved area.

During the 1960s, it was recognized that breast cancer is often microscopically disseminated at the time of initial diagnosis. The evolutionary concept that breast cancer is not only a local, but also a systemic, disease has resulted in major changes in local and systemic therapy. In 1980, the Commission on Cancer of the American College of Surgeons reported that there had been an apparent gradual shift from a radical to modified radical mastectomy since December of 1972.⁶¹ The modified radical mastectomy, also termed *total mastectomy with axillary lymph node dissection*, is not as precisely defined or

standardized as the radical mastectomy. The pectoralis minor muscle may be excised, divided, or left intact, and more importantly, there may be variation in the extent of axillary lymph node dissection, ranging from sampling to full dissection. It was recognized during this time period that a major factor in prognosis was involvement of axillary lymph nodes rather than the type of initial surgical procedure performed.

Results of a large trial conducted in the United States by the NSABP repudiated the Halsted theory and supported the alternative systemic hypothesis. NSABP B-04, randomized nearly 2,000 women among three treatment regimens: radical mastectomy, simple mastectomy with local-regional irradiation, and simple mastectomy and removal of nodes if they later became clinically positive.⁶² Forty percent of patients who underwent the radical mastectomy had pathologically positive lymph nodes; thus it can be assumed that 40% of patients in the other two groups had positive axillary nodes that were not removed. Despite the disparity in local-regional treatment, no significant difference in treatment failure, distant metastases, or overall survival was observed through more than 25 years of follow-up.

Based on the results of that trial, the NSABP instituted a second trial (B-06) in which patients with stage I or stage II breast cancer with a tumor size 4 cm or less were treated with either modified radical mastectomy or lumpectomy with or without radiation therapy.⁶³ Lumpectomy followed by radiation resulted in a 5-year survival of 85% compared to 76% for modified radical mastectomy; the 20-year results were consistent with the earlier results. This study also found that radiation therapy reduced the probability of local tumor recurrence by about 30% in patients treated with lumpectomy. The local failure rate of modified radical mastectomy was 8.1% compared to 7.2% for lumpectomy alone and 1.1% for lumpectomy and radiation therapy. Neither the rate of development of distant metastases nor contralateral breast cancer was different in the treatment groups.

The NIH Consensus Conference on the Treatment of Early Stage Breast Cancer addressed the roles of modified radical mastectomy versus breast conservation and concluded that primary therapy for breast cancer stages I and II should be *breast conservation*.⁵³ Breast conservation consists of lumpectomy, also referred to as segmental mastectomy or partial mastectomy, and is defined as excision of the primary tumor and adjacent breast tissue, followed by radiation therapy to reduce the risk of local recurrence. Removal of level I/II axillary lymph nodes is recommended for completeness of staging and prognostic information. The reason given for favoring breast conservation therapy is that it achieved similar results to more extensive surgical procedures, and had cosmetically superior results.

Most patients with breast cancer can be treated by lumpectomy and radiation therapy. Several factors should be considered in selecting patients for breast conservation therapy. Multiple sites of cancer within the breast and the inability to attain negative pathologic margins on the excised breast specimen are predictive for an increased risk of recurrence with breast-conserving therapy and are indications for mastectomy. Some pre-existing collagen vascular diseases (e.g., scleroderma and systemic lupus erythematosus) are a contraindication for the use of breast-conserving radiation and surgery. Although local recurrence following breast-conservation therapy is not associated with increased mortality, it is distressing to the patient and requires surgical removal of the breast. In addition, reconstructive therapy is often not feasible in a breast that has previously received irradiation. Another major consideration in selecting patients for breast-conserving therapy is the expected cosmetic result. Although the size of the tumor is not an important consideration for breast cancer recurrence, the relationship of the size of the tumor to the total breast volume is

an important cosmetic consideration. If the volume of the tissue removed is large in a woman with small breasts, better results can often be obtained with mastectomy and reconstruction. Despite the desire of the patient and the willingness of the surgeon to avoid mastectomy, in some circumstances a lumpectomy will approximate so closely a mastectomy that both the patient and the physician will agree that preservation of a very limited amount of breast tissue would not justify the inconvenience of radiation therapy. Another approach to therapy for these patients would be primary systemic therapy to potentially shrink the tumor and minimize surgery (see section on adjuvant systemic therapy for further details). Aside from the probability of local recurrence and the ability to achieve a satisfactory cosmetic result, consideration must be given to the availability of an external beam radiation facility and the patient's willingness to comply with the prescribed course of radiotherapy. In most instances, external beam radiation therapy used in conjunction with breast-conserving procedures involves 4 to 6 weeks of radiation therapy directed to the breast tissue (a total of 5,000 cGy administered in 200-cGy doses daily to eradicate residual disease). Complications associated with radiation therapy to the breast are minor and include reddening and erythema of the breast tissue and subsequent shrinkage of total breast mass beyond that predicted on the basis of breast tissue removal. Some clinical situations also require postmastectomy radiation therapy as well (see section on locally advanced breast cancer).

Simple or total mastectomy involves removal of the entire breast without dissection of the underlying muscle or axillary nodes. The major disadvantage of this procedure is that axillary nodal status is not determined, and therefore important prognostic information may be lost. This procedure is used in patients with carcinoma in situ, in whom there is a 1% incidence of axillary node involvement, or in cases of local recurrence following breast-conservation therapy. While axillary lymph node dissection with histopathologic study of the axillary specimen was the gold standard for detecting axillary nodal involvement and determining the number of lymph nodes containing tumor, the importance of stage I/II axillary dissection is being challenged. Although highly accurate, its morbidity is significant, with an acute complication rate as high as 20% to 30% and rates of chronic lymphedema also on the order of 20% to 30%.^{64,65}

A new procedure involving lymphatic mapping and sentinel lymph node biopsy is becoming more acceptable at many academic centers across the United States.⁶⁶ This procedure was first utilized in melanoma, but has been adapted for use with breast tumors.⁶⁷ The sentinel lymph node is the first lymph node that drains a cancer. Injection of a vital blue dye around the primary breast tumor results in identification of the sentinel lymph node in the majority of patients, and the status of this lymph node may predict the status of the remaining nodes in the nodal basin. In more recent series, the use of a radiolabeled colloid alone or in addition to the blue dye is generally associated with a higher rate of identification of the sentinel lymph node, but this is a controversial topic and may be related to experience of the surgeon or other factors. Regardless of the mapping technique and patient populations studied, a sentinel lymph node can be identified in 90% of patients, and can accurately predict the status of the remaining axillary nodes in 95% of patients.⁶⁷ Contraindications to this procedure are patients with clinically apparent lymph node involvement, tumors >5 cm in size or locally advanced, neoadjuvant chemotherapy, multicentric cancers, prior axillary surgery, and/or a large biopsy cavity. Patients who are pregnant or lactating are also not eligible for this procedure. Another issue that is raised is the experience and mastery of the procedure by the surgical team. It has been shown that an individual surgeon must perform approximately

20-60 procedures to attain competency.^{68,69} At present the long-term outcome of patients undergoing this procedure alone (without completion axillary dissection) are not available. Ongoing clinical trials will hopefully answer these questions, but this is a very controversial subject with much debate amongst even the most highly regarded breast surgeons. Thus, simple mastectomy may be a reasonable alternative for women who wish to avoid the inconvenience of radiation therapy and preserve their option for breast reconstruction in the future, understanding the lack of long-term data with sentinel lymph node biopsy alone.

The NSABP B-04 and B-06 trials are widely credited with the finding that breast conservation is an appropriate primary therapy for most women with stages I and II disease, and is preferable because it provides survival rates equivalent to those of modified radical mastectomy. But these trials were also important for the valuable information they provided regarding the natural history of the disease and the identification of pathologic prognostic factors associated with early cancer spread. The preponderance of information available regarding selecting women most likely to benefit from systemic adjuvant therapy was derived from pathologic evaluation of tissues archived from these trials. It is hoped that further investigation into less extensive surgery (now focused on the axilla) will continue to provide valuable information for the future.

■ SYSTEMIC ADJUVANT THERAPY

Systemic adjuvant therapy is defined as the administration of systemic therapy following definitive local therapy (surgery, radiation, or a combination of these) when there is no evidence of metastatic disease, but a high likelihood of disease recurrence. The concept of breast cancer being a systemic disease and the rationale of adjuvant chemotherapy was based on a series of laboratory and clinical investigations conducted during the 1960s and 1970s that were directed primarily toward achieving a better understanding of tumor metastases. Table 125–6 illustrates the laboratory findings, clinical ab-

TABLE 125–6. Laboratory Findings, Clinical Observations, and Biologic Hypothesis of Breast Cancer as a Systemic Disease and the Value of Adjuvant Chemotherapy

- By the time cancer becomes clinically detectable, it is advanced (about 30 doublings) and has had ample opportunity to establish distant micrometastases.
- There is no orderly pattern of tumor cell dissemination, and the bloodstream is of considerable importance in tumor spread.
- Operable breast cancer is often a systemic disease and variations in local-regional therapy have not substantially affected survival. Only by control of distant disease can there be an improvement in the outcome of breast cancer patients.
- Likelihood of disease recurrence is related to size of tumor mass and axillary node involvement at diagnosis.
- Recurrence of breast cancer following local-regional therapy is most commonly at sites distant from the breast.
- Tumor growth fraction is inversely related to tumor population site. Therefore, optimal kinetic conditions to achieve cure with chemotherapy exist in the setting of micrometastatic disease.
- Efficacy of chemotherapy is dose dependent and optimal doses of combination chemotherapy can be more safely and effectively administered in the adjuvant setting as opposed to the setting of advanced disease.

normalities, and biologic hypothesis that lead to recognition of breast cancer as a systemic disease and documented the value of adjuvant chemotherapy. The very earliest adjuvant trials in breast cancer consisted of perioperative administration of alkylating agents with the intent of eradicating micrometastases that were disseminated at the time of surgical excision of the tumor. Many collaborative research groups have conducted stepwise series of studies designed to identify appropriate candidates for systemic adjuvant therapy, as well as optimal regimens and duration of systemic adjuvant therapy. Several hundred randomized clinical trials evaluating various systemic adjuvant modalities have been reported. Most published results confirm that chemotherapy, hormonal therapy, or both, result in improved disease-free survival (DFS) and/or overall survival (OS) for all treated patients, or more commonly for patients in specific prognostic subgroups (e.g., nodal involvement, menopausal status, hormonal receptor status, growth fraction, or nuclear grade). The huge amount of data generated by these trials has resulted in a great deal of controversy, with different conclusions being reached by various experts.

A number of factors make interpretation of results of systemic adjuvant therapy trials difficult. These include differences in the patient populations studied, the variation in natural history of breast cancer, the absence of information regarding pathologic prognostic factors in many studies, and differences in treatment approach and methods of analysis. It is important to remember that the goal of systemic adjuvant therapy is cure. Therefore patients in these studies must be followed for long periods of time before results can be determined. In addition, because most patients with early breast cancer (50% to 90%) in the various trials are cured with local-regional therapy alone, large numbers of patients are required to show a statistically significant difference that can be attributed to systemic adjuvant therapy. For these reasons, combined analysis, or meta-analysis, of all breast cancer trials has been conducted, and until recently was the most frequently referred to information regarding systemic adjuvant therapy. This effort, organized by the Early Breast Cancer Trialists' Collaborative Group, is based on a worldwide collaboration involving 133 randomized trials conducted between 1957 and 1985.⁷⁰ The results of the Early Breast Cancer Trialists' Collaborative Group meta-analyses were published in 1988, 1992, and 1998. Many important questions regarding the optimal way to administer adjuvant chemotherapy^{70,71} and hormonal therapy,^{70–73} and the degree of benefit in terms of DFS or OS to clinically relevant subsets of patients have been answered by these meta-analyses. Simply stated, the results of the meta-analyses support the use of adjuvant hormonal therapy in all patients with positive hormone-receptor status, and this finding is reflected in the 2000 NIH Consensus Development Conference Statement⁵³ that adjuvant hormonal therapy should be recommended to women whose tumors contain hormone receptor protein regardless of age, menopausal status, involvement of axillary lymph nodes, or tumor size. The results of these meta-analyses also support a benefit of adjuvant chemotherapy, again reflected in the 2000 NIH Consensus Development Conference Statement that it is accepted practice to offer cytotoxic chemotherapy to most women with lymph node metastases or with primary breast cancers larger than 1 cm in diameter (both node-negative and node-positive).⁵³

It is important to understand the relative and absolute magnitude of the benefit associated with adjuvant systemic therapy in breast cancer. Table 125–7 shows the proportional reduction in the annual odds of recurrence and death by age for adjuvant polychemotherapy and adjuvant tamoxifen given for 5 years in women with tumors that are positive for hormone receptors based on the results of these meta-analyses. Throughout these reports, the results are presented as they

TABLE 125-7. Ten-Year Results of the Overview Analysis

| Age | Tamoxifen | | Polychemotherapy | |
|--------------|--------------------------|-----------|--------------------------|-----------|
| | Reduction in Annual Odds | | Reduction in Annual Odds | |
| | Recurrence (%) | Death (%) | Recurrence (%) | Death (%) |
| All patients | 47 ± 3 | 26 ± 4 | 24 ± 2 | 15 ± 2 |

| 50–59 | 37 ± 6 | 11 ± 8 | 22 ± 4 | 14 ± 4 |
| 60–69 | 54 ± 5 | 33 ± 6 | 18 ± 4 | 8 ± 4 |
| ≥70 | 54 ± 13 | 34 ± 13 | NS | NS |

NS, not significant.

From Paridaens et al¹¹¹ and Mauras et al.¹¹²

are in Table 125-7, as proportional benefits that compare the effects of two groups, in this case, chemotherapy or hormonal therapy versus no chemotherapy or hormonal therapy. A proportional reduction of 25% might equivalently be described as an odds ratio or hazard ratio of 0.75, an odds reduction of 25%, or a 25% reduction in the death rate. For a given proportional reduction in death rate, the absolute improvement in 10-year survival will depend on the risk of death with no treatment, which for breast cancer is known to vary based on prognostic factors that include patient characteristics, disease characteristics and biomarkers identified earlier in this chapter. Table 125-8 shows the number of deaths avoided per 100 patients treated in several hypothetical subsets of patients with different estimated 10-year survivals without adjuvant therapy, as a function of different estimates of treatment benefit shown as the proportional reductions in mortality if they did receive adjuvant therapy. Approximately 15 of every 100 patients benefited at 10 years from adjuvant therapy when a 30% proportional reduction in mortality is observed in the highest-risk subgroups (50% death rate with no adjuvant therapy). In contrast, the same 30% proportional reduction in mortality translated into a benefit for 3 of 100 patients in the lowest-risk subset (10% death rate with no adjuvant therapy). Thus the absolute benefit of adjuvant therapy depends on both the proportional reduction in mortality and the risk of disease recurrence, with the greatest benefit observed in the highest-risk treatment groups given a fixed proportional reduction in mortality. Table 125-9 further demonstrates this by using data from the meta-analysis to show the absolute benefits of adjuvant chemotherapy in terms of age and nodal status. In the highest-risk group, node-positive women younger than 50 years of age, only 41.4% were alive at 10 years with no polychemotherapy as compared to 53.8% with polychemotherapy,

which translates into an absolute survival benefit of 12.4%. However, in the node-negative group, patients less than 50 years old where survival with no polychemotherapy was highest (i.e., 71.9%), the addition of polychemotherapy produced an absolute benefit of only 5.7%. It should be pointed out that all of these differences in survival are highly statistically significant and form the basis of the 2000 NIH Consensus Development Group recommendation that it is accepted medical practice to offer cytotoxic chemotherapy to most women with early-stage breast cancer.⁵³ However, the absolute benefit in node-positive women age 50 to 69 years is quite small (2.3%), and depending on other disease characteristics and comorbid conditions, patients may elect not to pursue treatment. Although a 2% absolute reduction in death attributable to polychemotherapy may appear small, at least two investigators have reported that most patients with breast cancer would accept severe toxicity from treatment to achieve as little as a 1% to 5% improvement in survival.^{74,75}

Several international and national groups have developed guidelines for treatment of early-stage breast cancer based on specific patient and disease characteristics and the results of these meta-analyses. In March 2003, an international group of researchers met in St. Gallen, Switzerland for the Eighth International Conference of Adjuvant Therapy of Primary Breast Cancer.⁷⁶ At the conclusion of the conference, a consensus panel of experts reviewed and modified its previous guidelines and recommendations for selection of adjuvant systemic therapies in specific patient populations outside of the framework of clinical trials (Table 125-10). Criteria used to construct Table 125-10 included risk of relapse, predicted response, results of treatment from randomized clinical trials, and patient preferences concerning risks and benefits of effective therapy. Patient populations are categorized into groups based on risk of relapse. The panel defined node-negative, minimal/low-risk as patients with all of the following: ER/PR-positive tumors with all of the following characteristics: pathologic tumor size ≤2 cm, grade 1, and age ≥35 years. Average-risk node-negative patients have at least one of the following: pathologic tumor size >2 cm, grade 2 or 3, or age <35 years. Patients with average-risk, node-negative tumors are further classified into endocrine responsive or nonresponsive disease, based on the presence or absence of hormone receptors, respectively. Node-positive patients are by definition at high risk of relapse.

The National Comprehensive Cancer Network (NCCN) has also developed practice guidelines for the treatment of breast cancer. Figure 125-3 illustrates the NCCN 2004 guidelines for adjuvant treatment of stages I to IIIA breast cancer following total mastectomy or lumpectomy. These more recent guidelines reflect the increasing trend toward the use of chemotherapy in postmenopausal (age >50 years)

TABLE 125-8. Absolute Reduction in Mortality at 10 Years per 100 Patients Treated

| Estimated 10-year Death Rate With No Therapy | Hypothetical Proportional Reduction in Mortality Due to Treatment | | | | |
|--|---|-----|-----|-----|-----|

^aOr ovarian ablation.

^bTamoxifen therapy should not be started until after chemotherapy is finished.

^cThe addition of chemotherapy is considered an acceptable option based on evidence from clinical trials. Considerations about a low relative risk of relapse, age, toxic effects, socioeconomic implications, and information on patient preference might justify the use of endocrine therapy alone.

^dIndicates treatments still being tested in randomized clinical trials.

^eIn the presence of chemotherapy, adding tamoxifen to ovarian suppression may improve outcome. Use of a GnRH analog alone has been shown to be as effective as chemotherapy and is an option if tamoxifen is not indicated.

^fIn women in whom tamoxifen is not acceptable (contraindicated or not tolerated), then an aromatase inhibitor (data are limited to anastrozole) may be used.

GnRH, gonadotropin-releasing hormone (goserelin is most extensively studied).

Figure 125-3 is not available in digital format.

patients, as well as the well-established premenopausal (age <50 years) patient group, hormonal therapy in all hormone receptor-positive women regardless of age or menopausal status, and the combination of both chemotherapy and hormonal therapy.⁷⁷ These guidelines differ from the St. Gallen expert consensus guidelines in the recommendation of chemotherapy for women with node-negative tumors 0.6 to 1 cm in size. If the characteristics of these tumors are unfavorable (angiolympathic invasion, high nuclear or histologic grade, *HER-2* overexpression, or hormone receptor-negative), then chemotherapy is recommended with or without hormonal therapy, depending on hormone-receptor status.

Intensive research efforts are directed toward identifying those characteristics of the primary tumor (pathologic prognostic factors) that may predict for a higher or lower likelihood of metastases and death in node-negative patients. Although a multitude of prognostic factors are being investigated, no single factor or combination of factors sufficiently identifies those at risk of metastases or is sufficiently standardized to be reproducibly applicable to all patients. For a more in-depth discussion of the issues and controversies regarding adjuvant therapy of breast cancer, the reader is referred to two excellent references.^{78,79}

In contrast to adjuvant systemic therapy, the use of preoperative systemic therapy is gaining favor in both early-stage and locally-advanced breast cancers. This approach to therapy, referred to as *neoadjuvant* or *primary systemic therapy*, most often consists of chemotherapy, but in special circumstances may also include hormonal therapy (e.g., in inoperable patients with significant comorbidities). The advantages of preoperative systemic therapy include: (1) decrease in the size of the tumor to minimize surgery; and (2) to determine response to chemotherapy/hormone therapy in vivo (an important prognostic indicator). In a pivotal study conducted by the NSABP (B18), preoperative chemotherapy was compared to traditional chemotherapy given after surgery (same chemotherapy and same number of cycles).⁸⁰ While no difference was found in DFS or OS between these two groups, rates of breast-conserving surgery were higher in the group receiving preoperative chemotherapy (67.8% vs. 59.8%).⁸¹ This study also identified a small subset of patients (13%) who had a pathologically complete response (pCR; no tumor left at surgery) after chemotherapy. These patients went on to have a significantly better DFS compared with patients that did not achieve a pCR ($p < 0.0001$).⁸¹ While this approach to therapy is generally reserved for patients with inoperable tumors (locally advanced),

^xFAC may also be given with bolus doxorubicin administration, and the fluorouracil dose is then given on days 1 and 8.

^yPaclitaxel may also be given concurrently with doxorubicin or epirubicin as a combination regimen. Pharmacokinetic interactions make these regimens more difficult to give.

early-stage breast cancer patients who meet the criteria for breast-conserving therapy except for the size of the tumor may be considered for preoperative systemic therapy in order to decrease the size of the tumor, allowing for less radical surgery and better cosmetic results.

■ Adjuvant Chemotherapy

4 Cytotoxic drugs that have been used alone and in combination as adjuvant therapy in breast cancer include doxorubicin, epirubicin, cyclophosphamide, methotrexate, fluorouracil, paclitaxel, docetaxel, melphalan, prednisone, vinorelbine, and vincristine. The most common combination chemotherapy regimens employed in the adjuvant and metastatic setting are listed in Table 125–11.

The basic principle of adjuvant therapy for any cancer type is that the regimen with the highest response rate in advanced disease should be the optimal regimen for use in the adjuvant setting. However, results from individual clinical trials investigating specific regimens in the adjuvant setting are required to be able to identify the benefits and risks to a specific patient population. Early administration of effective combination chemotherapy at a time when the tumor burden is low should increase the likelihood of cure and minimize the emergence of drug-resistant tumor cell clones. Anthracyclines (doxorubicin and

epirubicin) have historically been referred to as the most active class of chemotherapy agents in the treatment of metastatic breast cancer. This has led to the assumption that anthracycline-containing regimens are associated with a higher cure rate than non-anthracycline-containing regimens when used in the adjuvant setting. The meta-analysis of polychemotherapy (discussed previously) investigated this question, presenting indirect evidence from 11 trials that compared an anthracycline-containing regimen with a cyclophosphamide, methotrexate, fluorouracil (CMF)-type regimen and demonstrating a significant advantage for the anthracycline regimens.⁷² In this meta-analysis, anthracycline-containing regimens were modestly superior in reducing recurrence and death compared to regimens without anthracyclines. A 12% ± 4% reduction in annual odds of recurrence and an 11% ± 5% reduction in annual odds of death were reported in the 1998 update, and this translated into an absolute difference in overall mortality at 5 years of 3%.⁷²

The taxanes (paclitaxel and docetaxel) are a newer class of agents that rival the anthracyclines in their activity in metastatic breast cancer, becoming (arguably) the most active class of chemotherapy for this disease. Since these agents are relatively new, adjuvant studies including them have not yet been incorporated into the overview meta-analysis. However, results from a few clinical trials have been reported and are reaching substantial follow-up to provide meaningful information. All trials have enrolled node-positive patients only, and all

TABLE 125–12. Adjuvant Taxane-Containing Regimens from Clinical Trials

AC, doxorubicin, cyclophosphamide; BCIRG, Breast Cancer International Research Group; CALGB, Cancer and Leukemia Group B; FAC, fluorouracil, doxorubicin, cyclophosphamide; NSABP, National Surgical Adjuvant Breast and Bowel Project; Pac, paclitaxel; TAC, docetaxel, doxorubicin, cyclophosphamide.

^aThe dose of paclitaxel differs in these two studies. The CALGB study used the dosing and schedule listed in Table 125–11. The NSABP study administered a higher dose of paclitaxel, at 225 mg/m² IV over 3 hours, every 21 days, for 4 cycles.

but one has been published in abstract form only (Table 125–12).^{82–84} Two studies have incorporated four cycles of paclitaxel into the adjuvant regimen sequentially after four cycles of AC.^{82,83} These two studies compared this new regimen to the standard regimen of four cycles of AC. Results from these studies indicate a modest but statistically significant advantage in DFS with the addition of paclitaxel (see Table 125–12). However, the increase in OS in one of these studies has not yet reached statistical significance. In earlier trials with anthracycline-containing regimens (meta-analysis), differences in survival were not seen until 7 to 10 years of follow-up were completed. Therefore this trial may require longer follow-up in order to demonstrate a difference in OS. Nonetheless, advantages in DFS and OS in one trial are sufficient for many clinicians to justify use of this regimen in the adjuvant setting.

Investigating the concurrent use of a taxane with an anthracycline has also been investigated in node-positive breast cancer patients. The Breast Cancer International Research Group (BCIRG) randomized node-positive breast cancer patients to receive six cycles of the standard fluorouracil, doxorubicin, and cyclophosphamide (FAC) regimen or six cycles of the paclitaxel, doxorubicin, and cyclophosphamide (TAC) regimen. Substantial increases in DFS and OS were found with the taxane regimen in this study, substantiating the role of the taxanes in the adjuvant setting for node-positive patients.⁸⁴ Because these studies were limited to node-positive patients, the benefits in node-negative patients are unknown.

CLINICAL CONTROVERSY

While the incorporation of the taxanes into many different regimens, both sequentially and concurrently, has led to a shift in therapy for node-positive breast cancer patients, the use of taxane-containing regimens in node-negative patients remains controversial. The use of an anthracycline-containing regimen has been established for both node-negative and node-positive breast cancer patients.

However, there is no apparent biological reason why node-negative disease should respond differently to the taxanes than node-

positive disease. The only difference may be that the absolute benefit for this patient population may be smaller, and may not be large enough to warrant a change from the standard of care. Further follow-up from these trials will continue to address this issue.

No validated predictive factors exist for response to chemotherapy. However, *HER-2/neu* status and ER-negativity may be useful predictors of response, depending on the outcome of several ongoing clinical trials. Retrospective studies have suggested that the benefit with the anthracycline-containing regimens over CMF-like regimens may be limited to those tumors that overexpress *HER2/neu*. However, this is based on retrospective data and should be viewed with skepticism. The use of trastuzumab, a monoclonal antibody directed against the *HER2/neu* receptor (see section on metastatic breast cancer), is currently being investigated for use in the adjuvant setting with chemotherapy.

CLINICAL CONTROVERSY

The addition of trastuzumab to chemotherapy has resulted in a survival advantage for metastatic breast cancer patients with *HER2*-overexpressing/amplified tumors compared with chemotherapy alone. However, the use of trastuzumab-chemotherapy combinations in the adjuvant setting has yet to be substantiated. These patients tend to have a poor prognosis with chemotherapy alone and may benefit from additional therapy. However, there are not yet data to demonstrate additional benefit with this combination compared with chemotherapy alone.

These trials are still ongoing and preliminary efficacy data are not yet available. ER-status has also been looked at for predictability. Several clinical trials have attempted to correlate ER-negative status with better response to adjuvant chemotherapy. These results are inconsistent and current practice does not recommend tailoring chemotherapy based on ER-status. Further investigation into both of these markers may provide evidence to suggest otherwise, but until those data are available, current practice does not incorporate these into decisions regarding adjuvant chemotherapy.

Although the optimal duration of adjuvant chemotherapy administration is unknown, it appears to be on the order of 12 to 24 weeks and may depend on the regimen being used. Chemotherapy is usually initiated within 3 weeks of surgical removal of the primary tumor. “Dose intensity” and “dose density” appear to be critical factors in achieving optimal outcomes in adjuvant breast cancer therapy. *Dose intensity* is defined as the amount of drug administered per unit of time and is typically reported in milligrams per square meter of body surface area per week (mg/m^2 per week). Increasing dose, decreasing time, or both can increase dose intensity. *Dose density* is equivalent to the concept of increasing dose intensity, but not by increasing the amount of drug given, as occurs with dose escalation, but instead by decreasing the time between treatment cycles. The issue of dose intensity first received wide attention in 1981, when the Milan group reported a retrospective analysis of their original CMF adjuvant study, suggesting that only those patients who received at least 85% of their planned CMF dose benefited significantly from adjuvant therapy, whereas those receiving less than 65% of the planned dose had the same disease-free survival and overall survival as the group of control patients treated by surgery alone.⁸⁵ More recent studies that have escalated the dose of cyclophosphamide or doxorubicin in standard anthracycline-containing regimens reported that this intervention offers no therapeutic advantage and is associated with greater toxicity. A study by the Cancer and Leukemia Group B (CALGB) that is often discussed assigned 1,572 women to three treatment groups given different doses and schedules of CAF.⁸⁶ The high-dose arm had twice the dose intensity and twice the drug dose as the low-dose arm (basically representing what we now consider “standard dose” CAF). The moderate-dose arm had two-thirds the dose intensity as the high-dose arm, but the same total drug dose. At a median follow-up of 9 years, DFS and OS for patients on the moderate- and high-dose arms were superior to those for the patients in the low-dose arm. There was no difference in DFS or OS between the moderate- and the high-dose arms. Therefore it would appear that reducing the dose for standard treatment regimens should be avoided, unless necessitated by severe toxicity. But increasing doses beyond those contained in standard treatment regimens does not appear to be beneficial. In a more recent study conducted by the CALGB, the dose of doxorubicin was escalated ($60 \text{ mg}/\text{m}^2$, $75 \text{ mg}/\text{m}^2$, or $90 \text{ mg}/\text{m}^2$) in combination with cyclophosphamide at a fixed dose of $600 \text{ mg}/\text{m}^2$.⁸² No benefits were seen with the higher dose levels in this trial. Therefore it appears that there is a threshold for dosing adjuvant chemotherapy under which there may be a lack of benefit. *Dose intensity* above that threshold does not appear to add benefit and imparts additional toxicity.

A recent study investigating the idea of *dose density* has now been reported. The CALGB conducted yet another study looking not only at dose density, but also at the question of using sequential versus combination chemotherapy regimens. Using a 2×2 factorial design, investigators randomized node-positive breast cancer patients after surgery to compare sequential versus concurrent chemotherapy, and standard dose versus dose density.⁸⁷ The arms of the study were as follows: (1) sequential doxorubicin (A) for four cycles, followed by paclitaxel (P) for four cycles, followed by cyclophosphamide (C) for four cycles, with all cycles given every 3 weeks; (2) sequential A for four cycles, followed by P for four cycles, followed by C for four cycles, with all cycles given every 2 weeks with filgrastim; (3) concurrent AC for four cycles, followed by P for four cycles, with all cycles given every 3 weeks; and (4) concurrent AC for four cycles, followed by P for four cycles, with all cycles given every 2 weeks with filgrastim. After a median follow-up of 36 months, the patients receiving every-2-week chemotherapy had a significantly prolonged DFS (at 3 years 85% vs.

81%; RR = 0.74, $p = 0.01$) and OS (92% vs. 90%; RR = 0.69, $p = 0.013$) compared with every 3-week chemotherapy.⁸⁷ The use of sequential versus concurrent chemotherapy did not show a benefit for one over the other in terms of DFS or OS. Due to the statistical design of this trial, it does not indicate which of the four regimens tested is the best one to use. It does, however, indicate a benefit with more frequent dosing, at least with the drugs, doses, and combinations used here. Patients in the concurrent every-2-week group (group 4) had significantly more regimen-related toxicity, including a very high rate of red blood cell transfusions for anemia (13% of cycles).⁸⁷ Red blood cell transfusions are rarely required with most other standard adjuvant chemotherapy regimens used for breast cancer. Previous data with paclitaxel given weekly versus every 3 weeks indicates that this drug is more effective when given weekly in the neoadjuvant setting.⁸⁸ Therefore some have speculated that the different paclitaxel schedule is the primary reason for the success with this approach to therapy. All of this information leaves many clinicians wondering whether it is prudent, based on the available evidence, to incorporate this regimen into standard of care. Hopefully, as other clinical trials investigate this and other questions, clinicians will be better equipped to choose the optimal adjuvant chemotherapy regimen for their patients. Until that time this approach to therapy is certainly an option for some patients, recognizing the additive toxicity.

A major focus in clinical investigation was the use of more high-dose chemotherapy regimens as adjuvant therapy. Because bone marrow suppression is the dose-limiting toxicity for most chemotherapeutic agents, high-dose chemotherapy regimens followed by colony-stimulating factors or reinfusion of autologous hematopoietic stem cells have been developed. Trials to define the specific usefulness of high-dose regimens, as well as autologous hematopoietic stem cell transplantation in conjunction with dose-intense regimens, were justified given the positive response rates seen in the metastatic breast cancer setting and the very poor prognosis associated with disease that involves 4 to 9, and particularly 10 or more, axillary lymph nodes. Several cooperative groups have conducted trials of high-dose chemotherapy versus conventional adjuvant therapy. None of the trials have shown a significant difference in DFS or OS. Based on available evidence, this approach to therapy is not worth the added toxicity.

The short-term toxic effects of chemotherapy used in the adjuvant setting are generally well tolerated. Although a number of investigators have demonstrated a reduction in quality of life, most patients are able to maintain a reasonable level of function and emotional and social well being during treatment.⁸⁹ In general, supportive therapy of the patient receiving systemic adjuvant chemotherapy has improved in the past decade. Increased attention to the impact of symptoms on quality of life may account for some of this improvement. In addition, serotonin-antagonist antiemetics have become available to assist in managing chemotherapy-induced nausea and vomiting, and colony-stimulating factors are often helpful in preventing febrile neutropenia, particularly in elderly patients or patients receiving high-dose and dose-dense chemotherapy regimens. However, a number of side effects are common with the regimens employed and patients should be appropriately counseled regarding the likelihood of alopecia, weight gain, and fatigue. Patients who are menstruating will often experience a cessation of menses that may or may not return. Along with cessation of menses are accompanying signs and symptoms of menopause. Deep vein thrombosis has been reported in women receiving combination chemotherapy regimens.⁹⁰ A recent study estimated that 1 to 10 of 10,000 patients treated for 6 months with cyclophosphamide-based regimens might be expected to have leukemia within 10 years of diagnosis of breast cancer.⁹¹

Cardiomyopathy induced by doxorubicin occurs less than 1% of the time in women whose total dose of doxorubicin is less than 320 mg/m².⁹² It should be noted that epirubicin in the adjuvant setting is given at a dose of 100 to 120 mg/m².⁹³ At this dose epirubicin has an equal chance of causing cardiomyopathy as standard doxorubicin doses when both agents are given as bolus or short infusions. Taxanes are often associated with hypersensitivity reactions, peripheral neuropathy and/or myalgias and arthralgias for a few days following the infusion.

Before we leave the topic of adjuvant chemotherapy in stage I and II breast cancer, it is important to note that the magnitude of survival benefit for chemotherapy appears to be small, with an absolute reduction in mortality of only 5% at 10 years for patients with negative axillary lymph nodes and 10% for patients with positive axillary lymph nodes. In addition, there is currently no means to identify patients who will attain this survival benefit. However, two investigators report that most patients with breast cancer would accept severe toxicity from treatment to achieve as little as a 1% to 5% improvement in survival.^{74,75} Therefore in the absence of the ability to predict who will benefit, it is likely that most patients with stage I and stage II breast cancer will choose an adjuvant chemotherapy treatment. The optimal chemotherapy regimen for use in the adjuvant setting has yet to be identified and depends on many patient and tumor characteristics. All of the regimens previously mentioned are appropriate in the settings in which they were discussed.

■ Adjuvant Endocrine Therapy

4 Hormonal therapies that have been studied in the treatment of primary or early breast cancer include tamoxifen, oophorectomy, ovarian irradiation, luteinizing hormone-releasing hormone (LHRH) agonists, anastrozole, letrozole, and exemestane.

Tamoxifen was traditionally the gold standard adjuvant hormonal therapy and has been used in the adjuvant setting for three decades. Tamoxifen is antiestrogenic in breast cancer cells, but it appears to have estrogenic properties in other tissues and organs.^{94,95} Newer information confirms that tamoxifen and other similar drugs have many estrogenic and antiestrogenic effects that depend on the tissue and the gene in question, and they are more appropriately called selective estrogen receptor modulators (SERMs). Women receiving adjuvant tamoxifen therapy have a reduction in recurrence and mortality compared to women not receiving adjuvant tamoxifen therapy.⁷¹ This observation, coupled with evidence of tamoxifen's tolerability including beneficial estrogenic effects on the lipid profile and bone density, led to tamoxifen being the hormonal agent of choice, at least until evidence with the antiaromatase agents became available in postmenopausal women. Premenopausal patients may derive equivalent benefit from ovarian ablation via surgery or administration of LHRH agonists.⁷³

The optimal dose of tamoxifen is unclear. The Early Breast Cancer Trialists' Group showed that more is not necessarily better for response rates.⁷¹ Lower doses of tamoxifen may be effective, but no clinical trials have addressed this question. Therefore the current recommended dose for tamoxifen in both the adjuvant, as well as the metastatic and preventative settings, is 20 mg/day. Because tamoxifen has a long biologic half-life, it can be administered as a single daily dose. Adjuvant tamoxifen therapy is generally initiated shortly after surgery or as soon as pathology results are known and the decision to administer tamoxifen as adjuvant therapy is made. An interesting theory with some laboratory and clinical support held that tamoxifen antagonized the beneficial effect of chemotherapy in women aged

50 years or younger. Chemotherapy acts by inhibiting DNA synthesis, resulting in death of tumor cells, whereas tamoxifen is believed to have a static effect on tumor cell growth. The growth inhibitory effect of tamoxifen may therefore diminish the cytotoxic effect of chemotherapy, resulting in subsequent recurrence of disease in women who received the two agents concurrently. A phase III intergroup trial conducted investigating this question was reported in 2002.⁹⁶ Investigators randomized patients to receive chemotherapy for six cycles with concurrent tamoxifen, followed by continued tamoxifen for a total of 5 years, or chemotherapy with sequential tamoxifen for 5 years. After a median follow-up of 8.5 years, the administration of sequential tamoxifen resulted in an estimated DFS advantage of 18% (hazard ratio [HR] = 1.18) compared to the concurrent use of tamoxifen with chemotherapy.⁹⁶ Therefore the administration of tamoxifen should be limited to administration after completion of chemotherapy.

The optimal duration of tamoxifen therapy in the adjuvant setting is currently defined as 5 years. Studies examining prolonged administration (e.g., 10 years) have failed to demonstrate any advantage and may in fact be associated with a slightly worse survival.⁹⁷

The best information regarding the side effects of tamoxifen come from the National Surgical Adjuvant Breast and Bowel Project (NSABP), Breast Cancer Prevention Trial (P1).⁹⁸ This trial randomized 13,388 women at increased risk for breast cancer, 35 years of age or older, to placebo (n = 6,707) or 20 mg/day of tamoxifen (n = 6,681) for 5 years. Although the primary finding of this study was that tamoxifen reduced the risk of invasive breast cancer by 49%, this study also provides an excellent opportunity to objectively quantitate side effects associated with tamoxifen, due to its placebo control. Information was collected with regard to the occurrence of hot flashes, vaginal discharge, irregular menses, fluid retention, nausea, skin changes, diarrhea, and weight gain or loss. The self-administered depression scale and a global quality of life and a sexual function scale were administered at each follow-up visit. The only symptomatic differences noted between the placebo and tamoxifen group were related to hot flashes and vaginal discharge, both of which occurred more often in the latter group. There were no notable differences between the two groups relative to any of the findings obtained from the various self-reporting instruments. Tamoxifen administration did not alter the average annual rate of ischemic heart disease, but a reduction in hip radius and spine fractures was observed. Of note, the rates of stroke, pulmonary embolism, and deep vein thrombosis were elevated in the tamoxifen group (stroke, RR = 1.59; pulmonary embolism, RR = 3.01; and deep vein thrombosis, RR = 1.60). These events occurred more frequently in women age 50 years or older. The rate of endometrial cancer was increased in the tamoxifen group (RR = 2.53), and this increased risk occurred predominantly in women age 50 years or older. The increased risk of endometrial carcinoma is similar in magnitude to that associated with postmenopausal estrogen replacement therapy and is likely a consequence of an estrogenic effect of tamoxifen on the endometrium. Some experts argue that this risk is acceptable because the endometrial cancer induced by tamoxifen is low-stage, low-grade, and easily treated with surgery or other means and does not pose a life-threatening risk to women. There is also an increased risk of uterine sarcomas (a more aggressive form of endometrial cancer) with tamoxifen use, but this risk appears to be lower than the more common endometrial cancers identified in the NSABP P-1 study.⁹⁹ Currently, routine endometrial biopsy is not recommended for women receiving tamoxifen therapy. However, gynecologic exams and education regarding the importance of immediately reporting vaginal bleeding to primary physicians for further evaluation are important counseling points to women receiving tamoxifen therapy. In the NSABP-P1 trial,

no increase in liver, colon, rectal, ovarian, or other tumors was observed in the tamoxifen group as compared to the group who received placebo.

