PHARMACOTHERAPY

A Pathophysiologic Approach

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The editors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the editors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

This book is sold with codes for access to an Online Learning Center and an e-book version of the text. This book is not returnable unless the shrink-wrap and the scratch-off coating on the codes are intact.

Please tell the authors and publisher what you think of this book by sending your comments to pharmacotherapy@mcgraw-hill.com. Please put the author and title of the book in subject line.

This book was set in Times Roman by TechBooks, Inc.

The editors were Michael Brown, Andrew Hall, Karen G. Edmonson, and Peter J. Boyle.

The production supervisor was Richard Ruzycka.

The text designer was Joan O'Connor.

The cover designer was Elizabeth Pisacreta.

Barbara Littlewood prepared the index.

RR Donnelley was printer and binder.

This book is printed on acid-free paper.

Cover images copyright © 1999 by Obi-Tabot Tabe. The images used on the cover and spine are taken from a 9' × 4-1/2' oil painting by Obi-Tabot Tabe, PharmD, a painter, graphic designer, scientific illustrator, and pharmacist. Dr. Tabe, originally from Cameroon, is a graduate of the University of Pittsburgh, School of Pharmacy. The painting incorporates the artist's impressions of concepts introduced in the pharmacy curriculum. The painting can be seen in the student lounge of Salk Hall at the university.

Cataloging-in-publication data is on file for this title at the Library of Congress.

Dedication

To those pharmacists who had the courage and perseverance to pioneer the development of the clinical practice of pharmacy.

To the contemporary pharmaceutical care practitioners who continue to expand their impact on patient outcomes and thereby serve as role models for their colleagues and students while clinging tenaciously to the highest standards of practice.

To our mentors, whose vision provided educational and training programs that encouraged our professional growth and challenged us to be innovators in our patient care, research, and educational endeavors.

To our faculty colleagues for their efforts and support for our mission to provide a comprehensive and challenging educational foundation for the clinical pharmacists of the future.

And finally to our families for the time that they have sacrificed so that this sixth edition would become a reality.

FOREWORD

Drug therapy often represents the best treatment for human diseases and illnesses, and the spectrum of effective medications continues to improve at a remarkable pace. This is likely to continue over the coming years, as our understanding of disease pathogenesis and molecular pharmacology rapidly expands, fueling the discovery of new classes of medication. This, coupled with impressive advances in technology and our understanding of the human genome, promises to usher in a new wave of targeted therapies and individualized medicine that may further improve the efficacy and reduce the toxicity of medications. However, most of the highly effective medications currently available for clinical use emerged from classical pharmacology and chemistry, on a foundation of incomplete knowledge of disease mechanisms. This may contribute in part to the propensity of many medications to produce adverse drug effects or to exhibit limited efficacy in a subset of patients with a given diagnosis. These imperfect medications will remain the mainstay of therapeutics for years to come.

The limited efficacy and potential toxicity of many of today's medications, coupled with the rapidly expanding portfolio of medications for disease treatment and prevention, creates enormous complexity in selecting optimal medications for individual patients. Thus, the expertise of clinically educated and trained pharmacists is increasingly important if we are to ensure patients receive the most effective medications in the doses and combinations that are optimal for them and their illnesses.

The sixth edition of *Pharmacotherapy: A Pathophysiologic Approach* contains a wealth of information that will be an invaluable resource to students and practitioners who work to expand their knowledge of pharmacotherapy and translate it into better drug therapy for individual patients. In a perfect world, every patient would benefit from the collective talents of a health care team that is fully able to integrate knowledge of disease pathogenesis and pharmacotherapy, thereby optimizing drug therapy for each individual. Such a team is incomplete without a clinical pharmacist.

How many clinical pharmacists does it take in this day and age? Can one justify 25 pharmacists for a 58-bed hospital? That's the reality at St. Jude Children's Research Hospital, where I have worked for the last 25 years. And this wasn't even seriously challenged when the "health care consultants" rolled into town 10 years ago. Why not? The reasons are multiple, yet simple in the end: Pharmacists are integrally involved in the pharmacotherapy of every patient. The medical staff would not have it any other way, and the patients deserve no less. That's as it should be everywhere, in hospitals and clinics and community pharmacies. Moreover, pharmacists have become integral to the process of defining the future state of pharmacotherapy, by bringing unique expertise to the research enterprise. That must continue as well. The pharmacists of the present and future must integrate pharmacology, pathophysiology, therapeutics, and, increasingly, genetics into complex treatment decisions.

Pharmacotherapy: A Pathophysiologic Approach is an important tool to this end. By providing pharmacy students and practicing pharmacists (plus physicians and nurses) with a comprehensive and definitive source of information about diseases and their drug treatment, it is a conduit to the clinical use of pharmacotherapeutic principles by pharmacists, which is the *sine qua non* of pharmacy practice in the twenty-first century.

Health care in the United States and other developed countries has made great progress in recent decades, yet there are many opportu-

nities to improve the way these advances are deployed, especially drug therapy. Studies have shown that even when there are clear guidelines for appropriate use of medications for specific diseases, too many patients receive suboptimal drug therapy for too long. This is caused in part by far more drug therapy choices than most clinicians can master and also by aggressive marketing—to physicians, pharmacists, and directly to consumers—which can inappropriately shape prescribing habits. Who is to intervene in the name of rational therapeutics? The well-armed pharmacist, for one!

Reality is even more alarming when one also considers adverse drug effects. A 2000 Institute of Medicine (IOM) report documented that adverse drug effects are common in the United States, representing the sixth leading cause of death according to published meta-analyses. This is staggering news. Yet even if overstated by 100% it is an enormous concern for patients. Pharmacists must intervene and make definitive strides to reduce the adverse effects of medications, and they must be armed with pharmacotherapeutic knowledge and given time in their clinical practice to do so. This textbook serves as a source of such knowledge for those who are devoted to this end, whether they are matriculating toward their pharmacy degree or striving to advance their contributions in a busy clinical practice.

A 2001 IOM report documented a substantial gap in health care between those who receive the best and those who receive the average in health care in the United States. Recent studies have also documented that when patients exceed their cap in prescription drug coverage, they often discontinue medications or take fewer doses of prescribed therapy, even when adverse consequences can result if chronic diseases are left untreated. The cost-consequences of inadequate prescription drug coverage may well exceed the cost-savings of capping or limiting prescription drug benefits.

How might pharmacists change this equation for the better? Perhaps one approach would be to avoid the use of unnecessarily expensive medications when less expensive medications are equally effective. Another would be to help minimize the adverse economic and health care impact of adverse drug effects. The pages of this text are filled with information that could simultaneously translate into greater efficacy, lower toxicity, and more cost-effective use of medications. Pharmacists who translate this knowledge to everyday treatment decisions can play a vital role in showing not only that the best drug therapy can be safe and cost-effective, but that it does not always require the newest medication on the market. This will require a wealth of knowledge and determination by pharmacists, if they are to offset the power of marketing prescription drugs to prescribers and directly to the public. *Pharmacotherapy: A Pathophysiologic Approach* is a comprehensive scholarly effort by leading practitioners and educators who have created a definitive and unbiased resource that is based on a wealth of clinical experience and academic expertise. It offers a solid foundation for the education of future clinicians and for the practice of pharmacotherapy today, loaded with ammunition to fight the forces of irrational prescribing.

William E. Evans, PharmD
Professor of Pharmacy and Pediatrics
University of Tennessee Colleges of Pharmacy and Medicine
Director and CEO
St. Jude Children's Research Hospital
Memphis, Tennessee

FOREWORD TO THE FIRST EDITION

Evidence of the maturity of a profession is not unlike that characterizing the maturity of an individual; a child's utterances and behavior typically reveal an unrealized potential for attainment, eventually, of those attributes characteristic of an appropriately confident, independently competent, socially responsible, sensitive, and productive member of society.

Within a period of perhaps 15 or 20 years, we have witnessed a profound maturation within the profession of pharmacy. The utterances of the profession, as projected in its literature, have evolved from mostly self-centered and self-serving issues of trade protection to a composite of expressed professional interests that prominently include responsible explorations of scientific/technological questions and ethical issues that promote the best interests of the clientele served by the profession. With the publication of *Pharmacotherapy: A Pathophysiologic Approach*, pharmacy's utterances bespeak a matured practitioner who is able to call upon unique knowledge and skills so as to function as an appropriately confident, independently competent pharmacotherapeutics expert.

In 1987, the Board of Pharmaceutical Specialties (BPS), in denying the petition filed by the American College of Clinical Pharmacy (ACCP) to recognize "clinical pharmacy" as a specialty, conceded nonetheless that the petitioning party had documented in its petition a specialist who does in fact exist within the practice of pharmacy and whose expertise clearly can be extricated from the performance characteristics of those in general practice. A refiled petition from ACCP requests recognition of "pharmacotherapy" as a Specialty Area of Pharmacy Practice. While the BPS had issued no decision when this book went to press, it is difficult to comprehend the basis for a rejection of the second petition.

Within this book one will find the scientific foundation for the essential knowledge required of one who may aspire to specialty practice as a pharmacotherapist. As is the case with any such publication, its usefulness to the practitioner or the future practitioner is limited to providing such a foundation. To be socially and professionally responsible in practice, the pharmacotherapist's foundation must be continually supplemented and complemented by the flow of information appearing in the primary literature. Of course this is not unique to the general or specialty practice of pharmacy; it is essential to the fulfillment of obligations to clients in any occupation operating under the code of professional ethics.

Because of the growing complexity of pharmacotherapeutic agents, their dosing regimens, and techniques for delivery, pharmacy is obligated to produce, recognize, and remunerate specialty practitioners who can fulfill the profession's responsibilities to society for service expertise where the competence required in a particular case exceeds that of the general practitioner. It simply is a component of our covenant with society and is as important as any other facet of that relationship existing between a profession and those it serves.

The recognition by BPS of pharmacotherapy as an area of specialty practice in pharmacy will serve as an important statement by the profession that we have matured sufficiently to be competent and

willing to take unprecedented responsibilities in the collaborative, pharmacotherapeutic management of patient-specific problems. It commits pharmacy to an intention that will not be uniformly or rapidly accepted within the established health care community. Nonetheless, this formal action places us on the road to an avowed goal, and acceptance will be gained as the pharmacotherapists proliferate and establish their importance in the provision of optimal, cost-effective drug therapy.

Suspecting that other professions in other times must have faced similar quests for recognition of their unique knowledge and skills I once searched the literature for an example that might parallel pharmacy's modern-day aspirations. Writing in the *Philadelphia Medical Journal*, May 27, 1899, D. H. Galloway, MD, reflected on the need for specialty training and practice in a field of medicine lacking such expertise at that time. In an article entitled "The Anesthetizer as a Specialty," Galloway commented:

The anesthetizer will have to make his own place in medicine: the profession will not make a place for him, and not until he has demonstrated the value of his services will it concede him the position which the importance of his duties entitles him to occupy. He will be obliged to define his own rights, duties and privileges, and he must not expect that his own estimate of the importance of his position will be conceded without opposition. There are many surgeons who are unwilling to share either the credit or the emoluments of their work with anyone, and their opposition will be overcome only when they are shown that the importance of their work will not be lessened, but enhanced, by the increased safety and dispatch with which operations may be done. . . .

It has been my experience that, given the opportunity for one-on-one, collaborative practice with physicians and other health professionals, pharmacy practitioners who have been educated and trained to perform at the level of pharmacotherapeutics specialists almost invariably have convinced the former that "the importance of their work will not be lessened, but enhanced, by the increased safety and dispatch with which" individualized problems of drug therapy could be managed in collaboration with clinical pharmacy practitioners.

It is fortuitous—the coinciding of the release of *Pharmacotherapy: A Pathophysiologic Approach* with ACCP's petitioning of BPS for recognition of the pharmacotherapy specialist. The utterances of a maturing profession as revealed in the contents of this book, and the intraprofessional recognition and acceptance of a higher level of responsibility in the safe, effective, and economical use of drugs and drug products, bode well for the future of the profession and for the improvement of patient care with drugs.

Charles A. Walton, PhD
San Antonio, Texas

PREFACE

Pharmacists and other health care professionals who evaluate, design, and recommend pharmacotherapy for the management of their patients face many new and exciting challenges in these early years of the twenty-first century. As we complete our work on the sixth edition of *Pharmacotherapy: A Pathophysiologic Approach*, we recognize just how much our tasks as editors have become equally complicated, trying to balance the need to provide accurate, thorough, and unbiased information about the treatment of diseases against the hard publishing realities of deadlines, word counts, and book length. We thus strive to keep foremost in our minds the precepts that first led us to embark on this endeavor:

- Advance the quality of patient care through optimal medication management based on sound pharmacotherapeutic principles.
- Stimulate the student to achieve higher levels of learning.
- Motivate young practitioners to enhance the breadth, depth, and quality of care they can provide to each of their patients.
- Challenge established pharmacists and other primary-care providers to learn the new concepts and refine their understanding of the basic tenets of pathophysiology and therapeutics.
- Inform the pharmacy and medical communities about the standards of medication therapy management toward which we all should strive and which all patients will one day expect and, yes, demand.

While our emphasis in past editions has been on how to incorporate diseases that were previously untreatable with pharmacologic agents, new features in this sixth edition are focused more on the realities of teaching entry-level doctor of pharmacy students and meeting their postgraduate needs. We have incorporated a number of new pedagogical devices into chapters that will enable students and practitioners to more quickly grasp the important concepts and find related passages in the text. The addition of more features to disease-oriented chapters and the inclusion of more design elements give this edition a striking new look:

- Key concepts are listed at the beginning of each chapter and are identified in the text with numbered icons so that the reader can jump to the material of interest.
- The most common signs and symptoms of diseases as manifested in typical patients are presented in highlighted Clinical Presentation tables in disease-specific chapters.
- Clinical controversies in treatment or patient management are highlighted in shaded boxes to assure that the reader is aware of these issues and how practitioners are responding to them.
- Each chapter has about 100 of the most important and current references relevant to each disease, with most published since 1997.
- For easy reference, abbreviations and acronyms and their meanings are presented at the end of each chapter.
- A glossary of the medical terms used throughout the text is tabulated and presented at the end of the book.

- Finally, the diagnostic flow diagrams, desired outcomes of treatment, dosing guidelines, monitoring approaches, and treatment algorithms that were present in the fifth edition have been refined.

This edition includes two new chapters: Documentation of Pharmacy Services, which addresses the critical need for pharmacists to record their medication therapy management interventions, and Solid-Organ Transplantation, which combines material that was previously spread throughout several organ-specific chapters.

Before writing for this edition began, each editor read chapters from other editors' sections and made suggestions for enhancement. During editing, we reviewed each passage of text—and the references cited—for continued relevance and accuracy. We made deletions, asked authors to summarize concepts more succinctly or use tables to present details more concisely, included new medications as they entered the U.S. market or emerged in other countries, and updated references. This process continued as the book entered production, and even during the review of final proofs, we continued to make changes to ensure that this book is as current and complete as is possible.

Standard formats have remained relatively unchanged since the first edition of *Pharmacotherapy*. When seeking information in the disease-oriented chapters, users will find these sections: Key Concepts, Epidemiology, Etiology, Pathophysiology, Clinical Presentation (including diagnostic considerations), Treatment (including desired outcomes, general approaches, nonpharmacologic therapy, pharmacologic therapy, and pharmacoeconomic considerations), and Evaluation of Therapeutic Outcomes.

As the world increasingly relies on electronic means of communication, we are committed to keeping *Pharmacotherapy* and its companion works, *Pharmacotherapy Casebook: A Patient-Focused Approach* and *Pharmacotherapy Handbook*, integral components of clinicians' toolboxes. With the launch of this edition the Web site with unique features designed to benefit students, practitioners, and faculty that was initiated with the fifth edition has been extensively expanded. One can now find learning objectives and self-assessment questions for each chapter on the site.

In closing, we also stop once again to acknowledge the many hours that *Pharmacotherapy's* 200 authors contributed to this labor of love. Without their devotion to the cause of improved pharmacotherapy and dedication in maintaining the accuracy, clarity, and relevance of their chapters, this text would unquestionably not be possible. In addition, we thank Michael Brown and his colleagues at McGraw-Hill—especially Jack Farrell, Marty Wonsiewicz, and Peter Boyle—for their consistent support of the *Pharmacotherapy* family of resources, insights into trends in publishing and higher education, and the necessary and critical attention to detail so necessary in a book such as this one.

Associate Professor of Pharmacy, Vice Chair for Education, Virginia Commonwealth University, Richmond, Virginia
Chapters 69 and 70

Leroy C. Knodel, PharmD

Director of Drug Information Service and Associate Professor, Department of Pharmacology, University of Texas Health Sciences Center at San Antonio, Clinical Associate Professor, College of Pharmacy, University of Texas at Austin, Austin, Texas
Chapter 115

Jill M. Kolesar, PharmD, BCPS

Associate Professor, University of Wisconsin School of Pharmacy, Faculty Supervisor-Analytical Instrumentation Laboratory, Madison, Wisconsin
Chapter 128

Connie K. Kraus, PharmD, BCPS

Clinical Associate Professor of Pharmacy, University of Wisconsin School of Pharmacy, Madison, Wisconsin
Chapter 76

Abhijit V. Kshirsagar, MD, MPH

Assistant Professor of Medicine, University of North Carolina at Chapel Hill, Attending Physician UNC Hospitals, Chapel Hill, North Carolina
Chapter 43

Vanessa J. Kumpf, PharmD, BCNSP

Clinical Specialist, Nutrishare, Inc, Elk Grove, California
Chapters 135 and 138

Janet L. Kwiatkowski, MD

Assistant Professor of Pediatrics, University of Pennsylvania School of Medicine, Attending Hematologist, Division of Hematology, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Chapter 100

Thomas E. Lackner, PharmD

Professor of Pharmacy and Clinical Pharmacist Specialist in Geriatrics, Institute for the Study of Geriatric Pharmacotherapy, Experimental and Clinical Pharmacotherapy, University of Minnesota, College of Pharmacy, Minneapolis, Minnesota
Chapter 83

Y. W. Francis Lam, PharmD

Associate Professor of Pharmacology and Medicine, Clinical Associate Professor of Pharmacy, Departments of Pharmacology and Medicine, University of Texas Health Science Center at San Antonio, San Antonio, Texas
Chapter 6

Alan H. Lau, PharmD, FCCP

Professor, University of Illinois at Chicago College of Pharmacy, Chicago, Illinois
Chapter 47

Helen L. Leather, B Pharm, BCPS

Clinical Assistant Professor, University of Florida, College of Pharmacy, Clinical Pharmacy Specialist, BMT/Leukemia, Shands at the University of Florida, Gainesville, Florida
Chapter 131

Mary W. Lee, PharmD, BCPS, FCCP

Dean and Professor of Pharmacy Practice, Midwestern University, Chicago College of Pharmacy, Downers Grove, Illinois
Chapters 81 and 82

Timothy S. Lesar, PharmD

Director of Pharmacy, Albany Medical Center, Department of Pharmacy, Albany, New York
Chapter 92

Stephanie M. Levine, MD

Professor of Medicine, Division of Pulmonary and Critical Care Medicine, University of Texas Health Science Center, San Antonio, Texas
Chapter 25

Peter A. LeWitt, MD

Professor of Neurology, Psychiatry and Behavioral Neurosciences, Wayne State University School of Medicine, Clinical Neuroscience Center-A Parkinson Foundation Center of Excellence, Southfield, Michigan
Chapter 57

Catherine I. Lindblad, PharmD

Assistant Clinical Specialist and Assistant Professor, Department of Experimental and Clinical Pharmacology, Institute for the Study of Geriatric Pharmacotherapy, University of Minnesota College of Pharmacy, Clinical Pharmacist Specialist in Geriatrics, Minneapolis Veterans Affairs Medical Center, Minneapolis, Minnesota
Chapter 8

Celeste M. Lindley, PharmD, BCPS, BCOP

Associate Professor, School of Pharmacy, University of North Carolina, Chapel Hill, North Carolina
Chapter 125

George E. MacKinnon, III, RPh, MS, PhD, FASHP

Adjunct Professor, Thunderbird, The Garvin School of International Management, Glendale, Arizona, Associate Medical Director, Center for Pharmaceutical Appraisal and Outcomes Research, Abbott Laboratories, Abbott Park, Illinois
Chapter 4

Neil J. MacKinnon, RPh, MS, PhD

Associate Professor and Merck Frosst Chair of Patient Health Management, Dalhousie University College of Pharmacy, Halifax, Canada
Chapter 4

Eugene H. Makela, PharmD, BCPP

Associate Professor, Department of Clinical Pharmacy, West Virginia University School of Pharmacy, Morgantown, West Virginia
Chapter 70

Michael Malkin, MD

Assistant Clinical Director, UCLA, Director, Juvenile Court Mental Health Services (Psychiatrist), Los Angeles County Department of Mental Health, Los Angeles, California
Chapter 61

Patricia A. Marken, BS Pharm, PharmD, FCCP, BCPP

Chair and Professor of Pharmacy Practice, Professor of Psychiatry, School of Pharmacy and Medicine, University of Missouri–Kansas City, Kansas City, Missouri

Chapters 60 and 62

Patricia L. Marshik, PharmD

Associate Professor, University of New Mexico, Health Sciences Center, Albuquerque, New Mexico

Chapter 29

Steven J. Martin, PharmD, BCPS, FCCM

Associate Professor and Director, Infectious Diseases Research Laboratory, University of Toledo College of Pharmacy, Toledo, Ohio

Chapter 111

Barbara J. Mason, PharmD

Professor and Vice Chair, Department of Pharmacy Practice, Idaho State University College of Pharmacy, Primary Care Clinical Pharmacist, Boise Veterans Affairs Medical Center, Boise, Idaho

Chapter 99

Todd W. Mattox, PharmD, BCNSP

Clinical Assistant Professor, Department of Pharmacy Practice, University of Florida, Clinical Assistant Professor, Department of Pharmacy Practice, Nova Southeastern College of Pharmacy, Coordinator, Nutrition Support Team, H. Lee Moffitt Cancer Center and Research Institute, Tampa, Florida

Chapter 137

Gary R. Matzke, PharmD, FCP, FCCP

Professor, Department of Pharmacy and Therapeutics, School of Pharmacy, Renal-Electrolyte Division, School of Medicine, University of Pittsburgh, Pittsburgh, Pennsylvania

Chapters 46, 48, and 51

J. Russell May, PharmD, FASHP

Clinical Professor, Department of Clinical and Administrative Pharmacy, University of Georgia College of Pharmacy, Pharmacist, Medical College of Georgia Health System, Augusta, Georgia

Chapter 93

Teresa C. McCarthy, MD, MS

Assistant Professor, Department of Family Medicine and Community Health, University of Minnesota Medical School, Minneapolis, Minnesota

Chapter 8

Jeannine Sue McCune, BSPHarm, PharmD

Assistant Professor, University of Washington, Seattle, Washington

Chapter 126

Timothy R. McGuire, PharmD, FCCP

Associate Professor, College of Pharmacy, University of Nebraska, Omaha, Nebraska

Chapter 132

Patrick J. Medina, PharmD, BCOP

Assistant Professor, University of Oklahoma College of Pharmacy, Oklahoma City, Oklahoma

Chapter 127

Sarah T. Melton, PharmD, BCPP

Consultant Pharmacist, Melton Healthcare Consulting, LLC, Lebanon, Virginia

Chapter 69

Renee-Claude Mercier, PharmD

Associate Professor of Pharmacy and Medicine, College of Pharmacy, University of New Mexico–Health Sciences Center, Albuquerque, New Mexico

Chapter 40

Giuseppe Micali, MD

Professor of Dermatology, Department of Dermatology, University of Catania, Catania, Italy

Chapters 95 and 96

Laura Boehnke Michaud, PharmD, BCOP

Clinical Pharmacy Specialist–Breast Oncology, Division of Pharmacy, University of Texas M.D. Anderson Cancer Center, Houston, Texas

Chapter 125

Gary Milavetz, PharmD

Associate Professor of Pharmacy and Assistant Head for Academic Affairs, Division of Clinical and Administrative Pharmacy, University of Iowa College of Pharmacy, Clinical Pharmacist, Pediatric Allergy and Pulmonary Division, University of Iowa Hospitals and Clinics, Iowa City, Iowa

Chapter 30

Patricia A. Montgomery, PharmD

Clinical Pharmacy Specialist, Mercy General Hospital, Sacramento, California

Chapter 39

Reginald H. Moore, MD

Assistant Professor, University of Texas Health Science Center at San Antonio, Department of Pediatrics, Hematology, Oncology, & Immunization, Associate Director of Regional Sickle Cell Program Christus Santa Rosa Children's Hospital, San Antonio, Texas

Chapter 101

Bruce A. Mueller, PharmD, FCCP, BCPS

Professor and Department Chair, Clinical Sciences Department, College of Pharmacy, University of Michigan, Ann Arbor, Associate Director, Department of Pharmacy Services University of Michigan Health Systems, Ann Arbor, Michigan

Chapter 42

Stuart Munro, MD

Chair, Department of Psychiatry, University of Missouri–Kansas City, School of Medicine, Assistant Medical Director, Western Missouri Mental Health Center, Kansas City, Missouri

Chapter 60

Maria Letizia Musumeci, MD, PhD

Dermatologist, Department of Dermatology, University of Catania, Catania, Italy

Chapter 95

Milap C. Nahata, MS, PharmD

Professor of Pharmacy, Pediatrics and Internal Medicine,
Division Chairman, Pharmacy Practice and Administration,
Ohio State University College of Pharmacy, Associate Director,
Department of Pharmacy, Ohio State University Medical Center,
Columbus, Ohio
Chapter 7

Jean M. Nappi, PharmD, FCCP, BCPS

Professor of Pharmacy and Clinical Sciences, College of Pharmacy,
Medical University of South Carolina Clinical Specialist, Cardiology,
Medical University of South Carolina, Charleston, South Carolina
Chapter 18

Merlin V. Nelson, PharmD, MD

Neurologist, Department of Neurology, Affiliated Community
Medical Center, Willmar, Minnesota
Chapter 57

Fenwick T. Nichols, III, MD, FACP

Professor of Neurology, Medical College of Georgia,
Augusta, Georgia
Chapter 52

Thomas D. Nolin, PharmD, PhD

Clinical Pharmacologist, Division of Nephrology and
Transplantation, Maine Medical Center, Portland, Maine
Chapter 46

Mary Beth O'Connell, PharmD, BCPS, FCCP, FSHP

Associate Professor, Department of Pharmacy Practice, Wayne State
University, Eugene Applebaum College of Pharmacy and Health
Sciences, Detroit, Michigan
Chapter 88

Dennis R. Ownby, MD

Professor of Pediatrics and Internal Medicine, Head, Section of
Allergy and Immunology, Medical College of Georgia,
Augusta, Georgia
Chapter 86

Manjunath P. Pai, PharmD, BCPS

Assistant Professor, University of New Mexico College of Pharmacy,
Albuquerque, New Mexico
Chapter 40

Paul M. Palevsky, MD

Professor of Medicine, University of Pittsburgh School of Medicine,
Chief, Renal Section, VA Pittsburgh Healthcare System,
Pittsburgh, Pennsylvania
Chapter 51

James Paparello, MD

Clinical Assistant Professor, Feinberg School of Medicine,
Northwestern University, Evanston, Illinois
Chapter 43

Robert B. Parker, PharmD, FCCP

Associate Professor, Department of Pharmacy, University of
Tennessee, College of Pharmacy, Memphis, Tennessee
Chapter 14

Alkesh D. Patel, MD

Clinical Assistant Professor, University of Maryland, Baltimore
School of Medicine, Baltimore, Maryland, Family Physician,
University Care at Shipley's Choice, Millersville, Maryland
Chapter 79

J. Herbert Patterson, PharmD, FCCP, BCPS

Associate Professor of Pharmacy and Research Associate Professor
of Medicine, University of North Carolina at Chapel Hill, School of
Pharmacy, Chapel Hill, North Carolina
Chapter 14

Steven Z. Pavletic, MD

Principal Investigator, National Cancer Institute, Head,
Graft-versus-Host and Autoimmunity Unit, National Cancer Institute,
Bethesda, Maryland
Chapter 132

Charles A. Peloquin, PharmD

Adjoint Professor of Pharmacy and Medicine, University of Colorado,
Denver, Director, Infectious Disease Pharmacokinetics Laboratory,
National Jewish Medical and Research Center, Denver, Colorado
Chapter 110

Susan L. Pendland, MS, PharmD

Associate Professor, Section of Infectious Diseases Pharmacotherapy,
Department of Pharmacy Practice, University of Illinois at Chicago,
College of Pharmacy, Chicago, Illinois
Chapter 108

Janelle B. Perkins, PharmD, BCPS

Assistant Professor, College of Medicine, University of Florida,
Manager, BMT Clinical Research H. Lee Moffitt Cancer Center &
Research Institute, Tampa, Florida
Chapter 134

Jay I. Peters, MD

Professor of Medicine, Division of Pulmonary Diseases and Critical
Care Medicine, University of Texas Health Science Center at
San Antonio, San Antonio, Texas
Chapter 25

William P. Petros, PharmD

Mylan Chair of Pharmacology, Associate Professor of Pharmacy and
Medicine, West Virginia University Health Sciences Center,
Associate Director for Anti-Cancer Drug Development, MRB/WVU
Cancer Center, Morgantown, West Virginia
Chapter 98

Stephanie J. Phelps, PharmD, FCCP

Professor, Departments of Pharmacy and Pediatrics, Vice-Chair,
Professional Experiential Program, The University of Tennessee
Health Science Center, Director, Pharmacokinetics Service,
LeBonheur Children's Medical Center, Memphis, Tennessee
Chapters 55 and 56

Denise Walbrandt Pigarelli, PharmD

Clinical Associate Professor of Pharmacy, School of Pharmacy,
University of Wisconsin-Madison, Clinical Pharmacy Specialist,
William S. Middleton Memorial VA Hospital,
Madison, Wisconsin
Chapter 76

L. Michael Posey, BS Pharm

President, PENS Pharmacy Editorial and News Services,
Athens, Georgia
Chapter 3

Beth E. Potter, MD

Assistant Professor, Department of Family Medicine, University of
Wisconsin–Madison, Madison, Wisconsin
Chapter 76

Randall A. Prince, PharmD

Professor, College of Pharmacy, University of Houston, Adjunct
Professor of Medicine, University of Texas M. D. Anderson Cancer
Center, Houston, Texas
Chapter 114

Marsha A. Raebel, PharmD, BCPS, FCCP

Pharmacotherapy Research Manager, Clinical Research Unit, Kaiser
Permanente of Colorado, Adjoint Associate Professor, University of
Colorado Health Sciences Center School of Pharmacy,
Aurora, Colorado
Chapter 40

Daniel W. Rahn, MD

President, Medical College of Georgia, Professor of Medicine and
Rheumatology, Medical College of Georgia Hospital and Clinics,
Augusta, Georgia
Chapter 91

Hengameh H. Raissy, PharmD

Research Assistant Professor of Pediatrics, Department of Pediatrics,
University of Mexico Health Sciences Center, Albuquerque,
New Mexico
Chapter 29

J. Laurence Ransom, MD, FAAP

Clinical Associate Professor of Pediatrics, University of
North Carolina at Chapel Hill, Medical Director, Neonatal Intensive
Care Unit, Moses Cone Health System, Greensboro,
North Carolina
Chapter 28

Charles A. Reasner, II, MD, FACE, FACP

Professor of Medicine, University of Texas Health Science Center at
San Antonio, Medical Director, Texas Diabetes Institute, San
Antonio, Texas
Chapter 72

Michael D. Reed, PharmD, FCCP, FCP

Professor of Pediatrics School of Medicine, Case Western Reserve
University, Director, Pediatric Clinical Pharmacology and
Toxicology, Rainbow Babies and Children's Hospital, Pediatric
Pharmacology Division, Cleveland, Ohio
Chapter 106

Pamela D. Reiter, PharmD, BCPS

Adjoint Assistant Professor, University of Colorado, School of
Pharmacy, Clinical Pharmacy Specialist, Pediatric ICU and Trauma,
Children's Hospital, Denver, Colorado
Chapters 136 and 137

John C. Rotschafer, PharmD

Professor, Experimental and Clinical Pharmacology, University of
Minnesota, Minneapolis, Minnesota
Chapter 105

Eric S. Rovner, MD

Associate Professor of Urology, Department of Urology, Medical
University of South Carolina, Charleston, South Carolina
Chapter 83

Maria I. Rudis, PharmD, ABAT, BCPS

Assistant Professor of Clinical Pharmacy and Clinical Emergency
Medicine, School of Pharmacy and Keck School of Medicine,
University of Southern California, Los Angeles, USC School of
Pharmacy, Director, Emergency Medicine and Critical Care
Pharmacy Residency Program, Los Angeles, California
Chapter 23

Michael J. Rybak, PharmD

Associate Dean for Research, Professor of Pharmacy and Medicine,
Director, Anti-Infective Research Laboratory, Eugene Applebaum
College of Pharmacy and Health Sciences, Wayne State University,
Detroit, Michigan
Chapter 103

Gordon S. Sacks, PharmD, BCNSP, FCCP

Clinical Associate Professor, University of Wisconsin Schools of
Pharmacy and Medicine, Nutrition Support Team Coordinator,
University of Wisconsin Hospital and Clinics,
Madison, Wisconsin
Chapter 136

John V. St. Peter, PharmD, BCPS

Associate Professor, Experimental and Clinical Pharmacology,
Division of Endocrinology, University of Minnesota College of
Pharmacy, Hennepin Center for Diabetes and Endocrinology,
Hennepin County Medical Center, Minneapolis, Minnesota
Chapter 140

Lisa A. Sanchez, PharmD

President, PE Applications, Highlands Ranch, Colorado
Chapter 1

Joseph J. Saseen, PharmD, FCCP, BCPS

Associate Professor of Clinical Pharmacy and Family Medicine,
University of Colorado Health Sciences Center,
Denver, Colorado
Chapter 13

Robert R. Schade, MD

Professor, Department of Medicine, Chief, Section of
Gastroenterology and Hepatology, Medical College of Georgia,
Augusta, Georgia
Chapters 32 and 34

Mark E. Schneiderhan, PharmD, BCPP

Clinical Assistant Professor, Department of Pharmacy Practice,
University of Illinois at Chicago, Pharmacist, Department of
Psychiatry, University of Illinois Medical Center, Chicago, Illinois
Chapter 60

Marieke Dekker Schoen, PharmD, BCPS

Clinical Associate Professor, Departments of Pharmacy Practice and
Medicine, Section of Cardiology, University of Illinois,
Chicago, Illinois
Chapter 17

Kristine S. Schonder, BS Pharm, PharmD

Assistant Professor, University of Pittsburgh School of Pharmacy,
Clinical Pharmacist, Thomas E. Starzl Transplantation Institute,
Pittsburgh, Pennsylvania
Chapter 87

Arthur A. Schuna, MS

Clinical Professor, University of Wisconsin School of Pharmacy,
Clinical Coordinator and Pharmacotheapist in Rheumatology,
William S. Middleton VA Medical Center, Madison, Wisconsin
Chapter 89

Rowenta N. Schwartz, PharmD, BCOP

Associate Professor, School of Pharmacy, University of Pittsburgh,
Pittsburgh, Pennsylvania
Chapter 133

Laura Scuderi, MD

Resident in Dermatology, Department of Dermatology, University of
Catania, Catania, Italy
Chapter 96

Terry L. Seaton, PharmD

Professor of Pharmacy Practice, St. Louis College of Pharmacy,
Clinical Pharmacist Faculty, Mercy Family Medicine,
St. Louis, Missouri
Chapter 88

Jeffrey J. Smith, MD

Associate Professor of Pediatrics (Clinical), University of Iowa
College of Medicine, University of Iowa Hospitals and Clinics,
Iowa City, Iowa
Chapter 30

Philip H. Smith, MD

Assistant Professor of Medicine, Medical College of Georgia,
Augusta, Georgia, Children's Medical Center of Georgia, VAH
Augusta, Augusta, Georgia
Chapter 93

Roger W. Sommi, Jr., BS Pharm, PharmD, FCCP, BCPP

Professor of Pharmacy Practice and Psychiatry, University of
Missouri Kansas City, Department of Pharmacy, Kansas City, MO
Chapter 62

Christine A. Sorkness, PharmD

Professor of Pharmacy and Medicine, University of
Wisconsin–Madison, Madison, Wisconsin
Chapter 26

Sarah A. Spinler, PharmD, FCCP

Associate Professor of Clinical Pharmacy, Philadelphia College of
Pharmacy, University of the Sciences in Philadelphia,
Philadelphia, Pennsylvania
Chapter 16

William J. Spruill, PharmD

Associate Professor, Department of Clinical and Administrative
Pharmacy, College of Pharmacy, University of Georgia,
Athens, Georgia
Chapter 36

Andy Stergachis, PhD, RPh

Professor, Departments of Epidemiology and Pharmacy, Northwest
Center for Public Health Practice, University of Washington, Seattle,
Washington
Chapter 9

James J. Stragand, MD, PhD, FACC, FACP

Attending Gastroenterologist, St. Charles Medical Center,
Bend, Oregon
Chapter 37

Deborah Ann Sturpe, PharmD, BCPS

Assistant Professor, University of Maryland School of Pharmacy,
Baltimore, Maryland
Chapter 79

Carol Taketomo, PharmD

Assistant Clinical Professor of Pharmacy Practice, University of
Southern California School of Pharmacy, Pharmacy Manager,
Children's Hospital of Los Angeles, Los Angeles, California
Chapter 7

Robert L. Talbert, PharmD, FCCP, BCPS

Professor, College of Pharmacy, University of Texas at Austin;
Professor, Departments of Medicine and Pharmacology, University of
Texas Health Science Center at San Antonio, Texas
Chapters 11, 15, 21, 22, and 73

A. Thomas Taylor, PharmD

Assistant Dean and Associate Department Head, University of
Georgia College of Pharmacy, Clinical Professor of Family Medicine,
Department of Family Medicine, Medical College of Georgia School
of Medicine, Augusta, Georgia
Chapter 35

Karen A. Theesen, PharmD, BCPP

Senior Regional Medical Scientist II, Research and Development,
GlaxoSmithKline, Minneapolis, Minnesota
Chapter 61

E. Gregory Thompson, MD

Affiliate Faculty, Department of Pharmacy Practice, Idaho State
University, Meridian, Idaho, Clinical Instructor of Medicine,
University of Washington, Seattle, Washington
Chapter 99

Edward G. Timm, PharmD, MS

Senior Clinical Pharmacy Specialist, Critical Care and Adjunct
Assistant Professor, Albany Medical Center Hospital and Albany
College of Pharmacy, Albany, New York
Chapter 37

Shelly D. Timmons, MD, PhD

Neurological Surgeon, Semmes-Murphey Neurologic and Spine
Institute, Memphis, Tennessee
Chapter 56

Margaret E. Tonda, PharmD

Director of Clinical Development, Alza Corp, Mountain View,
California
Chapter 130

John Mark Tovar, PharmD

Clinical Fellow in Pharmacy and Family Medicine, Departments of Pharmacy Practice and Community Health and Family Medicine, University of Florida, Gainesville, Florida
Chapter 74

Curtis L. Triplitt, PharmD, CDE, BCPS

Instructor, Department of Medicine, Division of Diabetes, Clinical Assistant Professor of Pharmacy, University of Texas Health Science Center at San Antonio, Texas
Chapter 72

Amy Wells Valley, PharmD, BCOP

Oncology Pharmacy Specialist and Senior Consultant, Pharmacy Healthcare Solutions, Grapevine, Texas, Clinical Assistant Professor, University of Texas College of Pharmacy, Austin, Texas
Chapter 124

Angie Veverka, BS, PharmD

Assistant Professor of Pharmacy, Wingate University School of Pharmacy, Wingate, North Carolina
Chapter 109

William E. Wade, PharmD, FASHP, FCCP

Professor of Pharmacy, College of Pharmacy, University of Georgia, Athens, Georgia
Chapter 36

Sherman Jay Weaver, PharmD, MPH

Manager, Health Information and Outcomes, ACS State HealthCare Solutions, Atlanta, Georgia
Chapter 102

Lynda S. Welage, PharmD, FCCP

Professor of Pharmacy and Associate Dean for Academic Affairs, University of Michigan College of Pharmacy, Clinical Pharmacist, Critical Care, Department of Pharmacy, University of Michigan Health System, Ann Arbor, Michigan
Chapter 33

Barbara G. Wells, PharmD, FASHP, FCCP, BCPP

Dean and Professor, School of Pharmacy, University of Mississippi, University, Mississippi
Chapters 67 and 70

Dennis P. West, PhD

Professor of Dermatology and Director, Dermatopharmacology Program, Department of Dermatology, Northwestern University, Chicago, Illinois
Chapters 95 and 96

Lee E. West, BS

Consultant Pharmacist, Department of Dermatology, Northwestern University, Chicago, Illinois
Chapters 95 and 96

Dennis M. Williams, PharmD, BCPS

Associate Professor, Division of Pharmacotherapy and Experimental Therapeutics, School of Pharmacy, University of North Carolina, Chapel Hill, Clinical Specialist, Pulmonary Disease, UNC Hospitals, Chapel Hill, North Carolina
Chapter 27

Dianne B. Williams, PharmD, BCPS

Clinical Assistant Professor, University of Georgia College of Pharmacy, Durg Information Specialist MCG Health, Inc, Augusta, Georgia
Chapter 32

Daniel M. Witt, PharmD

Adjoint Assistant Professor, University of Colorado School of Pharmacy, Manager, Clinical Pharmacy Services, Kaiser Permanente of Colorado Pharmacy Administration, Aurora, Colorado
Chapter 19

Jean F. Wyman, PhD, RN

Professor and Cora Medil Siehl Chair in Nursing Research, University of Minnesota School of Nursing, Minneapolis, Minnesota
Chapter 83

Jack A. Yanovski, MD, PhD

Head, Unit on Growth and Obesity, Developmental Endocrinology Branch, National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, Maryland
Chapter 75

Gary C. Yee, PharmD

Professor and Chair, Department of Pharmacy Practice, College of Pharmacy, University of Nebraska Medical Center, Omaha, Nebraska
Chapters 129 and 134

Sunshine J. Yocum, PharmD

Assistant Professor of Pharmacy Practice, Samford University McWhorter School of Pharmacy, Birmingham, Alabama
Chapter 139

William C. Zamboni, PharmD

Assistant Professor, Pharmaceutical Sciences and Medicine, University of Pittsburgh Schools of Pharmacy and Medicine, Assistant Member of Molecular Therapeutics and Drug Development Program, University of Pittsburgh Cancer Institute, Pittsburgh, Pennsylvania
Chapter 130

Mario Zeolla, PharmD

Assistant Professor of Pharmacy Practice, Albany College of Pharmacy, Patient Care Pharmacist, Eckerd Patient Care Center, Albany, New York
Chapter 19

George G. Zhanel, PharmD, PhD

Professor, Department of Medical Microbiology, University of Manitoba, Coordinator-Antibiotic Resistance Program, Department of Medicine, Health Sciences Centre, Microbiology Health Sciences Centre, Winnipeg, Canada
Chapter 107

Michael R. Zile, MD, FACC

Charles Ezra Daniel Professor of Medicine, Medical University of South Carolina, Director of MICU, Ralph H. Johnson Department of Veterans Affairs Medical Center, Charleston, South Carolina
Chapter 18

GUIDING PRINCIPLES OF PHARMACOTHERAPY

1. There should be a justifiable and documented indication for every medication that is used.
2. A medication should be used at the lowest dosage and for the shortest duration that is likely to achieve the desired outcome.
3. When a patient is adequately treated with a single drug, monotherapy is preferred.
4. Newly approved medications should be used only if there are clear advantages over older medications.
5. Whenever possible, the selection of a medication regimen should be based upon evidence obtained from controlled clinical trials.
6. The timing of drug administration should be considered as a possible influence on drug efficacy, adverse effects, and interactions with other drugs and food.
7. A medication regimen should be simplified as much as possible to enhance patient adherence.
8. A patient's perception of illness or the risks and benefits of therapy may affect adherence and treatment outcomes.
9. Careful observation of a patient's response to treatment is necessary to confirm efficacy, prevent, detect, or manage adverse effects, assess compliance, and determine the need for dosage adjustment or discontinuation of drug therapy.
10. A medication should not be given by injection when giving it by mouth would be just as effective and safe.
11. Before medications are used, lifestyle modifications should be made, when indicated, to obviate the need for drug therapy or to enhance pharmacotherapy outcomes.
12. Initiation of a drug regimen should be done with full recognition that a medication may cause a disease, sign, symptom, syndrome, or abnormal laboratory test.
13. When a variety of drugs are equally efficacious and equally safe, the drug that results in the lowest health care cost or is most convenient for the patient should be chosen.
14. When making a decision about drug therapy for individual patients, societal effects should be considered.
15. The possible reasons for failure of medication regimens include inappropriate drug selection, poor adherence, improper drug dose or interval, misdiagnosis, concurrent illness, interactions with foods or drugs, environmental factors, or genetic factors.

PHARMACOTHERAPY

A Pathophysiologic Approach

1

PHARMACOECONOMICS: PRINCIPLES,
METHODS, AND APPLICATIONS

Lisa A. Sanchez

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Pharmacoeconomics identifies, measures, and compares the costs and consequences of drug therapy to health care systems and society.
- 2 The perspective of a pharmacoeconomic evaluation is paramount because the study results will be highly dependent on the perspective selected.
- 3 Health care costs can be categorized as direct medical, direct nonmedical, indirect nonmedical, intangible, opportunity, and incremental costs.
- 4 Economic, humanistic, and clinical outcomes should be considered and valued using pharmacoeconomic methods, to inform local decision making whenever possible.
- 5 To compare various health care choices, economic valuation methods are used, including cost-minimization, cost-benefit, cost-effectiveness, and cost-utility analyses. These methods all provide the means to compare competing treatment options and are similar in the way they measure costs (dollar units). They differ, however, in their measurement of outcomes and expression of results.
- 6 In today's health care settings, pharmacoeconomic methods can be applied for effective formulary management, individual patient treatment, medication policy determination, and resource allocation.
- 7 When evaluating published pharmacoeconomic studies, the following factors should be considered: study objective, study perspective, pharmacoeconomic method, study design, choice of interventions, costs and consequences, discounting, study results, sensitivity analysis, study conclusions, and sponsorship.
- 8 Use of economic models and performance of pharmacoeconomic analyses on a local level both can be useful and relevant sources of pharmacoeconomic data when rigorous methods are employed, as outlined in this chapter.

Today's cost-sensitive health care environment has created a competitive and challenging workplace for clinicians. Competition for diminishing resources has necessitated that the appraisal of health care goods and services extends beyond evaluations of safety and efficacy and considers the economic impact of these goods and services on the cost of health care. A challenge for health care professionals is to provide quality patient care with minimal resources.

An interest in defining the *value* of medicine is a common thread that unites today's health care practitioners. With serious concerns about rising medication costs and consistent pressure to decrease pharmacy expenditures and budgets, clinicians/prescribers, pharmacists, and other health care professionals must answer the question, "What is the value of the pharmaceutical goods and services I provide?" *Pharmacoeconomics*, or the discipline of placing a value on drug therapy,¹ has evolved to answer this question.

Challenged to provide high-quality patient care in the least expensive way, clinicians have developed strategies aimed at containing costs. However, most of these strategies focus solely on determining the least expensive alternative rather than the alternative that

represents the best value for the money. The "cheapest" alternative—with respect to drug acquisition cost—is not always the best value for patients, departments, institutions, and health care systems.

Quality patient care must not be compromised while attempting to contain costs. The products and services delivered by today's health professionals should demonstrate *pharmacoeconomic value*, that is, a balance of economic, humanistic, and clinical outcomes. Pharmacoeconomics can provide the systematic means for this quantification. This chapter discusses the principles and methods of pharmacoeconomics and how they can be applied to clinical pharmacy practice and thereby how they can assist in the valuation of pharmacotherapy and other modalities of treatment in clinical practice.

PRINCIPLES OF PHARMACOECONOMICS

DEFINITIONS

- 1 *Pharmacoeconomics* has been defined as the description and analysis of the cost of drug therapy to health care systems and

society.² More specifically, pharmacoeconomic research is the process of identifying, measuring, and comparing the costs, risks, and benefits of programs, services, or therapies and determining which alternative produces the best health outcome for the resource invested.³ For most practitioners, this translates into weighing the cost of providing a pharmacy product or service against the consequences (outcomes) realized by using the product or service to determine which alternative yields the optimal outcome per dollar spent. This information can assist clinical decision makers in choosing the most cost-effective treatment options.⁴

There is a distinct relationship between pharmacoeconomics, outcomes research, and pharmaceutical care. Pharmacoeconomics is not synonymous with outcomes research. *Outcomes research* is defined more broadly as studies that attempt to identify, measure, and evaluate the results of health care services in general.⁵ Outcomes research is discussed further in Chapter 2. Pharmacoeconomics is a division of outcomes research that can be used to quantify the value of pharmaceutical care products and services. *Pharmaceutical care* has been defined as the responsible provision of drug therapy for the purposes of achieving definite outcomes.⁶ By accepting this as the paradigm or vision for our profession, pharmacy is accepting responsibility for managing drug therapy so that positive outcomes are produced.

Cost is defined as the value of the resources consumed by a program or drug therapy of interest. *Consequence* is defined as the effects, outputs, or outcomes of the program of drug therapy of interest. Consideration of both costs and consequences differentiates most pharmacoeconomic evaluation methods from traditional cost-containment strategies and drug-use evaluations.

PERSPECTIVES

2 Assessing costs and consequences—the value of a pharmaceutical product or service—depends heavily on the perspective of the evaluation. Common perspectives include those of the patient, provider, payer, and society. A pharmacoeconomic evaluation can assess the value of a product or service from single or multiple perspectives. However, clarification of the perspective is critical because the results of a pharmacoeconomic evaluation depend heavily on the perspective taken. For example, if comparing the value of alteplase (tissue plasminogen activator, or tPA) with that of streptokinase from a patient or societal perspective, tPA may be the best-value alternative because a 1% reduction in mortality rates is observed in this large population. Yet, from a small community hospital's perspective, streptokinase may represent a better value because it provides similar outcomes for less money. Once the perspective is clear, a full evaluation of the relevant costs and consequences can begin. Again, perspective is critical because the value placed on a treatment alternative will be dependent heavily on the point of view taken.

PATIENT PERSPECTIVE

Patient perspective is paramount because patients are the ultimate consumers of health care services. Costs from the perspective of patients are essentially what patients pay for a product or service, that is, the portion not covered by insurance. Consequences, from a patient's perspective, are the clinical effects, both positive and negative, of a program or treatment alternative. For example, various costs from a patient's perspective might include insurance copayments and out-of-pocket drug costs, as well as indirect costs, such as lost wages. This perspective should be considered when assessing the impact of

drug therapy on quality of life or if a patient will pay out-of-pocket expenses for a health care service.

PROVIDER PERSPECTIVE

Costs from the provider's perspective are the actual expense of providing a product or service, regardless of what the provider charges. Providers can be hospitals, managed-care organizations (MCOs), or private-practice physicians. From this perspective, direct costs such as drugs, hospitalization, laboratory tests, supplies, and salaries of health care professionals may be identified, measured, and compared. However, indirect costs may be of less importance to the provider. When making formulary management or drug-use policy decisions, the viewpoint of the health care organization should dominate.

PHARMACOECONOMIC CONTROVERSY

Surprisingly few providers are prepared to identify and measure their true economic costs. Charge data may be more readily available but usually are not reflective of the true costs of health care. Thus it can be challenging translating charges into costs. A cost-to-charge ratio may be useful in many instances. Additionally, a common proxy used for costs of medications is average wholesale price (AWP). However, realistically, there are no providers actually paying AWP for their drugs, and AWP therefore is not an accurate proxy for drug-cost data.

PAYER PERSPECTIVE

Payers include insurance companies, employers, or the government. From this perspective, costs represent the charges for health care products and services allowed, or reimbursed, by the payer. The primary cost for a payer is of a direct nature. However, indirect costs, such as lost workdays and decreased productivity, also may contribute to the total cost of health care to the payer. When insurance companies and employers are contracting with MCOs or selecting health care benefits for their employees, then the payer's perspective should be employed.

SOCIETAL PERSPECTIVE

The perspective of society is the broadest of all perspectives because it is the only one that considers the benefit to society as a whole. Theoretically, all direct and indirect costs are included in an economic evaluation performed from a societal perspective. Costs from this perspective include patient morbidity and mortality and the overall costs of giving and receiving medical care. An evaluation from this perspective also would include all the important consequences an individual could experience. In countries with nationalized medicine, society is the predominant perspective.

PHARMACOECONOMIC CONTROVERSY

Controversy surrounds the issue of study perspective. Many researchers assert that society is the only relevant and the most appropriate perspective from which to conduct a pharmacoeconomic analysis. However, in the United States, these studies can be very resource-intensive in terms of time and money. Further, organizations may need to focus solely from their own perspectives to obtain the data necessary to inform timely decision making.

TABLE 1–1. Example of Health Care Cost Categories

| Cost Category | Costs |
|-------------------------|---|
| Direct medical costs | Medications Supplies Laboratory tests Health care professionals’ time Hospitalization |
| Direct nonmedical costs | Transportation Food Family care Home aides |
| Indirect costs | Lost wages (morbidity) Income forgone due to premature death (mortality) |
| Intangible costs | Pain Suffering Inconvenience Grief |
| Opportunity costs | Lost opportunity Revenue forgone |

COSTS

3 Once a perspective is chosen, the costs and consequences associated with a given product or service may be identified and measured using pharmacoeconomic methods. A comparison of two or more treatment alternatives should extend beyond a simple comparison of drug acquisition costs. Health care costs or economic outcomes can be grouped into several categories: direct medical, direct nonmedical, indirect nonmedical, and intangible costs.⁷ Other costs often discussed in pharmacoeconomic evaluations include opportunity and incremental costs. Inclusion of these various cost categories, when appropriate, provides a more accurate estimate of the total economic impact of a health care program or treatment alternatives on a specific population, organization, or patient. Table 1–1 contains examples of these costs. Again, the costs that are identified, measured, and ultimately compared vary depending on the perspective.

DIRECT MEDICAL COSTS

Direct medical costs are the costs incurred for medical products and services used to prevent, detect, and/or treat a disease.⁷ Direct medical costs are the fundamental transactions associated with medical care that contribute to the portion of gross national product spent on health care. Examples of these costs include drugs, medical supplies and equipment, laboratory and diagnostic tests, hospitalizations, and physician visits. Direct medical costs can be subdivided into fixed and variable costs. Fixed costs are essentially “overhead” costs (e.g., heat, rent, electricity) that are not readily influenced at the treatment level and thus remain relatively constant. For this reason, they are often not included in most pharmacoeconomic analyses. Variable costs, which change as a function of volume, include medications, fees for professional services, and supplies. As more services are used, more funding must be used to provide them.

PHARMACOECONOMIC CONTROVERSY

Should personnel costs be considered fixed or variable costs? In a hospital setting, one might consider whether switching

from a drug that requires a three-times-daily versus once-daily administration truly saves time for health care personnel. Some argue that staffing is relatively constant and that such a change would not cause the hospital to reduce its overall personnel levels, whereas others maintain that such a change allows personnel to perform other activities that provide value. In times of *downsizing*, personnel often are viewed as variable costs by hospital administrators.

DIRECT NONMEDICAL COSTS

Direct nonmedical costs are any costs for nonmedical services that are results of illness or disease but do not involve purchasing medical services.⁷ These costs are consumed to purchase services other than medical care and include resources spent by patients for transportation to and from health care facilities, extra trips to the emergency department, child or family care expenses, special diets, and various other out-of-pocket expenses.

INDIRECT NONMEDICAL COSTS

Indirect nonmedical costs are the costs of reduced productivity (e.g., morbidity and mortality costs).^{7–9} Indirect costs are costs that result from morbidity and mortality and are an important source of resource consumption, especially from the perspective of the patient. Morbidity costs are costs incurred from missing work (i.e., lost productivity), whereas mortality costs represent the years lost as result of premature death. To estimate indirect costs, two techniques typically are used: (1) human capital (HC) and (2) willingness-to-pay (WTP) methods. The HC approach attempts to value morbidity and mortality (primarily wages and productivity) losses based on an individual’s earning capacity using standard labor wage rates.¹⁰ This approach raises an ethical dilemma because the value of a life is related directly to income. Using the WTP approach (contingent valuation), the indirect and intangible aspects of a disease can be valued. Patients are asked how much money they would be willing to spend to reduce the likelihood of illness.¹¹ However, the values obtained through this method may be unreliable because of the substantial differences in valuations of life that result from the subjective nature of this approach.

INTANGIBLE COSTS

Intangible costs are those of other nonfinancial outcomes of disease and medical care.⁷ Examples include pain, suffering, inconvenience, and grief, and these are difficult to measure quantitatively and impossible to measure in terms of economic or financial costs. In pharmacoeconomic analyses, frequently intangible costs are identified but not quantified formally.

OPPORTUNITY COSTS

Opportunity costs represent the economic benefit forgone when using one therapy instead of the next best alternative therapy.¹² Therefore, if a resource has been used to purchase a program or treatment alternative, then the opportunity to use it for another purpose is lost. In other words, opportunity cost is the value of the alternative that was forgone.

INCREMENTAL COSTS

Incremental costs represent the additional cost that a service or treatment alternative imposes over another compared with the additional effect, benefit, or outcome it provides.¹³ As medical interventions become increasingly intense, costs generally increase. However, the additional outcome gained per additional dollar spent generally decreases. At some point of increasing expenditures, there may be no additional benefits or even a reduction in outcome. Thus incremental costs are the extra costs required to purchase an additional unit of effect and provide another way to assess the pharmacoeconomic impact of a service or treatment option on a population.

CONSEQUENCES

4 Similar to costs, the outcomes or consequences of a disease and its treatment are an equally important component of pharmacoeconomic analyses. The manner in which consequences are quantified is a key distinction among pharmacoeconomic methods because the assessment of costs is relatively standard.

Like costs, the consequences (or outcomes) of medical care also can be categorized. One approach is to separate outcomes into three categories: economic, clinical, and humanistic. *Economic outcomes* are the direct, indirect, and intangible costs compared with the consequences of medical treatment alternatives.¹⁴ *Clinical outcomes* are the medical events that occur as a result of disease or treatment (e.g., safety and efficacy end points).¹⁴ *Humanistic outcomes* are the consequences of disease or treatment on patient functional status or quality of life along several dimensions (e.g., physical function, social function, general health and well-being, and life satisfaction).¹⁴ Assessing the economic, clinical, and humanistic outcomes (ECHO) associated with a treatment alternative provides a complete model for decision making.

POSITIVE VERSUS NEGATIVE CONSEQUENCES

These consequences (outcomes) can be further categorized as positive or negative. An example of a positive outcome is a desired effect of a drug (efficacy or effectiveness measure), possibly manifested as cases cured, life-years gained, or improved health-related quality of life (HRQOL). Since all drugs have adverse effects, negative consequences also can occur with their use. A negative outcome is an undesired or adverse effect of a drug, possibly manifested as a treatment failure, an adverse drug reaction (ADR), a drug toxicity, or even death. Pharmacoeconomic evaluations should include assessments of both types of outcomes. Evaluating only positive outcomes may be misleading because of the potential detriment and expense associated with negative outcomes. Thus the balancing of positive and negative consequences is important in any pharmacoeconomic evaluation.

INTERMEDIATE AND FINAL CONSEQUENCES

Consequences also can be discussed in terms of intermediate and final outcomes. Intermediate outcomes can serve as a proxy for more relevant final outcomes. For example, achieving a decrease in low-density lipoprotein cholesterol levels with a lipid-lowering agent is an intermediate consequence that may serve as a proxy for a more final outcome such as a decrease in myocardial infarction rate.¹⁵ Intermediate consequences are used commonly in clinical and pharmacoeconomic analyses as proxies predictive of final outcomes because their use reduces the cost and time required to conduct a trial.

PHARMACOECONOMIC CONTROVERSY

The challenge with using intermediate consequences of medical interventions lies in finding appropriate interim outcome indicators that can reliably predict the long-term effects of a program or treatment alternative.

METHODS OF PHARMACOECONOMICS

5 The pharmacoeconomic methods of evaluation are listed in Fig. 1–1. These methods or tools can be separated into two distinct categories: economic and humanistic evaluation techniques. These methods have been used in a variety of fields and are being applied increasingly to health care.¹⁶

ECONOMIC EVALUATION METHODS

The basic task of economic evaluation is to identify, measure, value, and compare the costs and consequences of the alternatives being considered. The two distinguishing characteristics of economic evaluation are as follows: (1) Is there a comparison of two or more alternatives? and (2) Are both costs and consequences of the alternatives examined?¹⁷ A full economic evaluation encompasses both characteristics, whereas a partial economic evaluation addresses only one. Pharmacoeconomic evaluations conducted in today's health care settings may be either partial or full economic evaluations.

Partial economic evaluations may include simple descriptive tabulations of outcomes or resources consumed and thus require a minimum of time and effort. If only the consequences or only the costs of a program, service, or treatment are described, the evaluation illustrates an outcome or cost description. A cost-outcome or cost-consequence analysis (CCA) describes the costs and consequences of an alternative but does not provide a comparison with other treatment options.¹⁵ Another partial evaluation is a cost analysis that compares the costs of two or more alternatives without regard to outcome.

Full economic evaluations include cost-minimization, cost-benefit, cost-effectiveness, and cost-utility analyses. Each method is used to compare competing programs or treatment alternatives. The methods are all similar in the way they measure cost (in dollars) and different in their measurement of outcomes. Although a full economic evaluation generally provides higher-quality and more useful information, the time, resources, and effort employed are also great. Thus health care practitioners and clinicians also find it necessary to employ various partial economic evaluations.

Application of economic evaluation methods to health care products and services, especially pharmaceuticals, may increase their acceptance by health care professionals and society.¹⁸ The methods used most commonly by health care practitioners are discussed in the next sections and summarized briefly in Table 1–2.

FIGURE 1–1. Components of pharmacoeconomics.

TABLE 1–2. Summary of Pharmacoeconomic Methodologies

| Method | Description | Application | Cost Unit | Outcome Unit |
|--------|--|--|-----------|-------------------------|
| COI | Estimates the cost of a disease on a defined population | Use to provide baseline to compare prevention/treatment options against | \$\$\$ | NA |
| CMA | Finds the least expensive cost alternative | Use when benefits are the same | \$\$\$ | Assume to be equivalent |
| CBA | Measures benefit in monetary units and computes a net gain | Can compare programs with different objectives | \$\$\$ | \$\$\$ |
| CEA | Compares alternatives with therapeutic effects measured in physical units; computes a C/E ratio | Can compare drugs/programs that differ in clinical outcomes and use the same unit of benefit | \$\$\$ | Natural units |
| CUA | Measures therapeutic consequences in utility units rather than physical units; computes a C/U ratio | Use to compare drugs/programs that are life extending with serious side effects or those producing reductions in morbidity | \$\$\$ | QALYs |
| QOL | Physical, social, and emotional aspects of patient's well-being that are relevant and important to the patient | Examines drug effects in areas not covered by laboratory or physiologic measurements | NA | QOL score |

Key: CBA, cost-benefit analysis; CEA, cost-effectiveness analysis; CMA, cost-minimization analysis; COI, cost-of-illness evaluation; CUA, cost-utility analysis; QOL, quality of life; QALY, quality-adjusted life-year.

COST-OF-ILLNESS EVALUATION

A cost-of-illness (COI) evaluation identifies and estimates the overall cost of a particular disease for a defined population.⁸ This evaluation method is often referred to as *burden of illness* and involves measuring the direct and indirect costs attributable to a specific disease. The costs of various diseases, including peptic ulcer disease, mental disorders, and cancer, in the United States have been estimated.

By successfully identifying the direct and indirect costs of an illness, one can determine the relative value of a treatment or prevention strategy. For example, by determining the cost of a particular disease to society, the cost of a prevention strategy could be subtracted from this to yield the benefit of implementing this strategy nationwide. COI evaluation is not used to compare competing treatment alternatives but to provide an estimation of the financial burden of a disease. Thus the value of prevention and treatment strategies can be measured against this illness cost. Various examples of COI studies are available in the literature, including the burden or cost of Alzheimer's disease.^{19,20}

COST-MINIMIZATION ANALYSIS

Cost-minimization analysis (CMA) involves the determination of the least costly alternative when comparing two or more treatment alternatives. With CMA, the alternatives must have an assumed or demonstrated equivalency in safety and efficacy (i.e., the two alternatives must be equivalent therapeutically). Once this equivalency in outcome is confirmed, the costs can be identified, measured, and compared in monetary units (dollars).

CMA is a relatively straightforward and simple method for comparing competing programs or treatment alternatives as long as the therapeutic equivalence of the alternatives being compared has been established. If no evidence exists to support this, then a more comprehensive method such as cost-effectiveness analysis should be employed. Remember, CMA shows only a "cost savings" of one program or treatment over another.²¹

Employing CMA is appropriate when comparing two or more therapeutically equivalent agents or alternate dosing regimens of the same agent.²¹ For example, if drugs A and B are antiulcer agents and have been documented as equivalent in efficacy and incidence of adverse drug reactions (ADRs), then the costs of using these drugs could be compared using CMA. These costs should extend beyond a comparison of drug acquisition costs and include costs of drug preparation (pharmacist and technician time), administration (nursing time), and storage. When appropriate, other costs to be valued may include the cost of physician visits, number of hospital days, and pharmacokinetic consultations. The least expensive agent, considering all these costs, should be preferred. This method has been used frequently, and its application could expand given the increasing number of "me too" products and generic competition in the pharmaceutical marketplace.²²

COST-BENEFIT ANALYSIS

Cost-benefit analysis (CBA) is a method that allows for the identification, measurement, and comparison of the benefits and costs of a program or treatment alternative. The benefits realized from a program or treatment alternative are compared with the costs of providing it. Both the costs and the benefits are measured and converted into equivalent dollars in the year in which they will occur.^{8,16} Future costs and benefits are discounted or reduced to their current value.

These costs and benefits are expressed as a ratio (a benefit-to-cost ratio), a net benefit, or a net cost. A clinical decision maker would choose the program or treatment alternative with the highest net benefit or the greatest benefit-to-cost (B/C) ratio.⁹ Guidelines for the interpretation of this ratio are indicated^{16,21,23}:

- If the B/C ratio is greater than 1, the program or treatment is of value. The benefits realized by the program or treatment alternative outweigh the cost of providing it.

- If the B/C ratio equals 1, the benefits equal the cost. The benefits realized by the program or treatment alternative are equivalent to the cost of providing it.
- If the B/C ratio is less than 1, the program or treatment is not economically beneficial. The cost of providing the program or treatment alternative outweighs the benefits realized by it.

CBA should be employed when comparing treatment alternatives in which the costs and benefits do not occur simultaneously. CBA also may be used when comparing programs with different objectives because all benefits are converted into dollars. CBA also can be used to evaluate a single program or compare multiple programs. However, valuing health benefits in monetary terms can be difficult and controversial. The expression of some health benefits as monetary units is neither appropriate nor widely accepted. Therefore, unless the benefits of a program or treatment alternative are expressed appropriately in dollars, CBA should not be employed.²¹

CBA may be an appropriate method to use in justifying and documenting the value of an existing health care service or the potential worth of a new one. For example, when a clinical pharmacy service is competing for institutional resources, CBA can provide data to document that the service yields a high return on investment compared with other institutional services competing for the same resources. However, the relative magnitude of the costs and benefits for the service must be considered when making this resource-allocation decision. If a service costs \$100 to implement and results in a benefit to the hospital of \$1000 and a service that costs \$100,000 to implement results in a benefit of \$1 million, both have a B/C ratio of 10.²¹ Thus caution should be exercised when using B/C ratios and CBA as a comparison tool.

Numerous examples of CBAs have been published in the literature recently.^{24–27} However, of all pharmacoeconomic evaluation methods, CBA is probably used the least. Although this method has the advantage of valuing indirect costs monetarily (using the HC and WTP approaches) and intangible benefits (using the WTP approach), the valuation of outcomes such as productivity and quality of life is difficult to perform reliably and meaningfully.^{10,28}

Because of difficulties in measuring indirect and intangible benefits, many CBAs measure and quantify direct costs and direct benefits only. Some researchers assert that these should not be considered “true” CBAs because they do not take into account the indirect costs and benefits.²⁸

COST-EFFECTIVENESS ANALYSIS

Cost-effectiveness analysis (CEA) is a way of summarizing the health benefits and resources used by competing health care programs so that policymakers can choose among them.¹⁷ CEA involves comparing programs or treatment alternatives with different safety and efficacy profiles. Cost is measured in dollars, and outcomes are measured in terms of obtaining a specific therapeutic outcome. These outcomes are often expressed in physical units, natural units, or non-dollar units (lives saved, cases cured, life expectancy, or drop in blood pressure).^{8,13,29}

The results of CEA are also expressed as a ratio—either as an average cost-effectiveness ratio (ACER) or as an incremental cost-effectiveness ratio (ICER). An ACER represents the total cost of a program or treatment alternative divided by its clinical outcome to yield a ratio representing the dollar cost per specific clinical outcome gained, independent of comparators. The ACER can be summarized as follows^{7,13,21}:

$$\text{ACER} = \frac{\text{health care costs (\$)}}{\text{clinical outcome (not in \$)}}$$

This allows the costs and outcomes to be reduced to a single value to allow for comparison. Using this ratio, the clinician would choose the alternative with the least cost per outcome gained.⁹ The most cost-effective alternative is not always the least costly alternative for obtaining a specific therapeutic objective. In this regard, cost-effectiveness need not be cost reduction but rather cost optimization.³⁰

Often clinical effectiveness is gained at an increased cost. Is the increased benefit worth the increased cost? Incremental CEA may be used to determine the additional cost and effectiveness gained when one treatment alternative is compared with the next best treatment alternative.⁷ Thus, instead of comparing the ACERs of each treatment alternative, the additional cost that a treatment alternative imposes over another treatment is compared with the additional effect, benefit, or outcome it provides. The ICER can be summarized as follows:

$$\text{ICER} = \frac{\text{cost}_A(\text{\$}) - \text{cost}_B(\text{\$})}{\text{effect}_A(\%) - \text{effect}_B(\%)}$$

This formula yields the additional cost required to obtain the additional effect gained by switching from drug A to drug B.

CEA is particularly useful in balancing cost with patient outcome, determining which treatment alternatives represent the best health outcome per dollar spent, and deciding when it is appropriate to measure outcome in terms of obtaining a specific therapeutic objective. In addition, CEA may provide valuable data to support drug policy, formulary management, and individual patient treatment decisions. Globally, CEA is being used to set public policies regarding the use of pharmaceutical products (national formularies) in countries such as Australia,³¹ New Zealand, and Canada.³² These countries, along with others, including Spain, the United Kingdom, Italy, and the United States, even have their own guidelines for conducting research.

PHARMACOECONOMIC CONTROVERSY

Which ratio is the right ratio to use in pharmacoeconomic analyses? Experts differ over which ratio, ACER or ICER, is the most appropriate and useful. ACER reflects the cost per benefit of a new strategy independent of other alternatives, whereas ICER reveals the cost per unit of benefit of switching from one treatment strategy (that already may be in place) to another.¹³

COST-UTILITY ANALYSIS

Pharmacoeconomists sometimes want to include a measure of patient preference or quality of life when comparing competing treatment alternatives. Cost-utility analysis (CUA) is a method for comparing treatment alternatives that integrates patient preferences and HRQOL. CUA can compare cost, quality, and the quantity of patient-years. Cost is measured in dollars, and therapeutic outcome is measured in patient-weighted utilities rather than in physical units. Often the utility measurement used is a quality-adjusted life year (QALY) gained. QALY is a common measure of health status used in CUA, combining morbidity and mortality data.³³

Results of CUA are also expressed in a ratio, a cost-utility ratio (C/U ratio). Most often this ratio is translated as the cost per QALY gained or some other health-state utility measurement.^{8,16} The preferred treatment alternative is that with the lowest cost per QALY (or other health-status utility). QALYs represent the number of full years at full health that are valued equivalently to the number of years as experienced. For example, a full year of health in a disease-free patient would equal 1.0 QALY, whereas a year spent with a specific disease might be valued significantly lower, perhaps as 0.5 QALY, depending on the disease.

CUA is the most appropriate method to use when comparing programs and treatment alternatives that are life extending with serious side effects (e.g., cancer chemotherapy),³⁴ those which produce reductions in morbidity rather than mortality (e.g., medical treatment of arthritis),^{30,35} and when HRQOL is the most important health outcome being examined. CUA is employed less frequently than other economic evaluation methods because of a lack of agreement on measuring utilities, difficulty comparing QALYs across patients and populations, and difficulty quantifying patient preferences. CUA is complex, and thus CUA may be limited in scope of application from a hospital or MCO perspective. Nevertheless, when comparing treatment alternatives where HRQOL is the most important health outcome being examined, CUA should be considered.

PHARMACOECONOMIC CONTROVERSY

Because QALYs and other utility measures are highly subjective, there is some disagreement among researchers regarding which scales should be preferred for measuring utility.

HUMANISTIC EVALUATION METHODS

Pharmacoeconomic evaluations also may focus on humanistic concerns. Methods for evaluating the impact of disease and treatment of disease on a patient's HRQOL, patient preferences, and patient satisfaction are all growing in popularity and application to pharmacotherapy decisions. These methods also can assist clinicians in quantifying the value of pharmaceuticals.

HRQOL has been defined as the assessment of the functional effects of illness and its consequent therapy as perceived by the patient.³⁶ These effects often are displayed as physical, emotional, and social effects on the patient.¹⁷ Measurement of HRQOL usually is achieved through the use of patient-completed questionnaires. Many questionnaires are available, and most are either disease-specific or generic measures of health status.^{37,38} Various overviews on HRQOL and its application to pharmacy have been published.^{15,38–41} For further discussion on health outcomes and HRQOL, refer to Chapter 2.

APPLICATIONS OF PHARMACOECONOMICS

Health care practitioners, regardless of practice setting, can benefit from applying the principles and methods of pharmacoeconomics to their daily practice settings. *Applied pharmacoeconomics* is defined as putting pharmacoeconomic principles, methods, and theories into practice to quantify the *value* of pharmacy products and pharmaceutical care services used in real-world environments. Today's practitioners increasingly are required to justify the value of the products and services they provide. Applied pharmacoeconomics can provide the means or tools for this valuation.

One of the primary applications of pharmacoeconomics in clinical practice today is to aid clinical and policy decision making. Through the appropriate application of pharmacoeconomics, practitioners and administrators can make better, more-informed decisions regarding the products and services they provide. Complete pharmacotherapy decisions should contain assessments of three basic outcome areas whenever appropriate: clinical, economic, and humanistic outcomes. Traditionally, most drug therapy decisions were based solely on the clinical outcomes (e.g., safety and efficacy) associated with a treatment alternative. Over the past 10 to 15 years, it has become quite popular also to include an assessment of the economic outcomes associated with a treatment alternative. The current trend is also to

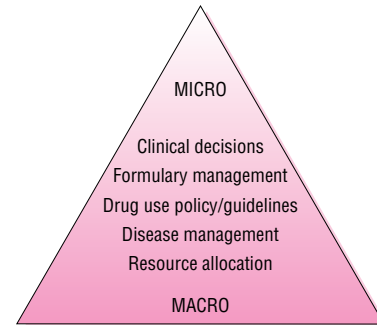

FIGURE 1-2. Decisions for pharmacoeconomic applications.

incorporate the humanistic outcomes associated with a treatment alternative, that is, to bring the patient back into this decision-making equation. This ECHO model for medical decision making has become **4** prevalent in current health care settings.¹⁴ In today's health care environment, it is no longer appropriate to make drug-selection decisions based solely on acquisition costs. Thus, through the appropriate application of pharmacoeconomic principles and methods, incorporating these three critical components into clinical decisions can be accomplished.

Pharmacoeconomic data can be a powerful tool to support various clinical decisions, ranging from the level of the patient to the **6** level of an entire health care system. Figure 1–2 shows various decisions that may be supported using pharmacoeconomics, including effective formulary management, individual patient treatment, medication policy, and resource allocation.^{13,21} For discussion purposes, the application of pharmacoeconomics to decision making is divided into two basic areas: drug therapy evaluation and clinical pharmacy service evaluation.

DRUG THERAPY EVALUATION

6 Historically, pharmacoeconomic principles and methods have been applied commonly to assist clinicians and practitioners in making more informed and complete decisions regarding drug therapy. For example, pharmacoeconomics can provide critical cost-effectiveness data to support the addition or deletion of a drug to or from a hospital formulary with or without restriction. In fact, the pharmacoeconomic assessment of formulary actions is becoming a standardized part of many pharmacy and therapeutic (P&T) committees.

Selecting the most cost-effective drugs for an organizational formulary is important. However, it is equally important to determine the most appropriate way to use and prescribe these agents. Hence, developing and implementing appropriate use guidelines or policies based on sound pharmacoeconomic data can have a great impact on influencing prescribing patterns. Further, implementing sound drug-use guidelines/policies will ensure the most appropriate and cost-effective use of pharmaceutical agents throughout the health care system.

The application of pharmacoeconomics also can be useful for making a decision about an individual patient's therapy. Evaluating the impact a drug has on a patient's HRQOL can be useful when deciding between two agents for customizing a patient's pharmacotherapy. Although this can be one of the most difficult applications of pharmacoeconomics, it is also one of the most important.

CLINICAL PHARMACY SERVICE EVALUATION

6 The most recent application of pharmacoeconomic principles and methods has been for justifying the value of various health

care services, particularly pharmacy services. When a specific service is competing for hospital resources, pharmacoeconomics can provide the data necessary to justify that the service maximizes the resources allocated by health care system administrators. Pharmacoeconomics can be useful in determining the value of an existing service, estimating the potential worth of implementing a new service, or capturing the value of a “cognitive” clinical intervention. Practitioners and administrators can then use these data to make more informed resource-allocation decisions.

For example, suppose you want to implement a pharmacy-based therapeutic drug monitoring program. It is hypothesized that this service will improve quality of patient care and save money for the health care system. After negotiating with hospital administrators, the funding for this service is approved for a 1-year trial basis, after which you must document and justify the value of this practice. Theoretically, all the relevant costs and benefits of the program should be measured and, if appropriate, converted into dollars using CBA. Potential benefits may include decreased total drug costs and decreased incidence of ADRs. Potential program costs are primarily the salary and benefits for a pharmacist and additional laboratory tests to monitor patients. Data documenting that the benefit of this pharmacy service yields a high return on investment (ROI) should increase the probability of the program continuing to be funded by the health care system.

Unfortunately, previous reviews of the literature have revealed a disappointing number of rigorous economic evaluations of clinical pharmacy services published to date.^{42–44} However, a recently published review shows that the quality of published studies finally may be increasing.⁴⁵ For example, McGhan and colleagues⁴² evaluated 35 potential CBAs or CEAs of pharmacy services published before 1978 and concluded that only 5 of these studies were legitimate CBAs or CEAs. MacKeigan and Bootman⁴³ reviewed 22 CBAs or CEAs published between 1978 and 1987 and concluded that CBAs and CEAs have not been adopted extensively for the evaluation of clinical pharmacy services. In 1996, Schumock and associates⁴⁴ reviewed economic evaluations of pharmacy services published between 1988 and 1995. Of the studies reviewed, only 19 were considered “full” or legitimate economic analyses, and the authors concluded that although the number of articles published has increased over the years, there is still a need for improvement in the quality or rigor of study design. Despite the relatively low number of methodologically sound studies, this review also revealed some results that demonstrate the potential

value of clinical pharmacy services. Of the 109 studies evaluated, the various clinical services reviewed in this study yielded an average C/B ratio of 16:1. In 2003, these authors updated their review and included articles published from 1996 to 2000.⁴⁵ After reviewing 59 articles, these authors noted an improvement in the overall quality of the research (more studies included comparison groups and measured both costs and outcomes). Studies were conducted in hospital settings (52%), community pharmacies and clinics (41%), and community/clinic settings (18%). For the studies reporting the statistic, B/C ratios ranged from 1.74:1 to 17.01.⁴⁵

STRATEGIES TO INCORPORATE PHARMACOECONOMICS INTO PHARMACOTHERAPY

Various strategies are available to incorporate pharmacoeconomics into pharmacotherapy. Popular strategies for applying pharmacoeconomics to assess the value of pharmaceutical products and services include using the results of published pharmacoeconomic studies, building economic models, and conducting pharmacoeconomic research.⁴⁶ Advantages and disadvantages of these strategies are summarized in Table 1–3.

USE THE PHARMACOECONOMIC LITERATURE

7 Quantifying the value of pharmaceuticals through pharmacoeconomics has increased in popularity. Many pharmacoeconomic analyses are published in primary medical and pharmacy literature sources. Over the past 30 or more years, the actual number of pharmacoeconomic studies published exceeded 35,000 in 1993. However, the eagerness to conduct pharmacoeconomic evaluations of drugs often exceeds the quality of these evaluations. Variations in quality and indiscriminate use of pharmacoeconomic terminology are documented in medical and pharmacy literature sources.^{4,42–45,47–49} To use this literature as an aid in clinical decision making, it must be (1) critically evaluated for quality and rigor and (2) interpreted correctly. Therefore, prior to using pharmacoeconomic data to make clinical and policy decisions, decision makers should recognize the potential limitations of those data.

TABLE 1–3. Advantages and Disadvantages of Pharmacoeconomic Application Strategies

| Strategy | Advantage | Disadvantage |
|----------------------------------|--|--|
| Use published literature | Quick Inexpensive Subject to peer review Results may be from RCT Variety of results can be examined | Results from RCT Difficult to generalize results May not be comparative Misuse of pharmacoeconomic terms Variations in rigor/quality |
| Build an economic model | Quick Relatively inexpensive Yields organization-specific results Bridges efficacy and effectiveness Data collection is unobtrusive | Results dependent on assumptions Potential for researcher bias Controversial Reluctance of decision makers to accept results |
| Conduct a pharmacoeconomic study | Flexible Usually comparative Yields organization-specific data Reflects “usual care” or effectiveness Data from multiple sources can be used | Expensive Time-consuming Difficult to control and randomize Potential for patient selection bias Potential for small sample size |

RCT, randomized controlled trial.

A primary consideration when evaluating and interpreting a study is the ability to generalize or transfer the results to other health care settings and countries. It can be difficult to generalize and transfer the results of a published study primarily because of wide variations in practice patterns, patient populations, and costs among health care systems and countries. Further, differences in study perspectives, data sources, and analytic styles may present a challenge for practitioners attempting to extrapolate or relate exact cost savings or cost ratios to their own practice settings. To enhance the ability to use pharmacoeconomic results published in the literature, consider the following points:

1. What is the technical merit of the study?
2. Are the results applicable to local decision making?
3. Do the results apply generally in different jurisdictions with different perspectives?⁵⁰

Various guidelines, criteria, reviews, and consensus-based recommendations for evaluating, conducting, and reporting pharmacoeconomic literature have been published.^{7,17,31,32,51–60} These guidelines and criteria have been combined and summarized into 11 categories most pertinent to pharmacotherapy.⁵⁴ A summary of these 11 criteria and pertinent questions for each category are given in Table 1–4. Each evaluation criterion is briefly discussed next.

STUDY OBJECTIVE

A clear statement of the purpose of the study should be given. This objective should be clear, concise, well defined, and measurable.

STUDY PERSPECTIVE

The researcher must select one or more perspectives (e.g., patient, provider, payer, or society) from which the analysis will be conducted.⁹ This perspective should be appropriate given the scope

of the pharmacoeconomic problem identified. An evaluation may be conducted from single or multiple perspectives as long as the costs and consequences identified are relevant to the perspective(s) chosen.

PHARMACOECONOMIC METHOD

It should be clear which pharmacoeconomic method was employed (CEA, CMA, CBA, or CUA), and this method should be appropriate given the problem (e.g., CMA is appropriate if comparing two alternatives equivalent in therapeutic outcome but not if the alternatives differ in therapeutic outcome). Also, a researcher may claim that a specific method was employed (e.g., CEA) but actually employ another method (e.g., CMA).

STUDY DESIGN

Pharmacoeconomic evaluations can be prospective or retrospective. Although prospective designs usually are preferred, retrospective evaluations can be rich with information and reflective of usual care. Many pharmacoeconomic evaluations today are conducted as a part of randomized, controlled clinical trials. Two cautions for interpreting pharmacoeconomic data collected in this manner include (1) costs can be protocol-driven, not necessarily reflective of using a drug in common practice,⁶¹ and (2) control of subjects and decreased complications may yield greater costs and benefits than those observed in common practice.⁵¹

CHOICE OF INTERVENTIONS

All relevant treatment options that are available should be described completely or mentioned. The treatment alternatives and dosages being compared should be those used in common practice, and evidence of their effectiveness should be established. Because pharmacoeconomic methods are tools to aid in choosing among treatment

TABLE 1–4. Basic Criteria for Evaluation of Pharmacoeconomic Literature

| | |
|--|--|
| <p>Objective What is the question(s) being considered? Is the question clear, defined, and measurable?</p> <p>Perspective What is/are the perspective(s) of the analysis? Is the perspective appropriate given the scope of the problem?</p> <p>Pharmacoeconomic Method What pharmacoeconomic tool was used? Is it appropriate given the problem? Is it actually what was conducted?</p> <p>Study Design What was the study design? What were the data sources? Is the evaluation suitable if carried out in a clinical trial?</p> <p>Choice of Interventions Were all appropriate alternatives considered and described? Were any appropriate alternatives omitted? Are the alternatives relevant to the perspective and clinical nature of the study? Is there evidence that the alternatives' effectiveness has been established?</p> <p>Costs and Consequences What are the costs and consequences (outcomes) included? Are the costs and outcomes relevant to the perspective chosen?</p> | <p>Sensitivity Analysis Are cost ranges for significant variables tested for sensitivity? Are the appropriate and relevant variables varied? Do the findings follow the anticipated trend?</p> <p>Conclusions Are the conclusions of the study justified? Is it possible to extrapolate the conclusions to daily clinical practice?</p> <p>Sponsorship Was there any bias due to the sponsorship of the study? Do they include negative outcomes (failures, ADRs)? How were they valued? Were costs and consequences measured in the appropriate physical units?</p> <p>Discounting Was the study performed over time? Were costs and consequences that occur in the future discounted to their present value? Was any justification given for the discount rate used?</p> <p>Results Are the results accurate and practical for medical decision makers? Were the appropriate statistical analyses performed? Was an incremental analysis performed? Are all the assumptions and limitations of the study discussed?</p> |
|--|--|

alternatives, assessing the cost of a single alternative is considered a partial economic evaluation.

COSTS AND CONSEQUENCES

All the important and relevant costs and consequences for each program or treatment alternative should be identified. The costs and consequences identified must be relevant to the study perspective(s) and measured in suitable terms using the appropriate physical units. Costs should include direct, indirect, and intangible costs. Consequences should include the positive and negative clinical and humanistic outcomes associated with the program or treatment alternative. All these costs and consequences must be valued credibly, with the data sources clearly identified.

DISCOUNTING

The comparison of programs or treatment alternatives should be made at one point in time; thus any costs and consequences not occurring in the present must be addressed. *Discounting*, or adjusting for differential timing, is the process of reducing any costs and consequences that may occur in the future back to their present value. If a study is performed over time (more than 1 year), or if future cost savings are projected, discounting should be done using an appropriate discount rate. The rate recommended by most investigators is typically 3% to 8% per annum, representing annual inflation or bank interest rates. However, the modal rates used in pharmacoeconomic evaluations appear to be 5%.

Researchers disagree about which discount rate to use, as well as about whether to discount costs and health benefits (simultaneously) using the same discount rate(s).

STUDY RESULTS

A full discussion of the study assumptions and limitations and how to interpret the results in the context of different practice settings¹⁷ should be provided. This discussion should include all relevant issues of concern to potential users of the study. The results should show that the appropriate statistical analyses were performed. Also, it may be appropriate to express the study results in terms of increases, that is, to use incremental cost analysis (additional cost of gaining an additional benefit by using one drug over another).

SENSITIVITY ANALYSIS

It is imperative that researchers test the sensitivity of study results using sensitivity analysis. Using this method, practitioners and researchers can deal with data uncertainties and assumptions and their effect on study conclusions. *Sensitivity analysis* (SA) is the process of testing the robustness of an economic evaluation by examining changes in results. Specific variables such as percent effectiveness, incidence of ADRs, and dominant resources can be varied over a range of plausible values and the results recalculated. The four general approaches to SA are simple SA, threshold analysis, analysis of extremes, and Monte Carlo simulation analysis.⁶² SA is of paramount importance because of the very common need for investigators to use assumptions and estimates for unknown variables.⁴⁹

STUDY CONCLUSIONS

Researchers should assist the reader in extrapolating study conclusions to clinical practice. The conclusions drawn from the study

results should be justified (internal validity) and able to be generalized (external validity).⁵⁴ Also, conclusions drawn from results that were *statistically* significant may or may not be *clinically* relevant, and vice versa.

SPONSORSHIP

Similar to evaluating the quality of a clinical trial, sponsorship of a pharmacoeconomic study should be considered when evaluating the quality and usefulness of that study.⁵² The quality of studies conducted or funded by different companies or organizations will vary by sponsor, company, product, or evaluation, and the potential for bias should be neither ignored nor assumed. For example, many of the studies sponsored or conducted by the pharmaceutical industry to date have been academically rigorous as well as informative. A clear understanding of how to evaluate, critique, and use the pharmacoeconomic literature appropriately will minimize any potential effects of this criterion on clinical decision making.

CONTROVERSIES WITH PHARMACOECONOMIC LITERATURE

Over the years, the literature has highlighted the misuse of pharmacoeconomic terms, inconsistent reporting, and disagreement on the methods used for pharmacoeconomic analyses. Since pharmacoeconomics is a fairly new discipline that lacks strong consensus with respect to its methods and technically appropriate applications, the disagreement between leading researchers in this field has been widespread and evident.⁶⁰ Unfortunately, this has led to some external skepticism, as well as the inability of clinicians to use the findings of these analyses as extensively as they could to inform their local decision making.⁶⁰ Creating and implementing a standardized system for conducting and reporting results of pharmacoeconomic analyses are critical to minimize or eliminate some of these controversies. A review of national guidelines for various countries was published and revealed some areas of emerging standardization.⁶³ Such a standardized system would enhance clinicians' and decision makers' comprehension of the available data, as well as provide increased assurance that the results reported are methodologically sound.

BUILD AN ECONOMIC MODEL

8 Studies that *model* the economic impact of a pharmaceutical product or service on a defined population are increasing in popularity. Modeling studies use existing clinical and/or epidemiologic data to project future outcomes.⁶⁴ Use of economic models can provide support for various clinical decisions, especially those which are time-contingent.⁴⁶ Identifying assumptions regarding the treatment alternatives being compared, the patient outcomes under study, and the probability of those outcomes occurring can provide the basis for an economic simulation to assist in the medication decision-making process.

These studies can use data from various sources available within (internal) and from outside (external) a specific health care organization. Common approaches to modeling are to modify and adapt existing models or to develop a distinct model to answer a specific question.⁶⁵ Typically, economic modeling in today's practice settings employs *clinical decision analysis*, which has been defined as an explicit, quantitative, and prescriptive approach to choosing among

alternative outcomes.^{66,67} The tool used in decision analysis is a decision tree. A decision tree provides a framework to display graphically primary variables, including treatment options, outcomes associated with those treatment options, and probabilities of the outcomes. The researcher can then algebraically reduce all these factors into a single value, allowing for comparison.

Many examples of decision-analytic models are available in the literature, spanning many therapeutic areas, including the treatment of depression,⁶⁸ migraine,⁶⁹ type 2 diabetes,⁷⁰ and community-acquired pneumonia (CAP).⁷¹ In fact, by 1996, more than 80 published articles had been identified that applied decision analysis to questions regarding pharmaceutical products.⁷² This simple decision-analysis approach is well suited for comparisons of treatment alternatives with relatively immediate consequences, for example, treating a patient with CAP. However, chronic conditions or diseases such as chronic hepatitis C are difficult to model using simple decision trees for various reasons, including time-dependent clinical outcomes, and thus may require alternate modeling techniques.

Markov models are another method of decision analysis that provides an alternative way to arrange the decision process so that clinical outcomes and time-dependent risk changes are managed efficiently. The Markov model is designed to simulate the most important aspects of a disease and can be used to estimate the long-term clinical, humanistic, and economic dimensions of the disease.⁷³ There are examples of Markov models available in the literature, including estimates of the cost-effectiveness of interferon- α therapy for the treatment of chronic hepatitis C infection.^{74–76} Although Markov models can be stand-alone models, they often are combined with simple decision trees to predict the long-term effects of therapies.⁷³ These models can be complex; thus clinicians who attempt to use these data or perform their own Markov modeling should become familiar with these techniques.^{73,77}

Using an economic model can help the clinician to forecast the impact of medication-use decisions on a patient, institution, or health care system. Also, as new drugs are marketed that can displace older agents, an economic model can expedite the reappraisal process for formulary management and drug-use policy decisions.⁷⁸ For building an economic model to assist in clinical decision making, various published studies and a review can be considered.^{72,79–83} Further, guidelines for economic modeling are available, and health care practitioners considering using modeling techniques should refer to them.^{84–86}

CONDUCT A PHARMACOECONOMIC EVALUATION

8 Clinicians may need to conduct a pharmacoeconomic evaluation if there is insufficient literature, if published results cannot be extrapolated to clinical practice, or if building a model is not appropriate. Before conducting a pharmacoeconomic evaluation, clinicians should be familiar with the similarities, differences, and appropriate application of pharmacoeconomic methods (discussed earlier in this chapter).

The decision to conduct a local pharmacoeconomic study is not without its own costs. Because both time and monetary resources are consumed by these evaluations, specific pharmacy products and services for pharmacoeconomic evaluation should be targeted. Thus this strategy should be reserved for pharmacy decisions that may have a significant impact on cost or quality of care.

Conducting pharmacoeconomic research in a hospital or managed-care environment can be challenging. Lack of institutional

resources, small sample sizes, difficulty randomizing, inability to compare with placebo, and difficulty generalizing results all may be limitations. For example, when asked to determine and recommend the most cost-effective antihypertensive agent for a formulary management decision, clinicians may lack monetary and time resources to conduct a scientifically rigorous study.

Conducting a pharmacoeconomic evaluation should be guided by the criteria for quality economic evaluations.^{8,17,32,51–59} A 10-step process identified by Jolicoeur and associates⁸⁷ and four additional steps that I have added can provide readers with guidance for conducting a local pharmacoeconomic study.⁸⁸ This process contains 14 fundamental steps for conducting a pharmacoeconomic evaluation in a health care system and can be applied to virtually any therapeutic area or health care service. Although some of these steps are similar to the evaluation criteria detailed earlier in this chapter, they will now be discussed briefly in the context of conducting an evaluation.

STEP 1: DEFINE THE PHARMACOECONOMIC PROBLEM

A broad problem might be, “Which antiemetic regimen represents the best value for the prevention of chemotherapy-induced emesis (CIE)?” However, a more succinct and measurable problem would be, “Which regimen is the best value for preventing acute CIE in patients receiving highly emetogenic chemotherapy?”

STEP 2: ASSEMBLE A CROSS-FUNCTIONAL STUDY TEAM

The study team can provide early buy-in and additional resources for a pharmacoeconomic evaluation. Team members vary depending on the analysis but may include representatives from medicine, nursing, pharmacy, hospital administration, and information systems.

STEP 3: DEFINE THE APPROPRIATE STUDY PERSPECTIVE

Choose a study perspective(s) most relevant to the problem. For example, if the problem is as listed in step 1, then the perspective of the institution or health care system may be most appropriate.

STEP 4: IDENTIFY TREATMENT ALTERNATIVES AND OUTCOMES

Treatment alternatives can include pharmacologic and nonpharmacologic options but should include all clinically relevant alternatives. The outcomes identified should include both positive and negative clinical outcomes.

STEP 5: IDENTIFY THE APPROPRIATE PHARMACOECONOMIC METHOD TO EMPLOY

Pharmacoeconomic methods to choose from include CMA, CBA, CEA, and CUA. Employing the incorrect method can adversely affect medication decisions influencing both cost and quality of care.

STEP 6: PLACE A MONETARY VALUE ON TREATMENT ALTERNATIVES AND OUTCOMES

Placing a monetary value on treatment alternatives and outcomes includes not only drug administration and acquisition costs but also the

cost of positive and negative clinical outcomes (e.g., determining the cost of ADRs and treatment failures). This can be measured prospectively or retrospectively or estimated using comprehensive databases or expert panels.

STEP 7: IDENTIFY RESOURCES TO CONDUCT STUDY IN AN EFFICIENT MANNER

Resources necessary will vary by study but may include access to medical or computerized records, average medical personnel wages, and specialty medical staff.

STEP 8: IDENTIFY PROBABILITIES THAT OUTCOMES MAY OCCUR IN THE STUDY POPULATION

What are the probabilities of the outcomes identified in step 4 actually occurring in clinical practice? Using primary literature and expert opinion, these probabilities can be obtained and may be manifested as efficacy rates and incidence of ADRs.

STEP 9: EMPLOY DECISION ANALYSIS

The use of decision analysis can assist in conducting various economic evaluations, including CEA. Although not necessary for all pharmacoeconomic evaluations, decision analysis and decision trees may provide a solid backbone or platform for the decision at hand. Using a decision tree, treatment alternatives, outcomes, and probabilities may be presented graphically and may be reduced algebraically to a single value for comparison (i.e., cost-effectiveness ratio).

When comparing antiemetic agents for the development of a policy for CIE prevention, CEA can be employed. Many of these agents differ with respect to effectiveness, safety, and cost. By performing a thorough CEA, these variables can be reduced to a single number (cost-effectiveness ratio), which will allow for a meaningful comparison. The treatment alternative with a better cost-effectiveness ratio than the others (i.e., lower cost per unit of outcome) would be selected and promoted for use.

Figure 1–3 contains an example of a decision tree illustrating how the probabilities of various outcomes can be organized. To calculate the ACER for drug A using “averaging out and folding back,” these steps are followed:

1. Multiply the cost of path 1 by the probability of no ADE ($\$250 \times 0.89$). Repeat for path 2 ($\400×0.11).
2. Add these two numbers and multiply by the probability of success ($\$266.50 \times 0.93 = \247.80).
3. Repeat the two preceding steps for paths 3 and 4, and then add the resultant values ($\$247.80 + \$50.50 = \$298.30$).
4. Add the cost of the drug to this value ($\$298.30 + \60), and divide by the probability of a success (93%, or 0.93); thus $\$358.30/0.93 = \385 .
5. Repeat this process for drug B using paths 5 through 8.

Using the values in Table 1–5, another way to calculate the ACER for these treatment options is to multiply the cumulative probabilities (P) by the cumulative costs for each path, then sum the costs for each path 1 through 4 (for drug A) and 5 through 8 (for drug B), and then divide by each drug’s respective effectiveness for acute CIE. On completion, the ACERs for drugs A and B are \$385 and \$369, respectively. Therefore, despite the 33% increase in the cost of drug B

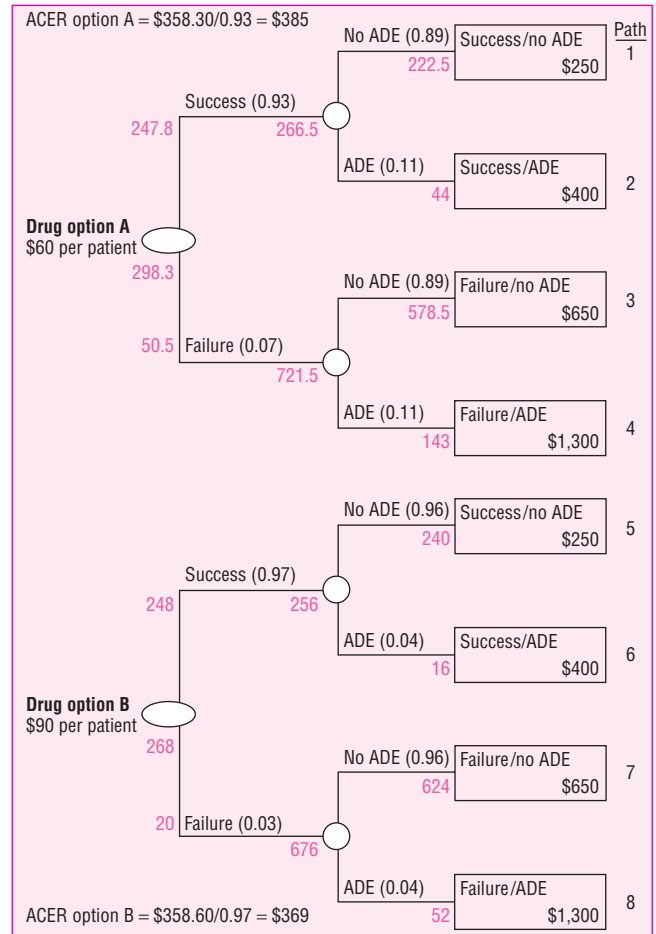

FIGURE 1–3. Example of a pharmacoeconomic decision tree comparing two drugs. *Option B* is a drug that is more specific for the target receptor in the body, is more effective, and produces fewer adverse effects than does *option A*. However, because drug *B* is more expensive than drug *A*, the cost of the added benefits must be analyzed using pharmacoeconomic techniques. This figure was completed using the safety and efficacy values for drugs *A* and *B* from Table 1–5. Values in color are calculated numbers, only included to illustrate the process of “averaging out and folding back.” ACER = average cost-effectiveness ratio; ADE = adverse drug event; P = probability (a decimal fraction between 0 and 1 indicating the likelihood of a particular event occurring in a given period). (Data from Sanchez LA, Lee JT. *Applied pharmacoeconomics: Modeling data from internal and external sources. Am J Health Syst Pharm* 2000;57:146–158.)

over drug A, its increased efficacy for acute CIE and its decreased incidence of ADRs actually make it a more cost-effective option.

STEP 10: DISCOUNT COSTS OR PERFORM A SENSITIVITY OR INCREMENTAL COST ANALYSIS

Costs and consequences that occur in the future must be discounted back to their present value. Sensitive variables must be tested over a clinically relevant range and results recalculated. If appropriate, an incremental analysis of the costs and consequences should be performed.

STEP 11: PRESENT STUDY RESULTS

Results should be presented to the cross-functional team and the appropriate committees. Presentation style and content may vary depending on the audience.

TABLE 1–5. Comparison of Costs of Two Drug Options for Preventing Acute Chemotherapy-Induced Emesis

| Path | Drug Cost (\$) | Chemotherapy Cost (\$) | Lab Cost (\$) | Extra Therapy Cost (\$) | Delay in Clinic Cost (\$) | Hospital Cost (\$) | Cumulative Cost (\$) | Cumulative Probabilities | Cost of path (\$) |
|----------------|----------------|------------------------|---------------|-------------------------|---------------------------|--------------------|----------------------|--------------------------|-------------------|
| Drug A | | | | | | | | | |
| 1 | 60 | 200 | 50 | | | | 310 | 0.827 | 256.37 |
| 2 | 60 | 200 | 100 | 100 | | | 460 | 0.102 | 46.92 |
| 3 | 60 | 200 | 100 | 200 | 150 | | 710 | 0.062 | 44.02 |
| 4 | 60 | 200 | 150 | 300 | 150 | 500 | 1360 | 0.007 | 9.52 |
| Cost of option | | | | | | | | | \$356.83 |
| Drug B | | | | | | | | | |
| 5 | 90 | 200 | 50 | | | | 340 | 0.931 | 316.54 |
| 6 | 90 | 200 | 100 | 100 | | | 490 | 0.038 | 18.62 |
| 7 | 90 | 200 | 100 | 200 | 150 | | 740 | 0.028 | 20.72 |
| 8 | 90 | 200 | 150 | 300 | 150 | 500 | 1390 | 0.001 | 1.39 |
| Cost of option | | | | | | | | | \$357.27 |

STEP 12: DEVELOP A POLICY OR AN INTERVENTION

Take the study results and develop a policy or an intervention that can improve or maintain quality of care, possibly at a cost savings.

STEP 13: IMPLEMENT POLICY AND EDUCATE PROFESSIONALS

Spend adequate time and resources strategically implementing the policy or intervention. Educate the health care professionals most likely to be affected by this policy using various strategies, including verbal, written, and online communication.

STEP 14: FOLLOW-UP DOCUMENTATION

Once the intervention or policy has been implemented for a reasonable period of time, collect follow-up data. These data will provide feedback on the success and quality of the policy or intervention.

For additional information and hands-on practice conducting a pharmacoeconomic evaluation in the real world, practitioners should consider a recently published case study. In 2003, Okamoto⁸⁹ published a case study on conducting a pharmacoeconomic evaluation using 16 steps that readers also may find useful. In this case, clinicians are challenged to conduct a faux economic analysis from an MCO (provider) perspective to support a review of inhaled corticosteroids for formulary management purposes.

CONCLUSIONS

The principles and methods of pharmacoeconomics provide the means to quantify the value of pharmacotherapy through balancing costs and outcomes. Providing quality care with minimal resources is the future, and the future is here. By understanding the principles, methods, and application of pharmacoeconomics, health care professionals will be prepared to make better, more-informed decisions regarding the use of pharmaceutical products and services, that is, decisions that ultimately represent the best interests of the patient, the health care system, and society.

ABBREVIATIONS

ACER: average cost-effectiveness ratio
ADR: adverse drug reaction

AWP: average wholesale price

B/C ratio: benefit-to-cost ratio

CAP: community-acquired pneumonia

CBA: cost-benefit analysis

CCA: cost-consequence analysis

CEA: cost-effectiveness analysis

COI: cost of illness

CMA: cost-minimization analysis

CUA: cost-utility analysis

ECHO: economic, clinical, and humanistic outcomes

HRQOL: health-related quality of life

ICER: incremental cost-effectiveness ratio

MCO: managed-care organization

QALY: quality-adjusted life year

SA: sensitivity analysis

WTP: willingness-to-pay

2

HEALTH OUTCOMES AND QUALITY OF LIFE

Stephen Joel Coons

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The evaluation of health care is focused increasingly on assessment of the *outcomes* of medical interventions.
- 2 An essential patient-reported outcome is self-assessed function and well-being or health-related quality of life (HRQOL).
- 3 In certain chronic conditions, HRQOL may be the most important health outcome to consider in assessing treatment.
- 4 Information about the impact of pharmacotherapy on HRQOL can provide additional data for making medication-use decisions.
- 5 HRQOL instruments can be categorized as generic/general or targeted/specific.
- 6 In HRQOL research, the quality of the data-collection tool is the major determinant of the overall quality of the results.

Over the past two decades, the medical care marketplace in the United States has undergone unprecedented change.¹ This change is evidenced by a variety of developments, including an increase in investor-owned organizations, heightened competition, numerous mergers and acquisitions, increasingly sophisticated clinical and administrative information systems, and new financing and organizational structures. In this dynamic and increasingly competitive environment, there is a concern that health care quality is being compromised in the push to  contain costs. As a consequence, there has been a growing movement to focus the evaluation of health care on the assessment of the end results, or *outcomes*, associated with medical care delivery systems, as well as specific medical interventions. The primary objective of this effort is to maximize the net health benefit derived from the use of finite health care resources.² However, there is a serious lack of critical information as to what value is received for the tremendous amount of resources expended on medical care.³ This lack of critical information as to the outcomes produced is an obstacle to optimal health care decision making at all levels.

HEALTH OUTCOMES

Although the implicit objective of medical care is to improve health outcomes, until relatively recently, little attention was paid to the explicit measurement of outcomes. An outcome is one of the three components of the conceptual framework articulated by Donabedian⁴ for assessing and ensuring the quality of health care: *structure*, *process*, and *outcome*. Traditionally, the approach to evaluating health care has emphasized the structure and processes involved in medical care delivery rather than the outcomes. However, health care regulators, payers, providers, manufacturers, and patients are placing increasing emphasis on the outcomes that medical care products and services produce.⁵ As stated by Ellwood,⁶ outcomes research is “designed to help patients, payers, and providers make rational medical care choices based on better insight into the effect of these choices on the patient’s life.”

TYPES OF OUTCOMES

The types of outcomes that result from medical care interventions can be described in a number of ways. One classic list, called the *five D’s*, although quite negatively worded, captures a wide range of outcomes used in assessing the quality of medical care.⁷ The five D’s are death, disease, disability, discomfort, and dissatisfaction.

A more comprehensive conceptual framework, the ECHO model, places outcomes into three categories: *economic*, *clinical*, and *humanistic outcomes*.⁸ The model covers the five D’s within the clinical and humanistic outcomes and provides an added economic outcomes dimension. As described by Kozma and associates,⁸ *clinical outcomes* are the medical events that occur as a result of the condition or its treatment. *Economic outcomes* are the direct, indirect, and intangible costs compared with the consequences of a medical  intervention. Along with patient satisfaction, an essential humanistic or patient-reported outcome is self-assessed function and well-being, or *health-related quality of life* (HRQOL). This chapter focuses on HRQOL as an outcome of pharmacotherapeutic interventions.

QUALITY OF LIFE

DEFINITION

As mentioned earlier, one of the essential elements of outcomes research is the assessment of patient *health-related quality of life*. However, there is no consensus on the definition of quality of life (QOL) or its overall conceptual framework.⁹ In the literature, the term *quality of life* has been used in a variety of ways. It has been proposed that studies of health outcomes use the term *health-related quality of life* (HRQOL) to distinguish health effects from the effects of standard of living, family life, friendships, job satisfaction, and other factors on overall quality of life.¹⁰ Only health outcomes are discussed in this chapter, so *quality of life* and *health-related quality of life* are used interchangeably, along with *health status*.

HRQOL CONTROVERSY

Some observers question whether, when completing HRQOL instruments, respondents are able to distinguish between the impact of health versus the impact of other important life domains on their functioning and well-being.

QOL, like other aspects of the human experience, is hard to define. In much of the empirical literature, explicit definitions of QOL are rare; readers must deduce the implicit definition of QOL from the manner in which it is measured. However, some authors have provided definitions. For example, Schron and Shumaker¹¹ define HRQOL as “a multidimensional concept referring to a person’s total well-being, including his or her psychological, social, and physical health status.” Patrick and Erickson¹² propose that HRQOL is “the value assigned to duration of life as modified by the impairments, functional states, perceptions, and social opportunities that are influenced by disease, injury, treatment, or policy.” Although the two definitions differ in certain respects, a conceptual characteristic they share is the multidimensionality of QOL. Although the terminology may vary with the author, commonly measured domains of HRQOL include

- Physical health and functioning
- Mental health and functioning
- Social and role functioning
- Perceptions of general well-being

HRQOL CONTROVERSY

Should symptoms of a disease or the adverse effects of treatment interventions be assessed explicitly by HRQOL instruments? Although some instruments include items addressing specific symptoms or side effects (particularly in the mental health domain), most HRQOL instruments are developed based on the premise that if a symptom or adverse effect is sufficiently problematic, it will be manifested in one or more of the measured HRQOL domains.

RELEVANCE OF QOL AS AN OUTCOME

For medical care providers, HRQOL increasingly is viewed as a therapeutic end point. An overriding factor leading to this has been the gradual shift in the focus of primary medical care from limiting mortality to limiting morbidity and the patient-reported impact of that morbidity. The pattern of illness in the United States has shifted from mostly acute disease to one in which chronic conditions predominate. In the early part of the twentieth century, many individuals died from infectious diseases for which cures (e.g., antibiotics) or effective preventive measures (e.g., vaccines, increased sanitation) were unavailable or underused. Today, although there are many diseases that may shorten life expectancy, it is more likely that a disease will have adverse health consequences leading to dysfunction and decreased well-being. For conditions that shorten life expectancy and for which there are no cures, managing symptoms and maintaining function and well-being should be the primary objectives of medical care.

Because therapeutic interventions such as medications have the potential to increase or decrease HRQOL, medical care providers must strive to achieve enhanced HRQOL as an outcome of therapy. Although it must be assumed that HRQOL always has played an implicit role in the provision of health care, it has not always been viewed as equal in importance to the more clinical or physiologic outcome parameters (e.g., blood pressure). The subjective

nature of HRQOL assessment has made many people uneasy with it as a measure of the patient outcomes produced by medical treatment.¹³

3 However, there is growing awareness that in certain diseases, HRQOL may be the most important health outcome to consider in assessing treatment.¹⁴ Physiologic measures may change without improving functioning and well-being. Likewise, patients may feel and function better without measurable change in physiologic values.

QOL AND PHARMACOTHERAPY

As described by Smith,¹⁵ there are four possible QOL outcomes associated with pharmacotherapy: (1) QOL is improved, (2) QOL is actively maintained, (3) QOL is decreased, or (4) QOL remains unaffected. To assess these possible outcomes effectively, moving beyond consideration of only the biologic or physical manifestations of a disease or its treatment is essential. The use of standardized measurement tools (e.g., self-reported HRQOL instruments) to collect information regarding the impact of pharmacotherapy on the quality of patients’ lives is increasing.^{16,17} However, the vast majority of HRQOL claims in prescription drug advertisements continue to be based on physiologic parameters and/or clinician-assessed physical function rather than patient-reported functioning and well-being.¹⁸

A study by Croog and colleagues¹⁹ was one of the first in a growing body of literature reporting the QOL impact of pharmacotherapy, specifically the use of antihypertensive agents. Along with hypertension, examples of other therapeutic areas that are receiving increasing attention are arthritis, asthma, cancer, diabetes, and HIV/AIDS.^{20–25} The type of condition and type of treatment dictate the importance of HRQOL data in determining the value of pharmacotherapy. As discussed by Badia and Herdman,²⁶ in chronic conditions and palliative treatments (i.e., ameliorating symptoms but not curing the underlying disease), HRQOL may be the primary measure of efficacy. However, with acute conditions and curative treatments, HRQOL is likely to be secondary (although excluding it may underestimate the positive and negative impacts of the treatment).

4 Information about the impact of pharmacotherapy on QOL can provide additional data for making medication-use policy decisions. In fact, the Academy of Managed Care Pharmacy, in its *Format for Formulary Submissions*, states that manufacturers of pharmaceutical, biologic, and vaccine products should include outcomes data (e.g., QOL data) in their formulary submission dossiers.²⁷ When available, pharmacy and therapeutics committees should incorporate QOL data into the formulary and practice guideline decision-making process. HRQOL as an input to clinical decision making at the patient level is also very important. For example, alternative treatments may have equal efficacy based on traditional clinical parameters (e.g., blood pressure reduction) but produce very different effects on the patient’s HRQOL. Thus a provider’s selection among competing alternatives may hinge on documented differential impact on HRQOL. A perceived decrease in QOL attributed by the patient to an adverse effect of a drug may lead to a decrease in adherence to the medication regimen.¹⁵

MEASURING QOL

TYPES OF INSTRUMENTS

Hundreds of HRQOL instruments are available.^{28–30} Table 2–1 gives 5 a taxonomy of the different types of instruments.³¹ A primary distinction among HRQOL instruments is whether they are generic or specific.