Toremifene is a recently marketed antiestrogen whose primary advantage is a lower estrogenic:antiestrogenic ratio as compared to tamoxifen (based on laboratory data).¹⁰⁰ Toremifene (60 mg orally daily) has been found to have efficacy similar to that of tamoxifen in metastatic disease and a generally similar side-effect profile.¹⁰¹ Currently, toremifene is indicated as an alternative to tamoxifen in patients with metastatic breast cancer, but studies are ongoing that evaluate its safety and efficacy in the adjuvant setting.

In premenopausal women, the use of LHRH-agonists or other means of ovarian ablation have been shown to provide benefit in the adjuvant setting.⁷³ The use of goserelin (an LHRH-agonist), alone or with tamoxifen, has been compared with standard chemotherapy (CMF) for six cycles. As a single agent, goserelin appears to provide similar benefit compared with CMF for six cycles for node-positive, ER-positive, premenopausal breast cancer patients.¹⁰² In another trial, the combination of goserelin and tamoxifen was compared with CMF for 6 cycles.¹⁰³ After a median follow-up of 6 years, this trial demonstrated a significant advantage over endocrine therapy in terms of DFS. Both of these trials require longer follow-up to determine the long-term consequences of this type of therapy. Similar comparative evidence is not available with anthracycline-containing regimens, although a clinical trial designed to answer this question was stopped due to slow accrual. However, ongoing studies are underway to look at this question. There are no data comparing an LHRH-agonist to tamoxifen alone in the adjuvant setting. Therefore optimal endocrine therapy is not known for these women. Also, based on retrospective reviews, premenopausal women who cease to menstruate with chemotherapy may have a better survival compared to women who continue to menstruate.¹⁰⁴ Therefore the role of an LHRH-agonist after chemotherapy in women who continue to menstruate is also being investigated.

In postmenopausal women, recently reported evidence supporting the use of aromatase inhibitors in the adjuvant setting is intriguing and may usurp the role of tamoxifen. Three different approaches to therapy have been undertaken with these new agents: (1) direct comparison with tamoxifen for adjuvant hormonal therapy, (2) sequential use after 5 years of adjuvant tamoxifen therapy, and (3) sequential use after 2 to 3 years of adjuvant tamoxifen. In the former setting, anastrozole was compared with tamoxifen or the combination in postmenopausal women with hormone-receptor positive, early-stage breast cancer (ATAC trial). In the most recent preliminary analysis of this study, after a median of 47 months of follow-up, anastrozole continues to produce superior DFS (86.9% vs. 84.5%; HR = 0.86; $p = 0.03$) compared with tamoxifen alone.¹⁰⁵ The combination of anastrozole and tamoxifen resulted in similar outcomes as tamoxifen alone, imparting no benefit for patients in that arm of the study. These data are very controversial due to the preliminary nature of the results and the lack of long-term safety information with the aromatase inhibitors. Concerns surrounding loss of bone density and an increased risk of osteoporosis are evident from the preliminary data.¹⁰⁵ However, the overall impact on quality of life and survival has yet to be determined, but successful coadministration of bisphosphonates with the aromatase inhibitors has been accomplished in many patients in the metastatic setting.

The other approach to adjuvant hormonal therapy advances looks at the sequential use of newer agents after the optimal 5 years of tamoxifen or only 2 to 3 years of tamoxifen. Five additional years of letrozole, in a highly publicized study reported in the *New England*

Journal of Medicine, was compared with placebo in postmenopausal breast cancer patients who had completed 5 years of tamoxifen therapy.¹⁰⁶ After a median follow-up of 2.4 years, letrozole was associated with superior estimated 4-year DFS compared with placebo in this setting (93% vs. 87%; $p < 0.001$). While these results were preliminary, patients were unblinded and allowed to crossover to the active arm of therapy. Therefore effects on survival will never be ascertained. However, further follow-up will be completed with regard to safety and DFS in those patients randomized to letrozole from the beginning of the trial. Based on the results of this study, letrozole received FDA approval in November 2004 for extended adjuvant therapy (i.e., after 5 years of tamoxifen therapy). In another recent trial, patients who had completed 2 to 3 years of adjuvant tamoxifen therapy were randomized to continue tamoxifen or crossover to exemestane for the remainder of the 5 years. After a median follow-up of 30.6 months, DFS was substantially longer with exemestane compared with continuation of tamoxifen (91.5% vs. 86.8%; HR = 0.68, $p = 0.00005$).¹⁰⁷ Concerns regarding long-term safety also arise with this study, with data indicating a possible increase in cardiovascular disease, osteoporosis, and visual disturbances with exemestane compared with tamoxifen.

CLINICAL CONTROVERSY

The optimal use of antiaromatase agents in the adjuvant setting for postmenopausal women with hormone-receptor positive tumors is controversial. Multiple studies have recently been published with results indicating a benefit to regimens that include an aromatase inhibitor as initial therapy or after tamoxifen. However, many questions remain as to the optimal drug, dose, sequence, and duration of therapy for these newer agents.

Tamoxifen, as mentioned previously, has been utilized in the adjuvant setting for nearly 30 years and has a very well defined safety and efficacy profile in this setting. It is difficult to change the entire way early breast cancer is treated based on the results of single studies, albeit very large, well designed studies. Nonetheless, these data should be discussed with breast cancer patients who are postmenopausal and have tumors that are hormone-receptor positive.

LOCALLY ADVANCED BREAST CANCER (STAGE III)

5 *Locally advanced cancer breast cancer* generally refers to breast carcinomas with significant primary tumor and nodal disease, but in which distant metastases cannot be documented. A wide variety of clinical scenarios can be seen within this group of patients, including neglected tumors that have spread locally, to inflammatory breast cancers that are a unique entity. Inflammatory breast cancer is associated with similar clinical findings compared to other neglected, locally advanced breast tumors (e.g., erythema representing skin involvement). The distinction between the two diagnoses lies in the rapidity of onset of symptoms. Many locally advanced breast cancers are diagnosed in patients that have had symptoms for months to years and have neglected to seek medical attention. While these women have a poor prognosis due to the delay in diagnosis, they are not classified as inflammatory breast cancer. The hallmark of inflammatory breast cancers is the rapid onset of symptoms within weeks to months, including erythema of the skin with or without a detectable

underlying breast mass. These patients are often inappropriately treated for cellulitis with antibiotics for several weeks to months. Due to the aggressive nature of this disease, a delay in diagnosis may be fatal for some of these women.

The natural history of locally advanced breast cancer suggested that even when local-regional control was accomplished, systemic relapse and death from breast cancer eventually occurred in most patients.¹⁰⁸ This led to interest in the use of neoadjuvant or primary chemotherapy in locally advanced breast cancer, as discussed previously. This approach to therapy renders inoperable tumors resectable, and can increase rates of breast-conserving therapy. Theoretical advantages also include potential benefits related to early initiation of systemic therapy, delivery of drugs through an intact vasculature, in vivo assessment of response to therapy, and the opportunity to study the biologic effects of the systemic treatment. However, this approach to therapy also results in a loss of standard, well-validated pathologic prognostic markers, such as initial tumor size and the number of axillary lymph nodes involved. Also, as discussed earlier, OS with adjuvant compared with neoadjuvant chemotherapy is similar, making either approach reasonable for a patient with operable breast cancer. For patients with inoperable breast cancer, including inflammatory breast cancer, the initial approach to therapy should be chemotherapy with the goal of achieving resectability.

After neoadjuvant chemotherapy, most tumors respond with more than a 50% decrease in tumor size; about 70% of patients experience downstaging. Chemotherapy regimens used in this setting are similar to those used in the adjuvant setting. Supporting evidence for each individual regimen differs, but most of the available data support the use of anthracycline-containing regimens, incorporation of the taxanes in some manner, and other approaches to improve dose-density or dose-intensity. For more detailed information regarding the specific regimen-related information, the reader is referred to a recently published review.¹⁰⁸ Neoadjuvant endocrine therapy may be an option for patients who have unresectable, hormone receptor-positive tumors who are unable to receive chemotherapy (e.g., multiple comorbid conditions). In terms of local therapy, this usually follows chemotherapy and the extent of surgery will be determined by response to chemotherapy, the wishes of the patient, and the cosmetic results likely to be achieved. However, many patients may be able to have breast-conserving surgery if an acceptable response to chemotherapy is achieved. Adjuvant radiation therapy should be administered to all locally advanced breast cancer patients to minimize local recurrences, regardless of the type of surgery utilized for that individual patient (e.g., mastectomy or segmental mastectomy). Inoperable tumors that are unresponsive to systemic chemotherapy may require radiation therapy for local management and may or may not be eligible for surgical resection after that radiation. These patients are not commonly seen, but have a very poor prognosis. For most patients in this category, cure is still the primary goal of therapy and can be achieved in a large number of patients when all treatment modalities are employed.

■ METASTATIC BREAST CANCER (STAGE IV)

6 The goal of therapy with early and locally advanced breast cancer is to cure the disease. But breast cancer is currently incurable after it has advanced beyond local-regional disease. The goal of treatment of metastatic breast cancer is to improve symptoms and quality of life and extended survival. Thus it is important to choose therapy with good activity while minimizing toxicities. Treatment of

metastatic breast cancer with either cytotoxic or endocrine therapy often results in regression of disease and improvements in quality of life. In patients who respond to therapy, duration of survival is also increased. The choice of therapy for metastatic disease is based on the site of disease involvement and presence or absence of certain characteristics. For example, patients who experience a long DFS following local-regional therapy, or have disease that is primarily located in the bone or soft tissue will likely respond to endocrine therapy. The most important factor predicting response to endocrine therapy is the presence of estrogen and progesterone receptors in the primary tumor tissue. Fifty to sixty percent of ER-positive patients and 75% to 80% of ER- and PR-positive patients will respond to hormonal therapy, while those with ER- and PR-negative tumors have a less than 10% response rate. Thus the largest factor determining choice of endocrine versus cytotoxic chemotherapy is the presence of hormone receptors in the primary breast tumor. Site of disease is also important in that numerous studies have shown that endocrine therapy is more likely to be effective in patients with bone and soft tissue metastases. Patients with asymptomatic visceral involvement (e.g., liver or lung) may be candidates for hormonal therapy, depending on the clinical circumstance (generally hormones work more slowly than chemotherapy). Patients with symptomatic visceral and/or central nervous system involvement generally have more rapidly growing cancer that requires chemotherapy. Endocrine therapy is the treatment of choice for patients who are hormone receptor-positive and exhibit the first sign of metastatic disease in soft tissue, bone, or pleura, owing to the equal probability of response to hormonal compared to chemotherapy, and the lower toxicity profile of endocrine therapy.

7 Patients who respond to initial endocrine therapy often respond to a second (or even third) hormonal manipulation. Response rate is lower and duration of response is shorter with second (and third) hormonal manipulations. Patients are sequentially treated with endocrine therapy until their tumors cease to respond, at which time cytotoxic chemotherapy can be given. Combinations of different hormonal therapies or chemotherapy plus hormones are not employed in the setting of metastatic breast cancer, secondary to lack of increased efficacy and evidence of increased toxicity. Women with hormone receptor-negative tumors, with rapidly progressive or symptomatic lung, liver, or bone marrow involvement, or those having progressed on initial endocrine therapy are usually treated initially with cytotoxic chemotherapy. Patients with tumors that have *HER2* overexpression or amplification should be considered for treatment with trastuzumab alone or with chemotherapy.

■ ENDOCRINE THERAPY

6 The pharmacologic goals of endocrine therapy for breast cancer are to either decrease circulating levels of estrogen and/or prevent the effects of estrogen at the breast cancer cell (targeted therapy) through blocking the hormone receptors or downregulating the presence of those receptors. Achievement of the first goal depends on the menopausal status of the patient, but achievement of the second goal is independent of menopausal status. Many endocrine therapies are available to target either goal of therapy, and combination studies have also been conducted, attempting to combine differing mechanisms of action and improve outcomes. Unfortunately, combinations have not demonstrated any efficacy benefits, but have increased toxicity. Therefore combinations of endocrine agents for breast cancer are not recommended outside the context of a clinical trial. The concept of sequencing these agents is now becoming popular in the adjuvant setting and may play a role in the metastatic setting when a patient

TABLE 125–13. Endocrine Therapies Used for Metastatic Breast Cancer

| Class | Drug | Dose | Side Effects | |
|-----------------------------|--------------|----------------------|-------------------------------|--|
| <i>Aromatase inhibitors</i> | Nonsteroidal | Anastrozole | 1 mg orally daily | |
| | | Letrozole | 2.5 mg orally daily | |
| | Steroidal | Exemestane | 25 mg orally daily | Hot flashes, arthralgias, myalgias, headaches, diarrhea, mild nausea |
| <i>Antiestrogens</i> | SERMs | Tamoxifen | 20 mg orally daily | |
| | | Toremifene | 60 mg orally daily | Hot flashes, vaginal discharge, mild nausea, thromboembolism, endometrial cancer |
| | SERDs | Fulvestrant | 250 mg IM every 28 days | Hot flashes, injection site reactions, possibly thromboembolism. |
| <i>LHRH analogs</i> | | Goserelin | 3.6 mg SC every 28 days | |
| | | Leuprolide | 7.5 mg IM every 28 days | |
| | | Triptorelin | 3.75 mg IM every 28 days | Hot flashes, amenorrhea, menopausal symptoms, injection site reactions |
| <i>Progestins</i> | | Megestrol acetate | 40 mg orally four for a day | |
| | | Medroxyprogesterone | 400–1000 mg IM every week | Weight gain, hot flashes, vaginal bleeding, edema, thromboembolism |
| <i>Androgens</i> | | Fluoxymesterone | 10 mg orally twice a day | Deepening voice, alopecia, hirsutism, facial/truncal acne, fluid retention, menstrual irregularities, cholestatic jaundice |
| <i>Estrogens</i> | | Diethylstilbestrol | 5 mg orally three for a day | |
| | | Ethinyl estradiol | 1 mg orally three for a day | |
| | | Conjugated estrogens | 2.5 mg orally three for a day | Nausea/vomiting, fluid retention, anorexia, thromboembolism, hepatic dysfunction |

SERM, selective estrogen receptor modulator; SERD, selective estrogen receptor downregulator; LHRH, luteinizing hormone-releasing hormone.

is progressing on one agent after gaining significant benefit. These patients are often treated with a series of endocrine agents, often over several years, before chemotherapy is considered.

Until recently, there was little evidence that the response or survival benefit from one endocrine therapy was clearly superior to that achieved with other therapies. Antiestrogens, progestins, aminoglutethimide, estrogens, and androgens, as well as surgical procedures including oophorectomy, adrenalectomy, and hypophysectomy were equivalent in many randomized trials in patients with metastatic breast cancer. Due to the equality in efficacy, the choice of a particular endocrine therapy was based primarily on toxicity (Table 125–13). Based on these criteria, tamoxifen was the preferred initial agent when metastases are present. An exception to this occurs when the patient is receiving adjuvant tamoxifen at the time or within 1 year of occurrence of metastatic disease. In these cases, other agents are generally employed.

Over the past decade, new information has been published regarding the use of a new generation of aromatase inhibitors. These data have changed the way we treat metastatic breast cancer, as well as early-stage breast cancer (as was noted previously). In postmenopausal and castrated women, the main source of estrogen is derived from the peripheral conversion of androstenedione, produced by the adrenal gland, into estrone and estradiol. This conversion requires

the enzyme aromatase. Aromatase also catalyzes the conversion of androgens to estrogens in the ovary in premenopausal women and in extraglandular tissue, including the breast itself, in postmenopausal women. Therefore aromatase inhibitors effectively reduce the level of circulating estrogens, as well as estrogens in the target organ. Aminoglutethimide was the prototype aromatase inhibitor, but was a nonspecific, weak enzyme inhibitor associated with a many toxicities. Many analogues and derivatives of aminoglutethimide have been tested over the years to try and improve on the efficacy:toxicity ratio of this agent. Third-generation aromatase inhibitors are now available, including anastrozole, letrozole, and exemestane. These agents have far greater selectivity and higher potency for the aromatase enzyme than aminoglutethimide. A major advantage of these newer compounds is their reduced toxicity profile, which consists mainly of nausea, hot flashes, arthralgias/myalgias, and mild fatigue. Anastrozole and letrozole are nonsteroidal compounds that exhibit reversible, competitive inhibition of aromatase. These are triazole compounds and have no intrinsic hormonal activity in and of themselves. Exemestane is a steroidal compound and binds irreversibly to aromatase, forming a covalent bond. While this mechanism may appear to be superior to the reversible binding seen with the nonsteroidal agents, there is no clinical evidence that this drug produces superior results over the other agents in this class. Exemestane does possess some androgenic

properties that are evident at very high doses, generally much higher than what is used clinically.

The new inhibitors have been compared with megestrol acetate as second-line therapy in postmenopausal women with positive or unknown hormone receptor status who have progressed while on tamoxifen therapy. While response rates with these agents have not been significantly better with the newer agents, time to progression and OS have been significantly better with at least two of the three aromatase inhibitors (anastrozole and exemestane).¹⁰⁹ Rates of clinical benefit (objective response + stabilization of disease for 24 weeks) are also improved with the new aromatase inhibitors. Clinical benefit, a category of response used in metastatic breast cancer clinical trials, is a clinically relevant end point, due to its similar OS compared to tumors that exhibit an objective response.¹¹⁰ Tolerability is also improved with the aromatase inhibitors compared with megestrol acetate. Toxicity patterns showed more nausea, vomiting, and hot flashes with the aromatase inhibitor and more weight gain and fluid retention with megestrol acetate. All three agents are approved for second-line therapy of advanced breast cancer in postmenopausal women, moving megestrol acetate to third-line therapy.

Both anastrozole and letrozole are also approved for first-line therapy for advanced breast cancer in postmenopausal women. Large trials have compared these agents to tamoxifen and found similar response rates and a longer median time to progression for patients receiving the selective aromatase inhibitor.¹⁰⁹ A consistent finding in these trials was a lower incidence of thromboembolic events and vaginal bleeding in patients who received selective aromatase inhibitors, which, together with the advantage in terms of time to progression, led to the conclusion that the new aromatase inhibitors are superior to tamoxifen as first-line therapy for advanced breast cancer in postmenopausal women. Phase III data with exemestane as first-line therapy compared with tamoxifen are expected in late 2004. A small, randomized phase II trial comparing exemestane to tamoxifen in this setting has demonstrated an advantage with exemestane over tamoxifen in terms of response rates and time to progression.¹¹¹ However, this study is not large enough to draw conclusions from, and we await the results of the larger, phase III study to help guide decisions in this setting. Use of a steroidal aromatase inhibitor (exemestane) after a patient progresses on a nonsteroidal inhibitor (anastrozole or letrozole) may provide some benefit and is a common practice based on small clinical trials investigating this sequential approach to therapy.¹⁰⁹ The opposite sequence has also shown some benefit. Therefore patients may receive two aromatase inhibitors (first-line and second-line, sequentially), especially in patients who progress while on adjuvant tamoxifen therapy.

As mentioned several times so far, the aromatase inhibitors are only appropriately used in women who are postmenopausal. Pre- or perimenopausal women, whose ovaries are functioning, are not appropriate candidates for these therapies, at least based on the available evidence. Use of the aromatase inhibitors in addition to ovarian ablation (e.g., oophorectomy or LHRH-agonists) is currently being investigated. Also, the use of aromatase inhibitors in men with advanced breast cancer should be avoided. Available evidence suggests that use of these agents in men increases circulating levels of testosterone, which may negate the therapeutic effects of the drug.¹¹²

Antiestrogens bind to estrogen receptors, preventing receptor-mediated gene transcription and are therefore used to block the effect of estrogen on the end target. This class of agents is now subdivided into two pharmacologic categories, SERMs and pure antiestrogens. SERMs include tamoxifen and toremifene and demonstrate tissue-specific activity, both estrogenic and antiestrogenic, as described previously. The agonistic activity is thought to be responsible for many of

the adverse reactions seen with these agents, including the increased risk of endometrial cancer. Research into how to minimize this agonistic activity has led to the production of pure estrogen receptor antagonists that lack estrogen agonist activity. Pure antiestrogens are a new class of agents that are also referred to as selective estrogen receptor downregulators (SERDs). These molecules bind to the ER, inhibiting estrogen binding, but cause a degradation of the drug-ER complex, decreasing the amount of ER on the tumor cell surface. There is currently only one pure antiestrogen commercially available in the United States, fulvestrant.

Tamoxifen is generally considered to be the antiestrogen of choice in both premenopausal and postmenopausal women with metastatic breast cancer who have tumors that are hormone receptor-positive. Tamoxifen is usually administered in 20 mg once-daily doses. There is no advantage for higher doses of tamoxifen. Moreover, long-term administration of very high doses of tamoxifen (e.g., 12 months of 60 to 100 mg/m² twice daily) is associated with decreased visual acuity and retinopathy.

A dose schedule of tamoxifen 20 mg/day reaches a steady-state concentration after about 4 months of therapy. The half-life of tamoxifen during chronic dosing is 7 days. Serum tamoxifen concentrations can be detected 6 weeks after discontinuation of therapy. Thus the maximum beneficial effects of tamoxifen are not observed for at least 2 months following initiation of therapy, and it is unlikely that symptoms of metastatic disease will return if patients miss several doses. The toxicities of tamoxifen are described in the section on adjuvant endocrine therapy. The only additional toxicity that one might expect to find in the setting of metastatic breast cancer (specifically bone metastases) is a tumor flare or hypercalcemia, which occurs in approximately 5% of patients following the initiation of any SERM therapy and is not an indication to discontinue SERM therapy. It is generally accepted that this is a positive indication that the patient will respond to endocrine therapy. As was mentioned previously, toremifene is another commercially available SERM for the treatment of breast cancer. It exhibits similar efficacy and tolerability compared with tamoxifen in the metastatic setting and is given at a dose of 60 mg daily. The same issues apply to toremifene as were discussed with tamoxifen. Cross-resistance to toremifene has been demonstrated in patients with tamoxifen-refractory disease.¹¹³ Therefore at the current time, toremifene appears to be an alternative to tamoxifen in postmenopausal patients with positive or unknown hormone receptor status with metastatic breast cancer. Raloxifene, another SERM, received approval in December 1997 for prevention of osteoporosis in postmenopausal women. Currently, available data with raloxifene as a treatment for breast cancer are not encouraging (very low response rates, no clinical benefit). The use of this agent for breast cancer treatment should be discouraged. Investigation into the use of raloxifene for prevention of breast cancer in women at high risk is currently underway (see section on prevention and screening).

Fulvestrant is a new agent approved for the second-line therapy of postmenopausal metastatic breast cancer patients who have tumors that are hormone receptor-positive. It is given as an intramuscular injection every 28 days and is marketed as a single injection of 5 mL or two injections of 2.5 mL each.¹¹⁴ Studies examining the role of fulvestrant in the treatment of metastatic breast cancer have compared this agent to anastrozole. Due to the nature of anastrozole's mechanism of action, only postmenopausal women were eligible for these trials. There is no biologic reason why fulvestrant should not produce similar outcomes in premenopausal women, but no data exist to confirm the safety or efficacy in premenopausal women. In the comparative trials with fulvestrant and anastrozole, similar efficacy and safety were demonstrated with both agents when given after

patients progressed on tamoxifen therapy.^{115,116} Adverse events related to fulvestrant include injection site reactions, hot flashes, asthenia, and headaches. The dose of fulvestrant is 250 mg given intramuscularly every 28 days. This agent is covered by Medicare and is a good option for patients who are unable to take an oral medication.

Another goal of antitumor treatment is to reduce estrogen production in premenopausal women with surgery, irradiation, or medication. No difference has been found in two randomized trials of the overall response rate between tamoxifen and oophorectomy in premenopausal women. However, the secondary response rate to oophorectomy after tamoxifen treatment was somewhat higher than the response to tamoxifen after primary oophorectomy (33% vs. 11%).¹¹⁷ Some experts interpret this as suggesting that tamoxifen does not completely antagonize available estrogen, particularly in premenopausal women. Ovarian ablation (surgically or chemically) is still commonly used in some parts of the United States and is considered by many specialists to be the endocrine therapy of choice in premenopausal women. The mortality rate with surgical oophorectomy is low, usually less than 2% to 3% in appropriately selected patients. Irradiation of the ovaries was a means of castration many years ago, but was associated with multiple complications and is no longer performed for these purposes. Chemical castration with LHRH analogs is increasingly used in lieu of oophorectomy in premenopausal women.

Medical castration with LHRH analogs has been used in premenopausal metastatic breast cancer patients and induces remission in about one-third of unselected cases. The mechanism of action of LHRH analogs in breast cancer is thought to result from downregulation of LHRH receptors in the pituitary. Decreased levels of luteinizing hormone subsequently lead to a decrease in estrogen to castrated levels. Thus the effect of LHRH analogs on circulating estrogen levels in premenopausal breast cancer simulates oophorectomy. The three agents available in the United States are leuprolide, goserelin, and triptorelin, but only goserelin is approved for the treatment of metastatic breast cancer. These agents are administered as an injection every 4 weeks (all products have extended formulations, lasting 3 to 4 months) and are associated with minimal side effects including amenorrhea, hot flashes, and occasional nausea (see Table 125–13). A recent meta-analysis was reported on combined tamoxifen and LHRH agonists versus LHRH agonists alone in premenopausal patients with metastatic breast cancer.¹¹⁸ With a median follow-up of 6.8 years, there was a significant survival benefit and progression-free survival benefit in favor of the combined treatment. The overall response rate was significantly higher on combined endocrine treatment. However, this analysis did not compare tamoxifen alone to the combination of an LHRH agonist with tamoxifen. Therefore if an LHRH agonist is used as first-line therapy for metastatic breast cancer, it should be used in combination with tamoxifen. If tamoxifen is used as first-line therapy for metastatic breast cancer, then there are no data supporting adding an LHRH agonist to this setting. This is a very controversial topic that may be answered through clinical trials in the next few years, but currently it is up to the individual clinician and patient to decide. LHRH agonists may also produce a flare response due to an initial surge in LH and estrogen production for the first 2 to 4 weeks. This flare response is similar to that seen with tamoxifen and patients should be monitored for increasing pain and/or hypercalcemia during the initiation period.

Progestins such as megestrol acetate and medroxyprogesterone acetate have been compared with tamoxifen in randomized trials and have been found to yield equal response rates. Although there were no direct comparisons of these two forms of progestational therapy, they appear to be equally effective. Medroxyprogesterone acetate is

more frequently used in Europe, and megestrol acetate is more frequently used in the United States. Based on efficacy and tolerability, these agents are generally reserved as third-line therapy after patients have received an aromatase inhibitor and a SERM (tamoxifen or toremifene). The most common dose used for megestrol acetate is 160 mg/day; the most common side effect is weight gain, occurring in 20% to 50% of patients. Patients experiencing weight gain may have fluid retention, but fluid retention is not totally responsible for total weight gain. In cachectic cancer patients, the weight gain may be desirable, but this is not uniformly true of all patients with metastatic breast cancer. Additional side effects associated with progestins include vaginal bleeding in 5% to 10% of patients either while patients are taking the progestational agent or when it is discontinued, and somewhat less than a 10% incidence of hot flashes. Thromboembolic complications are also significant with these agents.

High-dose estrogens and androgens are rarely used today because these agents are more toxic than the other hormonal agents discussed thus far. About one-third of patients placed on high-dose estrogens will discontinue them because of side effects, the most important of which are thromboembolic events, vomiting, and fluid retention. Less common side effects include areolar hyperpigmentation, breast tenderness and engorgement, vaginal discharge, incontinence, hot flashes, and phlebitis. All the effective androgens cause masculinizing effects, including hirsutism and acne, in more than 50% of patients. In addition to their toxicities, the mechanism by which these agents exert a therapeutic effect in breast cancer is unknown. About 20% response rates were reported in clinical trials conducted in the 1960s and 1970s in unselected groups of breast cancer patients. Given the recent availability of the aromatase inhibitors, use of androgens and estrogens has become rare.

■ CYTOTOXIC THERAPY

8 Cytotoxic chemotherapy is eventually required in most patients with metastatic breast cancer. Patients with hormone receptor-negative tumors require chemotherapy as initial therapy of symptomatic metastases. Patients who initially respond to hormonal manipulations eventually cease to respond and go on to require chemotherapy. Combination chemotherapy results in an objective response in about 40% of patients previously unexposed to chemotherapy. Most patients have partial responses, and complete disappearance of disease occurs in fewer than 10% of patients treated. The median duration of response is 5 to 12 months, but some patients will have an excellent response to an initial course of chemotherapy and may live 5 to 10 years or longer without evidence of disease. In general, median survival of patients after treatment with commonly used drug combinations for metastatic breast cancer is 14 to 33 months. The median time to response has ranged from 2 to 3 months in most studies, but this period depends in large part on the site of measurable disease. The median time to appearance of response is between 3 and 6 weeks in patients whose disease is primarily in the skin and lymph nodes, 6 to 9 weeks for patients with metastatic lung involvement, 15 weeks with hepatic involvement, and nearly 18 weeks in patients with bone involvement. Thus it is often the case that an immediate response to therapy is not apparent, and in general, once a chemotherapy regimen has been initiated, it is continued until there is unequivocal evidence of progressive disease.

There are no well-defined clinical characteristics or established tests to identify patients likely to benefit from chemotherapy. Factors associated with an increased probability of response that have been identified include a good performance status, a limited number (one

to two) of disease sites, and patients who respond to chemotherapy or hormonal therapy with a long disease-free interval. Patients who have progressive disease during chemotherapy have a lower probability of response to a different type of chemotherapy. However, this is not necessarily true for patients who are given chemotherapy after some interval during which they have received no chemotherapy. Patients who do not respond to endocrine therapy are as likely to respond to chemotherapy as patients who are treated with chemotherapy as their initial treatment modality. Age, menopausal status, and receptor status have not been associated with favorable or unfavorable response to chemotherapy.

A number of chemotherapeutic agents have demonstrated activity in the treatment of breast cancer, including doxorubicin, epirubicin, paclitaxel, docetaxel, capecitabine, fluorouracil, cyclophosphamide, methotrexate, vinblastine, vinorelbine, gemcitabine, mitoxantrone, mitomycin-C, thiotepa, and melphalan. The most active classes of chemotherapy in metastatic breast cancer are the anthracyclines and the taxanes, producing response rates as high as 50% to 60% in patients who have not received prior chemotherapy for metastatic disease.¹¹⁹ Paclitaxel was approved by the FDA in 1994 for single-agent treatment of metastatic breast cancer for patients who had relapsed following therapy with a doxorubicin-containing regimen. The FDA-recommended dose of paclitaxel is 175 mg/m² every 21 days, which is considerably higher than the dose used for treatment of ovarian cancer, the other disease for which paclitaxel has obtained FDA approval for use. Studies investigating the optimal dose and schedule of paclitaxel indicate higher response rates and less toxicity with weekly administration versus every-3-week administration.⁸⁸ The most useful weekly dose in the metastatic setting appears to be 80 mg/m² per week with no breaks in therapy. With this approach, the toxicity profile of paclitaxel changes with less myelosuppression and delayed onset of peripheral neuropathy, but slightly more fluid retention and skin and nail changes. Also, at such low doses, the incidence of hypersensitivity reactions is slightly less, requiring fewer premedications. However, the incidence of hypersensitivity reactions remains approximately 3%, even with all available preventive measures. Docetaxel has also demonstrated high single-agent activity against metastatic breast cancer. The FDA approved it in 1995 for treatment of metastatic breast cancer for patients with relapse following therapy with doxorubicin-containing regimens. The approved dose is 60 to 100 mg/m² administered every 3 weeks. Impressive overall response rates of 54% to 68% were reported in four studies of docetaxel 100 mg/m² as first-line chemotherapy. A randomized study comparing doses of 60 mg/m², 75 mg/m², and 100 mg/m² was recently published, demonstrating a dose-response relationship with regard to response rates only.¹²⁰ Time to progression and overall survival were similar between all three dose levels. Therefore dose remains important for symptomatic patients who require a rapid response to therapy. In asymptomatic patients requiring docetaxel chemotherapy, lower doses may be appropriate. Myelosuppression is the major dose-limiting toxicity of docetaxel. Nonhematologic toxicities include fatigue, mucosal toxicity, mild to moderate nausea and vomiting, diarrhea, and neurosensory complaints. Results from a single randomized trial appear to indicate that docetaxel is associated with less neuropathy, myalgia, and hypersensitivity than paclitaxel given every 3 weeks; but febrile neutropenia, fluid retention, and skin reactions appear to occur more frequently with the newer taxane.¹²¹ The median cumulative docetaxel dose to the onset of fluid retention is 400 mg/m² in nonpremedicated patients. Recent data demonstrate that the prophylactic use of dexamethasone 8 mg orally, twice a day for 3 days, starting 24 hours before the docetaxel infusion can significantly delay the onset and reduce the severity of fluid retention, as well as decrease the inci-

dence and severity of hypersensitivity reactions, nausea, and skin rashes.

Capecitabine is a novel agent approved in the mid-1990s with significant activity in metastatic breast cancer patients who have progressed on an anthracycline-containing regimen as well as a taxane regimen. This agent is a prodrug for fluorouracil with somewhat targeted activity towards malignant cells. The parent compound undergoes a three-step enzymatic conversion to become fluorouracil at the target cell. The third and final step in this conversion is more likely to occur in malignant cells than normal cells due to the presence of higher levels of the responsible enzyme in malignant tissues. In patients who have been exposed to an anthracycline and a taxane, capecitabine produces response rates of about 25%, which is impressive compared to other tested chemotherapy agents.¹²² The dose-limiting side effects with this agent are unique and include palmar-plantar erythrodysesthesias (hand-foot syndrome), diarrhea, and mucositis. Very little myelosuppression or nausea is experienced with this agent, but monitoring patients for these adverse events is still warranted. Capecitabine is an oral chemotherapy agent that is given twice a day for 14 days, followed by 1 week of rest in a 21-day cycle. The approved dose of capecitabine is 2,500 mg/m² per day divided twice daily as indicated above. In retrospective studies, this dose appears to be poorly tolerated and dose reductions are required in nearly all patients.^{123,124} Therefore, many clinicians prefer to start at 2,000 mg/m² per day in a similar schedule, especially in light of the goals of therapy for metastatic breast cancer. The retrospective analyses appear to indicate no loss of efficacy with this approach, but randomized controlled trials looking at different doses of capecitabine have not yet been completed.

Vinorelbine, a microtubule interactive agent, has also shown impressive response rates in metastatic breast cancer.¹²⁵ Vinorelbine was approved by the FDA in 1994 for the treatment of non-small-cell lung cancer. It is not approved for breast cancer, but response rates to weekly IV doses of 30 mg/m² of vinorelbine range from 30% to 50%, with an overall 5% complete response rate in the phase I and phase II studies in patients with advanced breast cancer. As has been observed with paclitaxel and docetaxel, patients with less prior treatment have a higher response rate than those who are more heavily pretreated. Importantly, paclitaxel, docetaxel, and vinorelbine do not appear to be cross-resistant with anthracyclines, which are arguably considered first-line in treatment of metastatic breast cancer.

Gemcitabine is another agent that is used quite frequently in patients who have received the aforementioned chemotherapy regimens, who still have a good performance status and may benefit from additional chemotherapy. This is a nucleotide analogue that inhibits DNA synthesis. Response rates ranging from 13% to 42% have been reported in a number of phase II trials.¹²⁵ In patients who have been exposed to an anthracycline and a taxane, gemcitabine appears to provide similar benefit to capecitabine. However, the studies with gemcitabine are much smaller than with capecitabine. Nonetheless, gemcitabine is utilized for the treatment of metastatic breast cancer and many ongoing trials are further investigating where this agent may fit into therapy. The dose of gemcitabine varies depending on the extent of prior therapy and bone marrow reserve, but generally ranges from 800 to 1,250 mg/m² given IV on days 1, 8, and 15 every 28 days. The day 15 dose is often omitted due to myelosuppression. This agent appears to affect platelets more frequently than other chemotherapy previously mentioned, and close monitoring is required for patients receiving this agent. Other common adverse events include a flu-like syndrome with fever, chills, myalgias and arthralgias, and mild nausea.

Combination chemotherapy regimens are associated with higher response rates than are single-agent therapies in the treatment of

metastatic breast cancer, but the higher response rates have not usually translated into significant differences in time to progression and OS. The use of sequential single-agent chemotherapies versus the combination regimens has been widely debated for metastatic breast cancer.

CLINICAL CONTROVERSY

The benefits of combination chemotherapy regimens for metastatic breast cancer over sequential single agents have not been clearly defined. There are a few trials that have compared combination regimens to single agent chemotherapy, with higher response rates seen with the combination. However, these trials fail to include an arm with the same agents given sequentially. Therefore it is not clear whether sequential single agents or combination regimens are optimal in this setting.

One trial investigating the combination of doxorubicin with paclitaxel versus each single agent with crossover to the other agent upon progression set out to help answer the question of which is more effective.¹²⁶ While response rates were higher with the combination regimen, time to progression and OS were similar between all arms of the study. This was more than likely due to the fact that most patients who progressed on their first single agent, went on to receive the second-line single agent, thereby negating any potential survival benefits seen with improved response rates. In another study comparing single-agent docetaxel to the combination of docetaxel with capecitabine, the combination arm produced higher response rates, time to progression, and OS compared with the single agent.¹²⁷ However, only 15% of patients in the docetaxel alone arm received capecitabine after progression. Therefore this study does not answer the question of whether combination therapy is better than sequential single-agent therapy. It is widely accepted that combination regimens do impart greater toxicity. In the palliative metastatic setting, using the least toxic approach is preferred when efficacy is considered equal. In clinical practice, patients who require a rapid response to chemotherapy (e.g., those with symptomatic bulky metastases) often receive combination therapy despite the added toxicity. This decision is complex and should be made on an individual patient basis.

Because most patients are given adjuvant chemotherapy, regimens chosen for first-line use in the metastatic setting are often different from those used in the adjuvant setting. If a patient's cancer recurs within 1 year of finishing adjuvant chemotherapy, those chemotherapy agents are not considered effective for treatment of her metastatic disease. However, if the patient recurs more than 1 year after the end of her adjuvant chemotherapy, the same agents may also be helpful in the metastatic setting.

■ BIOLOGIC THERAPY

Trastuzumab is a humanized monoclonal antibody that binds with a specific epitope of the HER-2/neu protein. The parent antibody (monoclonal antibody, 4D5) induces a specific biologic response through activation of *HER-2/neu*; this response includes autophosphorylation of the tyrosine kinase internal domain leading to inhibition of cellular growth, decreased malignant potential, and possibly reversal of resistance to certain chemotherapies and possibly endocrine therapy. Single-agent treatment with trastuzumab has a response rate of 15% to 20% and a clinical benefit rate of nearly 40% of patients with *HER-2/neu*-overexpressing cancers.¹²⁸ Moreover, the results of a large randomized trial demonstrated that trastuzumab is at least

additive, and perhaps has synergistic activity with other chemotherapeutic agents.¹²⁹ In this pivotal trial comparing chemotherapy in combination with trastuzumab versus chemotherapy alone, the addition of trastuzumab increased response rates, time to progression, and overall survival when compared to chemotherapy alone. Patients in this trial who were anthracycline naïve were treated with an anthracycline (mostly doxorubicin, some epirubicin) plus cyclophosphamide, and patients who had received an adjuvant anthracycline regimen were treated with paclitaxel. During this trial, it became apparent that patients receiving the anthracycline-trastuzumab combination had a very high incidence of cardiotoxicity (27%), leading to discontinuation of this arm of the study and a black box warning regarding this contraindication in the product information for trastuzumab. Many investigators are attempting to circumvent this toxicity while giving these two classes of agents together (e.g., liposomal doxorubicin or continuous-infusion doxorubicin). However, until further information regarding the safety of these approaches becomes available, this combination should not be given outside the context of a clinical trial. Many other chemotherapy agents have successfully been administered with trastuzumab. Only one other phase III trial has been published comparing chemotherapy alone versus chemotherapy plus trastuzumab. Extra and colleagues compared docetaxel alone versus docetaxel with trastuzumab in patients with previously untreated *HER2/neu*-positive metastatic breast cancer.¹³⁰ This trial demonstrated significant advantages to the combination in terms of response rates, time to progression, and OS.