TABLE 2–1. Taxonomy of Quality-of-Life Instruments

| |
|--|
| Generic Instruments |
| Health profiles |
| Preference-based measures |
| Specific Instruments |
| Disease specific (e.g., diabetes) |
| Population specific (e.g., frail older adults) |
| Function specific (e.g., sexual functioning) |
| Condition or problem specific (e.g., pain) |

Adapted from Ref. 32.

GENERIC INSTRUMENTS

Generic, or general, HRQOL instruments are designed to be applicable across all diseases or conditions, across different medical interventions, and across a wide variety of populations.³² Table 2–2 lists the dimensions or domains of five generic instruments. In choosing or evaluating the use of an instrument, the specific dimensions of functioning and well-being covered must be considered. The instruments in Table 2–2 share common dimensions, but they also reflect the diversity and range of dimensions covered. The two main types of generic instruments are health profiles and preference-based measures.

HEALTH PROFILES

Health profiles provide an array of scores representing individual dimensions or domains of HRQOL or health status. An advantage of a health profile is that it provides multiple outcome scores that may be useful to clinicians and/or researchers attempting to measure differential effects of a condition or its treatment on various QOL domains.

TABLE 2–2. Domains Included in Selected Generic Instruments

| | |
|---|-------------------------|
| EuroQoL Group's EQ-SD³³ | |
| Mobility | Self-care |
| Usual activity | Pain/discomfort |
| Anxiety/depression | |
| Nottingham Health Profile (NHP)³⁴ | |
| Part I: Distress within the following domains | |
| Emotions | Energy |
| Sleep | Pain |
| Social isolation | Mobility |
| Part II: Health-related problems within the following domains | |
| Occupation | Sex life |
| Housework | Hobbies |
| Social life | Holidays |
| Home life | |
| Quality of Well-Being Scale (QWB)³⁵ | |
| Symptoms/problems | Physical activity |
| Mobility | Social activity |
| Sickness Impact Profile (SIP)³⁶ | |
| Sleep and rest | Home management |
| Eating | Recreation and pastimes |
| Work | Body care and movement |

TABLE 2–3. SF-36 Scales and Number of Items per Scale (SF-36/SF-12)

| |
|---|
| Physical functioning (10/2) |
| Role limitations attributed to physical problems (4/2) |
| Bodily pain (2/1) |
| General health (5/1) |
| Vitality (4/1) |
| Social functioning (2/1) |
| Role limitations attributed to emotional problems (3/2) |
| Mental health (5/2) |
| Health transition (1/0) |

Compiled from Refs. 38 and 42.

A commonly used profile instrument is the Medical Outcomes Study 36-Item Short-Form Health Survey (SF-36).³⁸ This instrument includes nine health concepts or scales (Table 2–3). The SF-36 can be self-administered or administered by a trained interviewer (face to face or via telephone). This instrument has several advantages. For example, it is brief (it takes about 5–10 minutes to complete), and its reliability and validity have been documented in many clinical situations and disease states.^{39,40} A means of aggregating the items into physical (PCS) and mental (MCS) component summary scores is available.⁴¹ In addition, an abbreviated version of the SF-36 containing only 12 items (SF-12) has been introduced.⁴² However, the scale scores and mental and physical component summary scores derived from the SF-12 are based on fewer items and fewer defined levels of health and, as a result, are estimated with less precision and less reliability. The loss of precision and reliability in measurement can be a problem in small samples and/or with small expected effect sizes for an intervention.

PREFERENCE-BASED MEASURES

HRQOL as assessed by preference-based measures is a single overall index score on a scale anchored by 1.0 (full health) and 0.0 (dead). Health states considered worse than dead can be reflected by negative numbers on the scale. This approach combines the measurement of an individual's health status with an adjustment for the relative desirability of or preference for that health state. The preferences are measured or assigned empirically through a variety of procedures. Although often called health state *utilities*, the term *preferences* will be used in this chapter as the broader term because it subsumes both *utilities* and *values*.⁴³

Preference-based measures are useful in pharmacoeconomic research, specifically cost-utility analysis (CUA).⁴⁴ CUA, an economic technique discussed in Chapter 1, involves comparing the costs of an intervention (e.g., a medication) with its outcomes expressed in units such as quality-adjusted life years (QALYs) gained. QALYs gained is an outcome measure that incorporates both quantity and quality of life. This can be a key outcome measure, especially in diseases such as cancer, where the treatment itself can have a major impact on patient functioning and well-being. Numerous published studies have used CUA to evaluate the economic efficiency of health care interventions. A review of CUAs published from 1976 to 1997 by Neumann and colleagues⁴⁵ found that the number increased markedly during that time. Of the 228 articles reviewed, about one-third focused on pharmaceutical interventions. CUA data compiled during this extensive review can be accessed on the Web (<http://www.hsph.harvard.edu/cearegistry>).

QALYs can be produced by increases in QOL and/or length of life. Figure 2–1 represents a case in which QALYs were gained

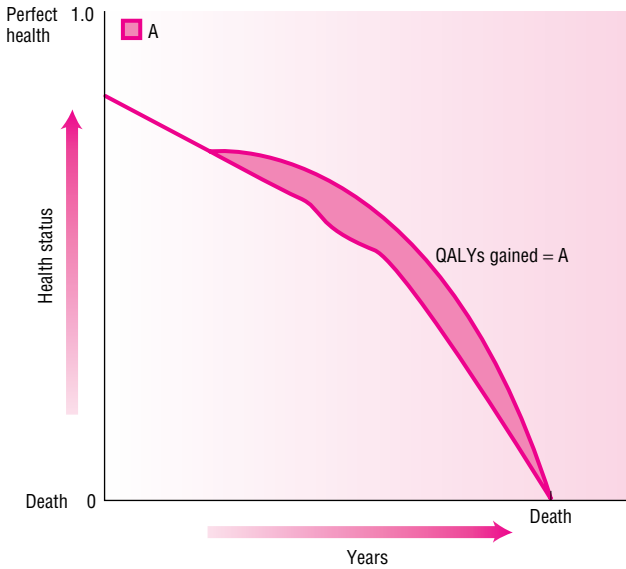

FIGURE 2-1. QALYs gained (i.e., area between the curves) as the outcome of a hypothetical health care intervention, such as a drug.

through an increase in QOL alone. The top curve represents the hypothetical life course of a cohort of individuals receiving a specific health care intervention compared with the life course of a cohort (i.e., lower curve) that did not receive the intervention. Average age at death did not differ between the two cohorts, but the intervention led to improvements in QOL in the treatment cohort. The area between the curves represents the QALYs gained through the intervention. This hypothetical case reflects a chronic disease, such as osteoarthritis, in which functioning and well-being are increased, but survival remains unchanged. Other hypothetical combinations of quality and quantity of life can be graphed in this manner. For example, an alternative scenario could reflect a temporary decrease in QOL but an increase in survival that may result from a chemotherapeutic regimen for cancer.

HRQOL CONTROVERSY

Although the QALY is the most commonly used health outcome summary measure, it is not the only one. Other conceptually equivalent outcomes include *years of healthy life* (YHL), *well years* (WYs), *health-adjusted person-years* (HAPYs), and *health-adjusted life expectancy* (HALE). An alternative concept called *healthy year equivalents* (HYES) has been proposed as theoretically superior to QALYs, but its practical significance has been limited.

Direct Measures of Health-State Preferences

The most commonly used direct measurement techniques include visual analog scales, standard gamble, and time tradeoff.⁴⁶

Visual Analog Scales. The *visual analog scale* is a line, typically 10 to 20 cm in length, with the end points well defined (e.g., 0 = worst imaginable health state and 100 = best imaginable health state). The respondent is asked to mark the line where he or she would place a real or hypothetical health state in relation to the two end points. In addition, since death may not always be considered the worst possible health state, the subject's placement of death on the scale in relation to the other health states must be explicitly elicited. If a subject has placed death at 0 and rates a health state at the midpoint between

FIGURE 2-2. Standard gamble for a chronic health status. The subject is offered the choice between A and B. A involves the certainty of living in health state *i* (a suboptimal health state) for a specified period of time. B involves an intervention that could lead to full health for the same period of time or immediate death. The probabilities associated with the outcomes of healthy and dead are p and $1 - p$, respectively. As p is varied, the indifference point between choices A and B represents the utility of state *i*.

0 and 100 on the scale, that subject's preference for that health state is 0.5.

Standard Gamble. The *standard gamble* offers a choice between two alternatives: choice A, living in health state *i* with certainty, or choice B, taking a gamble on a new treatment for which the outcome is uncertain. Figure 2-2 shows this gamble.⁴³ The subject is told that a hypothetical treatment will lead to perfect health, for a defined remaining lifetime, with a probability of p or immediate death with a probability of $1 - p$. The subject can choose between remaining, for the same defined lifetime, in state *i*, which is intermediate between healthy and dead, or taking the gamble and trying the new treatment. The probability p is varied until the subject is indifferent between choices A and B. For example, if a subject is indifferent between the choices A and B when $p = 0.75$, the preference (i.e., utility) of state *i* is 0.75.

Time Tradeoff. Figure 2-3 represents the time-tradeoff technique for a chronic disease state.⁴⁷ Here, the subject is offered a choice of living for a variable amount of time x in perfect health or a defined amount of time t in a health state *i* that is less desirable. By reducing the time x of being healthy (at 1.0) and leaving the time t in the suboptimal health state fixed, an indifference point can be determined ($h_i = x/t$). For example, a subject may indicate that undergoing chronic

FIGURE 2-3. Time tradeoff for a chronic health state. The subject chooses between living a varying amount of time in full health (x) and living a specified amount of time (t) in state *i*. The length of time in full health is shortened until the subject is indifferent between the two choices. The value of health state i (h_i) is then calculated by dividing x/t .

hemodialysis for 2 years is equivalent to perfect health for 1 year. Therefore, the value of that health state would be 0.5 ($h_i = 1/2$).

HRQOL CONTROVERSY

There is considerable debate regarding the best approach to the direct measurement, or elicitation, of health-state preferences. The empirical literature consistently shows that there are differences in the preferences derived through the different elicitation methods. Although there have been calls for the development of standardized preference-elicitation protocols, it is likely that the lack of consensus will continue into the foreseeable future.

Multiattribute Health-Status Classification Systems

In addition to direct measures, instruments are available for which the health-state preferences have been derived empirically through population studies. The instruments are administered to measure respondents' health status, which is then mapped onto a multiattribute health status classification system. Examples of such instruments include the Quality of Well-Being Scale (QWB),³⁵ the Health Utilities Index (HUI),³⁷ and the EuroQOL Group's EQ-5D.³³ Although each will be described briefly below, more thorough descriptions of these three instruments are provided elsewhere.^{43,48}

The QWB is a generic HRQOL instrument that includes symptoms or problems plus three dimensions of functional health status (see Table 2–2). Standardized preference values for the health states represented by the QWB have been measured (via the category rating scale method, a technique related to visual analog scales) and validated on a general population sample.³⁵ The QWB was available originally only as an interviewer-administered version, but a self-administered version is now available.⁴⁹

The HUI is another generic instrument that describes the health status of a person at a point in time in terms of his or her ability to function on a set of attributes or dimensions of health status. The HUI Mark II/III is available as a 15-item self-administered form. The measurements for the development of the health-state preference system were made with visual analog scales (VASs) and the standard gamble technique. The dimensions covered in the most recent version of the HUI (Mark III) are listed in Table 2–2.³⁷

The EQ-5D was developed concurrently in five languages (Dutch, English, Finnish, Norwegian, and Swedish) by a multidisciplinary team of European researchers.³³ It was designed to be self-administered and short enough to be used in conjunction with other measures. The first of two parts classifies subjects into one of 243 health states within five dimensions. The most commonly used set of health-state preferences was estimated using the time-tradeoff technique in a random sample of adults in the United Kingdom. A set of preference weights derived from the general U.S. adult population is forthcoming. The second part of the EQ-5D is a 20-cm VAS that has end points labeled “best imaginable health state” and “worst imaginable health state” anchored at 100 and 0, respectively. Respondents are asked to indicate how they rate their own health state by drawing a line from an anchor box to that point on the VAS that best represents their own health on that day.

HRQOL CONTROVERSY

Whose preferences should be used in the calculation of QALYs for CUA? Some authors have argued that health-state preferences elicited from the general population should not

TABLE 2–4. Selected Disease-Specific Quality-of-Life Instruments

| Medical Outcomes Study HIV Health Survey (MOS-HIV) ⁵⁵ |

be applied to specific patient groups. However, when public resource-allocation decisions are being made, general population preferences may be the most appropriate.

SPECIFIC INSTRUMENTS

Specific or targeted instruments are intended to provide greater detail concerning particular outcomes, in terms of functioning and well-being, uniquely associated with a condition and/or its treatment. Several selected examples of disease-specific instruments are listed in Table 2–4. One of the instruments listed is the Asthma Quality of Life Questionnaire (AQLQ), a 32-item instrument developed to assess the impact of asthma on patients' everyday functioning and well-being.⁵¹ Results from research in which the AQLQ was used have appeared in promotional materials for the salmeterol inhaler (GlaxoSmithKline). As opposed to prior prescription drug advertisements that involved predominantly physiologic-based QOL claims,¹⁸ this was one of the first times a pharmaceutical firm has promoted a product based on data from trials involving QOL as a primary outcome measure. This is likely to occur with increasing frequency as pharmaceutical firms look for ways to demonstrate value and differentiate their products from those of the competition.^{56,57} Leidy and colleagues⁵⁸ have provided useful recommendations for evaluating the validity of QOL claims for labeling and promotion of pharmaceuticals.

Although not always, disease- or condition-specific instruments can be more sensitive than a generic measure to particular changes in HRQOL secondary to the disease or its treatment. In addition, specific measures may appear to be more clinically relevant to patients and health care providers.³¹

However, a concern regarding the use of only specific instruments is that by focusing on the specific impact, the general or overall impact on functioning and well-being may be overlooked. In studies involving pharmacotherapy, the use of both a generic and a specific instrument may be the best approach. The generic instrument provides a more general outcome assessment and allows comparability across other disease states or conditions in which it has been used. An appropriately selected specific instrument should provide more detailed outcome information regarding expected changes in the particular patient population.

MEASUREMENT ISSUES

A number of issues must be considered when evaluating existing HRQOL research and/or choosing the appropriate instrument to use when designing a study involving QOL assessment. A thorough review of these issues is not within the scope of this chapter; more in-depth reviews of methodologic considerations are available in the literature.^{12,59,60} Of particular concern are the psychometric properties of a chosen instrument. *Psychometrics* refers to the measurement of psychological constructs, such as QOL. Instruments should be developed and tested such that one can place confidence in the

measurement made. Psychometric properties of measures (e.g., reliability and validity) are considered in the review criteria developed by the Scientific Advisory Committee of the Medical Outcomes Trust (MOT).⁶¹ The MOT is a depository and distributor of standardized health outcomes measurement instruments. Every instrument that is proposed for addition to the MOT list of approved instruments is reviewed against a rigorous set of eight attributes. These attributes provide a useful evaluative framework. The eight attributes of an instrument addressed by the review criteria are as follows: (1) conceptual and measurement model, (2) reliability, (3) validity, (4) responsiveness, (5) interpretability, (6) respondent and administrative burden, (7) alternate forms, and (8) cultural and language adaptations.

CONCEPTUAL AND MEASUREMENT MODELS

A *conceptual model* is the rationale for and description of the concepts that a measurement instrument is intended to assess and the interrelationships of those concepts. A *measurement model* is an instrument's scale and subscale structure and the procedures followed to create scale and subscale scores. An example is the well-defined conceptual and measurement models for the scales and scale structure of the SF-36.⁶² The SF-36 contains 36 items that cover nine theory-based health concepts. Eight of these health concepts are measured by multi-item scales. There is a clearly defined means of creating the individual scale scores and the physical and mental component summary scales.⁴¹

RELIABILITY

Reliability refers to the extent to which measures give consistent or accurate results. The purpose of evaluating the reliability of a QOL instrument is to estimate how much of the variation in a score is real as opposed to random. The two reliability assessment methods discussed most often in the HRQOL literature are internal consistency and test-retest reliability. *Internal consistency* is an assessment of the performance of items within a scale. It is a function of the number of items and their covariation.⁶³ Internal consistency is commonly measured using Cronbach's alpha coefficient. Alpha coefficients above 0.90 are recommended for making comparisons between individuals and above 0.70 for comparisons between groups.⁶⁴

Test-retest reliability refers to the relationship between scores obtained from the same instrument on two or more separate occasions when all pertinent conditions remain relatively unchanged. It is usually evaluated using the intraclass correlation coefficient (ICC).⁶⁰ However, QOL is not assumed to be constant over the course of time. In fact, most clinical studies attempt to assess how QOL changes. Test-retest reliability estimates may have limited value in evaluating measures that are designed to assess a dynamic process.

Interrater reliability and *equivalent-forms reliability* are two other approaches to reliability assessment that are not used as commonly in QOL research. More in-depth discussions of these and the other reliability assessment methods are found elsewhere.^{60,65}

VALIDITY

Reliability is necessary but not sufficient for valid measurement.⁶³ *Validity* is an estimation of the extent to which the instrument is measuring what it is supposed to be measuring. Validity is not an absolute property of an instrument. Hence a measurement instrument is not "valid," but empirical data can provide evidence to support its validity. Three types of validity commonly considered are criterion, content, and construct.

Criterion validity is demonstrated when a new measure corresponds to an established measure or observation that accurately reflects the phenomenon of interest. By definition, the criterion must be a superior measure of the phenomenon if it is to serve as a comparative norm. However, in QOL assessment, "gold standards," or criterion measures, rarely exist against which a new measure can be compared.

Content validity, which is tested infrequently statistically, refers to how adequately the questions/items capture the relevant aspects of the domain or concept being measured.

Construct validity refers to the relationship between measures purporting to measure the same underlying theoretical construct (convergent evidence) or purporting to measure different constructs (discriminant evidence). For example, convergent evidence for the validity of a new measure of emotional well-being could be established by showing a strong association between the new scale and the Beck Depression Inventory.⁶⁶ Evidence for the construct validity of other aspects of the measure might be established through comparisons with physiologic measures, organ pathology, or clinical signs.

RESPONSIVENESS

Responsiveness, or sensitivity to change, is the ability or power of the measure to detect clinically important change when it occurs.⁶⁷ Although some authors have suggested that responsiveness is a psychometric property of a measure distinct from validity,⁶⁸ others argue that responsiveness is an aspect of validity rather than a separate property.^{63,69}

HRQOL CONTROVERSY

What constitutes a minimally important difference on an HRQOL measure? Although the statistical significance of a change, or difference score, is used often to denote important change, it may over- or underestimate the true impact of the disease and/or its treatment in terms of change that is perceptible and important to patients. Discussions regarding the concept of minimally important difference are appearing increasingly in the literature.

INTERPRETABILITY

Interpretability is the degree to which one can assign qualitative meaning to an instrument's quantitative scores. Interpretability is facilitated by comparison of a score or change in scores to a qualitative category that has clinical or commonly understood meaning. For example, it would be helpful to know how scale scores obtained in a specific patient sample compare with the scale scores of the general population. Ware and colleagues⁶² have provided very useful U.S. population-based normative data for the SF-36.

RESPONDENT AND ADMINISTRATIVE BURDEN

Respondent burden refers to the time, energy, and other demands placed on those to whom the instrument is administered. *Administrative burden* refers to the demands placed on those who administer the instrument. A practical aspect of the measurement of HRQOL is length of the instrument or the administration time involved. Instruments should be as brief as possible without severely compromising the validity and reliability of the measurement. The longer an instrument, the greater is the respondent burden. This can lead to an

individual's unwillingness or refusal to complete the instrument or to incomplete responses.

ALTERNATE FORMS

Alternate forms of an instrument include all modes of administration other than the original source instrument. Evidence should be provided that supports the comparability of the alternate mode of administration with that of the original instrument.⁷⁰ Many QOL measures can be administered in different ways. The primary modes of administration are (1) interviewer-administered, either in person or over the telephone, or (2) self-administered questionnaires.³¹ Other self-completed modes include computer-based (using the keyboard or touch screen to respond) and telephone touchtone administration. Used but not recommended are proxy responders (i.e., using a health care provider, family member, or friend to respond for the subject when the subject is unable to complete the instrument). Because QOL is such a subjective concept, patients must have the opportunity to provide their perspective on the impact of illness and/or medical care on their functioning and well-being. The patient's perspective has been shown to be quite different from that of outside observers, including physicians, family members, or others close to the patient.⁷¹

CULTURAL AND LANGUAGE ADAPTATIONS

Methods used to achieve conceptual and linguistic equivalence of cross-culturally adapted instruments should be stated explicitly.⁷² Evidence should be provided that the measurement properties of the adaptation are comparable with those of the original instrument. It is obvious that this is an extremely important issue when planning cross-national QOL assessment projects. However, it is also very important within countries that are multicultural, such as the United States.⁷³ Many of the English-language instruments have been developed for the dominant U.S. culture and may not be appropriate for all patients.

OTHER MEASUREMENT ISSUES

SELECTION OF AN APPROPRIATE INSTRUMENT

It is essential that the purpose of the measurement be well defined before selection of an HRQOL instrument. Is the purpose of the measurement to describe the health status or HRQOL of a patient population at a particular time or over time?⁷⁴ Is it to document change in health outcomes associated with a particular intervention? These and other questions should be answered before HRQOL instruments are selected. Too many practitioner-researchers attempting to demonstrate improvements in outcomes resulting from a pharmaceutical product or service select a commonly used generic instrument, such as the SF-36, with the expectation that it will be sufficiently responsive to changes that may occur. The best approach may be to use the SF-36 or other generic instrument in conjunction with a more targeted, disease-specific instrument.

AVAILABILITY OF INSTRUMENTS

Many HRQOL instruments are in the public domain. However, although they can be used for no or little cost, there may be a fee associated with the purchase of a user's guide or scoring manual. The MOT (www.outcomes-trust.org) is a source for a number of instruments, including the Duke Health Profile, QWB, MOS-HIV Health Survey, Migraine Specific Quality of Life (MSQOL), and Sickness

Impact Profile (SIP). For information on availability of the SF-36 and SF-12, go to <http://www.sf36.org>. The Functional Assessment of Chronic Illness Therapy (FACIT) Web site (<http://www.facit.org>) provides an extensive array of cancer- and chronic-disease-targeted instruments. Developers of particular instruments often can be contacted through addresses provided in other books referenced at the end of this chapter.^{28–30, 60}

CONCLUSIONS

The concept of HRQOL has gained increasing attention in the evaluation of the outcomes associated with medical care, including pharmacotherapy. In fact, in certain diseases, HRQOL may be the most important outcome to consider in assessing the effectiveness of health care interventions. Health care practitioners and policymakers must remember that efforts to increase length of life must not outstrip the ability to maintain or improve QOL.

HRQOL assessment is a relatively new field of endeavor, and a number of theoretical and methodologic issues remain unresolved. However, some general concepts in the measurement of HRQOL outcomes should be considered carefully when designing a study, evaluating existing research, or evaluating new programs or services. This chapter has provided only a brief overview of the concepts in an effort to sensitize students and health care practitioners to the importance of the area, as well as to provide insight as to how these concepts can and should be incorporated into their practices.

ABBREVIATIONS

AIMS: Arthritis Impact Measurement Scales
 AQLQ: Asthma Quality of Life Questionnaire
 CUA: cost-utility analysis
 DQOL: Diabetes Quality of Life
 ECHO: economic, clinical, and humanistic outcomes
 FACIT: Functional Assessment of Chronic Illness Therapy
 HALE: health-adjusted life expectancy
 HAPYs: health-adjusted person years
 HRQOL: health-related quality of life
 HIV/AIDS: human immunodeficiency virus/acquired immunodeficiency syndrome
 HUI: Health Utilities Index
 HYE: healthy-year equivalents
 ICC: intraclass correlation coefficient
 KDQOL: Kidney Disease Quality of Life instrument
 MCS: mental component summary scale of the SF-36
 MOS-HIV: Medical Outcomes Study HIV Health Survey
 MOT: Medical Outcomes Trust
 MSQOL: Migraine Specific Quality of Life
 NHP: Nottingham Health Profile
 PCS: physical component summary scale of the SF-36
 QALY: quality-adjusted life year
 QOL: quality of life
 QOLIE: Quality of Life in Epilepsy
 QWB: Quality of Well-Being scale
 SF-36: MOS 36-Item Short-Form Health Survey
 SIP: Sickness Impact Profile
 VAS: visual analog scale
 WY: well year
 YHL: years of healthy life

EVIDENCE-BASED MEDICINE

Elaine Chiquette and L. Michael Posey

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The best current evidence integrated into clinical expertise ensures optimal care for patients.
- 2 The four steps in the process of applying evidence-based medicine (EBM) in practice are (a) formulate a clear question from a patient's problem, (b) identify relevant information, (c) critically appraise available evidence, and (d) implement the findings in clinical practice.
- 3 The decision as to whether to implement the results of a

specific study, conclusions of a review article, or another piece of evidence in clinical practice depends on the quality (i.e., internal validity) of the evidence, its clinical importance, whether benefits outweigh risks and costs, and its relevance in the clinical setting and patient's circumstances.

- 4 EBM strategies can be applied to help in keeping current.
- 5 EBM is realistic.

In the information age, clinicians are presented with a daunting number of diseases and possible treatments to consider as they care for patients each day. As knowledge increases and as the technology for accessing information becomes widely available, health care professionals are expected to stay current in their fields of expertise and to remain competent throughout their careers. In addition, the number of information sources for the typical practitioner has ballooned, and clinicians must sort out information from many sources: college courses and continuing education (including seminars and journals), pharmaceutical representatives, and colleagues, as well as guidelines from committees of health care facilities, governmental agencies, and expert committees and organizations.

1 How does the health care professional find valid information from such a cacophony? Increasingly, clinicians are turning to the principles of evidence-based medicine (EBM) to identify the best course of action for each patient. EBM strategies help health care professionals to ferret out these gold nuggets, enabling them to integrate the best current evidence into their pharmacotherapeutic decision making. These strategies can help physicians, pharmacists, and other health care professionals to distinguish reliably beneficial pharmacotherapies from those which are ineffective or harmful. Also, EBM approaches can be applied to keep up to date and to make an overwhelming task seem more manageable.

This chapter describes for the reader the principles of EBM, offers guidance for finding EBM sources on the World Wide Web, provides a model for applying EBM in patient care, and explains how EBM strategies can help a practitioner stay current.

WHAT IS EVIDENCE-BASED MEDICINE?

EBM is an approach to medical practice that uses the results of patient care research and other available objective evidence as a component of clinical decision making. Similarly, evidence-based pharmacotherapy, defined by Etminan and colleagues,¹ is an approach to decision

making whereby clinicians appraise the scientific evidence and its strength in support of their therapeutic decisions.

While few would argue against the necessity for basing clinical decisions on the best possible evidence available, considerable controversy actually surrounds the practice of EBM. Critics note that not all questions relevant to the care of a patient are of a scientific nature and that EBM favors a “cookbook” approach. In fact, EBM integrates knowledge from research with other factors affecting clinical decision making. EBM does not replace clinical judgment. Rather, it informs clinical judgment with the current best evidence. The expertise and experience of the clinician who understands the disease are crucial in determining whether the external evidence applies to the patient and whether it should be integrated in the therapeutic plan. Also, nonmedical factors affect decision making, such as the patient's preferences and readiness and the health care delivery system's characteristics.

Other critics state that EBM considers randomized, controlled trials (RCTs) as the only evidence to be used in clinical decision making. Actually, EBM seeks the best existing evidence from basic science to clinical research with which to inform clinical decision. For example, a decision about the accuracy of a diagnostic test is best informed by evidence from a cross-sectional study, not an RCT. A cohort study, not an RCT, best answers a question about prognosis. However, in selecting a treatment, the randomized trial is the best study design to provide the most accurate estimate of treatment efficacy and safety.

EBM opponents note that RCTs usually are conducted in idealized environments or situations that are not sufficiently similar to the conditions of the “real world.” In addition, errors can be made when results of an RCT of one drug are extrapolated to all members of that class of drugs.^{2,3}

Regardless of one's view, RCTs have confirmed the value of many therapeutic options today and have disproved or clarified the usefulness of others. For example, in 1970, observational studies had indicated a possible association between the occurrence of premature ventricular contractions (PVCs) in patients after myocardial infarction

(MI) and sudden death. As a result, the eighth edition of *Harrison's Principles of Internal Medicine* recommended the use of antiarrhythmic agents to eradicate post-MI PVCs and thereby minimize the risk of sudden death. However, an RCT tested the antiarrhythmic therapy in patients with frequent PVCs, and it showed that class I antiarrhythmic agents increased rather than decreased the risk of sudden death.^{4,5} Today, guidelines discourage the use of antiarrhythmic agents to suppress PVCs in post-MI patients.⁶

More recently, the 1996 guidelines for the management of patients with acute MI concluded that observational studies “indicate that estrogen therapy does reduce mortality in women with moderate and severe coronary disease.”⁷ Subsequently, an RCT found no reduction in overall risk for nonfatal MI or coronary death with estrogen therapy. Rather, significantly more coronary events occurred during the first year of the trial among women receiving estrogen therapy compared with women taking placebo.⁸ These results prompted revision of the guidelines to conclude: “On the basis of the finding of no overall cardiovascular benefit and a pattern of early increase in risk of coronary events, starting estrogen plus progestin is not recommended for the purpose of secondary prevention of coronary disease.”⁶

In both these examples, conventional wisdom was wrong. Results from observational studies proved incorrect. Only through careful assessment using RCT methodology was the true estimate of the efficacy and safety of the therapeutic options discovered.

CLINICAL CONTROVERSY

In many ways, EBM is controversial, with some people feeling that it prevents the application of common sense and experience-based reasoning to clinical care. Some joke that a clinician called an EBM center and asked whether parachutes are effective when jumping from a plane. We do not know came the response—there are no randomized, controlled trials comparing jumping from a plane with and without one!

EBM ON THE WORLD WIDE WEB

For additional information and resources relevant to EBM, several comprehensive EBM sites exist on the World Wide Web. These sites include information on the history and development of EBM, glossaries of EBM terms, tutorials, training programs, software, links to EBM organizations and practice centers, guides to searching the medical literature, and results of evidence-based studies. For an excellent list of EBM links, access “Netting the Evidence: A SchARR Introduction to Evidence Based Practice” (<http://www.shef.ac.uk/~scharr/ir/netting/>). A specialized EBM site dedicated to pharmacotherapy deserves special mention. It is provided by the Centre for Evidence-Based Pharmacotherapy (<http://www.aston.ac.uk/pharmacy/cebpf/>). The mission of the center, created in 1995 by pharmacy professor Alain Li Wan Po, is to undertake research into the methodology of medicines assessment, pharmacoepidemiology, and pharmacoecconomics. In addition, the center offers postgraduate and distance learning in evidence-based pharmacotherapy.

INCORPORATING EBM INTO PHARMACOTHERAPEUTIC DECISION MAKING

2 The practice of EBM is to recognize an information need while caring for a patient, identify the best existing evidence to help resolve the problem, consider the evidence in light of the actual circumstances, and integrate the evidence into a medical plan. In this

section, the four steps involved in applying the EBM process to a pharmacotherapeutic decision are described⁹:

1. Recognize information needs and convert them into answerable questions.
2. Conduct efficient searches for the best evidence with which to answer these questions.
3. Critically appraise the evidence for its validity and usefulness.
4. Apply the results to patient situations to best assist clinical decision making.

BUILDING A FOCUSED QUESTION

Clinicians constantly balance the benefits and risks of various therapeutic choices. The questions they face are patient-specific:

- Should clopidogrel be prescribed to this 65-year-old man with unstable angina?
- Should hormone-replacement therapy be prescribed for this postmenopausal woman?
- Is sildenafil safe in this patient with type 2 diabetes?

When searching for the best evidence to answer such questions, the questions must be rephrased with more precision and specificity. A well-formulated question includes the following elements: the patient or problem being addressed, the intervention being considered, the comparison intervention, and the outcome(s) of interest.¹⁰ Using these four elements, the preceding questions can be reframed as follows:

- Would clopidogrel in addition to aspirin (*intervention*) prevent death or coronary events (*clinically relevant outcome*) in this patient with unstable angina (*patient with a problem*) who is currently on aspirin alone (*comparison intervention*)?
- Should we begin hormone-replacement therapy (*intervention compared with no intervention*) to prevent cardiovascular events (*outcome*) in this asymptomatic postmenopausal woman with a family history of coronary artery disease (*patient*)?
- If sildenafil is begun (*intervention*), what is the risk of myocardial ischemia (*outcome*) in this asymptomatic patient with known coronary artery disease (CAD) and newly diagnosed with type 2 diabetes (*patient*)?

The acronym *PICO* can be helpful to remember the elements of a well-balanced question¹¹:

P = patient
I = intervention
C = comparison
O = outcome

Focusing the question clarifies the target of the literature search and permits use of the appropriate guides for assessing external validity, that is, the applicability of the evidence found in the study to appropriate parts of the “real world.”

CONDUCTING AN EFFICIENT SEARCH

Health care professionals have four options as they try to identify the best evidence available to answer a well-framed question:

1. Ask a colleague for his or her expert opinion.
2. Review practice guidelines (evidence-based or expert-opinion-based) or a textbook for appropriate disease management.

TABLE 3–1. North American Sources of Evidence-Based Clinical Practice Guidelines

| Resource/Web Address | Special Features |
|--|---|
| <p>National Guideline Clearinghouse (NGC) (www.guideline.gov) NGC is a collaboration of U.S. Department of Health and Human Services and the Agency for Healthcare Research and Quality (AHRQ), in partnership with the American Medical Association (AMA) and the American Association of Health Plans (AAHP). NGC provides access to full text guidelines (when available) produced by a number of different professional medical associations and health care organizations. Each guideline is critically appraised using a standard instrument. The site permits side-by-side comparison of several guidelines.</p> | <ul style="list-style-type: none"> • 966 guideline summaries • Weekly e-mail alerts • Advanced search queries based on guideline attributes • Annotated bibliography of resources relevant to guideline methodology |
| <p>National Library of Medicine's Health Services/Technology Assessment Text (http://hstat.nlm.nih.gov/hq/Hquest/screen/HquestHome/s/55240) This World Wide Web resource is a collection of AHRQ Supported Guidelines, AHRQ Technology Assessments and Reviews, ATIS (HIV/AIDS Technical Information), NIH Warren G. Magnuson Clinical Research Studies, NIH Consensus Development Program, Public Health Service (PHS) Guide to Clinical Preventive Services and the Substance Abuse, and Mental Health Services Administration's Center for Substance Abuse Treatment (SAMHSA/CSAT) Prevention Enhancement and Treatment Improvement Protocols.</p> | <ul style="list-style-type: none"> • 199 full-text guidelines • Metasearch capabilities to PubMed, Centers for Disease Control and Prevention (CDC) Prevention Guidelines Database, and National Guideline Clearinghouse • Access to quick-reference guides for clinicians and consumer brochures. |
| <p>Primary Care Clinical Practice Guidelines (http://medicine.ucsf.edu/resources/guidelines) This Web resource offers a listing of online guidelines.</p> | <ul style="list-style-type: none"> • Searchable by clinical content and organization |
| <p>CDC Prevention Guidelines Database Home Page (http://www.phppo.cdc.gov/cdcrecommends) The site is a comprehensive collection of all the official guidelines and recommendations published by the CDC about prevention of diseases, injuries, and disabilities.</p> | <ul style="list-style-type: none"> • More than 500 prevention guidelines/documents • Searchable • Sort by date, by topic, or alphabetically |
| <p>Cancer Care Ontario Practice Guidelines Initiative (CCOPGI) (http://www.cancercare.on.ca) This Web page includes published and unpublished guidelines related to cancer care. These guidelines are created by the CCOPGI and are available full text.</p> | <ul style="list-style-type: none"> • 75 guidelines • When information is scarce, evidence summaries are created to review the best evidence available |
| <p>Agency for Healthcare Research and Quality's Evidence-Based Practice Centers (AHRQ EPCs) (http://www.ahrq.gov/clinic/epcix.htm) AHRQ has established 12 Evidence-Based Practice Centers to analyze and synthesize the scientific literature and develop evidence reports and technology assessments on clinical topics.</p> | <ul style="list-style-type: none"> • 84 evidence reports • Full text available |

3. Consult electronic databases of systematic reviews and/or meta-analyses.
4. Conduct a literature search using an electronic database such as MEDLINE.

Each of these options has advantages and disadvantages, as described below.

OPTION 1

Asking an expert or colleague may provide a quick and easy answer to a clinical question. Exercise caution, however. These sources have become less reliable as the volume and complexity of medical information have grown exponentially. Colleagues may be out of date or biased by their own experiences.

OPTION 2

Online practice guidelines or current textbooks with evidence links are useful if the question relates to a common or well-established issue (e.g., *UpToDate*, *Harrison's Online*, and *Scientific American*

Medicine Online electronic textbooks). As their names suggest, evidence-based clinical guidelines are guided by objective data and should be preferred over expert-opinion-based guidelines that refer loosely to evidence to support their opinions. Expert-opinion guidelines vary in their scientific validity and reproducibility.¹²

One Web site—the National Guideline Clearinghouse on the Web (<http://www.guideline.gov>)—provides links to many evidence-based clinical practice guidelines. For each guideline, this comprehensive database offers a short summary of the key attributes, including the bibliographic sources, guideline developers and endorsers, status of the guidelines, and major recommendations. In addition, the site provides the ability to generate side-by-side comparisons for any combination of two or more guidelines. Table 3–1 presents an annotated list of additional resources to find and access evidence-based clinical practice guidelines.

OPTION 3

Consulting electronic databases of systematic reviews and meta-analyses is attractive because of the limited amount of time health care professionals have to research and review the literature before they

answer clinical questions or reach patient care decisions. Busy health care professionals prefer summaries of information. Traditional narrative reviews are useful for broad overviews of particular therapies or diseases or for reports on the latest advances in a particular area where research may be limited.¹³ However, information from narrative reviews is often gathered ad hoc, and the author's biases may enter into the process of gathering, analyzing, and reporting information.

In contrast, systematic reviews employ a comprehensive, reproducible data search and selection process to summarize all the best evidence. They follow a rigorous process to appraise and analyze the information, quantitatively (through the meta-analysis technique) or qualitatively, to best answer a defined clinical question. Systematic reviews are a useful means of assessing whether findings from multiple individual studies are consistent and can be generalized.¹⁴

The Cochrane Library represents one of the most comprehensive sources of systematic reviews summarizing the evidence about health care. About 2000 Cochrane reviews are currently available, and another 1441 reviews were in progress when this chapter was finalized in spring 2004. Since new reviews are added quarterly, eventually all areas of health care will be covered. The Cochrane Library includes the Database of Abstracts of Reviews of Effectiveness, which contains more than 2500 structured abstracts of good-quality

published reviews about the effectiveness of health interventions. Table 3–2 lists accessible sources of systematic reviews and provides a search strategy developed by librarians at McMaster University to locate systematic reviews and meta-analyses on MEDLINE efficiently.¹⁵

OPTION 4

Consider conducting a literature search on an electronic database such as MEDLINE if the question relates to new developments in therapeutic options. In this case, health care professionals must consult primary literature. Dozens of electronic databases exist as primary sources of original research reports.

MEDLINE and PubMed, both produced by the National Library of Medicine (NLM), are the largest and best known bibliographic databases of biomedical journal literature. PubMed's in-process records provide basic citation information and abstracts *before* the citations are indexed with NLM's Medical Subject Headings (MeSH) Terms and added to MEDLINE. To optimize the efficiency of a clinical search, PubMed offers specialized searches using methodologic filters. These filters, based on work by Haynes and colleagues,¹⁵ are validated search strategies to identify clinically relevant studies

TABLE 3–2. Selected Resources for Systematic Reviews

| Resources | Advantages | Disadvantages |
|---|---|--|
| <p>Best Evidence Electronic version of both American College of Physicians (ACP) Journal Club and Evidence-Based Medicine (http://hiru.mcmaster.ca/acpj/acpod.htm). Available on CD-ROM.</p> | <ul style="list-style-type: none"> • All review articles are systematic reviews. • Updated every 6 months • Short title includes meta-analysis or review to facilitate identification | <ul style="list-style-type: none"> • Includes systematic reviews from only the journal scanned by ACP Journal Club and Evidence-Based Medicine |

Twenty-eight have been completed, and 38 are in progress. | <ul style="list-style-type: none"> • Limited number of guidelines and assessments available |

TABLE 3–3. Metasearch Engines for Web-Based Health Information**Turning Research Into Practice (TRIP)****Web address:** www.update-software.com/trip/about.htm**Sources:** Fifty-eight sites categorized as evidence-based, peer-reviewed journals, guidelines, or other. Sites include top 20 medical journals, EMB sites such as Bandolier, Critically Appraised Bank, Cochrane Database of Systematic Reviews, Journal Club on the Web, Evidence-Based Medicine series, guideline and systematic review sites such as SIGN, DARE, NICE, and National Guideline Clearinghouse.**Special features:** Updated monthly. Searches use keywords in the title only. Results are displayed by categories: evidence-based, peer-reviewed journals, guidelines, or other.**SUMSearch****Web address:** <http://SUMSearch.uthscsa.edu>**Sources:** Three Internet sites: The National Library of Medicine, the Database of Abstracts of Reviews of Effectiveness, and the National Guideline Clearinghouse.**Special features:** If the first search resulted in too many or not enough hits, SUMSearch uses metasearching and contingency search techniques to query the sites again.**Search.com****Web address:** <http://www.search.com>**Sources:** Twenty-two Internet sites containing health and medical information. Some of these sites are American College of Physicians Online, Centers for Disease Control and Prevention, *New England Journal of Medicine*, Agency for Healthcare Research and Quality, *Journal of the American Medical Association*, PubMed, Merck, Mayo Clinic, Food and Drug Administration, World Health Organization, WebMD, and Medical Subject Headings (MeSH).**Special features:** The site allows customization in choosing search engines and how to display results.**Query Server****Web address:** <http://queryserver.com>**Sources:** Twelve sites containing health and medical information. These sites are American Health Consultants, American Heart Association, Centers for Disease Control and Prevention, Department of Health and Human Services, Food and Drug Administration, Johns Hopkins Infectious Diseases, Leukemia and Lymphoma Society, MEDLINE, Medscape Clinical Content, Medscape News, National Institutes of Health, National Library of Medicine.**Special features:** Results are sorted according to content and/or source.

that answer questions about etiology, prognosis, diagnosis, or therapy of a disease.

To facilitate the searches of multiple Internet sources, metasearching is useful. Metasearch tools launch a single query across a set of Web-based health sites. One query returns a merged and often ranked list of hits, allowing the user to search several databases at once. Table 3–3 describes the specifics of new metasearch engines available to search for Internet-based health information.

Once the evidence is gathered, the clinician needs to determine whether the identified guideline, review article, or study report will help to answer the clinical problem. This is accomplished by considering the validity and by judging the clinical relevance (usefulness) of the information.¹⁶

ASSESSING VALIDITY

3 The *external validity* refers to applicability and generalization and is outlined in the section, “Applying the Results.” The remainder of this section focuses on critically appraising the quality—that is, the *internal validity*—of individual trials. The internal validity is determined by how well the trial ensures that the known and unknown risk factors are equally distributed between the treatment and control groups. To ensure validity, the conduct of the trial should minimize systematic bias and random error as much as possible to provide results that are as accurate and close to the truth as possible. Four sources of bias are possible in trials of health care interventions: selection bias, performance bias, attrition bias, and detection bias. Bias can result in an overestimation or underestimation of the effectiveness of a drug therapy and mislead the reader. While it is beyond

the scope of this chapter to present extensive details about critical appraisal, here are some questions that must be answered in assessing the internal validity of an RCT:

- *Was the subject’s treatment allocation randomized?* To minimize selection bias, all participants should have an equal chance to be allocated to the treatment or control group. Randomization is the best method to create groups of similar known and unknown confounders. If important risk factors known to affect prognosis (such as disease severity or presence of comorbidities) are unevenly distributed between groups, then selection bias could falsely estimate the benefit of the intervention. Furthermore, recruiters should not know which assignment (treatment or control group) is next in line. Recruiters who assess eligibility criteria and are aware of the next random allocation may consciously or unconsciously select the healthiest patient to be enrolled in the control group or vice versa. Approaches to randomization that may allow the recruiters to manipulate the assignment include improper use of record numbers (e.g., if all odd numbers were assigned to control group), dates of birth, day of the week, or open lists of random numbers. Examples of bias-free random allocations include centralized randomization (e.g., a central office unaware of subject characteristics allocates group assignments), pharmacy-controlled randomization (assuming that the pharmacist is not recruiting the subjects), and opaque envelopes that are numbered sequentially and sealed.¹⁷
- *Was the study double-blinded?* To minimize performance bias (systematic differences in the care provided, apart from the intervention being evaluated), the subjects and the clinicians should be unaware of the therapy received. The double-blind

method prevents subjects or clinicians from adding any additional treatments (or cointerventions) to one of the groups. For example, clinicians who know that certain patients are receiving the therapy they perceive to be less effective (control group) may opt to check on those patients more often than is required in the study protocol. A third blind can be applied to the outcome assessor (e.g., a statistician or clinician whose role is to measure the outcome) to minimize detection bias (systematic differences in outcome assessment). The necessity for blinding outcome assessors is controversial at this time.

- *Was intention-to-treat analysis performed?* Intention-to-treat analysis means that the results from all subjects randomized in the study were accounted for and attributed to the group to which they were assigned. This strategy minimizes attrition bias and ensures that the known and unknown prognostic factors are kept equally distributed. For example, exclusion of subjects who withdrew early in treatment may bias the

comparison because the reasons people withdraw early are often related to prognosis.¹⁸ Excluding early withdrawals from the final analysis may select the subjects most likely to get the best outcome and thereby overestimate the benefit of the intervention.

For a more detailed description of the concepts in critical appraisal, a series of articles published in the *Journal of the American Medical Association (JAMA)* provides a useful tool for practitioners who are evaluating clinical trials.^{19–50} These users' guides to the medical literature—developed by The Evidence-Based Medicine Working Group, a group of clinicians at Canada's McMaster University and colleagues across North America—can help to assess the validity of primary studies as well as review articles.

Online materials to support teaching of evidence-based health care, including the Users' Guides to Evidence-Based Practice, are now supported through the Centres for Health Evidence at <http://www.cche.net>. Table 3–4 summarizes the key elements to be

TABLE 3–4. Checklist for Critical Appraisal of Articles Addressing Pharmacotherapeutic Decisions

Therapy

Internal validity

- Was subject's treatment allocation randomized?
- Was the study double-blinded?
- Was intention-to-treat analysis performed?
- Was the randomization successful?

Magnitude of the effect

- What was the impact of the treatment?
- How narrow is the 95% confidence interval range?
- Were clinically relevant outcomes considered?

Applicability

- Does this patient fulfill inclusion criteria for the trial?
- Do the treatment benefits outweigh the risks?

Harm

Internal validity

- Were the control subjects similar to the cases?
- Was bias minimized while measuring exposure and outcomes?
- Was length of follow-up appropriate?
- Does exposure precede the adverse outcome?
- Is there a dose-response relationship?

Magnitude of the effect

- How strong is the association between exposure and outcome?
- How precise is the estimate?
- How many patients must be exposed to the agent to cause an adverse event?

Applicability

- What is the likelihood of harm in my patient?
- What are the consequences of eliminating the agent from my patient's therapy?

Overview, Systematic Reviews, Meta-analysis

Internal validity

- Did the overview clearly state a well-formulated question?
- Were the criteria used to select articles for inclusion appropriate?
- Were all relevant studies included?
- Were included articles critically appraised for quality?
- Was bias minimized in the selection, data extraction, and analysis processes?
- Were all clinically important outcomes considered?
- Were the studies appropriately combined?

Magnitude of the effect

- What is the average effect?
- How precise are the results?

Applicability

- Are this patient's characteristics similar to the subjects included in the studies?
- Do the treatment benefits outweigh the risks?

Practice Guidelines

Internal validity

- Were the management options and outcomes clearly specified?
- Was all evidence relevant to each arm of the evidence model sought?
- Were systematic and explicit methods used to identify, select, and combine evidence?
- Were all clinically relevant outcomes evaluated?
- Is the guideline up-to-date?
- Does the guideline clearly present the evidence to support the benefit of following the recommendations?
- Has the guideline been peer-reviewed?

Magnitude of the effect

- How strong are the recommendations?
- What is the impact of uncertainty in the evidence on outcomes?

Applicability

- Are the guideline recommendations targeting my practice (e.g., family practice setting versus endocrinology setting)?
- Is my patient the intended target for this guideline?

Economic Analyses

Internal validity

- Were both costs and outcomes evaluated for all strategies considered?
- Were costs and outcomes measured and valued accurately?
- Was the potential impact of uncertainties in the analysis evaluated?
- Was the potential impact of different baseline risk in the treatment population estimated on costs and outcomes?

Magnitude of the effect

- What were the incremental costs and outcomes of each strategy considered?
- Do incremental costs and outcomes vary between selected groups of patients?
- What is the impact of sensitivity analyses on incremental cost?

Applicability

- Do the treatment benefits outweigh the treatment risk and cost?
- Are the results transferable to my practice setting (e.g., similar patient types, similar costs of resources)?

addressed for each type of evidence to appraise internal validity and usefulness.^{19–50}

CONSIDERING CLINICAL RELEVANCE

Once the clinician has gathered all relevant studies, eliminated those which addressed other questions, and identified those with the best methods, one question remains: So what? Also known as the “who cares” test,⁵¹ applying this admittedly crude criterion begins the process of asking oneself, “Will these findings change the way I will treat or prevent this disease in my practice—and specifically for the patient sitting in front of me right now?”

The first step in making this decision is to consider the clinical value of the beneficial outcomes reported. Are the outcomes demonstrating improvements important to the patients? For example, a drug therapy that improves left ventricular ejection fraction (a surrogate end point) does not have the same clinical value as a drug that is shown to decrease mortality or improve functional status (primary end points) in an individual with heart failure.

The usefulness of an intervention depends not only on its efficacy but also on whether the magnitude of the benefit outweighs the risks,

costs, and benefits of existing alternative interventions. In this context, the number needed to treat (NNT) and the number needed to harm (NNH) are clinically useful measures. NNT and NNH describe the number of patients who need to be treated and for how long to achieve one favorable or harmful outcome, respectively (Table 3–5 illustrates the values of NNT and NNH). The NNT strategy provides a way to estimate an intervention’s impact and tradeoffs and to decide whether this therapy should be implemented.

The relative risk reduction (RRR), as a measure of the magnitude of an intervention’s effect, can be misleading. It does not discriminate between large and trivial absolute differences between the control and experimental groups. For example, an intervention may result in a 50% risk reduction for the adverse outcome, and this amount of decrease would sound impressive to most clinicians and patients. However, it might represent only a small difference in the risk of a rare event (e.g., 0.2% of patients in a placebo group died compared with 0.1% of patients on active drug). In contrast, a 50% risk reduction might reflect a much more meaningful difference, for instance, when 50% of placebo group died versus 25% of patients in the intervention group (an absolute difference of 25%). The RRR is the same for both examples, but the magnitude of the impact of the intervention is drastically different. The information provided by the RRR is incomplete

TABLE 3–5. Number Needed to Treat and Number Needed to Harm

In this example, the clinical question is whether the addition of clopidogrel to the regimen of a 65-year-old man with unstable angina who is already taking aspirin would prevent death or coronary event? A search of published trials and presented papers at scientific meetings uncovered only one relevant study. It was presented in abstract form at the American College of Cardiology meeting on March 19, 2001.

In the trial:

- 12,562 subjects with coronary syndrome were randomized to aspirin alone or aspirin plus clopidogrel.
- On average, patients were followed for 9 months.
- The primary endpoint was to prevent cardiovascular (CV) death, myocardial infarction (MI), or stroke.

To calculate the number needed to treat (NNT), first calculate the absolute risk reduction (ARR). This is the absolute difference between the event rate in the control group (CER) minus the event rate in the experimental group (EER). The NNT is the inverse of the ARR.

The trial reports that 11.47% of the aspirin alone group (control group) had MI, stroke, or CV death. In contrast, 9.28% of the aspirin plus clopidogrel (experimental group) had these events.

| Control Event Rate (Aspirin-Alone Group) | Experimental Event Rate (Aspirin Plus Clopidogrel) | RRR= (CER – EER)/CER | ARR = (CER – EER) | NNT = 1/ARR |
|--|--|----------------------|-------------------|-------------|
| 11.47% | 9.28% | 19% | 2.19% | 46 |

Thus the NNT is 46. That is, treating 46 patients with unstable angina for 9 months with aspirin with clopidogrel should prevent MI, stroke, or CV death in 1 patient. To balance risks versus benefits of an intervention, we can generate a similar number needed to harm to express the risks associated to the intervention.

The trial reports that 2.7% of the aspirin-alone group had major nonfatal bleeding events compared with 3.6% in the intervention group (aspirin plus clopidogrel).

To calculate the number needed to harm (NNH), first calculate the absolute risk increase (ARI). This is the absolute difference between the event rate in the experimental group (EER) minus the event rate in the control group (CER). The NNH is the inverse of the ARI.

| Control Event Rate | Experimental Event Rate | ARI (Absolute Risk Increase) | NNH |
|--------------------|-------------------------|------------------------------|-----|
| 2.7% | 3.6% | 0.9% | 111 |

The NNH is thus 111, meaning that treating 111 patients with both drugs for 9 months would result in 1 major nonfatal bleed. Combining the NNT and NNH and projecting the results to 1000 patients would lead to this conclusion: This randomized, controlled trial suggests that treating 1000 individuals with unstable angina with the combination of aspirin plus clopidogrel would prevent 21 patients from having a stroke, MI, or CV death at the cost of 9 major nonfatal bleeding events.

because it does not take into account the baseline risk of subjects in the trial.

CLINICAL CONTROVERSY

NNT and NNH can be a bit nebulous when it comes to applying these values in clinical situations. *P* values are considered significant routinely when they fall below 0.05, but what is a good NNT in one study may not be so good in another trial. NNT and NNH provide visualizations for how much risk and benefit are present when a group of similar patients—such as those seen by a physician or cared for in a pharmaceutical care clinic—are all treated with a medication or other intervention.

APPLYING THE RESULTS

For every health care professional, the ultimate test of which studies are important and which are not comes down to the decision of how to treat each patient. Thus clinical judgment is crucial in assessing the importance of drug-therapy evidence.

Several patient-specific factors must be considered in the final analysis:

1. *Compare the patient with those in the study (similar disease state and stage, similar baseline characteristics).* This assessment should ensure that the population studied has a similar disease state and prognostic factors as the patient now being treated. For instance, the results of a trial assessing the mortality benefit of simvastatin in dyslipidemic men with known coronary artery disease would not likely apply to dyslipidemic women with no other coronary risk factors.
2. *Consider the patient's baseline risk for the outcome of interest and other potential risks associated with the therapy.* If this patient has a higher baseline risk for the outcome than the population studied, then treatment may yield an even higher benefit. In contrast, if the patient has a lower baseline risk than the population studied, then treatment-associated risks may outweigh the potential benefit. For example, premenopausal women, in general, have a lower cardiovascular mortality risk than do men. Therefore, an intervention shown to prevent cardiovascular mortality in men may result in a smaller benefit in women.
3. *Consider the patient's values, beliefs, concerns, and readiness for the intervention.* In addition, health care delivery characteristics (cost and accessibility) must be factored in. While not very long ago health care professionals were considered patriarchal figures who directed the patient's treatment, today patients are fully engaged partners in decisions about therapy. The evidence must be discussed and integrated with the specific patient's circumstances to result in successful outcomes.

KEEPING UP TO DATE BY USING EBM

4 The same combination of clinical experience and EBM skills that enables health care professionals to resolve patient-specific

pharmacotherapeutic questions also aids health care professionals' continued efforts to keep up to date. The process is the same: (1) Recognize information needs (the areas of one's practice), (2) identify literature relevant to clinical practice, (3) critically appraise the evidence for validity and utility, and (4) devise a mechanism to implement new evidence in daily practice.

As with human knowledge in general, medical information is growing exponentially. Clinicians have difficulty staying current; a few statistics explain why. The National Library of Medicine contains more than 11 million citations covering nearly 4500 biomedical journals.⁵² The number of citations *doubled* in just 6 years, from 1995 to 2001. Each year, 10,000 RCTs addressing the impact of health care interventions are published. Some influence how clinicians practice, others provide preliminary evidence that is too early to act on or is irrelevant to clinical practice, and others are seriously flawed and should not be implemented. Who has time to read it all and separate the good from the bad? A literature-sorting strategy, using the EBM approach, is one solution.

First, the clinician must recognize the areas important in his or her practice (e.g., internal medicine, cardiology, nuclear medicine, nutrition, psychiatry, or pharmacokinetics). Second, scan the literature for clinically relevant studies in that area of interest or practice. These are studies addressing clinical outcomes likely to be relevant to clinical practice and possibly change prescribing behaviors, such as those which report the effect of a pharmacotherapy on quality of life, cost-effectiveness, mortality, or morbidity. In contrast, trials addressing the impact of drug therapy on surrogate end points (e.g., biochemical markers) most often are irrelevant to current clinical practice and rarely would result in a change in practice. When in a "keeping up-to-date mode," choose the studies reporting clinically relevant outcomes over those with surrogate end points. Third, critically appraise the evidence for validity and usefulness. When addressing therapeutic efficacy, RCTs are considered the "gold standard" and should be preferred over observational studies for most clinical questions. Scan the abstracts of RCTs for obvious design flaws and size of the effect before appraising further. Shaughnessy and colleagues⁵³ have created a formula to help determine the usefulness of medical information (Fig. 3–1). Finally, integrate the new findings into one's daily practice.

If this process seems too labor-intensive for keeping pace with the medical literature, consider an evidence-based abstraction service. These services, which have grown tremendously in the past 10 years, claim to reduce by 98% the amount of clinical literature a clinician needs to read, enabling the busy health care professional to concentrate on the 2% that is most methodologically rigorous and useful to his or her practice.⁵⁴ In general, abstraction services consist of an editorial team that scans dozens of journals, usually organized by specialty. They identify articles of potential clinical relevance, critically appraise the studies, and provide commentary on the quality/validity and clinical significance of the results reported. Table 3–6 presents a selected list of translation journals offering evidence-based abstracts of original research.

$$\text{Usefulness of Medicine Information} = \frac{\text{Relevance} \times \text{Validity}}{\text{Work Factor}}$$

FIGURE 3–1. In this usefulness formula, *relevance* represents patient-oriented evidence that matters and affects health care, *validity* refers to a true estimate of the effect, and *work factor* describes the effort required to review the information.

TABLE 3–6. Evidence-Based Abstraction Services

|---|
| ACP Journal Club (http://www.acponline.org/journals/acpj/jcmenu.htm) |
| Audience: Internal medicine, primary care |
| Selection criteria: Original articles, systematic reviews, English, adult, clinically relevant with important outcomes, randomized controlled trials for treatment questions |
| Journals scanned: 26 journals |
| Bandolier (http://www.jr2.ox.ac.uk/bandolier/) |
| Audience: Internal medicine |
| Selection criteria: Those which look remotely interesting are read, and where they are both interesting and make sense, they are summarized |
| Journal scanned: Each month PubMed and the Cochrane Library are searched for systematic reviews and meta-analyses published in the recent past |
| Evidence-Based Cardiovascular Medicine (http://www.harcourt-international.com/journals/ebcm/) |
| Audience: Cardiology (adult and pediatric) |
| Selection criteria: Original articles, English, clinically relevant, adult or pediatric humans randomized controlled trials, double blinded |
| Journals scanned: 25 journals mostly cardiology specialty journals |
| Evidence-Based Health Care (http://www.harcourt-international.com/journals/ebhc/) |
| Audience: Managers |
| Selection criteria: Articles providing evidence for decision making; articles that are likely to be widely applicable |
| Journals scanned: More than 50 journals mostly with economics and public health focus |
| Evidence-Based Medicine (http://www.evidence-basedmedicine.com) |
| Audience: Internal medicine, general and family practice, surgery, psychiatry, pediatrics, and obstetrics and gynecologists |
| Selection criteria: Original articles, Cochrane Reviews, randomized controlled trial or therapeutic efficacy trial, clinically relevant outcomes, 80% follow-up |
| Journals scanned: More than 30 journals |
| Evidence-Based Mental Health (http://www.ebmentalhealth.com/) |
| Audience: Mental health clinicians |
| Selection criteria: Original articles, Cochrane Reviews, randomized controlled trial or therapeutic efficacy trial, clinically relevant outcomes, 80% follow-up |
| Journals scanned: Not available |
| Journal Watch series (http://www.jwatch.org/) |
| Audience: General medicine, dermatology, cardiology, psychiatry, women's health, emergency medicine, infectious disease, neurology, gastroenterology (specialty Journal Watch for each audience) |
| Selection criteria: Not given |
| Journals scanned: More than 50 journals |
| Journal of Family Practice (http://www.jfp.msu.edu) |
| Audience: Family practice, pharmacists |
| Selection criteria: High-quality articles with patient-oriented outcomes that have the greatest potential to change the way that primary care clinicians practice |
| Journals scanned: 80 journals |
| Journal Club on the Web (http://www.journalclub.org) |
| Audience: Internal medicine |
| Selection criteria: Not given |
| Journals scanned: <i>New England Journal of Medicine, Annals of Internal Medicine, Journal of the American Medical Association, The Lancet</i> |

CONCLUSIONS

5 Is EBM realistic? The needed skills for practicing EBM may appear daunting, but once acquired, they can help health care professionals to better use available resources and time by knowing how to focus a search and be more critical in what reading and information to integrate into their knowledge base. Several sites have demonstrated that EBM can be incorporated into practice successfully.^{55–58}

Why practice EBM? Implementing EBM in a practice provides a framework and the skills to strengthen confidence in pharmacotherapeutic decisions and results in better communication with colleagues involved in the decision-making process. Furthermore, an

evidence-based pharmaceutical care plan facilitates dialogue with patients about the rationale for the management decisions. Finally, using EBM principles enables practicing health care professionals to update their knowledge continuously.

This chapter provides tools for health care professionals to

1. Identify rapidly evidence-based clinical practice guidelines
2. Identify rapidly systematic reviews
3. Conduct validated searches to identify studies answering pharmacotherapy questions
4. Critically appraise the literature found
5. Assess relevance and applicability of the evidence

- Develop strategies to triage the most useful literature and help to keep pace with the evidence that makes a difference in one's practice

ABBREVIATIONS

CAD: coronary artery disease
 EBM: evidence-based medicine
 MeSH: medical subject headings
 MI: myocardial infarction
 NLM: National Library of Medicine
 NNH: number needed to harm
 NNT: number needed to treat
 PICO: patient, intervention, comparison, outcome
 PVC: premature ventricular contraction
 PCT: randomized, controlled trial
 RRR: relative risk reduction

DOCUMENTATION OF PHARMACY SERVICES

George E. MacKinnon III and Neil J. MacKinnon

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Documentation of pharmacists' interventions and intent and their actions and impact on patient outcomes is central to the process of pharmaceutical care.
- 2 Unless pharmacists in all practice settings document their activities and communicate with other health professionals, they may not be considered an essential and integral part of the health care team.
- 3 Manual systems of documentation for pharmacists have been described in detail, but increasingly electronic systems are used to facilitate integration with payer records and health care systems.
- 4 Integrated electronic information systems can facilitate provision of seamless care as patients move among ambulatory, acute, and long-term care settings.
- 5 Federal systems of documentation are becoming increasingly important models in the United States as the Medicare Part D (oral prescription drug) benefit is implemented.
- 6 Electronic medical records have several advantages over manual systems that will facilitate access by community pharmacists and their participation as fully participating members of the health care team.

As the opportunities to become more patient-focused increase and market pressures exert increased accountability for pharmacists' actions, the importance of documenting pharmacists' professional activities related to patient care will become paramount in the years to come. Processes to document the clinical activities and therapeutic interventions of pharmacists have been described extensively in the pharmacy literature, yet universal adoption of documentation throughout pharmacy practice remains inconsistent, incomplete, and misunderstood.

1 Documentation is central to the provision of pharmaceutical care.¹ Pharmaceutical care is provided through a "system" in which feedback loops are established for monitoring purposes. This has advantages compared with the traditional medication-use process because the system enhances communication among members of the health care team and the patient. Pharmaceutical care requires responsibility by the provider to identify drug-related problems (DRPs), provide a therapeutic monitoring plan, and ensure that patients receive the most appropriate medicines and ultimately achieve their desired level of health-related quality of life (HRQOL).

To provide pharmaceutical care, the pharmacist, patient, and other providers enter a covenantal relationship that is considered to be mutually beneficial to all parties. The patient grants the pharmacist the opportunity to provide care, and the pharmacist, in turn, must accept this and the responsibility it entails. Documentation enables the pharmaceutical care model of pharmacy practice to be maximized and communicated to vested parties. Communication among sites of patient care must be accurate and timely to facilitate pharmaceutical care. As discussed by Hepler,¹ documentation supports care that is coordinated, efficient, and cooperative.

Conversely, failure to document activities and patient outcomes can directly affect patients' quality of care. There are several reasons for failure to document in the medication-use system, and these are

related to the process of documentation, the specific data collected on a consistent basis, how documentation is shared (e.g., other pharmacists, health care providers, patients, insurers), and methods by which the data are shared.

In describing the medication-use system, Grainger-Rousseau and colleagues^{2,3} have proposed eight essential structures, or elements, that must be in place for drug therapy to be both safe and effective (Table 4-1). When interventions are being planned to improve the medication-use system, all eight elements must be considered. When one or more of these eight essential elements are missing in the care of a patient, that patient is at a high risk of experiencing a DRP. One of these elements (number 7) is documentation and communication.

The lack of a universal reimbursement model for cognitive services provided by pharmacists can serve as a roadblock for initiating documentation; however, the opportunity to demonstrate contributions to patient outcomes and safety should serve as a catalyst for pharmacists to document their services provided in all practice settings. While a reimbursement model associated with professional services for the profession may emerge as Medicare Part D is implemented, its description is beyond the scope of this chapter. The reasons why pharmacists should document their patient care activities, along with the specific information that should be recorded, as well as examples of documentation systems and forms that have been used successfully, are illustrated in this chapter.

NEED FOR PHARMACIST DOCUMENTATION

The 1999 Institute of Medicine (IOM) Report (*To Err Is Human: Building a Safer Health System*) detailed the finding that as many as 98,000 Americans die unnecessarily every year as a result of medical

TABLE 4–1. Eight Elements of a Safe and Effective Drug Therapy System^{2,3}

| Element | Examples |
|---|--|
| Timely recognition of drug indications and other signs and symptoms relevant to drug use with accurate identification of underlying disease | “Correct” therapy for a late or incorrect diagnosis cannot improve a patient’s quality of life |
| Safe, accessible, and cost-effective medicines | Safe and cost-effective (efficient) drug products must be legally and financially available |
| Appropriate prescribing for explicit (clear, measurable, and communicable) objectives | Explicit therapeutic objectives simplify the assessment of prescribing appropriateness and are necessary for assessing (monitoring) therapeutic outcomes |
| Drug product distribution, dispensing, and administration with appropriate patient advice | Including (1) ensuring that a patient actually obtained the medicine, (2) negotiating a regimen that the patient can tolerate and afford, (3) ensuring that a patient (or caregiver) can correctly use the medicine and administration devices, (4) advising to empower the patient or caregiver to cooperate in his or her own care as much as possible |
| Patient participation in care (intelligent adherence) | The ambulatory patient or caregiver should consent to therapeutic objectives and know the signs of therapeutic success, adverse effects, and toxicities; when to expect them; and what to do if they appear |
| Monitoring (problem detection and resolution) | Many failures can be detected while they are still problems and before they become adverse outcomes or treatment failures |
| Documentation and communication of information and decisions | Communication and documentation are necessary for cooperation in a system |
| Product and system performance evaluation and improvement | Practice guidelines, performance indicators, and databases are a useful approach to achieving and maintaining improved system performance (outcomes) |

mistakes and errors, of which 7000 deaths were attributable to medication errors, costing upwards of \$9 billion.⁴ Handwritten prescriptions, orders, notes, and other methods of communication, unless transcribed electronically, are fraught with potential for misinterpretation and are error-prone. Through professional obligations, pharmacists in all settings (e.g., community, hospital, long-term care) play a pivotal role in ensuring the appropriate use of medications through prescription procurement or compounding, verification of the appropriateness of prescribed products (e.g., dose, duration, dosage form, and intended use) with prescribers, processing of prescription insurance-related claims, counseling of patients, and ultimately, follow-up and monitoring. The ability to continue to support uncompensated professional services and act as a critical safety net with respect to medication use in the health care system is now at a critical juncture and requires the profession’s immediate attention and subsequent action.

2 Documentation is the primary method to demonstrate value within an organized health care system. More importantly, it is the accepted method by which health care providers communicate with one another with respect to patient care decision making and clinical outcomes. Thus, if pharmacists in all practice settings are not communicating data/information routinely with other providers, they may not be considered an essential and integral part of the health care team.

FORCES AFFECTING CLINICAL DOCUMENTATION

- The need for enhanced communication among health care providers
- A focus on reducing redundancy and the potential for fatal and nonfatal medical errors and preventable drug-related morbidity in all practice settings

- The emergence of electronic medical records (EMRs) in health care, thereby facilitating the sharing of data and aiding in clinical decision making
- The need to maintain secure patient and provider data while also making this information available to other key individuals
- The desire of patients to communicate more regularly with health care providers and to obtain health care information in a more convenient manner

In the community setting, pharmacists may be one of the most accessible health care providers seen by patients on a regular basis (e.g., when medications are dispensed or over-the-counter products and diagnostics are purchased). By actively participating in the management of prescribed and nonprescribed drug products, as well as monitoring associated clinical outcomes, pharmacists can make a valuable contribution to patient care and demonstrate their impact on clinical and economic outcomes. While such activities presently are occurring in community practice, the provision of timely documentation to other providers and patients alike often is lacking.

STRUCTURE AND ORGANIZATION OF DOCUMENTATION

3 A great deal has been written about manual documentation systems in the pharmacy literature, both in clinical practice and in education, but these systems tend to be individualized applications in which the transfer of data to other providers is nonexistent or quite limited.^{5–8} Many documentation systems in pharmacy focus on the generation of reports for workload analysis or accreditation purposes. Unfortunately, the information gathered and analyzed in such

applications does little, if anything, to improve patient care if it is not in a real-time format.

The principal purpose of clinical documentation is to provide a record of what a practitioner does, why it is done, and when possible, what outcomes are achieved. It is essential to document succinctly the patient-specific recommendations and actions taken by pharmacists and why these decisions were made. Functions performed by pharmacists, such as obtaining medication histories, counseling patients, performing limited patient assessment and monitoring, conducting drug regimen reviews, and providing drug information are direct services that benefit patients, pharmacists, and other health care providers in various practice settings. The provision of these services by pharmacists and their associated outcomes need to be documented and communicated on a consistent basis. Documentation that occurs in a vacuum and devoid of real-time dissemination ultimately may not benefit patient care.

KEY CHARACTERISTICS OF CLINICAL DOCUMENTATION

- The primary purpose of clinical documentation is to provide a record of what a practitioner does, why it is done, and where possible, what outcomes are achieved.
- Clinical documentation should provide a real-time trail of care provided to patients.
- Documentation systems and applications must be easy to use, portable, produce useful reports, be replicated by others consistently, and allow for knowledge sharing with other providers.

While convenient and easy to use, paper documentation forms can be time-consuming to complete accurately, are inefficient in terms of producing useful information, and often result in inconsistent reporting because there is great variance in their format and use among practitioners. Efficient and effective documentation systems capable of capturing data supporting the involvement of the profession in direct patient care activities must be developed, tested in clinical settings, and used uniformly in practice.

TYPES OF PATIENT INFORMATION TO DOCUMENT

A well-designed documentation system serves a multitude of purposes. It encompasses a complete and comprehensive archive of the patient's drug-related information, a record of pharmaceutical care interventions, and all care plans and outcomes, and it also may serve as a legal record of the care that has been provided.⁹

PROBLEM-ORIENTED MEDICAL RECORD

Information within a patient's file must be organized in a fashion that facilitates quick retrieval. One commonly used and efficient method of organization is the problem-oriented medical record (POMR) format, whereby documents within a patient's file are organized according to a list of problems.¹⁰ This process, pioneered by Dr. Lawrence Weed, consists of four major components: a defined database, a problem list, an initial plan, and progress notes. Each document is to be filed according to the source from which it comes, typically physician orders, nursing notes, and laboratory and diagnostic results. The clinical notes for each medical problem commonly are organized according to the SOAP approach: subjective and objective data, assessment, and therapeutic plan.

Subjective data are related to the identified problem and associated symptoms as described by the patient himself or herself (or in some cases by the caregivers of the patient). *Objective data* include observations made and information acquired by the health care practitioner that is determined to be relevant to the identified patient problems. The *assessment* refers to the practitioner's clinical opinion or judgment about the problem based on subjective and objective data, as well as the practitioner's previous experiences related to similar clinical problems and patients. The *plan* is the course of action deemed appropriate for each identified problem given the data available to the clinician.

DRUG-RELATED PROBLEMS

While the SOAP approach is very practical and systematic, it may not be appropriate for many pharmacists because there are limitations with respect to consistent access to certain data elements available in many practice settings. Additional concerns relate to the redundancy created in a patient record if the pharmacy documentation is to become part of an existing record. Such patient medical records are already voluminous, and only succinct, essential information needs to be added. Thus the contributions of pharmacist-generated documentation should be supportive of a patient's care plan to assist in achieving defined therapeutic objectives and/or avoiding drug-related problems (DRPs) where appropriate.¹¹

DRUG-RELATED PROBLEMS

- Untreated indication
- Improper drug selection
- Subtherapeutic dosage
- Overdosage/toxicity
- Failure to receive drug
- Adverse drug reactions/events
- Interactions
- Drug use without indication

When a pharmacist identifies a DRP, it may be listed and counted among the documents for an existing problem (e.g., subtherapeutic dose of a proton pump inhibitor for treatment of an ulcer), or if the cause is not readily identifiable, it may be listed as a new problem. All patient files established by a pharmacist should contain similar basic elements. For example, to provide pharmaceutical care, such as identification of DRPs, pharmacists need specific knowledge about the patient, such as demographic characteristics, social and medical history, general appearance, health status, and third-party insurance or billing information.⁹

Currie and colleagues¹² devised a tool to assess the quality of pharmacists' documentation. These researchers created a list of data elements after a comprehensive literature search and input from practitioners and expert panels. The elements are divided into two groups: those essential to each individual patient encounter and those essential to a patient record (Table 4-2). The acquisition of each of these elements is critical to the provision of pharmaceutical care.

COMMUNICATION OF DOCUMENTATION AND FINDINGS

4 Once patient information has been documented appropriately, it should be made available to other health care providers for review when necessary. Without a universal electronic documentation

TABLE 4–2. Elements to Be Documented by the Pharmacist¹²

| Status of Element | For Patient Encounters* | For Patient Records |
|----------------------------|--|---|
| Essential | Patient identifier Date of encounter Reason for encounter Pharmacist identifier History of present illness Relevant prescription, over-the-counter, and alternative mediations (history and compliance) Assessment (conclusions reached by the pharmacists after assessment of the drug therapy) Plan(s)/action(s) to correct problem(s) (A listing of planned steps to achieve the goals established with the patient for the patient's drug therapy; the goal of the therapy should be implicitly or explicitly stated) Monitoring plan and follow-up (steps to monitor the outcomes of actions taken) | Patient identifier Date of birth Sex Contact information Allergies and adverse drug reactions Medical problem(s), current and past Prescription, nonprescription, and alternative medications (history and adherence) Payment method and economic situation |
| To be included if relevant | Past medical history Family history Social history (diet, alcohol, tobacco use, caregiver status, etc.) Objective information (e.g., vital signs, laboratory results, diagnostic signs or physical examination results) | Family history Social history Ethnic background Objective information (a compilation of testing results from the pharmacy practice or other testing site) Special needs of patient (e.g., need for assistive devices, special educational needs) Nonmedication therapy |

*The essential elements may be present in the chart and referred to in the note and not repeated in the encounter note itself. If there is a follow-up encounter, the note could be abbreviated.

system in place for pharmacists, various means of communication (e.g., mail, fax, phone, or e-mail) can be used to communicate with other health care providers and patients where appropriate. One patient may have several patient files at different sites of care (e.g., in the hospital, in various physicians' offices, and in community pharmacies), thus complicating the manner of communication. However, it is critical to determine what information must be passed on to fellow health care workers.

An integral part of providing pharmaceutical care is monitoring patient outcomes. To follow patients effectively throughout the course of their therapy, monitoring parameters and desired outcomes must be determined and documented. Examples of monitoring parameters include reducing the blood pressure in a hypertensive post-myocardial infarction patient to less than 120/80 mm Hg and reducing the low-density lipoprotein cholesterol to less than 100 mg/dL. Properly documenting this information assists other pharmacists and health care professionals during follow-up appointments because the preestablished monitoring parameters and recommended changes (based on collected data from all providers) can be reviewed readily.

DOCUMENTATION AND SEAMLESS CARE

Although the exact terminology may vary, *seamless care* is a concept that has been viewed widely as a fundamental component of the optimal delivery of health care services. Several different health professions, including nursing, occupational therapy, and others, have published studies in which seamless care was provided within the context of their own practice environments.¹³ Where seamless care is provided, effort is placed on developing multidisciplinary teams that work together across any transitions of care that may arise.¹⁴

In recent years, the average length of hospital stays has shortened, and consequently, patients are being discharged into the ambulatory setting and long-term care facilities at a higher level of acuity. Regrettably, in most health systems, an effective means of communication regarding patients' drug therapy has not been established across the continuum of care. Such communication is vital since drugs may be added to or discontinued from a patient's drug regimen during hospitalization, or dosing may be altered. One study that tracked changes in medications over a hospitalization period in the elderly (age 65 and over) reported that 71% of patients had at least one of their admission medications discontinued by the time they were discharged from hospital, accounting for 40% of all admission medications.¹⁵

Patients, caregivers, and community pharmacists may be unclear as to what medication changes have been made in the inpatient setting and the reasons for these changes. Subsequently, there may be DRPs in the patient's medication regimen that will not be identified or resolved in a timely fashion. The community pharmacist, who may fill discharge prescriptions, generally is not privy to information regarding the patient's diagnosis and laboratory test results. In essence, the community pharmacist is uninformed and at a disadvantage to monitor for future DRPs that may result from previous medication regimen alterations. A study in the United Kingdom indicated that 95.7% of community pharmacists surveyed would not even know if one of their patients had been admitted recently to a hospital.¹⁶

Problems stemming from care that is not seamless are not limited to patients who are moving from a hospital to the community. Equally important is the provision of seamless care from the hospital to long-term care setting and the community pharmacy to the hospital pharmacy setting.

TABLE 4–3. Seven Principles of the Australian National Seamless Care Guidelines²⁰

| | |
|--------------------|---|
| Principle 1 | It is the responsibility of the admitting institution to ensure the development and coordination of a medication discharge plan for each patient. The person responsible for coordinating the development, implementation, and monitoring of the medication discharge plan, including medication supply and medication information, should be identified as soon as practicable after admission. |
| Principle 2 | Hospital staff should obtain an accurate medication history, including prescription and nonprescription medicines and other therapies such as herbal products, at the time of admission. |
| Principle 3 | Hospital staff should evaluate the current medication at the time of admission, in consultation with the patient's general practitioner, with a view to (1) identifying the appropriateness and effectiveness of current medication and rationalizing current medications if appropriate, (2) paying particular attention to any problems associated with current drug therapy, including any possible relationship with the current medical conditions, and (3) documenting allergies and any previous adverse drug reactions. |
| Principle 4 | During the hospital stay, treatment plans relating to the probable medication management during the stay and, where applicable, at discharge should be developed in consultation with the patient and/or caregiver. Hospital staff should negotiate with the patient issues relating to treatment and the development of a discharge plan, and these discussions should be documented in the patient's notes. This plan should form part of the overall care plan or critical pathway. |
| Principle 5 | Prior to discharge, predischARGE medication review and dispensing of adequate medication should take place in a planned and timely fashion. Adequate medication means sufficient medication to carry the patient through to the next arranged review or to complete course of treatment. |
| Principle 6 | At the time of discharge, each patient should be provided with a discharge folio containing relevant information such as consumer medicine information, a medication record, patient/care plan, and information on the availability and future supply of medication. |
| Principle 7 | No patient should be discharged from hospital until the details of the admission, medication changes, and arrangements for follow-up have been communicated to the health care provider(s) identified by the patient as being responsible for his or her ongoing care. |

STUDIES INVOLVING THE EVALUATION OF DOCUMENTATION BY PHARMACISTS ACROSS THE CONTINUUM OF CARE

Several studies evaluating the impact of the provision of proper documentation by pharmacists across the continuum of care have been conducted in Australia, Canada, the United Kingdom, the United States, and beyond. Examples of such studies are presented. The examples are not meant to be a comprehensive list of all such activities but rather are reviewed to give an indication of the state of pharmacist documentation in each country.

PHARMACIST-DIRECTED DOCUMENTATION INITIATIVES IN AUSTRALIA

Pharmacist-directed documentation activities in Australia have been the center of considerable attention in recent years. The need for these services has been articulated in the *Australian Journal of Hospital Pharmacy*: "... hospital-based services developed with little thought to what happens to patients before they come to the hospital and after they leave. This has placed hospital pharmacy in a dangerously isolated position," and "presently Australia has no system that effectively manages information relating to medications. This lack of timely and accurate medication information remains a significant barrier to ensuring the quality use of medications by the community at large."¹⁷ The Department of Pharmacy at the Royal North Shore Hospital in Sydney reported on a practice guide for the provision of pharmaceutical care that, among other things, helped to educate the patient at the time of discharge to promote seamless care as the patient returned back into the community.¹⁸

The Pharmacy Continuity of Care Project, a study by the Faculty of Pharmacy at the University of Sydney, promoted the use of patient discharge forms that were sent by the hospital pharmacist to (1) the community pharmacist and (2) case conferences between these two individuals and the patient's general practitioner.¹⁹

One of the more significant developments in Australia has been the publication of the Australian Pharmaceutical Advisory Council's *National Guidelines to Achieve the Continuum of Quality Use of Medicines Between Hospital and Community*. This 1998 publication contained seven principles that are recommended to be followed to help to attain a high level of seamless pharmaceutical care²⁰ (Table 4–3).

PHARMACIST-DIRECTED DOCUMENTATION INITIATIVES IN CANADA

The profession of pharmacy in Canada also has been active in documentation activities across the continuum of care. In 1994, Cameron²¹ reported on the findings of a pilot project in Halifax, Nova Scotia, in which forms completed by the hospital pharmacist that contained either the rationale for inpatient medication changes or recommendations for future changes were sent to family physicians and community pharmacists. Austin²² provided an overview of seamless care issues in Canada in 1995, including the description of a seamless care program called Palliative At-Home Care Team at the Scarborough General Hospital in Ontario. More recently, other researchers have evaluated the use of hospital discharge prescription summary forms in Halifax, Nova Scotia,²³ and Montreal, Quebec.²⁴ Seamless care pilot projects also have been undertaken in Calgary; Alberta; Montreal, Quebec; and Pictou County, Nova Scotia, as described in the cases at the end of this chapter.

A randomized controlled study was carried out at the Moncton Hospital in Moncton, New Brunswick, to determine the impact of a pharmacist-directed seamless care program on economic, clinical, and humanistic outcomes and processes of care.²⁵ A total of 253 patients (119 in the control group and 134 in the intervention group) completed the study. A mean of 3.59 drug therapy problems for seamless monitoring per intervention patient was identified, and 72.1% of these problems were scored as having a *significant* or *very significant*

clinical impact level. Participating community pharmacists who were surveyed believed that seamless care service helped them to provide better pharmaceutical care and improved efficiency in their pharmacies. In conclusion, the study researchers argued that a pharmacist-directed seamless care service can effectively resolve many drug therapy problems and improve drug-related processes of care in hospital and community pharmacies. On a national level, the Canadian Society of Hospital Pharmacists and the Canadian Pharmacists Association have had a joint task force on seamless care in operation for several years.

PHARMACIST-DIRECTED DOCUMENTATION INITIATIVES IN THE UNITED KINGDOM

In the United Kingdom, some health researchers have concluded that the medication-use system requires seamless care services to improve communication and safety. A study conducted in a large general hospital in England showed that breakdowns in the present discharge system can create problems for patients.²⁶ Thus 13% of participants had at least one discrepancy in their take-home prescriptions transcribed from the discharge notes. When the discharge letter was compared with the discharge notes, 27% of the patients' letters had a drug discrepancy. The researchers found that the mean time for the discharge letter to arrive from the hospital to the general practitioner's office was 26.9 days, and one-half took longer than 32 days. At follow-up, 57% of patients were experiencing a DRP that by clinical pharmacists' standards required intervention.

The results of the completed surveys from 163 U.K. Trust Hospitals showed that a wide variation still exists among various institutions in their ability to meet patients' needs.²⁷ Pharmacists were involved in the preparation of discharge prescriptions in only one-third of the hospitals, and their impact there was close to negligible. Alarming, 95% of institutions did not have their clinical pharmacists communicating with their community counterparts. The authors made the following recommendations: implementation of medication compliance charts, telephone medicine help lines, additional copies of discharge prescriptions for the general practitioner and the community pharmacist, regular involvement of the pharmacist in preparation of discharge medications (checking against the ward chart), and directly faxing copies of the prescriptions (complete with reasons for changes) to the general practitioner's office.

Studies that have evaluated pharmacist-directed seamless care services in the United Kingdom have had mixed results. In a randomized controlled trial of 362 patients that evaluated the effectiveness of a pharmacy discharge plan in hospitalized older adults, no impact on patient outcomes was found.²⁸ A smaller study of 32 patients found a positive impact on unintentional medication discrepancies in the intervention group,²⁹ whereas a seamless care feasibility study was received positively by participating community pharmacists.³⁰ Pharmacists in the United Kingdom also have begun to take an expanded role in primary care groups, working closely with physicians and nurses.

In 1993, the Royal Pharmaceutical Society of Great Britain created checklists for pharmacists that served as a guide to the types of communication that should occur between hospital and community pharmacists regarding patients' medication and pharmaceutical needs.³¹ These checklists contained information that should be completed by the community pharmacist to the hospital pharmacist on hospital admission of a patient, such as the medication history and domiciliary circumstances and known adverse drug reactions (ADRs),

and information to be provided by the hospital pharmacist to the community pharmacist, such as the medication plan.

PHARMACIST-DIRECTED DOCUMENTATION INITIATIVES IN THE UNITED STATES

Many of the activities in the United States in this area relate to initiatives regarding the expanded scope of practice of pharmacists in the hospital, community, and managed-care settings. Most states now allow pharmacists to enter into collaborative prescribing agreements with physicians. The American Society of Health-System Pharmacists' Statement on the Pharmacist's Role in Primary Care advocates a larger role for pharmacists, including participation in multidisciplinary reviews of patients' progress, initiating or modifying medication therapy on the basis of patient responses, and performing limited physical assessments.³² The American College of Physicians–American Society of Internal Medicine also has put forward a pharmacist's scope of practice, including the pharmacist's role in collaborative practice with physicians; pharmacist involvement in patient education and hospital medical rounds; pharmacist prescribing, immunizing, and therapeutic substitution; and reimbursement for pharmacists' cognitive services.³³ This expanded scope of practice also has legal implications; as Brushwood and Belgado explain, "The expanding availability of knowledge will expand professional responsibilities—and legal duties will not be far behind."³⁴

Some pharmacist-directed seamless care evaluation studies have been conducted in the United States. Community and ambulatory care pharmacists who received a referral form from the hospital pharmacist when patients were discharged believed that the form helped them to better tailor patient counseling to the needs of the patients and positively affected the pharmacist–patient relationship.³⁵ Two studies that evaluated the impact of a hospital pharmacist providing pharmaceutical care at the time of discharge revealed the service to be well received by physicians and nurses³⁶ and patients.³⁷ Kuehl, Chrischilles, and Sorofman reported on a novel pharmacist-directed seamless care program among ambulatory care, hospital care, and long-term care pharmacists in five pharmacies in the midwestern United States.³⁸ In this study of 156 patients, patient-specific information significantly increased the number of interventions by the hospital and ambulatory care pharmacists.

HOSPITAL PHARMACY TO COMMUNITY PHARMACY

Most research projects to date have focused on the transfer of information from hospital pharmacies to community-based facilities primarily involving the general practitioner and the community pharmacist. These projects have clearly addressed a real need. In a survey of community pharmacists in the United Kingdom, 95.7% indicated that they would not know if one of their patients had been admitted to a hospital, and almost one-third had never seen a copy of the discharge information provided to patients and their general practitioners.¹⁶

COMMUNITY PHARMACY TO HOSPITAL PHARMACY

Far fewer initiatives have focused on the transfer of information from the community pharmacist to other members of the health care team. This is unfortunate because the community pharmacist often possesses valuable patient information by virtue of seeing the patient regularly for prescription refills and other self-care needs. Developing stronger ties between the community pharmacy and other sites of

care can only serve to increase communication to improve the quality of patient care delivered.

COMMUNICATION WITH PHYSICIANS

Communication between the pharmacists and a patient's physician or physicians is crucial to the delivery of high-quality care, but such relationships can be threatened by perceived turf battles and misunderstandings. As discussed by Buerger,³⁹ improving the pharmacist-physician relationship requires effort and understanding on the part of both parties. Various stresses inherent in health care delivery make effective communication rather challenging in certain situations. To strengthen ties between physicians and pharmacists, all parties should focus on improving their communication skills and exercising their conflict-resolution skills.³⁹

COMMUNICATION WITH PATIENTS

In this era of an ever-increasing desire on the part of patients to be involved in their own health care, an increasing number of self-care products (e.g., diagnostic, pharmaceutical, and nutraceutical) in the marketplace, and advanced communication technologies available to consumers (e.g., cell phones, personal digital assistants, electronic mail, and the Internet), community pharmacists have a unique opportunity to assume a pivotal role among other health care providers and patients in communicating, interpreting, and monitoring for the desired health outcomes. While not commonplace today, pharmacists should begin to communicate more regularly with their patients with respect to their health care needs and, where possible, should refer those patients back to health care providers when necessary. For example, how often has a patient presented himself or herself to a community pharmacy describing a condition or possible DRP in which the recommendation of the pharmacist following a brief triage is to refer the patient to his or her physician or other caregivers (e.g., dentist or optometrist) for follow-up? Unfortunately, this interaction seldom involves documentation by the pharmacist to the patient or other provider involved, and more than likely, follow-up with either party is by serendipity. This situation in the medical community would result in what is commonly known as a *referral* from one health care provider to another. Clearly, anecdotal reports of patients who have presented to a pharmacist, and describe significantly negative health outcomes and possibly death were averted because of this interaction with the pharmacist. However, such actions commonly went undocumented and therefore were not reported or traceable and possibly underappreciated or undervalued. Many patients have not experienced such formal and consistent documentation from the pharmacy profession, and it would prove valuable. Once these activities are consistent and valued by patients and providers alike, this may begin to set the parameters for patient payments directly to pharmacists while ultimately contributing to beneficial health outcomes of the patients served.

BILLING CONSIDERATIONS AND DOCUMENTATION SYSTEMS

MEDICAL BILLING SYSTEMS IN THE UNITED STATES

5 The Centers for Medicare and Medicaid Services (CMS) universal claim form is used by health care providers for third-party billing related to the provision of services. This form is required by Medicare and other third-party payers in the United States and uses

the *International Classification for Disease, 9th Revision, Clinical Modification* (ICD-9-CM) coding system by providers for reimbursement, and this system is becoming increasingly important as Medicare Part D (oral prescription drug) coverage is implemented. Categories 1 to 15 (codes 001–779) identify diseases and related common medical conditions. Category 16 (codes 780–799) designates symptoms, signs, and ill-defined conditions. Category 19 (codes 800–999) relates to injury and poisoning. Each category contains additional codes that provide greater specificity and precision in terms of the condition or illness. There are two additional subsets of codes: V codes, which are used to classify routine screening examinations, and E codes, which are related to environmental injury or illness.

Use of Current Procedural Terminology (CPT) codes or the Common Procedure Coding System is required for completion of the universal claims form. CPT codes were created to be a listing of descriptive terms and identifying codes for medical services and procedures performed. Codes 99201 to 99205 are used for an office visit with a new patient, and codes 99211 to 99215 are used for an office visit with an existing patient. The differentiation among codes used is based on the intensity of service provided by the health care provider and the time involved. While not used commonly in pharmacy, these codes have been used by pharmacists to document the provision of patient-centered services in ambulatory and community settings when completing the universal claims form for billing purposes to third-party payers.

PHARMACY BILLING SYSTEMS

Recognizing issues related to nomenclature, compatibility, and transmission of data, some organizations have created guidelines to assist in the standardization of documentation systems for pharmacy. Historically, these efforts have been centered on the outpatient arena, focusing primarily on prescription claims related to the procurement and dispensing of prescription pharmaceutical products to patients from community pharmacies and by mail order. Founded in 1976, the National Council for Prescription Drug Programs (NCPDP) developed standards that allow for electronic data interchange (EDI) among providers of pharmaceuticals (e.g., pharmacies) and third-party administrators [e.g., pharmacy benefit management (PBM) organizations] primarily for the adjudication (i.e., financial approval) of prescriptions. This adjudication historically has centered on the assessment of the formulary status of a prescribed medication, resulting in verification or denial of the prescription and resulting payment to the dispensing pharmacy.

The payment formula for pharmaceuticals (and not professional services) typically has included a discounted cost of ingredients [e.g., the average wholesale price (AWP) discounted by a given percentage] plus a dispensing fee. The dispensing fee, often in the range of \$1 to \$2 per prescription, is paid irrespective of the pharmacist time involved in processing the prescription (procuring/compounding the product, verifying with the prescriber patient- and product-specific concerns identified, addressing insurance-related claims issues, and conducting patient counseling/follow-up monitoring). Arguably, no uniform standard has been adopted by pharmacists and third-party administrators to allow for billing and financial compensation associated with the provision of professional services by pharmacists both in scope and in intensity of services provided.

Having a reimbursement system tied only to product dispensing is fraught with problems. For example, in community pharmacy practice, if a pharmacist provides a recommendation to discontinue

therapy and this recommendation is followed, no reimbursement to the pharmacy will take place because no product would be dispensed (although the third-party administrator and the patient would save money). However, if the recommendation is ignored and the product is dispensed, the third-party payer would incur a cost related to dispensing the prescription. Clearly, the issue related to the appropriateness of the prescription is somewhat lost.

Recent efforts by the NCPDP and other professional organizations such as the National Community Pharmacists Association have recognized the need for allowing the transmission and adjudication not only of electronic prescriptions but also of requests for refills and other transactions among prescribers (e.g., physicians) and pharmacists. As a result, various initiatives have been undertaken to allow for such levels of transmission among pharmacists, physicians and other health care providers, payers, and ultimately, patients.

6 ROLE OF TECHNOLOGY IN CLINICAL DOCUMENTATION

Emerging technologies will have a profound effect on health care, thus offering opportunities for the pharmacy profession in maintaining constant vigilance related to the procurement, preparation, and distribution of pharmaceuticals and allowing for more consistent provision of pharmaceutical care. Digital documentation, such as computer-stored medical records or electronic medical records (EMRs), is one vehicle that, if adapted universally, would assist in enhancing the communication among providers in all settings. EMRs must be implemented by 2009 under the new Medicare Part D regulations, and this is expected to drive adoption of the new technologies by prescribers. Significant benefits to EMRs have been described as the following: (1) improved logistics and organization of the medical record to speed care and improve efficiency, (2) automatic computer review of the medical record to limit errors and control costs, and (3) systematic analysis of past clinical experience to guide future practices and policies.⁴⁰ The use of EMRs that include pharmacy-specific data (e.g., history of medication usage, both prescription and over the counter; history of refills; assessment of adherence and persistence; and other information deemed appropriate for inclusion by pharmacists) allows for improved communication, enhanced decision making, and the ability to follow up on outcomes associated with care plans.

Advances in technology can facilitate the generation and transfer of patient documentation. As more pharmacies use the Internet as a means of communication, information can be transferred quickly and accurately over greater distances. Handheld computers and specialty software allow health care practitioners to document information in an electronic format that can be transformed immediately for rapid transfer to others. Reports in the literature have described methods to assess pharmacist interventions related to medication errors,⁵ the use of computer-based systems,⁶ and recently, the use of personal digital assistants (PDAs) in specific patient care areas.⁷ Many of these documentation systems tend to be individualized applications in which the transfer of data to other providers is not possible or quite limited. Often these systems focus on the generation of reports for workload analysis or accreditation purposes.

The internal pharmacy environment may dictate the method for data collection and documentation as well. While pharmacists in some practice settings routinely use personal computers (PCs), others tend to be more mobile, and therefore, access to portable technology is more crucial (e.g., laptops and PDAs). For example, a community pharmacist may be more likely to document his or her activities on

a PC as opposed to a PDA because the internal workflow would necessitate this. In contrast, a consultant pharmacist who travels among various long-term care facilities may prefer a portable device for documentation.

CONSIDERATIONS WHEN SELECTING ELECTRONIC DOCUMENTATION SYSTEMS FOR PHARMACISTS

- Cost to implement and support the system
- Ability to interface with pharmacy billing, dispensing, and drug information systems
- Compatibility with other operating systems in the organization
- Ability to ensure private and secure data
- Support for enhancements and updates to the software and hardware
- Compatibility with the workflow of pharmacists

Internal operating systems and their incompatibility with other operating systems present challenges as well. The inability to interface with other systems can create redundancies that potentially can lead to serious misinterpretations and mistakes in the translation of data that can compromise patient care. In choosing an electronic documentation program for pharmacists, consideration must be given to the ability to interface not only with the pharmacy system (billing and automated dispensing) but also with other electronic records throughout an organization. When a pharmacy system does not interface with the laboratory system of the EMRs of a hospital, the ability of providers to communicate effectively is reduced.

Pharmacists in community settings must communicate more regularly with hospital pharmacists, and vice versa, yet this is often not the case.^{14,27} Interventions often need to be shared with other pharmacists at shift changes, transfer of patients from one care area to another, or even transfer of patients to new health systems altogether. One study assessed the use of computerized reminders to physicians to increase preventive care in inpatient settings for pneumococcal and influenza vaccinations and prophylactic heparin and prophylactic aspirin at discharge with the use of a computerized order-entry system. The investigators concluded that computerized reminders significantly increased the rate of delivery of the intended therapies.⁴¹ Future digital technologies not only will prompt and remind practitioners of situations that require their attention but also will prevent such occurrences.

Likewise, electronic mail and the Internet can be used as vehicles to communicate not only among health care providers but also with patients. Electronic reminders aiding medication adherence, answering medication- and disease-related questions, and providing product comparisons can be sent via e-mail from pharmacy providers. Access to the Internet in the work setting, however, may be a limiting factor for many community pharmacists, in particular, those in chain pharmacies,⁴² and must be overcome to allow for universal adoption in community pharmacy practice. The benefits to allowing Internet access in community pharmacies far outweigh potential concerns for inappropriate use in the work setting when patients' lives may depend on the information contained within resources available through the Internet.

PDAs are efficient tools that can be used to collect, process, and transmit data that ultimately have an impact on the care delivered to patients, although they do have limitations, such as their memory capabilities, screen size, and overall functionality.⁴³ In some software applications, a synchronization interface can be written to allow for

an automatic link to a Web site to deposit and collate aggregate data from PDA users or directly from a computer linked to the Internet.⁴⁴ An example of an electronic documentation system is provided in the case study.

TRAINING CONSIDERATIONS FOR PHARMACISTS AND SUPPORT STAFF IN DOCUMENTATION

Pharmacists often are not comfortable in documenting their activities related to patient care within the pharmacy setting and are even more uncomfortable in communicating this information to other health care providers. All too often communications from pharmacists to physicians relate to pharmaceutical product usage and restrictions (i.e., nonformulary issues) and do not focus on patient care issues. Thus attention must be directed toward practicing pharmacists and providing them with education and training related to why documentation is necessary, how to document, and use of technology to assist in the documentation process. The training of support staff, such as pharmacy technicians, must not be overlooked because these individuals can assist in the routine collection of both pharmaceutical data and retrievable patient information (e.g., from medical charts and laboratory reports) that can be presented to pharmacists for assessment and needed follow-up.

Although the concepts of documentation are consistent irrespective of practice settings, the process by which data are collected and the tools for documentation can be quite different. Thus the training associated with documentation must be specific to the respective practice environments of pharmacists. For example, access to health care providers, medical records, laboratory data, and patients is more common in hospital pharmacy practice than in community pharmacy practice, where direct access to patients is often the only source of information. As a result, data collection, documentation, and communication with other health care providers and patients will vary based on the practice setting. However, as the use of EMRs and digital documentation becomes more common, the ability of pharmacists to interface with these systems will become less of a logistical barrier.

CONCLUSIONS

While the common maxim, “If it wasn’t documented, it wasn’t done,” applies to all providers of health care, for the pharmacy profession, this is the mantra the profession needs to embrace if it is to remain

an active and valued participant in the health care systems of industrialized countries. The profession must not wait for the creation and implementation of a universal billing system related to the provision of cognitive services by pharmacists; rather, the focus should remain centrally on the patient; one in which pharmacists universally assume a pivotal role between other health care providers and patients in communicating, interpreting, and monitoring the desired health outcomes associated with prescription and nonprescription therapies and all actions are documented and communicated effectively to all stakeholders in a convenient, consistent, and interpretable manner.

CASE STUDY

This case could be seen in either a community or hospital setting (if the prescription was a handwritten order in the medical chart of the patient).

A 59-year-old African-American man who has atrial fibrillation presents a handwritten prescription that appears to read, “warfarin sodium 25 mg PO qd.” The pharmacist identifies this as too high of a dose (most likely missing the decimal point for the dose of 2.5 mg) and contacts the prescriber immediately. The pharmacist would proceed to log this intervention as shown in Fig. 4-1.

Continuing, in the box on the first “Reasons” page under the subheading of “Order Clarification,” “Illegible writing” would be checked, and under “Drug Regimen Selection,” “Dose” would be checked (Fig. 4-2), given that the prescription was written poorly (e.g., illegibly) and the dose appeared incorrect.

As with most interventions by pharmacists, typically, recommendations are made to health care providers, patients, or caregivers. Using the preceding example with the warfarin prescription, the box under the recommendation subheading “Medication Related” would be checked, and “Change dose” would be indicated (Fig. 4-3). In this case, additional “Patient Care Related” recommendations could have been made, such as the ordering of “laboratory tests” and “therapeutic drug monitoring.”

The next step would be to check the box under the subheading “Contact” entitled, “Contact health care provider,” to ensure that the illegible prescription and the incorrect dose were interpreted correctly and that the appropriate medication and strength were verified by the pharmacist and dispensed to the patient (Fig. 4-4).

With respect to outcomes, the following items would be indicated for the prescription if the prescriber agreed with (accepted) the interpretation that the prescription was in fact for “Warfarin sodium

FIGURE 4-1. PSDS initial patient screen.

FIGURE 4-2. PSDS reason for intervention screen.

FIGURE 4-3. PSDS intervention recommendation screen.

FIGURE 4-4. PSDS intervention action screen.

FIGURE 4-5. PSDS intervention outcomes screen.

FIGURE 4-6. PSDS professional services screen.

2.5 mg PO qd” and not “Warfarin sodium 25 mg PO qd” as written in the “Result of Intervention” section. The intervention required 10 minutes of the pharmacist’s time, captured in “Time Involved.” It was assumed that this action by the pharmacist would have an “Anticipated Outcome” of “Increased safety” for the patient (Fig. 4–5).

In a situation where point-of-care diagnostic monitoring for anticoagulation is available to the pharmacist, under the “Professional Services” subheading, “Laboratory tests” could have been checked (Fig. 4–6).

In many instances, this interaction and others quite similar take place on a daily basis, but the valuable contributions pharmacists make in averting potentially lethal medication-related errors are never captured. More importantly, without this systematic approach to documentation of specific classes of agents, most common reasons for interventions and outcomes of recommendations would not be known or available for follow-up.

CLINICAL PHARMACOKINETICS AND PHARMACODYNAMICS

Larry A. Bauer

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Clinical pharmacokinetics is the discipline that describes the absorption, distribution, metabolism, and elimination of drugs in patients requiring drug therapy.
- 2 Clearance is the most important pharmacokinetic parameter because it determines the steady-state concentration for a given dosage rate. Physiologically, clearance is determined by blood flow to the organ that metabolizes or eliminates the drug and the efficiency of the organ in extracting the drug from the bloodstream.
- 3 The volume of distribution is a proportionality constant that relates the amount of drug in the body to the serum concentration. The volume of distribution is used to calculate the loading dose of a drug that will immediately achieve a desired steady-state concentration. The value of the volume of distribution is determined by the physiologic volume of blood and tissues and how the drug binds in blood and tissues.
- 4 Half-life is the time required for serum concentrations to decrease by one-half after absorption and distribution are complete. Half-life is important because it determines the time required to reach steady state and the dosage interval. Half-life is a dependent kinetic variable because its value depends on the values of clearance and volume of distribution.
- 5 The fraction of drug absorbed into the systemic circulation after extravascular administration is defined as its bioavailability.
- 6 Most drugs follow linear pharmacokinetics, whereby steady-state serum drug concentrations change proportionally with long-term daily dosing.
- 7 Some drugs do not follow the rules of linear pharmacokinetics. Instead of steady-state drug concentration changing proportionally with dose, serum concentration changes more or less than expected. These drugs follow nonlinear pharmacokinetics.
- 8 Pharmacokinetic models are useful to describe data sets, to predict serum concentrations after several doses or different routes of administration, and to calculate pharmacokinetic constants such as clearance, volume of distribution, and half-life. The simplest case uses a single compartment to represent the entire body.
- 9 Factors to be taken into consideration when deciding on the best drug dose for a patient include age, gender, weight, ethnic background, other concurrent disease states, and other drug therapy.
- 10 Cytochrome P450 is a generic name for the group of enzymes that are responsible for most drug metabolism oxidation reactions. Several P450 isozymes have been identified, including CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4.
- 11 The importance of transport proteins in drug bioavailability and elimination is now better understood. The principal transport protein involved in the movement of drugs across biologic membranes is P-glycoprotein. P-glycoprotein is present in many organs, including the gastrointestinal tract, liver, and kidney.
- 12 When deciding on initial doses for drugs that are renally eliminated, the patient's renal function should be assessed. A common, useful way to do this is to measure the patient's serum creatinine concentration and convert this value into an estimated creatinine clearance ($CrCl_{est}$). For drugs that are eliminated primarily by the kidney ($\geq 60\%$ of the administered dose), some agents will need minor dosage adjustments for $CrCl_{est}$ between 30 and 60 mL/min, moderate dosage adjustments for $CrCl_{est}$ between 15 and 30 mL/min, and major dosage adjustments for $CrCl_{est}$ less than 15 mL/min. Postdialysis supplemental doses of some medications also may be needed for patients receiving hemodialysis if the drug is removed by the artificial kidney.
- 13 When deciding on initial doses for drugs that are hepatically eliminated, the patient's liver function should be assessed. The Child-Pugh score can be used as an indicator of a patient's ability to metabolize drugs that are eliminated by the liver. In the absence of specific pharmacokinetic dosing guidelines for a medication, a Child-Pugh score equal to 8 or 9 is grounds for a moderate decrease ($\sim 25\%$)

in initial daily drug dose for agents that are metabolized primarily hepatically ($\geq 60\%$), and a score of 10 or greater indicates that a significant decrease in initial daily dose ($\sim 50\%$) is required for drugs that are metabolized mostly hepatically.

- 14 For drugs that exhibit linear pharmacokinetics, steady-state drug concentration (C_{ss}) changes proportionally with dose (D). To adjust a patient's drug therapy, a reasonable starting dose is administered for an estimated three to five half-lives. A serum concentration is obtained, assuming that it will reflect C_{ss} . Independent of the route of administration, the new dose (D_{new}) needed to attain the desired C_{ss} ($C_{ss,new}$) is calculated: $D_{new} = D_{old}(C_{ss,new}/C_{ss,old})$,

Pharmacokinetic concepts have been used successfully by pharmacists to individualize patient drug therapy for about a quarter of a century. Pharmacokinetic consultant services and individual clinicians routinely provide patient-specific drug dosing recommendations that increase the efficacy and decrease the toxicity of many medications. Laboratories routinely measure patient serum or plasma samples for many drugs, including antibiotics (e.g., aminoglycosides and vancomycin), theophylline, antiepileptics (e.g., phenytoin, carbamazepine, valproic acid, phenobarbital, and ethosuximide), methotrexate, lithium, antiarrhythmics (e.g., lidocaine, procainamide, quinidine, and digoxin), and immunosuppressants (e.g., cyclosporine and tacrolimus). Combined with a knowledge of the disease states and conditions that influence the disposition of a particular drug, kinetic concepts can be used to modify doses to produce serum drug concentrations that result in desirable pharmacologic effects without unwanted side effects. This narrow range of concentrations within which the pharmacologic response is produced and adverse effects prevented in most patients is defined as the *therapeutic range* of the drug. Table 5-1 lists the therapeutic ranges for commonly used medications.

TABLE 5-1. Selected Therapeutic Ranges

| Drug | Therapeutic Range |
|-------------------------------------|---|
| Digoxin | 0.5–2 ng/mL |
| Lidocaine | 1.5–5 mcg/mL |
| Procainamide/N-acetylprocainamide | 10–30 mcg/mL (total) |
| Quinidine | 2–5 mcg/mL |
| Amikacin ^a | 20–30 mcg/mL (peak) <5 mcg/mL (trough) |
| Gentamicin, tobramycin, netilmicin* | 5–10 mcg/mL (peak) <2 mcg/mL (trough) |
| Vancomycin | 20–40 mcg/mL (peak) 5–10 mcg/mL (trough) |
| Chloramphenicol | 10–20 mcg/mL |
| Lithium | 0.6–1.4 mEq/L |
| Carbamazepine | 4–12 mcg/mL |
| Ethosuximide | 40–100 mcg/mL |
| Phenobarbital | 15–40 mcg/mL |
| Phenytoin | 10–20 mcg/mL |
| Primidone | 5–12 mcg/mL |
| Valproic acid | 50–100 mcg/mL |
| Theophylline | 10–20 mcg/mL |
| Cyclosporine | 150–400 ng/mL (blood) |

*Using a multiple dose per day dosage schedule, single daily dose therapeutic concentrations not yet established.

where D_{old} and $C_{ss,old}$ are the old dose and old C_{ss} , respectively.

- 15 If it is necessary to determine the pharmacokinetic constants for a patient to individualize his or her dose, a small pharmacokinetic evaluation is conducted in the individual. Additionally, Bayesian computer programs that aid in the individualization of therapy are available for many different drugs.
- 16 Pharmacodynamics is the study of the relationship between the concentration of a drug and the response obtained in a patient. If pharmacologic effect is plotted versus concentration for most drugs, a hyperbola results with an asymptote equal to maximum attainable effect.

Although most individuals experience favorable effects with serum drug concentrations in the therapeutic range, the effects of a given serum concentration can vary widely among individuals. Clinicians should never assume that a serum concentration within the therapeutic range will be safe and effective for every patient. The response to the drug, such as number of seizures a patient experiences while taking an antiepileptic agent, always should be assessed when serum concentrations are measured.

Throughout this chapter, abbreviations for various pharmacokinetic parameters are used frequently. Commonly used abbreviations are listed in Table 5-2.

TABLE 5-2. Pharmacokinetic Abbreviations

| Abbreviation | Definition |
|--------------|--|
| Cl | Clearance |
| k_0 | Intravenous infusion rate |
| C_{ss} | Steady-state concentration |
| D | Dose |
| τ | Dosage interval |
| F | Fraction of drug absorbed into the systemic circulation |
| Q | Blood flow |
| E | Extraction ratio |
| f_b | Fraction of drug in the blood that is unbound |
| Cl_{int} | Intrinsic clearance |
| $C_{ss,u}$ | Steady-state concentration of unbound drug |
| V_D | Volume of distribution |
| LD | Loading dose |
| MD | Maintenance dose |
| $t_{1/2}$ | Half-life |
| k | Elimination rate constant |
| k_a | Absorption rate constant |
| α | Distribution rate constant |
| β | Terminal rate constant |
| t' | Postinfusion time |
| T | Duration of infusion |
| AUC | Area under serum or blood concentration-versus-time curve |
| V_{max} | Maximum rate of drug metabolism |
| K_m | Serum concentration at which the rate of metabolism equals $V_{max}/2$ |
| C_{max} | Maximum serum or blood concentration |
| C_{min} | Minimum serum or blood concentration |
| DR | Dosage rate |
| PGP | P-glycoprotein |

CLINICAL PHARMACOKINETIC CONCEPTS

1 Clinical pharmacokinetics is the discipline that describes the absorption, distribution, metabolism, and elimination of drugs in patients requiring drug therapy. When a drug is administered extravascularly to patients, it must be absorbed across biologic membranes to reach the systemic circulation. If the drug is given orally, the drug molecules must pass through the gastrointestinal tract wall into capillaries. For transdermal patches, the drug must penetrate the skin to enter the vascular system. In general, the pharmacologic effect of the drug is delayed when it is given extravascularly because time is required for the drug to be absorbed into the vascular system.

The vascular system generally provides the “transportation” for the drug molecule to its site of activity. After the drug reaches the systemic circulation, it can leave the vasculature and penetrate the various tissues or remain in the blood. If the drug remains in the blood, it may bind to endogenous proteins such as albumin or α_1 -acid glycoprotein. This binding usually is reversible, and an equilibrium is created between protein-bound drug and unbound drug. Unbound drug in the blood provides the driving force for distribution of the agent to body tissues. If unbound drug leaves the bloodstream and distributes to tissue, it may become tissue-bound, it may remain unbound in the tissue, or if the tissue can metabolize or eliminate the drug, it may be rendered inactive and/or eliminated from the body. If the drug becomes tissue-bound, it may bind to the receptor that causes its pharmacologic or toxic effect or to a nonspecific binding site that causes no effect. Again, tissue binding is usually reversible so that the tissue-bound drug is in equilibrium with unbound drug in the tissue.

Certain organs—such as the liver, gastrointestinal tract wall, and lung—possess enzymes that metabolize drugs. The resulting metabolite may be inactive or have a pharmacologic effect of its own. The blood also contains esterases, which cleave ester bonds in drug molecules and generally render them inactive.

Drug metabolism usually occurs in the liver through one or both of two types of reactions. Phase I reactions generally make the drug molecule more polar and water soluble so that it is prone to elimination by the kidney. Phase I modifications include oxidation, hydrolysis, and reduction. Phase II reactions involve conjugation to form glucuronides, acetates, or sulfates. These reactions generally inactivate the pharmacologic activity of the drug and may make it more prone to elimination by the kidney.

Other organs have the ability to eliminate drugs or metabolites from the body. The kidney can excrete drugs by glomerular filtration or by such active processes as proximal tubular secretion. Drugs also can be eliminated via bile produced by the liver or air expired by the lungs.