Other chemotherapy agents that have been evaluated in several phase II trials include vinorelbine, gemcitabine, capecitabine, and the platinum agents (cisplatin and carboplatin). In phase II trials vinorelbine in combination with trastuzumab has shown very high response rates even in heavily pretreated patients.¹³¹ This combination is now in phase III clinical trials to investigate whether this combination may be better than a taxane-trastuzumab combination as front-line therapy for metastatic breast cancer. In another phase III trial, the triplet combination of paclitaxel, carboplatin, and trastuzumab was compared with paclitaxel and trastuzumab as a dual therapy.¹³² This study demonstrated superior response rates and time to progression with the triplet regimen versus the doublet regimen. However, toxicities with the addition of carboplatin were significantly greater in terms of myelosuppression and nausea. This is important information to keep in mind when making treatment decisions for metastatic breast cancer patients, recalling the importance of palliation of symptoms in this setting.

These studies suggest that trastuzumab is reasonably well tolerated. The most common adverse effects are infusion-related, primarily fever and chills, and occur in about 40% of patients during the initial infusion. These effects generally are mild to moderate and last approximately 1 to 2 hours after the infusion is started. Other infusion-related reactions include nausea, vomiting, pain at tumor sites, rigors, headaches, dizziness, dyspnea, hypotension, rash, and asthenia, which are much less common.¹³³ These reactions are also usually mild to moderate and rarely require discontinuation of therapy. Acetaminophen and diphenhydramine may be given and/or the infusion rate reduced to help alleviate the symptoms related to these reactions. If infusion-related symptoms occur, subsequent doses should be infused over 90 minutes. Infusion over 30 minutes is appropriate if symptoms subside. A more severe reaction consisting of severe hypersensitivity and/or pulmonary reactions have been reported, but are rare. It is important to educate patients regarding the pulmonary reactions, as these may occur up to 24 hours after the infusion and can be fatal if not promptly treated. Again, this is a rare occurrence, but patient education is paramount to ensure a successful outcome.

Trastuzumab may increase the incidence of infection, diarrhea, and/or other adverse events when given with chemotherapy. However, most of these increases are not clinically significant for the individual patient.

One exception to this statement is the cardiotoxicity seen with this agent both in combination and as a single agent. As mentioned previously, when given with an anthracycline the rates of heart failure are unacceptably high, but even when given as a single agent there is about a 5% incidence of heart failure. Fortunately, the heart failure seen with trastuzumab is somewhat reversible with pharmacologic management and some patients have continued therapy with trastuzumab after their left ventricular ejection fraction has returned to normal. There are no systematic guidelines for cardiac monitoring with this agent. However, close monitoring for clinical signs and symptoms of heart failure is important in order to intervene with appropriate cardiac treatments.

Trastuzumab is administered as an initial loading dose of 4 mg/kg; this is followed by a 2-mg/kg dose administered weekly. One small, phase II study has demonstrated successful administration of trastuzumab on a 3-week schedule with a 8-mg/kg loading dose followed 3 weeks later with a 6-mg/kg maintenance dose given every 3 weeks.¹³⁴ This method of administration is more convenient than weekly administration, but comparative data with this dose and schedule versus the standard dose and schedule are not available at this time. When patients progress on therapy with trastuzumab, many clinicians will continue the trastuzumab and change the chemotherapy regimen. This approach to management is not systematically addressed in the literature, but is a very important question to answer. It is hoped that in the near future there will be a clinical trial to answer this question. Until that time, continuing trastuzumab and changing chemotherapy appears to be a reasonable approach to managing metastatic breast cancer patients.

Although trastuzumab is currently indicated only for the treatment of metastatic breast cancer, several cooperative groups are evaluating its safety and efficacy in women with *HER-2/neu*-overexpressing breast cancer in the adjuvant and neoadjuvant settings. It should be noted that only 20% to 30% of patients with metastatic breast cancer overexpress *HER-2/neu*, and commercially available IHC tests that are reported back as 2+ for *HER-2/neu* are often negative by the more sensitive and specific FISH technique. To date, there is no benefit associated with the administration of trastuzumab to the subset of patients who are *HER-2/neu*-negative, and a very questionable benefit associated with administration of trastuzumab to women who are 2+ for *HER-2/neu* by IHC staining alone. The patients who benefit most from trastuzumab therapy include those whose tumors express HER2 protein at the 3+ level and/or demonstrate gene amplification by FISH testing.

■ RADIATION THERAPY

Radiation is an important modality in the treatment of symptomatic metastatic disease. The most common indication for the treatment with radiation therapy is painful bone metastases or other localized sites of disease refractory to systemic therapy. Radiation therapy gives significant pain relief to approximately 90% of patients who are treated for painful bone metastases. Radiation is also an important modality in the palliative treatment of metastatic brain lesions and spinal cord lesions, which respond poorly to systemic therapy, as well as eye or orbit lesions and other sites where significant accumulation of tumor cells occurs. Skin and/or lymph node metastases confined to the chest wall area may also be treated with radiation therapy for palliation (e.g., open wounds or painful lesions).

PREVENTION AND EARLY DETECTION

Current efforts at breast cancer prevention are directed toward the identification and removal of risk factors. Unfortunately, a number of risk factors associated with development of breast cancer, such as family history of breast cancer or personal history of breast or other gynecologic malignancies, cannot be modified. Isolation and cloning of breast cancer susceptibility genes now allows screening of women with histories suggestive of “breast cancer families” and identification of appropriate candidates for prophylactic bilateral mastectomy. There are currently no absolute indications for prophylactic bilateral mastectomy. This surgery is considered for women at very high risk for the development of breast cancer, particularly if the women’s breasts are difficult to evaluate by both physical examination and mammography, and they have persistent disabling fears that they will be diagnosed with the disease.

In the past 10 years, there has been increasing interest in chemoprevention of breast cancer. This includes interventions directed at inhibiting neoplastic development through pharmacologic measures. Two important classes of agents being studied for breast cancer chemoprevention are the retinoids and SERMs. Retinoids (all vitamin A and its isomer derivatives and synthetic analogs) are biologic regulators of orderly epithelial cell development, and are therefore potentially ideal agents for controlling abnormal epithelial proliferation that occurs in carcinogenesis. While only preclinical data are available suggesting a benefit with these types of therapies, clinical trials

are needed to further investigate the role of the retinoids in prevention of breast cancer.

The agent that is currently receiving the most attention as a chemoprevention agent for breast cancer is tamoxifen. As previously described, tamoxifen is useful as an adjunct after treatment of primary breast cancer. In randomized trials of tamoxifen as an adjuvant treatment for breast cancer, women who received tamoxifen were also found to have a reduced incidence of contralateral primary breast carcinomas.⁷¹ The NSABP, in a large, randomized, placebo-controlled study, demonstrated significant reductions in risk of invasive and noninvasive breast cancers with 5 years of tamoxifen therapy (20 mg/day).⁹⁸ While this study is controversial, other studies have also been reported around the world investigating the role of tamoxifen in chemoprevention. A recent meta-analysis of these trials is available and indicates a consistent benefit in reducing the incidence of ER-positive breast cancers (48%).¹³⁵ Tamoxifen has been repeatedly shown to be a relatively safe drug with an acceptable toxicity profile when used to treat patients with breast cancer. However, its estrogenic effects on the uterus and the coagulation system increase the risk of serious adverse effects that may be critical for patients taking this agent in the prevention setting. Toxicities associated with tamoxifen were further described in the section on adjuvant endocrine therapy. Therefore any decision to use tamoxifen for chemoprevention should not be made lightly, and all the information regarding the individual woman’s risk of breast cancer, the potential benefits of tamoxifen, and the potential serious adverse events associated with tamoxifen,

TABLE 125–14. Guidelines for Early Detection of Breast Cancer

| | American Cancer Society ¹³⁶ | U.S. Preventive Services Task Force ¹³⁷ | National Cancer Institute ¹³⁸ |
|-----------|---|--|--|
| BSE | Age ≥20: risk/benefit discussion | All ages: ± | NR |
| CBS | Age 20–30: every 3 years Age ≥40: every year | All ages: ± (recommended with mammogram) | All ages: every year |
| Mammogram | Age ≥40: interval not designated | Age ≥40: every 1–2 years (± CBE) | Age 40–49: every 1–2 years Age ≥50: every 1–2 years |

BSE, breast self-examination; CBE, clinical breast examination; NR, not recommended; ±, insufficient data to recommend for or against.

should all be discussed at length with every patient considering this agent.

Although raloxifene was shown to reduce the risk of invasive breast cancer by a similar percentage (in clinical trials in which it was evaluated for osteoporosis), the use of raloxifene should be reserved for its approved indication, which is to prevent bone loss in postmenopausal women. The ongoing Study of Tamoxifen and Raloxifene trial directly compares the efficacy and safety of tamoxifen and raloxifene in the chemoprevention of breast cancer. Use of raloxifene for this indication should await the results of this trial. At the present time, the use of tamoxifen or raloxifene with other medications, such as hormone replacement therapy, and tamoxifen and raloxifene in combination or sequentially, has not been adequately studied. However, an increased risk of thromboembolic complications may be seen with these combinations, possibly causing more harm than good. A similar reduction in the incidence of contralateral primary breast cancers was demonstrated with anastrozole in the adjuvant ATAC study (discussed previously), leading to the premise that aromatase inhibitors may also play a role in chemoprevention of breast cancer.¹⁰⁵ No data are yet available investigating these agents in the setting of prevention, but clinical trials are planned.

◀ The rationale for early detection of breast cancer is based on the clear relationship between stage of breast cancer at diagnosis and the probability for cure. Thus if all breast cancer could be detected at a very early stage of the disease (i.e., small primary tumor and negative lymph nodes), then more patients with the disease could be cured. Screening guidelines for early detection of breast cancer have been put forward by the American Cancer Society, the U.S. Preventive Services Task Force, and the National Cancer Institute (Table 125–14).^{136–138} These all include recommendations for women at average risk, with some general statements regarding screening for high-risk women as well.

Currently, the American Cancer Society recommends that all women over the age of 20 years be informed of the benefits and limitations of breast self-examinations (BSE).¹³⁶ There are several studies that have attempted to investigate the benefits of BSE. These trials were primarily conducted prior to the age of mammographic screening and demonstrated an inferential benefit in diagnosis of earlier stages of breast cancer. One more recent trial, the Shanghai trial, appeared to indicate no benefit, but a higher rate of biopsies in women who were taught BSE compared with women who were not taught BSE.¹³⁹ The investigators from this trial caution that this was a study of BSE instruction and not BSE performance. Compliance and competency with the BSE were not guaranteed nor looked at in this trial. Due to the lack of direct evidence to support or refute a benefit with BSE, the ACS has taken the stance that it is not recommended, but women of all ages should be instructed and encouraged to be aware

of their breasts in order to recognize any changes and promptly report these to a health professional.¹³⁶ The U.S. Preventive Services Task Force and the NCI came to similar conclusions.^{137,138}

Recommendations for breast examination by a health care professional (clinical breast examination) vary among the three available screening guidelines. The rate of breast cancer detection using clinical breast examination (CBE) alone is low, with even lower rates in younger women and women with higher body weight.¹³⁶ Randomized clinical trials have inconsistent results and often looked at use of this screening tool in conjunction with mammograms. The American Cancer Society recommends CBE in conjunction with mammography for women aged 40 and older.¹³⁶ For younger patients it is recommended as part of a periodic health examination every 3 years, but this recommendation is based on weak evidence. The NCI recommends CBE for women 40 and older in conjunction with mammography every 1 to 2 years.¹³⁸ The U.S. Preventive Services Task Force guidelines for screening state that there is insufficient evidence to recommend for or against CBE alone.¹³⁷ Nonetheless, with most yearly visits for gynecologic examination (e.g., pelvic exam and Pap smears), the health professional usually performs a breast exam as part of that evaluation.

Clearly, the largest area of controversy in screening recommendations for breast cancer surrounds annual mammography. Most, if not all, guidelines recommend annual mammography for women 50 years of age and older. Nearly 75% of all breast cancer occurs in women 50 years of age or older, and it has been conclusively demonstrated that regular use of screening mammography can reduce mortality from breast cancer by 20% to 40% in this age group. Controversy regarding the use of screening mammography is largely confined to women younger than 50 years of age. After many years of debate, the three available guidelines discussed here recommend mammograms in this age group of women every 1 to 2 years.^{136–138} Controversy lies in the nuances of these data. Clearly the benefits in terms of mortality with screening a younger population are numerically smaller. Nonetheless, there is a reduction in mortality with screening mammograms in women ages 40 to 49. There are also many other debates within this controversial area and the reader is referred to these references for further details.^{136–138} Other radiologic methods of breast imaging are also being investigated (e.g., digital mammography and magnetic resonance imaging [MRI]). Recommendations for women with a high risk of breast cancer are not fully established.

It should also be noted here that the risks associated with screening mammography are present and should be discussed with each patient so they are able to make an informed decision regarding these procedures. The risks involved with screening mammograms include false-negative results, false-positive results, overdiagnosis (true-positives that will not become clinically significant), and radiation risk. The rate of false-negative results with the current

technology is about 20%, which is why CBE is an important adjunct to screening for many women. While the specificity of mammography is quite high (90%), the majority of abnormal exams are false-positives, leading to additional biopsies and psychological distress. The issue of overdiagnosis refers primarily to the growth in detection of DCIS from screening mammography. The biological significance of these tumors is unknown, as only a portion of them would become invasive if left in place. So the question remains, are we treating women who do not require treatment? Experts in the field continue to debate this issue. Radiation exposure also has been discussed in the context of screening mammography, but the small doses of radiation exposure with mammograms (2 to 4 mGy per standard two-view exam) appears to be overshadowed by other benefits in terms of reduction in mortality due to early cancer detection.¹³⁸

Significant advances in the safety and efficacy of screening mammography have occurred during the past two decades. These advances have enabled superior visualization of breast and breast tissue with a concurrent reduction in the dose of radiation that is delivered. About 10% of all palpable masses are not detected by mammography. This is most commonly observed in premenopausal women, and may be directly related to the increased density of breast tissue in this estrogenic environment.

Although the safety and efficacy of screening mammography in terms of image quality and dosimetry are very acceptable, the American College of Radiology (ACR) has recognized for some years the need for greater quality control in mammography. A voluntary accreditation program developed by this organization and adopted by various state and federal agencies has greatly improved the overall quality of mammography in the majority of facilities in this country. Many of the details of the accreditation process have recently been adopted for use by governmental agencies, culminating in the Mammography Quality Standards of 1992. This act, which essentially codifies the ACR program, assures that all mammographic facilities will now be required to achieve a common high standard of quality assurance. Responsibility for operation of the act has been given to the FDA. As of October 1, 1994, all facilities that offer mammography must be FDA-certified to remain open. Passage of this landmark legislation, as well as provision of appropriate levels of funding to conduct this program, represents an important contribution to the health of women.

EVALUATION OF THERAPEUTIC OUTCOMES

9 The desired therapeutic outcome of adjuvant therapy of breast cancer differs significantly from that of metastatic disease. Adjuvant therapy—chemotherapy, hormonal therapy, or both—is administered with curative intent. The rationale for adjuvant therapy is that breast cancer, even when diagnosed in early stages when clinical evidence of distant spread is not apparent, is a systemic disease that spreads early to distant sites. Adjuvant therapy is intended to eradicate these micrometastases and thus cure the patient of breast cancer. Therefore the overall goal of adjuvant therapy is to cure the disease, which is something that cannot be fully evaluated for years following initial diagnosis and treatment. In addition, because there is no clinical evidence of disease at the time adjuvant therapy is started, assessment of disease response is not possible. Instead, a predetermined number of cycles of adjuvant therapy and/or years of hormonal therapy are administered. Adjuvant chemotherapy is often associated with significant toxicity. Maintaining dose intensity has been demonstrated to be important in the cure of disease, and therefore optimizing supportive care measures such as antiemetics and growth factors is highly

recommended. The goals of therapy with neoadjuvant chemotherapy are slightly different. These goals focus on earlier end points of tumor response in order to minimize surgery, determine prognosis, and potentially conserve the breast tissue for a better cosmetic result. The other outcomes discussed with adjuvant therapy also apply to this scenario as well, in terms of improving survival and decreasing recurrences compared to no systemic therapy.

Palliation is the therapeutic outcome in treatment of metastatic breast cancer. In general, the least toxic therapies are used initially, with increasingly aggressive therapies applied in a sequential fashion and in a manner that does not significantly compromise the quality of the patient's life. Tumor response to a particular treatment regimen may be measured by clinical chemistry such as liver enzyme elevation in a patient with hepatic metastases, or imaging techniques such as bone scans or chest x-rays. However, assessment of the patient's clinical status and symptom control is often adequate to evaluate response to the therapy administered. In the patient with metastatic breast cancer, it is common to initiate hormonal therapy or chemotherapy and continue administration until signs and symptoms of disease progress or new signs and symptoms present. Optimizing quality of life is the therapeutic end point in the treatment of patients with metastatic breast cancer. A number of valid and reliable tools are available for objective assessment of quality of life in patients with breast cancer.

CONCLUSIONS

Breast cancer is the most commonly occurring cancer in women in the United States, and is second only to lung cancer as the most common cancer cause of death. The etiology of breast cancer is unknown, but a number of factors that increase a woman's chances of developing the disease have been identified. These risk factors, as well as information regarding the biology of the disease, suggest that a complex interplay between hormones, genetic factors, and environmental and lifestyle influences all contribute to the etiology of this disease. The recent identification of the *BRCA1* and *BRCA2* genes, tumor-suppressor genes important in the development of inherited and perhaps sporadic breast and ovarian cancer, holds promise in identifying patients at high risk, as well as improving our basic understanding of the causes of breast and ovarian cancer.

Most breast cancers are diagnosed in early stages before the disease has disseminated to sites distant from the breast. Treatment consists of local management, as well as systemic adjuvant therapy with chemotherapy, hormonal therapy, or a combination of these. Breast-conservation therapy, which consists of complete removal of the tumor (lumpectomy), combined with breast irradiation and axillary lymph node sampling, is currently the preferred method of treatment for most patients with localized breast cancer. Patients who are not candidates for breast conservation or who do not choose this local therapy will generally receive the modified radical mastectomy.

It is apparent from clinical and laboratory experiments and observation that the spread of breast cancer via the bloodstream occurs early in the course of the disease. This results in patients relapsing with systemic metastatic disease following local curative therapy. The likelihood of later development of metastatic disease is related to the size of the primary tumor, presence of lymph node involvement and number of nodes affected, and a number of additional pathologic prognostic factors, which include proliferative capacity, nuclear grade, hormone receptor status, and presence or absence of oncogenes and other protein products. Systemic adjuvant therapy is commonly

administered to patients with localized breast cancer following surgical procedures to diminish the risk of or delay disease recurrence. The NIH and other groups have developed guidelines for adjuvant systemic therapy for early-stage breast cancer based on expert consensus, and these treatment recommendations continue to evolve as new data become available.

Advanced breast cancer includes locally advanced breast cancer (stage III) and metastatic breast cancer (stage IV). Treatment of stage III breast cancer generally consists of a combination of surgery, radiation, and chemotherapy administered in an aggressive approach. Although response rates and survival have improved, there is still much progress to be made in stage III breast cancer. Metastatic breast cancer is usually incurable. The only exception to this is that some promising long-term response rates have been observed in a subset of patients with metastatic disease who have a complete or near complete response to conventional chemotherapy. Unfortunately, this represents a small number of the total population of patients with metastatic breast cancer. Metastatic breast cancer is treated with endocrine therapy or chemotherapy. Patients who are hormone receptor–positive will generally receive initial endocrine therapy followed by combination chemotherapy when endocrine therapy fails. Patients who are hormone receptor–negative or who have symptomatic disease involving the liver, lung, or central nervous system will generally receive chemotherapy as first-line therapy of metastatic disease. Chemotherapy will result in an objective response in about 50% to 60% of patients previously unexposed to chemotherapy. Most patients have partial response, and complete disappearance of disease occurs in fewer than 20% of patients treated. Median duration of response is 5 to 12 months; although some patients will have an excellent response to an initial course of chemotherapy and may live 5 to 10 years without evidence of disease. In general, survival of patients after treatment with commonly used drug combinations for metastatic breast cancer is a median of 14 to 33 months. The response rate to second- and third-line combination chemotherapy varies from 20% to 40%, depending on the previous chemotherapy regimens the patient has received. The availability of capecitabine, vinorelbine, and gemcitabine offers the promise of more successful second- and third-line treatments for metastatic breast cancer in the future. Development of novel targeted agents (e.g., trastuzumab) has also changed the outlook for patients whose tumors overexpress *HER2/neu*.

Current efforts at breast cancer prevention are directed toward the identification and removal of risk factors. In addition, two classes of agents, the retinoids and SERMs, are being evaluated for their ability to prevent breast cancer. Any statement regarding the value of these modalities awaits the results of ongoing clinical trials. Early detection of breast cancer remains important for decreasing breast cancer mortality. The rationale for early detection of breast cancer is based on the clear relationship between stage of breast cancer at diagnosis and the probability of a cure. The American Cancer Society, the U.S. Preventive Services Task Force, and the National Cancer Institute have developed screening guidelines for early detection of breast cancer. While these guidelines differ in their nuances, the overall benefits of screening mammography are apparent in their recommendations. However, the debate continues as to the absolute benefits and risks of these procedures.

Intensive research efforts are ongoing in all aspects of breast cancer etiology, detection, prevention, and treatment. Thanks to the thousands of patients who volunteered for these clinical trials, a substantial reduction in mortality has been seen in selected patient subsets. It is hoped that the information obtained in the next decade will result in the knowledge required to significantly reduce mortality from breast cancer for all women. Only through these continued

efforts and participation of patient volunteers will advances be made in the management of this disease.

LUNG CANCER

Rebecca S. Finley and Jeannine S. McCune

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Lung cancer is the leading cause of cancer deaths in both men and women in the United States. The overall 5-year survival rate for all types of lung cancer is approximately 15%.
- 2 Cigarette smoking is responsible for about 83% of all lung cancers. Smoking cessation should be encouraged, particularly in those receiving curative treatment (i.e., stage I to IIIA non-small cell lung cancer and limited stage small cell lung cancer).
- 3 Non-small cell lung cancer (NSCLC) is diagnosed in the majority (80%) of lung cancer patients. NSCLC typically has a slower growth rate and doubling time than small cell lung cancer (SCLC).
- 4 Many lung cancers go undetected until they are advanced because individuals who have a long history of cigarette smoking are unlikely to notice the early symptoms of cough or dyspnea. It is often symptoms associated with large tumors or metastatic disease that prompt medical attention.
- 5 Surgery has had an established role in curing early-stage NSCLC, but SCLC rapidly metastasizes and thus surgery has a minimal role in its management. Radiotherapy has a role in the management of both diseases, particularly for management of symptomatic metastatic disease. Chemotherapy has had an established role in the management of SCLC for over 25 years. For NSCLC patients, chemotherapy for stage IV NSCLC is preferred over best supportive care, and data continue to be positive for the role of chemotherapy in earlier stages of NSCLC.
- 6 The most appropriate treatment for NSCLC is determined by the size and location of the tumor, extent of lymph node spread, presence or absence of metastatic sites, and condition of the patient. Surgery is the treatment of choice for early-stage NSCLC (stage I or II); some patients may benefit from postoperative chemotherapy and/or radiation. For patients with locally advanced NSCLC (stage III), chemotherapy with or without radiation followed by surgery improves survival over radiation followed by surgery. Doublet chemotherapy including cisplatin or carboplatin and another active drug (e.g., vinorelbine, paclitaxel, docetaxel, or gemcitabine) is recommended for patients with unresectable stage III or stage IV disease.
- 7 Because SCLC has the propensity to disseminate early on in the disease, surgery is not usually indicated. SCLC is radiosensitive, and radiotherapy is used in combination with chemotherapy in patients with limited disease. Prophylactic cranial irradiation is used in select patients to reduce the risk of CNS metastases. Combination chemotherapy will prolong the survival of most patients with SCLC. Patients with limited disease are more likely to have a complete response to chemotherapy and longer survival than those who have extensive disease at the time of diagnosis. The most widely used chemotherapy regimens for SCLC include cisplatin or carboplatin plus etoposide. Despite very high response rates to chemotherapy, most patients with SCLC eventually have disease progression and die from this disease.

Lung cancer is a major cause of morbidity and mortality that has reached epidemic proportions in many industrialized countries and is the most frequently fatal malignancy in the world. The American Cancer Society estimates that the age-adjusted incidence of lung cancer will be 90 and 54 per 100,000 for men and women, respectively, in the United States during 2005, which represents nearly 175,000 new cases during this year. Approximately 163,510 deaths will be attributed to this malignancy.¹ Despite major advances in the understanding and management of lung cancer, the overall 5-year survival rate for all types of lung cancer remains a dismal 15%, although evidence suggests that the death rate from lung cancer in the U.S. has declined slightly in recent years.^{1,2} This is in contrast to many developing countries where the death rate from lung cancer is increasing. These differences are attributed to changes in smoking habits (de-

creasing in the U.S. and increasing in developing countries), the tar content of cigarettes, and to a lesser extent, availability of treatment. Although the overall 5-year survival rate for lung cancer is low, it may be curable with surgical resection if detected in the early stages, and many patients experience significant survival and symptom-relief benefits from systemic chemotherapy or radiation.

1 Lung cancer is estimated to account for 13% of all newly diagnosed cancers in adults.¹ It remains the leading cause of cancer death in both adult men and women.¹ The incidence and death rate due to lung cancer are declining more rapidly in men than women, which reflects the patterns of tobacco use. In 1987, for the first time, lung cancer surpassed breast cancer as the primary cause of cancer death among American women.¹ Because the risk of lung cancer increases with the duration and extent of tobacco exposure, it is not surprising

that the incidence of lung cancer increases with age; the peak age of diagnosis is between 55 and 65 years. Among patients 40 years of age and older, the likelihood that a solitary pulmonary nodule seen on chest x-ray is a carcinoma is high and this probability increases proportionately with age. Patients with lung cancer may undergo surgery, chemotherapy, radiation, or multimodality therapy, depending on the histologic type of the tumor, its size and location, and the presence of metastases at diagnosis. Two leading oncology groups representing leading clinicians in the U.S. have published clinical practice guidelines for the treatment of lung cancer. The National Comprehensive Cancer Network (NCCN) has developed evidence-based guidelines that provide recommendations regarding the screening, staging, and treatment of both SCLC and NSCLC.^{3,4} The American Society of Clinical Oncology (ASCO) first published evidence-based guidelines regarding the staging and treatment of NSCLC in 1997, which were subsequently updated in 2003.⁵

ETIOLOGY

Lung carcinomas arise from normal bronchial epithelial cells that have acquired multiple genetic lesions and are capable of expressing a variety of phenotypes.⁶ The natural history of lung cancer begins with exposure of these normal cells to carcinogens, which cause chronic inflammation eventually leading to the genetic and cytologic changes that progress to carcinoma. Activation of protooncogenes, inhibition or mutation of tumor-suppressor genes, and production of autocrine growth factors also contribute to cellular proliferation and malignant transformation.⁶ Under normal circumstances, cell surface peptidases produced by epithelial cells degrade and regulate these growth factors, but these enzymes are expressed at low or undetectable levels by most lung cancer cells, thus facilitating uncontrolled growth.⁷ Although individual lung carcinomas may have multiple molecular abnormalities, some specific changes have been associated with the various types of lung cancer. For example, *p53* mutations have been observed in about 90% of small cell lung cancers, but in only about 50% of non-small cell lung cancers, and this type of mutation appears to be more frequent in the squamous cell and large cell subtypes of non-small cell

lung cancers than in adenocarcinomas.^{8,9} Evidence is accumulating that such molecular changes not only influence the transformation from normal to malignant cell, but also may have an impact on the progression of the disease and its response to therapy, and therefore strongly influence the patient's prognosis (Table 126–1). In particular, the overexpression of epidermal growth factor receptor (EGFR) on the surface of NSCLC cells has become an important target for new treatment strategies discussed later in the chapter. As in many other malignant diseases, further elucidation of the molecular profile of lung cancer has led to improved preventive, diagnostic, prognostic, and therapeutic strategies.

2 Numerous studies have established the relationship between tobacco exposure and lung cancer. The American Cancer Society estimates that cigarette smoking is responsible for about 83% of all lung cancer cases, and studies have established a dose-response relationship between the number of cigarettes smoked, the number of years an individual has smoked, the tar and nicotine content of cigarettes, and the development of lung cancer.² Likewise, smokers with obstructive airway disease or chronic bronchitis have a three- to fivefold greater risk of developing lung cancer than do smokers with normal pulmonary function.¹⁶ Mattson and associates estimated that a 35-year-old man who smokes 25 cigarettes per day or more has a 13% risk of dying of lung cancer before age 75.¹⁷ The increased rate of lung cancer deaths among women has also been attributed to increased smoking.¹ Cessation of smoking is associated with a gradual decrease in the risk, but a long period of time (more than 6 years) is necessary before an appreciable decline of the risk occurs. Antismoking campaigns, increased tobacco taxes, and smoke-free areas in many public areas and businesses, along with societal pressures have been somewhat successful in reducing the number of adult Americans who smoke. However, the high number of lung cancers in ex-smokers emphasizes the need to prevent individuals from ever starting to smoke. Passive exposure to cigarette smoke is believed to contribute to the increased risk of lung cancer in nonsmokers living with smokers. Other carcinogens also increase the risk of lung cancer and may act synergistically with cigarette smoking.² Occupational or environmental exposure to asbestos, chloromethyl ethers, various heavy metals, polycyclic aromatic hydrocarbons, and radon has also

TABLE 126–1. Examples of Relationship of Molecular Changes in Lung Cancer to Clinical Outcomes

| Molecular Changes | Impact on Clinical Outcome | Reference |
|---|--|---|
| Microsatellite alterations | Reduced survival | Sekido et al ⁶ |
| Overexpression of <i>BCL2</i> | Decreased response to chemotherapy and radiation therapy | Sekido et al ⁶ |
| Expression of gastrin-releasing peptide and other bombesin-like peptides (SCLC) | Promote tumor growth | Sekido et al ⁶ |
| Overexpression of <i>MYC</i> (SCLC) | Reduced survival | Sekido et al ⁶ |
| Overexpression of <i>HER2/neu</i> (NSCLC) | Shorter survival, multidrug resistance | Tsai et al ¹⁰ |

NSCLC, non-small cell lung cancer; SCLC, small cell lung cancer.

been associated with the development of lung cancer.² In addition, the incidence of lung cancer is higher in urban than in rural areas, and air pollution has been implicated as a possible causative agent.

Data from observational studies suggest that intake of β -carotene and carotene (vitamin A) is inversely associated with lung cancer risk.¹⁸ The first prospective randomized chemoprevention trial with antioxidants in a large, well-nourished population was reported in 1994.¹⁹ In that trial, more than 29,000 middle-aged male smokers were randomized to receive dietary supplementation with β -carotene, α -tocopherol, or both for 6 years. Interestingly, the trial failed to detect any significant protective effect of either vitamin, and surprisingly, significantly more new cases of lung cancer developed in the group treated with β -carotene. Other prospective trials have also failed to demonstrate beneficial effects of carotenoids, vitamin C, or vitamin E against lung cancer. Conversely, several other trials and case-control studies show a significant difference in relative risk related to intake of one of these antioxidants.^{2,18} Additional studies are necessary to define the role of antioxidants in lung cancer prevention.

HISTOLOGIC CLASSIFICATION

3 The World Health Organization lung cancer classification is accepted worldwide (Table 126–2).²⁰ Four major cell types of carcinomas (squamous cell, adenocarcinoma, large cell, and small cell carcinomas) account for more than 90% of all lung tumors. Histologic confirmation of cell type is usually made by light microscopy and is essential in treatment planning because of differences in the natural histories, clinical features, and response to therapy of the various types. As noted earlier, several additional biologic and cytogenetic characteristics (e.g., secretion of peptide hormones, autocrine growth factor receptors, specific mutations, or chromosomal deletions of lung tumors) are currently being evaluated for their prognostic significance. In terms of management strategy and overall prognosis, adenocarcinoma, squamous cell, and large cell carcinomas are frequently grouped together and referred to as non-small cell lung cancer (NSCLC).

Although once the most common type of NSCLC, squamous cell (or epidermoid) carcinoma now accounts for less than 30% of all lung cancers, and is distinguished histologically by evidence of squamous differentiation. This tumor tends to be central in origin, arising from metaplastic bronchial epithelium, and frequently extends into the bronchial lumen, resulting in obstruction. Squamous cell carcinoma

(along with small cell lung cancers [SCLC]) have a much higher incidence among smokers and among males and appear to have a strong dose-response relationship to tobacco exposure.^{2,21} Although they can grow rapidly, most squamous cell carcinomas tend to be slow growing and confined to the lungs (especially early in the disease course). Such tumors may eventually metastasize to the hilar and mediastinal lymph nodes, liver, adrenal glands, kidneys, bone, and gastrointestinal tract.

Adenocarcinoma is now the most common type of lung cancer in the United States, accounting for about 40% of cases. This is partly a result of the increased incidence of lung cancer in women, who tend to have more adenocarcinomas than epidermoid cancers. Interestingly, it does not have a dose-response relationship to tobacco exposure. These tumors are usually located in the peripheral sections of the lung and are distinguished pathologically by a glandular or papillary pattern and mucin production.² The presentation and natural history of adenocarcinomas are quite variable. These tumors can present as a single nodule, multifocal nodules, or rapidly progressing, bilateral, diffuse processes. They are likely to metastasize at an early stage (often before the diagnosis of the primary tumor) and spread widely to distant sites including the contralateral lung, liver, bone, adrenal glands, kidneys, and central nervous system. As a result, adenocarcinoma has a worse prognosis than squamous cell carcinoma.

Large cell carcinomas are anaplastic tumors that show no evidence of differentiation. These tumors account for only about 15% of all lung cancers.² These tumors tend to be large and bulky tumors arising in the periphery of the lung, to have a propensity to metastasize in a pattern quite similar to adenocarcinomas, and to be associated with a similar poor prognosis.

3 Small cell carcinomas account for about 20% of all lung tumors. Almost all cases are associated with a history of smoking. They are distinguished by a proliferation of neoplastic cells with round to oval nuclei. These tumors tend to arise in the central portion of the lung, but may also be found in the lung periphery. SCLC is a very aggressive and rapidly growing tumor with approximately 60% to 70% of patients initially presenting with disseminated disease outside of the hemithorax.²¹ These tumors commonly express neuroendocrine differentiation that may account for some of the paraneoplastic syndromes frequently associated with this disease. SCLC secretes gastrin-releasing peptide that acts as an autocrine growth factor. Secretion of other peptide hormones, cytogenetic abnormalities, and amplification and increased expression of oncogenes are also common. This disease has a propensity to metastasize to the lymph nodes, opposite lung, liver, adrenal glands and other endocrine organs, bone, bone marrow, and central nervous system.

Lung tumors frequently exhibit more than one histology, and it is now evident that all types of lung cancer share a common pluripotent stem cell. Studies of lung cancer cells have also shown that cell lines may spontaneously change phenotype, which may explain the mixed histology. Occasionally, patients can also have multiple lung nodules arising in different lobes or the contralateral lung. This is referred to as *synchronous tumors*, and the nodules may be of similar or different cell types. This usually worsens the patient's overall prognosis.

CLINICAL PRESENTATION

4 Location and extent of the tumor determine the presenting signs and symptoms. If the lesion is in the central portion of the bronchial tree, it is likely to cause symptoms at an earlier stage than will a lesion in the periphery of the lung, which may remain asymptomatic until the lesion is quite large or has spread to other areas. The most common initial signs and symptoms include cough, dyspnea,

chest pain, sputum production, and hemoptysis. Unfortunately, many patients with lung cancer also have chronic pulmonary and/or cardiovascular diseases (usually related to smoking), and such symptoms may go unnoticed or be attributed to the concomitant disease. Many patients also exhibit systemic symptoms such as anorexia, weight loss, and fatigue that are suggestive of a malignancy.^{2,21} Patients can also have other signs and symptoms at the time of diagnosis or at any point during its recurrence or progression. Disseminated disease also may be responsible for extrapulmonary signs and symptoms such as neurologic deficits resulting from central nervous system metastases, bone pain or pathologic fractures secondary to bone metastases, or liver dysfunction resulting from tumor involvement in the liver.

CLINICAL PRESENTATION OF LUNG CANCER

LOCAL SIGNS AND SYMPTOMS ASSOCIATED WITH PRIMARY TUMOR OR REGIONAL SPREAD WITHIN THE THORAX

Cough
Hemoptysis
Dyspnea
Rust-streaked or purulent sputum
Chest, shoulder, or arm pain
Wheeze and stridor
Superior vena caval obstruction
Pleural effusion or pneumonitis
Dysphagia (secondary to esophageal compression)
Hoarseness (secondary to laryngeal nerve paralysis)
Horner's syndrome
Phrenic nerve paralysis
Pericardial effusion/tamponade
Tracheal obstruction

EXTRAPULMONARY SIGNS AND SYMPTOMS ASSOCIATED WITH METASTATIC INVOLVEMENT

Bone pain and/or pathologic fractures
Liver dysfunction
Neurologic deficits
Spinal cord compression

PARANEOPLASTIC SYNDROMES

Weight loss
Cushing's syndrome
Hypercalcemia
Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)
Pulmonary hypertrophic osteoarthropathy
Clubbing
Anemia
Eaton-Lambert myasthenic syndrome

Paraneoplastic syndromes are signs and symptoms that occur at sites away from the primary tumor or its metastases and are not associated with direct tumor involvement. They may be caused by the production of biologically active substances (e.g., peptide hormones) or antibodies, or by other undefined mechanisms. Paraneoplastic syndromes occur more frequently with lung cancer than with any other tumor. These syndromes may be the first signs of a tumor and may prompt the search for an underlying malignancy. Paraneoplastic syndromes that commonly occur in association with lung cancers include cachexia, hypercalcemia, syndrome of inappropriate secretion of antidiuretic hormone, and Cushing's syndrome.^{2,21}

SCREENING

At the time of initial diagnosis, many patients with lung cancer have advanced disease, and unfortunately the prognosis for these patients is poor. In tumor types such as breast and colon cancers, early detection has contributed to a substantial improvement in overall survival rates, and over the past 30 years numerous trials have evaluated the impact of using various techniques in the early detection of lung cancer. In particular, large screening studies have been conducted in high-risk populations (e.g., men older than age 40 who smoke).^{22–24} Chest x-rays and sputum cytology are the most commonly used screening techniques in these older studies. Although several of these studies have reported that lung cancers may be detected at an earlier stage, actual mortality rates were not affected.^{23,24} Other investigations have also documented that chest x-rays are not sensitive enough to detect very small (<2 cm) lung tumors, which might account for the lack of impact of this screening technique.^{25,26} Furthermore, chest x-rays and sputum cytology may be associated with false-positive results in these high-risk individuals, leading to unnecessary and costly work-ups and anxiety. A recent reanalysis of one of the earlier screening trials that used different methods to remove or control potential bias indicated that early detection may improve survival because more tumors are diagnosed while they are still able to be surgically resected.^{22,27} However, the American Cancer Society does not currently recommend screening for early detection of lung cancer.

Over the years, since these early screening studies, diagnostic technologies have improved and have been evaluated in screening studies. In several uncontrolled trials, low-dose spiral or helical computed tomography (CT) has detected lung tumors at sizes significantly smaller than with conventional chest x-rays (approximately 1.5 cm vs. 2 to 3 cm).^{26,28,29} Controlled trials that assess the impact on survival and mortality of spiral CT versus conventional methods of lung cancer detection are underway, but until they are completed, it should not be assumed that detection at this smaller size will change outcomes, because many lung tumors are known to develop micrometastases while the primary tumors are quite small.³⁰ Although evidence shows that conventional sputum cytology as an early detection tool does not lead to improvement in lung cancer outcomes, several serum and sputum biomarkers of malignant transformation are under evaluation in high-risk populations. However, none have been identified as having sufficient sensitivity and specificity to reliably screen for early lung cancer.

DIAGNOSIS

Once signs and symptoms of lung cancer have been recognized, chest x-rays, CT scans, and positron emission tomography (PET) scans are the most valuable diagnostic tests. Chest x-ray is the primary method of lung cancer detection, and may also be useful in measuring tumor size, establishing gross lymph node enlargement, and aiding in detection of other tumor-related findings, such as pleural effusion, lobar collapse, and metastatic bone involvement of ribs, spine, and shoulders. CT is helpful in all of the foregoing, as well as in evaluation of parenchymal lung abnormalities, detection of masses only suspected on the chest x-ray, and assessment of mediastinal and hilar lymph nodes. PET scans, however, are reportedly more accurate than CT scans in distinguishing malignant from benign lesions, detecting mediastinal lymph node metastases, and identifying metastatic spread.^{31–33} Most recently, the use of integrated CT-PET technology has been reported to improve the diagnostic accuracy in the staging of NSCLC over either CT or PET technology alone.³³

Clinical characteristics of a lung nodule may also help to differentiate benign from malignant nodules and thus determine when invasive diagnostic tests are warranted. For example, benign lesions usually have sharp borders, whereas malignant lesions usually have irregular or radiating borders.

When there is clinical and radiologic evidence of a tumor, pathologic confirmation must be established. This may be accomplished by examination of sputum cytology and/or tumor biopsy by fiberoptic bronchoscopy, percutaneous needle biopsy, or open-lung biopsy. All patients must also have a thorough history and physical examination with emphasis on detecting signs and symptoms of the primary tumor, regional spread of the tumor, distant metastases, and paraneoplastic syndromes. The physical examination also aids in determining whether or not a patient may be able to withstand aggressive surgery or chemotherapy.

Unfortunately, by the time the tumor is diagnosed, dissemination has already occurred in many patients. Determination of the extent (or stage) of the tumor involvement is important because it will aid in the selection of treatment, and estimation of the probability of cure and survival, as well as facilitating comparison of the individual patient to large-scale clinical trials.

STAGING

NON-SMALL CELL LUNG CANCER

The American Joint Committee on Cancer³⁴ has established a TNM staging classification for lung cancer based on the primary tumor size and extent (T), regional lymph node involvement (N), and presence or absence of distant metastases (M). Table 126–3 outlines this staging system. For comparison of various therapeutic modalities, a simpler stage grouping system is also used in which stage I refers to tumors confined to the lung without lymphatic spread; stage II refers to large tumors with ipsilateral peribronchial or hilar lymph node involvement; stage III includes other lymph node and regional involvement; and stage IV includes any tumor with distant metastases.³⁴

The primary tumor is assessed with chest x-rays and fiberoptic bronchoscopy, whereas lymphatic spread is usually assessed by mediastinoscopy, gallium-67 citrate scanning, and CT and/or PET scans.² If the history and physical examination or other routine clinical studies (e.g., complete blood cell count and liver function tests) suggest the possibility of metastatic disease, then special scans (e.g., bone, brain, or liver) or biopsies (e.g., bone marrow or liver) may be necessary for staging.²

SMALL CELL LUNG CANCER

A two-stage classification established by the Veterans Administration Lung Cancer Study Group is widely used in the United States to stage SCLC.²¹ Limited disease is classified as disease confined to one hemithorax and to the regional lymph nodes. All other disease is classified as extensive. Approximately 70% of patients initially present

TABLE 126–3. Tumor (T), Node (N), Metastasis (M) Staging for Lung Cancer

| | | | |
|------------------------|---|----------------|----------------|
| T _x | Positive malignant cell; no lesion seen | | |
| T ₁ | ≤3 cm surrounded by lung or visceral pleura | | |
| T ₂ | >3 cm or involvement of main bronchus 2 cm or more distal to the carina, or invasion of visceral pleura, or associated atelectasis or obstructive pneumonitis extending to hilar region | | |
| T ₃ | Direct invasion of chest wall, diaphragm, mediastinal pleura, or parietal pericardium; or tumor in main bronchus less than 2 cm distal to the carina; or associated atelectasis or obstructive pneumonitis of the entire lung | | |
| T ₄ | Invasion of mediastinum, heart, great vessel, trachea, esophagus, vertebral body, or carina; or tumor with a malignant pleural effusion | | |
| N ₀ | No regional lymph node involvement | | |
| N ₁ | Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph node(s), including direct extension | | |
| N ₂ | Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s) | | |
| N ₃ | Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s) | | |
| M ₀ | No distant metastases | | |
| M ₁ | Distant metastases | | |
| Stage Groupings | | | |
| Stage IA | T ₁ | N ₀ | M ₀ |
| Stage IB | T ₂ | N ₀ | M ₀ |
| Stage IIA | T ₁ | N ₁ | M ₀ |

| Stage IIIA | T ₁ –T ₃ | N ₂ | M ₀ |
| | T ₃ | N ₁ | M ₀ |
| Stage IIIB | Any T | N ₃ | M ₀ |
| | T ₄ | Any N | M ₀ |
| Stage IV | Any T | Any N | M ₁ |

From AJCC.³⁴

with extensive disease. Because of this high frequency of disseminated disease at diagnosis (bone 38%; liver 22% to 28%; bone marrow 17% to 23%; central nervous system [CNS] 8% to 14%), a comprehensive past medical history and physical examination are necessary. Any suspicious signs or symptoms detected during the physical examination should be carefully investigated. In addition, it is necessary to obtain laboratory tests (i.e., complete blood cell count with differential, platelet count, serum electrolytes, liver function tests, calcium, lactate dehydrogenase [LDH], blood urea nitrogen, and serum creatinine), chest CT, bone scan, and brain imaging.³ The need for a bone marrow biopsy is controversial;³⁵ recent NCCN guidelines recommend a bone marrow aspirate for those who have limited stage disease, but not for those with extensive stage disease.³ Pulmonary function tests, electrocardiogram, and cardiac function tests should be conducted if clinically indicated, especially if chest radiotherapy is being considered.³

▶ TREATMENT: Lung Cancer

■ NON-SMALL CELL LUNG CANCER

5 6 Surgery, radiation therapy, and systemic therapy using nonspecific cytotoxic chemotherapy or targeted therapies are all used in the management of NSCLC. Currently, only surgery, and to a lesser extent radiation therapy, offer an opportunity for long-

term survival in a significant percentage of patients, although only about 30% of unselected patients have localized disease (stage I or II) that is amenable to local therapy.² Curative therapy in this disease is determined by the anatomic stage of the disease (it must be localized with no evidence of distant metastases) and the ability of the patient to tolerate aggressive therapy. If left untreated, most patients with NSCLC die within 1 year of diagnosis.

Radiation therapy (radiotherapy) is used in a variety of settings for the treatment of NSCLC. Thoracic radiotherapy may be administered with curative intent for treatment of small localized tumors in some patients. Radiotherapy is most commonly administered postsurgically (adjuvant therapy) for prevention of local disease recurrence, as well as in advanced disease for the palliation of tumor-related symptoms (i.e., control of pain from bone metastases, hemoptysis, or obstructive symptoms).

Historically, NSCLC has been considered less responsive to conventional cytotoxic chemotherapy than many other types of cancer including leukemias, lymphomas, breast cancer, and even SCLC. Until recently, the use of chemotherapy was considered controversial. However, studies have consistently shown that although chemotherapy is not curative, patients with advanced stage NSCLC who respond to chemotherapy are more likely to have a survival benefit and reduced symptoms as compared to patients who do not respond to chemotherapy.² Combination chemotherapy regimens that include newer active agents are demonstrating higher response rates and longer median survival durations than ever before. In addition, as discussed below, chemotherapy now appears to have a role in the management of early stage disease in combination with surgery and radiation. The use of chemotherapy in the management of NSCLC is most extensively discussed in the section on stage IV disease (advanced NSCLC).

■ STAGE I AND IIA NON-SMALL CELL LUNG CANCER

5 **6** Surgical resection (pneumonectomy or lobectomy) is the treatment of choice for NSCLC patients with clinical stage I and II (disease that by all evidence is stage I or II prior to surgical resection and examination of lymph nodes) disease. Overall, more than 50% of patients with stage I and 35% of patients with stage II disease who undergo complete surgical resection survive 5 years without disease recurrence.³⁶ The most important prognostic factors for patients undergoing surgical resection are the size of the tumor, the presence or absence of lymph node involvement, and residual tumor in the surgical margins.⁴ The addition of spiral CT and PET scanning of the chest to the initial preoperative staging plan have markedly improved the accuracy of clinical staging. However, mediastinal lymph node sampling via mediastinoscopy or dissection at the time of surgery is important to confirm the presence or absence of lymph node involvement. If mediastinal lymph nodes are found to be involved at the time of surgery, a complete lymph node dissection should be done.

The size of the tumor is of prognostic importance in stage I and stage II disease, with tumors <2 cm having the best long-term survival rates. Typically, removal of the involved lobe of the lung (e.g., lobectomy) is the recommended surgical procedure for stage IA tumors, but there is some evidence that pneumonectomy may reduce the rate of local recurrences for patients with larger size stage IB tumors.^{36,37}

Stage II (T₁N₁) disease has a poorer prognosis, with a 5-year survival rate after complete surgical resection of approximately 40%.² Pneumonectomy, or removal of the entire lung (versus lobectomy), is the recommended surgical procedure for stage II disease with lymph node involvement (T₁₋₃N₁). Despite complete resection (no apparent residual disease remaining), as many as 50% of patients with stage II disease develop recurrent disease and die within 2 years.² It is therefore postulated that many of these patients may benefit from postoperative radiotherapy to improve local control, as well as from chemotherapy to decrease the risk of undiagnosed systemic micrometastasis.³⁶ Although some trials have reported benefit from postoperative adjuvant radiation in patients with stage I or II disease, others have not

shown benefit and several have reported adverse outcomes associated with radiation.³⁸⁻⁴⁰ Therefore adjuvant thoracic radiotherapy is recommended postoperatively when surgical margins indicate that there is residual disease.^{4,40} The goal of radiotherapy in this setting is curative, by eliminating the residual disease and reducing the risk of local disease recurrence. Because micrometastases are known to develop while lung tumors are quite small, the use of systemic postoperative chemotherapy has been extensively evaluated. Cisplatin-based systemic chemotherapy with or without radiation therapy is recommended for patients with positive surgical margins, when there is documented involvement of the ipsilateral mediastinal or subcarinal lymph nodes, and in patients with primary tumors >3 cm.⁴ Although many clinical trials evaluating adjuvant chemotherapy following surgical resection have not demonstrated a clear-cut benefit, a recent report by the International Adjuvant Lung Cancer Trial Collaborative Group reported a 17% improvement in disease-free survival and a 14% improvement in overall survival for patients receiving cisplatin-based adjuvant therapy versus those receiving no adjuvant therapy.⁴¹ This trial included 1867 patients with stages I, II, and III NSCLC who received cisplatin in combination with either etoposide, vinblastine, vinorelbine, or vindesine without radiation therapy.

CLINICAL CONTROVERSY

The use of adjuvant chemotherapy in patients with stage I or IIA NSCLC is controversial. The recent report by the International Adjuvant Lung Cancer Collaborative Group shows that adjuvant chemotherapy results in a modest improvement in disease-free and overall survival. It is not clear, however, whether this modest improvement is worth the cost and side effects associated with chemotherapy.

Radiotherapy alone (without chemotherapy or surgery) is the treatment of choice for stage I and II patients who refuse surgery or who are considered high surgical risks because of concomitant illness or restrictive pulmonary reserve.² It is also used when the tumor is unresectable because of fixation to a major blood vessel, the trachea, or the esophagus. Of those patients, the 2- and 5-year survival rates appear to be highest for patients whose tumors would otherwise be considered resectable.

■ STAGE IIB, IIIA, AND IIIB NON-SMALL CELL LUNG CANCER

6 Management of locally advanced NSCLC stage IIB, IIIA (T₁₋₃N₂, T₃N₁), and IIIB tumors is more controversial. Although many of these tumors are resectable or potentially resectable, the prognosis is poor, with 5-year survival rates ranging from 10% to 30%, depending on tumor size and lymph node involvement.² Both postoperative adjuvant and preoperative neoadjuvant chemotherapy and/or radiation therapy have been extensively evaluated in an effort to improve the overall survival rate. Adjuvant or neoadjuvant thoracic radiotherapy is used to reduce the risk of local disease recurrence. However, when given without chemotherapy, it does not impact overall survival rates because many of these patients develop systemic (distant) metastases.² The use of radiotherapy alone or postoperatively (without chemotherapy) in stage III disease should be reserved for those patients with a poor performance status who are at high risk for significant chemotherapy-induced toxicity.

For patients with surgically resectable, locally advanced stage IIB, IIIA, and more advanced IIIB (any T N₃ or T₄ any N) disease,

neoadjuvant (before surgery) chemotherapy with or without concurrent radiotherapy, followed by surgery, improves local and regional control and overall survival when compared to preoperative radiation followed by surgery.^{4,40} As in earlier-stage disease, cisplatin-based two-drug combinations are generally recommended for preoperative chemotherapy regimens. Cisplatin plus etoposide or cisplatin plus vinorelbine or another vinca alkaloid have been the most widely studied cisplatin-based two-drug regimens in adjuvant and neoadjuvant trials, but newer combinations such as cisplatin and paclitaxel or cisplatin and docetaxel have demonstrated improved outcomes in patients with advanced NSCLC, and may be used in these earlier stages. Preoperative chemotherapy may also increase the likelihood that an advanced local tumor may be completely resected at the time of surgery.² Alternatively, depending on the tumor location and size and the extent of lymph node involvement, NCCN guidelines also indicate that initial surgery followed by postoperative RT and/or cisplatin-based chemotherapy is also an acceptable treatment plan.⁴ Large phase III trials continue to evaluate various combinations of neoadjuvant chemotherapy with or without radiotherapy versus initial surgery followed by adjuvant therapy. Accurate disease staging, consistent eligibility criteria, and multidisciplinary communication are essential to the success of these trials in elucidating the role of future neoadjuvant therapy in locally advanced NSCLC. Stage IV disease with systemic metastasis is, by definition, not surgically resectable for cure, and is therefore classified as nonresectable.

CLINICAL CONTROVERSY

Management of locally advanced (stage IIB, IIIA, and IIIB) NSCLC is controversial. Both postoperative adjuvant and preoperative neoadjuvant chemotherapy, with or without concurrent radiotherapy, have been used.

■ STAGE IV METASTATIC OR RECURRENT AND UNRESECTABLE STAGE III NON-SMALL CELL LUNG CANCER

5 6 Although surgery and radiation therapies have been the mainstay of treatment options for patients with localized or regional disease, about 70% of NSCLC patients present with advanced, poor-prognosis stage III and IV disease at the time of diagnosis. The majority of these advanced tumors are not surgically resectable due to disseminated (multiple sites) metastatic disease or metastatic sites that are not amenable to surgery. Patients with single metastatic sites may undergo surgical resection of both the primary tumor in the lung and the metastatic site.⁴ Patients who have recurrent disease following surgical resection are usually not candidates for further surgical interventions and are managed similarly to those who present with stage IV disease. Although chemotherapy (single-agent and combination regimens) has been used for treatment of NSCLC for more than three decades, the overall survival benefits were not clearly established until just a few years ago. Beneficial effects of chemotherapy have been recognized both due to the discovery of new more active drugs, more optimal use of drugs, and improvement in the design of clinical trials.² Several studies have compared chemotherapy to the best supportive care and have shown a consistently better outcome for chemotherapy.^{2,42–44} In 1995, the Non-small Cell Lung Cancer Collaborative Group reported the results of a large meta-analysis encompassing over 25 years of clinical trials of chemotherapy in the management of NSCLC.⁴⁵ This meta-analysis included data for 9387 patients from 52 randomized clinical trials that compared

chemotherapy alone versus best supportive care and chemotherapy plus radiotherapy or surgery versus either single-treatment modality. Best supportive care generally consisted of symptom management with palliative radiotherapy, corticosteroids, pain management, and antibiotics as required. The results of this meta-analysis and other evidence suggest that chemotherapy, when combined with either surgery and/or radiotherapy, improves survival for patients with advanced stage NSCLC by 2 to 4 months, and increases the 1-year survival rate by 10% to 20%.^{38,45} Cisplatin-containing chemotherapy regimens appear to be superior to older non-cisplatin-containing regimens, and regimens containing alkylating agents generally produced inferior outcomes. The roles of individual chemotherapy agents or regimens were not compared in this particular meta-analysis and require further evaluation.⁴⁵

Both the NCCN and ASCO guidelines recommend the use of platinum-based (cisplatin or carboplatin) chemotherapy for unresectable NSCLC.^{4,5} Duration of treatment with combination chemotherapy plus radiotherapy for advanced-stage NSCLC should be a minimum of two cycles to a maximum of eight cycles in most cases.^{4,5}

Over the past 30 years, thousands of clinical trials have evaluated chemotherapy for the treatment of advanced NSCLC. The results have often been inconsistent or even conflicting. Direct comparison of study results between clinical trials is difficult and requires critical assessment of the study design, inclusion criteria (performance status, history of prior weight loss, and staging criteria), exclusion criteria, and assessment methodology. An excellent example is the importance of enrollment criteria for stage III locally advanced disease. Subset analysis is particularly important for stage III disease, because IIIA includes locally advanced disease, while stage IIIB includes more bulky regional disease with an overall poorer prognosis. Also, whether or not pathologic documentation of stage IIIA (N₂) disease was required in the trial is important because, if it was not, then some stage II (N₁) patients with a better prognosis may have been erroneously enrolled. Poorly defined stage III patient enrollment, with or without documented N₂ disease, may have contributed to the wide ranges reported in long-term survival rates and response rates between study arms in many of the early clinical trials.

Standardized response criteria are also important for the comparison of clinical trial results. The standard definition of a complete response (CR) is the complete disappearance of all evidence of the tumor as verified by two scans at least 4 weeks apart, whereas a partial response (PR) is defined as a reduction in measurable tumor mass of more than 50% for ≥ 4 weeks. Because many lung tumors do not have definite margins and are difficult to measure, the term *objective response* (OR) has been used to describe disease in which there has been a definite decrease in the size of the lesion without the appearance of any new lesions.² Tumor response to chemotherapy is generally evaluated at the end of the second or third cycle and at the end of every second cycle thereafter. Patients with stable disease, with OR, or with measurable decrease in tumor size (CR or PR) should continue with the same chemotherapy regimen, although several trials have found that prolonged administration of chemotherapy does not appear to improve survival, but may be associated with increased toxicity.^{46–48} Although the ASCO and NCCN guidelines recommend a maximum of eight and six cycles of chemotherapy, respectively, other experts recommend that the number of cycles be limited to three or four cycles in patients with advanced disease.^{4,5,38} The chemotherapy regimen should always be discontinued for documented progressive disease, and an alternative regimen or investigational protocol should be considered.

Several prognostic factors have important implications in terms of response and survival for NSCLC patients selected to receive

chemotherapy. These factors include the patient's current performance status, percentage of weight loss from baseline, and extent of disease (stage).² Among these factors, an initial favorable performance status (Eastern Cooperative Oncology Group [ECOG] performance status of 0 to 2) appears to be the most consistent factor predicting a better response and improved survival after chemotherapy. There is little evidence to support the usefulness of chemotherapy in persons with an ECOG performance status of ≥ 3 (Karnofsky performance status of less than 50%).² Patients with an unfavorable prognosis (poor performance status, elevated LDH, weight loss $> 5\%$, and/or significant concomitant diseases) should receive supportive care and palliative radiation when necessary.

Phase II and phase III randomized trials with subset selection and disease documentation are ongoing to evaluate the efficacy of various combinations of chemotherapy, radiation, and surgery. Clinicians must refrain from extrapolating the results from early clinical trials into their general daily practice and should continue, whenever possible, to refer patients to carefully designed randomized trials to define the optimal therapy for the various subsets of NSCLC.

Chemotherapy for stage IV NSCLC is not curative, despite significant advances in available treatment options. But improved response rates, a modest increase in survival, and decreased toxicity profiles observed with many of the newer chemotherapy agents and combination regimens have led most experts to agree that most patients with stage IV disease should receive at least one chemotherapy regimen.^{4,5}

The cost-effectiveness ratio for the use of chemotherapy versus best supportive care in advanced stages III and IV NSCLC has also been evaluated. Jaakimainen and colleagues demonstrated a modest increase in survival, improved symptom management, and decreased medical costs for patients receiving chemotherapy versus those receiving best supportive care.⁴⁹ The potentially high costs of chemotherapy, especially with the newer agents, are generally offset by the use of outpatient oncology clinics for drug administration and by the decreased costs incurred from best supportive care for symptom management and hospitalization (often prolonged). Cost calculations for cisplatin plus one of the new agents given in a combination regimen for advanced stage NSCLC is less than \$20,000 per life-year gained, which is in the range of other widely accepted interventions.⁵⁰

■ SINGLE-AGENT CHEMOTHERAPY

Single-agent chemotherapy has generally demonstrated objective response rates of 5% to 25% with no significant effect on overall survival. When responses do occur with single-agent chemotherapy, the duration of the response is usually brief (2 to 4 months) and complete responses are rare.² Among the most active single agents in NSCLC are cisplatin, carboplatin, docetaxel, etoposide, gemcitabine, ifosfamide, irinotecan, mitomycin, paclitaxel, topotecan, vinblastine, vinorelbine, and the EGFR tyrosine kinase inhibitors, gefitinib and erlotinib. Numerous other investigational agents, including marimastat, a matrix metalloproteinase inhibitor (cytostatic agent); tirapazamine, a cytotoxic that targets hypoxic cells; and other EGFR inhibitors are currently undergoing evaluation as single agents and in combination therapy in phase II and phase III clinical trials.

■ COMBINATION CHEMOTHERAPY

Combinations of two or more chemotherapy agents have been used in the management of NSCLC since the late 1960s. Response rates for

combination chemotherapy regimens generally have been better than single-agent therapy, but improvement in overall survival rates has not been consistently observed.^{51,52} Active combination chemotherapy regimens that have consistently reported response rates exceeding 30% have used various combinations of cisplatin, carboplatin, gemcitabine, ifosfamide, or mitomycin, and vinblastine, vindesine, or vinorelbine (Table 126–4). Evidence suggests that cisplatin dose may have an impact on tumor response, and the most widely recommended first-line regimens now include either cisplatin or carboplatin in combination with one other active agent.

For a number of years, the combination of cisplatin (60 to 100 mg/m² on day 1) and etoposide (80 to 120 mg/m² on days 1, 2, and 3 of the treatment cycle) given every 21 to 28 days was regarded as the most active regimen in the treatment of advanced NSCLC.² Newer chemotherapeutic agents in several distinct classes have shown single-agent activity of greater than 20% in NSCLC. The plant alkaloids (vinorelbine), taxanes (antimicrotubule agents; paclitaxel and docetaxel), antimetabolites (gemcitabine), and topoisomerase I inhibitors (topotecan and irinotecan) have been extensively studied in various combinations with platinum compounds (cisplatin or carboplatin). In 2000, the first trial documenting a superior response rate to cisplatin and etoposide was reported with the combination of cisplatin and paclitaxel.⁵³ Other trials have subsequently reported similar survival and adverse event outcomes with other platinum-based two-drug combinations.^{54–56} Whereas earlier studies of chemotherapy focused primarily on response rates, newer studies focus on disease-free survival and overall survival, time to disease progression, quality of life, toxicity (short- and long-term), and cost effectiveness. These outcome measures are felt to provide more insight regarding the meaningful impact of the therapy on patients' lives. Results from many recently published trials combining these new chemotherapy agents with platinum-based regimens suggest improved 1-year survival rates in advanced NSCLC of 30% to 40% vs. 15% to 25% with the older cisplatin-based combination regimens (see Table 126–4).

Addition of a third drug to these two-drug combinations has not appeared to provide benefit and in some cases has been associated with increased toxicity.^{64,65}

Vinorelbine is a semisynthetic vinca alkaloid. Single-agent activity has been demonstrated in advanced NSCLC, with response rates of up to 33%, median survivals of 40 weeks, and 1-year survival rates of 24% to 30%.⁵⁹ The combination of vinorelbine plus cisplatin has demonstrated superior efficacy to either agent alone, and to vindesine plus cisplatin in randomized phase III trials.^{59,66}

The taxanes, paclitaxel and docetaxel, are antimicrotubular agents that bind to the microtubules and promote and stabilize microtubular assembly, resulting in the inhibition of mitosis and cell death. Paclitaxel as a single agent and in combination regimens has been evaluated in patients with advanced NSCLC with positive results. Regimens have included paclitaxel administered by 1-hour, 3-hour, and 24-hour continuous infusion schedules at low doses (175 mg/m²) and high doses (250 mg/m²) with granulocyte colony-stimulating factor (G-CSF) support.

In a study conducted by ECOG, 574 evaluable patients were randomized to receive either cisplatin plus paclitaxel 175 mg/m² given as a 24-hour continuous infusion; cisplatin plus paclitaxel 250 mg/m² given as a 24-hour continuous infusion with G-CSF support; or the standard regimen of cisplatin plus etoposide.⁵³ Survival for patients who received paclitaxel was significantly longer than those receiving etoposide. Although no difference in survival was observed between the low- and high-dose paclitaxel arms (median of 9.9 months; 1-year survival rate of 39%), the high-dose arm resulted in significantly greater toxicity (myalgia, peripheral neuropathy, and possibly

cardiac toxicity) and was more costly, whereas the lower-dose paclitaxel regimen (without filgrastim) had a higher incidence of grade 4 granulocytopenia. The median duration of survival in the cisplatin plus etoposide group was 7.6 months (1-year survival rate 32%).

Other studies have evaluated paclitaxel given for shorter durations of infusion. In a phase II trial, 53 patients with stage IIIB or IV NSCLC were treated with paclitaxel (135 to 215 mg/m²) via 24-hour continuous infusion plus carboplatin dosed to an area under the curve (AUC) of 7.5 on day 2 and given every 3 weeks.⁶⁷ Severe myelosuppression was observed, with moderate-to-severe neutropenia in 57% of patients after the first cycle, which led to the addition of G-CSF for the second and subsequent cycles. Significant thrombocytopenia and anemia were also reported in 47% and 33% of patients, respectively. Despite initially high response rates of 62% and an encouraging 1-year survival rate of 54%, the 2-year and 3-year survival rates remain poor at 15% and 4%, respectively. A subsequent trial by Langer and colleagues⁶⁸ compared a 1-hour versus a 24-hour infusion of paclitaxel plus carboplatin. The 1-hour regimen was associated with an increased rate of peripheral neuropathy and minimal myelosuppression, but the response rate decreased to 27%. The shorter (<3 hours) infusions of paclitaxel are easily administered in the outpatient oncology setting and rarely require G-CSF support, which makes them more convenient and acceptable to patients than the 24-hour infusions. The results of ongoing cooperative trials in advanced NSCLC will clarify the most appropriate infusion schedule and the role of paclitaxel in combination with platinum compounds and the other newer agents.

Docetaxel is an active semisynthetic taxoid, without the schedule-dependent efficacy and somewhat different toxicity issues than those associated with paclitaxel administration. Most of the early docetaxel clinical trials used dosages of 60, 75, or 100 mg/m² infused intravenously over 1 hour every 3 weeks. Initial phase II single-agent docetaxel studies reported response rates from 25% to 38%, median survivals of 9 months, and a 1-year survival rate of about 38% in chemotherapy-naïve patients with advanced NSCLC.^{2,69} Docetaxel 75 mg/m² every 3 weeks in combination with cisplatin is indicated in previously untreated patients with unresectable NSCLC and also as a second-line single agent (100 mg/m² every 3 weeks) against previously platinum-treated NSCLC with response rates of 15% to 21%, median survival of 7 months, and 1-year survival of 25%.^{2,69,70}

Docetaxel received FDA approval in 1999 for the treatment of advanced stage IIIB and stage IV metastatic NSCLC after failure of a platinum-based chemotherapy regimen. Approval was granted based on the preliminary analysis of data from two randomized trials. The first trial compared docetaxel to best supportive care in 204 patients previously treated with platinum. The initial dose of docetaxel of 100 mg/m² (D 100) IV over 1 hour every 3 weeks was decreased to 75 mg/m² (D 75) after an interim study analysis reported a greater risk of severe neutropenia with the higher dose. The D 75 dose level was active and reported a significant advantage to best supportive care in terms of time-to-disease progression (10.6 weeks vs. 6.7 weeks), median survival (7.5 months vs. 4.6 months; $p = 0.047$), and 1-year survival (37% vs. 11%; $p = 0.003$).⁷¹

Docetaxel has been successfully administered to chemotherapy-naïve patients in combination with either cisplatin or carboplatin. Docetaxel 75 mg/m² plus cisplatin (75 to 100 mg/m²) infused on day 1 every 3 weeks is active and well tolerated, with neutropenia being the dose-limiting toxicity.⁶⁹ Based on phase II data, this combination was included as one of the four arms in the randomized phase III ECOG 1594 trial (see discussion of this trial in the gemcitabine section).⁵⁷ The addition of filgrastim allowed a greater dose intensity in one phase II docetaxel plus cisplatin trial, resulting in a higher initial response rate and a slightly increased median survival. The

combination of docetaxel (65 to 80 mg/m²) plus carboplatin (AUC 5 to 6) administered every 3 weeks is also active.⁶⁹ Decreasing the carboplatin AUC to 5 while maintaining a higher docetaxel dose intensity appears to maintain efficacy and to cause less neutropenia, and is thus being further investigated. However, the results of these encouraging studies must be confirmed in larger phase III trials. Numerous phase II and III multi-institutional and cooperative group trials are ongoing to evaluate the efficacy and toxicity of docetaxel with carboplatin, cisplatin, vinorelbine, gemcitabine, irinotecan, and thoracic radiation therapy.

Gemcitabine is a nucleoside analog (antimetabolite) that is phosphorylated intracellularly by deoxycytidine kinase. It has an increased membrane permeability and affinity for deoxycytidine kinase, yielding higher intracellular concentrations of the active metabolite and prolonged inhibition of DNA, as compared to its structurally related predecessor cytarabine. Phase I and II trials of gemcitabine have demonstrated antitumor activity against a variety of solid tumors, including lung, breast, ovarian, and pancreatic cancers. The overall toxicity profile for single-agent gemcitabine is modest. Gemcitabine was approved in the United States in 1998 for use in first-line combination therapy with cisplatin for the treatment of nonresectable, locally advanced or metastatic NSCLC. This indication for gemcitabine was based on data presented from 657 patients who participated in two randomized clinical trials with cisplatin. In one trial, gemcitabine 1000 mg/m² IV on days 1, 8, and 15 plus cisplatin 100 mg/m² IV on day 1 every 28 days was compared to single-agent cisplatin.⁷² The second registration trial compared gemcitabine 1250 mg/m² IV on days 1 and 8 plus cisplatin 100 mg/m² IV on day 1 every 21 days, to cisplatin 100 mg/m² IV on day 1 plus etoposide 100 mg/m² IV on days 1, 2, and 3⁶¹ (see Table 126–4). In both studies, the objective response rates (26% vs. 10% and 33% vs. 14%, respectively), median survival (9 months vs. 7.6 months and 8.7 months vs. 7 months, respectively), and time to disease progression was significantly better for the gemcitabine plus cisplatin combinations.

An Eastern Cooperative Oncology Group (ECOG 1594) trial randomized patients with advanced NSCLC to three platinum-containing regimens (cisplatin plus either gemcitabine [GC] or docetaxel [DC] vs. paclitaxel plus carboplatin [PCb]) to the standard reference arm of cisplatin plus paclitaxel (CP).⁵⁷ Of the 1207 patients enrolled from October 1996 through May 1999, 1155 were eligible for data analysis. Enrollment included patients with stage IIIB with a poorer prognosis, which included a pleural or pericardial effusion (disease not responsive to radiotherapy), and patients with stage IV NSCLC. Patients were stratified by performance status and baseline weight loss. Patients with performance status 0 to 2 were initially eligible for the trial, but an interim analysis revealed that patients with a performance status of 2 experienced increased toxicity with the cisplatin-containing regimens, and the study was subsequently limited to patients with performance status 0 and 1 only. There were no significant differences between the paclitaxel plus cisplatin control arm and the other three regimens in response rate, median survival, or 1-year survival (see Table 127–4). However, the GC regimen resulted in a modest 1 month advantage in time to disease progression ($p = .002$).

As expected, different toxicity patterns were reported for the four regimens. The PCb regimen was the most well-tolerated regimen, but it also had the lowest response rate and time to disease progression. The GC regimen had a higher incidence of severe thrombocytopenia and moderate to severe renal dysfunction, but the lowest incidence of severe neutropenia and febrile neutropenia. Moderate nausea was a problem for all of the cisplatin-containing regimens and was the greatest in the GC regimen with the higher dosage of cisplatin (100 mg/m² vs. 75 mg/m²). Overall, the results of the four regimens were

quite similar in this trial, and no clear advantage for one regimen over another was evident.⁵⁷ The high proportion of patients with stage IV disease in this trial is probably responsible for the disappointingly low overall response rates and median survival. In the community setting, the PCb regimen may be slightly easier to administer and monitor. Both the GC and DC regimens warrant further investigation in advanced NSCLC with varying dosages and infusion schedules to evaluate efficacy and improve toxicity. Altering the gemcitabine dose and schedule to days 1 and 8 only, eliminating the day 15 dose, has successfully improved the toxicity profile in other gemcitabine-containing regimens.

Irinotecan is a water-soluble analog of camptothecin, which is a potent inhibitor of topoisomerase I, the nuclear enzyme responsible for maintaining DNA topologic structure. Inhibition of topoisomerase I stabilizes single-strand DNA breaks and prevents re-ligation (resealing), resulting in DNA dysfunction and apoptosis. Single-agent irinotecan studies reported initial response rates of up to 35% in chemotherapy-naïve advanced-stage NSCLC patients.^{2,4} Unfortunately, response rates were low for previously treated patients with refractory disease. Combination chemotherapy with irinotecan plus cisplatin yielded response rates of 40% to 54% in patients with chemotherapy-naïve advanced-stage NSCLC. The irinotecan-cisplatin combination produced modest improvements in 1-year survival rates of 35% to 47%.^{62,63,73} Irinotecan plus cisplatin is currently being evaluated worldwide in numerous combination regimens combined with gemcitabine, docetaxel, and/or vinorelbine.

Preclinical data indicate that radiotherapy increases the proportion of cells in the S phase, which may enhance the efficacy of topoisomerase I inhibitors. Thus trials evaluating irinotecan as a single agent in combination chemotherapy regimens plus radiotherapy have been undertaken. A phase I/II trial of bimodality therapy for locally advanced NSCLC with single-agent irinotecan 60 mg/m² weekly for 6 weeks, plus concurrent thoracic radiotherapy to the tumor site and regional lymph nodes resulted in an objective response rate of 77%.⁷⁴ The combined modality therapy resulted in dose-limiting esophagitis, severe pneumonitis, and diarrhea. The combination initially appears to be promising, and a phase II continuation trial with irinotecan decreased to 45 mg/m² weekly plus concurrent radiotherapy will provide further toxicity evaluation and survival data for the regimen.

Recognition that many NSCLCs overexpress the EGFR has led to the evaluation of several EGFR inhibitors in the management of NSCLC. In 2003, gefitinib, an orally active EGFR inhibitor, was approved by the FDA as a single agent for patients with advanced NSCLC whose disease progressed despite a platinum plus docetaxel regimen. Gefitinib is a small molecule that blocks the intracellular tyrosine kinase portion of the EGFR. Signals initiated by cell surface membrane EGFRs are vital in the proliferation and survival of cancer cells. Because the EGFR is frequently overexpressed in NSCLC cells, it is a logical target in the treatment of this disease. Early clinical trials demonstrated that gefitinib was well tolerated and demonstrated antitumor responses in 12% to 18% of patients who had previously progressed following other chemotherapy for NSCLC.^{75,76} About 40% of patients in that trial experienced relief of symptoms associated with the disease. Presently the use of gefitinib is controversial because of its low response rates and the data regarding its effects on survival.

CLINICAL CONTROVERSY

The approval of the orally active EGFR inhibitor gefitinib provides clinicians with a drug with a novel mechanism of action. However, its use is controversial because of its low response rate and its lack of survival benefit.

Two large randomized phase III studies, however, failed to demonstrate improved response rates or survival when gefitinib was added to chemotherapy as compared to chemotherapy alone.^{77,78} Further analyses of these two phase III trials showed that responses were more common in women, patients who had never smoked, and in patients with bronchoalveolar carcinomas or adenocarcinomas with bronchoalveolar features. However, the response rate was low, even in patients with these favorable prognostic factors. In addition, the intensity of immunohistochemical staining of the tumor for EGFR also did not correlate with the likelihood of a response. It has been recently reported that tumors with heterozygous mutations within the tyrosine kinase portion of the EGFR are more likely to respond to gefitinib.⁷⁹ These mutations appear to activate growth factor signaling due to enhanced stabilization between the tyrosine kinase and adenosine triphosphate or its competitive inhibitor, gefitinib. Prospective evaluation of this molecular marker of gefitinib response may assist clinicians in selecting patients who are most likely to respond to this targeted therapy.

In November 2004, a second orally active EGFR inhibitor, erlotinib (Tarceva), was approved by the FDA as a single agent for patients with locally advanced or metastatic NSCLC after failure of at least one prior chemotherapy regimen. Its approval was based on an international, multicenter, randomized, double-blind phase III trial in 731 patients with locally advanced or metastatic (stage IIIB or IV) NSCLC who had failed at least one prior chemotherapy regimen.⁸⁰ Patients were randomized to receive either erlotinib 150 mg or placebo orally once daily. Patients in the erlotinib group had a significantly higher objective response rate (8.9% vs. 0.9%, $p < .001$) and longer median progression-free and overall survival (9.9 wk vs. 7.9 wk, $p < .001$ and 6.7 mo vs. 4.7 mo [hazard ratio = 0.73], $p < .001$, respectively) than those in the placebo group. Patients in the erlotinib group also had significantly improved symptom control, as measured as time to deterioration of cough, dyspnea, and pain. Erlotinib, like gefitinib, showed no benefit when added to conventional platinum-based chemotherapy.

Although there are no head-to-head comparisons of erlotinib and gefitinib, review of the available evidence suggests that erlotinib is more active than gefitinib. Erlotinib has been shown to significantly prolong survival in a large randomized controlled trial, whereas gefitinib failed to show a significant survival benefit in the ISEL (Iressa Survival Evaluation in Lung cancer) trial.⁸¹

RADIATION THERAPY FOR ADVANCED NON-SMALL CELL LUNG CANCER

5 Palliative radiotherapy with chemotherapy may be used in selected patients to control local and systemic disease and to reduce disease-related symptoms. Brain metastases are also commonly treated with radiotherapy; in the case of a solitary brain lesion, surgical resection may be used.

When thoracic radiotherapy is used with curative intent, high total-dose fractions (≥ 60 Gy) are required because of the correlation between dose and local control of NSCLC. These higher dosages of radiotherapy frequently result in severe esophagitis, pneumonitis, and pulmonary toxicity in the surrounding normal tissues. Improved radiotherapy delivery techniques, such as multiple daily radiation fractions (hyperfractionated radiotherapy) and three dimensional treatment planning, allow delivery of greater dosage fractions specifically to the tumor site while decreasing the toxicity to surrounding normal tissues, as compared to standard radiotherapy. However, concurrent radiotherapy plus chemotherapy with radiosensitizing agents, such as

cisplatin, paclitaxel, and gemcitabine, further complicate the risks for severe toxicity, often necessitating dose reductions in one or both treatment modalities.⁸² Numerous randomized combined modality

trials have been initiated to evaluate the optimal delivery method, schedule, and dosages for radiotherapy in concert with cisplatin and the newer chemotherapy agents.

EVALUATION OF THERAPEUTIC OUTCOMES

Following initial therapy for NSCLC, patients must be monitored for evidence of disease recurrence. For patients who have undergone surgical resection with or without chemotherapy and/or radiation, a physical examination and chest x-ray are recommended every 3 to 4 months for the first 2 years, then every 6 months for 3 years, and then annually; and a low-dose spiral chest CT scan is recommended

annually to monitor for evidence of locoregional recurrence. Suspicious symptoms or physical findings (e.g., bone pain, visual abnormalities or headache, or elevated liver function tests) should prompt an evaluation to rule out distant metastases.⁴

For patients with advanced disease receiving chemotherapy, diagnostic tests used in initial staging should be repeated after the second cycle to evaluate for response to determine if further therapy is warranted.