LINEAR PHARMACOKINETICS

6 Most drugs follow linear pharmacokinetics: Serum drug concentrations change proportionally with long-term daily dosing. For example, if a drug dose were doubled from 300 to 600 mg/day, the patient’s serum drug concentration would double.

When a drug is given by continuous intravenous infusion, serum concentrations increase until an equilibrium is established between the drug dosage rate and the rate of drug elimination. At that point, the rate of drug administration equals the rate of drug elimination, and the serum concentrations therefore remain constant (Fig. 5–1). For example, if a patient were receiving a continuous intravenous infusion of theophylline at 40 mg/h, the theophylline serum concentration

FIGURE 5–1. Normal serum concentration-time curve following a continuous intravenous infusion.

would increase until the patient’s body was eliminating theophylline at 40 mg/h. When serum drug concentrations reach a constant value, steady state is achieved.

If the drug is given at intermittent dosage intervals, such as 250 mg every 6 hours, steady state is achieved when the serum-concentration-versus-time curves for each dosage interval are superimposable. The amount of drug eliminated during the dosage interval equals the dose.

BIOAVAILABILITY AND BIOEQUIVALENCE

When drugs are administered extravascularly, drug molecules must be released from the dosage form (dissolution) and pass through several biologic barriers before reaching the vascular system (absorption). The fraction of drug absorbed into the systemic circulation (F) after extravascular administration is defined as its *bioavailability* and can be calculated after single intravenous and extravascular doses as¹

$$F = \frac{D_{iv}(AUC_{0-\infty})}{D(AUC_{iv,0-\infty})}$$

where D and D_{iv} are the extravascular and intravenous doses, respectively, and $AUC_{iv,0-\infty}$ and $AUC_{0-\infty}$ are the intravenous and extravascular areas under the serum- or blood-concentration-versus-time curves, respectively, from time zero to infinity. The AUC represents the body’s total exposure to the drug and is a function of the fraction of the drug dose that enters the systemic circulation via the administered route and clearance (Fig. 5–2). When F is less than 1 for a drug administered extravascularly, either the dosage form did not release all the drug contained in it, or some of the drug was eliminated or destroyed (by stomach acid or other means) before it reached the systemic circulation.

When the extravascular dose is administered orally, part of the dose may be metabolized by enzymes or removed by transport proteins contained in the gastrointestinal tract wall or liver before it reaches the systemic circulation.^{2,3} This occurs commonly when drugs have a high liver extraction ratio or are subject to gastrointestinal tract wall metabolism because, after oral administration, the drug must pass through the gastrointestinal tract wall and into the portal circulation of the liver. Transport proteins are also present in the gastrointestinal tract wall that can actively pump drug molecules that already have been absorbed back into the lumen of the gastrointestinal tract. P-Glycoprotein (PGP) is the primary transport protein that

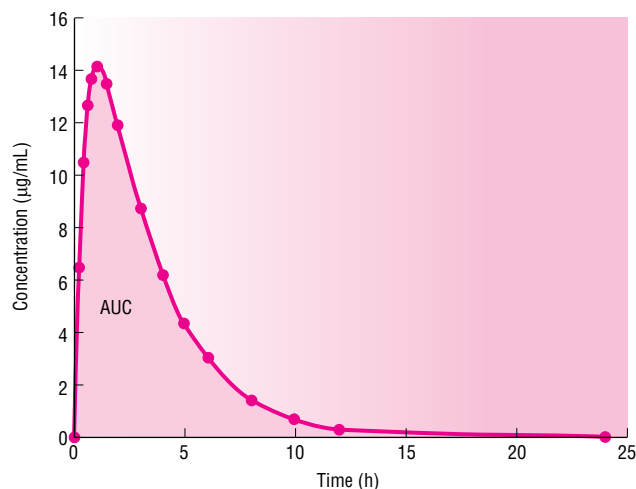

FIGURE 5-2. Area under the concentration-time curve (AUC) after the administration of an extravascular dose. The AUC is a function of the fraction of drug dose that enters the systemic circulation and clearance. AUCs measured after intravenous and extravascular doses can be used to determine bioavailability for the extravascular dose.

interferes with drug absorption by this mechanism. For example, if an orally administered drug is 100% absorbed from the gastrointestinal tract but has a hepatic extraction ratio of 0.75, only 25% of the original dose enters the systemic circulation. This first-pass effect through the liver and/or gastrointestinal tract wall is avoided when the drug is given by other routes of administration. The computation of F does not separate loss of oral drug metabolized by the first-pass effect and drug not absorbed by the gastrointestinal tract. Special techniques are needed to determine the fraction of drug absorbed orally for drugs with high liver extraction ratios or substantial gut wall metabolism.

Two different dosage forms of the same drug are considered to be bioequivalent when the $AUC_{0-\infty}$, maximum serum or blood concentrations (C_{max}), and the times that C_{max} occurs (t_{max}) are neither clinically nor statistically different. When this occurs, the serum-concentration-versus-time curves for the two dosage forms should be superimposable and therefore identical. Bioequivalence studies have become very important because many expensive drugs have become available recently in generic form. Most bioequivalence studies involve 18 to 25 healthy adults who are given the brand-name product and the generic product in a randomized, crossover study design.

CLEARANCE

Clearance (Cl) is the most important pharmacokinetic parameter because it determines the steady-state concentration for a given dosage rate. When a drug is given at a continuous intravenous infusion rate equal to k_0 , the steady-state concentration (C_{ss}) is determined by the quotient of k_0 and Cl ($C_{ss} = k_0/Cl$). If the drug is administered as individual doses (D) at a given dosage interval (τ), the average steady-state concentration (C_{ss}) over the dosage interval is given by the equation⁴

$$C_{ss} = \frac{F(D/\tau)}{Cl}$$

where F is the fraction of dose absorbed into the systemic vascular system. The average steady-state concentration over the dosage interval is the steady-state concentration that would have occurred had the same dose been given as a continuous intravenous infusion (e.g., 300 mg every 6 hours would produce an average C_{ss} equivalent to the

actual C_{ss} produced by a continuous infusion administered at a rate of 50 mg/h).

Physiologically, clearance is determined by (1) blood flow (Q) to the organ that metabolizes (liver) or eliminates (kidney) the drug and (2) the efficiency of the organ in extracting the drug from the bloodstream.⁵ Efficiency is measured using an extraction ratio (E), calculated by subtracting the concentration in the blood leaving the extracting organ (C_{out}) from the concentration in the blood entering the organ (C_{in}) and then dividing the result by C_{in} :

$$E = \frac{C_{in} - C_{out}}{C_{in}}$$

Clearance for that organ is calculated by taking the product of Q and E ($Cl = QE$). For example, if liver blood flow equals 1.5 L/min and the drug's extraction ratio is 0.33, hepatic clearance equals 0.5 L/min. Total clearance is computed by summing all the individual organ clearance values. Clearance changes occur in patients when the blood flow to extracting organs changes or when the extraction ratio changes. Vasodilators such as hydralazine or nifedipine increase liver blood flow, whereas congestive heart failure and hypotension can decrease hepatic blood flow. Extraction ratios can increase when enzyme inducers increase the amount of drug-metabolizing enzyme. Extraction ratios may decrease if enzyme inhibitors inhibit drug-metabolizing enzymes or necrosis causes loss of parenchyma.

INTRINSIC CLEARANCE

The extraction ratio also can be thought of in terms of the unbound fraction of drug in the blood (f_b), the intrinsic ability of the extracting organ to clear unbound drug from the blood (Cl_{int}), and blood flow to the organ (Q)^{6,7}:

$$E = \frac{f_b(Cl_{int})}{Q + f_b(Cl_{int})}$$

By substituting this equation for E , the clearance equation becomes

$$Cl = \frac{Q[f_b(Cl_{int})]}{Q + f_b(Cl_{int})}$$

Clearance changes will occur when blood flow to the clearing organ changes [in conditions where blood flow is reduced (e.g., shock, congestive heart failure) or when medications such as vasodilators increase blood flow], binding in the blood changes (e.g., if the concentration of binding proteins is low or highly protein-bound drugs are displaced), or intrinsic clearance of unbound drug changes (e.g., when metabolizing enzymes are induced or inhibited by other drug therapy or functional organ tissue is destroyed by disease processes).

If Cl_{int} is large (enzymes have a high capacity to metabolize the drug), the product of f_b and Cl_{int} is much larger than Q . When $f_b(Cl_{int})$ is much greater than Q , the sum of Q and $f_b(Cl_{int})$ in the denominator of the clearance equation almost equals $f_b(Cl_{int})$:

$$f_b(Cl_{int}) \approx Q + f_b(Cl_{int})$$

Substituting this expression in the denominator of the clearance equation and canceling common terms leads to the following expression for drugs with a large Cl_{int} : $Cl \approx Q$. In this case, clearance of the drug is equal to blood flow to the organ; such drugs are called *high-clearance drugs* and have large extraction ratios. Propranolol, verapamil, morphine, and lidocaine are examples of high-clearance drugs. High-clearance drugs such as these typically exhibit high first-pass effects when administered orally.

If Cl_{int} is small (enzymes have a limited capacity to metabolize the drug), Q is much larger than the product of f_b and Cl_{int} . When Q

is much greater than $f_b(Cl_{int})$, the sum of Q and $f_b(Cl_{int})$ in the denominator of the clearance equation becomes almost equal to Q : $Q \approx Q + f_b(Cl_{int})$. Substituting this expression in the denominator of the clearance equation and canceling common terms leads to the following expression for drugs with a small Cl_{int} : $Cl \approx f_b(Cl_{int})$. In this case, clearance of the drug is equal to the product of the fraction unbound in the blood and the intrinsic ability of the organ to clear unbound drug from the blood; such drugs are known as *low-clearance drugs* and have small extraction ratios. Warfarin, theophylline, diazepam, and phenobarbital are examples of low-clearance drugs.

As mentioned previously, the concentration of unbound drug in the blood is probably more important pharmacologically than the total (bound plus unbound) concentration. The unbound drug in the blood is in equilibrium with the unbound drug in the tissues and reflects the concentration of drug at its site of action. Therefore, the pharmacologic effect of a drug is thought to be a function of the concentration of unbound drug in the blood. The unbound steady-state concentration ($C_{ss,u}$) can be calculated by multiplying C_{ss} and f_b : $C_{ss,u} = C_{ss}f_b$. The effect that changes in Q , f_b , and Cl_{int} have on $C_{ss,u}$ and therefore on the pharmacologic response of a drug depends on whether a high- or low-clearance drug is involved. Because $Cl = Q$ for high-clearance drugs, a change in f_b or Cl_{int} does not change Cl or C_{ss} ($C_{ss} = k_0/Cl$). However, a change in unbound drug fraction does alter $C_{ss,u}$ ($C_{ss,u} = f_b C_{ss}$), thereby affecting the pharmacologic response. Plasma-protein-binding displacement drug interactions are thus very important clinically, but they are also dangerous because the changes in $C_{ss,u}$ are not reflected in changes in C_{ss} . Since laboratories usually measure only total concentrations (concentrations of unbound drug are difficult to determine), the interaction is hard to detect. If Cl_{int} changes for high-clearance drugs, Cl , C_{ss} , $C_{ss,u}$, and pharmacologic response do not change. Changes in Q cause a change in Cl ; changes in C_{ss} , $C_{ss,u}$, and drug response are indirectly proportional to changes in Cl .

For low-clearance drugs, total clearance is determined by unbound drug fraction and intrinsic clearance: $Cl = f_b(Cl_{int})$. A change in Q does not change Cl , C_{ss} , $C_{ss,u}$, or pharmacologic response. However, a change in f_b or Cl_{int} does alter Cl and C_{ss} ($C_{ss} = k_0/Cl$). Changes in Cl_{int} will cause a proportional change in Cl . Changes in C_{ss} , $C_{ss,u}$, and drug response are indirectly proportional to changes in Cl . Altering f_b for low-clearance drugs produces interesting results. A change in f_b alters Cl and C_{ss} ($C_{ss} = k_0/Cl$). Since Cl and C_{ss} change in opposite directions with changes in f_b , $C_{ss,u}$ ($C_{ss,u} = f_b C_{ss}$) and pharmacologic response do not change with alterations in the fraction of unbound drug in the blood. For example, a low-clearance drug is administered to a patient until steady-state is achieved:

$$Cl = f_b(Cl_{int})$$

$$C_{ss} = \frac{k_0}{Cl}$$

Suppose that another drug is administered to the patient that displaces the first drug from plasma-protein-binding sites and doubles f_b (f_b now equals $2f_b$). Cl doubles because of the protein-binding displacement [$2Cl = 2f_b(Cl_{int})$], and C_{ss} decreases by one-half because of the change in clearance [$1/2(C_{ss}) = k_0/(2Cl)$]. $C_{ss,u}$ does not change because even though f_b is doubled, C_{ss} decreased by one-half ($C_{ss,u} = f_b C_{ss}$). The potential for error in this situation is that clinicians may increase the dose of a low-clearance drug after a protein-binding displacement interaction because C_{ss} decreased. Since $C_{ss,u}$ and the pharmacologic effect do not change, the dose should remain unaltered. Plasma-protein-binding decreases occur commonly in patients taking phenytoin. Low albumin concentrations (as in trauma or pregnant patients), high concentrations of endogenous plasma-protein-binding displacers

(as with high concentrations of bilirubin), or plasma-protein-binding drug interactions (as with concomitant therapy with valproic acid) can result in subtherapeutic total phenytoin concentrations. Despite this fact, unbound phenytoin concentrations usually are within the therapeutic range, and often the patient is responding appropriately to treatment. Thus, in these situations, unbound rather than total phenytoin serum concentrations should be monitored and used to guide future therapeutic decisions.

CLEARANCES FOR DIFFERENT ROUTES OF ELIMINATION AND METABOLIC PATHWAYS

Clearances for individual organs can be computed if the excretion the organ produces can be obtained. For example, renal clearance can be calculated if urine is collected during a pharmacokinetic experiment. The patient empties his or her bladder immediately before the dose is given. Subsequent urine production is collected until the last serum concentration (C_{last}) is obtained. Renal clearance (Cl_R) is computed by dividing the amount of drug excreted in the urine by $AUC_{0-t, last}$. Biliary and other clearance values are computed in a similar fashion.

Clearances also can be calculated for each metabolite that is formed from the parent drug. This computation is particularly useful in drug-interaction studies to determine which metabolic pathway is stimulated or inhibited. In the following metabolic scheme, the parent drug (D) is metabolized into two different metabolites (M_1 , M_2) that subsequently are eliminated by the kidney (M_{1R} , M_{2R}):

To compute the formation clearance of M_1 and M_2 (Cl_{FM1} , Cl_{FM2}), urine would be collected for five or more half-lives after a single dose or during a dosage interval at steady state. The amount of metabolite eliminated in the urine is then determined. The fraction of the dose (in moles, because the molecular weights of the parent drug and metabolites are not equal) eliminated by each metabolic pathway ($f_{M1} = M_{1R}/D$ and $f_{M2} = M_{2R}/D$) can then be computed. Formation clearance for each pathway can be calculated using the following equations: $Cl_{FM1} = f_{M1}Cl_M$ and $Cl_{FM2} = f_{M2}Cl_M$, where Cl_M is the metabolic clearance for the parent drug.

VOLUME OF DISTRIBUTION

3 The volume of distribution (V_D) is a proportionality constant that relates the amount of drug in the body to the serum concentration (amount in body = CV_D). V_D is used to calculate the loading dose (LD) of a drug that will immediately achieve a desired C_{ss} ($LD = C_{ss}V_D$). However, in practice, the patient's own V_D is not known at the time the loading dose is administered. In this case, an average V_D is assumed and used to calculate a loading dose. Because the patient's V_D is almost always different from the average V_D for the drug, a loading dose does not attain the calculated C_{ss} , but it hopefully achieves a therapeutic concentration. As usual, steady-state conditions are achieved in three to five half-lives for the drug.

The numeric value for the volume of distribution is determined by the physiologic volume of blood and tissues and how the drug binds in blood and tissues⁸:

$$V_D = V_b + (f_b/f_t)V_t$$

FIGURE 5-3. Calculation of the half-life of a drug following intravenous bolus dosing.

where V_b and V_t are the volumes of blood and tissues, respectively, and f_b and f_t are the fractions of unbound drug in blood and tissues, respectively.

HALF-LIFE

4 Half-life ($t_{1/2}$) is the time required for serum concentrations to decrease by one-half after absorption and distribution are complete. It takes the same amount of time for serum concentrations to drop from 200 to 100 mg/L as it does for concentrations to decline from 2 to 1 mg/L (Fig. 5-3).

Half-life is important because it determines the time required to reach steady state and the dosage interval. It takes approximately three to five half-lives to reach steady-state concentrations during continuous dosing. In three half-lives, serum concentrations are at about 90% of their ultimate steady-state values. Because most serum drug assays have about a 10% error, it is difficult to differentiate concentrations that are within 10% of each other. For this reason, many clinicians consider concentrations obtained after three half-lives to be C_{ss} .

Half-life is also used to determine the dosage interval for a drug. For instance, it may be desirable to maintain maximum steady-state concentrations at 20 mg/L and minimum steady-state concentrations at 10 mg/L. In this case, it would be necessary to administer the drug every half-life because the minimum desirable concentration is one-half the maximum desirable concentration.

Half-life is a dependent kinetic variable because its value depends on the values of Cl and V_D .⁸ The equation that describes the relationship among the three variables is $t_{1/2} = 0.693V_D/Cl$. Changes in $t_{1/2}$ can result from a change in either V_D or Cl ; a change in $t_{1/2}$ does not necessarily indicate that Cl has changed. Half-life can change solely because of changes in V_D . The elimination rate constant (k) is related to the half-life by the following equation: $k = 0.693/t_{1/2}$. Both the half-life and elimination rate constant describe how quickly serum concentrations decrease in the serum or blood.

NONLINEAR PHARMACOKINETICS

MICHAELIS-MENTEN KINETICS

7 Some drugs do not follow the rules of linear pharmacokinetics. Instead of C_{ss} and AUC increasing proportionally with dose,

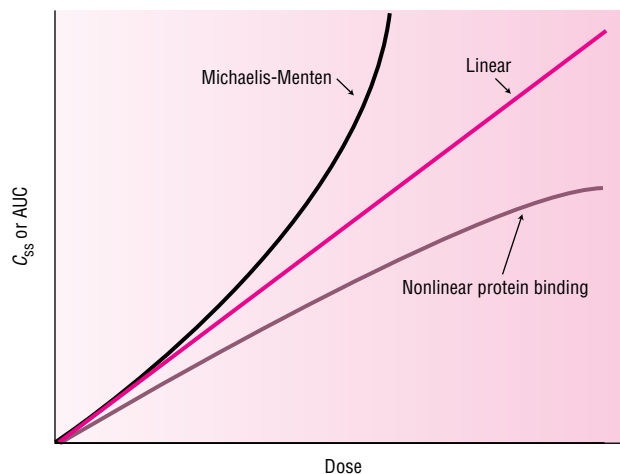

FIGURE 5-4. Relationship of dose and C_{ss} or AUC under linear and nonlinear conditions.

serum concentrations change more or less than expected (Fig. 5-4). One explanation for the greater than expected increase in C_{ss} and AUC after an increase in dose is that the enzymes responsible for the metabolism or elimination of the drug may start to become saturated. When this occurs, the maximum rate of metabolism (V_{max}) for the drug is approached. This is called *Michaelis-Menten kinetics*. The serum concentration at which the rate of metabolism equals $V_{max}/2$ is K_m . Practically speaking, K_m is the serum concentration at which nonproportional changes in C_{ss} and AUC start to occur when dose is increased. The Michaelis-Menten constants (V_{max} and K_m) determine the dosage rate (DR) needed to maintain a given C_{ss} : $DR = V_{max}C_{ss}/(K_m + C_{ss})$. Most drugs eliminated by the liver are metabolized by enzymes but still appear to follow linear kinetics. The reason for this disparity is that the therapeutic range for most drugs is well below the K_m of the enzyme system that metabolizes the agent. The therapeutic range is higher than K_m for some commonly used drugs. The average K_m for phenytoin is about 4 mg/L. The therapeutic range for phenytoin is usually 10 to 20 mg/L. Most patients experience Michaelis-Menten kinetics while taking phenytoin.

NONLINEAR PROTEIN BINDING

Another type of nonlinear kinetics can occur if C_{ss} and AUC increase less than expected after an increase in dose of a low-clearance drug. This usually indicates that plasma-protein-binding sites are starting to become saturated so that f_b increases with increases in dose (see Fig. 5-4). For a low-clearance drug, Cl depends on the values of f_b and Cl_{int} ($Cl = f_b Cl_{int}$). When a dosage increase takes place, f_b increases because nearly all plasma-protein-binding sites are occupied and no binding sites are available. If f_b increases, Cl increases and C_{ss} increases less than expected with the dosage change ($C_{ss} = k_0/Cl$). However, $C_{ss,u}$ increases proportionally with dose because $C_{ss,u}$ depends on Cl_{int} for low-clearance drugs ($C_{ss,u} = k_0/Cl_{int}$). Valproic acid⁹ and disopyramide¹⁰ both follow saturable-protein-binding pharmacokinetics.

PHARMACOKINETIC MODELS AND EQUATIONS

8 Pharmacokinetic models are useful to describe data sets, to predict serum concentrations after several doses or different routes of administration, and to calculate pharmacokinetic constants such as Cl , V_D , and $t_{1/2}$.¹¹ Compartmental models depict the body as one

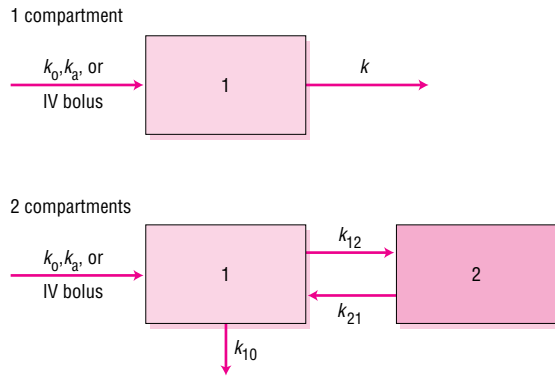

FIGURE 5-5. Visual representations of one- and two-compartment drug-distribution models.

or more discrete compartments to which drug is distributed and/or from which drug is eliminated. The shape of the serum-concentration-versus-time curve determines the number of compartments in the pharmacokinetic model and the equation used in computations (Fig. 5-5). First-order rate constants, known as *microconstants*, describe the rate of transfer from one compartment to another. Each compartment also has its own V_D . For clinical dosage adjustment purposes using drug concentrations, a one-compartment model is the most commonly used pharmacokinetic model.

ONE-COMPARTMENT MODEL

The simplest case uses a single compartment to represent the entire body (see Fig. 5-5). Drug enters the compartment by continuous intravenous infusion (k_0), absorption from an extravascular site with an absorption rate constant of k_a , or intravenous bolus (D). After an intravenous bolus, serum concentrations decline in a straight line when plotted on semilogarithmic coordinates (see Fig. 5-3). The slope of the line is $-k/2.303$; $t_{1/2}$ can be computed by determining the time required for concentrations to decrease by one-half ($t_{1/2} = 0.693/k$). The equation that describes the data is $C = (D/V_D)e^{-kt}$. V_D is calculated by dividing the intravenous dose by the y intercept (the concentration at time zero, C_0) of the graph. Cl is computed by taking the product of k and V_D . Once V_D and k are known, concentrations at any time after the dose can be computed [$C = (D/V_D)e^{-kt}$].

When an extravascular dose is given, one-compartment-model serum concentrations rise during absorption, reach C_{max} , and then decrease in a straight line with a slope equal to $-k/2.303$. The equation that describes the data is $C = \{(FDk_a)/[V_D(k_a - k)]\}(e^{-kt} - e^{-k_a t})$, where F is the fraction of the dose absorbed into the systemic circulation. The absorption rate constant (k_a) is obtained using the method of residuals.

The method of residuals is used to obtain the individual rate constants (Fig. 5-6). A is determined by extrapolating the terminal slope to the y axis; k_a can be obtained by calculating the slope or $t_{1/2}$ and using the formulas given for the intravenous bolus case. At each time point in the absorption portion of the curve, the concentration value from the extrapolated line is noted and called the *extrapolated concentration*. For each point, the actual concentration is subtracted from the extrapolated concentration to compute the *residual concentration*. When the residual concentrations are plotted on semilogarithmic coordinates, a line with y intercept equal to A and slope equal to $-k_a/2.303$ is obtained. When these values are calculated, they can be placed into the equation ($C = Ae^{-kt} - Ae^{-k_a t}$, where $A = FDk_a/[V_D(k_a - k)]$) and used to compute the serum concentration at any time after the

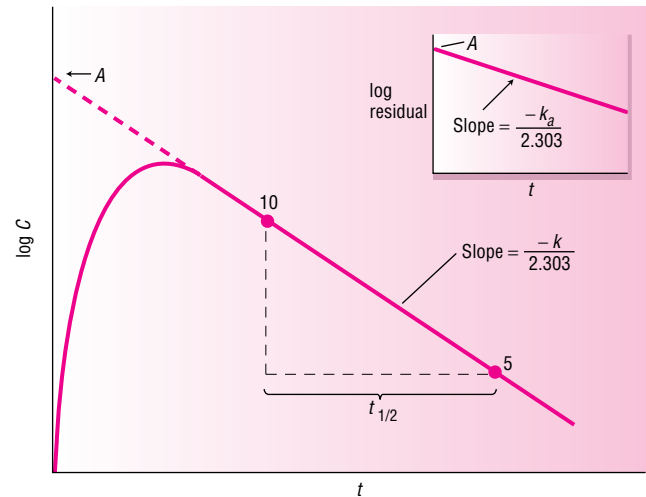

FIGURE 5-6. Calculation of the half-life of a drug following oral, intramuscular, or other extravascular dosing route.

extravascular dose. The intercepts and rate constants also can be used to compute Cl and V_D : $Cl = FD/(A/k - A/k_a)$ and $V_D = Cl/k$, where F is the fraction of the dose absorbed into the systemic circulation.

During a continuous intravenous infusion, the serum concentrations in a one-compartment model change according to the following function: $C = (k_0/Cl)(1 - e^{-kt})$. If the infusion has been running for more than three to five half-lives, the patient will be at steady state, and Cl can be calculated ($Cl = k_0/C_{ss}$). When the infusion is discontinued, serum concentrations appear to decline in a straight line when plotted on semilogarithmic paper with a slope of $-k/2.303$. V_D is computed by dividing Cl by k (Fig. 5-7).

MULTICOMPARTMENT MODEL

After an intravenous bolus dose, serum concentrations often decline in two or more phases. During the early phases, drug leaves the bloodstream by two mechanisms: (1) distribution into tissues and (2) metabolism and/or elimination. Because the drug is leaving the bloodstream through these two mechanisms, serum concentrations decline rapidly. After tissues and blood are in equilibrium, only metabolism and/or elimination remove drug from the blood. During this terminal

FIGURE 5-7. Achievement of steady-state serum concentrations after three to five half-lives of a drug. Note the elimination phase after discontinuance of the infusion.

FIGURE 5-8. Calculation of α and β half-lives following intravenous dosing.

phase, serum concentrations decline more slowly. The half-life is measured during the terminal phase by determining the time required for concentrations to decline by one-half.

After an intravenous bolus dose, serum concentrations decrease as if the drug were being injected into a central compartment that not only metabolizes and eliminates drug but also distributes drug to one or more other compartments. Of these multicompartment models, the two-compartment model is encountered most commonly (see Fig. 5-5). After an intravenous bolus injection, serum concentrations decrease in two distinct phases described by the equation:

$$C = \frac{D(\alpha - k_{21})}{V_{D1}(\alpha - \beta)} e^{-\alpha t} + \frac{D(k_{21} - \beta)}{V_{D1}(\alpha - \beta)} e^{-\beta t}$$

or $C = Ae^{-\alpha t} + Be^{-\beta t}$, where k_{21} is the first-order rate constant that reflects the transfer of drug from compartment 2 to compartment 1, V_{D1} is the V_D of compartment 1, $A = D(\alpha - k_{21})/[V_{D1}(\alpha - \beta)]$ and $B = D(k_{21} - \beta)/[V_{D1}(\alpha - \beta)]$. The rate constants α and β found in the exponents of the equations describe the distribution and elimination of the drug, respectively (Fig. 5-8). A and B are the y intercepts of the lines that describe drug distribution and elimination, respectively, on the log concentration-versus-time plot.

The residual line is calculated as before using the method of residuals. The terminal line is extrapolated to the y axis, and extrapolated concentrations are determined for each time point. Because actual concentrations are greater in this case, residual concentrations are calculated by subtracting the extrapolated concentrations from the actual concentrations. When plotted on semilogarithmic paper, the residual line has a y intercept equal to A . The slope of the residual line is used to compute α (slope = $-\alpha/2.303$). With the rate constants (α and β) and the intercepts (A and B), concentrations can be calculated for any time after the intravenous bolus dose ($C = Ae^{-\alpha t} + Be^{-\beta t}$), or pharmacokinetic constants can be computed: $Cl = D/[(A/\alpha) + (B/\beta)]$, $V_{D,\beta} = Cl/\beta$, $V_{D,ss} = \{D[(A/\alpha^2) + (B/\beta^2)]\}/[(A/\alpha) + (B/\beta)]^2$.

If serum concentrations of a drug given as a continuous intravenous infusion decline in a biphasic manner after the infusion is discontinued, a two-compartment model describes the data set^{12,13} (Fig. 5-9). In this instance, the postinfusion concentrations decrease according to the equation $C = Re^{-\alpha t'} + Se^{-\beta t'}$, where t' is the postinfusion time ($t' = 0$ when infusion is discontinued) and R , S , α , and β are determined from the postinfusion concentrations using the method of residuals with the y axis set at $t' = 0$. R and S are used to compute

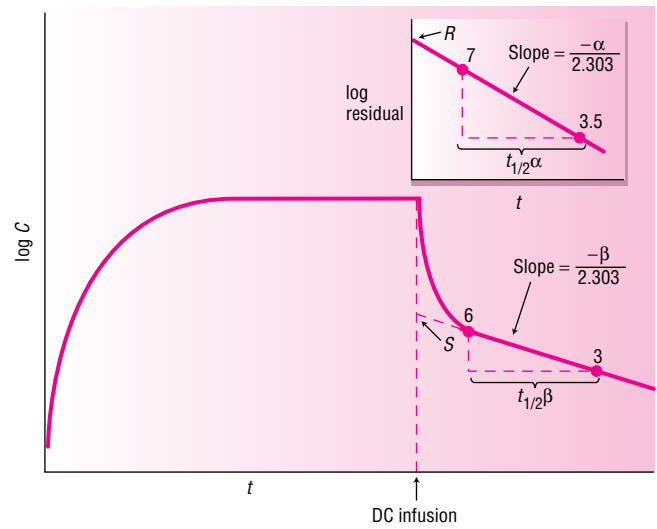

FIGURE 5-9. Calculation of α and β half-lives following a steady-state infusion.

A and B . A and B are the y intercepts that would have occurred had the total dose given during the infusion ($D = k_0 T$) been administered as an intravenous bolus dose:

$$A = \frac{RD\alpha}{k_0(1 - e^{-\alpha T})}$$

$$B = \frac{SD\beta}{k_0(1 - e^{-\beta T})}$$

where T is the duration of infusion. Once A , B , α , and β are known, the equations for an intravenous bolus are used to compute the pharmacokinetic constants. Often, when a drug is given as an intravenous bolus or continuous intravenous infusion, a two-compartment model is used to describe the data, but when the same agent is given extravascularly, a one-compartment model applies.¹⁴ In this case, distribution occurs during the absorption phase, so a distribution phase is not observed.

VOLUMES OF DISTRIBUTION IN MULTICOMPARTMENT MODELS

Two different V_D values are needed as proportionality constants for drugs that require multicompartment models to describe the serum-concentration-versus-time curve. The V_D that is used to compute the amount of drug in the body during the terminal (β) portion of the curve is called $V_{D,\beta}$ (amount of drug in body = $V_{D,\beta} C$). During a continuous intravenous infusion at steady state, $V_{D,ss}$ is used to compute the amount of drug in the body (amount of drug in body = $V_{D,ss} C$). $V_{D,ss}$ is also the V_D that can be computed using the physiologic volumes of blood and tissues and the ratio of unbound drug in blood to that in tissues [$V_{D,ss} = V_b + (f_b/f_t)V_t$]. Because the value of $V_{D,\beta}$ changes when Cl changes, $V_{D,ss}$ should be used to indicate if drug distribution changes during pharmacokinetic or drug-interaction experiments.

MULTIPLE DOSING AND STEADY-STATE EQUATIONS

Any of these compartmental equations can be used to determine serum concentrations after multiple doses. The multiple-dosing factor $(1 - e^{-nK\tau})/(1 - e^{-K\tau})$, where n is the number of doses, K is the appropriate rate constant, and τ is the dosage interval, is simply multiplied by each exponential term in the equation, substituting the rate constant of each

exponent for K . Time (t) is set at 0 at the beginning of each dosage interval. For example, a single-dose two-compartment intravenous bolus is calculated as follows: $C = Ae^{-\alpha t} + Be^{-\beta t}$. The equation for a multiple-dose two-compartment intravenous bolus is therefore

$$C = Ae^{-\alpha t} \frac{1 - e^{-n\alpha\tau}}{1 - e^{-\alpha\tau}} + Be^{-\beta t} \frac{1 - e^{-n\beta\tau}}{1 - e^{-\beta\tau}}$$

A single-dose one-compartment intravenous bolus is calculated as $C = (D/V_D)e^{-kt}$. For a multiple-dose one-compartment intravenous bolus, the concentration is $C = (D/V_D)e^{-kt} [(1 - e^{-nk\tau}) / (1 - e^{-k\tau})]$.

At steady state, the number of doses becomes large, $e^{-nk\tau}$ approaches zero, and the multiple-dosing factor equals $1/(1 - e^{-k\tau})$. Therefore, the steady-state versions of the equations are simpler than their multiple-dose counterparts:

$$C = \frac{Ae^{-\alpha t}}{1 - e^{-\alpha\tau}} + \frac{Be^{-\beta t}}{1 - e^{-\beta\tau}}$$

and

$$C = \frac{(D/V_D)e^{-kt}}{1 - e^{-k\tau}}$$

for a steady-state two-compartment intravenous bolus and a steady-state one-compartment intravenous bolus, respectively.

USE OF PHARMACOKINETIC CONCEPTS FOR INDIVIDUALIZATION OF DRUG THERAPY

9 Many factors must be taken into consideration when deciding on the best drug dose for a patient. For example, the age of the patient is important because the dose (in milligrams per kilogram) for pediatric patients may be higher and for geriatric patients may be lower than the typically prescribed dose for young adults. Gender also can be a factor because males and females metabolize and eliminate some drugs differently. Patients who are significantly obese or cachectic also may require different drug doses because of clearance and volume of distribution changes. Other drug therapy that could cause drug interactions needs to be considered. Disease states and conditions may alter the drug-dosage regimen for a patient. Three disease states that deserve special mention are congestive heart failure, renal disease, and hepatic disease. Renal and hepatic diseases cause loss of organ function and decreased drug elimination and metabolism. Congestive heart failure causes decreased blood flow to organs that clear the drug from the body.

Many drug compounds are racemic mixtures of stereoisomers. In most cases, one of the isomers is more pharmacologically active than the other isomer, and each isomer may exhibit different pharmacokinetic properties. Warfarin, propranolol, verapamil, and ibuprofen are all racemic mixtures of stereoisomers. Some drug interactions inhibit or increase the elimination of only one stereoisomer. The importance of the drug interaction depends on which isomer is affected. Other drugs, such as dextromethorphan, levofloxacin, and diltiazem, are composed of just one stereoisomer.

10 Genetics also plays a role in drug metabolism. *Cytochrome P450* is a generic term for the group of enzymes that are responsible for most drug metabolism oxidation reactions. Several cytochrome P450 isozymes have been identified that are responsible for the metabolism of many important drugs (Table 5–3). CYP2C19 (P450IIC19, P450_{mp}, formerly included in CYP2C9) is responsible for aromatic hydroxylation of mephenytoin, and CYP2D6 (P450IID6, P450_{db}) oxidizes debrisoquine.¹⁵ These subsets of the cytochrome P450 enzyme family are also responsible for the metabolism of several other drugs (CYP2D6: many tricyclic antidepressants, codeine,

metoprolol; CYP2C19: most proton pump inhibitors, sertraline, voriconazole). Both these isozymes appear to be under genetic control. As a consequence, there are “poor metabolizers” who have a defective mutant gene for the isozyme, cannot manufacture a fully functional isozyme, and therefore cannot metabolize the drug substrate very well. “Extensive metabolizers” have the standard gene for the isozyme and metabolize the drugs normally. Poor metabolizers usually are a minority of the general population. They may achieve toxic concentrations of drug when usual doses are prescribed for them or, if the active drug moiety is a metabolite, may fail to have any pharmacologic effect from the drug. The ethnic background of the patient can affect the likelihood that he or she will be a poor metabolizer.¹⁵ For example, the incidence of poor metabolizers for CYP2D6 is about 5% to 10% for Caucasians and about 0% to 1% for Asians, whereas for CYP2C19, poor metabolizers make up about 3% to 6% of the Caucasian population and about 20% of the Asian population.

Other cytochrome P450 isozymes have been isolated.¹⁵ CYP1A2 (P450IA2) is the enzyme that is responsible for the demethylation of caffeine and theophylline; CYP2C9 (P450IIC9) metabolizes phenytoin, tolbutamide, losartan, and ibuprofen; most antiretroviral protease inhibitors, cyclosporine, nifedipine, and atorvastatin are metabolized by CYP3A4 (P450IIIA4); and ethanol is a substrate for CYP2E1 (P450IIE1). It is important to recognize that a drug may be metabolized by more than one cytochrome P450 isozyme. While most tricyclic antidepressants are hydroxylated by CYP2D6, *N*-demethylation probably is mediated by a combination of

CYP2C19, CYP1A2, and CYP3A4. Acetaminophen appears to be metabolized by both CYP1A2 and CYP2E1. The 4-hydroxy metabolite of propranolol is produced by CYP2D6, but side-chain oxidation of propranolol is probably a product of CYP2C19. The CYP3A enzyme family comprises approximately 90% of the drug-metabolizing enzyme present in the intestinal wall but only approximately 30% of the drug-metabolizing enzyme found in the liver. The remainder of hepatic drug-metabolizing enzyme is approximately 20% for the CYP2C family, approximately 13% for CYP1A2, approximately 7% for CYP2E1, and approximately 2% for CYP2D6.

Understanding which cytochrome P450 isozyme is responsible for the metabolism of a drug is extraordinarily useful in predicting and understanding drug interactions. Some drug-metabolism inhibitors and inducers are highly selective for certain cytochrome P450 isozymes.¹⁵ Quinidine is an extremely potent inhibitor of the CYP2D6 enzyme system¹⁵; a single 50-mg dose of quinidine can change a rapid metabolizer of debrisoquine into a poor metabolizer. Ciprofloxacin and zileuton inhibit whereas tobacco or marijuana smoke induce CYP1A2. Some drugs that are enzyme inhibitors are also substrates for that same enzyme system and appear to cause drug interactions by being a competitive inhibitor. For example, erythromycin is both a substrate for and an inhibitor of CYP3A4. Obviously, if one knows that a new drug is metabolized by a given cytochrome P450 enzyme system, it is logical to assume that the new drug will exhibit drug interactions with the known inducers and inhibitors of that cytochrome P450 isozyme.

11 The importance of transport proteins in drug bioavailability and elimination is now better understood. The principal transport protein involved in the movement of drugs across biologic membranes is PGP. PGP is present in many organs, including the gastrointestinal tract, liver, and kidney. If a drug is a substrate for PGP, its oral absorption may be decreased when PGP transports drug molecules that have been absorbed back into the gastrointestinal tract lumen. In the liver, some drugs are transported by PGP from the blood into the bile, where the drug is eliminated by biliary secretion. Similarly, some drugs eliminated by the kidney are transported from the blood into the urine by PGP. Digoxin is a substrate of PGP. Other possible mechanisms for drug interactions are when two drugs that are substrates for PGP compete for transport by the protein and when a drug is an inhibitor or inducer of PGP. Drug interactions involving inhibition of PGP decrease drug transportation in these organs and potentially can increase gastrointestinal absorption of orally administered drug, decrease biliary secretion of the drug, or decrease renal elimination of drug molecules. The drug interaction between amiodarone and digoxin probably involves all three of these mechanisms, and this explains why digoxin concentrations increase so dramatically in patients receiving amiodarone. Many drugs that are metabolized by CYP3A4 are also substrates for PGP, and some of the drug interactions attributed to inhibition of CYP3A4 may be due to decreased drug transportation by PGP. Drug interactions involving induction of PGP have the opposite effect in these organs and may decrease gastrointestinal absorption of orally administered drug, increase biliary secretion of the drug, or increase renal elimination of drug molecules.

SELECTION OF INITIAL DRUG DOSES

12 When deciding on initial doses for drugs that are eliminated renally, the patient's renal function should be assessed. A common, useful way to do this is to measure the patient's serum creatinine concentration and convert this value into an estimated creatinine clearance ($CrCl_{est}$). Serum creatinine values alone should not be used to

assess renal function because they do not include the effects of age, body weight, or gender. The Cockcroft-Gault equation¹⁶ is probably the most widely used method to estimate creatinine clearance (in milliliters per minute) in adults (18 years or older) who are within about 30% of their ideal body weight and have stable renal function:

$$\begin{aligned} \text{Male: } CrCl_{est} &= \frac{(140 - \text{age})BW}{S_{Cr} \times 72} \\ \text{Female: } CrCl_{est} &= \frac{0.85(140 - \text{age})BW}{S_{Cr} \times 72} \end{aligned}$$

where BW is body weight (in kilograms), age is the patient's age (in years), 0.85 is a correction factor to account for lower muscle mass in females, and S_{Cr} is serum creatinine (in milligrams per deciliter). For children, the following estimation equations are available according to the age of the child¹⁷: age 0 to 1 years: $CrCl_{est}$ (in mL/min/1.73 m²) = $(0.45 \times Lt)/S_{Cr}$; age 1 to 20 years: $CrCl_{est}$ (in mL/min/1.73 m²) = $(0.55 \times Lt)/S_{Cr}$, where Lt is patient length in centimeters. Other methods to determine $CrCl_{est}$ for obese adults¹⁸ and patients with rapidly changing renal function¹⁹ are available. Creatinine is a by-product of muscle breakdown in the body, so none of these estimation methods work well in patients with muscle disease, such as multiple sclerosis, or diseases that alter muscle mass, such as cachexia, malnutrition, cancer, or spinal cord injury. Nomograms that adjust initial doses according to a patient's renal function are available for several drugs, including digoxin,²⁰ vancomycin,²¹ and the aminoglycoside antibiotics.²² For many other drugs, William M. Bennett^{23,24} occasionally updates his monograph on drug dosing in renal disease, which includes suggested dosage adjustments. For drugs that are eliminated primarily by the kidney ($\geq 60\%$ of the administered dose), some agents will need minor dosage adjustments for $CrCl_{est}$ between 30 and 60 mL/min, moderate dosage adjustments for $CrCl_{est}$ between 15 and 30 mL/min, and major dosage adjustments for $CrCl_{est}$ less than 15 mL/min. Postdialysis supplemental doses of some medications also may be needed for patients receiving hemodialysis if the drug is removed by the artificial kidney.

13 A similar assessment of liver function should be made for drugs that are metabolized hepatically. Unfortunately, there is no single test that can estimate liver drug-metabolism capacity accurately, and those which are used do not always prove accurate. High aminotransferase (AST or SGOT and ALT or SGPT) and alkaline phosphatase concentrations usually indicate acute hepatic cellular damage and do not establish poor liver drug metabolism reliably. Abnormal values for three tests that usually indicate that drugs will be metabolized poorly by the liver are high serum bilirubin concentration, low serum albumin concentration, and a prolonged prothrombin time. Bilirubin is metabolized by the liver, and albumin and clotting factors are manufactured by the liver, so aberrant values for all three of these tests are a more reliable indicator of abnormal liver drug metabolism. The Child-Pugh score,²⁵ a widely used clinical classification for liver disease that incorporates clinical signs and symptoms (ascites and hepatic encephalopathy) in addition to these three laboratory tests, can be used as an indicator of a patient's ability to metabolize drugs that are eliminated by the liver. A score in excess of 10 suggests very poor liver function. As a general rule, patients with cirrhosis have the most severe decreases in liver drug metabolism. Patients with acute or chronic hepatitis often retain relatively normal or slightly decreased hepatic drug-metabolism capacity. In the absence of specific pharmacokinetic dosing guidelines for a medication, a Child-Pugh score equal to 8 to 9 is grounds for a moderate decrease (approximately 25%) in initial daily drug dose for agents that are metabolized primarily ($\geq 60\%$) hepatically, and a score of 10 or greater indicates that a significant decrease in initial daily dose (approximately 50%)

TABLE 5-4. Theophylline Pharmacokinetic Parameters for Selected Disease States/Conditions

is required for drugs that are metabolized mostly by the liver. As in any patient with or without liver dysfunction, initial doses are meant as starting points for dosage titration based on patient response and avoidance of adverse effects.

Since there are no good markers of liver function, clinicians have come to rely on pharmacokinetic parameters derived in various patient populations to compute initial doses of drugs that are eliminated hepatically. Table 5-4 contains average pharmacokinetic parameters for theophylline in several disease states. Initial doses of many liver-metabolized drugs are computed by determining which disease states and/or conditions the patient has that are known to alter the kinetics of the drug and by using these average pharmacokinetic constants to calculate doses. The patient is then monitored for therapeutic and adverse effects, and drug serum concentrations are obtained to ensure that concentrations are appropriate and to adjust doses, if necessary. The following computations illustrate the estimated intravenous loading dose and the intravenous continuous infusion necessary to achieve a theophylline concentration of 10 mg/L for a 55-year-old, 70-kg male with liver cirrhosis (mean kinetic parameters obtained from Table 5-4):

$$V_D = (0.5 \text{ L/kg})(70 \text{ kg}) = 35 \text{ L}$$

$$\begin{aligned} LD &= C_{ss} V_D = (10 \text{ mg/L})(35 \text{ L}) \\ &= 350 \text{ mg theophylline infused over 20 to 30 min} \end{aligned}$$

$$Cl(\text{in L/h}) = \frac{(0.35 \text{ mL/min/kg})(70 \text{ kg})(60 \text{ min/h})}{1000 \text{ mL/L}}$$

$$= 1.5 \text{ L/h}$$

$$\begin{aligned} k_0 &= C_{ss} Cl = (10 \text{ mg/L})(1.5 \text{ L/h}) \\ &= 15 \text{ mg/h of theophylline to begin after loading dose is given} \end{aligned}$$

If theophylline is to be given as the aminophylline salt form, each dose would need to be changed to reflect the fact that aminophylline contains only 85% theophylline ($LD = 350 \text{ mg of theophylline}/0.85 = 410 \text{ mg of aminophylline}$ infused over 20 to 30 minutes, $k_0 = 15 \text{ mg/h of theophylline}/0.85 = 18 \text{ mg/h of aminophylline}$ to begin after loading dose is given).

Heart failure is often overlooked as a disease state that can alter drug disposition. Severe heart failure decreases cardiac output and therefore reduces liver blood flow. Theophylline,²⁶ lidocaine,²⁷ and drugs with high extraction ratios are compounds whose clearance declines with decreased liver blood flow. Initial dosages of these drugs should be reduced in patients with moderate to severe heart failure (New York Heart Association class III or IV) by 25% to 50% until steady-state concentrations and response can be determined.

USE OF STEADY-STATE DRUG CONCENTRATIONS

Serum drug concentrations are readily available to clinicians to use as guides for the individualization of drug therapy. The therapeutic ranges for several drugs have been identified, and it is likely that new drugs also will be monitored using serum concentrations. Although several individualization methods have been advocated for specific drugs, one simple, reliable method is used commonly. For drugs that exhibit linear pharmacokinetics, C_{ss} changes proportionally with dose. To adjust a patient's drug therapy, a reasonable starting dose is administered for an estimated three to five half-lives. A serum concentration is obtained, assuming that it will reflect C_{ss} . Independent of the route of administration, the new dose (D_{new}) needed to attain the desired C_{ss} ($C_{ss,new}$) is calculated: $D_{new} = D_{old}(C_{ss,new}/C_{ss,old})$, where D_{old} and $C_{ss,old}$ are the old dose and old C_{ss} , respectively. To use this method, $C_{ss,old}$ must reflect steady-state conditions. Often patients are noncompliant with regard to their drug dosage and therefore are not at steady state. This occurs not only in outpatients but also in hospital inpatients. Inpatients can spit out oral doses or alter the infusion rates on intravenous pump rates after the nurse leaves the hospital room. Doses also can be missed if the patient is absent from his or her room at the time medications are to be administered. If $C_{ss,old}$ is much larger or smaller than expected for the D_{old} the patient is taking, one should suspect noncompliance and repeat the serum concentration determination after another three to five half-lives or change the patient's dose cautiously and monitor for signs of toxicity or lack of effect.

MEASUREMENT OF PHARMACOKINETIC PARAMETERS IN PATIENTS

If it is necessary to determine the kinetic constants for a patient to individualize his or her dose, a small kinetic evaluation is conducted in the individual. In these cases, the number of serum concentrations obtained from the patient is held to the minimum needed to calculate accurate pharmacokinetic parameters and doses. The reason for using fewer serum drug concentration determinations is to be as cost-effective as possible because these laboratory tests generally cost \$20 to \$50 each.

Although many drugs follow two-compartment-model pharmacokinetics (especially after intravenous administration), a one-compartment model is used to compute kinetic parameters in patients because too many serum concentration determinations would be needed to determine accurately both the distribution and elimination phases found in the two-compartment model. Because of this, serum concentrations usually are not measured in patients during the distribution phase. Another important reason serum concentrations are not measured during the distribution phase for therapeutic drug-monitoring purposes in patients is that drug in the blood and drug in the tissues are not in equilibrium during this time so that serum concentrations do not reflect tissue concentrations. When drug serum concentrations are obtained in patients for the purpose of assessing efficacy or toxicity, it is important that they be measured in the post-distribution phase when drug in the blood is in equilibrium with drug at the site of action.

In the case where the patient has received enough doses to be at steady state, pharmacokinetic parameters can be computed using a predose minimum concentration and a postdose maximum concentration. Under steady-state conditions, serum concentrations after each dose are identical, so the predose minimum concentration is the same before each dose (Fig. 5-10). This situation allows the predose concentration to be used to compute both the patient's $t_{1/2}$ and V . If the drug was given extravascularly or has a significant distribution

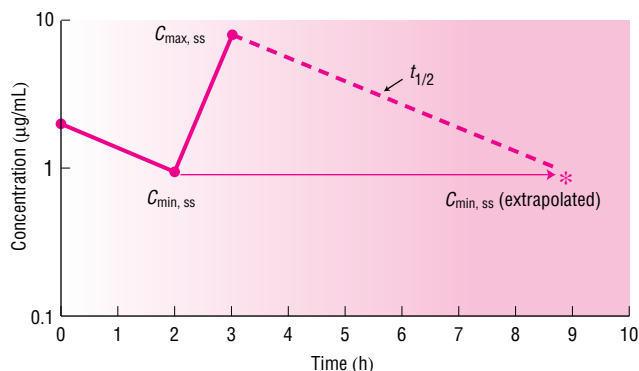

FIGURE 5-10. When a patient has received enough doses to be at steady state, steady-state maximum ($C_{\max,ss}$) and minimum ($C_{\min,ss}$) concentrations can be used to compute clearance, volume of distribution, and half-life. At steady state, consecutive $C_{\min,ss}$ values are equal, so the predose value can be extrapolated to the time before the next dose and be used to calculate half-life (dashed line).

phase, the postdose concentration should be determined after absorption or distribution is finished. To ensure that steady-state conditions have been achieved, the patient needs to receive the drug on schedule for at least three to five estimated half-lives. To make sure that this is the case, inpatients should have their medication administration records checked, and the patient's nurse should be consulted regarding missed or late doses. Outpatients should be interviewed about compliance with the prescribed dosage regimen. When compliance with the dosage regimen has been verified, steady-state conditions reasonably can be assumed.

If the patient is not at steady state, an additional postdose serum concentration determination should be done to compute the patient's pharmacokinetic parameters. Ideally, the third concentration (C_3) should be acquired approximately one estimated half-life after the postdose maximum concentration. Determining serum concentrations too close together will hamper the drug assay's ability to measure differences between them, and getting the third sample too late could result in a concentration too low for the assay to detect. In this situation, the predose minimum and postdose maximum concentrations are used to compute V , and both postdose concentrations are used to calculate $t_{1/2}$ (Fig. 5-11).

After Cl , V , and $t_{1/2}$ have been computed for a patient, the dose and dosage interval necessary to achieve desired steady-state serum

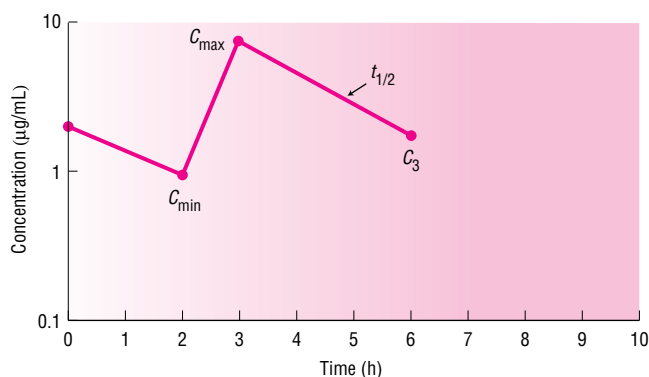

FIGURE 5-11. If a patient has not received enough doses to be at steady state, or doses have been given on an irregular schedule, the minimum concentration (C_{\min}), maximum concentration (C_{\max}), and an additional postdose concentration (C_3) can be used to compute clearance, volume of distribution, and half-life.

concentrations can be calculated using one-compartment-model equations. Specific examples of these methods to calculate initial doses and individualized doses using serum concentrations are discussed later in this chapter for the aminoglycoside antibiotics, vancomycin, digoxin, theophylline, phenytoin, and cyclosporine.

COMPUTER PROGRAMS

Computer programs that aid in the individualization of therapy are available for many different drugs. The most sophisticated programs use nonlinear regression to fit Cl and V_D to actual serum concentrations obtained in a patient.²⁸ After drug doses and serum concentrations are entered into the computer, nonlinear least-squares regression programs adjust Cl and V_D until the sum of the squared error between actual (C_{act}) and computer-estimated concentrations (C_{est}) is at a minimum [$\sum(C_{est} - C_{act})^2$]. Once estimates of Cl and V_D are available, doses are calculated easily.

Many programs also take into account what the Cl and V_D should be on the basis of disease states and conditions present in the patient.²⁹ Incorporation of expected population-based parameters allows the computer to use a limited number of serum concentrations (one or two) to provide estimates of Cl and V_D . This type of computer program is called *Bayesian* because it incorporates portions of Bayes' theorem during the fitting routine.³⁰ Bayesian pharmacokinetic dosing programs are used widely to adjust the dose of a variety of drugs. In the case of renally eliminated drugs (e.g., aminoglycosides, vancomycin, and digoxin), population estimates for kinetic parameters are generated by entering the patient's age, weight, height, gender, and serum creatinine concentration into the computer program. For hepatically eliminated drugs (e.g., theophylline and phenytoin), population estimates for kinetic parameters are computed using the patient's age, weight, and gender, as well as other factors that might change hepatic clearance, such as the presence or absence of disease states (e.g., cirrhosis or congestive heart failure) or other drug therapy that might cause a drug interaction. The Bayesian estimates of the pharmacokinetic parameters are then modified using nonlinear least-squares regression fits of serum concentrations to result in individualized parameters for the patient. The individualized parameters are used to compute doses for the patient that will result in desired steady-state concentrations of the drug.

AMINOGLYCOSIDES

Although aminoglycoside pharmacokinetics follow multicompartment models,³¹ a one-compartment model appears sufficient to individualize doses in patients.³² Aminoglycosides usually are given as short-term intermittent intravenous infusions and administered as a single daily dose or multiple doses per day. Initial doses for aminoglycosides can be computed using estimated kinetic parameters derived from population pharmacokinetic data. The elimination rate constant is estimated using the patient's creatinine clearance in the following formula: k (in h^{-1}) = $0.00293(CrCl) + 0.014$, where $CrCl$ is the measured or estimated creatinine clearance in milliliters per minute. The volume of distribution is estimated using the average population value for normal-weight (within 30% of ideal weight) individuals equal to 0.26 L/kg [$V = 0.26(Wt)$, where Wt is the patient's weight] or for obese individuals (over 30% ideal weight)³³ by taking into account the patient's excess adipose tissue: $V = 0.26[IBW + 0.4(TBW - IBW)]$, where IBW is ideal body weight [IBW_{males} (in kilograms) = $50 + 2.3(Ht - 60)$ or $IBW_{females}$ (in kilograms) = $45 + 2.3(Ht - 60)$, where Ht is the patient's height in inches]. Additional

volume-of-distribution population estimates are available for other disease states and conditions such as cystic fibrosis,³⁴ ascites,³⁵ and neonates.³⁶

Appropriate $C_{\max,ss}$ and $C_{\min,ss}$ values are selected for the patient based on the site and severity of the infection and the sensitivity of the known or suspected pathogen, as well as avoidance of adverse effects. For example, $C_{\max,ss}$ values of 8 to 10 mg/L generally are selected for gram-negative pneumonia patients, whereas $C_{\min,ss}$ values of less than 2 mg/L usually are chosen to avoid aminoglycoside-induced nephrotoxicity when tobramycin and gentamicin are prescribed using conventional multiple-daily-dosing regimens. Once appropriate steady-state serum concentrations are selected, the dosage interval required to achieve those concentrations is calculated, and τ is rounded to a clinically acceptable value (e.g., 8, 12, 18, 24, 36, or 48 hours): $\tau = [(\ln C_{\max,ss} - \ln C_{\min,ss})/k] + T$. Finally, a dose is computed for the patient using the one-compartment-model intermittent intravenous infusion equation at steady state, and the dose is rounded off to the nearest 5 to 10 mg:

$$D = TkV_D C_{\max,ss} \frac{1 - e^{-k\tau}}{1 - e^{-kT}}$$

The Hull and Sarrubi aminoglycoside dosage nomogram (Table 5-5) is based on this dosage-calculation method and includes precalculated doses and dosage intervals for a variety of creatinine clearance values.²² The nomogram assumes that $V_D = 0.26$ L/kg and should not be used to compute doses for disease states with altered V_D .