► TREATMENT: Small Cell Lung Cancer

5 7 The use of aggressive combination chemotherapy regimens in SCLC results in four- to fivefold increases in median survival. Without treatment, survival is generally less than 5 to 7 weeks for patients with metastatic disease (extensive-disease SCLC) and less than 12 weeks for patients with regional disease (limited-disease SCLC). With treatment, median survival rates for extensive- and limited-disease are 8 to 13 months and 14 to 20 months, respectively.³

Prognostic factors used to determine the appropriate therapy for SCLC patients include the stage of disease (i.e., limited stage vs. extensive stage) and performance status (e.g., an ECOG performance status of 0, or ability to carry out all normal activity without restriction). Patients who initially present with limited disease and are treated with aggressive chemotherapy regimens demonstrate a significantly longer median survival than do patients presenting with extensive disease treated with the same regimens.²¹ Patients with a better performance status at the time of initial diagnosis also have an improved prognosis.²¹ Patients with normal pretreatment serum LDH are more likely to have limited disease, higher complete response rates, and longer median survivals.²¹ Females appear to have a better prognosis than do males, as do patients younger than age 60 to 70 years. Weight loss and serum neuron-specific enolase, a biologic marker, have also been suggested as relevant prognostic factors.⁸³

■ SURGERY AND RADIATION THERAPY

Because SCLC has the propensity to disseminate early on in the disease, surgery is indicated only for the rare patient with small, isolated lesions.³

7 SCLC is considered very radiosensitive. Radiotherapy is used in combination with chemotherapy to treat limited-stage disease or used alone for management of symptomatic metastases. The rationale for combined modality therapy is based on the premise that the addition of radiotherapy to chemotherapy will better control bulky disease within the chest primary tumor site.²¹ In most randomized trials, combined modality therapy has only modestly improved disease-free survival and 2-year survival over that achieved with chemotherapy alone. The optimal dose and scheduling of thoracic radiotherapy (once-daily vs. twice-daily) plus chemotherapy have not been fully defined by large-scale randomized clinical trials. However, it appears that thoracic radiotherapy given concurrently with cycle one of chemotherapy versus later cycles, or alternating with chemotherapy, are more likely to produce favorable responses than when radiotherapy is administered following chemotherapy.^{21,84} Unfortunately,

many studies of combined-modality therapy have been associated with increased morbidity when compared to chemotherapy alone or radiotherapy after chemotherapy. Patients who receive twice-daily radiotherapy experience a greater incidence of severe esophagitis, and those who receive radiotherapy combined with radiosensitizing drugs (e.g., doxorubicin) have a higher incidence of radiation esophagitis and pneumonitis. Factors that are associated with a higher risk for severe radiation pneumonitis include performance status of 1, female gender, and forced expiratory volume of the lungs in 1 second <2 L.⁸⁵ Interestingly, chemotherapy regimen, radiotherapy dose, and field size were not predictors of severe radiation pneumonitis. Combined-modality clinical trials currently underway are evaluating various dosages, schedules, and new techniques such as three-dimensional radiotherapy, in combination with a variety of chemotherapeutic agents in an attempt to maximize tumor control with an acceptable degree of toxicity.

For SCLC patients, radiotherapy is utilized to prevent and treat brain metastases. Brain metastases are present at the time of diagnosis in 10% of SCLC patients. The cumulative incidence of brain metastasis rises to 50% in patients alive at 2 years.^{21,86} The role of prophylactic cranial irradiation (PCI) is based on the theory that eradication of microscopic or subclinical brain metastases would prevent or delay the onset of brain metastases. Based on the potential toxicity of PCI and an unconfirmed survival advantage, the role of PCI has been a point of controversy for many years.^{21,87} However, the Prophylactic Cranial Irradiation Overview Collaborative Group recently published meta-analysis results from seven SCLC trials enrolling patients from 1985 onward. The analysis included data from 987 patients with SCLC in complete remission after initial therapy, and compared overall survival with the addition of PCI to an observation group. The pooled relative risk of death in the patients receiving PCI compared to the observation group was 0.84, which corresponded to a modest 5.4% absolute increase in overall survival at 3 years (15.3% alive in the observation group vs. 20.7% alive in the PCI group; $p = .01$).⁸⁷ In addition, PCI increased the rate of disease-free survival and decreased the incidence of brain metastases with a trend toward greater benefit with earlier delivery of PCI. Based on this analysis, in patients without significant cognitive impairment or cerebral atrophy, PCI is recommended in those with limited disease in complete response, and should be considered in those with extensive disease in complete response.³ PCI is also not recommended in patients with advanced age or poor performance status.³ Doses ranging from 24 Gy in 8 fractions to 36 Gy in 18 fractions are recommended.³

For patients with symptomatic brain metastases, therapeutic dosages of cranial irradiation usually control the CNS disease.

Dexamethasone (to decrease intracranial pressure) and anticonvulsants are routinely administered to patients with brain metastases for symptomatic control and seizure prevention, respectively. Combination chemotherapy should also be administered, with administration occurring after whole-brain irradiation in those patients with symptomatic brain metastases.³

CHEMOTHERAPY

A number of cytotoxic agents have demonstrated significant single-agent activity in chemotherapy-naïve patients with limited- and extensive-disease SCLC, but the activity in recurrent or refractory SCLC is modest. Among the more commonly used chemotherapy agents in the United States are cisplatin, carboplatin, etoposide (intravenous and oral regimens), topotecan, paclitaxel, docetaxel, and gemcitabine.

Combination chemotherapy is clearly superior to single-agent therapy.⁸⁸ Despite the apparent benefit of combination chemotherapy, the higher incidence of acute toxicity, neutropenic fever, and toxic death in the palliative (metastatic disease, noncurable) treatment setting must be considered.

➤ In the United States, the most frequently used regimens in newly diagnosed patients are: PE (or EP): cisplatin (P) + etoposide (E); EC (CE): etoposide (E) + carboplatin (C); and CP: irinotecan (CPT-11; C) + cisplatin (P).^{3,89} Overall response rates (80% to 90% vs. 60% to 80%) and survival durations (12 to 20 months vs. 7 to 11 months) are generally superior for patients with limited disease versus those with extensive disease. According to the NCCN guidelines, chemotherapy with concurrent radiation is recommended for patients with limited-disease SCLC and good performance status (a category 1 recommendation, which indicates uniform consensus based on high-level evidence).³ The same recommendation was made for patients with limited-disease SCLC with poor performance status, although the grade of evidence was lower (category 2A, which indicates uniform consensus based on lower-level evidence including clinical experience).³ The 2-year disease-free survival rate for patients with limited disease at diagnosis is 15% to 40%.³ In comparison, very few patients with extensive disease at diagnosis are alive at 2 years without disease.³

The optimal choice of combination chemotherapy regimen and scheduling is not clear. A meta-analysis of 19 randomized trials (4054 evaluable patients) compared cisplatin-based to non-cisplatin-based chemotherapy regimens.⁹⁰ Of these 19 trials, 10 trials randomized patients to cisplatin plus etoposide (PE) versus a regimen without either drug (e.g., CAV or cyclophosphamide + doxorubicin + vincristine), and 9 trials compared PE to a regimen without cisplatin, but that may have included etoposide. Both the overall and subset analysis concluded that cisplatin-containing regimens had a higher response rate, improved overall survival, lower incidence of life-threatening myelosuppression, and no increased risk of treatment-related mortality versus the non-cisplatin-containing regimens.

Carboplatin is often substituted for cisplatin in numerous SCLC regimens and has been shown to have similar efficacy with somewhat less toxicity, particularly for patients with pre-existing renal dysfunction or severe neuropathy.²¹ In a randomized comparison of carboplatin and etoposide (CE) versus PE in patients with SCLC, the overall survival was 11.8 months for the CE group and 12.5 months for the PE group.⁹³ Based on these data, PE or CE have become the most commonly used regimens to treat SCLC in the United States.

ALTERNATING CROSS-RESISTANT CHEMOTHERAPY

Because the duration of response is usually brief (less than 1 year) for patients achieving a complete response, drug-resistant cells are often responsible for treatment failure. The Goldie-Coldman theory predicts that cycling of two active, non-cross-resistant chemotherapy regimens may overcome this problem.⁹⁴ At least two phase III clinical trials have used alternating, non-cross-resistant regimens in the management of SCLC, and most have failed to demonstrate substantial benefits.^{91,92} Four cycles of PE has equivalent efficacy to six cycles of CAV and CAV alternating with PE with no significant difference in response rate or median survival.^{91,92} Toxicity differed between the arms, with the PE regimen causing more severe nausea and vomiting, and the CAV regimen more frequent severe myelosuppression, neurotoxicity, and cardiac toxicity.

DOSE INTENSITY AND DOSE DENSITY

Experimental animal and human tumor data suggest that the amount of drug administered over a unit of time (i.e., mg/m² per week) may be critical to the degree of tumor cell kill.⁹⁵ The importance of dose-intensity has been evaluated in many types of human cancer, particularly those like SCLC, which are initially responsive to chemotherapy, but are not usually curable with conventional therapies. Randomized trials comparing dose-intensive (high-dose) CAE (cyclophosphamide, doxorubicin, and etoposide), CAV (cyclophosphamide, doxorubicin, and vincristine), PE, CEEP (cyclophosphamide, 4'-epidoxorubicin, etoposide, and cisplatin), and cyclophosphamide plus vincristine, versus standard-dose regimens have failed to demonstrate significant differences in overall survival.^{96,97} Furthermore, a meta-analysis of 60 clinical trials failed to show a consistent relationship between dose intensity and survival for most SCLC chemotherapy regimens.⁹⁸ Although a significant difference in survival was observed in limited-stage SCLC patients receiving two dosage levels of cisplatin, cyclophosphamide, doxorubicin, and etoposide,⁹⁹ some researchers suggest that this study compared insufficient to sufficient doses of chemotherapy.⁹⁶

Dose intensity can be increased by shortening the interval between cycles (i.e., dose density). The data with dose-dense chemotherapy regimens is conflicting, with findings of both no survival difference^{100–102} and improved survival with dose-dense regimens.^{103,104}

The incidence and severity of toxicities such as granulocytopenia, febrile neutropenia, mucositis, and weight loss are significantly higher in patients who receive dose-intensive treatment regimens. Currently, dose-intensive chemotherapy regimens should not be considered as standard oncology practice and should be reserved for clinical trials, in patients with limited-disease stage SCLC, and for the evaluation of newer agents.

ALTERNATIVE COMBINATION CHEMOTHERAPY REGIMENS

The addition of other active chemotherapy agents in patients who have relapsed following PE have provided minimal improvement in survival. The addition of ifosfamide improved survival, but also toxicity.^{105,106} The addition of paclitaxel to PE resulted in similar overall survival,^{107,108} while adding paclitaxel to CE increased overall survival only in limited-disease SCLC patients.¹⁰⁹ The addition

of paclitaxel to PE increases myelosuppression and grade 3 and 4 neurotoxicity, diarrhea, and asthenia.¹⁰⁷

Combination chemotherapy regimens that include irinotecan have shown promise in both chemotherapy-naïve and previously treated limited-disease stage and extensive-disease stage SCLC.⁸⁹ The Japanese Clinical Oncology Group compared CP (irinotecan [CPT-11] 60 mg/m² IV on days 1, 8, and 15 combined with cisplatin 60 mg/m² IV day 1 given every 4 weeks for four cycles) versus EP (etoposide and cisplatin given every 3 weeks for four cycles) in 154 patients with extensive-disease stage SCLC.⁸⁹ Study enrollment was halted after the interim analysis results showed a statistically significant difference in median survival and 1-year survival in the CP arm. CP was well tolerated, with significantly less moderate to severe neutropenia (66% vs. 92%) and thrombocytopenia (5% vs. 18%) versus the EP arm, respectively. As expected, moderate to severe diarrhea was reported in 16% of patients receiving irinotecan. It should be noted, however, that the difference in overall survival, while statistically significant, represents only a modest improvement. Additional studies are ongoing to evaluate combinations of irinotecan with various conventional and newer agents.

■ MAINTENANCE CHEMOTHERAPY

Maintenance chemotherapy after induction appears to offer minimal benefit, although study design flaws have been noted in the available trials.¹¹⁰ Since 1980, over 13 randomized clinical trials have evaluated the benefit of maintenance chemotherapy. Most trials, however, were conducted with older induction chemotherapy regimens (i.e., CAV) and not with PE or CE. It is possible that there is a subset of patients, perhaps those with particularly chemotherapy-sensitive

disease treated with moderately intensive chemotherapy, who may benefit from a maintenance program. In unselected patients, treatment programs that extend beyond four cycles of chemotherapy have not demonstrated an advantage in survival and may be associated with reduced quality of life.^{3,21} Maintenance with the targeted therapy marimastat, a matrix metalloproteinase inhibitor, did not improve progression-free or overall survival, but diminished quality of life in limited- and extensive-disease SCLC.¹¹¹ Similarly, inhibition of c-kit tyrosine kinase by imatinib does not appear to be an effective agent for monotherapy for SCLC, based on preclinical xenograft models.¹¹²

■ CHEMOTHERAPY FOR RELAPSED DISEASE

After disease recurrence, the median survival is about 4 months.³ Unfortunately, when disease recurs, it is usually less sensitive to chemotherapy. The agent of choice for second-line chemotherapy is often based on the time span between completion of the induction chemotherapy regimen and relapse.³ Ifosfamide, paclitaxel, docetaxel, and gemcitabine are options for those with a good performance status (i.e., performance status 0 to 2) who relapse <3 months after induction chemotherapy was completed.³ In those who relapse between 3 and 6 months after PE or CE, options include topotecan, irinotecan, CAV (cyclophosphamide, doxorubicin, and vincristine), gemcitabine, paclitaxel, docetaxel, oral etoposide, methotrexate, or vinorelbine. Topotecan administered as a second-line agent in patients with drug-resistant tumors produced objective responses and decreased symptoms in 25% to 38% of patients.^{113,114} The original chemotherapy regimen is used for those who have a long duration of disease control (i.e., >6 months between induction chemotherapy and relapse).³

EVALUATION OF THERAPEUTIC OUTCOMES

Restaging to determine the efficacy of induction therapy is done after two to three cycles of treatment. At this point, therapy is continued for patients with a complete or partial response or stable disease, and discontinued or changed to a non-cross-resistant regimen in patients demonstrating evidence of progressive disease. The induction chemotherapy regimen is administered for four to six cycles if the SCLC disease is responsive. In those with a complete response, PCI is offered as discussed above. After recovery from initial therapy, follow-up visits should occur every 3 months for years 1, 2, and 3, then every 6 months for years 4 and 5, then annually for patients with either a partial or complete response.³

COMPLICATIONS AND SUPPORTIVE CARE

Patients with lung cancer frequently have numerous concurrent medical problems. Such problems may be related to invasion of the primary tumor and its metastases, paraneoplastic syndromes (see clinical presentation, above), chemotherapy and radiotherapy toxicity, or concomitant disease states (e.g., cardiac disease, renal dysfunction, chronic obstructive pulmonary disease, asthma, or diabetes). Depression is also common and sometimes persistent in patients with SCLC and NSCLC and should be treated. Identification, diagnosis, and treatment of the patient as a whole may improve the patient's overall quality of life and tolerance to cancer treatments.

The chemotherapy regimens used in the management of lung cancer are intensive and are associated with a wide variety of toxic

effects. Nausea and vomiting may be severe. Cisplatin-containing regimens require the use of aggressive acute and delayed antiemetic regimens containing a serotonin antagonist plus dexamethasone. Patients experiencing protracted nausea and vomiting may require intravenous hydration and nutritional support. Myelosuppression is often the dose-limiting toxicity associated with chemotherapy. Granulocytopenia places patients at a high risk for serious infections. Other toxic effects associated with these chemotherapy regimens include mucositis, nephrotoxicity, peripheral neuropathies, and ototoxicity.

Patients receiving radiation therapy may experience complications including severe esophagitis, fatigue, radiation pneumonitis, and cardiac toxicity. These toxicities are usually more common and severe when radiation is combined with chemotherapy. The patient's baseline performance status and the degree of pulmonary dysfunction (e.g., chronic obstructive pulmonary disease from years of tobacco use) must be considered in the decision of radiation dosage and fractionation.

It is readily apparent that many lung cancer patients receive complex pharmacologic regimens that may include chemotherapeutic agents, antiemetics, antibiotics, analgesics, anticoagulants, bronchodilators, corticosteroids, anticonvulsants, and cardiovascular agents. Such regimens necessitate intensive therapeutic monitoring in order to avoid drug-related and radiotherapy-related toxic effects and to optimize therapeutic outcome for individual patients.

COLORECTAL CANCER

Patrick J. Medina and Lisa E. Davis

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Maintaining a diet with high-fiber and low fat intake has not been proved to reduce colorectal cancer risk, but is beneficial for reducing risk of other chronic diseases.
- 2 In certain patient populations, the risk of colon cancer may be reduced by the use of aspirin and other nonsteroidal anti-inflammatory drugs, hormone replacement therapy, and calcium supplementation.
- 3 Effective colorectal cancer screening programs incorporate annual fecal occult blood testing in combination with regular examination of the entire colon starting at age 50 for average-risk individuals. Colorectal adenomas can progress to cancer and should be removed.
- 4 The stage of colorectal cancer upon diagnosis—determined by depth of bowel invasion, lymph node involvement, and presence of metastases—is the most important prognostic factor for disease recurrence and survival.
- 5 The goal for stage I, II, and III colon cancer is cure; surgery should be offered to all eligible patients for this purpose. Adjuvant chemotherapy, consisting of 6 months of fluorouracil plus leucovorin, significantly reduces the risk of cancer recurrence and overall mortality compared to observation alone in patients with stage III disease.
- 6 Adjuvant therapy consisting of fluorouracil-based chemosensitized radiation therapy should be offered to patients with stage II or III cancer of the rectum. Adjuvant fluorouracil chemotherapy plus radiation decreases risk of local and distant disease recurrence as compared to observation alone.
- 7 Chemotherapy is palliative for metastatic disease. Fluorouracil-based chemotherapy regimens combined with leucovorin, administered in a variety of schedules, provide a modest improvement in survival and can be highly beneficial in reducing patient symptoms.
- 8 Triple-drug therapy consisting of fluorouracil and leucovorin with oxaliplatin or irinotecan improves survival compared to fluorouracil plus leucovorin alone, and is considered as standard first-line therapy for metastatic disease. Bevacizumab, in combination with fluorouracil-based chemotherapy, is also indicated for initial treatment of metastatic colorectal cancer. Patients may benefit from more than one regimen during the treatment of their disease.
- 9 Capecitabine is an acceptable alternative to intravenous fluorouracil for metastatic colorectal cancer, as it provides similar efficacy and its oral dosing may offer greater patient convenience. The role of capecitabine as a replacement for intravenous fluorouracil in combination regimens is under investigation.
- 10 Individuals whose disease progresses during or is refractory to irinotecan may benefit from cetuximab, either alone or combined with continuing irinotecan. Their tumor should be epidermal growth factor receptor–positive.

Colorectal cancer involves the colon, rectum, and the anal canal. It is one of the three most common cancers occurring in adult men and women in the United States, and accounts for approximately one in nine cancer diagnoses. In 2005, an estimated 145,290 new cases will be diagnosed, of which 104,950 will involve the colon and 40,340 the rectum.¹

For both adult men and women, colorectal cancer is the third leading cause of cancer-related deaths in the United States. An estimated 56,290 deaths will occur during 2005.¹ Overall, the mortality and incidence associated with colorectal cancer has decreased during the past 30 years. Mortality rates associated with colorectal cancer in the United States are comparable to those of other industrialized areas around the world.²

Multiple factors are associated with the development of colorectal cancer, including acquired and inherited genetic susceptibility, environmental elements, and lifestyle choices. Overall, about 37% of

affected individuals undergo a surgical procedure alone intended for cure. An additional 37% of individuals can potentially be cured by undergoing surgery followed by radiation therapy (XRT), chemotherapy, or both. Curability is influenced primarily by extent of tumor invasion into adjacent tissues or organs and presence of metastatic disease. Five-year survival rates are close to 91% and 88% for persons with early stages of colon and rectal cancer, respectively.³ After the tumor has spread regionally to adjacent lymph nodes or tissues, five-year survival rates drop to 69% for colon cancer and to 63% for cancer of the rectum. Five-year survival for individuals with metastatic disease is about 9%.

Treatment modalities for colorectal cancer include surgery, XRT, chemotherapy, immunotherapy, and new targeted molecular therapies. Surgery is the most important and definitive procedure associated with cure; radiation therapy can be used to improve curability following surgical resection and to reduce symptoms and complications

associated with advanced disease. Chemotherapy is used in adjuvant treatment regimens as well as in treatment for advanced stages of disease. Much progress has been made in the treatment of advanced disease, in the ability to identify candidates for potentially curative surgical procedures, and the availability of active drug regimens that can improve patients' survival.

EPIDEMIOLOGY

Incidence rates worldwide vary by as much as 20-fold. The highest incidence rates occur in highly industrialized areas such as North America, Northern and Western Europe, Australia, and New Zealand. The lowest incidence rates are seen in India and in less-developed areas such as South America and rural Africa.⁴ Rates have increased substantially, however, in previously lower-risk countries such as Japan and China, as well as among persons migrating from low-risk areas to the United States. Within one or two generations, the incidence rates among migrating groups approximate those of the new host country, suggesting that environmental and dietary factors may influence a late stage in colorectal carcinogenesis. However, colorectal cancers are known to develop more frequently in certain families and genetic predisposition to this disease is also well-recognized.

The incidence of colon cancer is greatest among males, who have an age-adjusted incidence rate of 44.3 per 100,000, as compared to females for whom the rate is 34.8 per 100,000.³ Cancer of the rectum occurs less frequently; the incidence rate is 19.1 and 11.6 per 100,000 for males and females, respectively. Cancer of the colon and rectum is the third most frequent malignancy among U.S. men and white and African-American women, but is second next to breast cancer for Hispanic, American Indian/Alaskan Native, and Asian/Pacific Islander women. The overall incidence of colon and rectal cancers in

the United States has declined since 1992 at an average rate of 0.7% per year; this rate of decrease is beginning to level off.³ This decline is attributable primarily to decreasing rates among white males and females, although rates in African-American males and females have also declined but more slowly.

Although it is difficult to compare trends because of large year-to-year variations in colorectal cancer incidence rates in minority population groups, downward trends in colorectal cancer incidence appear to be greater for whites, African-Americans, Asian/Pacific Islanders, and American Indian/Alaskan Native Americans than for Hispanics. Trends for incidence and mortality rates among white and African-American males and females in the United States can be compared in Fig. 127-1.

The median age at diagnosis is about 72 years.³ Fewer than 5% of affected persons are younger than age 44 years. An individual's risk, however, increases with increasing age. Seventy percent of cases develop in adults older than 65 years of age. The stage of disease at presentation is similar among different ethnic groups, although the tendency to present with later-stage disease is slightly higher for African-Americans.

About 10% of all cancer deaths are a result of cancer of the colon or rectum. It is estimated that 56,290 individuals will die of colorectal cancer in the United States in 2005, despite a decline in overall combined mortality for both colon and rectal cancer observed during the last 20 years. For women, the decline in colorectal cancer mortality rates has been evident since 1950, whereas death rates among men did not start to decline until the late 1970s.³ These trends in mortality rates are similar to those observed in other countries. Overall mortality rates remain higher among African-American males and females, and the rates of decline are lower as compared to those for white males and females. Colorectal cancer mortality rates are lower for Hispanics, American Indians/Alaskan Natives, and Asian/Pacific Islanders than for whites or African-Americans. Factors contributing to the overall

FIGURE 127-1. SEER incidence and mortality rates for invasive colon and rectum cancer, 1975–2000, age-adjusted and age-specific. Rates are per 100,000 and age-adjusted to the 2000 U.S. standard population. (From Ries et al.³)

decline in colorectal cancer mortality likely include decreasing incidence rates, screening programs with early polyp removal, and more effective and better-tolerated treatments.

ETIOLOGY AND RISK FACTORS

Numerous studies suggest that the development of colorectal cancer can be caused or promoted by dietary or environmental factors that affect the bowel, lifestyle choices, and certain comorbid conditions, in addition to physical and genetic susceptibilities.

DIETARY INTAKE AND NUTRIENTS

◀ Epidemiologic studies of worldwide incidence of colorectal cancer suggest that economic development and dietary habits strongly influence its development. Although findings based on epidemiologic data are subject to potential biases, as well as inconsistencies in how dietary factors are categorized and measured, numerous studies have attempted to ascertain the true contribution of dietary habits as independent risk factors for colon cancer development.

FIBER

◀ Dietary fiber is the part of ingested plant material that is not processed by normal human digestive enzymes. Fibers are frequently classified as either water soluble (pectins, gums, and mucilages) or insoluble (celluloses, hemicellulose, and lignins). The insoluble fibers have been most consistently associated with reduced cancer risk. Foods that are high in fiber include vegetables, fruit, grains, and cereals. Postulated protective effects of dietary fiber include dilution or reduced absorption of carcinogens in the bowel, reduced fecal pH, reduced bowel transit time, alterations in bile acid metabolism, or increased production of short-chain fatty acids.⁵ The protective effects of fiber may also reflect an associated concomitant reduction in dietary fat intake associated with high-fiber diets. The degree of colorectal cancer risk reduction associated with increased consumption of vegetables and fruit is variable but generally modest. Conflicting data exist as to whether one category of dietary fiber is superior to another.

In a meta-analysis of six case-control studies of vegetable consumption and colon cancer risk, a combined odds ratio of 0.48 was observed between the highest and lowest quintiles of consumption.⁶ Two large prospective studies have also demonstrated an inverse relationship between fiber intake and colon cancer. The Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial found that participants in the highest quintile of dietary fiber intake had a 27% lower risk of adenoma than those in the lowest quintile.⁷ The inverse association was strongest for fiber from grains and cereals and from fruits. A European trial has reported similar results with a 25% risk reduction in the incidence of colorectal cancer for the highest versus lowest quintile of intake.⁸ In contrast, data from a prospective, cohort study of dietary factors and risk of colorectal adenomas in men and women using data from the Health Professionals Follow-Up Study and from the Nurse's Health Study found no association between fiber intake and risk of colorectal adenoma or cancer in over 120,000 participants, although a weak inverse association existed between dietary fiber and colorectal cancer with respect to participants with low folate consumption.⁹ Thus the evidence that increased dietary fiber consumption reduces colorectal cancer risk is suggestive, but not conclusive, and the amount, type, and duration of fiber intake may determine who benefits.

FAT

◀ Epidemiologic studies suggest that a relationship exists between dietary fat intake and colorectal cancer risk, although this has not been consistently seen.⁶ This may have resulted from the use of dietary evaluations that focused on the quantity, origin, or type (saturated, monounsaturated, and polyunsaturated) of fat rather than specific fatty acids ingested. The association between red meat consumption and colorectal cancer is strongest, possibly a result of the heterocyclic amines formed during cooking or the presence of specific fatty acids in red meat such as arachidonic acid.

The role of dietary fat in cancer development may be a result of its influence on fecal bile acid concentrations. The release of bile acids is stimulated following ingestion of dietary fat. These acids are then converted by colonic flora to secondary bile acids, which are associated with bowel mucosal irritation and cell proliferation responses and may promote tumor growth.¹⁰

Therefore while data indicate that animal meat and saturated fat intake and processing appear to be associated with an increased risk of colorectal cancer, the magnitude of this risk has not been determined.

CALCIUM AND MICRONUTRIENTS

◀ The role of calcium intake on colorectal cancer risk has been investigated in cohort, case-control, and randomized studies. The risk of colon cancer was shown in two prospective cohort studies to be inversely related to calcium intake. The decrease in risk was limited to distal colon cancer with no change seen in the incidence of proximal cancers. Calcium's protective effect may be related to a reduction in mucosal cell proliferation rates or through its binding to bile salts in the intestine. High levels of dietary folate, a key constituent of vegetables, are also associated with decreased colorectal cancer and adenoma risk.⁵ Folate availability influences DNA methylation, which is an important process in maintaining normal bowel mucosa. Evidence exists that an adequate dietary folate intake may be enough to lower the risk of colon cancer, and exceeding normal intake may not add any protective effects. Additional micronutrient deficiencies that have been demonstrated through several studies to increase colorectal cancer risk include selenium, vitamin C, vitamin D, vitamin E, and β -carotene; however, the benefit of dietary supplementation does not appear to be substantial.¹⁰

LIFESTYLE FACTORS

NONSTEROIDAL ANTI-INFLAMMATORY DRUG AND ASPIRIN USE

◀ Several lifestyle factors are known to affect colorectal cancer risk (Table 127-1). Studies have consistently demonstrated that regular (at least two doses per week) nonsteroidal anti-inflammatory drug (NSAID) and aspirin use is associated with a reduced risk of colorectal cancer.⁵ In the Nurse's Health Study, a decreased risk of colorectal cancer was seen in women who took aspirin regularly for at least 10 consecutive years, with the greatest reduction occurring with an intake of four to six tablets per week.¹¹ This benefit has also been seen with NSAID users. A population-based study of individuals who had taken NSAIDs for at least 48 months of the previous 5 years demonstrated a relative risk of colorectal cancer one-half that of nonusers.¹² Additional studies support these findings that regular aspirin or NSAID use may decrease the risk of colorectal cancer by as much as 50%. The potential mechanisms by which these agents exert their protective effects appear to be linked primarily to their inhibition

TABLE 127–1. Lifestyle Factors Associated with Colorectal Cancer Risk

| Factor | Comments |
|-----------------------------------|---|
| Aspirin and non-aspirin NSAID use | Regular use associated with risk reduction, perhaps as much as 50% |
| Postmenopausal hormone use | Exogenous hormone intake decreases risk 19%–34% |
| Alcohol intake | Heavy use increases colorectal risk two- to threefold |
| Physical inactivity and obesity | Elevated BMI and physical inactivity associated with increased risk |
| Tobacco use | Use of tobacco products estimated to contribute to up to 12% of colorectal cancer deaths annually |
| Diabetes | Hyperinsulinemia may promote colorectal cancer development |
| Western diet | High fat, red meat consumption, and low fiber intake possibly associated with increased risk |

BMI, body mass index; NSAID, nonsteroidal anti-inflammatory drug. From Potter.⁵

of cyclooxygenase-2 (COX-2) and free radical formation. COX-2 overexpression is seen in precancerous and cancerous lesions in the colon and is associated with a decrease in colon cancer cell apoptosis, as well as enhanced production of angiogenesis-promoting factors.¹³ Inhibition of COX by NSAIDs, aspirin, and coxibs restores apoptosis and decreases expression of proangiogenic factors.

EXOGENOUS HORMONE USE

Exogenous hormone use, particularly postmenopausal hormone replacement therapy, is associated with a significant reduction in colorectal cancer risk in most studies.^{5,14} A meta-analysis of 18 epidemiologic studies of postmenopausal hormone replacement therapy showed a 20% reduction in risk of colon cancer, and a 19% reduction in risk of rectal cancer, in women who received hormone replacement therapy as compared to women who never used hormone replacement therapy.¹⁴ The risk is reduced in postmenopausal women receiving both estrogen only and combined estrogen and progestin therapy, and persists for approximately 10 years after therapy is discontinued. Risk reduction appears greatest among women who are currently receiving hormone replacement therapy. However, prospective data on exogenous hormone use and colon cancer risk are conflicting. The Women's Health Initiative showed that colorectal cancer rates were reduced by 37% with combined estrogen/progestin use, whereas the Heart and Estrogen/Progestin Replacement Study Follow-up study demonstrated no significant decrease in risk.^{14,15} Furthermore, although invasive colorectal cancer occurred less frequently with estrogen/progestin use in the Women's Health Initiative, colorectal cancers were diagnosed at a much later stage in women who took hormones as compared to placebo.¹⁶

Several mechanisms for a protective effect of estrogens on the bowel have been identified.^{5,14} Declining estrogen levels associated with aging are associated with estrogen receptor hypermethylation, resulting in reduced expression of the estrogen receptor gene and dysregulated colonic mucosal cell growth. In addition, estrogen use may reduce serum levels of insulin-like growth factor-1, an important mitogen that influences cell-cycle progression in certain cells.

OBESITY AND PHYSICAL INACTIVITY

Physical inactivity and elevated body mass index (BMI), independent of level of physical activity, are associated with an elevated risk of colon adenoma, colon cancer, and rectal cancer.¹⁰ Individuals with a total higher level of activity throughout life have the lowest risk. Hypotheses for these relationships include the observation that physical activity stimulates bowel peristalsis, resulting in decreased bowel transit time, and the possibility that exercise-induced alterations in body glucose, insulin levels, and perhaps other hormones may reduce tumor cell growth.⁵

The risk of colon cancer may be increased as much as twofold in men who are in the highest quintile of body size. The evidence linking elevated BMI with increased colon cancer risk is less consistent for women, although, the Iowa Women's Health Study showed that cancer risk was 40% higher in women who were in the highest quintile of BMI as compared to the cancer risk of women in the lowest quintile.⁵ The relationship between obesity and colorectal cancer among women may diminish with age. Premenopausal obese women appear to be at the greatest risk, while postmenopausal obese women do not have an elevated risk of colon cancer. In a prospective cohort study, obesity (BMI ≥ 30 kg/m²) was associated with a 75% higher risk of colon cancer among women who were premenopausal at baseline; no association was found between BMI and colon cancer risk in postmenopausal women.¹⁷ Type 2 diabetes mellitus, independent of body mass size and physical activity level, is also associated with an increased risk of colorectal cancer in women. Data from the Nurse's Health Study suggest that colon cancer risk may be increased by 49% in diabetic women as compared to nondiabetic women.¹⁸ These and other findings support a role for hyperinsulinemia as a possible link between obesity, sedentary lifestyle, and diabetes mellitus and colon cancer.

ALCOHOL AND TOBACCO USE

High alcohol consumption increases the risk of rectal and colon cancer, perhaps as much as two- to threefold, although some studies have found no significant increase in risk.^{6,10} The evidence is strongest in men, but alcohol consumption is generally greater in men than in women. The impact of alcohol consumption and colon cancer may be greatest when folate intake is low, possibly resulting from the antifolate properties of alcohol. Smoking tobacco products, including cigarettes, cigars, and pipes, may contribute to as much as 12% of all colorectal cancer deaths.¹⁹ The cancer-promoting effects of alcohol and tobacco may be through generation of carcinogens or their direct toxic effects on bowel tissue.

CLINICAL RISK FACTORS

CHRONIC INFLAMMATORY DISEASES

Chronic ulcerative colitis, particularly when it involves the entire large intestine, predisposes individuals to colorectal cancer at a rate that is 4- to 20-fold greater than average.²⁰ The risk is even greater for young individuals and increases for all affected individuals with increasing extent of bowel involvement and disease duration. The cumulative risk of colorectal cancer is low early in life, and increases by 0.5% to 1% each year for 8 to 10 years after diagnosis.²⁰ Although a precise causative link has not been established, chronic underlying inflammation may be a significant predisposing factor. The progressive dysplastic changes that bowel mucosa undergo are similar to those observed in adenomatous polyps. Similarly, patients with Crohn's

disease are also at increased risk, although the relative risk is slightly lower than that of patients with ulcerative colitis. This difference may be related to the decreased length of bowel affected by the chronic inflammatory process in individuals with Crohn's disease. Overall, persons diagnosed with either disease constitute about 1% to 2% of all new cases of colorectal cancer each year.

GENETIC SUSCEPTIBILITY

HEREDITARY

There are three specific patterns in which colon cancer is generally observed: sporadic, inherited, and familial.²¹ While the majority of cases of colon cancer are sporadic in nature, as many as 10% of cases are thought to be hereditary. The two most common forms of hereditary colon cancer are familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC). Each of these results from a specific germline mutation.²¹ FAP is a rare autosomal dominant trait that is caused by inactivating mutations of the adenomatous polyposis coli (*APC*) gene and accounts for 0.5% to 1% of all colorectal cancers. The disease is manifested by hundreds to thousands of tiny sessile adenomatous polyps that carpet the colon and rectum, typically arising during adolescence.⁵ Symptoms generally present between the ages of 25 and 35 years, at which time cancer is already present in about half of patients. The risk of developing colorectal cancer for individuals with untreated FAP is virtually 100%; most will develop colorectal cancer by their fourth decade of life. Several variants of FAP exist and are associated with different extra-colonic manifestations.⁵

HNPCC, also referred to as Lynch syndrome I or II, is an autosomal dominant inherited syndrome that accounts for 1% to 5% of colon cancer cases.⁵ A mutation in one of the DNA mismatch-repair (MMR) genes, most commonly *MLH1* or *MSH2*, is responsible for HNPCC.²¹ In contrast to FAP, adenomatous polyps are not a primary manifestation of the HNPCC. Polyps that do form tend to be located primarily in the proximal colon. The average age of these patients is between 40 and 44 years. Because the clinical presentation of HNPCC is difficult to distinguish from "sporadic" forms of colorectal cancer, the diagnosis of HNPCC can be confirmed by the presence of germline mutations in a family of genes responsible for DNA MMR. Criteria for diagnosis of HNPCC have been established.²¹ Testing for *MLH1/MSH2* mutations is generally reserved for those individuals who meet these strict criteria. Carriers of a germline mutation have an 80% to 85% risk of developing colorectal cancer over their lifetime.²²

Familial colon cancer represents the least understood pattern of colorectal cancer. Up to 25% of patients who develop colorectal cancer will have a family history of colorectal cancer. In these families, the frequency of colorectal cancer is too high to be considered sporadic, but the pattern is not consistent with an inherited syndrome. First-degree relatives of patients diagnosed with colorectal cancer have an increased risk of the disease that is at least two to four times that of persons in the general population without a family history.²³

ENZYME POLYMORPHISMS

Increasing evidence suggests that certain high-prevalence genetic polymorphisms, such as *N*-acetyltransferases (NAT1 and NAT2), certain cytochrome (CYP450) isoenzymes, methylenetetrahydrofolate reductase (MTHFR) enzymes, and hemochromatosis gene mutations may confer genetic susceptibility to colorectal cancer.⁵ Individuals

with certain variations in NAT1, NAT2, and CYP450 1A2 enzyme genotypes may be particularly susceptible to carcinogenic effects of a high dietary intake of meat or tobacco smoke. Variants of MTHFR may influence the association of colorectal cancer risk with dietary folate or vitamin B₁₂ intake. Mutations in the hemochromatosis gene are associated with increased colon cancer risk with increasing age and total iron intake.

SUMMARY OF RISK FACTORS

In summary, the true association between most dietary factors and risk of colon cancer is unclear. The protective effects of fiber, calcium, and a diet low in fat are not completely known at this time. Lifestyle factors such as NSAID use and hormone replacement use appear to decrease the risk of colorectal cancer, but questions remain about how to best use these agents. Obesity and alcohol use appear to increase risk of colon cancer, but their association is not well defined. Genetic and clinical risk factors such as inflammatory bowel disease are well known risks for colon cancer.

PATHOPHYSIOLOGY

ANATOMY AND BOWEL FUNCTION

The large intestine consists of the cecum; ascending, transverse, descending, and sigmoid colon; and the rectum (Fig. 127–2). In adults, it extends approximately 1.5 m and has a diameter ranging from 8 cm in the cecum to 2 cm in the sigmoid colon. The function of the large intestine is to receive 500 to 2000 mL of ileal contents per day. Absorption of fluid and solutes occurs in the right colon or the segments proximal to the middle of the transverse colon, with movement and storage of fecal material in the left colon and distal segments of the colon. Mucus secretion from goblet cells into the intestinal lumen lubricates the mucosal surface and facilitates movement of the dehydrated feces. It also serves to protect the luminal wall from bacteria and colonic irritants such as bile acids.

Four major tissue layers, from the lumen outward, form the large intestine: the mucosa, submucosa, muscularis externa, and serosa (Fig. 127–3). Embedded in the submucosa and muscularis externa is a rich lymphatic capillary system. Lymphatic channels do not extend into the mucosa. The muscularis externa consists of circular smooth

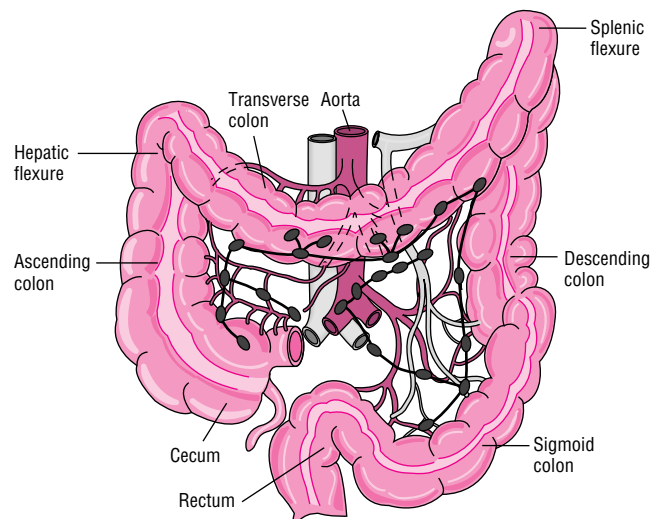

FIGURE 127–2. Colon and rectum anatomy.