For extended-interval therapy, $C_{\max,ss}$ values of 20–30 mg/L and $C_{\min,ss}$ values less than 1 mg/L generally are accepted as appropriate for gram-negative pneumonia patients. A minimum 24-hour dosage interval is chosen for this dosing technique, and the dosing interval is increased in 12- to 24-hour increments for patients with renal dysfunction.

An example of this initial dosage scheme for a typical case is provided to illustrate the use of the various equations. Mr. JJ is a 65-year-old, 80-kg, 6-ft-tall man with the diagnosis of gram-negative pneumonia. His serum creatinine concentration is 2.1 mg/dL and is stable. Compute a conventional gentamicin dosage regimen (infused over 1 hour) that would provide approximate peak and trough concentrations of $C_{\max,ss} = 8$ mg/L and $C_{\min,ss} = 1.5$ mg/L, respectively. The patient is within 30% of his ideal body weight [$IBW_{\text{male}} = 50 + 2.3(72 \text{ in} - 60) = 78$ kg] and has stable renal function, so the Cockcroft-Gault creatinine clearance estimation equation can be used: $CrCl_{\text{est}} = [(140 - 65 \text{ yrs})80 \text{ kg}]/[72(2.1 \text{ mg/dL})] = 40$ mL/min. The patient's weight and estimated creatinine clearance are used to compute his V and k , respectively: $V = 0.26$ L/kg(80 kg) = 20.8 L; $k = 0.00293(40 \text{ mL/min}) + 0.014 = 0.131 \text{ h}^{-1}$ or $t_{1/2} = 0.693/0.131 \text{ h}^{-1} = 5.3$ h. The dosage interval and dose for the desired serum concentrations would then be calculated: $\tau = [(\ln 8 \text{ mg/L} - \ln 1.5 \text{ mg/L})/0.131 \text{ h}^{-1}] + 1 \text{ h} = 13.7 \text{ h}$ rounded to 12 h; $D = (1 \text{ h})(0.131 \text{ h}^{-1})(20.8 \text{ L})(8 \text{ mg/L})[(1 - e^{-(0.131 \text{ h}^{-1})(12 \text{ h})})/(1 - e^{-(0.131 \text{ h}^{-1})(1 \text{ h})})] = 140$ mg. Thus the prescribed dose would be gentamicin 140 mg every 12 hours administered as a 1-hour infusion. If a loading dose were deemed necessary, it would be given as the first dose [$LD = (20.8 \text{ L})(8 \text{ mg/L}) = 166$ mg rounded to 170 mg infused over 1 hour], and the first maintenance dose would be administered 12 hours (e.g., one dosage interval) later. Using the Hull and Sarrubi nomogram for the same patient, the loading dose is 160 mg (gentamicin loading dose for serious gram-negative infection is 2 mg/kg; 2 mg/kg \times 80 kg = 160 mg), and the maintenance dose is 115 mg every 12 hours (for a 12-hour dosage interval and $CrCl_{\text{est}} = 40$ mL/min, maintenance dose is 72% of the loading dose: $0.72 \times 160 \text{ mg} = 115$ mg).

TABLE 5-5. Aminoglycoside Dosage Chart

1. Compute patient's creatinine clearance (CrCl) using Cockcroft–Gault method: $CrCl = [(140 - \text{age})BW]/(\text{Scr} \times 72)$. Multiply by 0.85 for females.
2. Use patient's weight if within 30% of IBW; otherwise use adjusted dosing weight = $IBW + [0.40(\text{TBW} - \text{IBW})]$.
3. Select loading dose in mg/kg to provide peak serum concentrations in range listed below for the desired aminoglycoside antibiotic:

| Aminoglycoside | Usual Loading Doses | Expected Peak Serum Concentrations |
|----------------|---------------------|------------------------------------|
| Tobramycin | 1.5 to 2.0 mg/kg | 4 to 10 mcg/mL |
| Gentamicin | | |
| Netilmicin | | |
| Amikacin | 5.0 to 7.5 mg/kg | 15 to 30 mcg/mL |
| Kanamycin | | |

4. Select maintenance dose (as percentage of loading dose) to continue peak serum concentrations indicated above according to desired dosage interval and the patient's creatinine clearance. To maintain usual peak/trough ratio, use dosage intervals in clear areas.

Percentage of Loading Dose Required for Dosage Interval Selected

| CrCl (mL/min) | Est. Half-Life (h) | 8 h (%) | 12 h (%) | 24 h (%) |
|-----------------|--------------------|---------|----------|----------|
| >90 | 2=3 | 90 | – | – |
| 90 | 3.1 | 84 | – | – |
| 80 | 3.4 | 80 | 91 | – |
| 70 | 3.9 | 76 | 88 | – |
| 60 | 4.5 | 71 | 84 | – |
| 50 | 5.3 | 65 | 79 | – |
| 40 | 6.5 | 57 | 72 | 92 |
| 30 | 8.4 | 48 | 63 | 86 |
| 25 | 9.9 | 43 | 57 | 81 |
| 20 | 11.9 | 37 | 50 | 75 |
| 17 | 13.6 | 33 | 46 | 70 |
| 15 | 15.1 | 31 | 42 | 67 |
| 12 | 17.9 | 27 | 37 | 61 |
| 10 ^a | 20.4 | 24 | 34 | 56 |
| 7 ^a | 25.9 | 19 | 28 | 47 |
| 5 ^a | 31.5 | 16 | 23 | 41 |
| 2 ^a | 46.8 | 11 | 16 | 30 |
| 0 ^a | 69.3 | 8 | 11 | 21 |

^aNote: Dosing for patients with $CrCl \leq 10$ mL/min should be assisted by measuring serum concentrations.

CLINICAL CONTROVERSY

Some clinicians use conventional dosing or extended-interval dosing exclusively for patients requiring aminoglycosides, whereas others use a mix of both approaches according to the perceived benefit to the patient. Definitive, authoritative recommendations to guide the choice of one method of aminoglycoside dosing over the other are not available.

If appropriate aminoglycoside serum concentrations are available, kinetic parameters can be calculated at any point in therapy. When the patient is not at steady state, serum aminoglycoside concentrations are obtained before a dose (C_{\min}), after a dose administered

as an intravenous infusion of about 1 hour or as a $1/2$ -hour infusion followed by a $1/2$ -hour waiting period to allow for drug distribution (C_{\max}), and at one additional postdose time (C_3) approximately one estimated half-life after C_{\max} . The $t_{1/2}$ and k values are computed using C_{\max} and C_3 : $k = (\ln C_{\max} - \ln C_3)/\Delta t$ and $t_{1/2} = 0.693/k$, where Δt is the time that expired between the times C_{\max} and C_3 were obtained. If the patient is at steady state, serum aminoglycoside concentrations are obtained before a dose ($C_{\min,ss}$) and after a dose administered as an intravenous infusion of about 1 hour or as a $1/2$ -hour infusion followed by a $1/2$ -hour waiting period to allow for drug distribution ($C_{\max,ss}$). The $t_{1/2}$ and k values are computed using $C_{\max,ss}$ and $C_{\min,ss}$: $k = (\ln C_{\max,ss} - \ln C_{\min,ss})/(\tau - T)$ and $t_{1/2} = 0.693/k$, where τ is the dosage interval and T is the dose infusion time or dose infusion time plus waiting time.

Assuming a one-compartment model, the following equation is used to compute V_D :³²:

$$V_D = \frac{(D/T)(1 - e^{-kT})}{k(C_{\max} - C_{\min}e^{-kT})}$$

where D is dose and T is duration of infusion. Once these are known, the dose and dosage interval (τ) can be calculated for any desired maximum C_{ss} ($C_{\max,ss}$) and minimum C_{ss} ($C_{\min,ss}$):

$$\tau = \frac{\ln C_{\max,ss} - \ln C_{\min,ss}}{k} + T$$

$$D = TkV_D C_{\max,ss} \frac{1 - e^{-k\tau}}{1 - e^{-kT}}$$

The dose and dosage interval should be rounded to provide clinically accepted values (every 8, 12, 18, 24, 36, and 48 hours for dosage interval, nearest 5 to 10 mg for conventional dosing or every 24, 36, and 48 hours for dosage interval, nearest 10 to 25 mg for extended interval dosing). This method also has been used to individualize intravenous theophylline dosage regimens.³⁷

To provide an example of this technique, the problem given previously will be extended to include steady-state concentrations. Mr. JJ was prescribed gentamicin 140 mg every 12 hours (infused over 1 hour) for the treatment of gram-negative pneumonia. Steady-state trough ($C_{\min,ss}$) and peak ($C_{\max,ss}$) values were obtained before and after the fourth dose was given (more than three to five estimated half-lives), respectively, and equaled $C_{\min,ss} = 2.8$ mg/L and $C_{\max,ss} = 8.5$ mg/L. Clinically, the patient was improving with decreased white blood cell counts and body temperatures and a resolving chest x-ray. However, the serum creatinine value had increased to 2.5 mg/dL. Because of this, a new dosage regimen with a similar peak (to maintain high intrapulmonary levels) but lower trough (to decrease the risk of drug-induced nephrotoxicity) concentrations was suggested. The patient's elimination rate constant and half-life can be computed using the following formulas: $k = (\ln 8.5 \text{ mg/L} - \ln 2.8 \text{ mg/L})/(12 \text{ h} - 1 \text{ h}) = 0.101 \text{ h}^{-1}$ and $t_{1/2} = 0.693/0.101 \text{ h}^{-1} = 6.9 \text{ h}$. The patient's volume of distribution can be calculated using the following equation:

$$V = \frac{(140 \text{ mg/1 h})[1 - e^{-(0.101 \text{ h}^{-1})(1 \text{ h})}]}{(0.101 \text{ h}^{-1})\{8.5 \text{ mg/L} - [(2.8 \text{ mg/L})e^{-(0.101 \text{ h}^{-1})(1 \text{ h})}]\}} = 22.3 \text{ L}$$

Thus the patient's volume of distribution was larger and half-life was longer than originally estimated, and this led to higher serum concentrations than anticipated. To achieve the desired serum concentrations ($C_{\min,ss} = 1.5$ mg/L and $C_{\max,ss} = 8$ mg/L), the patient's actual kinetic parameters are used to compute a new dose and dosage interval: $\tau = [(\ln 8 \text{ mg/L} - \ln 1.5 \text{ mg/L})/0.101 \text{ h}^{-1}] + 1 \text{ h} = 17.6 \text{ h}$, rounded

to 18 h and

$$D = (1 \text{ h})(0.101 \text{ h}^{-1})(22.3 \text{ L})(8 \text{ mg/L}) \frac{(1 - e^{-(0.101 \text{ h}^{-1})(18 \text{ h})})}{(1 - e^{-(0.101 \text{ h}^{-1})(1 \text{ h})})}$$

$$= 157 \text{ mg, rounded to 160 mg}$$

Thus the new dose would be gentamicin 160 mg every 18 hours and infused over 1 hour; the first dose of the new dosage regimen would be given 18 hours (e.g., the new dosage interval) after the last dose of the old dosage regimen.

Because aminoglycoside antibiotics exhibit concentration-dependent bacterial killing and the postantibiotic effect is longer with higher concentrations, investigators studied the possibility of giving a higher dose of aminoglycoside using an extended-dosage interval (24 hours or longer, depending on renal function). Generally, these studies have shown comparable microbiologic and clinical cure rates for many infections and about the same rate of nephrotoxicity (approximately 5% to 10%) as with conventional dosing. Ototoxicity has not been monitored using audiometry in most of these investigations, but loss of hearing in the conversational range, as well as signs and symptoms of vestibular toxicity, usually has been assessed and found to be similar to that with aminoglycoside therapy dosed conventionally. Based on these data, clinicians have begun using extended-interval dosing in selected patients. For *Pseudomonas aeruginosa* infections where the organism has an expected MIC ≈ 2 mg/L, peak concentrations between 20 and 30 mg/L and trough concentrations of less than 1 mg/L for gentamicin or tobramycin have been suggested.³⁸

At the present time, there is not a consensus on how to approach concentration monitoring using this mode of administration. Some clinicians obtain steady-state peak and trough concentrations and use the kinetic equations given earlier to adjust the dose and dosage interval in order to attain appropriate target levels. Other clinicians measure only trough concentrations, trusting that the large doses administered to patients achieve adequate peak concentrations.

Also, a nomogram that adjusts extended-interval doses based on a single postdose concentration to achieve these steady-state concentration goals has been proposed (Fig. 5-12). The dose is 7 mg/kg of gentamicin or tobramycin. The initial dosage interval is set according to the patient's creatinine clearance (see Fig. 5-12). The Hartford nomogram includes a method to adjust doses based on serum concentrations. This portion of the nomogram contains average serum concentration time lines for gentamicin or tobramycin in patients with creatinine clearances of 60, 40, and 20 mL/min. A serum concentration is measured 6 to 14 hours after the first dose is given, and this concentration/time point is plotted on the graph (see Fig. 5-12). The modified dosage interval is indicated by which zone the serum concentration/time point falls in. Because cystic fibrosis patients have a different volume of distribution (0.35 L/kg) than assumed by this dosing technique and extended-interval dosing has not been tested adequately in patients with endocarditis, the Hartford nomogram should not be used in these situations.

To illustrate how the nomogram is used, the same patient example used previously will be repeated for this dosage approach. Mr. JJ is an 80-kg man with a CrCl_{est} of 40 mL/min. Using the Hartford nomogram, the patient would receive gentamicin 560 mg every 36 hours ($7 \text{ mg/kg} \times 80 \text{ kg} = 560 \text{ mg}$, initial dosage interval for $\text{CrCl}_{\text{est}} = 40 \text{ mL/min}$ is 36 hours). Ten hours after the first dose was given, the serum gentamicin concentration is 8.2 mg/L. According to the graph contained in the nomogram, the dosage interval should be changed to 48 hours. The new dose is 560 mg every 48 hours.

1. Administer 7 mg/kg gentamicin with initial dosage interval:

| Estimated CrCl (mL/min) | Initial dosage interval |
|-------------------------|---|
| ≥60 mL/min | q24h |
| 40–59 mL/min | q36h |
| 20–39 mL/min | q48h |
| <20 mL/min | Monitor serial concentrations and administer next dose when <1 µg/mL. |

- Obtain timed serum concentration 6 to 14 hours after dose (ideally first dose).
- Alter dosage interval to that indicated by the nomogram zone (above q48h zone, monitor serial concentrations and administer next dose when <1 µg/mL)

FIGURE 5–12. Hartford nomogram for extended-interval aminoglycosides. (Adapted with permission from ref. 38.)

CLINICAL CONTROVERSY

“Trough only” measurement of steady-state vancomycin concentrations is becoming a mainstream method to monitor therapy. The exact range for this value is uncertain. Some clinicians recommend 5 to 10 mcg/mL, whereas others suggest 5 to 15 mcg/mL. Many clinicians continue to measure both steady-state peak and trough vancomycin concentrations.

VANCOMYCIN

Vancomycin requires multicompartment models to completely describe its serum-concentration-versus-time curves. However, if peak serum concentrations are obtained after the distribution phase is completed (usually $\frac{1}{2}$ to 1 hour after a 1-hour intravenous infusion), a one-compartment model can be used for patient dosage calculations. Also, since vancomycin has a relatively long half-life compared with the infusion time, only a small amount of drug is eliminated during infusion, and it is usually not necessary to use more complex intravenous infusion equations. Thus simple intravenous bolus equations can be used to calculate vancomycin doses for most patients. Although a recent review paper³⁹ questioned the clinical usefulness of measuring vancomycin concentrations on a routine basis, research articles^{40,41} have shown potential benefits in obtaining vancomycin concentrations

TABLE 5–5. Vancomycin Dosage Chart

- Compute patient’s creatinine clearance (CrCl) using Cockcroft-Gault method: $CrCl = [(140 - \text{age})BW]/(S_{Cr} \times 72)$. Multiply by 0.85 for females.
- Use patient’s total body weight to compute doses.
- Dosage chart designed to achieve peak serum concentrations of 30 µg/mL and trough concentrations of 7.5 µg/mL.
- Compute loading dose of 25 mg/kg.
- Compute maintenance dose of 19 mg/kg given at the dosage interval listed in the following chart for the patient’s CrCl:

| CrCl (mL/min) | Dosage Interval (Days) |
|---------------|------------------------|
| ≥120 | 0.5 |
| 100 | 0.6 |
| 80 | 0.75 |
| 60 | 1.0 |

Adapted from Ref. 45.

in selected patient populations. Some clinicians advocate monitoring only steady-state trough concentrations of vancomycin.⁴² The decision to conduct vancomycin concentration monitoring should be made on a patient-by-patient basis.

Initial doses of vancomycin can be computed for adult patients using estimated kinetic parameters derived from population pharmacokinetic data. Clearance is estimated using the patient’s creatinine clearance in the following equation⁴¹: Cl (in mL/min/kg) = $0.695(CrCl \text{ in mL/min/kg}) + 0.05$. The volume of distribution is computed assuming the standard value of 0.7 L/kg: $V_D = 0.7(Wt)$, where Wt is the patient’s weight. In the case of obese patients, actual or total body weight is used in the calculations of clearance, but ideal body weight is used to compute volume of distribution.⁴⁴ The elimination rate constant is calculated using clearance and volume-of-distribution estimates, correcting for possible differences in units for these parameters: $k = Cl/V_D$. A nomogram that uses this type of approach for vancomycin therapy is available to determine initial doses rapidly for patients⁴⁵ (Table 5–6).

Steady-state peak and trough concentrations are chosen for the patient based on the site and severity of the infection, as well as the known or suspected pathogen and avoidance of potential side effects. $C_{\max,ss}$ values of between 20 and 40 mg/L and $C_{\min,ss}$ values of between 5 and 10 mg/L typically are used for patients with moderate to severe methicillin-resistant *Staphylococcus aureus*, *Staphylococcus epidermidis*, or penicillin-resistant enterococcal infections. After appropriate steady-state concentrations are chosen, the dosage interval required to attain those concentrations is computed, and τ is rounded to a clinically acceptable value (12, 18, 24, 36, 48, or 72 hours): $\tau = (\ln C_{\max,ss} - \ln C_{\min,ss})/k$. Finally, the maintenance dose is computed for the patient using a one-compartment-model intravenous bolus equation at steady state, and the dose is rounded off to the nearest 100 to 250 mg:

$$D = C_{\max,ss} V_D (1 - e^{-k\tau})$$

If desired, a loading dose can be computed using the following equation:

$$LD = V_D C_{\max,ss}$$

The following case will illustrate the use of this dosage methodology. Ms HJ is a 65-year-old, 68-kg, 5-ft, 4-in-tall coronary artery bypass graft surgery patient who has developed a surgical wound infection with *S. aureus* the suspected pathogen. Her serum creatinine concentration is 1.8 mg/dL and stable. Compute a vancomycin dosage regimen that would provide approximate peak (obtained 1 hour after a 1-hour infusion) and trough concentrations of 30 and 7 mg/L, respectively. The patient is within 30% of her ideal body weight [$IBW_{\text{female}} = 45 + 2.3(64 \text{ in} - 60) = 54 \text{ kg}$] and has stable renal function, so the Cockcroft-Gault creatinine clearance estimation formula can be used: $CrCl_{\text{est}} = 0.85[(140 - 65 \text{ yrs})68 \text{ kg}]/[72(1.8 \text{ mg/dL})] = 33 \text{ mL/min}$. The patient's weight and estimated creatinine clearance are used to calculate her estimated Cl , V_D , and k , respectively: $Cl = 0.695 (33 \text{ mL/min}/68 \text{ kg}) + 0.05 = 0.387 \text{ mL/min/kg}$; $V_D = 0.7 \text{ L/kg}(68 \text{ kg}) = 48 \text{ L}$; and $k = [(0.387 \text{ mL/min/kg})(68 \text{ kg})(60 \text{ min/h})]/[(48 \text{ L})(1000 \text{ mL/L})] = 0.033 \text{ h}^{-1}$ or $t_{1/2} = 0.693/0.033 \text{ h}^{-1} = 21 \text{ h}$. The dosage interval, maintenance dose, and loading dose for the desired serum concentrations then can be computed: $\tau = (\ln 30 \text{ mg/L} - \ln 7 \text{ mg/L})/0.033 \text{ h}^{-1} = 44 \text{ h}$, rounded to 48 h; $D = (30 \text{ mg/L})(48 \text{ L})(1 - e^{-(0.033 \text{ h}^{-1})(48 \text{ h})}) = 1145 \text{ mg}$, rounded to 1200 mg; $LD = (48 \text{ L})(30 \text{ mg/L}) = 1440 \text{ mg}$, rounded to 1450 mg. Therefore, the prescribed doses would be vancomycin 1200 mg every 48 hours administered as a 1-hour infusion. If a loading dose was used, it would be given as the first dose, and the first maintenance dose would be administered 48 hours (one dosage interval) later. Using the Matzke nomogram for the same patient, the loading dose would be 1700 mg (vancomycin loading dose is 25 mg/kg: $25 \text{ mg/kg} \times 68 \text{ kg} = 1700 \text{ mg}$), followed by a maintenance dose of 1300 mg every 48 hours (for $CrCl_{\text{est}} = 30 \text{ mL/min}$, maintenance dose is 19 mg/kg every 2 days: $19 \text{ mg/kg} \times 68 \text{ kg} = 1292 \text{ mg}$, rounded to 1300 mg).

If appropriate vancomycin serum concentrations are available, kinetic parameters can be computed at any point in therapy. When the patient is not at steady state, serum vancomycin concentrations are obtained before a dose (C_{min}), after a dose administered as an intravenous infusion of 1 hour followed by a $1/2$ - to 1-hour waiting period to allow for drug distribution (C_{max}), and at one additional postdose time (C_3) approximately one estimated half-life after C_{max} . The $t_{1/2}$ and k values are computed using C_{max} and C_3 : $k = (\ln C_{\text{max}} - \ln C_3)/\Delta t$ and $t_{1/2} = 0.693/k$, where Δt is the time that expired between the times C_{max} and C_3 were obtained. If the patient is at steady state, serum vancomycin concentrations are obtained before a dose ($C_{\text{min,ss}}$) and after a dose administered as an intravenous infusion of about 1 hour followed by a $1/2$ - to 1-hour waiting period to allow for drug distribution ($C_{\text{max,ss}}$). The $t_{1/2}$ and k values are computed using $C_{\text{max,ss}}$ and $C_{\text{min,ss}}$: $k = (\ln C_{\text{max,ss}} - \ln C_{\text{min,ss}})/(\tau - T_{\text{max}})$ and $t_{1/2} = 0.693/k$, where τ is the dosage interval and T_{max} is the dose infusion time plus waiting time.

Assuming a one-compartment model, the following equation is used to compute V_D :

$$V_D = \frac{D}{C_{\text{max}} - C_{\text{min}}}$$

where D is dose. Once these are known, the dose and dosage interval (τ) can be calculated for any desired maximum C_{ss} ($C_{\text{max,ss}}$) and minimum C_{ss} ($C_{\text{min,ss}}$):

$$\tau = \frac{\ln C_{\text{max,ss}} - \ln C_{\text{min,ss}}}{k}$$

$$D = C_{\text{max,ss}} V_D (1 - e^{-k\tau})$$

The dose and dosage interval should be rounded to provide clinically accepted values (every 12, 18, 24, 36, 48, or 72 hours for dosage interval, nearest 100 to 250 mg for dose).

To provide an example for this dosage-calculation method, the preceding problem will be extended to include steady-state concentrations. Ms HJ was prescribed vancomycin 1200 mg every 48 hours (infused over 1 hour) for the treatment of a surgical wound infection. Steady-state trough ($C_{\text{min,ss}}$) and peak ($C_{\text{max,ss}}$) values ($C_{\text{max,ss}}$ obtained 1 hour after the end of the infusion) were obtained before and after the third dose was given (more than three to five estimated half-lives), respectively, and equaled $C_{\text{min,ss}} = 2.5 \text{ mg/L}$ and $C_{\text{max,ss}} = 22.4 \text{ mg/L}$. Clinically, the patient had improved somewhat, but her white blood cell count was still elevated, and the patient was still febrile. Because of this, a modified dosage regimen with a $C_{\text{max,ss}} = 30 \text{ mg/L}$ and $C_{\text{min,ss}} = 7 \text{ mg/L}$ was suggested to maintain trough concentrations three to five times above the minimal inhibitory concentration (MIC) for the suspected pathogen. The patient's actual elimination rate constant and half-life can be calculated using the following formulas: $k = (\ln 22.4 \text{ mg/L} - \ln 2.5 \text{ mg/L})/(48 \text{ h} - 2 \text{ h}) = 0.048 \text{ h}^{-1}$ and $t_{1/2} = 0.693/0.048 \text{ h}^{-1} = 14.4 \text{ h}$. The patient's volume of distribution can be calculated using the following equation:

$$V_D = \frac{1200 \text{ mg}}{22.4 \text{ mg/L} - 2.5 \text{ mg/L}} = 60 \text{ L}$$

Thus the patient's volume of distribution was larger and half-life shorter than originally estimated, and this led to lower serum concentrations than anticipated. To achieve the desired serum concentrations ($C_{\text{max,ss}} = 30 \text{ mg/L}$ and $C_{\text{min,ss}} = 7 \text{ mg/L}$), the patient's actual kinetic parameters are used to calculate a new dose and dosage interval:

$$\tau = \frac{\ln 30 \text{ mg/L} - \ln 7 \text{ mg/L}}{0.048 \text{ h}^{-1}}$$

$$= 30 \text{ h, rounded to 36 h}$$

$$D = (30 \text{ mg/L})(60 \text{ L})(1 - e^{-(0.048 \text{ h}^{-1})(36 \text{ h})})$$

$$= 1480 \text{ mg, rounded to 1500 mg}$$

The new dose would be vancomycin 1500 mg every 36 hours (infused over 1 hour); the first dose of the new dosage regimen would be given 36 hours (the new dosage interval) after the last dose of the old dosage regimen.

Some clinicians measure only steady-state vancomycin trough concentrations in patients. The justification for this approach is that since vancomycin exhibits time-dependent bacterial killing, the minimum concentration is the most important with regard to therapeutic outcome. Vancomycin pharmacokinetics also support this approach because the volume of distribution is relatively stable and is not changed by many disease states or conditions. Because of this important point, it is difficult to attain peak steady-state concentrations in the toxic range when the steady-state vancomycin trough is in the therapeutic range if typical doses are used (15 mg/kg or $\sim 1000 \text{ mg}$ for average-weight individuals). Also, toxic peak concentrations (generally greater than 80 to 100 mg/L) are quite a bit higher than therapeutic peak concentrations, which adds a safety margin between effective concentrations and those yielding adverse drug effects.

Coupled with trough-only vancomycin concentration monitoring is a widening of the therapeutic steady-state trough concentration range from 5 to 15 mg/L. The justification for increasing the top of the range from 10 to 15 mg/L comes from limited retrospective⁴¹ and prospective⁴² studies and until more clinical evidence is available should be reserved for severely ill patients, infections caused by bacteria with higher MICs, and patients not responding to trough concentrations within the usual 5- to 10-mg/L range.

When trough-only monitoring of vancomycin concentrations is chosen by a clinician, a simple variant of linear pharmacokinetics can

be used to adjust the dose (D) and dosage interval (τ): ($D_{\text{new}}/\tau_{\text{new}}$) = ($D_{\text{old}}/\tau_{\text{old}}$)($C_{\text{ss,new}}/C_{\text{ss,old}}$), where *new* and *old* indicate the new target trough concentration and the old measured trough concentration, respectively. This equation is an approximation of the actual new steady-state trough concentration that will be attained in the patient because, mathematically, $C_{\text{ss,new}}$ is an exponential function of τ .

An example of this approach is given in the following case. Mr. MK (72 years old, 72 kg weight, 5 ft, 9 in tall) was prescribed vancomycin 1000 mg every 12 hours (infused over 1 hour) for the treatment of an *S. epidermidis* central venous catheter infection. A steady-state trough ($C_{\text{min,ss}}$) value was obtained before the fifth dose was given (more than three to five estimated half-lives), and $C_{\text{min,ss}}$ equaled 19 mg/L. Clinically, the patient was improving, but the trough concentration was judged to be too high. Because of this, a modified dosage regimen with a $C_{\text{min,ss}} = 10$ mg/L was suggested to maintain trough concentrations three to five times above the minimal inhibitory concentration (MIC) for the suspected pathogen: ($D_{\text{new}}/\tau_{\text{new}}$) = (1000 mg/12 h)(10 mg/L/19 mg/L) = 44 mg/h. Because the patient is near his ideal weight, a new dose of 1000 mg can be used (D_{new}), and the new dosage interval (τ_{new}) can be computed: $\tau = 1000 \text{ mg}/44 \text{ mg/h} = 23 \text{ h}$, rounded to 24 h. The new prescribed dose for the patient would be 1000 mg every 24 hours.

DIGOXIN

Digoxin pharmacokinetics are best described by a two-compartment model. However, because digoxin has a long half-life compared with its dosage interval and a very long distribution phase, simple pharmacokinetic equations can be used to individualize dosing when postdistribution serum concentrations are used. Digoxin can be given as an intravenous injection and orally as elixir ($F = 0.8$), tablets ($F = 0.7$), or capsules ($F = 0.9$). When given orally, the appropriate bioavailability fraction must be used to compute the correct dose. Initial doses of digoxin can be computed using population pharmacokinetic data obtained from published studies. Digoxin clearance is estimated using the patient's creatinine clearance in the following formula²⁰: Cl (in milliliters per minute) = $1.303(\text{CrCl in milliliters per minute}) + \text{Cl}_m$, where Cl_m is metabolic clearance and equals 40 mL/min for patients with no or mild heart failure or 20 mL/min for patients with moderate to severe heart failure. The volume of distribution decreases with declining renal function and is estimated using the following equation²⁰: V_D (in liters) = $226 + [298(\text{CrCl in milliliters per minute})]/(29.1 + \text{CrCl in milliliters per minute})$. The elimination rate constant can be computed by taking the product of Cl and V_D : $k = \text{Cl}/V_D$. For obese individuals, digoxin dosing should be based on ideal body weight.⁴⁶

Appropriate C_{ss} values are chosen for the patient based on the disease state being treated, the goal of therapy, and avoidance of adverse effects. The inotropic effects of digoxin occur at lower concentrations than do the chronotropic effects. Therefore, initial serum concentrations of digoxin for the treatment of heart failure generally are 1 ng/mL or less and for the treatment of atrial fibrillation are 1–1.5 ng/mL. Once the appropriate C_{ss} is selected, a dose is computed for the patient: $D/\tau = (C_{\text{ss}}\text{Cl})/F$.

An example of this initial dosage scheme is provided in the following case. Mr. PO is a 72-year-old, 83-kg, 5-ft, 11-in man admitted to the hospital for the treatment of community-acquired pneumonia. While in the hospital, Mr. PO develops atrial fibrillation, and the decision is made to treat him with digoxin to provide ventricular rate control. His serum creatinine concentration is 2.5 mg/dL and stable. Calculate an intravenous loading dose and oral maintenance dose that will achieve a C_{ss} of 1.5 ng/mL. The Cockcroft-Gault equation can be

used to estimate the patient's creatinine clearance because his serum creatinine concentration is stable and he is within 30% of his ideal weight [$\text{IBW}_{\text{male}} = 50 + 2.3(71 \text{ in} - 60) = 75 \text{ kg}$]: $\text{CrCl} = [(140 - 72 \text{ yrs})83 \text{ kg}]/[72(2.5 \text{ mg/dL})] = 31 \text{ mL/min}$. Using the estimated CrCl, both Cl and V_D can be computed:

$$\text{Cl} = 1.303(31 \text{ mL/min}) + 40 = 80 \text{ mL/min}$$

$$V_D = 226 + \frac{298(31 \text{ mL/min})}{29.1 + 31 \text{ mL/min}} = 380 \text{ L}$$

The maintenance dose will be given as digoxin tablets, so $F = 0.7$ in the dosing equation: $D/\tau = [(1.5 \text{ mcg/L})(80 \text{ mL/min})(60 \text{ min/h})(24 \text{ h/day})]/[0.7(1000 \text{ mL/L})] = 247 \text{ mcg/day}$, rounded to 250 mcg/day. The loading dose will be given intravenously as a digoxin injection: $\text{LD} = (1.5 \text{ mcg/L})(380 \text{ L}) = 570 \text{ mcg}$, rounded to 500 mcg. The loading dose would be given 50% now (250 mcg), 25% (125 mcg) in 4 to 6 hours after monitoring the patient's heart rate and blood pressure and assessing the patient for digoxin adverse effects, and the final 25% (125 mcg) 4 to 6 hours later after monitoring the same clinical parameters. The first maintenance dose would be given one dosage interval (in this case 24 hours) after the first part of the loading dose was given.

Adjustment of digoxin doses using steady-state concentrations is accomplished using linear pharmacokinetics and dosage ratios: $D_{\text{new}} = D_{\text{old}}(C_{\text{ss,new}}/C_{\text{ss,old}})$. For example, Mr. PO's atrial fibrillation responded to digoxin therapy, and he was discharged after resolution of his pneumonia. A month later he was followed up in the clinic with moderate nausea, possibly due to digoxin toxicity. His heart rate was 55 beats per minute. A steady-state digoxin concentration was determined and reported by the clinical laboratory as 2.2 mcg/L. Compute a new dose for the patient to achieve a C_{ss} of 1.5 mcg/L. The digoxin C_{ss} and old dose would be used to calculate a new dose using the linear pharmacokinetic equation: $D_{\text{new}} = 250 \text{ mcg/day}[(1.5 \text{ mcg/L})/(2.2 \text{ mcg/L})] = 170 \text{ mcg/day}$. This approximate average daily dose could be achieved by having the patient alternate take two 125-mcg tablets (250 mcg) and one 125-mcg tablet daily, giving an average dose equal to 187.5 mcg/day [(250 mcg + 125 mcg)/2 = 187.5 mcg/day].

THEOPHYLLINE

Theophylline disposition is described most accurately by nonlinear kinetics.^{47,48} However, at the usual doses, theophylline acts as if it obeys linear kinetics in most patients. Initial theophylline doses are computed by taking a detailed medical history of the patient and noting disease states and conditions that are known to change theophylline disposition. Age, smoking of tobacco-containing products, heart failure, and liver disease are among the important factors that alter theophylline kinetic parameters and dosage requirements. Once the patient has been assessed, average theophylline kinetic parameters obtained from the literature for patients similar to the one being currently treated are used to compute either oral or intravenous doses. Dosage guidelines that take into account most common disease states and conditions that change theophylline kinetic parameters are available⁴⁹ (see Table 5–4). Once theophylline is administered, the patient is monitored for the therapeutic effect and potential adverse effects. Theophylline concentrations then are used to individualize the theophylline dose that the patient receives. An example of this approach was given previously for a patient in the section on drug dosing in patients with liver disease.

Continuous intravenous infusions of theophylline (or its salt, aminophylline) can be individualized rapidly by determining the

patient's Cl before steady state occurs.⁵⁰ Assuming that the patient receives theophylline only by continuous intravenous infusion (previous doses of sustained-release oral theophylline are completely absorbed), two serum theophylline concentration determinations are done 4 hours or more apart. The infusion rate (k_0) cannot be changed between the times the samples are drawn. With one-compartment model equations, the first (C_1) and second (C_2) theophylline concentrations are used to calculate theophylline Cl:

$$Cl = \frac{2k_0}{C_1 + C_2} + \frac{2V_D(C_1 - C_2)}{(C_1 + C_2)(t_2 - t_1)}$$

V_D is assumed to be 0.5 L/kg, and t_1 and t_2 are the times at which C_1 and C_2 , respectively, are obtained. Once Cl is known, k_0 can be computed easily for any desired C_{ss} ($C_{ss} = k_0/Cl$). This method probably can be applied to other drugs that are administered as continuous intravenous infusions, such as intravenous antiarrhythmics, when rapid individualization of drug dosage is desirable.

An example of this approach can be obtained by continuing the theophylline patient case from the section on drug dosing in liver disease. In this example, a 55-year-old, 70-kg man with liver cirrhosis was prescribed a loading dose of theophylline 350 mg intravenously over 20 to 30 minutes, followed by a maintenance dose of 15 mg/h of theophylline as a continuous infusion. The infusion began at 9 A.M., blood samples were obtained at 10 A.M. and 4 P.M., and the clinical laboratory reported the theophylline serum concentrations as 10.9 and 12.3 mg/L, respectively. The patient's theophylline clearance and revised continuous infusion to maintain a C_{ss} of 15 mg/L can be computed as follows (patient's V_D estimated at 0.5 L/kg):

$$Cl = \frac{2(15 \text{ mg/h})}{10.9 \text{ mg/L} + 12.3 \text{ mg/L}} + \frac{2(0.5 \text{ L/kg} \times 70 \text{ kg})(10.9 \text{ mg/L} - 12.3 \text{ mg/L})}{(10.9 \text{ mg/L} + 12.3 \text{ mg/L})(16 - 10 \text{ h})} = 0.59 \text{ L/h}$$

$$k_0 = C_{ss}Cl = (15 \text{ mg/L})(0.59 \text{ L/h}) = 9 \text{ mg/h theophylline}$$

If theophylline is to be given as the aminophylline salt form, the doses would need to be changed to reflect the fact that aminophylline contains only 85% theophylline ($k_0 = 9 \text{ mg/h theophylline}/0.85 = 11 \text{ mg/h aminophylline}$).

If continuous intravenous infusions or oral dosage regimens are given long enough for steady state to occur (three to five estimated half-lives based on previous studies conducted in similar patients), linear pharmacokinetics can be used to adjust doses for either route of administration: $D_{\text{new}} = D_{\text{old}} (C_{\text{ss,new}}/C_{\text{ss,old}})$. For example, a patient receiving 200 mg of sustained-release oral theophylline every 12 hours with a theophylline steady-state serum concentration of 9.5 mcg/mL can have the dose required to achieve a new steady-state concentration equal to 15 mcg/mL computed by applying linear pharmacokinetics: $D_{\text{new}} = 200 \text{ mg}[(15 \text{ mcg/mL})/(9.5 \text{ mcg/mL})] = 316 \text{ mg}$, rounded to 300 mg. Thus the new theophylline dose would be 300 mg every 12 hours.

PHENYTOIN

Phenytoin doses are very difficult to individualize because the drug follows Michaelis-Menten kinetics, and there is a large amount of interpatient variability in V_{max} and K_m . Initial maintenance doses of phenytoin in adults usually range between 4 and 7 mg/kg per day, yielding starting doses of 300 to 400 mg/day in most individuals. If

needed, loading doses of phenytoin or fosphenytoin (a prodrug of phenytoin used intravenously) can be administered in adults at a dose of 15 mg/kg, which is approximately 1000 mg in many individuals. Loading doses of phenytoin can be given orally but need to be administered in divided doses separated by several hours in order to avoid decreased bioavailability and gastrointestinal intolerance (400 mg, 300 mg, and then 300 mg with each dose separated by 4 to 6 hours). Since phenytoin is metabolized hepatically, decreased doses may be needed in patients with liver disease. Because phenytoin follows dose-dependent pharmacokinetics, the half-life of phenytoin increases for a patient as the maintenance dose increases. Therefore, the time to steady-state phenytoin concentrations increases with dose. On average, at a phenytoin dose of 300 mg/day, it takes approximately 5 to 7 days to achieve steady state; at a dose of 400 mg/day, it takes approximately 10 to 14 days to achieve steady state; and at a dose of 500 mg/day, it takes approximately 21 to 28 days to achieve steady state. It should be noted that the injectable and capsule dosage forms of phenytoin are phenytoin sodium, and the labeled dosage amounts contain 92% of active phenytoin [300-mg phenytoin sodium capsules contain 276 mg ($300 \text{ mg} \times 0.92 = 276 \text{ mg}$) of active phenytoin]. Unbound phenytoin concentrations are useful in patients with hypoalbuminemia (e.g., liver disease, nephrotic syndrome, pregnancy, cystic fibrosis, burns, trauma, and malnourishment, as well as the elderly), in patients in whom displacement with endogenous compounds is possible (e.g., hyperbilirubinemia, liver disease, or end-stage renal disease), or in patients receiving other drugs that may displace phenytoin from plasma-protein-binding sites (e.g., valproic acid, aspirin therapy of more than 2 g/day, warfarin, and nonsteroidal anti-inflammatory drugs with high albumin binding).

After steady state has occurred, phenytoin serum concentrations can be obtained as an aid to dosage adjustment. A simple, easy way to approximate new serum concentrations after a dosage adjustment with phenytoin is to temporarily assume linear pharmacokinetics and then add 15% to 33% for a dosage increase or subtract 15% to 33% for a dosage decrease to account for Michaelis-Menten kinetics. To avoid large disproportionate changes in phenytoin concentrations when using this empirical method, dosage adjustments should be limited to 50 to 100 mg/day. For example, Ms PP is a 35-year-old, 65-kg patient with grand mal seizures who is receiving phenytoin capsules 300 mg orally at bedtime. A steady-state concentration of 9.2 mcg/mL is measured. It is observed that her seizure frequency decreased by only about 15% and that she has had no adverse effects due to phenytoin treatment. Because of this, her phenytoin dose is increased to 400 mg orally at bedtime. The expected phenytoin steady-state concentration would be estimated using linear pharmacokinetics [$C_{\text{new}} = (D_{\text{new}}/D_{\text{old}})C_{\text{old}} = (400 \text{ mg}/300 \text{ mg})/(9.2 \text{ mcg/mL}) = 12.3 \text{ mcg/mL}$] and then increased by 15% to 33% to account for nonlinear kinetics [$C_{\text{new}} = 1.15(12.3 \text{ mcg/mL}) = 14.1 \text{ mcg/mL}$ or $C_{\text{new}} = 1.33(12.3 \text{ mcg/mL}) = 16.4 \text{ mcg/mL}$]. Thus the patient would be expected to have a steady-state phenytoin concentration of approximately 14 to 16 mcg/mL due to the dosage increase. An alternative approach would be to use a graphic Bayesian method that allows an estimate of V_{max} and K_m from one steady-state phenytoin concentration and the prediction of new steady-state concentrations when doses are changed.⁵¹

Other methods used to individualize phenytoin doses involve rearrangements of the Michaelis-Menten equation [$DR = V_{\text{max}}C_{\text{ss}}/(K_m + C_{\text{ss}})$], in which DR is the dosage rate at steady state] so that two or more doses and C_{ss} values can be used to obtain graphic solutions for V_{max} and K_m . One rearrangement⁵² is $DR = -K_m(DR/C_{\text{ss}}) + V_{\text{max}}$. When DR is plotted on the y axis and DR/C_{ss} is plotted on the x axis of Cartesian graph paper, a straight line with a y intercept of V_{max}

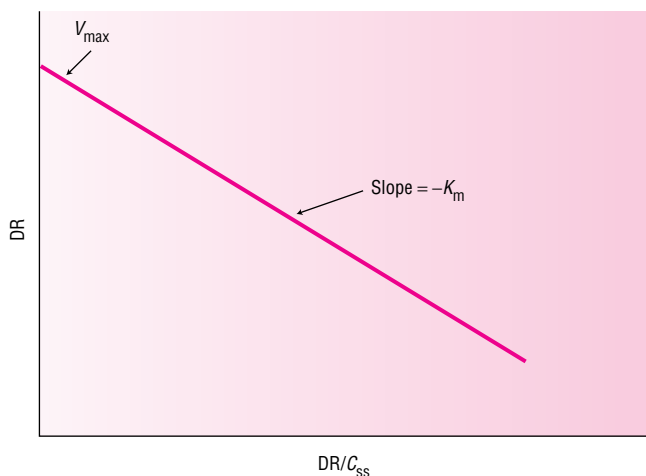

FIGURE 5-13. Relationship between dosage rate (DR) and steady-state serum concentrations (C_{ss}).

and slope equal to $-K_m$ is found (Fig. 5-13). To use this method, patients are prescribed an initial phenytoin dose, and C_{ss} is obtained. The phenytoin dose is then changed, and a second C_{ss} from the new dose is obtained. Each dose is divided by its respective C_{ss} to derive DR/C_{ss} values. The DR/C_{ss} and C_{ss} values are plotted on the graph to calculate V_{max} (y intercept) and K_m (minus slope). The steady-state Michaelis-Menten equation can be used to compute C_{ss} for a given DR or a DR for any C_{ss} .

CYCLOSPORINE

Because of the large amount of variability in cyclosporine pharmacokinetics, even when concurrent disease states and conditions are identified, many clinicians believe that the use of standard cyclosporine doses for various situations is warranted. Indeed, most transplant centers use doses that are determined employing a locally derived cyclosporine dosage protocol. The original computations of these doses were based on the pharmacokinetic dosing methods described in preceding sections and subsequently modified based on clinical experience. In general, the expected cyclosporine steady-state concentration used to compute these doses depends on the type of transplanted tissue and the posttransplantation time line. Generally speaking, initial oral doses of 8 to 18 mg/kg per day or intravenous doses of 3 to 6 mg/kg per day (one-third the oral dose to account for approximately 30% oral bioavailability) are used and vary greatly from institution to institution. For obese individuals (more than 30% over ideal body weight), ideal body weight should be used to compute initial doses.

It is likely that doses computed using patient population characteristics will not always produce cyclosporine concentrations that are expected or desirable. Additionally, there is a very high amount of interday variation in cyclosporine concentrations. Because of pharmacokinetic variability, the narrow therapeutic index of cyclosporine, and the severity of cyclosporine adverse side effects, measurement of cyclosporine concentrations is mandatory for patients to ensure that therapeutic, nontoxic levels are present. When cyclosporine concentrations are measured in patients and a dosage change is necessary, clinicians should seek to use the simplest, most straightforward method available to determine a dose that will provide safe and effective treatment. In most cases, a simple dosage ratio can be used

to change cyclosporine doses using steady-state concentrations and assuming that the drug follows linear pharmacokinetics:

$$D_{\text{new}} = D_{\text{old}} \frac{C_{\text{ss,new}}}{C_{\text{ss,old}}}$$

For example, LK is a 50-year-old, 75-kg, 5-ft, 11-in male renal transplant recipient who is receiving oral cyclosporine 400 mg every 12 hours. The current steady-state blood cyclosporine concentration is 375 ng/mL. To compute a cyclosporine dose that will provide a steady-state concentration of 200 ng/mL, linear pharmacokinetic equations can be used. The new dose to attain the desired concentration should be proportional to the old dose that produced the measured concentration (total daily dose = 400 mg/dose \times 2 doses/day = 800 mg/day):

$$D_{\text{new}} = D_{\text{old}} \frac{C_{\text{ss,new}}}{C_{\text{ss,old}}} = 800 \text{ mg/day} \frac{200 \text{ ng/mL}}{375 \text{ ng/mL}} = 427 \text{ mg/day,}$$

rounded to 400 mg/day

The new suggested dose would be 400 mg/day or 200 mg every 12 hours of cyclosporine capsules to be started at the next scheduled dosing time.

CLINICAL PHARMACODYNAMICS

16 Pharmacodynamics is the study of the relationship between the concentration of a drug and the response obtained in a patient. Originally, investigators examined the dose-response relationship of drugs in humans but found that the same dose of a drug usually resulted in different concentrations in individuals because of pharmacokinetic differences in clearance and volume of distribution. Examples of quantifiable pharmacodynamic measurements include changes in blood pressure during antihypertensive drug therapy, decreases in heart rate during β -blocker treatment, and alterations in prothrombin time or international normalized ratio during warfarin therapy.

For drugs that exhibit a direct and reversible effect, the following diagram describes what occurs at the level of the drug receptor:

According to this scheme, there is a drug receptor located within the target organ or tissue. When a drug molecule “finds” the receptor, it forms a complex that causes the pharmacologic response to occur. The drug and receptor are in dynamic equilibrium with the drug-receptor complex.

THE E_{max} AND SIGMOID E_{max} MODELS

The mathematical model that comes from the classic drug receptor theory shown previously is known as the E_{max} model:

$$E = \frac{E_{\text{max}} \times C}{EC_{50} + C}$$

where E is the pharmacologic effect elicited by the drug, E_{max} is the maximum effect the drug can cause, EC_{50} is the concentration causing one-half the maximum drug effect ($E_{\text{max}}/2$), and C is the concentration of drug at the receptor site. EC_{50} can be used as a measure of drug potency (a lower EC_{50} indicating a more potent drug), whereas E_{max} reflects the intrinsic efficacy of the drug (a higher E_{max} indicating greater efficacy). If pharmacologic effect is plotted versus concentration in the E_{max} equation, a hyperbola results with an asymptote equal to E_{max} (Fig. 5-14). At a concentration of zero, no measurable effect is present.

FIGURE 5-14. The E_{\max} model [$E = (E_{\max} \times C)/(EC_{50} + C)$] has the shape of a hyperbola with an asymptote equal to E_{\max} . EC_{50} is the concentration where effect = $E_{\max}/2$.

When dealing with human studies in which a drug is administered to a patient and pharmacologic effect is measured, it is very difficult to determine the concentration of drug at the receptor site. Because of this, serum concentrations (total or unbound) usually are used as the concentration parameter in the E_{\max} equation. Therefore, the values of E_{\max} and EC_{50} are much different than if the drug were added to an isolated tissue contained in a laboratory beaker.

The result is that a much more empirical approach is used to describe the relationship between concentration and effect in clinical pharmacology studies. After a pharmacodynamic experiment has been conducted, concentration-effect plots are generated. The shape of the concentration-effect curve is used to determine which pharmacodynamic model will be used to describe the data. Because of this, the pharmacodynamic models used in a clinical pharmacology study are deterministic in the same way that the shape of the serum-concentration-versus-time curve determines which pharmacokinetic model is used in clinical pharmacokinetic studies.

Sometimes a hyperbolic function does not describe the concentration-effect relationship at lower concentrations adequately. When this is the case, the sigmoid E_{\max} equation may be superior to the E_{\max} model:

$$E = \frac{E_{\max} \times C^n}{EC_{50}^n + C^n}$$

where n is an exponent that changes the shape of the concentration-effect curve. When $n > 1$, the concentration-effect curve is S- or sigmoid-shaped at lower serum concentrations. When $n < 1$, the concentration-effect curve has a steeper slope at lower concentrations (Fig. 5-15).

With both the E_{\max} and sigmoid E_{\max} models, the largest changes in drug effect occur at the lower end of the concentration scale. Small changes in low serum concentrations cause large changes in effect. As serum concentrations become larger, further increases in serum concentration result in smaller changes in effect. Using the E_{\max} model as an example and setting $E_{\max} = 100$ units and $EC_{50} = 20$ mg/L, doubling the serum concentration from 5 to 10 mg/L increases the effect from 20 to 33 units (a 67% increase), whereas doubling the serum concentration from 40 to 80 mg/L only increases the effect from 67 to 80 units (a 19% increase). This is an important concept for clinicians to remember when doses are being titrated in patients.

FIGURE 5-15. The sigmoid E_{\max} model [$E = (E_{\max} \times C^n)/(EC_{50}^n + C^n)$] has an S-shaped curve at lower concentrations. In this example, E_{\max} and EC_{50} have the same values as in Fig. 5-14.

LINEAR MODELS

When serum concentrations obtained during a pharmacodynamic experiment are between 20% and 80% of E_{\max} , the concentration-effect curve may appear to be linear (Fig. 5-16). This occurs often because lower drug concentrations may not be detectable with the analytic technique used to assay serum samples, and higher drug concentrations may be avoided to prevent toxic side effects. The equation used is that of a simple line: $E = S \times C + I$, where E is the drug effect, C is the drug concentration, S is the slope of the line, and I is the y intercept. In this situation, the value of S can be used as a measure of drug potency (the larger the value of S , the more potent the drug). The linear model can be derived from the E_{\max} model. When EC_{50} is much greater than C , $E = (E_{\max}/EC_{50})C = S \times C$, where $S = E_{\max}/EC_{50}$.

The linear model allows a nonzero value for effect when the concentration equals zero. This may be a baseline value for the effect that is present without the drug, the result of measurement error when determining effect, or model misspecification. Also, this model does not allow the prediction of a maximum response.

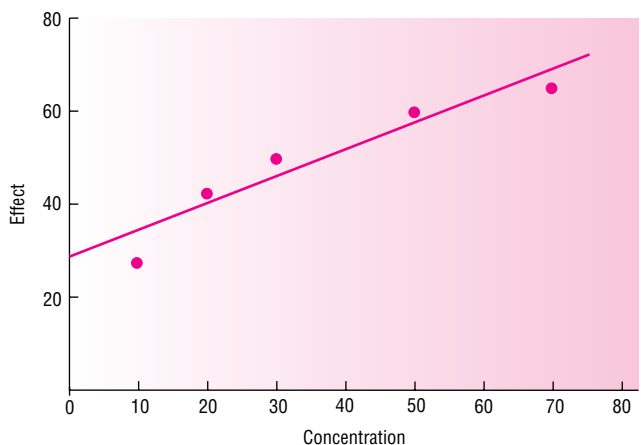

FIGURE 5-16. The linear model ($E = S \times C + I$) is often used as a pharmacodynamic model when the measured pharmacologic effect is 20% to 80% of E_{\max} . In this situation, the determination of E_{\max} and EC_{50} is not possible. To illustrate this, effect measurements from Fig. 5-14 between 20% and 80% of E_{\max} are graphed using the linear pharmacodynamic model.

Some investigators have used a log-linear model in pharmacodynamic experiments: $E = S \times (\log C) + I$, where the symbols have the same meaning as in the linear model. The advantages of this model are that the concentration scale is compressed on concentration-effect plots for experiments where wide concentration ranges were used, and the concentration values are transformed so that linear regression can be used to compute model parameters. The disadvantages are that the model cannot predict a maximum effect or an effect when the concentration equals zero. With the increased availability of nonlinear regression programs that can compute the parameters of nonlinear functions such as the E_{\max} model easily, use of the log-linear model has been discouraged.⁵³

BASELINE EFFECTS

At times, the effect measured during a pharmacodynamic study has a value before the drug is administered to the patient. In these cases, the drug changes the patient’s baseline value. Examples of these types of measurements are heart rate and blood pressure. In addition, a given drug may increase or decrease the baseline value. Two basic techniques are used to incorporate baseline values into pharmacodynamic data. One way incorporates the baseline value into the pharmacodynamic model; the other way transforms the effect data to take baseline values into account.

Incorporation of the baseline value into the pharmacodynamic model involves the addition of a new term to the previous equations. E_0 is the symbol used to denote the baseline value of the effect that will be measured. The form that these equations takes depends on whether the drug increases or decreases the pharmacodynamic effect. When the drug increases the baseline value, E_0 is added to the equations:

$$E = E_0 + \frac{E_{\max} \times C}{EC_{50} + C}$$

$$E = E_0 + \frac{E_{\max} \times C^n}{EC_{50}^n + C^n}$$

$$E = S \times C + E_0$$

When E_0 is not known with any better certainty than any other effect measurement, it should be estimated as a model parameter similar to the way that one would estimate the values of E_{\max} , EC_{50} , S , or n .^{54,55} If the baseline effect is well known and has only a small amount of measurement error, it can be subtracted from the effect determined in the patient during the experiment and not estimated as a model parameter. This approach can lead to better estimates of the remaining model parameters.⁵⁵ Using the linear model as an example, the equation used would be $E - E_0 = S \times C$.

If the drug decreases the baseline value, the drug effect is subtracted from E_0 in the pharmacodynamic models:

$$E = E_0 - \frac{E_{\max} \times C}{IC_{50} + C}$$

$$E = E_0 - \frac{E_{\max} \times C^n}{IC_{50}^n + C^n}$$

$$E = E_0 - S \times C$$

where E_{\max} represents the maximum reduction in effect caused by the drug, and IC_{50} is the concentration that produces a 50% inhibition of E_{\max} . These forms of the equations have been called the *inhibitory E_{\max}* and *inhibitory sigmoidal E_{\max} equations*, respectively. In this arrangement of the pharmacodynamic model, E_0 is a model parameter and can be estimated. If the baseline effect is well known and has little measurement error, the effect in the presence of the drug can be subtracted from the baseline effect and not estimated as a model

parameter. Using the inhibitory E_{\max} model as an example, the formula would be $E_0 - E = (E_{\max} \times C)/(IC_{50} + C)$.

When using the inhibitory E_{\max} model, a special situation occurs if the baseline effect can be obliterated completely by the drug (e.g., decreased premature ventricular contractions during antiarrhythmic therapy). In this situation, $E_{\max} = E_0$, and the equation simplifies to a rearrangement known as the *fractional E_{\max} equation*:

$$E = E_0 \left(1 - \frac{C}{IC_{50} + C} \right)$$

This form of the model relates drug concentration to the fraction of the maximum effect.