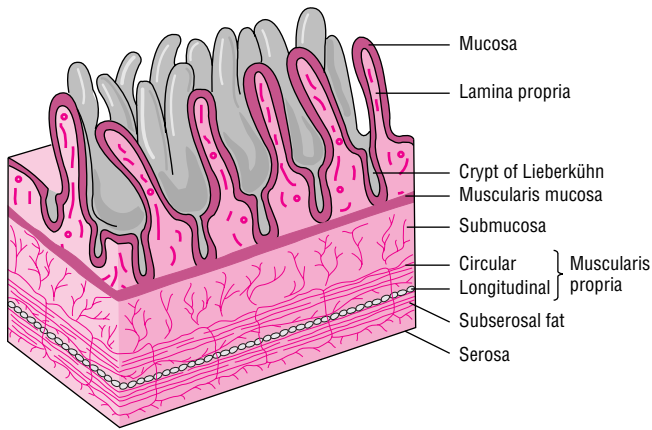

FIGURE 127-3. Cross-section of bowel wall.

muscle and three outer longitudinal smooth muscle bands. Contraction of these muscle groups moves colonic material toward the anal canal. The outermost layer of the colon, the serosa, secretes a fluid that allows the colon to slide easily over nearby structures within the peritoneum. The serosa covers only the anterior and lateral aspects of the upper third of the rectum. The lower third lies completely extraperitoneal and is surrounded by fibrofatty tissue as well as adjacent organs and structures.

The surface epithelium of the colonic mucosa undergoes continual renewal, and complete replacement of epithelial cells occurs every 4 to 8 days. Cell replication normally takes place within the lower third of crypts, the tubular glands located within the intestinal mucosa. The cells then mature and differentiate to either goblet or absorptive cells as they migrate toward the bowel lumen. The total number of epithelial cells remains relatively constant as the number of cells migrating from the crypts is balanced by the rate of exfoliation of cells from the mucosal surface. This two-phase process is

critical to the malignant transformation of the epithelial cells. The number of dysplastic and hyperplastic aberrant crypt foci increases with increasing age; as the mass of abnormal cells accumulates at the top of the crypt and starts to protrude into the stream of fecal matter, their contact with fecal mutagens can lead to further cell mutations and eventual adenoma formation.⁵

COLORECTAL TUMORIGENESIS

The development of a colorectal neoplasm is a multi-step process of several genetic and phenotypic alterations of normal bowel epithelium structure and function, leading to unregulated cell growth, proliferation, and tumor development. Since the majority of colorectal cancers develop sporadically, with no inherited or familial disposition, efforts have been directed toward identifying these alterations and learning whether detection of such changes may lead to improved cancer detection and/or treatment outcomes.

A genetic model has been proposed for colorectal tumorigenesis that describes a process of transformation from adenoma to carcinoma. However, at least three separate additional molecular pathways to developing colorectal cancer have been identified.⁵ These include a pathway for HNPCC, an ulcerative colitis–dysplasia–carcinoma sequence, and a pathway involving loss of function of the estrogen receptor gene through hypermethylation. Some of the molecular processes are common to more than one pathway.

Figure 127-4 is an overview of the adenoma-carcinoma model. The adenoma-carcinoma sequence of tumor development reflects an accumulation of mutations within colonic epithelium which confer a selective growth advantage to the affected cells. Key elements of this process include hyperproliferation of epithelial cells to form a small benign neoplasm or adenoma in conjunction with cellular gene mutations.^{24,25} These mutations occur early and frequently in sporadic cases of both adenomas and colorectal cancer. Somatic mutations

FIGURE 127-4. Genetic changes associated with the adenoma-carcinoma sequence in colorectal cancer. The accumulation of genetic changes in the pathogenesis of colorectal cancer includes DNA hypomethylation across the genome, mutation in the adenomatous polyposis coli (APC) gene or abnormalities in β catenin; *k-Ras* or *B-raf* oncogene activation; tumor suppressor gene deletions in chromosome 18q (SMAD-4 mutations) and disruption of tumor growth factor- β signaling; and defects in *p53* function. Shown also are points of possible chemopreventive activity by various agents. (From Midgley et al,²⁴ Robbins et al,²⁵ Arends,²⁶ and Jänne et al.³⁰)

TABLE 127–2. Genetic Mutations Associated with Colorectal Cancer

| Type of Mutation | Genes | Associated Disease |
|----------------------|--|---|

must occur in at least four or five genes to produce the malignant transformation.²¹

Genetic changes include activating mutations of oncogenes, inactivating mutations of tumor suppressor genes, and defects in DNA MMR genes. Specific genetic mutations that cause colorectal cancer are listed in Table 127–2. Activating mutations of *ras* protooncogenes, primarily involving the *K-ras* and *N-ras* genes, occur frequently in colorectal cancer.^{22,23} The *ras* family of genes is responsible for encoding proteins involved in transmission of extracellular growth signals to the nucleus. Activation of *ras* leads to a constitutive activity of the protein, resulting in continuous stimulus of cell proliferation and other activities that promote carcinogenesis.²¹

Tumor suppressor genes are normal cellular genes that are capable of transforming normal cells to cancerous cells through their deletion or inactivation. One of the earliest genetic changes in colorectal tumorigenesis involves the mutation or loss of the *APC* gene, a tumor suppressor gene localized on the long arm of chromosome 5q21. The *APC* gene encodes for a protein that binds to α - and β -catenin, which belong to a family of proteins associated with intracellular adhesion.²⁵ β -Catenin binds to the cytoplasmic domain of E-cadherin, an important molecule responsible for cell-cell adhesion. These activities, among others, are believed to be involved in regulation of cell shape and cell-to-cell communication, and may affect cell-cycle regulation or apoptosis. β -Catenin alterations may also lead to abnormal epithelial proliferation and differentiation of cells. Inactivation of the *APC* gene is the single gene defect responsible for FAP,

and is frequently an early event in the development of sporadic colorectal cancer cases.²¹ A specific *APC* mutation, I1307K, is a factor in the development of familial colon cancer in individuals of Ashkenazi Jewish ancestry.²¹

Mutational inactivation of two additional important tumor suppressor genes, *p53*, located on chromosome 17p, and the *DPC-4* (deleted in pancreatic cancer) gene, located on chromosome 18q, occur later during the adenoma-carcinoma sequence.^{24–26} Normal *p53* gene expression is important for G₁ cell-cycle arrest to facilitate DNA repair during replication, and to induce apoptosis, an irreversible cell process resulting in cell death. Inactivation of *p53* occurs in up to 75% of sporadic colorectal cancers.²¹

Previously, the *DCC* (deleted in colorectal carcinoma) gene was thought to be the tumor suppressor gene involved in 18q deletions. The protein encoded by the normal *DCC* gene is believed to share similar structural features to certain types of cell adhesion molecules, and as such may interact with various proteins to control cell-cell or cell-matrix interactions and cellular proliferation. Mutations of *DCC* are found in approximately 50% of advanced adenomas.²¹ The *DPC-4* gene, also referred to as *SMAD-4*, is located adjacent to the *DCC* gene, and has become identified as an important component involved in the transforming growth factor- β (TGF- β) signaling pathway.²⁶ The frequency of *SMAD-4* mutations in colorectal cancer is reported to be from 6% to 30%.²⁶

A distinct group of genetic traits has also been identified for individuals with HNPCC, but occur in sporadic cases of colorectal cancer, as well. Replication errors occur frequently and represent widespread alterations in the length of a series of repeated nucleotides, or microsatellites, within tumor DNA.²⁴ Mutations of those genes that appear to recognize and regulate DNA mismatch-repair errors, or MMR genes, contribute to microsatellite instability and colorectal tumorigenesis.²⁵ Failure to repair DNA mismatches results in microsatellite instability, which accelerates further gene mutations, leading to oncogene activation or tumor suppressor gene inactivation. Tumor progression may then be facilitated through a link between DNA repair defects and mutations of critical growth regulatory genes. Inactivation of a receptor for type II transforming growth factor- β , a protein that has antiproliferative effects on colonic epithelial cell growth, has been demonstrated in cells with replication errors.²⁷

Several additional genes and protein receptors are believed important in colorectal tumorigenesis, although their roles have not been completely determined. COX-2, which is induced in colorectal cancer cells, influences apoptosis and other cellular functions. The peroxisome proliferator activated receptor gene, a nuclear receptor that serves as a transcription factor, may interact with the COX pathway and affect tumorigenesis.²¹ The protooncogene *c-erb-B* is activated in a high percentage of human tumors, including colorectal cancer, and encodes for expression of epidermal growth factor receptor (EGFR), a transmembrane glycoprotein involved in signaling pathways that affect cell growth, differentiation, proliferation, and angiogenesis. These mechanisms are potentially important because of the availability of pharmacologic agents that can influence these processes and affect cell growth.

HISTOLOGY

Adenocarcinomas account for more than 90% of tumors of the large intestine.²⁸ Other histologic types such as mucinous adenocarcinoma, signet-ring adenocarcinoma, carcinoid simplex, and carcinoid tumors occur less frequently. Adenocarcinomas are assigned one of three

tumor grade designations based on the degree of cellular differentiation, the degree to which the tumor resembles the structure, and function of its cell of origin. The most differentiated adenocarcinomas, or grade I tumors, generally resemble adenomas, whereas grade III tumors are considered “high grade,” the most undifferentiated, and have frequently lost the characteristics of mature normal cells. Poorly differentiated tumors are associated with a worse prognosis than those that are better differentiated.²⁸

Mucinous adenocarcinomas possess the same basic structure as adenocarcinomas, but differ in that they secrete an abundant quantity of extracellular mucus. They account for only about 10% of colorectal carcinomas but tend to be frequent in patients with HNPCC and patients with coexisting ulcerative colitis.²⁸ Signet-ring adenocarcinomas have a characteristic appearance because of the displacement of the nucleus to one side by large vacuoles of intracellular mucin. Patients tend to present with a more advanced stage of disease and have a highly invasive tumor. Both mucinous and signet-ring adenocarcinoma histologies confer a poor prognosis.

PREVENTION AND SCREENING

Cancer prevention efforts can be considered as either primary or secondary. Primary prevention strategies are aimed at preventing the development of colorectal cancer in a population at risk. Secondary prevention approaches are undertaken to prevent malignancy in a population that has already manifested an initial disease process. The basis for primary prevention depends on identification of risk factors followed by eradication or alteration of their effects on carcinogenesis. Primary prevention also includes lifestyle and diet modification.^{29,30} Several primary preventive measures have undergone or are currently undergoing study; Table 127–3 lists some of the most promising strategies.

HIGH-FIBER LOW-FAT DIET

Although early studies suggest that a substantial increase in daily dietary fiber and/or decrease in dietary fat intake might significantly, reduce colorectal cancer risk results from recent ran-

domized trials are inconsistent. The role of a diet high in fiber, or the use of fiber supplementation, as a prevention strategy requires further investigation.

CHEMOPREVENTION

The most widely studied agents for the chemoprevention of colorectal cancer are aspirin and the NSAIDs. Although COX-2 expression is not elevated in normal colonic epithelium, up to 40% of colorectal adenomas and 90% of sporadic colon carcinomas have elevated levels of COX-2.^{13,33} COX-2 appears to play a role in polyp formation and COX-2 inhibition suppresses polyp growth. In contrast, COX-1 levels remain normal in both normal and malignant tissue. In randomized studies of individuals with FAP, sulindac and celecoxib, a selective COX-2 inhibitor, have been shown to reduce the size and number of adenomatous polyps.^{13,29} In 1999, the FDA approved the use of celecoxib to reduce the number of adenomatous colorectal polyps in FAP, as an adjunct to usual care. This approval was based primarily on results from a trial of 77 patients with FAP who received celecoxib, 400 mg orally twice daily, or placebo, for 6 months. Celecoxib administration resulted in a statistically significant reduction in mean polyp number (28% vs. 4.5%) and polyp burden (30.7% vs. 4.9%) compared to placebo.³³ The efficacy of celecoxib has not been compared to that of other agents. In addition, its effects are likely to be transient, because patients receiving sulindac were noted to experience an increase in size and number of polyps within 3 months after the sulindac was discontinued.³⁰ The use of aspirin as both a primary and secondary chemopreventive agent has also been studied. In a prospective, randomized trial, low-dose (81 mg/day) but not high-dose (325 mg/day) aspirin was shown to decrease the incidence of adenoma formation by 19% in patients with a previous history of at least one adenoma.³⁴ A similar benefit was seen in patients with a history of colorectal cancer.

The Calcium Polyp Prevention Study evaluated the effect of calcium carbonate supplementation on risk of recurrence of colorectal adenomas. Calcium supplementation was associated with a moderate reduction in risk of recurrent colorectal adenomas.³⁵ In a separate randomized study, calcium supplementation was associated with a reduced risk of adenoma recurrence as compared to placebo, but only in individuals with a serum vitamin D level above 29.1 ng/mL.³⁶

TABLE 127–3. Prevention Strategies for Colorectal Cancer

| Prevention Strategy | Proposed Mechanism of Protective Effect |
|--|---|
| High-fiber diet supplementation ^a | Decreases fecal bile acids; decreases bowel transit time; direct binding to fecal mutagens; dilution of fecal material |
| Dietary fat reduction ^a | Decreases fecal bile acids; reduces consumption of heterocyclic amines and other carcinogens that are produced through meat preparation and processing techniques |
| Nonsteroidal anti-inflammatory agents | Inhibit COX-2; induce apoptosis via 15-LOX-1 |
| Folic acid | Increases levels of intracellular folate |
| Calcium | Direct binding to bile and fatty acids; inhibits epithelial cell proliferation |
| Estrogens | Decrease synthesis of secondary bile acids; decrease production of IGF-1; direct antiproliferative effects on colorectal epithelium |
| Ursodeoxycholic acid | Modulates bile acid composition; inhibits cell proliferation |
| Aminosalicylates ^b | Inhibit cellular proliferation and induce apoptosis |
| Eflornithine | Inhibits cellular proliferation through alterations in polyamine metabolism |
| Oltipraz | Detoxifies activated carcinogens via glutathione S transferase inhibition |

^aTo date, findings from randomized trials have failed to demonstrate a protective effect of low-fat high-fiber fruit and vegetable dietary intake in reducing risk of recurrence of colorectal adenomas or colorectal cancer.

^bIn individuals with pre-existing ulcerative colitis or inflammatory bowel disease.

COX-2, cyclooxygenase-2; 15-LOX-1, 15-lipoxygenase-1; IGF-1, insulin-like growth factor 1. From Jänne et al,³⁰ Redaelli et al,³¹ and Steele.³²

Additional prospective studies have not shown a significant decrease in adenoma recurrence at 3 years. Although calcium intake appears to be inversely related to colon cancer, its role as a chemoprevention agent is still under investigation.

Additional intervention trials of various micronutrients, including selenium and folic acid, and other chemopreventive agents have been completed or are ongoing.^{29,30} Because of their different mechanisms of action and sites of influence on the process of colorectal carcinogenesis, certain populations of individuals may benefit most from selected agents.

SURGICAL RESECTION

Surgical resection remains an option to prevent colon cancer in individuals at extremely high risk for its development. Despite the potential for NSAIDs to reduce adenoma development and to induce adenoma regression in individuals with FAP, their effects are incomplete and therefore inadequate to replace surgical resection as an important means of cancer prevention for these high-risk individuals. Individuals with FAP who are found to have polyposis on lower endoscopy screening examinations should undergo total proctocolectomy and ileal pouch–anal anastomosis or total abdominal colectomy with an ileorectal anastomosis.³⁷ Because of the high incidence of metachronous cancers (25% to 40%) in patients with HNPCC, prophylactic total colectomy with an ileorectal anastomosis is recommended for those individuals.³⁷ Colonoscopic polypectomy, removal of polyps detected during screening colonoscopy, is considered the standard of care for all individuals to prevent the progression of premalignant adenomatous polyps to adenocarcinomas.

SCREENING

Based on the recognized incidence of colorectal cancer, identification of high-risk individuals, and the high rate of curability associated with localized lesions, screening recommendations for early detection of colorectal cancer have been established.³⁸ This section reviews available screening techniques for colon cancer.

DIGITAL RECTAL EXAMINATION

The digital rectal examination has been a traditional part of the annual physical examination in patients older than 40 years of age and accounts for the detection of about 10% of all colorectal cancers that are within 7 to 10 cm of the anus. By itself, the digital rectal

examination is not an effective screening tool; it should be performed at the same time as other screening examinations.³⁸

FECAL OCCULT BLOOD TESTING

The use of fecal occult blood tests (FOBT) annually or biannually have resulted in an increased number of asymptomatic individuals diagnosed with early stages of disease. Results from three randomized, controlled trials with a combined enrollment of over 250,000 patients have demonstrated that repeated FOBTs reduce colorectal cancer mortality by 15% to 33%.³⁹ Two main methods are available to detect occult blood in the feces: guaiac dye or derivative, and immunochemical methods. The Hemoccult II is the most commonly used FOBT in the U.S. This is a guaiac-based test that detects pseudoperoxidase activity in hemoglobin when hemoglobin comes in contact with a guaiac-impregnated paper. When a solution containing hydrogen peroxide is poured over the paper a blue color appears if the test is positive. The testing process is complex and requires specific patient counseling to avoid inaccurate results (Table 127–4). The Hemoccult Sensa, another guaiac-based test, is preferred by some organizations, as it may have increased sensitivity and specificity compared to the Hemoccult II. Clinical guidelines have been developed for performing and interpreting results of FOBT.³⁹ The limitations associated with fecal occult blood screening remain an issue of active concern. Many early-stage tumors do not bleed, and therefore the false-negative rates are about 70% for cancer and 90% for polyps. However, these concerns are addressed somewhat through continued serial screening with FOBT. In addition, about 1% to 5% of randomly selected individuals will have a positive test result and about 2% to 17% of those individuals will be found to have colorectal cancer.³⁹ False-positive results can prove to be very expensive and inconvenient for a patient because of the follow-up tests required to confirm a positive result. Nevertheless, studies evaluating the effects of FOBT as a screening modality have established that their annual use reduces colorectal cancer mortality by up to 33%.³⁹

Newer tests such immunochemical assays were developed to reduce the rate of false-positive results associated with the guaiac based tests. Immunochemical tests (InSure, and others) use antibodies to detect the globin protein portion of human hemoglobin. These tests have the advantage of improved specificity and sensitivity.⁴⁰ A potential increase in patient compliance is expected since these tests do not react with dietary factors or medications. To date these tests have not found widespread use in the United States because of commercial and technical reasons, although they, along with guaiac based tests, can be recommended in screening protocols.

TABLE 127–4. Patient Counseling Points Prior to Hemoccult II Testing

|--|---|
| <p>To avoid false-positives:</p> <ol style="list-style-type: none"> Dietary restrictions <ul style="list-style-type: none"> Avoid rare red meat and vegetables with peroxidase activity (turnips, broccoli, cauliflower, and radishes) for 3 days prior to testing Medical restrictions <ul style="list-style-type: none"> Avoid iron products, rectal administration of medications and digital rectal exams for 3 days prior to testing Avoid nonsteroidal anti-inflammatory drugs for up to 7 days prior to testing | <p>To avoid false-negatives:</p> <ul style="list-style-type: none"> Avoid vitamin C for 3 days prior to testing Avoid testing dehydrated samples (rehydrating of samples is not recommended) |
| <p>Procedure for Hemoccult II Testing: Patient applies two separate samples of three different stools to six test card windows</p> | |

FLEXIBLE SIGMOIDOSCOPY

3 Sigmoidoscopy is useful for examining the lower 35% to 60% of the bowel, depending on the instrument, and thus increases the detection rate by approximately two- to threefold.³⁹ A 60-cm flexible sigmoidoscope can be used to reach the splenic flexure in order to detect 50% to 60% of cancers, but it requires more operator training, is associated with increased risk, and is not tolerated as well as the 35-cm instrument. The combination of sigmoidoscopy plus FOBT improves sensitivity for lesions that will be missed by sigmoidoscopy alone, but not nonbleeding lesions such as polyps. Findings from the Kaiser-Permanente Medical Care Program show that screening sigmoidoscopy could effectively reduce mortality from colorectal cancer by 60%.⁴¹ These data, however, have yet to be validated through randomized trials.

TOTAL COLONIC EXAMINATION

3 Total colonic examination can be accomplished with colonoscopy or double-contrast barium enema. A colonoscope facilitates examination of the whole bowel to the cecum in the majority of patients, and allows for simultaneous removal of premalignant lesions. Although it allows for greater visualization of the colon, colonoscopy involves greater risk and inconvenience to patients. However, it is the preferred screening method based on its superior ability to detect lesions in the proximal colon as compared to sigmoidoscopy.³⁸ This may become increasingly important, as the proportion of tumors occurring in the proximal or right (cecum, ascending, and transverse colon) side of the colon has increased over the past 30 years, with fewer occurring in the rectum and distal or left (descending and sigmoid colon) side. It remains controversial whether this observation reflects a change in the biology of the disease or the nature of screening techniques. The majority of lesions, however, still occur in the distal colon.

A double-contrast barium enema (DCBE) produces an image of the entire colon in most examinations, and the retained barium outlines small polyps and mucosal lesions. This approach is the least expensive method of examining the entire colon, but is considered inferior to colonoscopy for detecting polyps and colorectal cancer.³⁸ In addition, a supplemental colonoscopy is required if suspicious lesions are identified. Because of these limitations, the combination of DCBE with flexible sigmoidoscopy is used to increase the sensitivity for detecting a colorectal malignancy versus DCBE alone, and is generally reserved for use when a colonoscopy is not feasible.

NOVEL SCREENING STRATEGIES

Molecular screening strategies include the analysis of stool samples for presence of oncogenes, tumor suppressor genes, or mutant DNA MMR genes in cells that are shed from premalignant polyps or adenocarcinomas in the bowel.⁴⁰ Although available tests have reliable sensitivity and specificity, the cost and complexity associated with their analysis make them unlikely screening tools for the general population at present. Genetic testing is an important cancer-screening approach for family members of individuals diagnosed with FAP or HNPCC, and is appropriate for selected individuals, but should only be offered in conjunction with genetic counseling.

Computed tomography (CT) colonography (virtual colonoscopy) is an imaging procedure that creates two- or three-dimensional images of the colon by combining multiple helical CT scans. Initial tests are promising, though patients still require bowel cleansing and colonoscopy to remove detected lesions.⁴⁰

SCREENING SUMMARY

Table 127–5 outlines the current American Cancer Society guidelines for screening and surveillance for early detection of colorectal polyps and cancer. Men and women who are 50 years of age and are at average risk (their only risk factor is age >50 years) should be screened with annual FOBT with examination of the colon every 5 to 10 years, depending on the type of test used.⁴² Although several methods for examining the colon are available, there is no evidence that one test should be chosen over another.³⁹ More rigorous (usually starting at an earlier age) screening recommendations are recommended for moderate- to high-risk individuals.

DIAGNOSIS

SIGNS AND SYMPTOMS

The signs and symptoms associated with colorectal cancer can be extremely varied, subtle, and nonspecific. Patients with early-stage colorectal cancer are often asymptomatic and lesions are usually found as a result of screening studies. Any change in bowel habits (e.g., constipation, diarrhea, or alteration in size or shape of stool), vague abdominal discomfort, abdominal pain, or distention may all be warning signs of a malignant process. Obstructive symptoms and changes in bowel habits frequently develop with tumors located in the transverse and descending colon. Bleeding may be acute or chronic and most commonly appears as bright red blood mixed with stool. Iron deficiency anemia, presenting as weakness and occasionally high-output congestive heart failure, frequently develops as a result of chronic occult blood loss.

PRESENTATION OF COLORECTAL CANCER

GENERAL

Patient symptoms are usually nonspecific and can vary drastically among patients.

SYMPTOMS

- Change in bowel habits (generally an increase in frequency) or rectal bleeding.
- Constipation, depending on the location of the tumor.
- Nausea, vomiting, and abdominal discomfort.
- Fatigue may be present if anemia is severe.

SIGNS

- Blood in the stool is the most common sign.
- Hepatomegaly and jaundice in advanced disease.
- Leg edema as a consequence of lymph node involvement, thrombophlebitis, fistula formation, weight loss, and pain in the lower back or radiating down the legs are indicative of widespread disease.

LABORATORY TESTS

- Positive guaiac stool test and anemia (iron deficiency) from blood loss
- Elevated carcinoembryonic antigen (most patients)
- Elevated liver enzymes may be present with metastatic disease.

About 20% of patients with colorectal cancer present with metastatic disease.³ Metastatic spread occurs as a result of direct tumor invasion of adjacent tissues or by lymphatic or hematogenous spread. The venous drainage of the colon and rectum influences the

TABLE 127–5. American Cancer Society Guidelines for Screening and Surveillance for Early Detection of Colorectal Polyps and Cancer

| Risk Category | Recommendation ^a | Age to Begin (Years) | Interval |
|---|---|--|--|
| Average risk | FOBT | 50 | Annually |
| | or Flexible sigmoidoscopy | 50 | Every 5 years |
| | or FOBT plus flexible sigmoidoscopy ^b | 50 | Annual FOBT with flexible sigmoidoscopy every 5 years |
| | or DCBE | 50 | Every 5 years |
| | or Colonoscopy | 50 | Every 10 years |
| Increased risk | | | |
| People with single, small (<1 cm) or multiple adenomatous polyps of any size | Colonoscopy ^c | 3–6 years after initial polypectomy | If exam is normal, screening as for average risk person |
| People with large (≥1 cm) or multiple adenomatous polyps, or adenomas with high-grade dysplasia or villous change | Colonoscopy ^c | Within 3 years after initial polypectomy | If normal, repeat in 3 years; if still normal, screening as per average risk |
| Personal history of curative-intent resection of colorectal cancer | Colonoscopy ^c | Within 1 year after resection | If normal, repeat in 3 years; if still normal, repeat every 5 years |
| Colorectal cancer or adenomatous polyps in first-degree relative younger than 60 years or in two or more first-degree relatives at any ages | Colonoscopy ^c | Age 40 or 10 years before the youngest case in family, whichever is earlier | Every 5–10 years |
| High risk | | | |
| Family history of familial adenomatous polyposis (FAP) | Early surveillance with endoscopy, and counseling to consider genetic testing | Puberty | If genetic test positive, colectomy is indicated |
| Family history of hereditary nonpolyposis colon cancer (HNPCC) | Colonoscopy and counseling to consider genetic testing | Age 21 | If genetic test positive, or if the patient has not had genetic testing, every 1–2 years until age 40, then annually |
| Inflammatory bowel disease; chronic ulcerative colitis; Crohn's disease | Colonoscopy biopsies for dysplasia | 8 years after the start of pancolitis or 12–15 years after the start of left-sided colitis | Every 1–2 years |

^aDigital rectal examination should be done at the time of each sigmoidoscopy, colonoscopy, or DCBE.

^bFOBT together with flexible sigmoidoscopy is preferred over FOBT or flexible sigmoidoscopy alone.

^cIf colonoscopy is not available or feasible, DCBE alone or together with flexible sigmoidoscopy are acceptable alternatives.

DCBE, double-contrast barium enema; FOBT, fecal occult blood testing.

Modified with permission from Smith et al.⁴²

pattern of metastases most commonly seen. The most common site of metastasis is the liver, often the only site of metastatic disease in 40% of patients, followed by the lungs and then bones, specifically the sacrum, coccyx, pelvis, and lumbar vertebrae. Liver metastases are present in 5% to 10% of patients at presentation.

WORK-UP

When a patient is suspected of having colorectal carcinoma, a careful history and physical examination should be performed. The patient history should include a past medical history and family history, especially noting the presence of inflammatory bowel disease, colorectal cancer, polyps, and cancers of the breast, ovary, and endometrium. A complete physical examination includes careful abdominal examination for the presence of masses or ascites, a rectal examination, and an assessment for possible hepatomegaly and lymphadenopathy. In all women, a breast and pelvic examination is recommended, especially in women with a history of breast, ovarian, or endometrial

cancer. Table 127–6 summarizes the recommended tests for pretreatment evaluation of patients with potentially curable colorectal cancer.

An unexplained anemia in an older patient requires surveillance of the entire large bowel, especially the right colon. Red blood cell indices (e.g., hemoglobin, hematocrit, mean corpuscular volume, and reticulocyte count) and a work-up of iron status (e.g., serum ferritin, serum iron, and total iron-binding capacity) may be useful to confirm acute or chronic blood loss and/or iron-deficiency anemia. An evaluation of the entire large bowel is undertaken with either colonoscopy or sigmoidoscopy and a double-contrast barium enema. A barium enema may be preferred in situations in which a partially obstructing lesion prohibits passage of the endoscope; however, it should be avoided if complete obstruction or perforation of the bowel is suspected. A characteristic finding indicative of colon cancer seen on barium enema is an apple core–shaped lesion with tumor involving the circumference of the bowel. When possible, the endoscope is used to collect tissue for a histologic evaluation and provide a preliminary diagnosis following the procedure.

TABLE 127–6. Recommended Pretreatment Evaluation for Patients with Potentially Curable Colorectal Cancer

- Personal medical history and family history of colorectal polyps, cancer, or other malignancies
- Physical examination, including evaluation for lymphadenopathy, hepatomegaly, and ascites; women should have appropriate evaluations to rule out breast, ovarian, or endometrial cancers
- Complete blood count, liver chemistries, and serum carcinoembryonic antigen
- Total colonic evaluation with colonoscopy or flexible sigmoidoscopy with double-contrast barium enema
- Chest x-ray
- Chest/abdominal/pelvic computed tomography scan
- Additional studies as indicated

From Skibber et al.²⁸

Baseline laboratory tests should be obtained and include a complete blood cell (CBC) count, platelet count, prothrombin time, activated partial thromboplastin time, and liver and renal function tests. Abnormal liver function tests may suggest liver involvement with tumor. However, patients with metastatic disease to the liver may have normal liver function tests, and abnormal liver function tests are not always indicative of metastatic disease.

Additional laboratory tests include a baseline carcinoembryonic antigen (CEA) level. CEA belongs to a group of cell-surface glycoproteins termed “oncofetal proteins,” which are expressed during embryonic development and re-expressed on the cell surfaces of many carcinomas, particularly those of the gastrointestinal tract. The concentration of CEA can be measured in the blood and can therefore potentially serve as a marker for colorectal cancer. However, not all colorectal cancers produce CEA, and elevated concentrations are even more frequent in patients with metastatic disease. It is important to recognize, however, several concomitant disease states that can elevate CEA: alcoholic and chronic hepatitis, diverticulitis, renal failure, cholelithiasis, fibrocystic breast disease, smoking, and other carcinomas.⁴⁴ Most commercially available assays list a normal range of less than 3 ng/mL and 5 ng/mL for nonsmokers and smokers, respectively. Although CEA measurement is too insensitive and nonspecific to be used as a screening test for early-stage colorectal cancer, it is useful for monitoring colorectal cancer response to treatment, particularly if the pretreatment concentration is elevated. The CEA test also has preoperative prognostic implications because it has been shown to correlate with the size and degree of differentiation of the carcinoma. Elevated preoperative CEA levels correlate with a poor survival and may predict likelihood of recurrence, regardless of tumor stage at diagnosis. After a potentially curative resection, CEA levels should return to normal within 4 to 6 weeks.⁴⁴ Persistently elevated CEA levels may indicate residual disease, while elevations after normalization may indicate relapsed disease.

Radiographic imaging studies evaluate the extent of disease involvement. A chest x-ray should be performed to rule out the presence of metastatic spread to the lungs. A CT scan of the abdomen and pelvis is often performed to evaluate hepatic and retroperitoneal involvement and occult abdominal and pelvic disease, and to determine the depth of tumor penetration into the bowel wall and/or invasion to adjacent organs. Detection of lymph node involvement with either study is limited by the difficulty of distinguishing inflammatory or reactive lymph nodes from those infiltrated with tumor. Because CT scans may not adequately detect peritoneal seeding, small distant lymph node metastasis, or liver metastasis in colon cancer, an occasional patient may

need to undergo a laparotomy, spiral CT, MRI, or positron emission tomography (PET) scan in order to confirm metastatic disease. PET imaging is also useful to discriminate between benign and malignant disease by detecting tumor-related metabolic alterations in affected tissues.⁴⁵ PET scans are commonly used for the detection of recurrent colorectal cancer in patients with rising CEA levels and inconclusive findings on standard imaging studies.

Intra-rectal or transrectal ultrasonography is a technique that is becoming more widely available for the evaluation of patients with rectal cancer. It is useful for detecting the depth of tumor penetration, and like pelvic CT scans, is fair to good in determining lymph node involvement. Cystoscopy or IV pyelography studies are rarely indicated except for very large rectal tumors found on examination, if the patient exhibits symptoms, or if a CT scan suggests bladder involvement. Intraluminal and hepatic MRI studies may also provide useful information.

Immunodetection of tumors using tumor-directed antibodies is receiving greater recognition as an imaging technique for the early detection and imaging of colorectal cancers. Several tumor-associated proteins have been identified within or on the surface membrane of colorectal malignant cells to which monoclonal antibodies have been targeted. Of these, TAG-72 and CEA have undergone the greatest amount of study.⁴⁶ Radiolabeled monoclonal antibodies directed against these antigens have been used in clinical studies for both external immunoscintigraphy as well as intraoperative localization of tumor. OncoScint, an indium-111–labeled monoclonal antibody targeted to the TAG-72 antigen is an FDA-approved diagnostic imaging agent available for determining the location and extent of extrahepatic disease in patients with colorectal cancer. The CEA scan is a Tc-99m–labeled anti-CEA antibody for the assessment of recurrent colorectal carcinoma. The use of these tests is generally reserved for those patients who have completed standard diagnostic imaging tests, but may still require additional information regarding the extent of disease. They may also play an important role in identifying metastatic or recurrent disease in individuals with rising CEA levels and negative standard radiographic studies.

STAGING

4 The purpose of the staging examinations is to precisely describe the malignancy at a point in its natural history that assists in developing patient treatment options and determining their overall prognosis. Traditionally, the Dukes classification, originally published in 1932, was used in the staging of colorectal cancers.²⁸ Since its original publication, it has undergone several modifications; a modified Astler-Coller (MAC) version is now used more extensively. However, because multiple staging systems exist and have been used for various clinical trials, the literature is often difficult to evaluate. Therefore, in an effort to standardize the staging system for colorectal cancer, the American Joint Committee on Cancer (AJCC) and the International Union Against Cancer (IUAC) jointly agreed to use and recommend the TNM classification system. This classification takes three aspects of cancer growth—T (tumor size), N (lymph node involvement), and M (presence or absence of metastases) into account. The TNM classification also allows for various subdivisions within each of the three categories, which is then used for determining the disease stage.²⁰ Table 127–7 is a summary of staging using the TNM system. Table 127–8 shows the stage assignment based on TNM classifications. Figure 127–5 is a representation of the relationship between the MAC and AJCC/IUAC staging systems.

TABLE 127–7. TNM Staging Definitions for Colorectal Cancer

| Criteria | Classification | Definition |
|--------------------------|-----------------|--|
| Primary tumor (T) | T _x | Primary tumor cannot be assessed |
| | T ₀ | No evidence of primary tumor |
| | T _{is} | Carcinoma in situ: intraepithelial or invasion of the lamina propria ^a |
| | T ₁ | Tumor invades submucosa |
| | T ₂ | Tumor invades muscularis propria |
| | T ₃ | Tumor invades through the muscularis propria into the subserosa, or into the nonperitonealized pericolic or perirectal tissues |
| | T ₄ | Tumor directly invades other organs or structures and/or perforates the visceral peritoneum ^{b,c} |
| Regional lymph nodes (N) | N _x | Regional nodes cannot be assessed |
| | N ₀ | No regional lymph node metastasis |
| | N ₁ | Metastasis in one to three regional lymph nodes |
| | N ₂ | Metastasis in four or more regional lymph nodes |
| Distant metastasis (M) | M _x | Distant metastasis cannot be assessed |
| | M ₀ | No distant metastasis |
| | M ₁ | Distant metastasis |

^aT_{is} includes cancer cells confined within the glandular basement membrane (intraepithelial) or lamina propria (intramucosal) with no extension through the muscularis mucosae into the submucosa.

^bDirect invasion in T₄ includes invasion of other segments of the colorectum by way of the serosa; for example, invasion of the sigmoid colon by a carcinoma of the cecum.

^cTumor that is adherent to other organs or structures macroscopically is classified T₄. However, if no tumor is present in the adhesion microscopically, the classification should be pT₃. The V and L substaging should be used to identify the presence or absence of vascular or lymphatic invasion.

PROGNOSIS

4 The stage of colorectal cancer upon diagnosis is the most important independent prognostic factor for survival and disease recurrence. Table 127–9 compares the stage of disease upon presentation and relative survival rates for individuals with colon and rectum cancer. Additional clinical and pathologic variables may affect the prognosis of patients with colorectal cancer. Consideration of these factors plays an important role in determining optimal strategies for treatment as well as appropriate follow-up. Clinical factors present at time of diagnosis that are associated with a poor prognosis and decreased survival include bowel obstruction or perforation, rectal bleeding, high preoperative CEA level, distant metastases, and location of the primary tumor in the rectum or rectosigmoid area.^{28,44}

Pathologic variables associated with a negative influence on prognosis include increasing depth of muscular invasion; presence of venous, lymphatic, or perineural invasion; increasing number of involved lymph nodes; presence of peritumoral lymphoid reaction; mucinous or signet-ring histology; high proliferation indices; tumor aneuploidy; and presence of certain molecular markers (18q/*DCC* mutation or loss, microsatellite stability, elevated thymidylate synthase [TS) expression, and *p53* mutation or loss).^{28,48}

Allelic loss of chromosome 18q, which is located on the *DCC* gene, is predictive of mortality, independent of tumor differentiation, vascular invasion, and TNM stage. Five-year survival rates decrease by 39% and 14% in patients with allelic loss of chromosome 18q and stage II or III colorectal cancer, respectively.⁴⁹ Tumors that overexpress TS, which is responsible for converting deoxyuridine monophosphate to deoxythymidine monophosphate, an

essential step for DNA synthesis, are less sensitive to fluorouracil chemotherapy. Patients whose colon cancers have higher levels of TS appear to have a significantly worse overall 5-year survival than patients whose cancers have a low level of TS.^{28,48} The importance of elevated TS and type of therapeutic interventions is unclear. Theoretically, patients with high levels of TS may benefit from a non-fluorouracil containing chemotherapy regimen, although a large cooperative group trial failed to identify any subgroup of patients that failed to benefit from fluorouracil plus leucovorin therapy based on tumor TS levels.

Similarly, tumors that overexpress mutant *p53* demonstrate a high degree of resistance to radiation, fluorouracil, and certain other chemotherapeutic agents and are associated with a poorer prognosis.⁴⁸ In contrast, colorectal cancers that demonstrate low frequency microsatellite instability or microsatellite stability appear to be

From Ries et al.³

associated with a more favorable outcome and may respond better to fluorouracil.⁵⁰ Tumors that have a high rate of proliferation are generally associated with a poor prognosis. Ki-67 is expressed in cells actively engaged in the cell cycle and has also been used as a measure of colon cancer proliferation. Interestingly, for unknown reasons, high levels of Ki-67 were associated with an increase in overall survival in patients with early-stage colon cancer. A large number of additional molecular factors including *K-ras* mutations, lack of p27 expression, and *bcl-2* and EGFR overexpression appear to have prognostic significance but have been studied less sufficiently to date.⁴⁸ Evaluation of these factors may provide important clues as to which patients will benefit most from more aggressive therapy, individuals who may not require systemic chemotherapy, and new therapeutic targets for the treatment of colorectal cancer.

▶ TREATMENT: Colorectal Cancer

■ DESIRED OUTCOME

Treatment goals for cancer of the colon or rectum are based on the stage of disease at presentation. Stages I, II, and III disease are considered potentially curable, and as such, are managed ideally with the intent of eradicating known and micrometastatic sites of tumor to achieve remission and avoid disease recurrence. Because stage IV disease is generally not curable, treatments are offered to reduce symptoms, avoid disease-related complications, and prolong survival. Treatment strategies for individuals who manifest premalignant forms of the disease (e.g., adenomatous polyps) should be undertaken to prevent polyp progression and transformation to malignancy.

■ GENERAL APPROACH TO TREATMENT

Although advanced age is not an absolute contraindication for relatively aggressive therapies, a consideration of the age of the patient, concomitant disease states, lifestyle factors, and the patient's preferences are incorporated into the treatment planning process. Special or emergent conditions, such as bowel perforation, spinal cord compression, and severe pain, anemia, or other symptomatic problems, need to be addressed acutely, after which time a more long-term disease-specific plan can be developed. The treatment approaches for colorectal cancer reflect two primary treatment goals: curative therapy for localized disease, and palliative therapy for metastatic cancer.