An alternative approach to the pharmacodynamic modeling of drugs that alter baseline effects is to transform the effect data so that they represent a percentage increase or decrease from the baseline value.⁵⁵ For drugs that increase the effect, the following transformation equation would be used: percent effect, = [(treatment, – baseline)/baseline] × 100. For drugs that decrease the effect, the following formula would be applied to the data: percent inhibition, = [(baseline – treatment,)/baseline] × 100. The subscript indicates the treatment, effect, or inhibition that occurred at time t during the experiment. If the study included a placebo control phase, baseline measurements made at the same time as treatment measurements (i.e., heart rate determined 2 hours after placebo and 2 hours after drug treatment) could be used in the appropriate transformation equation.⁵⁵ The appropriate model (excluding E_0) then would be used.

HYSTERESIS

Concentration-effect curves do not always follow the same pattern when serum concentrations increase as they do when serum concentrations decrease. In this situation, the concentration-effect curves form a loop that is known as *hysteresis*. With some drugs the effect is greater when serum concentrations are increasing, whereas with other drugs the effect is greater while serum concentrations are decreasing (Fig. 5–17). When individual concentration-effect pairs are joined in

FIGURE 5–17. Hysteresis occurs when effect measurements are different at the same concentration. This is commonly seen after short-term intravenous infusions or extravascular doses where concentrations increase and subsequently decrease. Counterclockwise hysteresis loops are found when concentration-effect points are joined as time increases (shown by arrows) and effect is larger at the same concentration but at a later time. Clockwise hysteresis loops are similar, but the concentration-effect points are joined in clockwise order and the effect is smaller at a later time.

time sequence, this results in clockwise and counterclockwise hysteresis loops.

Clockwise hysteresis loops usually are caused by the development of tolerance to the drug. In this situation, the longer the patient is exposed to the drug, the smaller is the pharmacologic effect for a given concentration. Therefore, after an extravascular or short-term infusion dose of the drug, the effect is smaller when serum concentrations are decreasing compared with the time when serum concentrations are increasing during the infusion or absorption phase. Accumulation of a drug metabolite that acts as an antagonist also can cause clockwise hysteresis.

Counterclockwise hysteresis loops can be caused by the accumulation of an active metabolite, sensitization to the drug, or delay in time in equilibration between serum concentration and concentration of drug at the site of action. Combined pharmacokinetic-pharmacodynamic models have been devised that allow equilibration lag times to be taken into account.

CONCLUSIONS

The availability of inexpensive, rapidly achievable serum drug concentrations has changed the way clinicians monitor drug therapy in patients. The therapeutic range for many drugs is known, and it is likely that more drugs will be monitored using serum concentrations in the future. Clinicians need to remember that the therapeutic range is merely an average guideline and to take into account interindividual pharmacodynamic variability when treating patients. Individual patients may respond to smaller concentrations or require concentrations that are much greater to obtain a therapeutic effect. Conversely, patients may show toxic effects at concentrations within or below the therapeutic range. Serum concentrations should never replace clinical judgment.

Three kinetic constants determine the dosage requirements of patients. Clearance determines the maintenance dose ($MD = ClC_{ss}$), volume of distribution determines the loading dose ($LD = V_D C_{ss}$), and half-life determines the time to steady state and the dosage interval. Several methods are available to compute these parameters.

Methods available to individualize drug therapy range from clinical pharmacokinetic techniques using simple mathematical relationships that hold for all drugs that obey linear pharmacokinetics to very complex computer programs that are specific to one drug. New techniques for monitoring serum drug concentrations are available on an experimental basis and may revolutionize clinical pharmacokinetics in the future.

PHARMACOGENETICS

Larisa H. Cavallari and Y. W. Francis Lam

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Genetic variations contribute to interpatient differences in drug response.
- 2 Genetic variations occur for drug metabolism, drug transporter, and drug target proteins, as well as disease-associated genes.
- 3 Genetic polymorphisms may be linked to drug efficacy and toxicity.
- 4 Pharmacogenetics is the study of the impact of genetic polymorphisms on drug response.
- 5 The goals of pharmacogenetics are to optimize drug efficacy and limit drug toxicity based on an individual's DNA.
- 6 Single-nucleotide polymorphisms are the most common variations in the human genome.
- 7 Gene therapy aims to cure disease caused by genetic defects by changing gene expression.
- 8 Inadequate gene delivery and expression and serious adverse effects are obstacles to successful gene therapy.

Great variability exists among individuals in response to drug therapy, and it is often difficult to predict how effective or safe a medication will be for a particular patient. For example, when treating a patient with hypertension, it may be necessary to try several agents or a combination of agents before achieving adequate blood pressure control with acceptable tolerability. A number of factors may influence drug response, including pharmacokinetics, age, ethnicity, and concomitant drug use. However, these alone do not predict the likelihood of drug efficacy or safety sufficiently for a given patient. For instance, identical antihypertensive therapy in two patients with similar demographic characteristics, medical histories, and concomitant drug therapy may produce inadequate blood pressure reduction in one patient and symptomatic hypotension in the other.

1 2 The observed interpatient variability in drug response may result largely from genetically determined differences in drug metabolism, drug distribution, and drug target proteins. The influence of hereditary factors on drug response was demonstrated as early as 1956 with the discovery that an inherited deficiency of glucose-6-phosphate dehydrogenase was responsible for hemolytic reactions to the antimalarial drug primaquine.¹ Variations in the genetic makeup of cytochrome P450 (CYP) and other drug-metabolizing enzymes are now well recognized as causes of interindividual differences in plasma concentrations of certain drugs. These variations may have serious implications for narrow-therapeutic-index drugs such as warfarin, phenytoin, and mercaptopurine.^{2–4} More recently, interest has been generated in the associations between drug response and genetic polymorphisms for drug transporters such as P-glycoprotein and drug targets such as receptors, enzymes, and proteins involved in intracellular signal transduction. Genetic variations for drug-metabolizing enzymes and drug transporter proteins may influence drug disposition, thus altering pharmacokinetic drug properties. Drug target genes may alter pharmacodynamic mechanisms by affecting sensitivity to a drug at its target site. Finally, genes associated

with disease severity have been correlated with drug efficacy despite having no direct effect on pharmacokinetic or pharmacodynamic mechanisms.

PHARMACOGENETICS: A DEFINITION

- 3 4 Pharmacogenetics involves the search for genetic variations that lead to interindividual differences in drug response. The term *pharmacogenetics* often is used interchangeably with the term *pharmacogenomics*. However, pharmacogenetics generally refers to monogenetic variants that affect drug response, whereas pharmacogenomics refers to the entire spectrum of genes that interact to determine drug efficacy and safety. For example, a pharmacogenetic study would be one that examines the influence of the β_1 -adrenergic receptor gene on blood pressure response to carvedilol. A pharmacogenomic study might examine the interaction between the CYP2D6, β_1 -, β_2 -, and α_1 -adrenergic receptor genes on carvedilol effects. To date, most studies of gene-drug responses are pharmacogenetic in nature. However, given that multiple proteins are involved in determining the ultimate response to most drugs, many investigators are now taking a more pharmacogenomic approach to elucidating genetic contributions to drug response. For simplicity, this chapter treats pharmacogenetics and pharmacogenomics as synonymous.
- 5 The goals of pharmacogenetics are to optimize drug therapy and limit drug toxicity based on an individual's genetic profile. Thus pharmacogenetics aims to use genetic information to choose a drug, drug dose, and treatment duration that will have the greatest likelihood for achieving therapeutic outcomes with the least potential for harm in a given patient. The results of pharmacogenetic research ultimately will provide opportunities for clinicians to use genetic tests to predict individual responses to drug treatments, specifically to select medications for patients based on DNA profiles, and to develop

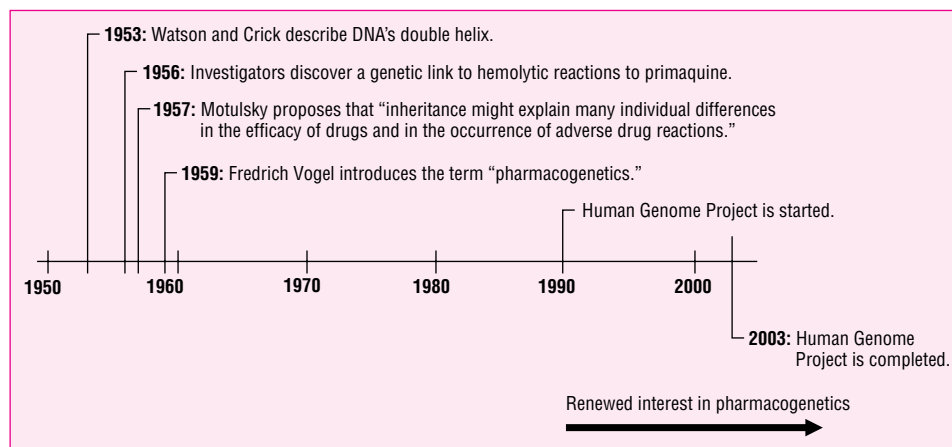

FIGURE 6-1. Timeline of genomic discoveries.

novel strategies for disease treatment and prevention based on an understanding of genetic control of cellular functions.

Although there has been considerable interest in genetic influences of drug response in recent years, pharmacogenetics is not a new area. As shown in Fig. 6-1, in 1957, shortly after the discovery of a genetic predisposition toward primaquine-induced toxicity, Arno Motulsky proposed that inheritance might underlie much of the disparity among individuals in drug response.⁵ Fredrich Vogel first introduced the term *pharmacogenetics* 2 years later.⁶ With the advent of the Human Genome Project in 1990 came a resurgence of interest in determining genetic contributions to drug response.

HUMAN GENOME PROJECT

In 1988, Congress commissioned the Department of Energy and the National Institutes of Health to plan and implement the Human Genome Project. The goal of the Human Genome Project was to determine the entire sequence of the human genome by 2005. The mapping of the human genome, which officially began in 1990, has led to a better understanding of genetic contributions to disease susceptibility. To encourage research and ultimately maximize the societal benefits of the Human Genome Project, sequence data from the Human Genome Project have been deposited into a freely accessible database run by the National Center for Biotechnology Information (www.ncbi.nlm.nih.gov). As a consequence of these shared data, research efforts in the 1990s accelerated the discovery of genetic variations affecting treatment response and development of new treatments and preventive strategies for human disease.

Largely because of advances in biotechnology, the initial working draft of the human genome sequence was completed in 2000, well ahead of schedule.⁷ In April of 2003, 50 years after James Watson and Francis Crick described the double-helix structure of DNA and over 2 years ahead of schedule, researchers announced the completion of the Human Genome Project.⁸ The final version contains 99% of the gene-containing sequence, with 99.9% accuracy.

Following completion of the Human Genome Project, the National Human Genome Research Institute announced its vision for the future of genomic research with the goal of improving human health and well-being.⁹ One of the challenges set forth to meet this goal is to develop genome-based approaches to predict drug response. This challenge will involve the accurate, unbiased determination of genetic variants linked to drug response, advanced technology to

reduce genotyping costs, and appropriate integration of genetic testing into the therapeutic decision process. The National Human Genome Research Institute also challenges investigators to develop new, gene-based approaches to disease management, which will require a thorough understanding of genetic determinants of disease susceptibility and progression.

GENETIC CONCEPTS

The human genome contains approximately 3 billion nucleotide bases, which code for approximately 30,000 genes. Two purine nucleotide bases, adenine (A) and guanine (G), and two pyrimidine nucleotide bases, cytosine (C) and thymidine (T), are present in DNA, with purines and pyrimidines always pairing together as A-T and C-G in the two strands that make up the DNA structure. Most nucleotide base pairs are identical from person to person, with only 0.1% contributing to individual differences.

According to the central dogma, when one strand of DNA is transcribed into RNA and translated to make proteins, three consecutive nucleotides form a codon. Each codon specifies an amino acid or amino acid chain termination. For example, the nucleotide sequence, or codon, GGA specifies the amino acid glycine. The genetic code has substantial redundancy, in that two or more codons code for the same amino acid. For example, both GGA and GGC code for glycine. Amino acids are the basic constituents of proteins, which mediate all cellular functions. Only 20 different amino acids, in various arrangements, form the basic units of all the proteins in the human body.

A gene is a series of codons that specifies a particular protein. Genes contain several regions: *exons* that encode for the final protein, *introns* that consist of intervening noncoding regions, and *promoter regions* that regulate gene transcription. At each gene locus, an individual carries two alleles, one from each parent. An *allele* is defined as the sequence of nucleic acid bases at a given gene chromosomal locus. Two identical alleles make up a *homozygous* genotype, and two different alleles make up a *heterozygous* genotype. A *phenotype* refers to the outward expression of the genotype.

TYPES OF GENETIC VARIATIONS

Genetic variations occur as either rare defects or polymorphisms. *Polymorphisms* are defined as variations occurring at a frequency of

at least 1% in the human population. For example, the genes encoding the CYP enzymes 2A6, 2C9, 2C19, 2D6, and 3A4 are polymorphic, with functional mutations of greater than 1% occurring in different ethnic groups. In contrast, rare mutations occur in less than 1% of the population and cause inherited diseases such as cystic fibrosis, hemophilia, and Huntington's disease. Common diseases, such as essential hypertension and diabetes mellitus, are polygenic in that multiple genetic polymorphisms likely interact to contribute to the disease susceptibility.

6 Single-nucleotide polymorphisms, abbreviated as SNPs and pronounced “snips,” are the most common genetic variations in human DNA, occurring approximately once in every 1000 base pairs. Approximately 3.7 million SNPs have been mapped thus far in the human genome. SNPs occur when one nucleotide base pair replaces another, as illustrated in Fig. 6–2. Thus SNPs are single-base differences that exist between individuals. Nucleotide substitution results in two possible alleles. One allele, typically either the most commonly occurring allele or the allele originally sequenced, is considered the *wild type*, and the alternative allele is considered the *variant allele*.

A SNP may change the codon resulting in amino acid substitution, which may or may not alter gene expression. For example, in Fig. 6–2, guanine (G) is substituted for adenine (A) at nucleotide 46. This results in the substitution of glycine for arginine at amino acid position 16. SNPs such as this that result in amino acid substitution are referred to as *nonsynonymous*. SNPs that do not result in amino acid substitution are called *synonymous*. Referring to a previous example of redundancy in the genetic code, replacement of adenine (A) with cytosine (C) in the codon GGA is an example of a synonymous SNP because the resulting amino acid is still glycine. Synonymous SNPs usually are abbreviated based on the nucleotides involved and the nucleotide base position. For example, A1166C or A1166→C indicates that cytosine is substituted for adenine at nucleotide position 1166 of a given gene region. Nonsynonymous SNPs usually are designated by the amino acids and codon involved. For example, Arg16Gly or

FIGURE 6–2. Nucleotide sequence of the β_2 -adrenergic receptor gene from codons 13 through 19. A. Nucleotide sequence of the wild-type allele with adenine (A) at nucleotide position 46 (*underlined*) located in codon 16 of the β_2 -adrenergic receptor gene. The AGA codon designates the amino acid arginine (Arg), with an average frequency of 39% in the human population. B. Nucleotide sequence of the variant allele with guanine (G) at nucleotide position 46 (*underlined*), located in codon 16. The GGA codon designates the amino acid glycine (Gly), which occurs at an average frequency of 61%. Although the Arg16 polymorphism occurs less commonly than the Gly16 polymorphism, it is referred to as the wild type because it was identified first.

Arg16→Gly indicates that glycine is substituted for arginine at codon 16. If a SNP changes the expression of a protein that contributes to drug response, it may alter a patient's sensitivity to a drug or predispose a patient to adverse reactions to drug therapy.

Other examples of genetic variants include

- *Insertion-deletion polymorphisms*, in which a nucleotide or nucleotide sequence is either added to or deleted from a DNA sequence
- *Tandem repeats*, in which a nucleotide sequence repeats in tandem (i.e., if “AG” is the nucleotide repeat unit, “AGAGAGAGAG” is a five-tandem repeat)
- *Frameshift mutation*, in which there is an insertion/deletion polymorphism, and the number of nucleotides added or lost is not a multiple of 3, resulting in disruption of the gene's reading frame
- *Defective splicing*, in which an internal polypeptide segment is abnormally removed, and the ends of the remaining polypeptide chain are joined
- *Aberrant splice site*, in which processing of the protein occurs at an alternate site
- *Premature stop codon polymorphisms*, in which there is premature termination of the polypeptide chain by a stop codon (specific sequence of three nucleotides that do not code for an amino acid but rather specify polypeptide chain termination)

For more detailed information about genetic concepts, refer to the recommended genetics textbook.¹⁰

As mentioned earlier, most common diseases are polygenic in nature. For example, independent studies have demonstrated associations between gene variants for proteins involved in the renin-angiotensin system, sympathetic nervous system, and renal sodium transport and the risk for essential hypertension.¹¹ Environmental factors are also well-known risk factors for diseases such as hypertension and often interact with genetic factors to influence disease susceptibility and progression. Given the complex pathophysiology of most common diseases, genes linked to disease susceptibility will not be discussed in this chapter. Rather, this chapter will focus on genetic variations linked to responses to pharmacologic agents.

POLYMORPHISMS IN GENES FOR DRUG-METABOLIZING ENZYMES

3 Polymorphisms in the drug-metabolizing enzymes represent the first recognized and, so far, the most documented examples of genetic variants with consequences in drug response and toxicity. The major phase I enzymes are the CYP superfamily of isoenzymes. *N*-acetyltransferase, thiopurine *S*-methyltransferase, and glutathione *S*-transferase are examples of phase II metabolizing enzymes that exhibit genetic polymorphisms. Table 6–1 lists selected examples of polymorphic metabolizing enzymes, corresponding drug substrates, and the consequences of altered enzyme function as a result of gene mutation.

CYTOCHROME P450 ENZYMES

Currently, 57 different CYP isoenzymes have been documented to be present in humans, with 42 involved in the metabolism of xenobiotics, including drugs, and endogenous substances such as steroids and prostaglandins.¹² Fifteen of these isoenzymes are known to be involved in the metabolism of xenobiotics, and functional

TABLE 6–1. Selected Examples of Genetic Polymorphisms in Drug-Metabolizing Enzymes and Response to Drug Therapy

| Genetic Variants/Genes | Drug | Drug Effect Associated with Polymorphism |
|---|---|--|
| <i>CYP2D6</i> *4, <i>CYP2D6</i> *5 | Perhexiline Codeine Tramadol | Neuropathy ¹⁸ Significant reduction in analgesic effect ^{22,23} |

| UDP-glucuronosyltransferase | Irinotecan | Increased severity of diarrhea and neutropenia in carrier of (<i>TA</i>) ₇ TAA allele ⁵⁹ |

genetic polymorphism has been discovered for *CYP2A6*, *CYP2C9*, *CYP2C19*, *CYP2D6*,¹³ and more recently, *CYP3A4/5*.^{14,15} A polymorphism in the regulatory region of the gene encoding for *CYP1A2*¹⁶ has been identified, but its functional importance remains to be determined.

CYP2D6

Polymorphisms in the *CYP2D6* gene are the best characterized of the CYP variants. Over the years, at least 48 gene variants and 53 alleles have been identified in the *CYP2D6* gene.¹⁷ Nevertheless, the *CYP2D6* extensive-metabolizer (EM) and poor-metabolizer (PM) phenotypes (outward expression of genotypes) can be predicted with up to 99% confidence with six genotypic variants. *CYP2D6**1 is considered the wild-type variant and exhibits normal enzyme activity. *CYP2D6**2 has the same activity as *CYP2D6**1 but is capable of duplication or amplification. Both these variants are present in EMs. The *CYP2D6**4 (defective splicing) and *CYP2D6**5 (gene deletion) variants are present in PMs and result in an inactive enzyme and absence of enzyme, respectively. The predominant variants in people of Asian and African heritage are *CYP2D6**10 (Pro34Ser) and *CYP2D6**17 (Arg296Cys), respectively, both resulting in single-amino-acid substitution and consequent reduction in enzyme activity.

Poor *CYP2D6* metabolizers carry two defective alleles, such as *CYP2D6**3, *CYP2D6**4 (more common), *CYP2D6**5, and *CYP2D6**6, resulting in a total absence of active enzyme and an impaired ability to metabolize *CYP2D6*-dependent substrates. Examples of *CYP2D6* substrates include neuroleptic medications, antidepressants such as tricyclic antidepressants and mianserin, antiarrhythmic drugs such as propafenone, and β -adrenergic antagonists such as metoprolol (see Table 6–1). Depending on the importance of the affected *CYP2D6* pathway to overall drug metabolism and the drug's therapeutic index, clinically significant side effects may occur in PMs as a result of elevated parent drug concentrations. For example, compared with EMs, PMs have been shown to develop

neuropathy after treatment with the antianginal agent perhexiline¹⁸ and have experienced more adverse effects with propafenone¹⁹ and neuroleptic agents such as perphenazine.^{20,21}

The therapeutic implication of *CYP2D6* polymorphism is different if the substrate in question is a prodrug. In this case, PMs would not be able to convert the drug into the therapeutically active metabolite. Two examples of prodrugs dependent on *CYP2D6*-mediated conversion to active forms are codeine and tramadol. Codeine and tramadol are converted by *CYP2D6* to morphine and *O*-desmethyltramadol, respectively, and thus poor *CYP2D6* metabolizers would experience little or no analgesic relief after taking these drugs.^{22,23}

Although PMs are at a disadvantage from the standpoint of drug toxicity and lack of efficacy for most *CYP2D6* substrates and prodrugs, data suggest that they may be “protected” from abusing opiates such as codeine, oxycodone, and hydrocodone. This is primarily based on an observation that no PMs were found among opiate-dependent subjects, which likely reflects their inability to convert these drugs of abuse into their respective “pharmacologically active” moieties.²⁴ Given the reduced potential for opiate abuse among *CYP2D6* PMs, investigators have used daily doses of fluoxetine 20 mg, a *CYP2D6* inhibitor, as adjunctive therapy in the management of opiate abuse to “metabolically convert” drug abusers who are EMs to PMs.²⁵

Furthermore, the potential and magnitude of drug interactions involving competitive inhibition of *CYP2D6* are much greater in EMs versus PMs, who have either deficient or absent enzyme activity.^{26,27} For example, Hamelin and colleagues²⁸ showed that in EMs, but not PMs, hemodynamic responses to metoprolol (a *CYP2D6* substrate) were pronounced and prolonged during concomitant diphenhydramine administration. Thus potent *CYP2D6* inhibitors may reduce the metabolic capacity of EMs significantly so that EMs appear phenotypically as PMs.

Patients who are EMs have a wide range of *CYP2D6* activity, with ultrarapid metabolizers (UMs) on one end of the spectrum and subjects with diminished activity on the other end. Both have clinical implications in terms of dosage adjustment for *CYP2D6* substrates.

UMs carry a duplicated or amplified mutant allele, resulting in two or multiple copies of the functional *CYP2D6*2* allele, and therefore show very high CYP2D6 activity. Nontherapeutic plasma concentrations of nortriptyline, a CYP2D6 substrate, were observed in a UM given normal doses of the drug.²⁹ The CYP2D6 enzyme converts nortriptyline to 10-hydroxynortriptyline, and one study demonstrated a directly proportional relationship between the number of functional *CYP2D6* genes and the concentration of 10-hydroxynortriptyline after nortriptyline ingestion.³⁰ A patient with three copies of *CYP2D6*2* was shown to require nortriptyline doses three- to fivefold higher than normally recommended to achieve therapeutic plasma concentrations (50–150 mcg/mL).^{29,31} In the same report, another patient with duplicated *CYP2D6*2* required twice the usual recommended daily dose (300 mg versus 25–150 mg) to achieve adequate therapeutic response.³¹ The UM genotype also has been reported to affect the potential for drug interaction with paroxetine, a CYP2D6 substrate as well as a potent CYP2D6 inhibitor.³²

The high prevalence of *CYP2D6*10* (associated with lower enzyme activity) in the Asian population provides a biologic and molecular explanation for the higher drug concentrations and/or lower dosage requirements of neuroleptic medications and mianserin in people of Asian heritage.^{33,34} The widespread presence of the *CYP2D6*17* variant among people of African heritage suggests that native African populations would metabolize CYP2D6 substrates at a slower rate than do other ethnic or racial groups.^{35,36} However, there are no current genotype- and phenotype-based data to document the need for prescribing lower doses of psychotropics and other CYP2D6 substrates in native African populations.

In addition to the therapeutic implications of genetic polymorphisms, a recent study showed that the CYP2D6 polymorphism also has an economic impact.³⁷ The annual cost of treating UMs and PMs (carriers of two nonfunctional CYP2D6 alleles) was \$4,000–\$6,000 higher than the cost of treating EMs or intermediate metabolizers (carriers of one nonfunctional allele and one allele associated with diminished activity). The cost of genotyping can be considerably less than that incurred in a patient with a serious adverse drug reaction. Brockmoller and colleagues³⁸ recently suggested how CYP2D6 genotyping can be used to achieve higher therapeutic success with the CYP2D6 substrate haloperidol.

CYP2C19

The principal defective alleles for the CYP2C19 genetic polymorphism are *CYP2C19*2* (aberrant splice site) and *CYP2C19*3* (premature stop codon), resulting in inactive CYP2C19 enzymes and the PM phenotype. The clinical implication of the CYP2C19 polymorphism has not been examined as extensively as that of the CYP2D6 polymorphism. However, PMs for the CYP2C19 polymorphism showed more than a 12-fold increase in the area under the curve (AUC) of the CYP2C19 substrate omeprazole compared with EMs.³⁹ In a separate study, the steady-state AUC of omeprazole and other CYP2C19 substrate proton-pump inhibitors was 5-fold higher in PMs versus EMs.⁴⁰

The presence of a defective CYP2C19 allele has been associated with improved *Helicobacter pylori* cure rates after dual (omeprazole and amoxicillin)⁴¹ or triple therapy (omeprazole, amoxicillin, and clarithromycin) with omeprazole,⁴² as well as with lansoprazole.⁴³ This difference likely reflects the higher achievable intragastric pH in the PM group.⁴⁴ The cure rate achieved with dual therapy was 100% in PMs compared with 60% and 29% in heterozygous and homozygous EMs, respectively.⁴¹ In two studies, EMs had *H. pylori*

eradication rates of 41% with dual therapy and 74% to 83% with triple therapy.^{42,43} In contrast, both dual- and triple-therapy regimens produced 100% cure rates in all 15 PMs included in the same studies. Interestingly, EMs who failed initial triple therapy (lansoprazole, clarithromycin, and amoxicillin) and were retreated with high-dose lansoprazole (30 mg four times daily) and amoxicillin achieved a 97% *H. pylori* eradication.⁴⁵

Similar to the CYP2D6 polymorphism, people of Asian heritage also metabolize most CYP2C19 substrates at a slower rate than do Caucasians.⁴⁶ This is a reflection of a higher prevalence of both PMs (13% to 20% versus 2% to 6% in Caucasians) and heterozygotes for the defective *CYP2C19* allele in Asians.⁴⁷ This genotypic difference may explain the practice of prescribing lower diazepam dosages for patients of Chinese heritage.⁴⁸

CYP2C9

Warfarin, phenytoin, and tolbutamide are examples of narrow-therapeutic-index drugs that are metabolized by CYP2C9. Warfarin is a racemic mixture, and the *S*-isomer, which possesses about three times the anticoagulant effects of the *R*-isomer, is metabolized by CYP2C9. *CYP2C9*2* and *CYP2C9*3* are the two most common CYP2C9 variants, and both exhibit single-amino-acid substitutions at positions critical for enzyme activity.⁴⁹ This could have clinically important consequences in warfarin-treated patients. For example, a 90% reduction in *S*-warfarin clearance was reported in *CYP2C9*3* homozygotes compared with subjects homozygous for the wild-type variant.⁵⁰ In another study, an overrepresentation of *CYP2C9* mutant alleles was observed in 81% of patients requiring low-dose warfarin therapy (≤ 1.5 mg/day).² The low-dose group was reported to have more difficulty with warfarin induction, requiring longer hospital stays to stabilize the warfarin regimen and experiencing a higher incidence of bleeding complications. In addition, a profound therapeutic response to usual doses of warfarin was observed in a patient homozygous for the *CYP2C9*3* allele, necessitating dose reduction to 0.5 mg/day.⁵¹

CYP2A6

A recent polymorphism was characterized for CYP2A6, with several variants identified: *CYP2A6*1* (wild type), *CYP2A6*2* (single-amino-acid substitution), *CYP2A6*3* (gene conversion), and three gene-deletion alleles: *CYP2A6*4A*, *CYP2A6*4B*, and *CYP2A6*4D*.⁵² Deletion of the *CYP2A6* gene is very common in Asian patients,^{52,53} which likely accounts for the dramatic difference in the frequency of PMs in Asian (20%) versus European and Caucasian populations ($\leq 1\%$). Nicotine is metabolized by CYP2A6, and the clinical relevance of the CYP2A6 polymorphism lies in management of tobacco abuse.⁵⁴ Investigators reported that nonsmokers were more likely to carry the defective *CYP2A6* allele than were smokers. Smokers who had the defective *CYP2A6* allele smoked fewer cigarettes and were more likely to quit.⁵⁴ The inability to metabolize nicotine, secondary to the presence of a defective *CYP2A6* allele, likely leads to enhanced nicotine tolerance and increased adverse effects from nicotine. Based on these observations, CYP2A6 inhibition may have a role in the management of tobacco dependency.⁵⁵

CYP3A4/5

Within the CYP3A subfamily, at least three isoenzymes, namely, CYP3A4, CYP3A5, and CYP3A7, have been characterized. Despite

as much as 40-fold interindividual variability in its expression, functional CYP3A4 is expressed in most adults. CYP3A4 variants with amino acid substitutions in exons 7 and 12 have been associated with altered catalytic activity for a CYP3A4 substrate, nifedipine.¹⁴ The clinical importance of this finding needs to be further elucidated and confirmed.

CYP3A5 is reported to be polymorphic in 60% of African-Americans and 33% of Caucasians. In contrast to individuals with the CYP3A5*1 allele, subjects with variant alleles such as CYP3A5*3 (aberrant splice site) in intron 3 have no functional CYP3A5 enzyme.¹⁵ It remains unknown whether there are clinically used drugs that are substrates for CYP3A5 but not CYP3A4 and vice versa.

PHASE II METABOLIZING ENZYMES

The clinical relevance of genetic polymorphisms in thiopurine-S-methyltransferase (TPMT), dihydropyrimidine dehydrogenase (DPD), and UDP-glucuronosyl transferase (UGT) enzymes has been demonstrated in the treatment of cancer.^{4,56,57} The TPMT gene has three mutant alleles: TPMT*3A (the most common), TPMT*2, and TPMT*3C. Patients who are homozygous or heterozygous for the TPMT mutant alleles are at higher risk for developing serious anemias during mercaptopurine treatment.⁴ DPD mediates the metabolism of 5-fluorouracil, and patients with a defective allele of the DPD gene cannot metabolize 5-fluorouracil and thus may experience enhanced drug-related neurotoxicity.⁵⁶ The camptothecin derivative irinotecan (CPT-11) is activated by carboxylesterase to SN-38, which is a potent topoisomerase I inhibitor. SN-38 is inactivated by glucuronidation via the polymorphic UDP-glucouronosyl transferase (UGT1A1) enzyme, which may play a role in CPT-11-related toxicity. A polymorphism in the promoter region of the UGT1A1 gene results in the (TA)₇TAA allele, which possesses lower enzyme activity than the wild-type (TA)₆TAA allele. A patient homozygous for the (TA)₇TAA allele had impaired SN-38 glucuronidation.⁵⁷ Since abnormally high SN-38 concentrations have been associated with diarrhea,⁵⁸ likely resulting from increased SN-38 excretion into the gut lumen, patients with the (TA)₇TAA allele may be predisposed to developing diarrhea with usual CPT-11 doses. This observation has been confirmed in a prospective clinical trial that demonstrated more severe diarrhea and neutropenia in patients who are homozygous or heterozygous carriers of the (TA)₇TAA allele.⁵⁹

POLYMORPHISMS IN DRUG TRANSPORTER GENES

Certain membrane-spanning proteins facilitate drug transport across the gastrointestinal tract, drug excretion into the bile and urine, and drug distribution across the blood-brain barrier. Genetic variations for drug transport proteins may affect the distribution of drugs that serve as substrates for these proteins and alter drug concentrations at their therapeutic sites of action. P-glycoprotein is one of the most recognized of the drug transport proteins that exhibit genetic polymorphism. P-glycoprotein is an energy-dependent transmembrane efflux pump encoded by the multidrug-resistance 1 (*MDR-1*) gene. P-glycoprotein was first recognized for its ability to actively export anticancer agents from cancer cells and promote multidrug resistance to cancer chemotherapy. Later, it was discovered that P-glycoprotein is also widely distributed on normal cell types, including intestinal enterocytes, hepatocytes, renal proximal tubule cells, and endothelial cells lining the blood-brain barrier. At these locations, P-glycoprotein serves a protective role by transporting toxic substances or metabolites out of cells. P-glycoprotein also affects the distribution of some

FIGURE 6-3. Active transport of drugs out of the cell by P-glycoprotein.

nonchemotherapeutic agents, including digoxin, the immunosuppressants cyclosporine and tacrolimus, and antiretroviral protease inhibitors (Fig. 6-3). Increased intestinal expression of P-glycoprotein can limit the absorption of P-glycoprotein substrates, thus reducing their bioavailability and preventing attainment of therapeutic plasma concentrations. Conversely, decreased P-glycoprotein expression may result in supratherapeutic plasma concentrations of relevant drugs and drug toxicity.

CLINICAL CONTROVERSY

Much of the data on individual variations in the multidrug resistance gene and response to P-glycoprotein substrates are inconsistent and even conflicting. The combination of multiple variations in the multidrug resistance gene eventually may prove to be a stronger predictor of drug response than any individual variation.

A number of polymorphisms have been identified in the promoter and exon regions of the *MDR-1* gene. Common SNPs occur in exons 12 (C1236T), 21 (G2677T), and 26 (C3435T). The exon 21 and 26 SNPs have been associated with intestinal *MDR-1* expression, P-glycoprotein activity, and digoxin plasma concentrations in healthy volunteers.⁶⁰ These data imply that the *MDR-1* genotype may be useful in predicting digoxin concentrations in patients with atrial arrhythmias or heart failure and in choosing initial digoxin doses accordingly.

The *MDR-1* exon 26 polymorphism also has been associated with plasma concentrations and clinical effects of protease inhibitors in patients infected with the human immunodeficiency virus (HIV).⁶¹ Specifically, following therapy with efavirenz or nelfinavir for 6 months, a greater rise in CD4 cell counts was observed in individuals with the exon 26 TT genotype compared with CC homozygotes. This findings suggest a role for *MDR-1* genotyping in predicting hematologic responses to protease inhibitors and individualizing antiretroviral drug therapy for HIV-infected patients.

Other examples of polymorphic drug transporter proteins include the dipeptide transporter, organic anion and cation transporters, and L-amino acid transporter. Their effects on drug distribution are the focus of ongoing research.

POLYMORPHISMS IN DRUG TARGET GENES

5 Genetic polymorphisms occur commonly for drug target proteins, including receptors, enzymes, and intracellular signaling proteins. Drug target genes may work in concert with genes that affect pharmacokinetic properties to contribute to overall drug response. Table 6–2 provides examples of drug target genes linked to drug response in clinical studies. The following section highlights some of the receptor, enzyme, and cell-signaling protein genes shown to influence the efficacy and safety of various pharmacologic agents.

RECEPTOR GENOTYPES AND DRUG RESPONSE

The β_1 - and β_2 -adrenergic receptor genes have been the focus of much research into genetic determinants of responses to β -agonists and β -antagonists. β_1 -Receptors are located in the heart and kidney, where they participate in blood pressure regulation. Two nonsynonymous SNPs commonly occur in the β_1 -receptor gene at codons 49 (Ser→Gly) and 389 (Arg→Gly), and there is evidence of their involvement in blood pressure control.⁶² Recently, investigators examined the influence of the β_1 -receptor gene on blood pressure response to β_1 -receptor blockade with metoprolol. Hypertensive patients who were homozygous for both the Ser49 and Arg389 alleles were found to have greater reductions in diastolic blood pressure with metoprolol monotherapy compared with carriers of the Gly49 and/or Gly389 alleles.⁶³ These data suggest that β_1 -receptor genotype may be an important determinant of blood pressure response to β -blockers in the management of hypertension. Given that a significant percentage of hypertensive patients fail to derive adequate blood pressure reduction with β -blocker monotherapy,⁶⁴ the ability to predict the likelihood of response based on genotype would have important clinical implications. Specifically, β -blockers could be started in patients expected to respond well to this drug class based on their β_1 -receptor genotype, whereas other classes of antihypertensive agents could be used in those expected to respond poorly to β -blockers.

β_2 -Receptors are located on vascular and bronchial smooth muscle cells, where they mediate vasodilation and bronchodilation, respectively, on exposure to the β_2 -receptor agonists. Inhaled β_2 -agonists are the most effective agents for the acute reversal of bronchospasm; however, the magnitude of their effects varies substantially among asthmatic patients.⁶⁵ More than 11 SNPs have been identified in the β_2 -receptor gene, 3 of which occur frequently and result in amino acid changes. Two common nonsynonymous SNPs are found in the gene's coding block region, at codons 16 and 27, and a third occurs upstream from the coding block in the gene's promoter region.

Three groups of investigators have examined the influence of the β_2 -receptor codon 16 (Arg→Gly) polymorphism on vasodilatory response to β_2 -agonist therapy. Two of these groups reported greater vasodilation with the homozygous Arg genotype, whereas the third reported greater response with the Gly/Gly form.^{66–68} A fourth group of investigators found that the combination of SNPs in the gene's coding block and promoter region was a better determinant of β_2 -agonist response than any individual SNP.⁶⁹ These data suggest that an individual SNP in the β_2 -receptor gene is an insufficient predictor of β_2 -agonist effects and that multiple receptor gene variations more accurately correlate with β_2 -agonist response.

Clozapine is an example of a drug for which there is evidence that multiple receptor genes interact to influence its effects. Clozapine is an atypical antipsychotic used in the treatment of schizophrenia. Because of its potential to produce agranulocytosis in 0.5% to 2% of treated patients, clozapine is reserved for schizophrenic patients who are unresponsive to other drug therapies. However, only 30% to 60% of patients with refractory schizophrenia respond to clozapine.⁷⁰ Clozapine's effects are believed to be mediated through dopaminergic, serotonergic, adrenergic, and histaminergic receptors in the central nervous system.⁷¹ Although several studies have demonstrated relationships between single genetic variants for these receptor subtypes and clozapine response, the data are inconsistent.⁷² In a more recent study, a combination of six polymorphisms in the histamine and serotonin 2A and 2C receptor genes and the serotonin transporter gene

TABLE 6–2. Genetic Polymorphisms in Drug Targets and Response to Drug Therapy

| Gene | Drug/Drug Class | Drug Effect Associated with Polymorphism |

were 77% predictive of antipsychotic response to clozapine.⁷⁰ These findings imply that, similar to other drug target gene–drug response relationships, a combination of polymorphisms, rather than any single polymorphism, provides a more accurate prediction of clozapine response.

ENZYME GENES AND DRUG RESPONSE

The angiotensin-converting enzyme (ACE) is an example of an enzyme with genetic contributions to drug response. An insertion/deletion (I/D) polymorphism in intron 16 of the ACE gene results in the presence or absence of a 287-base-pair fragment. This polymorphism has been linked consistently to plasma concentrations of ACE, the enzyme responsible for the conversion of angiotensin I to the potent vasoconstrictor angiotensin II.⁷³

ACE inhibitors are among the most commonly prescribed antihypertensive agents. However, ACE inhibitors fail to sufficiently lower blood pressure in over 50% of patients.⁶⁴ Given its association with ACE concentrations, a number of investigators have examined whether the ACE I/D polymorphism contributes to the interpatient variability in ACE inhibitor response. To date, much of the data with the ACE gene and response to ACE inhibitors are inconsistent and even conflicting. While some studies have demonstrated greater blood pressure reductions with ACE inhibitor therapy among individuals with the ACE DD genotype, others have shown greater blood pressure reductions with the II genotype.^{74–76} Still other investigators have reported no association between the ACE I/D genotype and the antihypertensive effects of ACE inhibition.^{77,78}

Numerous proteins are involved in the complex signaling pathway of the renin-angiotensin system, and multiple genetic polymorphisms have been identified for many of these proteins (Fig. 6-4). Thus one explanation for the inconsistent and conflicting ACE gene–drug response data is that a single polymorphism contributes little to the overall response to ACE inhibition. Rather, response to ACE inhibition is best determined by a combination of multiple polymorphisms occurring in multiple genes involved in the renin-angiotensin

pathway. Indeed, other renin-angiotensin system genes, including the angiotensinogen and aldosterone synthase genes, have been correlated with antihypertensive responses to ACE inhibitors and angiotensin receptor blockers,^{79,80} suggesting that ACE, angiotensinogen, aldosterone synthase, and probably other genes encoding for renin-angiotensin system proteins interact to influence ACE inhibitor response. Thus, before genotype may be used as a predictor of response to renin-angiotensin antagonists, the combination of genetic variants in the renin-angiotensin system that best determines drug response first must be elucidated.

The ACE gene also may predict the likelihood of adverse reactions of ACE inhibitors. Approximately 10% of patients receiving ACE inhibitors develop a cough that persists for the duration of treatment.⁸¹ The ACE I/D polymorphism was correlated with the ACE inhibitor–induced cough in one small study.⁸¹ However, a larger study found no such association.⁸² Given the proven benefits of ACE inhibitors in diseases such as hypertension, diabetes, and heart failure, it is unlikely that genes associated with the ACE inhibitor–induced cough, even if validated, would influence drug prescribing. This is so because the development of a cough during ACE inhibitor treatment may be bothersome and a potential threat to drug adherence, but it is unlikely that the cough will result in any serious outcomes. Thus one should not deprive a patient of the potential benefits from ACE inhibitor therapy on the basis of a genetic predisposition for drug-induced cough.

On the other hand, in cases where an adverse drug effect may have serious consequences, knowledge of a genetic propensity for such an effect would be of great clinical significance. Angioedema is an example of a serious and potentially life-threatening adverse drug effect that may have genetic influences. Angioedema is estimated to occur in approximately 0.1% to 0.2% of ACE inhibitor–treated patients.⁸³ Given its infrequent occurrence, genetic data from a relatively large number of affected patients would be necessary to establish a definite genetic cause for ACE inhibitor–induced angioedema. Investigators for many multicenter clinical drug trials are now asking study participants to provide consent for the collection of genetic material so that

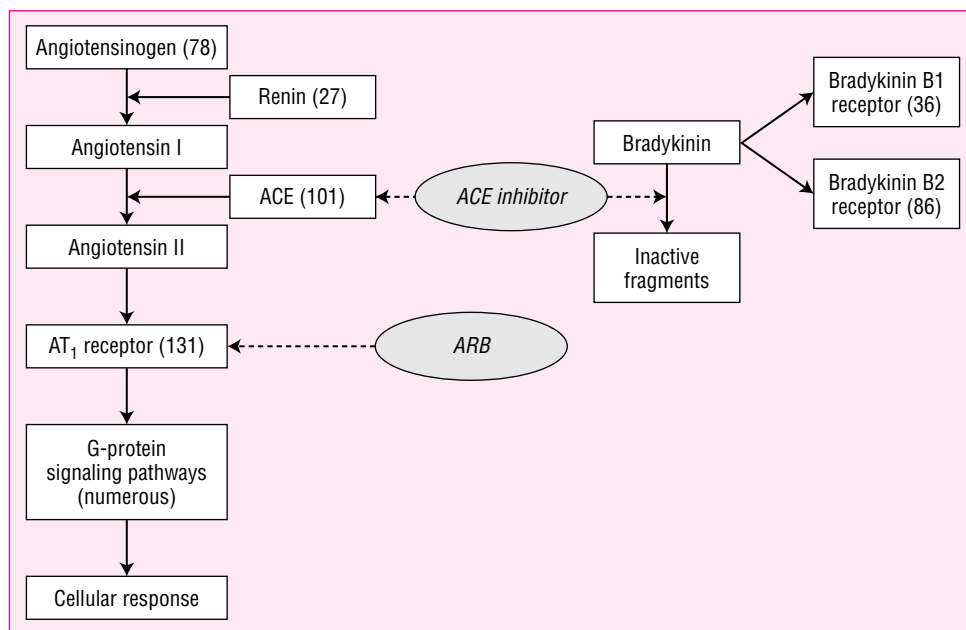

FIGURE 6-4. Single-nucleotide polymorphisms (SNPs) identified for renin-angiotensin system genes. The number of polymorphisms identified for each protein is shown in parenthesis after the protein name (<http://snp.cshl.org>). ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker.

in the future, genetic contributions to rare but serious adverse drug effects may be elucidated.

There is evidence of racial differences in antihypertensive response to ACE inhibitors. Specifically, African-Americans in general are believed to have diminished antihypertensive responses to ACE inhibitors compared with Caucasians.⁶⁴ The frequencies of many SNPs in the renin-angiotensin system vary between African-American and white populations and may contribute to the observed racial differences in ACE inhibitor response.⁸⁴ Indeed, most racial differences in drug response probably can be attributed to racial differences in genotype frequencies, although this is yet to be determined.

GENES FOR INTRACELLULAR SIGNALING PROTEINS, ION TRANSPORTERS, AND DRUG RESPONSE

Cellular responses to many drugs are mediated through GTP-binding proteins also called *G-proteins*. The β_1 -adrenergic receptor is an example of a G-protein-coupled receptor in which a stimulatory G-protein (G_s -protein) couples the receptor to intracellular signaling mechanisms to elicit a cellular response (Fig. 6–5). Receptor-coupled G_s -proteins contain α , β , and γ subunits that mediate the activation of adenylyl cyclase and the generation of cyclic AMP following receptor stimulation. A SNP in the α subunit of G_s -protein has been linked to the blood pressure response to β -blockers.⁸⁵ Whether the G_s -protein α -subunit gene interacts with the β_1 -adrenergic receptor gene or other intracellular signaling-protein genes to determine β -blocker response remains to be determined.

Disturbances in G-protein-mediated signal transduction have been implicated in the pathophysiology of depressive disorders.⁸⁶ In addition, data suggest that abnormalities in signal-transduction proteins contribute to antidepressant drug response.⁸⁷ A common SNP (C825→T) occurs in the gene for the inhibitory G-protein (G_i -protein) β_3 subunit and has been associated with enhanced intracellular signal transduction. In a study of patients treated with either tricyclic antidepressants or serotonin reuptake inhibitors, the TT genotype was correlated with greater improvement in depression symptoms,^{88,89} implying that the G_i -protein β_3 subunit gene may have a future role in therapeutic decisions for depression management.

There is evidence that the gene for α -adducin, a cytoskeletal protein involved in renal tubular ion transport, contributes to thiazide diuretic response. Substitution of tryptophan for glycine at codon 460 of the α -adducin gene has been associated with enhanced renal tubular sodium reabsorption.⁹⁰ Two separate studies demonstrated

FIGURE 6–5. β_1 -receptor coupled to intracellular signaling mechanisms by a stimulatory G-protein.

that hydrochlorothiazide produced greater blood pressure reductions in hypertensive individuals with at least one 460Trp allele (Trp/Trp homozygotes or Gly/Trp heterozygotes) compared with Gly/Gly homozygotes.⁹¹ In a subsequent population-based case-control study, hypertensive patients with at least one 460Trp allele appeared to derive superior protection against stroke and myocardial infarction from diuretic therapy compared with treatment with alternative agents.⁹² These findings suggest that the α -adducin genotype may be an important determinant not only of antihypertensive response to diuretic therapy but also, more important, of the effects of diuretic therapy on hypertension-related target-organ damage.

DISEASE-ASSOCIATED GENES

Numerous genes have been correlated with disease outcomes, and many of these have been found subsequently to influence response to pharmacologic disease management. These gene–drug response associations often occur despite the lack of a direct effect on pharmacokinetic or pharmacodynamic drug properties. Examples of such disease-associated genes are given below.

FACTOR V AND PROTHROMBIN GENES AND ORAL CONTRACEPTION

The use of oral contraceptives is associated with an increased risk for developing thromboembolic disorders, including deep venous thrombosis, pulmonary embolism, and thrombotic stroke. Variations in the genes for the coagulation factors prothrombin and factor V Leiden also have been identified as risk factors for thromboembolic disorders.^{93,94} In case-control studies, the presence of a factor V Leiden or prothrombin gene variation significantly increased the risk for deep vein thrombosis and cerebral vein thrombosis among oral contraceptive users.^{93,94} Thus it appears as though carrier status for either the prothrombin or factor V Leiden mutation markedly increases the risk of thrombosis with oral contraceptive use. These data suggest that alternative birth control measures should be employed in women with the prothrombin or factor V Leiden mutations.

CONGENITAL LONG-QT SYNDROME AND DRUG-INDUCED TORSADES DE POINTES

Drug-induced QT-interval prolongation and torsades de pointes are serious, potentially life-threatening adverse effects of many drugs. It is well recognized that many antiarrhythmic drugs can cause torsades de pointes. In addition, numerous noncardiovascular agents can induce torsades de pointes, and many have been withdrawn from the market as a result. Such drugs include the antihistamines terfenadine and astemizole, the fluoroquinolone antibiotic grepafloxacin, and the motility agent cisapride. Given the serious and unpredictable nature of torsades de pointes, there has been great interest in identifying genetic markers that predispose individuals to its occurrence.

Abnormalities in ion flux across the cardiac cell membrane resulting in an excess of intracellular positive ions and delayed ventricular repolarization are characteristic of long-QT syndromes. Mutations in genes for the pore-forming channel proteins that affect potassium and sodium transport across the cardiac cell membrane underlie congenital long-QT syndromes.⁹⁵ There is evidence that these mutations also may increase the risk for drug-induced torsades de pointes.^{96,97} The ability to screen for mutations associated with drug-induced torsades de pointes would be of clinical significance in that

individuals with a genetic predisposition for this life-threatening arrhythmia could be spared exposure to potentially causative agents and treated with alternative therapies.

CORONARY DISEASE PROGRESSION GENE AND RESPONSE TO STATIN THERAPY

Several large clinical trials in patients with coronary heart disease, including the Scandinavian Simvastatin Survival Study (4S), have demonstrated significant reductions in coronary events and mortality with HMG-CoA reductase inhibitors, or statins. The gene for apolipoprotein E has been correlated with hepatic cholesterol uptake and the risk for coronary heart disease.⁹⁸ Its contribution to coronary heart disease progression and statin response was examined in the 4S population.⁹⁹ Investigators found that the variant $\epsilon 4$ allele was associated with increased risk for all-cause mortality among placebo-treated study participants. However, no such association was observed in the simvastatin group, suggesting that simvastatin abolished the excess mortality risk associated with the $\epsilon 4$ allele.

Several other genes have been associated with responses to statins in coronary heart disease. These include the genes for the cholesteryl ester transfer protein, which is involved in the metabolism of high-density lipoprotein cholesterol; β -fibrinogen, which influences plasma fibrinogen concentrations; and stromelysin-1, which is involved in remodeling of the extracellular matrix of atherosclerotic plaques.^{100–102} In each case, the gene linked to worse disease progression or clinical outcomes also was associated with the greatest response to statin therapy. These data imply that genotype may be useful in identifying which coronary heart disease patients are at an increased risk for coronary events and death, in whom treatment with a statin would be of particular benefit.

NOVEL SITES FOR DRUG DEVELOPMENT

The discovery of genes that confer disease has led to an improved understanding of the molecular mechanisms involved in disease pathophysiology. Once associations between genes and diseases are discovered, scientists can elucidate the functions of the encoded proteins and more clearly define the consequences of genetic mutations. Insight into the genetic control of cellular functions may reveal new strategies for disease treatment and prevention.

For example, researchers have discovered that the gene for the cysteine protease calpain-10 confers susceptibility to type 2 diabetes and may serve as a new target for treatment intervention.¹⁰³ While the exact function of calpain-10 remains to be determined, it is expressed in tissues involved in the pathophysiology of type 2 diabetes mellitus, including the pancreatic islet cells, skeletal myocytes, and hepatocytes. These sites are important for controlling insulin secretion, peripheral insulin uptake, and hepatic glucose production, suggesting that the product of calpain-10 protein may influence glucose homeostasis.¹⁰⁴ Multiple SNPs have been identified in the calpain-10 gene, one of which has been correlated with reduced calpain-10 levels in skeletal muscle and insulin resistance.¹⁰³ The discovery of calpain-10 as a candidate gene for type 2 diabetes identifies a potential new drug target for glucose control and an opportunity to improve glucose homeostasis permanently in patients with diabetes through pharmacogenetics.

Similarly, the discovery that the apolipoprotein E gene is strongly linked to late-onset Alzheimer's disease¹⁰⁵ and that the α -synuclein gene is associated with Parkinson's disease¹⁰⁶ raises the possibility of

examining these gene as targets for future drug therapy in psychiatric and neurologic diseases.

GENE THERAPY

7 Gene therapy has emerged as a possible approach to treating and curing disease by altering gene expression. The goal of gene therapy is to correct genetic defects permanently and thereby restore normal cellular function.

Most gene therapy techniques attempt to replace defective genes with normally functioning ones. Exogenous genes, called *transgenes*, can be transferred into either somatic (body) or germ line (egg or sperm) cells of the recipient. In somatic cell gene transfer, genetic changes do not affect future generations. In contrast, germ line cell transfer, which is currently prohibited by the Food and Drug Administration (FDA),¹⁰⁷ results in the passage of genetic alterations to offspring.

Initially, the focus of gene therapy was for the treatment of inherited disorders such as cystic fibrosis, sickle cell anemia, hemophilia, and adenosine deaminase deficiency.¹⁰⁸ Gene therapy trials were later expanded to include patients with acquired diseases such as cancer and heart disease.

The first clinical gene therapy trial began in 1990 for the treatment of adenosine deaminase deficiency.¹⁰⁷ B and T lymphocytes fail to develop in this autosomal recessive disease, resulting in a severe combined immunodeficiency syndrome (SCID) made famous by the “bubble boys” whose lives were confined to tents in an effort to keep them in a germ-free environment. Only two patients were included in this trial, and although both continued to demonstrate clinical improvement 10 years later, gene therapy did not cure the disease, as investigators had hoped.

Since then, the FDA has approved more than 350 clinical gene therapy trials.¹⁰⁸ Most of these trials involve cancer patients; however, a number of studies also target inherited disorders. The results of gene therapy trials to date have been largely disappointing, with reports of serious toxicities and few therapeutic successes.

OBSTACLES TO SUCCESS

Reasons for limited success with gene therapy include inefficient gene delivery to target cells, inadequate gene expression, and unacceptable adverse effects.¹⁰⁷

Sufficient amounts of the transgene must be inserted into a sufficient number of recipient cells to produce a therapeutic response. In addition, the transgene must be inserted into the correct chromosomal position of the correct cell nucleus so as not to disrupt normal gene function and expression. Incorrect chromosomal insertion of the transgene is a problem referred to as *insertional mutagenesis*. Once the therapeutic gene is integrated correctly into host DNA, it must be expressed at adequate levels and at appropriate times to restore normal cell function. Finally, the gene delivery system and delivery technique should lack any potential to cause unwanted effects in the transgene recipient.

RETROVIRAL GENE DELIVERY

8 Because of their efficiency in integrating into human DNA, viruses are the most common vectors used to deliver therapeutic genes to recipient cell targets. Disease-causing genes are replaced with the desired therapeutic genes; the viral genes that control delivery mechanisms are retained.

The first viral vectors introduced were retroviruses, which are RNA viruses that integrate into the host cell genome and replicate during cell division. Thus retroviral gene transfer is capable of permanently altering gene expression. Retroviruses may be used to deliver genes through either direct infusion into target organs or ex vivo manipulation of harvested cells followed by reinfusion into the recipient. The disadvantages of retroviral vectors are the limited size of the gene they can carry, relatively low efficiency, and the risk of insertional mutagenesis. In fact, the FDA temporarily halted retroviral gene delivery into hematopoietic tissue in early 2003 after leukemia developed as a result of insertional mutagenesis in two SCID-affected children treated with retroviral gene therapy.¹⁰⁹

ADENOVIRAL GENE DELIVERY

Unlike retroviruses, adenoviruses do not integrate into the host genome and thus do not replicate. As a result, genes delivered by adenoviruses are only active temporarily. Adenoviral-mediated gene therapy is employed commonly in cancer patients because permanent gene expression is unnecessary in this patient population.

Tumor cells have been infused with adenoviral vectors carrying the herpes simplex virus-1 thymidine kinase gene and then exposed to ganciclovir as a mode of cancer chemotherapy.¹¹⁰ Thymidine kinase converts ganciclovir to its active, cytotoxic form, which is incorporated in the DNA of tumor cells, leading to their death. Adenoviruses can be grown in high titers and do not carry the risk of insertional mutagenesis. The major disadvantage of adenoviruses is their immunogenic potential, which has resulted in one death and prompted federal oversight of gene therapy trials.¹¹¹

OTHER MEANS OF GENE DELIVERY

Adeno-associated viruses are human DNA-containing viruses that appear neither to cause disease in humans nor to trigger immune responses on injection. Similar to retroviruses, adeno-associated viruses are incapable of carrying a large amount of genetic material, and their use entails the risk of insertional mutagenesis. Investigators have had some success in treating hemophilia B using intramuscular injections of an adeno-associated virus vector that expresses the human coagulation factor IX gene.¹¹²

Scientists are also experimenting with nonviral delivery methods such as the use of direct DNA injection, liposomes, and electroporation. There has been some success with intramyocardial transfection of plasmid DNA encoding for vascular endothelial growth factor into patients with severe, intractable angina.¹¹³ Initially, the procedure improved myocardial perfusion and angina in this patient population with few major adverse events. One year later, patients continued to report some improvement in their angina symptoms.¹¹⁴

Scientists have enjoyed few successes with gene therapy in recent years, and it is unlikely that gene therapy will progress to have a lasting impact on medicine during the next decade. Improvements in gene delivery techniques and a better understanding of molecular processes controlling gene expression are necessary before gene therapy can correct genetic defects successfully and thus cure associated diseases without inducing adverse effects. Because of limited success with traditional approaches to gene therapy, scientists are exploring other strategies, such as repairing defective genes rather than replacing them.¹¹⁵ It is important that gene therapy eventually succeeds so that diseases such as Huntington's disease, sickle cell anemia, and inherited immunodeficiency disorders may be cured and their associated morbidity and mortality alleviated.