For patients for whom treatment intent is curative, surgical resection of the primary tumor is the most important component of therapy.²⁸ Depending on the extent of disease and whether the tumor originated in the colon or rectum, further adjuvant chemotherapy or chemotherapy plus XRT may be appropriate. With few exceptions, surgery is used infrequently for metastatic disease. In this setting, systemic chemotherapy is the mainstay of treatment; XRT may also be useful for disease palliation of localized symptoms or when chemotherapy is no longer effective. Patients with metastatic disease who are asymptomatic may benefit from initiation of therapy and treatment should not be withheld until they develop symptoms.

■ OPERABLE DISEASE

■ SURGERY

5 Individuals with operable—stages I, II, and III—colorectal cancer should undergo a complete surgical resection of the primary tumor mass with a regional lymphadenectomy as a curative approach for their disease.²⁸ The surgical approach for colon cancer generally involves a complete resection of the tumor with an appropriate margin of tumor-free bowel and a regional lymphadenectomy. A total colectomy is rarely needed in colon cancer, but may be indicated for selected patients with FAP or chronic ulcerative colitis.

Surgery for rectal cancer depends on the region of tumor involvement. A low anterior resection is the procedure of choice in patients with lesions in the middle to upper rectum.⁵¹ Patients with lesions

in the lower portion of the rectum may require an abdominoperineal resection if either the amount of unaffected bowel is insufficient for a resection far enough away from the tumor, or too close to areas that cannot permit an anastomosis. Newer surgical techniques have been developed in an attempt to retain function of the rectal sphincter and still achieve complete tumor resection. Individuals who are not candidates for sphincter-sparing resections or have extensive local spread of tumor will require an abdominoperineal resection. This involves removal of the distal sigmoid, rectosigmoid, rectum, and anus with the establishment of a permanent sigmoid colostomy. Less than one-third of patients will require a permanent colostomy for rectal cancer.⁵¹ Other complications that occur frequently with surgery for rectal cancer include urinary retention, incontinence, impotence, and locoregional recurrence.

Overall, surgery for colorectal cancer is associated with a morbidity and mortality rate of 8% to 15% and 1% to 2%, respectively, depending on the type and extent of procedure.^{28,51} Common complications associated with colorectal surgery include infection, anastomotic leakage, obstruction, adhesion formation, and malabsorption syndromes.

■ ADJUVANT THERAPY FOR COLON CANCER

5 Adjuvant therapy in colorectal cancer is administered to selected individuals after complete tumor resection in an attempt to eliminate residual local or micrometastatic disease, thereby decreasing tumor relapse and improving patient survival. Since greater than 90% of patients with stage I colon or rectal cancer are cured by surgical resection alone, adjuvant therapy is not indicated.²⁸ The role of adjuvant chemotherapy for stage II colon cancer is less clear. Certain patients with stage II colon cancer are at a higher risk for recurrence, although adjuvant chemotherapy for all patients with stage II disease has not been shown to be superior to surgery alone. Although there is no lymph node involvement, these tumors can penetrate through the muscle wall, into surrounding structures, or through the visceral peritoneum. Consequently, an intermediate risk of relapse still exists because of the invasive nature of stage II disease.

Results of studies that have attempted to determine whether patients with stage II disease benefit from adjuvant therapy are conflicting. Most trials that suggest adjuvant therapy improves survival for stage II disease frequently enroll individuals with a high risk of relapse and do not include an untreated control group. Therefore at present, various tumor molecular genetic factors (e.g., chromosome 18q deletion, tumor ploidy, mutations of protooncogenes or tumor-suppressor genes, tumor TS expression, and tumor microsatellite instability) are being studied in an effort to identify subsets of patients with stage II disease who have an increased risk of relapse. Patients with stage II colon cancer should be enrolled in carefully controlled clinical trials to assess the impact of newer agents and whether molecular genetic factors can be used in this group of patients to predict risk of recurrence.

Adjuvant chemotherapy is standard therapy for patients with stage III colon cancer. The presence of lymph node involvement with tumor places patients with stage III colon cancer at high risk for relapse, and the risk of death within 5 years of surgical resection alone is as high as 70%.²⁸ In this population of patients, adjuvant chemotherapy significantly decreases risk of cancer recurrence and death and is considered standard of care.

Adjuvant XRT plus chemotherapy is considered standard treatment for patients with stage II/III rectal cancer.⁵¹ Tumors arising in the rectum are technically more difficult to resect with wide

circumferential margins, and lead to local recurrences more frequently than that seen with colon cancers. Therefore XRT is an important aspect of adjuvant therapy for rectal cancer to reduce risk of local tumor recurrence.

■ Adjuvant Radiation Therapy

There is currently no definitive role for adjuvant XRT in colon cancer because most recurrences are extrapelvic and occur in the abdomen.²⁸ Although local recurrence and debilitating pelvic pain are uncommon, a subset of patients with T₃ or T₄ tumors located in the cecum, hepatic and splenic flexures, and sigmoid are at increased risk of local recurrence and may benefit from postoperative XRT and chemotherapy. Early trials using effective doses of whole abdominal XRT were limited by considerable toxicity.⁵¹ However, results from studies combining abdominal XRT plus fluorouracil are promising. To date, postoperative local XRT may reduce the risk of local recurrence and improve survival compared to adjuvant chemotherapy alone, but should only be considered for select patients with colon cancer.²⁸

In patients undergoing surgery for rectal cancer, XRT is used to reduce risk of local tumor recurrence. Radiation therapy is given prior to or following surgery and can be delivered using a variety of dosing regimens, administration schedules, and techniques.⁵¹ Accumulating data suggest that preoperative XRT may be used to reduce the initial size of the tumor to such an extent that the tumor could be reclassified to a lower stage, or “downstaged,” and therefore rendered more resectable. This might then lead to improved patient survival or result in the need for a less extensive surgical procedure. Preoperative XRT is also administered to reduce the amount of tumor seeding that can occur during surgery; however, this approach is more likely to affect a greater area than is necessary.⁵¹ Postoperative administration of XRT may more adequately treat a defined area, but is associated with more toxicity because of a greater amount of bowel being present in the treatment field.

Adverse effects associated with XRT in colorectal cancer can be acute or chronic. Acute effects primarily include hematologic depression, dysuria, diarrhea, abdominal cramping, and proctitis. Chronic symptoms that sometimes persist for months following discontinuation of XRT may involve persistent diarrhea, proctitis or enteritis, small bowel obstruction, perineal tenderness, and impaired wound healing.

■ Adjuvant Chemotherapy

5 For more than 40 years, fluorouracil has been the most widely used chemotherapeutic agent for the adjuvant treatment of colorectal cancer, both as a single agent and in combination with other agents. Newer agents such as irinotecan, capecitabine, and oxaliplatin are currently being studied in combination chemotherapy regimens for the adjuvant treatment of colon cancer. Investigational chemotherapy agents, biologic therapies that target the underlying tumor biology, and new administration methods are also being developed.

Figure 127–6 depicts the National Comprehensive Cancer Network (NCCN) Practice Guidelines for adjuvant therapy of colon cancer.

■ **Single Agents.** Early results of adjuvant chemotherapy in colon cancer were disappointing and failed to improve results associated with surgery alone. Based on their activity for metastatic colon cancer, fluorouracil and floxuridine were investigated as single-agent

Figure 127-6 not available in digital format.

chemotherapy agents for use after surgery. In 1988, a meta-analysis of fluorouracil-based adjuvant therapy was published that evaluated phase III trials that compared adjuvant fluorouracil to surgery alone.⁵² A small, statistically insignificant improvement in survival was noted with fluorouracil-based regimens. These findings questioned the value of the standard use of IV bolus fluorouracil alone as adjuvant therapy for colon cancer, but results from recent studies suggest that protracted or continuous IV fluorouracil infusion treatment schedules are effective as adjuvant therapy.⁵³

Clinical studies comparing efficacy of bolus and continuous infusion schedules generally favor continuous infusion of fluorouracil. This is consistent with evidence that suggests that the duration of infusion may be an important determinant of the biologic activity of fluorouracil, particularly because of its short plasma half-life and S-phase specificity for optimal TS inhibition. Continuous IV infusions also permit increased fluorouracil dose intensity, which may account for the higher response rates observed with prolonged infusions of fluorouracil. However, because of the more costly and cumbersome nature of continuous IV infusions, fluorouracil has most commonly been administered as an IV bolus injection in the United States. Unlike continuous IV infusion where fluorouracil can be given alone, IV bolus regimens only include fluorouracil in combination with at least one other agent.

Clinically significant differences in toxicity also differ based on the dose, route, and schedule of fluorouracil administration. Leukopenia is the primary dose-limiting toxicity of IV bolus fluorouracil, although diarrhea, stomatitis, and nausea and vomiting can also occur.⁵⁴ The incidence and severity of stomatitis can be significantly reduced with the use of oral cryotherapy. In this approach, the patient is required to chew and hold ice chips in the mouth during the period between 5 minutes prior to and 30 minutes following the bolus

injection of fluorouracil. The basis for the protective effects of this procedure is based on the premise that local vasoconstriction caused by the ice chips temporarily reduces blood flow to the oral mucosa, thereby reducing drug exposure to the oral mucosa.

Although continuous IV infusion fluorouracil is generally well tolerated, dose-limiting toxicities can be substantial. A distinct toxicity, palmar-plantar erythrodysesthesia (“hand-foot syndrome”), and stomatitis occur most frequently with this route of administration.^{28,54} Hand-foot syndrome occurs in 24% to 40% of patients receiving extended continuous IV infusions and is characterized by painful swelling and erythroderma of the soles of the feet, palms of the hands, and distal fingers. This type of skin toxicity is fully reversible upon interruption of therapy or dose reduction and is not life-threatening; however, it can be significant and acutely disabling. The incidence of stomatitis, diarrhea, and hematologic toxicity is not substantial at standard doses, but increases with increasing doses of fluorouracil. No significant difference is noted in the incidence of mucositis, diarrhea, nausea and vomiting, or alopecia between continuous and bolus IV fluorouracil administration.^{28,54}

An additional determinant of fluorouracil toxicity, regardless of the method of administration, is related to its catabolism and pharmacogenomic factors. Dihydropyrimidine dehydrogenase (DPD) is the main enzyme responsible for the catabolism of fluorouracil to inactive metabolites. A pharmacogenetic disorder has been identified in cancer patients in which they have a complete or near-complete deficiency of this enzyme, resulting in severe toxicity, including death, after the administration of fluorouracil. Molecular studies have suggested there is a relationship between allelic variants in the *DPYD* gene (the gene that encodes DPD) and a deficiency in DPD activity.⁵⁵ About 3% of patients may be genotypically heterozygous for a mutant *DPYD* allele, although differences between sex and races are unknown at this time.

TABLE 127–10. Examples of Combination Fluorouracil Plus Leucovorin Treatment Regimens for Colorectal Cancer

| Regimen | Fluorouracil | Leucovorin | Frequency |
|---|--|--|------------------------------------|
| Roswell Park regimen ⁶⁰ | 600 mg/m ² per day IV, day 1 | 500 mg/m ² per day IV over 2 hours | Repeat weekly for 6 out of 8 weeks |
| Mayo Clinic regimen ⁶¹ | 425 mg/m ² per day IV, days 1–5 | 20 mg/m ² per day IV, days 1–5 | Repeat every 4–5 weeks |
| de Gramont regimen ⁶² | 400 mg/m ² per day IV bolus, followed by 600 mg/m ² CIV over 22 hours, days 1 and 2 for 2 consecutive days | 200 mg/m ² per day IV over 2 hours days 1 and 2 | Repeat every 2 weeks |
| Modified Machover regimen ⁶³ | 370–400 mg/m ² per day IV, days 1–5 | 200 mg/m ² per day IV, days 1–5 | Repeat every 4–5 weeks |

CIV, continuous intravenous infusion.

■ Combination Regimens

■ FLUOROURACIL PLUS LEVAMISOLE

In 1990, the National Institutes of Health Consensus Development Conference recommended that the use of fluorouracil and levamisole be considered standard therapy for patients with surgically treated stage III colon cancer. Levamisole is a synthetic, oral anthelmintic drug with immunomodulatory properties and minimal, generally reversible toxicities that include metallic taste, arthralgias, central nervous system toxicities (mood changes, sleep disorders, or cerebellar ataxia), rare myelosuppression, and hepatic toxicity.

In a study sponsored by the Mayo Clinic and the North Central Cancer Treatment Group (NCCTG), surgery alone was compared with postoperative levamisole and postoperative levamisole plus fluorouracil in patients with surgically treated stage II and stage III colorectal cancer.⁵⁶ Fluorouracil, 450 mg/m² per day, was administered by IV bolus injection for 5 consecutive days, starting within 21 to 35 days following surgery. Starting 1 month later, patients received fluorouracil, 450 mg/m², as a single IV bolus injection each week for 48 weeks. Levamisole was administered 50 mg orally every 8 hours for 3 consecutive days. Each 3-day cycle was repeated every 2 weeks and continued for 1 year. Although the combination of levamisole and fluorouracil significantly reduced recurrence rates, it did not confer a statistically significant survival advantage. However, a small but significant survival benefit for patients with stage III disease was identified through subset analysis of the data. Results of a larger Intergroup trial, first published in 1990 and later updated in 1995 after a median follow-up of 6.5 years, demonstrated that the combination of fluorouracil plus levamisole following surgical resection in patients with stage III colon cancer reduced the recurrence rate by 40% and the death rate by 33%.⁵⁷ Levamisole alone provided no significant reduction in either recurrence or deaths.

■ FLUOROURACIL PLUS LEUCOVORIN

6 The nature of the pharmacology of fluorouracil provides several opportunities to increase its antitumor activity, the most common of which is accomplished by using concomitant leucovorin. The addition of leucovorin increases the binding affinity of the active fluorouracil metabolite to TS, thus enhancing its cytotoxic activity. The combination of fluorouracil plus leucovorin has undergone extensive study in the adjuvant setting, based on the observation that fluorouracil plus leucovorin substantially improves response rates compared to fluorouracil alone for metastatic disease. Since the mid-1980s, several large randomized trials have evaluated the efficacy of fluorouracil plus leucovorin as adjuvant therapy for patients with stage II or III

colon cancer. In each of the studies, rates of recurrence and survival improved substantially for patients receiving fluorouracil plus “high dose” (200 to 500 mg/m² per day) or “low dose” (20 to 25 mg/m² per day) leucovorin compared to surgery alone.⁵⁸ The International Multicentre Pooled Analysis of Colon Cancer Trials (IMPACT) analyzed pooled data from three ongoing trials comparing surgery alone to adjuvant fluorouracil (370 to 400 mg/m² per day) plus high-dose leucovorin (200 mg/m² per day) given daily for 5 consecutive days, repeated every 28 days for 6 cycles (6 months).⁵⁹ The recurrence and death rates were reduced by 35% and 22%, respectively. These studies were initiated when a surgery-alone control group was appropriate for stage III colon cancer, before the results were available from the fluorouracil plus levamisole adjuvant trial.

Fluorouracil and leucovorin can be administered in a variety of treatment schedules, but none has proven superior with regard to overall patient survival. Table 127–10 lists examples of some of these regimens. In the U.S., the most common regimens include the Roswell Park regimen⁶⁰ and the Mayo Clinic regimen,⁶¹ while in Europe, treatments such as the de Gramont regimen⁶² favor a continuous intravenous schedule of fluorouracil. The weekly fluorouracil plus high-dose leucovorin (Roswell Park) and the daily fluorouracil plus low-dose leucovorin (Mayo Clinic) regimens were compared in a 4-arm U.S. Intergroup trial (INT-0089), that randomized patients with high-risk stage II and stage III colon cancer to either regimen, fluorouracil plus levamisole, or a combination of fluorouracil, leucovorin, and levamisole.⁶⁴ The standard fluorouracil plus levamisole regimen was administered over 12 months and the leucovorin-containing regimens were given for 6 cycles over a time period of 6 to 8 months. Overall survival (OS) was the primary end point with disease-free survival (DFS) as a secondary end point. For patients with stage II and III disease, the only significant difference was between fluorouracil plus levamisole versus fluorouracil plus leucovorin plus levamisole in terms of 5-year DFS (56% vs. 60%) and 5-year OS (63% vs. 67%). The high-dose leucovorin regimen was not superior to the low-dose leucovorin regimen, and the 3-drug combination was not superior to fluorouracil plus leucovorin alone. In addition, 6 months of adjuvant therapy with fluorouracil plus leucovorin was as effective as 12 months of fluorouracil plus levamisole.

An analysis of the treatment-related toxicities in the INT-0089 trial reveals several important differences (Table 127–11).⁵⁸ Grade 3 or worse toxicities, consisting of diarrhea, leukopenia, and stomatitis, usually occurred during the first month of therapy. Toxicities were most prevalent in the low-dose leucovorin arms with or without levamisole. The incidence of granulocytopenia and stomatitis were more commonly observed with low-dose leucovorin, while diarrhea occurred more frequently in the high-dose leucovorin arm. In a preliminary analysis of toxicity based on patient age, the risk of stomatitis and leukopenia appears greater in patients older than 70 years and in women.

TABLE 127–11. Treatment Toxicities in Intergroup Trial 0089

| Toxicity | Percentage of Grade III Toxicity or Worse | | | |
|-------------|---|------------|----------|-------------|
| | 5-FU/LD-LV | 5-FU/HD-LV | 5-FU/LEV | 5-FU/LV/LEV |

| Diarrhea | 21.1 | 30 | 11.4 | 17.9 |

5-FU, fluorouracil; HD-LV, high-dose leucovorin; LD-LV, low-dose leucovorin; LEV = levamisole.
 Reproduced with permission from Macdonald.⁵⁸

Other large trials have consistently shown 6 months of fluorouracil plus leucovorin to be at least equivalent to 12-month regimens containing levamisole.^{65,66} In the National Surgical Adjuvant Breast and Bowel Project (NSABP) C-04 trial, patients with stage II and III colon cancer were randomized to one of three study arms consisting of weekly fluorouracil plus high-dose (HD) leucovorin for 6 months, fluorouracil plus levamisole for 12 months, or the combination of fluorouracil plus HD-leucovorin and levamisole.⁶⁵ The fluorouracil and leucovorin were administered for 6 months; the levamisole was continued for a total of 12 months. In a pairwise comparison between fluorouracil plus HD-leucovorin versus fluorouracil plus levamisole, there was a significant prolongation in 5-year DFS (65% vs. 60%) and a trend toward improved 5-year OS (74% vs. 70%; $p = 0.07$) with HD-leucovorin. No difference was seen in DFS or OS between fluorouracil plus HD-leucovorin and fluorouracil plus HD-leucovorin plus levamisole.

Continuous IV infusion fluorouracil also does not improve efficacy in the adjuvant treatment setting.^{53,67} In a comparison of a 12-week protracted venous infusion (PVI) of fluorouracil versus the Mayo Clinic regimen for 6 months, OS was similar, but the PVI fluorouracil was associated with less toxicity.⁵³ Thus a 6-month regimen of fluorouracil plus leucovorin is the standard chemotherapy for patients with stage III colon cancer. Levamisole is no longer a required component of adjuvant chemotherapy regimens for colon cancer. Also, no standard exists for the best schedule of fluorouracil and leucovorin administration. Although there are no significant differences in efficacy between the Roswell Park and the Mayo Clinic regimen, toxicities can be different. With the exception of diarrhea, the Roswell Park regimen weekly HD-leucovorin regimen may be less toxic and is preferred by many practitioners. Although efficacy of HD- and LD-leucovorin with each of the regimens is similar, the costs of leucovorin doses ranging from 20 to 500 mg/m² are significantly different, and compliance issues regarding daily or weekly drug administration should be considered. Therefore the toxicity profiles of these regimens, overall treatment costs, and patient compliance issues should be considered to help determine the optimal adjuvant chemotherapy regimen for an individual patient.

The impact of adjuvant therapy on patients with stage II colon cancer is currently unknown. Most adjuvant trials have been conducted in mixed patient populations that included both stage II and stage III patients. Subset analyses of these trials, done in an attempt to identify the benefit of adjuvant therapy in stage II colon cancer, have produced conflicting results.²⁸ High-risk individuals (e.g., greater depth of muscle invasion, venous or lymphatic invasion, chromosome 18q allelic loss, tumor aneuploidy, mucinous or signet-ring histology, poor tumor differentiation, or mutant *p53* gene overexpression) probably benefit from adjuvant therapy. These individuals should be offered adjuvant chemotherapy, preferably in the setting of a randomized clinical trial, based on individual clinical, pathologic, and biologic prognostic factors. Despite the lack of a consensus regarding the

use of adjuvant chemotherapy for individuals with high-risk stage II colon cancer, many practitioners offer this therapy to selected patients. Optimal dosing, administration schedule, and duration of therapy have yet to be determined, but most practitioners choose to apply the same treatment approach as for stage III colon cancer.

CLINICAL CONTROVERSY

There is a lack of agreement among clinicians as to whether patients with stage II colon cancer should receive adjuvant chemotherapy. Some believe all patients should receive some form of chemotherapy, while others only recommend treatment or clinical trials for high-risk individuals.

■ **Investigational Approaches.** Despite the significant reduction in cancer recurrence and increased survival afforded with fluorouracil-based adjuvant chemotherapy, the results obtained thus far indicate need for continued improvement. Several strategies are underway, including protracted fluorouracil infusion, oral fluorinated pyrimidines, irinotecan, oxaliplatin, and immunotherapy-based therapies.^{58,68}

New chemotherapy agents and chemotherapy regimens are constantly being investigated in an attempt to improve on the response and safety of fluorouracil plus leucovorin in the adjuvant setting. Most attempts to improve the adjuvant therapy for colon cancer add a third active chemotherapy agent to existing fluorouracil/leucovorin regimens. Irinotecan and oxaliplatin, both active drugs in metastatic colon cancer, are currently being investigated in stage II and III colon cancer in regimens similar to those used in the metastatic setting.⁶⁸ In the MOSAIC trial, 2,246 patients with stage II or III colon cancer were randomized to receive fluorouracil plus leucovorin or FOLFOX4 postoperatively.⁶⁹ Results are promising; the addition of oxaliplatin resulted in a 23% risk reduction in disease recurrence and increased 3-year overall DFS (78.2% vs. 72.9%) compared to fluorouracil plus leucovorin alone. The addition of oxaliplatin did not substantially increase the toxicity of fluorouracil and leucovorin in the trial. These results will require longer follow-up prior to becoming standard of care in the adjuvant setting, although some practitioners are encouraged by these findings and have begun to incorporate oxaliplatin into adjuvant treatment regimens. Further modifications of the FOLFOX4 regimen may also improve tolerability. Capecitabine, an oral prodrug of fluorouracil, and other oral pyrimidines are also being evaluated in adjuvant studies as a replacement for fluorouracil in an attempt to improve the safety and ease of administration of the chemotherapy regimens.^{68,70}

■ **Portal Administration.** Because the liver is the site of recurrence in about 40% of patients, infusion of chemotherapy via the portal vein provides an additional adjuvant treatment approach. The rationale for this is based on a belief that intraoperative manipulation of the tumor

provides emboli of tumor that travel directly into the portal vein circulation, ultimately developing into hepatic micrometastasis.²⁸ Historically, fluorouracil has been the most common agent used for hepatic portal vein infusion. Because greater than 80% of a dose of fluorouracil administered systemically is metabolized by the liver, direct hepatic infusion of fluorouracil provides high local concentrations of the drug at the most common site of recurrence and minimizes systemic toxicity. Perioperative portal vein chemotherapy administration might then destroy cells before they can establish tumor growth.

An early trial evaluated the effect of a postoperative infusion of 1 g of fluorouracil infused via the portal vein daily for 7 days as compared to no further therapy following surgical resection in patients with stages I to III colorectal cancer. Heparin was also infused to reduce thrombosis.⁷¹ Those patients who received fluorouracil and heparin experienced a significant benefit in the reduction of hepatic metastasis and a dramatic improvement in survival. Results from a trial of 1,158 patients with stages I to III colon cancer, who were randomized to receive either a continuous infusion of fluorouracil 600 mg/m² per day for 7 days with heparin via the portal vein, or no therapy following surgical resection, showed a modest but statistically significant improvement in DFS (68% vs. 60%) and OS (76% vs. 71%) in the chemotherapy group.⁷²

Results of other trials evaluating postoperative portal vein infusions and fluorouracil or other agents are mixed. A meta-analysis of

4,000 patients in 10 randomized trials of portal vein infusion suggests a small (about 4%) improvement in 5-year OS with portal vein infusion.⁷³ However, these authors acknowledge that the flaws in some study designs and inadequate data to date require additional evidence from large randomized trials to determine whether this approach improves patient outcome. At this time, therefore, the value of portal vein infusion of fluorouracil for colon cancer remains unproven.

■ **Biologic Therapy.** Edrecolomab (17-1A monoclonal antibody) has been studied alone and in combination with fluorouracil following curative surgery for stage III colorectal cancer. It is administered as a 500-mg IV infusion given postoperatively that is followed by four monthly infusions of 100 mg. Edrecolomab's mechanism of action and common toxicities are described in Table 127–12. Compared to observation alone, antibody treatment with edrecolomab resulted in a 23% reduction in cancer recurrence and a 32% reduction in overall mortality in 189 patients with stage III cancer of the colon or rectum.⁷⁴ A randomized trial of 2761 patients who were randomly assigned to fluorouracil plus leucovorin alone, in combination with edrecolomab, or edrecolomab alone showed that DFS was lower with edrecolomab, and the addition of edrecolomab to fluorouracil plus leucovorin did not improve survival.⁷⁵ The future role of edrecolomab in adjuvant therapy is unclear.

TABLE 127–12. Investigational Agents for the Treatment of Colorectal Cancer

| Drug Name | Mechanism of Action | Common Adverse Reactions | Phase in Development |
|---|---|---|----------------------|
| Oral Fluorinated Pyrimidines | | | |
| Uracil-Tegafur (UFT, Ftorafur) | Tegafur: oral prodrug of fluorouracil; converted to fluorouracil by thymidine/uridine phosphorylase in the liver Uracil: Substrate for dihydropyridimidine dehydrogenase (DPD); inhibits degradation of fluorouracil | Vomiting, stomatitis, diarrhea, skin rash, and neurotoxicity (dizziness, confusion, ataxia) | Phase II/III |
| Eniluracil (776C85, 5-ethynyluracil) | DPD inactivator: binds to enzyme first in a reversible manner and then irreversibly inactivates it; inhibits fluorouracil degradation | Lacks systemic toxicity when administered alone | Phase III |
| Raltitrexed (ZD1694, Tomudex) | Folate analog: acts as a potent and selective thymidylate synthase inhibitor | Myelosuppression, nausea, vomiting, diarrhea, anorexia, reversible elevation of liver enzymes | Phase II |
| Monoclonal Antibodies | | | |
| Edrecolomab (17-1A MoAb, Panorex) | Murine monoclonal antibody directed against a tumor-specific glycoprotein located on colorectal tumor cells; antitumor activity via antibody-dependent cellular cytotoxicity (ADCC) | Diarrhea, abdominal pain, nausea, vomiting, infusion-related reactions (fever, chills) | Phase III |
| Signal Pathway Inhibitors | | | |
| Erlotinib (OSI-774, Tarceva) and others | Epidermal growth factor receptor (EGFR) tyrosine kinase inhibitor; inhibits cell proliferation signal transduction pathway | Acneiform skin rash, diarrhea, headache, mucositis, hyperbilirubinemia, neutropenia, anemia | Phase I |
| Tumor Vaccines | | | |
| Tipifarnib (R115777, Zarnesta) | Farnesyl transferase inhibitor, blocks Ras-activated signal transduction pathway | Myelosuppression, rash, fatigue, neuropathy | Phase II/III |
| CEA Vac and others | Monoclonal antibody vaccine targeting carcinoembryonic antigen | None reported | Phase III |
| Onco Vax | Prepared from autologous tumor cells mixed with bacille Calmette-Guérin, an organism with antitumor activity | Flu-like symptoms | Phase III |
| Antisense Therapy | | | |
| Oblimersen (G3139, Genasense) | Oligonucleotide that targets <i>Bcl-2</i> mRNA and inhibits expression of <i>Bcl-2</i> , an antiapoptotic oncogene | Myelosuppression, hypotension, fatigue, elevation of serum transaminases, mild hyperglycemia, fever | Phase II/III |

■ ADJUVANT CHEMOTHERAPY FOR RECTAL CANCER

6 Rectal cancer involves those tumors found below the peritoneal reflection in the most distal 15 cm of the large bowel, and as such is very distinct from colon cancer in that it has a propensity for both local and distant recurrence. The higher incidence of local failure and poorer overall prognosis associated with rectal cancer is due to anatomic limitations in excising adequate radial margins around the rectal tumor. Although an abdominoperitoneal surgical resection of the tumor and adjacent tissues results in a high probability of local control and long-term survival, the sequelae, including need for a permanent colostomy and high incidence of sexual and genitourinary dysfunction, has led to investigation of approaches that use multimodal therapies which preserve the integrity of the anal sphincter. In addition, because treatment with surgery, XRT, or systemic chemotherapy at the time of the recurrence is often suboptimal, adjuvant therapy after tumor resection is an important aspect of treatment of the primary tumor. The effectiveness of postoperative XRT and fluorouracil-based chemotherapy for stage II or III rectal cancer is well established. Although T₁ tumors with a favorable histology may be treated successfully with local excision alone, adjuvant XRT plus chemotherapy should be offered for larger lesions. Similar to adjuvant therapy for colon cancer, fluorouracil provides the basis for chemotherapy regimens for rectal cancer. The XRT decreases the rate of local pelvic recurrences, whereas the fluorouracil decreases the risk of distant tumor recurrence and enhances the effectiveness of the XRT. The optimal delivery schedule for these two therapies is the subject of ongoing investigation, but many trials have demonstrated improved local control and survival for patients who receive a combination of postoperative XRT and chemotherapy as compared to surgery alone. In 1990, based on results from the Gastrointestinal Tumor Study Group (GITSG) and the Mayo/NCCTG studies, the National Cancer Institute Consensus Conference recommended that standard postoperative adjuvant treatment for patients with stage II or III rectal tumors should consist of six cycles of fluorouracil-based chemotherapy with concurrent pelvic XRT.⁷⁶

The GITSG trial was designed to evaluate adjuvant postoperative treatment for patients with stage II or III rectal cancer. Patients were randomized into one of four groups: (1) observation only (control); (2) XRT alone; (3) chemotherapy alone (fluorouracil and semustine) for 18 months; or (4) combination XRT and chemotherapy.⁷⁷ Despite protocol violations and a short median follow-up, the study finished earlier than anticipated because of the statistically significant results that favored the combined modality treatment. The patients receiving the combination therapy had a reduction in both local (11% vs. 24%) and distant (26% vs. 34%) recurrence rates as compared to the control group. Although not seen initially, a re-estimate of survival probabilities at a median follow-up of 94 months demonstrated that the combination treatment was associated with a 24% OS advantage over the control group.⁷⁸ As expected, combined modality therapy resulted in more severe hematologic toxicity, enteritis, and diarrhea than either chemotherapy or XRT alone.

The Mayo/NCCTG trial compared postoperative XRT alone, postoperative XRT with concurrent fluorouracil plus semustine chemotherapy, and pre- and postirradiation chemotherapy in a similar population of 204 patients with rectal cancer.⁷⁹ This was the first randomized trial in which one cycle of combination chemotherapy was given before and after XRT in addition to the administration of fluorouracil during XRT. The use of combined chemotherapy and XRT significantly affected local recurrence, relapse-free survival, and OS as compared to XRT alone.⁵¹ Patients receiving combined therapy experienced an overall relative reduction of recurrence of 34% at

5 years as compared to the XRT-only group. A 36% improvement in DFS and 29% improvement in OS at 5 years were also observed in the combined group.

Acute complications such as severe hematologic toxicity (leukopenia and thrombocytopenia), enteritis, and diarrhea were commonly observed in the combined group. Hematologic toxicity was more noticeable during postirradiation chemotherapy, despite reduced doses. Although small bowel complications were uncommon, four deaths were reported as a result of complications as a consequence of small bowel obstruction, fistulas, septicemia resulting from perforation, and hemorrhage. There was a 6% incidence of primary cancers, equally divided between the XRT and combined groups. Because of the leukemogenic potential associated with semustine and results from prospective comparative trials that demonstrate that it does not contribute to overall treatment efficacy, semustine is no longer included in standard adjuvant treatment regimens. This regimen without semustine represents a popular adjuvant treatment regimen for rectal cancer.

Additional trials have sought to determine optimal combinations of concurrent radiation and fluorouracil. Based on preclinical studies that suggest continuous infusions of fluorouracil provide more effective radiosensitization than IV bolus injections, the Gastrointestinal Intergroup compared continuous IV fluorouracil infusion to intermittent bolus injections.⁸⁰ Six hundred sixty patients with stage II or III rectal cancer received either continuous infusion or IV bolus fluorouracil with postoperative pelvic XRT, in addition to pre- and postirradiation fluorouracil. At a median follow-up of 46 months, patients who received continuous infusion fluorouracil experienced a reduction in distant metastases and improved DFS and OS. The incidence of leukopenia (white blood cell count <2000/mm³) was greater in the IV bolus fluorouracil group, whereas diarrhea was more frequent in the protracted infusion group. Many treatment centers now employ continuous-infusion fluorouracil throughout the 5- or 6-week schedule of postoperative XRT for rectal cancer. Despite evidence that leucovorin improves efficacy of fluorouracil in other treatment settings, it does not appear to improve efficacy of adjuvant treatment for rectal cancer.⁸¹ Use of oral alternatives to fluorouracil that are also known to enhance radiation effects, such as capecitabine, are under investigation, with preliminary data suggesting the combination of capecitabine and XRT will be safe and effective.⁸²

■ Preoperative (Neoadjuvant) Versus Postoperative Therapy

6 Interest in preoperative or neoadjuvant therapy has increased based on advances in imaging techniques to more accurately stage rectal tumors preoperatively and the success of combined XRT plus fluorouracil administered in the postoperative setting. Both pre- and postoperative XRT administered in conventional doses effectively decreases local recurrence rates for rectal cancer by up to 50% as compared to rates with surgery alone.⁵⁸ Preoperative XRT, by shrinking and thereby downstaging the tumor prior to surgical resection, improves sphincter preservation, but the primary concern with this approach is potential overtreatment with XRT. While this is a common treatment strategy in some European countries, the issue of pre- versus postoperative XRT is a subject of debate and investigation in the United States. Furthermore, the way that XRT and fluorouracil are delivered varies widely. Some practitioners deliver XRT as 45 to 55 Gy in small fractions of 1.8 to 2.0 Gy over a period of 5 to 6 weeks, whereas short, intensive courses deliver therapy in five fractions over a period of 1 week. Moreover, variability in surgical technique can also influence outcome.⁸³ Fluorouracil can be administered as IV bolus injections for 3 or 4 days during the first and last weeks of XRT or via a

continuous IV infusion. Although concurrent XRT plus fluorouracil continuous infusion is theoretically more efficacious based on the results from postoperative chemoradiation trials, short intensive-course chemoradiation strategies are less expensive and more convenient for the patient. Preliminary results of NSABP Trial R-03 suggest that pre- and postoperative chemoradiation therapy are similarly safe and efficacious, but long-term survival and toxicity data will be needed to make a definitive conclusion.

Several trials that have compared preoperative therapy to surgery alone have failed to show a survival benefit with preoperative XRT; however, the Swedish Rectal Cancer Trial, a randomized trial of 1,168 patients with resectable rectal cancer who underwent a short course of intensive preoperative XRT followed by surgery within 1 week or surgery alone, was able to demonstrate improved local recurrence rates (11% vs. 27%) and 5-year survival for those patients who received XRT plus surgery versus surgery alone (58% vs. 48%).^{84,85} These findings will need to be verified in future trials before this therapy can be considered the standard of care. Moreover, the short-course therapy is unlikely to sufficiently downstage the tumor because it will have only been completed 1 week prior to surgery. Whether fluorouracil can be safely incorporated into such a regimen will also require further evaluation.

Results from the GITSG, NSABP, and Intergroup trials indicate that survival benefits can be achieved with the addition of fluorouracil to postoperative XRT for resectable rectal cancer.^{77–80} Adjuvant chemotherapy plus XRT decreases local tumor recurrence after surgery and increases the probability of sphincter preservation in patients with clinically resectable disease. Neoadjuvant therapy may provide similar benefits and additionally improve the rate of resectability in patients with locally advanced disease by downstaging the tumor, but regimens cannot be considered standard therapy at this time. The NCCN Practice Guidelines for rectal cancer indicate that postoperative fluorouracil-based chemotherapy plus XRT is considered appropriate adjuvant therapy for resectable T₂ or larger lesions.⁸⁶ Neoadjuvant fluorouracil chemoradiation followed by abdominoperineal or low anterior resection or surgery alone plus postoperative fluorouracil or fluorouracil plus XRT should be considered for locally unresectable tumors.

■ METASTATIC DISEASE

■ INITIAL THERAPY

Several advances have been made recently in developing efficacious treatment options for metastatic colorectal cancer. Whereas surgery and XRT are most often used to manage isolated sites of tumor, chemotherapy is most useful for patients with disseminated disease and is the primary treatment modality for unresectable metastatic colorectal cancer.

■ Surgery

Complete surgical resection of discrete hepatic, pulmonary, abdominal, or brain metastases in patients with colorectal cancer, if possible, may offer selected patients an opportunity to experience extended DFS. Patients who have from one to three small nodules isolated to the liver, lungs, or abdomen have the most favorable outcome. Up to 25% of patients will present with hepatic metastases at time of diagnosis, and 60% of patients with colorectal cancer will develop hepatic metastases sometime during the course of their disease.

Five-year survival for patients who undergo surgical resection of metastases isolated to the liver ranges from 20% to 39%, with a median survival duration of 28 to 40 months, and is associated with an operative mortality rate less than 5%.⁸⁷ These results are drastically greater than those in patients with unresectable metastatic colorectal cancer, in whom 5-year survival is uncommon and median survival is about 12 months. Patients with no significant general medical risk factors, fewer than four hepatic lesions, CEA levels less than 200 ng/mL, small tumor size, lack of extrahepatic tumor, and adequate surgical margins have the best opportunity for an improved long-term outcome. The primary site of tumor should also be completely resected. Ablative therapies that involve destroying the tumor through freezing and thawing (cryoablation), heat (radiofrequency), or alcohol injection may be useful for patients who have very small hepatic lesions and are unable to undergo liver resection surgery, but are less successful than surgical interventions.⁸⁷ Outcomes associated with resection of isolated pulmonary, abdominal, and brain metastases have been less studied; however, this approach is potentially curative and should be considered for patients with resectable disease who are appropriate surgical candidates.

Because approximately two-thirds of patients who undergo resection of hepatic metastases will have disease recurrence, adjuvant systemic and hepatic arterial infusion chemotherapy have been studied in an attempt to improve long-term outcomes. A randomized trial that compared 6 months of hepatic floxuridine and dexamethasone plus IV fluorouracil with leucovorin to IV fluorouracil with leucovorin alone following resection of hepatic metastases in 156 patients showed improved 2-year DFS (86% vs. 72%) and hepatic recurrence-free survival at 2 years (90% vs. 60%) with the combined therapy.⁸⁸ Many practitioners offer adjuvant chemotherapy to select patients following potentially curative hepatic resection, but further studies, especially those involving more active agents, are needed to determine an optimal treatment regimen.⁸⁹

■ Radiation

Symptom reduction is the primary goal of XRT for patients with advanced or metastatic colorectal cancer.

■ Chemotherapy

Accepted initial chemotherapy regimens for metastatic cancer of the colon or rectum consist of oxaliplatin plus fluorouracil and leucovorin, irinotecan plus fluorouracil and leucovorin, bevacizumab plus a fluorouracil-based regimen, or fluorouracil plus leucovorin alone. Examples of treatment regimens for metastatic colorectal cancer are listed in Table 127–13. The site(s) of tumor involvement and history of prior chemotherapy help to define an appropriate management strategy. In general, treatment options are similar for metastatic cancer of the colon and rectum.

Currently, metastatic colorectal cancer is incurable and treatment goals are to reduce patient symptoms, improve quality of life, and extend survival. Two recent meta-analyses were performed to estimate the magnitude of benefit and harm associated with palliative chemotherapy for metastatic colorectal cancer. In a pooled analysis of randomized trials comparing chemotherapy to observation or supportive care alone, a total of nine trials that included 614 patients were evaluated.¹⁰² All trials used fluorouracil-based chemotherapy, but three trials in which hepatic arterial or portal vein administration was used were also included. Several trials allowed delayed or

TABLE 127–13. Chemotherapeutic Regimens for Metastatic Colorectal Cancer

| | Regimen | Major Dose-Limiting Toxicities |
|--|---|---|
| Initial therapy | | |
| <i>Pyrimidine only</i> | | |
| Weekly, high-dose leucovorin; Roswell Park regimen ⁶¹ | Fluorouracil 600 mg/m ² IV + leucovorin 500 mg/m ² IV weekly × 6 out of 8 weeks | Diarrhea, mucositis |
| Consecutive day, low-dose leucovorin; Mayo Clinic regimen ⁶¹ | Fluorouracil 425 mg/m ² per day IV + leucovorin 20 mg/m ² per day IV days 1–5, for 5 consecutive days, repeated every 4–5 weeks | Mucositis, neutropenia |
| Bolus plus infusional fluorouracil; (LV5FU2) ⁶² ; de Gramont regimen | Leucovorin 200 mg/m ² per day IV over 2 hours followed by fluorouracil 400 mg/m ² per day IV bolus, then followed by fluorouracil 600 mg/m ² per day continuous IV infusion over 22 hours, days 1 and 2 for 2 consecutive days; repeat every 2 weeks | Neutropenia, mucositis |
| Capecitabine ⁹⁰ | 1250 mg/m ² orally twice daily for 14 days, repeated every 3 weeks | Diarrhea, hand-foot syndrome |
| <i>Oxaliplatin plus fluorouracil plus leucovorin</i> | | |
| Oxaliplatin plus bimonthly infusional fluorouracil; FOLFOX ⁹¹ | Oxaliplatin 85 mg/m ² IV day 1 plus bolus fluorouracil 400 mg/m ² IV plus leucovorin 200 mg/m ² IV followed by fluorouracil 600 mg/m ² IV in 22-hour infusion on days 1 and 2, every 2 weeks | Sensory neuropathy, neutropenia |
| High-dose oxaliplatin plus bimonthly infusional fluorouracil; FOLFOX ⁷² | Oxaliplatin 130 mg/m ² IV with leucovorin 400 mg/m ² IV day 1, followed by fluorouracil 400 mg/m ² IV bolus and 2400 mg/m ² continuous IV infusion over 46 hours started on day 1, repeated every 2 weeks | Sensory neuropathy, diarrhea, myelosuppression |
| <i>Irinotecan plus fluorouracil plus leucovorin</i> | | |
| Irinotecan plus bolus fluorouracil; IFL; Saltz regimen ⁹³ | Irinotecan 125 mg/m ² IV plus fluorouracil 500 mg/m ² IV plus leucovorin 20 mg/m ² IV weekly for 4 weeks out of 6 weeks | Diarrhea, neutropenia |
| Irinotecan plus infusional fluorouracil; FOLFIRI ⁹⁴ | Irinotecan 180 mg/m ² IV plus leucovorin 400 mg/m ² IV plus bolus fluorouracil 400 mg/m ² IV, followed by fluorouracil 2400 mg/m ² continuous IV infusion over 46 hours on day 1, repeated every 2 weeks | Nausea, diarrhea, mucositis, neutropenia |
| Biweekly irinotecan plus infusional fluorouracil ⁹⁵ | Irinotecan 180 mg/m ² IV plus leucovorin 200 mg/m ² plus fluorouracil 400 mg/m ² IV, followed by fluorouracil 600 mg/m ² continuous IV infusion over 22 hours, day 1, repeated every 2 weeks | Neutropenia, diarrhea |
| Weekly irinotecan plus infusional fluorouracil ⁹⁵ | Irinotecan 80 mg/m ² IV plus leucovorin 500 mg/m ² IV plus fluorouracil 2300 mg/m ² continuous IV infusion over 24 hours day 1, repeated weekly | Neutropenia, diarrhea |
| <i>Bevacizumab</i> | | |
| Bevacizumab plus bolus IFL ⁹⁶ | Irinotecan 125 mg/m ² IV plus fluorouracil 500 mg/m ² IV plus leucovorin 20 mg/m ² IV weekly for 4 out of 6 weeks, with bevacizumab 5 mg/m ² IV day 1, repeated every 2 weeks | Diarrhea, hypertension, asthenia, thrombosis, vomiting, proteinuria |
| Salvage therapy | | |
| <i>Irinotecan^a</i> | | |
| Weekly irinotecan ⁹³ | Irinotecan 125 mg/m ² IV every week for 4 out of 6 weeks | Neutropenia, diarrhea |
| Every 3-weekly irinotecan ⁹⁷ | Irinotecan 350 mg/m ² IV every 3 weeks | Neutropenia, diarrhea |
| <i>Oxaliplatin plus fluorouracil plus leucovorin^b</i> | | |
| Oxaliplatin plus bimonthly infusional fluorouracil; FOLFOX ⁹¹ | Oxaliplatin 85 mg/m ² IV day 1 plus bolus fluorouracil 400 mg/m ² IV plus leucovorin 200 mg/m ² IV followed by fluorouracil 600 mg/m ² IV in 22-hour infusion on days 1 and 2, every 2 weeks | Sensory neuropathy, neutropenia |
| High-dose oxaliplatin plus bimonthly infusional fluorouracil; FOLFOX ⁷² | Oxaliplatin 130 mg/m ² IV with leucovorin 400 mg/m ² IV day 1, followed by fluorouracil 400 mg/m ² IV bolus and 2400 mg/m ² continuous IV infusion over 46 hours started on day 1, repeated every 2 weeks | Sensory neuropathy, diarrhea, myelosuppression |
| <i>Cetuximab^c</i> | | |
| Cetuximab plus irinotecan ⁹⁸ | Continue irinotecan as previously dosed, plus cetuximab 400 mg/m ² IV loading dose, then cetuximab 250 mg/m ² IV weekly thereafter | Asthenia, diarrhea, nausea, acneiform rash, vomiting |
| Cetuximab ⁹⁸ | Cetuximab 400 mg/m ² IV loading dose, then cetuximab 250 mg/m ² IV weekly thereafter | Acneiform rash, asthenia, constipation, diarrhea |
| <i>Fluorouracil</i> | | |
| Protracted continuous infusion ⁹⁹ | Fluorouracil 250–300 mg/m ² per day continuous IV infusion until disease progression | Mucositis, hand-foot syndrome |
| Investigational | | |
| Xelox; CapOx ¹⁰⁰ | Capecitabine 1000 mg/m ² orally twice daily days 1–14 plus oxaliplatin 70 mg/m ² IV days 1 and 8; repeat every 3 weeks | Diarrhea, sensory neuropathy |
| Xeliri; CapIri ¹⁰⁰ | Capecitabine 1000 mg/m ² orally twice daily days 1–14 plus irinotecan 100 mg/m ² IV days 1 and 8; repeat every 3 weeks | Diarrhea, neutropenia |
| IROX ¹⁰¹ | Oxaliplatin 85 mg/m ² IV plus irinotecan 200 mg/m ² IV day 1, repeated every 3 weeks | Neutropenia, diarrhea, vomiting, sensory neuropathy |

^aIf first-line therapy, fluorouracil plus leucovorin or oxaliplatin plus fluorouracil plus leucovorin.^bIf first-line therapy, fluorouracil plus leucovorin or irinotecan plus fluorouracil plus leucovorin, or bevacizumab plus IFL.^cIf irinotecan-refractory disease.

discretionary use of chemotherapy in patients assigned to observation or supportive care alone; 12% to 57% of control patients received at least one course of chemotherapy. Despite these discrepancies, chemotherapy was associated with a significant reduction in mortality at 1 (relative risk ratio 0.69) but not 2 years (relative risk ratio 0.93).

The second meta-analysis to determine the benefit of chemotherapy in metastatic disease analyzed individual patient data and summary statistics from 13 randomized trials that included 1,365 patients.¹⁰³ Eligible trials compared palliative chemotherapy given via any route of administration to supportive care alone or treatments not involving chemotherapy. Trials that allowed chemotherapy use in control patients were not excluded. In the analysis of seven trials in which individual patient data were available, palliative chemotherapy was shown to reduce risk of death by 35%, which translates to a prolongation of median survival by 3.7 months. The investigators were unable to determine the extent to which treatment resulted in significant toxicities or affected quality of life because of inadequate data. However, the results of both analyses suggest that palliative chemotherapy is beneficial and improves survival in metastatic colorectal cancer. Because many patients assigned to control arms eventually received chemotherapy, the magnitude of survival benefit associated with chemotherapy could be underestimated.

Fluorouracil continues to be incorporated into current first-line chemotherapy regimens used for metastatic colorectal cancer. When administered in bolus injection treatment schedules, fluorouracil is given most frequently with leucovorin, which improves response rates but has minimal impact on overall survival. The addition of irinotecan to fluorouracil plus leucovorin significantly improves response rates, progression-free survival, and median survival, without adversely affecting quality of life. Oxaliplatin in combination with fluorouracil and leucovorin has also shown improvements in median survival when compared to the combination of irinotecan plus fluorouracil and leucovorin in the initial treatment of metastatic colon cancer. The addition of bevacizumab to fluorouracil-based regimens improves efficacy compared to chemotherapy alone. Either of these three- or four-drug combinations may be considered as first-line therapy for metastatic colorectal cancer. Ongoing trials are evaluating the sequencing of these regimens, as well as comparing the efficacy of combinations of fluorouracil plus leucovorin, to investigational treatments with capecitabine, oral fluoropyrimidines and newer agents. Table 127-14 summarizes comparative outcome data from potentially useful chemotherapeutic treatments for metastatic colorectal cancer.

Fluorouracil. Fluorouracil has been administered as a single agent by IV bolus injection but response rates are only 10% to 20%.^{28,104} As such, IV bolus fluorouracil as a single agent is considered ineffective for metastatic colorectal cancer.

A variety of continuous IV infusion fluorouracil regimens have been developed to increase the duration of drug exposure during the S phase of the cell cycle and increase DNA-dependent cytotoxicity. Some of these schedules involve short (24- to 48-hour) weekly or biweekly or protracted continuous fluorouracil infusions for up to 12 weeks.²⁸ Doses of fluorouracil employed in 24 to 48 hour infusions generally range from 1000 to 2000 mg/m² per day. A regimen utilizing 300 mg/m² per day for 10 weeks is considered the maximally tolerated dose for protracted continuous infusion. Based on the assumption that a dose-response relationship exists for colorectal cancer, this approach is one of the most efficacious methods of dose intensification for fluorouracil. The maximum cumulative fluorouracil dose that can be administered via continuous IV infusion in

a 28-day period is approximately 4000 to 7400 mg/m² as compared to 2,400 to 2,500 mg/m² with IV bolus fluorouracil.¹⁰⁵

Despite differences in dose intensity among the different regimens, no clear survival advantages or trends are obvious for any particular regimen. However, in comparison to IV bolus fluorouracil, response rates with continuous infusion fluorouracil are approximately doubled. In a meta-analysis of six randomized trials evaluating 1219 patients with advanced colorectal cancer that compared efficacy of continuous infusion and bolus IV fluorouracil, a significantly higher tumor response rate (22% vs. 14%) was observed in patients receiving fluorouracil by continuous IV infusion.¹⁰⁶ Although continuous infusion fluorouracil was also associated with a significant OS benefit (overall hazard ratio 0.88), this effect is generally considered as marginal. Therefore, until future studies demonstrate a clinical benefit with continuous infusion fluorouracil with respect to the added expense and complications associated with venous access devices and portable infusion pumps, some clinicians continue to favor IV bolus schedules for initial therapy of metastatic disease. Increased acceptance and added clinical benefit with continuous infusion fluorouracil has been demonstrated when fluorouracil is administered with other agents and is becoming more commonplace in clinical practice.

Fluorouracil Plus Leucovorin. Numerous studies have evaluated various doses and administration schedules of fluorouracil plus leucovorin in an attempt to improve treatment response rates and survival in metastatic colorectal cancer. Response rates of 14% to 58% have been observed with a variety of doses of fluorouracil in combination with leucovorin at doses ranging from 20 to 500 mg/m².²⁸ Leucovorin can be given by IV bolus, continuous infusion, and orally. The administration sequence and timing of leucovorin may be important factors in evaluating the efficacy of biochemical modulation with leucovorin. A schedule for administering leucovorin prior to fluorouracil is the most effective approach to enable the level of intracellular-reduced folates to accumulate prior to fluorouracil administration. However, the maximum tolerated dose of fluorouracil when given in combination with leucovorin is lower than that when given alone. In addition, a qualitative alteration of the toxicity pattern has been noted.

Despite significantly higher response rates and improved progression-free survival achieved with leucovorin-modulated fluorouracil regimens, their effect on OS is modest. The lack of any clear survival benefit detected in clinical trials might be explained by the generally short duration of tumor responses, the large number of patients who do not respond to treatment, or the effects of crossover administration of fluorouracil plus leucovorin in patients who fail single-agent fluorouracil. Phase III trials evaluating fluorouracil and leucovorin for metastatic colorectal cancer have been criticized because doses of fluorouracil used in control groups have been below the maximum-tolerated dose. As a result, the addition of leucovorin may appear to produce a greater antitumor effect when in fact it is being compared to a suboptimal dose of fluorouracil in the control group.

The most practical issue at present, however, is whether a weekly, biweekly, or monthly regimen of fluorouracil given as an IV bolus or continuous infusion with high- or low-dose leucovorin is most preferable. The most commonly used regimens for metastatic colorectal cancer in the U.S. have involved the Mayo Clinic regimen and the Roswell Park regimen (see Table 127-13). These regimens have been compared in randomized trials with conflicting results.

For a number of years the Mayo Clinic regimen has been the reference regimen in metastatic colon cancer. However, limitations with

TABLE 127–14. Comparative Outcomes from Selected Trials in Metastatic Colorectal Cancer

| Trial | Number | Outcome Measures | Results |
|--------------------------------|--------|--|--|
| <i>First-line</i> | | | |
| Goldberg et al ¹⁰¹ | 795 | Primary: TTP; secondary: OS, RR time to treatment discontinuation | Median TTP: IFL vs. FOLFOX 6.9 vs. 8.7 mo ($p = .0014$). Median survival 15.0 mo with IFL vs. 19.5 mo with FOLFOX ($p = .001$). Response rate with FOLFOX (45%) higher compared to IFL (31%; $p = .002$) and IROX (35%, $p = .03$). TTP and OS with IROX (6.5 and 17.4 mo) no different from FOLFOX. |
| de Gramont et al ⁹¹ | 420 | Primary: PFS; secondary: RR, OS, tolerability, QOL | Median PFS: 9.0 vs. 6.2 mo ($p = .0003$); RR: 50.7 vs. 22.3% ($p = .0001$), oxaliplatin plus LV5FU2 vs. LF5FU2 alone; no oxaliplatin plus LV5FU2 vs. LV5FU2 alone difference in OS (16.2 vs. 14.7 mo) or QOL |
| Saltz et al ⁹³ | 683 | Primary: PFS; secondary: RR, OS | Median PFS longer with IFL (7.0 mo) vs. FU/LV (4.3 mo; $p = .004$); PFS similar with irinotecan alone (4.2 mo) compared to FU/LV; RR higher with IFL vs. FU/LV (50 vs. 28%; $p < .001$); median survival longer with IFL (14.8 mo) vs. 12.6 mo with FU/LV ($p = .04$), which was similar to irinotecan (12.0 mo) |
| Douillard et al ⁹⁵ | 387 | Primary: RR; secondary: TTP, response duration, TTF, OS, QOL | Significantly higher RR with infusional IFL vs. infusional FU/LV alone (35 vs 22%; $p < .005$) by ITT; TTP longer with IFL (6.7 vs. 4.4 mo; $p < .001$) and OS longer with IFL vs. infusional FU/LV alone (17.4 vs. 14.1 mo; $p = .031$) |
| Tournigand et al ⁹⁴ | 226 | Test the best sequence of FOLFIRI vs. FOLFOX6; primary: second PFS; secondary: PFS, OS, RR, safety | Median survival 21.5 mo with FOLFIRI then FOLFOX6 vs. 20.6 mo with FOLFOX6 then FOLFIRI; median PFS also no different (14.2 vs. 10.9 mo), or RR or median PFS with first treatment: FOLFOX6 54% and 8.0 mo, vs. 56% and 8.5 mo with FOLFIRI |
| Hurwitz et al ⁹⁶ | 925 | Primary: OS; secondary: PFS, RR, response duration, QOL | Bevacizumab plus IFL increased median survival (20.3 mo) vs. IFL alone (15.6 mo; $p = .00003$), PFS (10.6 vs. 6.24 mo; $p < .00001$), RR (45% vs. 35%; $p = .0029$), and duration of response (10.4 vs. 7.1 mo; $p = .0014$) |
| Twelves ⁹⁰ | 1,207 | Primary: RR; secondary: TTP, OS, response duration | Tumor response to capecitabine greater than with FU/LV (25.7 vs. 16.7%; $p < .0002$), but no difference in median TTP (4.6 vs. 4.7 mo) or median survival (392 vs. 391 days) |
| <i>Second-line</i> | | | |
| Rougier et al ⁹⁹ | 267 | Primary: OS; secondary: PFS, RR, symptom-free survival, adverse effects, QOL | Irinotecan improved median PFS (4.2 vs. 2.9 mo; $p = .030$) compared to infusion fluorouracil and 1-year survival (45% vs. 35%; $p = .035$) but not median OS (10.8 vs. 8.5 mo). Median pain-free survival was similar ($p = .06$; 10.3 vs. 8.5 mo) between irinotecan and fluorouracil, as was QOL |
| Cunningham et al ⁹⁷ | 279 | Primary: OS; secondary; performance status, body weight, tumor-related symptoms, QOL | Compared to best supportive care, OS was improved with irinotecan (13.8% 1-year survival vs. 36.2%; $p = .0001$); survival without deterioration in performance status, weight loss greater than 5%, and pain-free survival were also improved with irinotecan |
| Cunningham et al ⁹⁸ | 329 | Primary: RR; secondary: TTP, OS | Addition of cetuximab to continuing irinotecan associated with 22.9% response rate compared to 10.9% with cetuximab alone ($p = .0074$); median survival with cetuximab plus irinotecan similar to cetuximab alone (8.6 vs. 6.9 mo; $p = 0.48$), but TTP was longer with cetuximab plus irinotecan (4.1 vs. 1.5 mo; hazard ratio 0.54; 95% CI, 0.42–0.71) |

this regimen are becoming more apparent. A trial comparing the Mayo Clinic regimen to either fluorouracil alone or fluorouracil (370 mg/m² per day for 5 days) with HD-dose leucovorin (200 mg/m² per day) found the Mayo Clinic regimen to be more effective, with a response rate of 42%, compared to response rates of 10% and 31% for fluorouracil alone or in combination with HD-leucovorin, respectively.¹⁰⁷ Although the LD-leucovorin regimen was more effective than the HD regimen, the difference in response could be attributed to the higher doses of fluorouracil that were administered in the Mayo Clinic regimen. Median survival, 12.7 months, was no different in either leucovorin-containing regimen. A subsequent collaborative trial

compared the Mayo Clinic regimen to the Roswell Park regimen in 372 patients with metastatic disease.¹⁰⁸ There were no differences in tumor response (35% vs. 31%), median survival (9.3 months vs. 10.7 months), or palliative responses. The LD-leucovorin regimen was, however, associated with significantly more leukopenia and stomatitis, whereas HD-leucovorin caused more diarrhea and a greater hospitalization requirement to manage toxicity. Similar modifications of leucovorin have been studied with the Roswell Park regimen. In a trial comparing high- (500 mg/m²) and low-dose (20 mg/m²) leucovorin plus weekly fluorouracil at equal doses (500 mg/m²) in 291 patients with inoperable or metastatic colorectal cancer, there were

no differences in median response duration, progression-free, or overall survival.¹⁰⁹ While the incidence of mucositis was similar for both groups (9.8% vs. 11.5%), grade 3 or 4 diarrhea was more common with high-dose leucovorin (27% vs. 16.1%).

Overall, response rates and survival outcomes with weekly and daily regimens of bolus fluorouracil plus LD- or HD-leucovorin appear comparable. Leucovorin doses greater than 20 mg/m² do not appear to increase overall survival, but rather add to the toxicity of either daily or weekly regimens of fluorouracil. Weekly (HD-leucovorin) treatment schedules are associated with a higher incidence of diarrhea, the primary dose-limiting toxicity, whereas mucositis and leukopenia are relatively infrequent.¹¹⁰ Mucositis tends to be dose-limiting and leukopenia is more common with the daily (LD-leucovorin) treatment schedule.

The Mayo Clinic regimen has also been compared to bimonthly and weekly regimens of infusional fluorouracil. Higher response rates of 24% to 54% have been noted in bimonthly regimens of fluorouracil administered first as an IV bolus infusion followed by a 22-hour continuous infusion in combination with high-dose leucovorin administered over 2 hours.¹¹⁰ However, the bimonthly combined IV bolus and continuous infusion fluorouracil schedule (de Gramont regimen) did not improve median survival compared to the Mayo Clinic schedule, although it was associated with a lower incidence of severe granulocytopenia, diarrhea, and mucositis.⁶² High response rates (39% to 58%) have also been observed in previously untreated and treated patients receiving weekly fluorouracil as a continuous 24-hour infusion in combination with HD-leucovorin given over 2 to 24 hours. In a recent trial of untreated metastatic colorectal cancer, 497 patients were randomly assigned to receive the Mayo Clinic regimen of fluorouracil/leucovorin or fluorouracil 2600 mg/m² as a 24-hour continuous infusion alone or in combination with HD-leucovorin weekly.¹¹¹ Though median survival rates were not different between groups, progression-free survival was prolonged when weekly fluorouracil was administered with HD-leucovorin. Similar to other toxicity results, leukopenia and mucositis were more frequent in patients receiving bolus fluorouracil plus leucovorin (Mayo Clinic regimen), while patients receiving continuous infusion fluorouracil plus leucovorin experienced more diarrhea and hand-foot syndrome.

In summary, the Mayo Clinic regimen of fluorouracil plus low-dose leucovorin is still an acceptable regimen, although a weekly schedule of leucovorin plus fluorouracil (either bolus or continuous infusion) may be more convenient for the patient in terms of fewer scheduled clinic appointments, less interference with work schedules, and ease of dose adjustments based on toxicity. Bimonthly infusions of fluorouracil given over 2 days produce higher response rates when compared to daily regimens and are gaining in acceptability. However, the incorporation of newer agents into treatment regimens rather than continual adjustments of fluorouracil and leucovorin doses and administration schedules will most likely result in the greatest advances in drug therapy for metastatic colorectal cancer.

CLINICAL CONTROVERSY

The best way to administer fluorouracil has been debated by clinicians for years. Although higher response rates are seen with continuous infusions of fluorouracil, many argue that this benefit is not clinically meaningful.

➤ **Irinotecan Plus Fluorouracil and Leucovorin.** Based on irinotecan's activity against untreated and fluorouracil-resistant colorectal cancer, in addition to its unique mechanism of action, several investigations have been completed to determine whether

the addition of irinotecan to fluorouracil plus leucovorin as initial therapy for metastatic disease could further improve survival. In a randomized trial of 387 previously untreated patients with advanced colorectal cancer, irinotecan plus fluorouracil and leucovorin was compared to fluorouracil plus leucovorin with regard to tumor response, survival, and quality of life⁹⁵ (see Table 127-14). The choice of one of two fluorouracil plus leucovorin regimens was left to the discretion of participating investigators. Patients randomized to fluorouracil plus leucovorin could receive weekly fluorouracil (2,600 mg/m²) as a 24-hour IV infusion plus leucovorin (500 mg/m²), or the de Gramont regimen of IV bolus and infusional fluorouracil. For the three-drug treatment, a weekly regimen of irinotecan (80 mg/m²) with a 24-hour infusion of fluorouracil (2300 mg/m²) plus leucovorin 500 mg/m², or an every 2-week regimen consisting of irinotecan (180 mg/m²) on day 1 with IV bolus fluorouracil (400 mg/m²) followed by a 22-hour IV infusion (600 mg/m²) plus leucovorin (200 mg/m² given on days 1 and 2) could be used. Tumor response, median time to disease progression, and OS were all greater in the irinotecan group. Diarrhea and neutropenia were the most common toxicities and were worse in the irinotecan-containing groups. Diarrhea was the most common reason for dose reduction or treatment discontinuation with the weekly regimens, and led to hospital admission for 32% of patients receiving irinotecan compared to 12% of patients who received only fluorouracil plus leucovorin. Neutropenia was the most common cause of dose reductions with the every-2-week regimens. Results from questionnaires indicated that a definite deterioration in quality of life developed consistently later in the irinotecan group.

A second randomized trial compared the addition of irinotecan (125 mg/m²) to weekly fluorouracil plus leucovorin (fluorouracil 500 mg/m² IV bolus plus leucovorin 20 mg/m² IV bolus, each given weekly for 4 weeks, repeated every 6 weeks) to the Mayo Clinic regimen and to irinotecan alone (125 mg/m² IV weekly for 4 weeks, repeated every 6 weeks) as first-line therapy in 683 patients with metastatic colorectal cancer.⁹³ The combination of irinotecan, fluorouracil, and leucovorin resulted in significantly increased tumor response rates and improved progression-free survival and OS as compared to fluorouracil plus leucovorin and irinotecan alone, respectively. The combined incidence of grade 3 or 4 diarrhea was 22.7% with the three-drug combination, compared to 13.2% with fluorouracil plus leucovorin and 31% with irinotecan alone. However, the incidence of grade 3 diarrhea was almost threefold greater with triple-drug therapy as compared to the two-drug regimen. Mid-cycle dose reductions caused by neutropenia, which were more common with the three-drug treatment, could potentially have lowered subsequent risk of grade 4 diarrhea. Mucositis was more frequent in the fluorouracil plus leucovorin group. Quality-of-life analyses did not indicate that the addition of irinotecan to fluorouracil plus leucovorin compromised quality of life. Based on these results, this became the most common administration schedule for irinotecan plus fluorouracil and leucovorin in the United States, although irinotecan-based regimens containing continuous infusions of fluorouracil (e.g., FOLFIRI) are preferred by many practitioners.

The most common adverse effects of irinotecan in these regimens are diarrhea, neutropenia, nausea and vomiting, asthenia, abdominal pain, and alopecia; diarrhea and neutropenia are dose limiting.^{93,95} Two distinct patterns of diarrhea have been described. Early-onset diarrhea occurs during or within 2 to 6 hours after irinotecan administration and is characterized by lacrimation, diaphoresis, abdominal cramping, flushing, and/or diarrhea. These cholinergic symptoms, thought to be due to inhibition of acetylcholinesterase, respond to atropine 0.25 to 1 mg given intravenously or subcutaneously. Approximately 10% of patients experience the acute symptoms during

or shortly following the irinotecan. More commonly, late-onset diarrhea appears, 1 to 12 days after irinotecan administration, and may last for 3 to 5 days.^{28,112} Late-onset diarrhea may require hospitalization or discontinuation of therapy, and fatalities have been reported. The incidence of late-onset diarrhea has been as high as 39% in some studies, but is now much lower with aggressive anti-diarrheal intervention.^{28,112}

Aggressive intervention with high-dose loperamide therapy should consist of 4 mg taken at the first sign of soft or watery stools, followed by 2 mg orally every 2 hours until symptom free for 12 hours. This regimen can be modified to 4 mg every 4 hours taken during the night. Of note, a significant correlation has been identified between the severity of delayed diarrhea, irinotecan, and SN-38 (irinotecan's active metabolite) area under the concentration-versus-time curve, as well as pharmacogenetic abnormalities in the enzyme UDP-glucuronosyltransferase (UGT1A1), which is responsible for the glucuronidation of SN-38 to inactive metabolites. The UGT1A1 enzyme exists in polymorphic states, and reduced or deficient levels of this enzyme are observed in Gilbert's syndrome, a familial hyperbilirubinemia disorder, and correlate with irinotecan-induced diarrhea and neutropenia.¹¹³

Based on these studies, the addition of irinotecan to fluorouracil plus leucovorin (IFL) has been proved to increase survival when compared to fluorouracil plus leucovorin in the first-line treatment of metastatic colorectal cancer. These data support the current consensus that the three-drug treatment regimen be considered a first-line option for metastatic colorectal cancer. Accordingly, irinotecan received approval from the FDA in 2000 as first-line therapy for metastatic colorectal cancer in combination with fluorouracil and leucovorin. The use of fluorouracil plus leucovorin without irinotecan is appropriate as first-line therapy when a less-toxic regimen is desirable, especially for patients with a poor performance status.

8 ■ Fluorouracil and Leucovorin Plus Oxaliplatin. Oxaliplatin, a 1,2-diaminocyclohexane platinum carrier ligand with a mechanism of action similar to cisplatin, in combination with infusional fluorouracil plus leucovorin, is approved by the FDA for use in first-line and salvage regimens for metastatic colorectal cancer (see Table 127–13). Oxaliplatin differs from cisplatin in that the DNA damage induced by oxaliplatin may not be as easily recognized by the DNA MMR complex.¹¹⁴ Thus oxaliplatin-induced DNA damage may play a particularly important role in colorectal cancers that are associated with defects in MMR genes, as are prevalent in HNPCC. Oxaliplatin's incorporation into fluorouracil-based regimens as first-line therapy for metastatic colorectal cancer is associated with higher response rates and improved progression-free survival and variable effects on OS. A comparison of the de Gramont regimen, with or without oxaliplatin 85 mg/m² as a 2-hour infusion on day 1 (FOLFOX4 regimen), was designed to evaluate progression-free survival as a primary end point in 420 previously untreated patients with metastatic disease.¹⁰³ Tumor response (50.7% vs. 22.3%) and progression-free survival (median, 9 months vs. 6.2 months) were improved with oxaliplatin compared to fluorouracil plus leucovorin alone; an observed improvement in OS did not reach statistical significance (median, 16.2 months vs. 14.7 months). Although the three-drug regimen was associated with higher frequencies of grade 3 and 4 toxicities, primarily neutropenia, diarrhea, and neurosensory toxicity, they did not significantly impair quality of life.

Intergroup Trial N9741, a comparison of oxaliplatin plus fluorouracil and leucovorin (FOLFOX4) to weekly irinotecan plus IV bolus fluorouracil and leucovorin (IFL), and a combination of irinotecan plus oxaliplatin (IROX) in 795 patients with previously untreated metastatic colorectal cancer showed superior efficacy with

FOLFOX4.¹⁰¹ The IROX arm showed no advantage over either of the other two arms. Significant improvements in response rates, progression-free survival, and median survival were seen with FOLFOX4 compared to IFL (see Table 127–14).¹⁰¹ The study design allowed patients who failed either regimen to crossover to irinotecan or oxaliplatin, depending on their initial treatment assignment. Sixty percent of patients who failed FOLFOX4 received salvage irinotecan, whereas 24% of IFL failures received salvage oxaliplatin. The impact that this crossover had on survival is unknown, but may have resulted in an improvement in survival for the FOLFOX4 arm. In addition, the method of fluorouracil administration, and its impact on study results, has been called into question. Patients on the IFL arm received weekly IV bolus fluorouracil, while FOLFOX4 administered fluorouracil as IV bolus followed by continuous infusion IV, which is known to increase response rates. Therefore it is not possible to compare the true contributions of oxaliplatin and irinotecan combined with fluorouracil plus leucovorin in this study. The deletion of fluorouracil (or any fluorinated pyrimidine) from a first-line regimen may be undesirable.

In a phase III cooperative group study, a simplified combined bolus and infusional fluorouracil regimen with irinotecan (FOLFIRI) was compared to oxaliplatin combined with the same fluorouracil plus leucovorin schedule (FOLFOX6) in previously untreated patients with advanced colorectal cancer to determine whether the sequence of administration of both regimens differed with regard to efficacy and toxicities.⁹⁴ Patients were randomized to receive initial treatment with FOLFIRI or FOLFOX6, and at disease progression the patients then received the alternate regimen. Both sequences resulted in similar response rates, progression-free survival, and median survival, but the toxicity profiles were different. As first-line therapy, the incidence of grade 3 or 4 mucositis, nausea and vomiting, neutropenia, thrombocytopenia, fatigue, and alopecia were significantly more common with FOLFIRI, and neurologic toxicities were more common with FOLFOX6. The comparative toxicities of FOLFOX6 and FOLFIRI⁹⁴ are consistent with those in the comparison between FOLFOX4 and IFL,¹⁰¹ where neuropathy and neutropenia were more common with oxaliplatin, with diarrhea, nausea, vomiting, dehydration, and febrile neutropenia being more common with IFL.

The decreased toxicity profile may be a result of oxaliplatin's distinct toxicity profile as compared with other platinum drugs. Oxaliplatin has minimal renal toxicity, myelosuppression, and nausea and vomiting when compared to other platinum-based drugs. Oxaliplatin is associated with both acute and persistent neuropathies.¹¹⁵ The acute neuropathies occur with 1 to 2 days of dosing and resolve within 2 weeks. The neuropathies usually occur peripherally, but may also occur in the jaw and tongue. A rare acute syndrome of pharyngolaryngeal dysesthesia (1% to 2% of patients) is characterized by subjective sensations of difficulty in swallowing and shortness of breath. Overall, acute neuropathies occur in approximately 90% of patients, and are precipitated or exacerbated by exposure to cold temperatures or cold objects. Therefore patients should be instructed to avoid cold drinks and use of ice, and to cover skin before exposure to cold or cold objects. Several prophylactic and treatment strategies have been studied with varying degrees of success. Carbamazepine, gabapentin, amifostine, and calcium and magnesium infusions have been used to both prevent and treat oxaliplatin-induced neuropathies. Persistent neuropathy is typically a cumulative adverse effect, occurring after 8 to 10 cycles, and is seen mostly in patients who are responding to therapy.¹⁰¹ The neuropathy is characterized by paresthesias, dysesthesias, and hypoesthesias, but may also include deficits in proprioception that can interfere with daily activities (e.g., writing, buttoning, swallowing, and difficulty walking due to impaired proprioception),

and occur in half of patients receiving oxaliplatin with infusional fluorouracil plus leucovorin, but usually resolve with dosage reductions or cessation of oxaliplatin therapy.¹¹⁵

CLINICAL CONTROVERSY

The results of N9741 have been debated between clinicians since their presentation. Whether an irinotecan-containing regimen (IFL or FOLFIRI) is still the standard of care for metastatic disease, or if it has been replaced by FOLFOX4 is an unanswered question. Most patients should receive irinotecan- and oxaliplatin-containing regimens at some point during treatment for their disease.

9 ■ **Capecitabine.** Capecitabine (Xeloda) is an oral, tumor-activated and tumor-selective fluoropyrimidine carbamate. Capecitabine is converted to fluorouracil through a three-step activation process, the final step being activation by thymidine phosphorylase, which is present in greatest concentrations at the tumor site. These activation steps lead to an approximate threefold increase in tumor and 1.4-fold increase in hepatic fluorouracil levels. Capecitabine has been compared to fluorouracil plus leucovorin as first-line therapy for metastatic colorectal cancer in two randomized phase III trials. In a pooled analysis of 1,207 patients randomized to capecitabine (1,250 mg/m² orally twice daily for 14 days, repeated every 3 weeks) or the Mayo Clinic regimen, tumor response to capecitabine was superior to that with fluorouracil plus leucovorin (25.7% vs. 16.7%).⁹⁰ Time to tumor progression and median survival, however, were no different. Hand-foot syndrome was more common with capecitabine, whereas grade 3 or 4 neutropenia and stomatitis was more common with fluorouracil plus leucovorin. The convenience of oral administration and different toxicity profile makes capecitabine a potentially useful alternative to IV fluorouracil regimens in the setting of metastatic disease. However, since the IV treatment arm in these comparative studies could be considered more toxic than the weekly IV fluorouracil plus leucovorin treatment schedule, it is premature to conclude that capecitabine is as efficacious and less toxic than all parenteral fluorouracil-based regimens. There is increasing evidence that infusional fluorouracil is superior to bolus administration, and that oral capecitabine may mimic this method of fluorouracil administration. These data, along with capecitabine's ease of administration, and data that irinotecan and oxaliplatin appear to have a greater effect when combined with infusional fluorouracil has led to capecitabine being evaluated as a replacement for infusional fluorouracil.

Both irinotecan and oxaliplatin have been combined with capecitabine and preliminary data suggest these combinations will be safe and effective in the initial treatment of metastatic colorectal cancer.^{100,116} The current FDA-approved indication for capecitabine is for use in metastatic colon cancer when therapy with a fluoropyrimidine alone is desired. Replacement of fluorouracil/leucovorin with capecitabine in other regimens is not currently approved, although longer follow-up of completed trials may prove capecitabine a suitable replacement for infusional fluorouracil in combination with irinotecan or oxaliplatin.

8 ■ **Biologic Therapy.** Bevacizumab (Avastin, rhu-MAb VEGF) is a recombinant, humanized monoclonal antibody that inhibits vascular endothelial growth factor (VEGF). Bevacizumab, in combination with intravenous fluorouracil-based chemotherapy, was approved by the FDA in 2004 for initial treatment of patients with

metastatic colorectal cancer. This represents the third available combination regimen for first-line treatment. Results from two randomized trials show increased benefit compared to chemotherapy alone. In a phase II study, patients were randomized to one of three arms: fluorouracil plus leucovorin given as the Roswell Park regimen alone (control), or chemotherapy combined with bevacizumab 5 mg/kg or 10 mg/kg, with bevacizumab administered as an IV infusion every 2 weeks until disease progression.¹¹⁷ Patients treated with bevacizumab 5 mg/kg responded significantly better than those treated with fluorouracil plus leucovorin alone, with a higher overall response rate (40% vs. 17%) and an increase in median survival (21.5 months vs. 13.8 months), respectively. Interestingly, for reasons unknown at this time, the 5-mg/kg group also had a better overall response than those who received bevacizumab 10 mg/kg.

A phase III trial of bevacizumab in combination with IFL as first-line therapy in patients with metastatic colorectal cancer has also been completed. Patients were randomized to receive IFL plus bevacizumab placebo or IFL plus bevacizumab 5 mg/kg every 2 weeks.⁹⁶ The addition of bevacizumab to IFL therapy resulted in an increase in median (15.6 vs. 20.3 months) and progression-free survival (6.24 vs. 10.6 months), as well as a higher response rate (34.7% vs. 44.9%) compared to IFL alone. The frequency of typical adverse effects associated with IFL chemotherapy was not increased with the addition of bevacizumab. Grade 3 hypertension was significantly increased in the bevacizumab group. The incidence of other safety concerns with bevacizumab, such as bleeding, thromboembolism, and proteinuria, were not increased in the bevacizumab group compared to placebo. The hypertension is easily managed with oral antihypertensive agents. The risk of gastrointestinal perforation was increased by the addition of bevacizumab to IFL, and patients complaining of abdominal pain associated with vomiting or constipation should be considered for this rare, but potentially fatal complication.

The results of this study show the relevance of angiogenesis as an important target for the treatment of metastatic colorectal cancer. Bevacizumab is currently being investigated in first-line and salvage treatment regimens in combination with other active agents, including oxaliplatin, capecitabine, and cetuximab. How the addition of bevacizumab to FOLFOX4 will compare to FOLFOX4 alone, or the other irinotecan-based combinations remains to be seen. Practitioners can select first-line treatment for metastatic colorectal cancer from among four currently approved treatments: oxaliplatin plus fluorouracil plus leucovorin; irinotecan plus fluorouracil plus leucovorin; bevacizumab plus fluorouracil-based chemotherapy; and capecitabine. Capecitabine may prove an appropriate substitute for intravenous fluorouracil in these combination regimens; fluorouracil plus leucovorin alone is also appropriate first-line treatment for those individuals for whom three-drug combination regimens are believed to be too toxic. Table 127–15 depicts current NCCN Practice Guidelines for treatment of advanced or metastatic colorectal cancer.

Investigational Approaches

■ **Chemotherapy.** Comparisons of fluorouracil-based regimens alone and in combination with other agents, including trimetrexate, raltitrexed, methotrexate, interferon- α , and N-(phosphonacetyl)-L-aspartate (PALA), have also been investigated in previously untreated patients with metastatic colorectal cancer.²⁸ Trimetrexate, raltitrexed, and methotrexate improve response rates and have small effects on progression-free intervals with minimal or no effect on overall survival. The addition of interferon- α or PALA to fluorouracil plus leucovorin increases toxicities and does not improve overall efficacy.

Table 127-15 is not available in digital format.

Pemetrexed, a multitargeted antifolate, and PTK787/ZK 222584, an oral tyrosine kinase VEGF receptor inhibitor, are among several agents that are in later phases of clinical trials.