ETHICAL CONSIDERATIONS

PHARMACOGENETICS

Traditionally, *genetic testing* refers to screening human genetic material to identify genotypes associated with disease susceptibility or carrier status for inherited diseases, such as Huntington's disease, Alzheimer's disease, or breast cancer. This kind of testing can have profound legal, ethical, and social implications. For example, knowledge that a patient is at risk for developing a genetic disorder could result in discrimination by employers or insurance companies. In addition, this information likely would cause emotional distress for the individual at risk and his or her family members.

Within the context of pharmacogenetics, however, testing involves searching for genetic variations linked to drug efficacy or toxicity rather than to disease susceptibility. This form of testing carries little risk for ethical, legal, and social concerns. To prevent public wariness and confusion, genetic testing in reference to pharmacogenetics needs to be defined or renamed so that it can be distinguished from genetic testing for susceptibility to inherited disorders.

CLINICAL CONTROVERSY

Many individuals are wary of the term *genetic testing* because this term is usually associated with determining genetic risk for serious diseases. Therefore, clinicians may cause unnecessary anxiety among patients if they refer to the screening for genetic variants associated with drug response as genetic testing.

GENE THERAPY

Many of the ethical concerns with gene therapy center on transgenic manipulation of somatic versus germ line cells. Somatic gene therapy only affects the recipient. That is, genetic alterations introduced by gene therapy are not passed on to future generations. In contrast, with manipulation of germ line cells, alterations are passed on to future children of the treated patient. Some argue that this is unethical because it violates the rights of future generations. Thus it appears that most gene therapy in the foreseeable future will focus on somatic gene transfer.

ROLE OF PHARMACISTS

Although pharmacogenetics provides opportunities to improve drug therapy outcomes, it likely will increase the complexity of drug prescribing. In addition to considering factors such as age, concomitant drug therapy, and renal and hepatic function, prescribers also will have to interpret the results of genetic analyses when making drug therapy decisions. Further complicating the drug-prescribing process are many medications whose effects are not determined by single polymorphisms in single genes. Rather, pharmacologic effects for most medications likely are determined by the interaction of polymorphisms in multiple genes that encode proteins involved in the various pathways of drug metabolism, distribution, and effects. For example, the immunosuppressants cyclosporine and tacrolimus are believed to be substrates for both P-glycoprotein and the CYP450 3A4 and possibly 3A5 enzymes.¹¹⁶ Thus it is possible that genes for both MDR-1 and CYP450 enzymes interact to influence cyclosporine and tacrolimus distribution and plasma concentrations.

Pharmacists are broadly trained in a number of medication-related areas, including pharmacology, pharmacokinetics, and

pharmacodynamics. This places pharmacists in an extremely valuable position in dealing with the complexities of the drug-decision process in the age of pharmacogenetics. Pharmacists will be in key positions to interpret the results of genetic tests, determine the ultimate effects of multiple genetic variations on drug response, and choose the most appropriate drug for a given patient based on the individual’s DNA. Thus it will be essential for pharmacists to stay abreast of significant discoveries in genotype–drug response relationships and understand how best to incorporate this genomic information into pharmacotherapeutic decisions.

Recognizing the challenges in health care delivery with advancing genetic discoveries, the National Coalition for Health Professional Education in Genetics established core competencies related to genetics for health care professionals that are available through the coalition’s Web site (www.nchpeg.org). The objective of these competencies is to encourage clinicians to incorporate genetics knowledge, skills, and attitudes into their clinical practices. Subsequently, the American Association of Colleges of Pharmacy developed recommendations to guide academic institutions in instilling these competencies in future pharmacists so that pharmacists will be prepared to provide appropriate pharmacotherapy in the age of genomics.¹¹⁷

APPLICATION OF PHARMACOGENETIC DATA TO DISEASE MANAGEMENT

Pharmacogenetics has the potential to greatly improve the pharmacologic management of disease. Clinicians may be able to predict the

likelihood that an individual will respond to a particular medication based on the patient’s genotype. Medications may be avoided or prescribed in lower doses with careful monitoring in patients genetically predisposed to their adverse effects. This would be of particular benefit for narrow-therapeutic-index drugs. For example, in warfarin candidates with a *CYP2C9**2 or *CYP2C9**3 allele, warfarin may be initiated at lower doses with closer monitoring. If the anticipated benefit from warfarin is low in a patient homozygous for the *CYP2C9**2 or *CYP2C9**3 alleles, it may be safer to withhold warfarin and institute alternative anticoagulant therapy.

With pharmacogenetics, it also may be possible to eliminate the trial-and-error approach to drug prescribing for many diseases. Instead, clinicians may be able to use genetic information to match the right drug to the right patient at the right dose while minimizing adverse effects. For example, the current approach to hypertension management involves the trial of various antihypertensives until blood pressure goals are achieved with acceptable drug tolerability. Commonly, the initial agent(s) fails to lower blood pressure to goal or produces intolerable adverse effects (Fig. 6–6). Trials of additional or alternative antihypertensive medications must be undertaken until treatment is deemed successful. In the interim, the patient remains hypertensive and at risk for hypertension-related target-organ damage. With pharmacogenetics, clinicians may choose the antihypertensive drug expected to provide the greatest response with the best tolerability for a particular patient based on his or her DNA. For example, if a hypertensive patient is found to have the 460Trp allele of the α -adducin gene, a thiazide diuretic may be the most appropriate initial antihypertensive agent because evidence suggests that diuretic

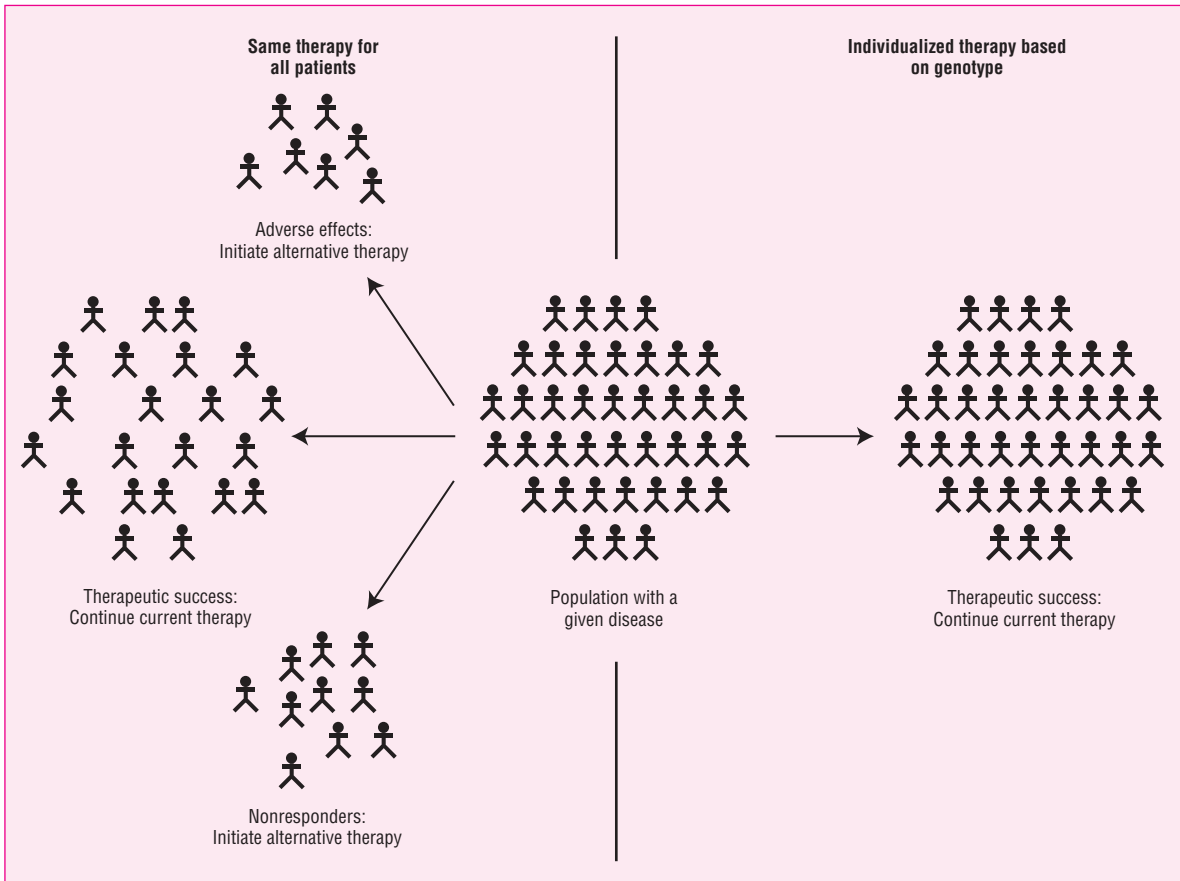

FIGURE 6–6. Current and future approaches to pharmacologic management of disease.

therapy in 460Trp allele carriers will lower blood pressure effectively and potentially improve clinical outcomes.

New drugs may be developed based on knowledge about genetic control of cellular functions. For example, the discovery that chronic myeloid leukemia (CML) was caused by chromosome translocation and consequent production of an enzyme capable of producing life-threatening lymphocyte levels led to accelerated FDA approval of Gleevec (also known as STI-571), an inhibitor of the translocation-created enzyme, for treatment of CML.¹¹⁸ In addition, future drug development may focus on treating specific genetic subgroups instead of broadly treating all individuals with a particular disease. Ultimately, pharmacogenetics may improve the quality and reduce the overall costs of health care by decreasing the number of treatment failures and the number of adverse drug reactions and leading to the discovery of new genetic targets and therapeutic interventions for disease management.

CLINICAL CONTROVERSY

For some drugs, variations in genes affecting both pharmacokinetic and pharmacodynamic drug properties may interact to determine the ultimate effects from drug therapy. Thus the challenge for researchers will be to identify the combination of gene variations that best predicts response for these drugs.

ABBREVIATIONS

CYP: cytochrome P450
 SNPs: single-nucleotide polymorphisms
 A: adenine
 C: cytosine
 G: guanine
 T: thymidine
 EM: extensive metabolizer
 PM: poor metabolizer

PEDIATRICS

Milap C. Nahata and Carol Taketomo

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Children are not just “little adults,” and lack of data on important pharmacokinetic and pharmacodynamic differences has led to several disastrous situations in pediatric care.
- 2 Variations in absorption of medications from the gastrointestinal tract, intramuscular injection sites, and skin are important in pediatric patients, especially in premature and other newborn infants.
- 3 The rate and extent of organ function development and the distribution, metabolism, and elimination of drugs differ not only between pediatric versus adult patients but also among pediatric age groups.
- 4 The effectiveness and safety of drugs may vary among various age groups and from one drug to another in pediatric versus adult patients.
- 5 Concomitant diseases may influence dosage requirements to achieve a targeted effect for a specific disease in children.
- 6 The myth that neonates and young children do not experience pain has led to inadequate pain management in this population.
- 7 Special methods of drug administration are needed for infants and young children.
- 8 Many medicines needed for pediatric patients are not available in appropriate dosage forms, and thus the dosage forms of drugs marketed for adults may have to be modified for infants and children, requiring assurance of potency and safety of drug use.
- 9 The pediatric medication-use process is complex and error-prone owing to multiple steps required in calculating, verifying, preparing, and administering doses.

Remarkable progress has been made in the clinical management of disease in pediatric patients. This chapter highlights important principles of pediatric pharmacotherapy that must be considered when the diseases discussed in other chapters of this book occur in pediatric patients, defined as those younger than 18 years of age. Newborn infants born before 37 weeks of gestational age are termed *premature*; those between 1 day and 1 month of age are *neonates*; 1 month to 1-year-old, *infants*; 1 year to 11 years of age, *children*; and 12 to 16 years, *adolescents*. Covered are notable examples of problems in pediatrics, pharmacokinetic differences in pediatric patients, drug efficacy and toxicity in this patient group, and various factors affecting pediatric pharmacotherapy. Specific examples of problems and special considerations in pediatric patients are cited to enhance understanding.

1 Infant mortality has declined from 200 per 1000 births in the nineteenth century to 75 per 1000 births in 1925 to 6.8 per 1000 births in 2001.¹ This success has resulted largely from improvements in identification, prevention, and treatment of diseases once common during delivery and the period of infancy. Although most marketed drugs are used in pediatric patients, only one-fourth of the drugs approved by the Food and Drug Administration (FDA) have indications specific for use in the pediatric population. Data on the pharmacokinetics, pharmacodynamics, efficacy, and safety of drugs in infants and children are scarce. Lack of this type of information led to such disasters as gray baby syndrome from chloramphenicol, phocomelia from thalidomide, and kernicterus from sulfonamide therapy. Gray baby syndrome was first reported in two neonates who died after excessive chloramphenicol doses (100–300 mg/kg per day); the serum

concentrations of chloramphenicol immediately before death were 75 and 100 mcg/mL. Patients with gray baby syndrome usually have abdominal distention, vomiting, diarrhea, a characteristic gray color, respiratory distress, hypotension, and progressive shock.

Thalidomide is well known for its teratogenic effects. Clearly implicated as the cause of multiple congenital fetal abnormalities (particularly limb deformities), it also can cause polyneuritis, nerve damage, and mental retardation. Isotretinoin (Accutane) is another teratogen. Because it is used to treat acne vulgaris, common in teenage patients who may be sexually active but not willing to acknowledge that activity to health care professionals, isotretinoin has presented a difficult problem in patient education since its marketing in the 1980s.

Kernicterus was reported in neonates receiving sulfonamides, which displaced bilirubin from protein-binding sites in the blood to cause a hyperbilirubinemia. This results in deposition of bilirubin in the brain and induces encephalopathy in infants.

Another area of concern in pediatrics is identifying an optimal dosage. Dosage regimens cannot be based simply on body weight or surface area of a pediatric patient extrapolated from adult data. Bioavailability, pharmacokinetics, pharmacodynamics, efficacy, and adverse-effect information can differ markedly between pediatric and adult patients, as well as among pediatric patients, because of differences in age, organ function, and disease state. Significant progress has been made in the area of pediatric pharmacokinetics during the last two decades, but few such studies have correlated pharmacokinetics with the outcomes of efficacy, adverse effects, or quality of life.

Several additional factors should be considered in optimizing pediatric drug therapy. Many drugs prescribed widely for infants and children are not available in suitable dosage forms. For example, extemporaneous liquid dosage forms of amiodarone, captopril, omeprazole, and spironolactone are prepared for infants and children who cannot swallow tablets or capsules, and injectable dosage forms of aminophylline, methylprednisolone, morphine, and phenobarbital are diluted to accurately measure small doses for infants. Alteration (dilution or reformulation) of dosage forms intended for adult patients raises questions about the bioavailability, stability, and compatibility of these drugs. Because of low fluid volume requirements and limited access to intravenous sites, special methods must be used for the delivery of intravenous drugs to infants and children. As simple as it may seem, administration of oral drugs to young patients continues to be a difficult task for nurses and parents. Similarly, ensuring adherence to pharmacotherapy in pediatric patients poses a special challenge.

Finally, the need for additional pharmacologic or therapeutic research brings up the issue of ethical justification for conducting research. The investigators proposing studies and institutional review committees approving human studies must assess the risk-benefit ratio of each study to be fair to children who are not in a position to accept or reject the opportunity to participate in the research project.

Enormous progress has been made in pharmacokinetics in pediatric patients. Two factors have contributed to this progress: (1) the availability of sensitive and specific analytic methods to measure drugs and their metabolites in small volumes of biologic fluids and (2) awareness of the importance of clinical pharmacokinetics in optimization of drug therapy. Absorption, distribution, metabolism, and elimination of many drugs are different in premature infants, full-term infants, and older children, and this topic is discussed in detail in the next few sections.

ABSORPTION

GASTROINTESTINAL TRACT

Two factors affecting the absorption of drugs from the gastrointestinal tract are pH-dependent passive diffusion and gastric emptying time. Both processes are strikingly different in premature infants compared with older children and adults. In a full-term infant, gastric pH ranges from 6 to 8 at birth but declines to 1 to 3 within 24 hours.² In contrast, the gastric pH is elevated in premature infants because of immature acid secretion.³

In premature infants, higher serum concentrations of acid-labile drugs—such as penicillin,⁴ ampicillin,⁵ and nafcillin⁶—and lower serum concentrations of a weak acid such as phenobarbital⁷ can be explained by higher gastric pH. Because of a lack of extensive data comparing serum concentration-time profiles after oral versus intravenous drug administration, differences in the bioavailability of drugs in premature infants are poorly understood. Although little is known about the influence of developmental changes with age on drug absorption in pediatric patients, a few studies with drugs (e.g., digoxin and phenobarbital) and nutrients (e.g., arabinose and xylose) have suggested that the processes of both passive and active transport may be fully developed by about 4 months of age.⁸ No data are available about the development and expression of the efflux transporter P-glycoprotein in the intestine.

Studies have shown that gastric emptying is slow in a premature infant.⁹ Thus drugs with limited absorption in adults may be absorbed efficiently in a premature infant because of prolonged contact time with gastrointestinal mucosa.

INTRAMUSCULAR SITES

Drug absorption from an intramuscular site also may be altered in premature infants. Differences in relative muscle mass, poor perfusion to various muscles, peripheral vasomotor instability, and insufficient muscular contractions in premature infants compared with older children and adults can influence drug absorption from the intramuscular site. The net effect of these factors on drug absorption is impossible to predict; phenobarbital has been reported to be absorbed rapidly,¹⁰ whereas diazepam absorption may be delayed.¹¹ Thus intramuscular dosing is used rarely in neonates except in emergencies or when an intravenous site is inaccessible.

SKIN

Percutaneous absorption may be increased substantially in newborns because of an underdeveloped epidermal barrier (stratum corneum) and increased skin hydration. The increased permeability can produce toxic effects after the topical use of hexachlorophene soaps and powders,¹² salicylic acid ointment, and rubbing alcohol.¹³ Interestingly, a study has shown that a therapeutic serum concentration of theophylline can be achieved to control apnea in premature infants of less than 30 weeks' gestation after a topical application of gel containing a standard dose of theophylline.¹⁴ The use of this route of administration may minimize the unpredictability of oral and intramuscular absorption and complications of intravenous drug administration for certain drugs.

DISTRIBUTION

Drug distribution is determined by the physicochemical properties of the drug itself (pK_a , molecular weight, partition coefficient) and the physiologic factors specific to the patient. Although the physicochemical properties of the drug are constant, the physiologic functions often vary in different patient populations. Some important patient-specific factors include extracellular and total body water, protein binding by the drug in plasma, and the presence of pathologic conditions modifying physiologic function. Total body water, as a percentage of total body weight, has been estimated to be 94% in the fetus, 85% in premature infants, 78% in full-term infants, and 60% in adults.¹⁴ Extracellular fluid volume is also markedly different in premature infants compared with older children and adults; the extracellular fluid volume may account for 50% of body weight in premature infants, 35% in 4- to 6-month-old infants, 25% in children 1 year of age, and 19% in adults.¹⁵ This conforms to the observed gentamicin distribution volumes of 0.48 L/kg in neonates and 0.20 L/kg in adults.¹⁶ Studies have shown that the distribution volume of tobramycin is largest in the most premature infants and decreases with increases in the gestational age and birth weight of the infant.¹⁷

Binding of drugs to plasma proteins is also decreased in newborn infants because of the decreased plasma protein concentration, lower binding capacity of protein, decreased affinity of proteins for drug binding, and competition for certain binding sites by endogenous compounds such as bilirubin. The plasma protein binding of many drugs—including phenobarbital, salicylates, and phenytoin—is significantly less in the neonate than in the adult.¹⁸ The decrease in plasma protein binding of drugs can increase their apparent volumes of distribution. Therefore, premature infants require a larger loading dose than older children and adults to achieve a therapeutic serum concentration of such drugs as phenobarbital¹⁹ and phenytoin.²⁰

The consequences of increased concentrations of free or unbound drug in the serum and tissues must be considered. Pharmacologic and toxic effects are related directly to the concentration of free drug in the body. Increases in free drug concentrations may result directly from decreases in plasma protein binding or indirectly from, for example, drug displacement from binding sites. The increased mortality from the development of kernicterus secondary to displacement of bilirubin by sulfisoxazole in neonates has been well documented.²¹ However, because drug bound to plasma proteins cannot be eliminated by the kidney, an increase in free drug concentration also may increase its clearance.²²

The amount of body fat is substantially lower in neonates compared with adults, which may affect drug therapy. Certain highly lipid-soluble drugs are distributed less widely in infants than in adults. The apparent volume of distribution of diazepam has ranged from 1.4 to 1.8 L/kg in neonates and from 2.2 to 2.6 L/kg in adults.²³ In recent years, the numbers of mothers breast-feeding their infants has climbed. Thus certain drugs distributed in breast milk may pose problems for the infants. The American Academy of Pediatrics recommends that bromocriptine, cyclophosphamide, cyclosporine, doxorubicin, ergotamine, lithium, methotrexate, phenindione, and all drugs of abuse (e.g., amphetamine, cocaine, heroin, marijuana, and phencyclidine, or PCP) be contraindicated during breast-feeding. Further, the use of nuclear medicines should be stopped temporarily during breast-feeding.²⁴ Note that these recommendations are based on limited data; other drugs taken over a prolonged period by the mother also may be toxic to the infant. For example, acebutolol, aspirin, atenolol, clemastine, phenobarbital, primidone, sulfasalazine, and 5-aminosalicylic acid have been associated with adverse effects in some nursing infants.^{24,25} Unless benefits outweigh the risks, the use of any drug should be avoided by the mother during pregnancy and while breast-feeding.

METABOLISM

Drug metabolism is substantially slower in infants compared with older children and adults. There are important differences in the maturation of various pathways of metabolism within a premature infant. For example, the sulfation pathway is well developed but the glucuronidation pathway is undeveloped in infants.²⁶ Although acetaminophen metabolism by glucuronidation is impaired in infants compared with adults, it is partly compensated for by the sulfation pathway. The cause of the tragic chloramphenicol-induced gray baby syndrome in newborn infants is a decreased metabolism of chloramphenicol by glucuronyl transferases to the inactive glucuronide metabolite.²⁷ This metabolic pathway appears to be age-related²⁸ and may take several months to a year to develop fully. Evidence for this is the increase in clearance with age up to 1 year.²⁹

Interestingly, higher serum concentrations of morphine are required to achieve efficacy in premature infants than in adults in part because infants are not able to metabolize morphine adequately to its 6-glucuronide metabolite (20 times more active than morphine).³⁰ This is balanced to some degree by the fact that the clearance of morphine quadruples between 27 and 40 weeks of postconceptional age.

Metabolism of drugs such as theophylline, phenobarbital, and phenytoin by oxidation is also impaired in newborn infants. The rate of metabolism, however, is more rapid with phenobarbital and phenytoin than with theophylline, perhaps owing to the involvement of different cytochrome P450 isozymes. Total clearance of phenytoin by CYP2C9 and to a lesser extent by CYP2C19 surpasses adult values by 2 weeks

of age, whereas theophylline clearance is not fully developed for several months.¹⁸ Two additional observations should be noted about theophylline metabolism by CYP1A2 in pediatric patients. First, in premature infants receiving theophylline for the treatment of apnea, a significant amount of its active metabolite caffeine may be present, unlike in older children and adults.¹⁸ Second, theophylline clearance in children 1 to 9 years of age exceeds the values in infants as well as adults. Thus a child with asthma often requires markedly higher doses on a weight basis of theophylline compared with an adult.³¹ Because of decreased metabolism, doses of such drugs as theophylline, phenobarbital, phenytoin, and diazepam should be decreased in premature infants.

The clearance of unbound *S*-warfarin, a substrate of CYP2C9, was substantially greater in prepubertal children than among pubertal children and adults even after adjustment for total body weight.³² Finally, the clearance of caffeine, metabolized by demethylation, declines to adult values when girls reach Tanner stage 2 (early puberty) and boys reach Tanner stage 4 and 5 (late puberty).³³

ELIMINATION

Drugs and their metabolites are often eliminated by the kidney. The glomerular filtration rate may be as low as 0.6–0.8 mL/min per 1.73 m² in preterm infants and about 2–4 mL/min per 1.73 m² in term infants. The processes of glomerular filtration, tubular secretion, and tubular reabsorption determine the efficiency of renal excretion. These processes may take several weeks to 1 year after birth to develop fully.

Studies in infants have shown that tobramycin clearance during the first postnatal week may increase with an increase in gestational age.¹⁷ In infants up to 1 month after birth, postnatal age also was correlated directly with aminoglycoside clearance.²⁹ Thus premature infants require a lower daily dose of drugs eliminated by the kidney during the first week of life; the dosage requirement then increases with age.

Because of immature renal elimination, chloramphenicol succinate can accumulate in premature infants. Although chloramphenicol succinate is inactive, this accumulation may be the reason for an increased bioavailability of chloramphenicol in premature infants compared with older children.²⁸ These data indicate that dose-related toxicity may result from an underdeveloped glucuronidation pathway, as well as increased bioavailability of chloramphenicol in premature infants.

DRUG EFFICACY AND TOXICITY

4 Besides the pharmacokinetic differences previously identified between pediatric and older patients, factors related to drug efficacy and toxicity also should be considered in planning pediatric pharmacotherapy. Unique pathophysiologic changes occur in pediatric patients with some disease states.

Examples of these pathophysiologic and pharmacodynamic differences are numerous. Clinical presentation of chronic asthma differs in children and adults.³⁴ Children present almost exclusively with a reversible extrinsic type of asthma, whereas adults have nonspecific, nonatopic bronchial irritability.³⁴ This explains the value of adjunctive hyposensitization therapy in the management of pediatric patients with extrinsic asthma.^{35,36}

The maintenance dose of digoxin is substantially higher in infants than in adults. This is explained by a lower binding affinity of receptors in the myocardium for digoxin and increased digoxin-binding

sites on neonatal erythrocytes compared with adult erythrocytes.³⁷ Insulin requirement is highest during adolescence because of the individual's rapid growth. Growth hormone therapy has allowed children with growth hormone deficiency to attain greater adult height. However, a recent study has shown that in "normal" short children (without growth hormone deficiency), early and rapid pubertal progression by growth hormone therapy may lead to a shorter final adult height than may have been attained naturally.³⁸ This emphasizes the need for identifying specific indications for the effective and safe use of drugs in pediatric patients.

Certain adverse effects of drugs are most common in the newborn period, whereas other toxic effects may continue to be important for many years of childhood. Chloramphenicol toxicity is increased in newborns because of immature metabolism and enhanced bioavailability. Similarly, propylene glycol—added to many injectable drugs, including phenytoin, phenobarbital, digoxin, diazepam, vitamin D, and hydralazine, to increase their stability—can cause hyperosmolality in infants.³⁹ Benzyl alcohol was a popular preservative in intravascular flush solutions until a syndrome of metabolic acidosis, seizures, neurologic deterioration, gasping respirations, hepatic and renal abnormalities, cardiovascular collapse, and death was described in premature infants. A decline in both mortality and the incidence of major intraventricular hemorrhage has been documented after the use of solutions containing benzyl alcohol was stopped in low-birth-weight infants.⁴⁰

Tetracyclines are also contraindicated in pregnant women, nursing mothers, and children younger than 8 years of age because they can cause dental staining and defects in enamelization of deciduous and permanent teeth, as well as a decrease in bone growth.⁴¹

CLINICAL CONTROVERSY

Are fluoroquinolones safe in pediatric patients younger than 1 year of age? The antibiotics of the fluoroquinolone class (e.g., ciprofloxacin) are not recommended for pediatric patients or pregnant women because of an association between these drugs and development of permanent lesions of the cartilage of weight-bearing joints and other signs of arthropathy in immature animals of various species.⁴² Reversible arthralgia, sometimes accompanied by synovial effusion, was associated with ciprofloxacin therapy in 1.8% of pediatric patients with cystic fibrosis.⁴³ Although these drugs are used to treat certain infections in pediatric populations, further safety data are needed before they can be prescribed routinely, especially in infants.

CLINICAL CONTROVERSY

Are antidepressants safe and effective in children and adolescents? Because of observations of an increased suicidality among adolescents (and adults, for that matter), experts are questioning whether these medications merely bring out an increased suicide risk that the patient has suppressed or has been too depressed to act on or actually increase the risk per se through some pharmacologic effect. Fluoxetine is the only selective serotonin reuptake inhibitor (SSRI) currently approved for use in pediatric patients in the United States. The British regulatory agency banned the use of another SSRI, paroxetine, in 2003 after analysis of the data indicated the occurrence of suicidal thoughts or episodes of self-harm at a rate of 1.5 to 3.2 times higher than that with placebo. Subsequently, the

FDA has cautioned about the use of and need for monitoring SSRI therapy in pediatric patients, and this area remained controversial when this chapter was finalized in the spring of 2004.

Some drugs may be less toxic in pediatric patients than in adults. Aminoglycosides appear to be less toxic in infants than in adults. In adults, aminoglycoside toxicity is related to both peripheral compartment accumulation and the individual patient's inherent sensitivity to these tissue concentrations.⁴⁴ Although neonatal peripheral tissue compartments for gentamicin have been reported to closely resemble those of adults with similar renal function,¹⁶ gentamicin is rarely nephrotoxic in infants. This dissimilarity in the incidence of nephrotoxicity implies that newborn infants may have less inherent tissue sensitivity for toxicity than adults.

The differences in efficacy, toxicity, and protein binding of drugs in pediatric versus adult patients raise an important question about the acceptable therapeutic range in children. Therapeutic ranges for drugs are first established in adults and often are applied directly to pediatric patients, but specific studies should be conducted in pediatric patients to define optimal therapeutic ranges of drugs.

FACTORS AFFECTING PEDIATRIC THERAPY

DISEASES

5 Because most drugs are either metabolized by the liver or eliminated by the kidney, hepatic and renal diseases are expected to decrease the dosage requirements in patients. Nevertheless, not all diseases require lower doses of drugs; for instance, patients with cystic fibrosis require larger doses of certain drugs to achieve therapeutic concentrations.⁴⁵

LIVER DISEASE

Because the liver is the main organ for drug metabolism, drug clearance usually is decreased in patients with hepatic disease; however, most studies on the influence of liver disease on dosage requirements have been carried out in adults, and these data may not be extrapolated uniformly to pediatric patients.

Drug metabolism by the liver depends on complex interactions among hepatic blood flow, ability of the liver to extract the drug from the blood, drug binding in the blood, and both type and severity of liver disease. Routine liver function tests—such as determinations of serum aspartate aminotransferase, serum alanine aminotransferase, alkaline phosphatase, and bilirubin levels—have not correlated consistently with drug pharmacokinetics. Further, because of different pathologic changes in various types of liver diseases, patients with acute viral hepatitis may have different abilities to metabolize drugs compared with patients with alcoholic cirrhosis.⁴⁶

On the basis of hepatic extraction characteristics, drugs can be divided into two categories. The first category consists of drugs with a high hepatic extraction ratio (>0.7 ; such drugs include morphine, meperidine, lidocaine, and propranolol). Clearance of these drugs is affected by hepatic blood flow. A decreased hepatic blood flow in the presence of such disease states as cirrhosis and congestive heart failure is expected to decrease the clearance of drugs with high extraction ratios. The second category consists of drugs with a low extraction ratio (<0.2) and a low affinity for plasma proteins. Metabolism of these drugs (e.g., theophylline, chloramphenicol, and acetaminophen)

is influenced mainly by hepatocellular function and not as much by changes in hepatic blood flow or plasma protein binding. One report suggested that theophylline clearance may decrease by 45% in a child with acute viral hepatitis.⁴⁷ Because of a lack of specific data on dosage adjustment in liver disease, drug therapy should be monitored closely in pediatric patients to avoid potential toxicity from excessive doses, particularly for drugs with narrow therapeutic indices.

RENAL DISEASE

Renal failure decreases the dosage requirement of drugs eliminated by the kidney. Once again, because of limited studies, dosage adjustments in pediatric patients are based largely on data obtained in adults. For many important drugs—such as aminoglycoside antibiotics—renal clearance or rate of elimination is directly proportional to the glomerular filtration rate, as measured by endogenous renal creatinine clearance.

In clinical practice, glomerular filtration rate (GFR) can be estimated from prediction equations such as the Schwartz formula, which takes into account serum creatinine concentration and the patient's height, gender, and age. The advantage of estimating GFR using the Schwartz equation is rapid determination and the avoidance of a cumbersome 24-hour urine collection.^{48,49} The following formula is used to estimate GFR:

$$\text{GFR} = K \times L/S_{\text{Cr}}$$

where GFR is expressed in milliliters per minute per 1.73 m², *K* is an age-specific constant of proportionality (see below), *L* is the child's length in centimeters; and *S*_{Cr} is the serum creatinine in milligrams per deciliter.

| Age | <i>K</i> |
|---|----------|
| <1 year of age, low-birth-weight infant | 0.33 |
| <1 year of age, full-term infant | 0.45 |
| 2- to 12-year-old child | 0.55 |
| 13- to 21-year-old female | 0.55 |
| 13- to 21-year-old male | 0.70 |

Studies comparing the Schwartz-predicted GFR versus measured GFR noted that the Schwartz formula overestimated GFR in patients with decreasing GFR. The formula may not provide an accurate estimation of GFR in patients with rapidly changing serum creatinine concentrations, as seen in the critical care setting, in infants younger than 1 week of age, and in patients with obesity, malnutrition, or muscle wasting. Factors that interfere with serum creatinine measurement also may cause errors in estimation of GFR.

Serum drug concentrations should be monitored for drugs with narrow therapeutic indices and eliminated largely by the kidney (e.g., aminoglycosides and vancomycin) to optimize therapy in pediatric patients with renal dysfunction. For drugs with wide therapeutic ranges (e.g., penicillins and cephalosporins), dosage adjustment may be necessary only in moderate to severe renal failure.

CYSTIC FIBROSIS

Drug therapy in pediatric patients with cystic fibrosis has been reviewed.⁵⁰ For unknown reasons, these patients require increased doses of certain drugs. Studies have reported a higher clearance of such drugs as gentamicin, tobramycin, netilmicin, amikacin, dicloxacillin, cloxacillin, azlocillin, piperacillin, and theophylline in

patients with cystic fibrosis compared with those without this disease; the apparent volume of distribution of certain drugs also may be altered in cystic fibrosis.⁵⁰ Severity of the illness may influence the change in dosage requirements, but this is not certain. Chapter 30 reviews these changes in detail.

OTHER DISEASES

Although specific dosage guidelines are not available, pediatric patients with gastrointestinal disease (e.g., celiac disease, gastroenteritis, and severe malabsorption) may require dosage adjustments.⁴⁵ Hypoxemia also has been shown to decrease the elimination of amikacin in low-birth-weight infants.⁵¹ Critically ill adult and pediatric patients with severe head trauma require higher than normal doses of phenytoin in part because of increased intrinsic clearance.⁵²

ISSUES IN PEDIATRIC DRUG THERAPY

PAIN MANAGEMENT

6 For many years, the term *pain* could not be found in the index of any major pediatric medicine or pediatric surgical textbooks.⁵³ The prevailing wisdom was that neonates did not experience pain owing to inadequately developed neuroendocrine systems and nerve pathways. During the last years of the twentieth century, however, many research and clinical studies were performed in the areas of pain management and assessment in neonates, infants, children, and adolescents. Today, results of these discoveries have been incorporated into clinical practice, making effective pain therapy a standard of care and pain assessment the fifth vital sign in modern pediatric practice.⁵⁴

The basic mechanisms of pain perception in infants and children are similar to those of adults except that pain impulse transmission in neonates occurs primarily along slow-conducting, nonmyelinated C fibers rather than along myelinated A δ fibers. In addition, less precision in pain signal transmission exists in the spinal cord, and descending inhibitory neurotransmitters are lacking. The result is that neonates and young infants may perceive pain more intensely and are more sensitive to pain than older children or adults.^{55,56} It is now known that previous pain experience leads to long-term consequences such as alterations in response to a subsequent painful event.⁵⁷ Taddeo and colleagues^{58,59} reported that boys circumcised with the topical anesthetic EMLA had a lower pain response to subsequent immunizations than those who were circumcised without topical anesthesia. An inadequately treated initial painful procedure may decrease the effect of adequate analgesia in subsequent procedures owing to altered pain response patterns.

Children consistently report that needles and shots are what they fear most. However, with the current immunization schedule that recommends 14 to 33 injections before adolescence, interventions to decrease injection pain need to be performed (Table 7-1).

Pharmacologic pain management for medical conditions and surgical and postoperative events has progressed considerably over the past decade with the use of continuous opioid infusions, epidural anesthesia, peripheral nerve blockade, local anesthetics, nonsteroidal anti-inflammatory drugs, different routes for traditional agents (i.e., transmucosal and transdermal), and nonopioid adjuvant drugs (Table 7-2). New pain management techniques, education, research, and increasing awareness of pain management options have helped to improve the quality of life in children.

TABLE 7–1. Techniques for Minimizing Pain Caused by Injection

| | |
|--|---|
| Pharmacologic Methods | |
| EMLA ⁶⁰ (eutectic mixture of lidocaine and prilocaine) | <i>Advantages:</i> Penetrates the skin to provide anesthesia to a depth of 5 mm; effective in decreasing the pain of IM and subcutaneous injections, venipuncture, IV cannulation, lumbar puncture, circumcision, skin-graft harvesting, and laser dermal therapy; safe and effective in newborns >37 weeks' gestation. <i>Disadvantages:</i> Requires 1 h before onset of adequate anesthesia, has a vasoconstrictive effect that may make starting IV catheters difficult, may induce methemoglobinemia. |
| Numby Stuff (lidocaine iontophoresis) ⁶¹ | <i>Advantages:</i> Provides dermal anesthesia to a depth of 10 mm within 10–20 min; effective in decreasing the pain of IM injection, IV cannulation, venipuncture, lumbar puncture, skin biopsy, and bone marrow aspiration. <i>Disadvantage:</i> Tingling, itching, or burning sensation from the electric current used to transport drug to the tissues. |
| Vapocoolant sprays (ethyl chloride or dichlorodifluoromethane) ⁶² | <i>Advantages:</i> Vapocoolant is sprayed directly onto the skin or applied to a cotton ball that is held on the area to be anesthetized; provides local anesthesia within 15 seconds; effective in reducing injection pain in children 4–6 years of age. <i>Disadvantages:</i> Brief duration of action so that procedure should be completed in 1 or 2 min; may not be effective in reducing injection pain in infants aged 2–6 months. |
| Local anesthetic (lidocaine) ⁶³ | <i>Advantage:</i> Reduces the pain of subsequent needle insertion. <i>Disadvantage:</i> Local anesthetic injection itself is associated with pain and burning sensation |
| Pacifier with sucrose ^{64,65} | <i>For preterm neonates:</i> 0.1–0.4 mL of a 12%–24% sucrose solution (place on pacifier or the tongue 2 min before procedure). <i>For term neonates:</i> 1–2 mL of a 12%–24% sucrose solution (place on pacifier or the tongue 2 min before procedure). <i>Advantage:</i> Noninvasive method to reduce pain associated with needle insertion in infants. <i>Disadvantage:</i> Sucrose solution's effect in reducing pain gradually decreases over time. |
| Other Techniques | |
| Site selection ⁶⁶ | <i>For children older than 18 months of age:</i> Use of the deltoid muscle for IM injections is associated with less pain than injections administered in the thigh. <i>For children older than 3 years of age:</i> Use of the ventrogluteal area for injection is associated with less pain than the anterior thigh or dorsogluteal area. |
| Z-tract technique | Z-tract intramuscular injection technique is less painful (pull skin taut at the injection site, give injection, and then release the skin); use a higher-gauge needle when the injectable solution is not viscous. |
| Behavioral | Use of distraction methods such as blowing bubbles, providing music by headphones, relaxation, imagery, self-hypnosis, or having parents present for the procedure can be helpful. |

DRUG ADMINISTRATION

Drugs often are given by the intravenous route to seriously ill patients. Flow rates and injection sites vary widely with pediatric intravenous drug delivery sets. Effective serum concentrations are expected to be achieved rapidly after drug infusion. Several studies demonstrated that the method of drug infusion has a profound influence on peak serum concentration and time to attain peak concentrations of chloramphenicol and tobramycin.^{67,68} This has practical implications for routine therapeutic drug monitoring in that anticipated serum concentrations may be inaccurate, leading to unjustified, costly, and potentially harmful alterations in doses. Proper recommendations for obtaining patient specimens can be made only with the knowledge of drug characteristics and infusion method.

Intravenous drugs commonly are infused in an antegrade fashion. By this method, the doses injected at various sites of the intravenous set (e.g., a Y-site and a volumetric chamber such as Metriset Buretrol) are expected to move directly toward the patient (Fig. 7–1).

In vitro studies with gentamicin and aminophylline have shown that the delivery of these drugs may be delayed substantially depending on the flow rate and injection site.⁶⁹ These observations were confirmed with infusion of chloramphenicol succinate⁶⁷ and tobramycin.⁶⁸ These studies clearly have demonstrated that the variables of intravenous drug infusion systems (e.g., flow rate,

injection site, volume of drug, and fluid volume of the tubing) can affect the serum concentrations of drugs markedly after infusions into pediatric patients. For example, mean peak serum concentrations of chloramphenicol can be 5 mcg/mL higher and occur 1 hour earlier after flashball injection compared with Buretrol injection in infants and children.⁶⁷ Similarly, the mean serum concentrations of tobramycin can be 2.3–2.5 mcg/mL higher and occur 1 to 1.5 hours earlier after an infusion from a syringe pump compared with infusions from the Y-site of a system similar to that of Fig. 7–1.⁶⁹ These differences can be important because of the narrow therapeutic indices of chloramphenicol and tobramycin. Furthermore, a lack of knowledge of these variables may result in inappropriate timing and interpretation of blood level data, leading to unnecessary dosage adjustments.

Specific gravity also can influence drug delivery at slow infusion rates.⁷⁰ For example, in vitro studies have indicated that drugs with a specific gravity lower than that of the maintenance fluid may layer at the top of the tubing, where delivery would be prolonged by laminar-flow characteristics.⁷⁰ Similarly, injections into a filter chamber, Y-site, or T-site with dead space also can prolong drug delivery.

No single infusion system is ideal for delivery of all drugs in all institutions for all patients. For example, a syringe pump with microbore tubing may be preferred for the infusion of vancomycin to neonates. Each facility must be cognizant of problems of drug delivery and develop specific guidelines for intravenous infusions.

TABLE 7-2. Opioid Administration for Acute and Severe Pain

| | |
|--|--|
| Intermittent IV or PO bolus administration (not as needed) | Weak opioids (e.g., codeine, hydrocodone, oxycodone) often are combined with acetaminophen or a nonsteroidal anti-inflammatory agent (NSAID) for moderate pain. With dose escalation of combination oral products, be aware that the dose does not exceed recommended daily amounts for acetaminophen or ibuprofen. IV administration of codeine has been associated with allergic reactions related to histamine release. Parenteral administration of codeine is not recommended. Intermittent opioid administration is associated with wide fluctuation between peak and trough levels so that the patient may alternate between peak blood levels associated with untoward effects and trough levels associated with inadequate pain relief when treating severe pain. |
| Intravenous continuous infusion ^{67,68} | Oxycodone and morphine are available in a sustained-release formulation for use with chronic pain (not acute pain). Tablet must be swallowed whole and cannot be administered to patients through gastric tubes. Loading dose is administered to achieve rapidly a therapeutic blood level and pain relief (i.e., morphine loading dose of 0.05–0.15 mg/kg in children; 0.1 mg/kg infused over 90 min in neonates). Loading dose is followed by a maintenance continuous infusion. Doses that are considered safe in children can cause respiratory depression and seizures in neonates because of decreased clearance, immature blood-brain barrier at birth that is more permeable to morphine, and neonates have an increased unbound fraction of morphine that increases CNS effects of the drug. |
| PCA (patient-controlled analgesia) ⁶⁹ | Gives patient some control over their pain therapy. PCA allows the patient to self-administer small opioid doses. The PCA-Plus pump allows the patient to receive a continuous infusion together with a set number of self-administered doses per hour. PCA helps to eliminate wide peak and trough fluctuations so that levels remain in a therapeutic range. Children as young as 6 or 7 years of age can master the use of PCA. |
| Epidural and intrathecal analgesia ⁷⁰ | Effective in the management of severe postoperative, chronic, or cancer pain. Spinal opioids can be administered by a single bolus injection into the epidural or subarachnoid space or by continuous infusion via an indwelling catheter. Dosage requirement by these routes is significantly less than with IV administration (epidural opioid doses: 10-fold lower than IV doses; intrathecal opioid doses: 100-fold lower than IV doses). Morphine, hydromorphone, fentanyl, and sufentanil are effective when administered intrathecally. The most commonly used local anesthetic in continuous epidural infusions is bupivacaine. Fentanyl, morphine, or hydromorphone is usually combined with bupivacaine for epidural infusions. |
| Transmucosal administration | Fentanyl lozenge is absorbed transmucosally. It is useful for providing analgesia during painful procedures. Advantages of this product include rapid onset of action (within 15 min), short duration of action (60–90 min), and painless administration because no injection is needed. A common side effect is vomiting and mild to moderate oxygen desaturation. Doses of 10–15 mcg/kg provide blood levels equivalent to 3–5 mcg/kg IV. |

At our institution, specific guidelines are provided for administration of each drug. These guidelines take into account various infusion rates and provide consistency of delivery with each dose. As long as the time for actual delivery can be anticipated, times to obtain blood samples can be adjusted accordingly to generate meaningful data.

ALTERATION OF DOSAGE FORMS

8 Many drugs used in pediatric patients are not available in suitable dosage forms. This necessitates dilution of high concentrations of drugs intended for adult patients. Examples of these drugs include atropine, carbamazepine, diazepam, digoxin, epinephrine, hydralazine, insulin, morphine, phenobarbital, and phenytoin. Volumes ranging from 0.01 to 0.1 mL must be measured to dispense these drugs for use in infants. This obviously can be associated with large errors in measurements, and such errors have caused intoxication with digoxin⁷¹ and morphine⁷² in infants. One solution to this problem is to dilute these concentrated products, but such alterations can influence the stability or compatibility of these drugs. Because of limited data, pharmacists justifiably may be reluctant to alter dosage forms of certain drugs.

Selection of the appropriate vehicle to dilute the adult dosage forms for use in pediatric patients also can be difficult. Phenobarbital sodium contains propylene glycol in the original product to improve drug stability. Because propylene glycol can cause hyperosmolality in infants,³⁹ further addition of this vehicle may not be wise. Because of limited access to intravenous sites in pediatric patients, drugs must be administered through the same site; however, data on their compatibility often are missing. Newborn infants often require aminoglycosides for presumed or proven sepsis and calcium gluconate to correct hypocalcemia. Tobramycin and calcium gluconate have been found to be compatible at least during a 1-hour period of administration at the same site.⁷²

Administration of oral drugs continues to challenge parents and nurses. Alteration of these drugs by crushing or mixing, refusal of patients to accept the medication, and loss of drug during administration are some factors that can affect pediatric therapy. A common practice is to mix medications in applesauce, syrup, ice cream, or other vehicles just before administration to make the drugs palatable.

A number of extemporaneous formulations for oral, intravenous, and rectal administration are included in a compilation of products for use in pediatric patients.⁷³ A specific reference on the stability

FIGURE 7-1. Schematic diagram of an intravenous set with a volumetric chamber (Metriset or Buretrol), Y-site, flashback, and butterfly. Values shown for the various components of the system are volume capacities. (From ref. 59, with permission.)

of many drugs of these formulations, however, is still lacking. This emphasizes the need for continued research in this area.

Drug administration into the middle ear, nose, or eye of a child requires special attention. Certain drugs (e.g., sodium valproate and morphine) can be administered rectally to infants who have limited access for intravenous drug administration or if oral drug administration cannot be accomplished.

Transdermal drug delivery can be used in pediatric patients (1) to avoid problems of drug absorption from the oral route and complications from the intravenous route and (2) to maximize duration of effect and minimize adverse effects of drugs. Unfortunately, the commercially available transdermal dosage forms (e.g., clonidine and scopolamine) are not intended for pediatric patients; these would deliver doses much higher than those needed for infants and children.

MEDICATION ADHERENCE

The issue of medication adherence is more complex in pediatric patients than in adults. The caregivers of young patients must appreciate the importance of understanding and following the prescribing information.

In one study, medication adherence was considered to be a problem in nearly 60% of adolescents (age 12–15 years with asthma). About 40% of patients had severe denial regarding their asthma and its severity. Nearly 80% of patients had preventable asthma exacerbations.⁷⁴

Among the factors that can negatively affect adherence are poor communication between the physician and patient or parent; insufficient prescribing information; lack of understanding about the

severity of illness by the patient or parent; lack of interest, e.g., among adolescents; fear of side effects; failure of the patient or parent to remember to administer the drugs; inconvenient dosage forms or dosing schedules involving administration of three or more doses daily; and unpalatability of drug products.⁷⁵ Studies in pediatric volunteers have been done to compare the palatability of antibiotics.⁷⁶ These data may have important implications for adherence in children.

DOSE REQUIREMENTS

Medication doses often are based on the body weight of neonates, infants, and children e.g., milligrams per kilogram of body weight per day to be given in one or more portions daily. However, certain drugs, including antineoplastic agents, may be given based on body surface area, e.g., milligrams per square meter in one or more doses daily. In either case, the total amount of weight- or surface area–based individual or daily dose in a pediatric patient, especially an adolescent, should not exceed the amount of drug indicated in an adult patient.

DRUG INTERACTIONS

Drug interaction studies generally are lacking in pediatric age groups. The data often are extrapolated from those in adult populations. Special attention should be given to adolescents, who may concurrently use alcohol, recreational/illicit drugs, or other prescription or nonprescription medications without the knowledge of the primary health care provider to avoid drug interactions.

COMPLEMENTARY AND ALTERNATIVE THERAPY

In a study of patients between 3 weeks and 18 years (mean 5.3 years) of age, 45% of caregivers were giving a product to the children; 27% had given three or more products in the past year. The most commonly used products were aloe plant/juice (44% of those reporting use of herbal therapies), echinacea (33%), and sweet oil (25%). The most dangerous combination was ephedra (which has since been withdrawn from the U.S. market) with albuterol in adolescents with asthma. Most caregivers did not recognize potential adverse effects or drug interactions associated with herbs. Friends or relatives were the main source of information for 80% of caregivers.⁷⁷

Little is known about the efficacy of herbal products in infants, children, and adolescents. Health care professionals must ask caregivers specifically about the use of complementary and alternative treatments to minimize the adverse effects and costs associated with ineffective therapies.

MEDICATION SAFETY

9 The Institute of Medicine (IOM) reported that between 44,000 and 98,000 Americans die each year in hospitals from medical errors.⁷⁸ According to this report, the vast majority of medical errors that cause harm to patients are preventable. Health care professionals have a responsibility for creating a safe medication environment and reducing risk to a vulnerable pediatric population.

Pediatric medication errors commonly occur at the medication-ordering step owing to multiple calculations required with weight-based dosing and adjustments needed in providing therapy to the developing pediatric patient.^{79–81} The United States Pharmacopeia (USP) Center for the Advancement of Patient Safety states that risk to patients when performing repeated calculations involving multiple steps can be minimized using computer-based algorithms.⁸² Since the

medication-preparation step is also a high-hazard point owing to the need for dilution or manipulation of commercially available products only available in adult doses, the USP recommends that compounded pediatric medications be prepared and labeled in the pharmacy and verified by a pharmacist. Among drug administration–related errors, wrong dose, wrong technique, and wrong drug are the three most common errors and may be related to an inability to access pediatric drug information. Risk-reduction strategies include placement of a clinical pharmacist on pediatric wards in hospitals, simplifying the process, ordering standardized concentrations and doses, implementing computerized physician order-entry systems with dose range checking, dispensing pharmacy-prepared/ready-to-administer doses, standardizing infusion equipment, and using bar-coded medications and bar-coding systems that check the medication at the point of care.^{81,83} Identifying and understanding the high-hazard areas or points of failure in the medication-use process will help us to design strategies to prevent problems before they arise.

CONCLUSIONS

Although tremendous progress has been made in the area of pediatric pharmacotherapy, many questions remain unanswered. The pharmacokinetics of many important drugs have been elucidated, but their pharmacodynamics have not been explored fully. Similarly, effect of disease states and patient characteristics such as genetic status have not been studied for most drugs. The effect of these factors on the development of cytochrome P450 isozymes (e.g., 3A4, 2D6, 1A2, 2C9, and 2C19) and other enzymes needs to be studied (see Chaps. 5 and 6). Similarly, comparative efficacy and safety data for many therapies are unavailable. Influence of drug therapy on clinical and economic outcomes and on quality of life needs to be studied in pediatric patients.

The development of new drugs has contributed to improved patient care. The new FDA regulations (Best Pharmaceuticals for Children Act of 2002) can require the industry to conduct studies and seek labeling of important drugs for pediatric patients. As an incentive, a 6-month patent extension and waiver of supplemental new drug application fee are offered to the industry. This should encourage the industry to develop and market more drugs for the pediatric population. However, greater emphasis also should be placed on disease prevention. Millions of children die because of preventable diseases, particularly in developing countries of the world. Administration of vaccines and control of diarrhea alone could save millions of these lives annually. However, the developed countries face different problems. The infant mortality rate in the United States is nearly twice as high among blacks as whites. Improved prenatal care, educational programs, and avoidance of alcohol, smoking, and drugs of abuse during pregnancy may decrease mortality as well as morbidity from illnesses, including acquired immunodeficiency syndrome.

Finally, efforts should be made to offer evidence-based pharmacotherapy. This is often difficult in pediatric populations when the drugs must be used outside the guidelines and indications approved by the FDA. The institutions should develop guidelines for the use of drugs in specific diseases and for the use of high-cost drugs such as colony-stimulating factors, palivizumab, dornase- α , epoetin- α , immunoglobulins, surfactants, and growth hormones.

Although much needs to be learned about the optimization of therapy, it is encouraging to witness the continued growth of knowledge in this area to improve the quality of life and survival from pharmacotherapy in pediatric patients.

GERIATRICS

Catherine I. Lindblad, Shelly L. Gray, David R. P. Guay, Emily R. Hajjar, Teresa C. McCarthy, and Joseph T. Hanlon

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS:

- 1 The population of persons 65 and older is increasing.
- 2 Age-related changes in physiology can affect the pharmacokinetics and pharmacodynamics of numerous drugs.
- 3 Improving and maintaining functional status is a cornerstone of care for elders.
- 4 Drug-related problems in the elderly are common and cause considerable morbidity.
- 5 Pharmacists can play a major role in optimizing drug therapy and preventing drug-related problems in the elderly.

Pharmacotherapy for the elderly can cure or palliate disease as well as enhance health-related quality of life (HRQOL). HRQOL considerations for the elderly include focusing on improvement in physical functioning (e.g., activities of daily living), psychological functioning (e.g., cognition, depression), social functioning (e.g., social activities, support systems), and overall health (e.g., general health perception).¹ Despite the benefits of pharmacotherapy, HRQOL can be compromised by drug-related problems. The avoidance of drug-related adverse consequences in the elderly requires health care practitioners to become knowledgeable about a number of age-specific issues. To address these knowledge needs, this chapter will discuss the epidemiology of aging; physiologic changes associated with aging, with emphasis on those which can affect the pharmacokinetics and pharmacodynamics of drugs; common clinical conditions seen in geriatric patients; epidemiology of drug-related problems in the elderly; and an approach to reduce drug-related problems through the provision of comprehensive geriatric assessment.

EPIDEMIOLOGY OF AGING

1 The older American population is very diverse and heterogeneous with respect to health status. The demographics and health characteristics of persons aged 65 to 74 years are different from those of persons 85 years of age and older, as are those of persons who are institutionalized compared with those living in the community. It is teasing apart the various threads of wellness and illness, independence and dependence, and function and dysfunction that makes the available demographic and health status data relevant for clinical practice. Understanding this diversity and growth of the older population will allow society to plan for the training, research, and resource needs necessary for future clinical practice and adequate health care.

In 2000, persons aged 65 or older accounted for 12.4% (35 million) of the total U.S. population.² Of those over 65 years of age, women outnumbered men and accounted for 58% of this segment of the population. The gender gap widens with increasing age in that women accounted for 70% of the cohort aged 85 years and older.³ By 2030, it is projected that one in five (20%) Americans will

be over the age of 65 years, with 2.5% of the U.S. population aged 85 years and older. This 20% projection for persons aged 65 years and older will persist until 2050. However, the number of persons aged 85 years and older will further increase by 2050 to 5% (19 million) of the total U.S. population.⁴ The increase in the number of older persons is not just due to the post-World War II birth rate but also to a declining mortality rate and overall better health among elders.⁵ The decline in early death and better health of older adults arise for a variety of reasons: (1) public health measures affecting all age groups (e.g., immunizations, prenatal care), (2) advances in medical procedures and drugs, (3) promotion of a healthy lifestyle, and (4) improvements in social living conditions.^{6–8} More relevant to providers of care for older Americans is life expectancy at age 65. In 2000, white women 65 years of age can expect an average additional 19.2 years of life; black women, 17.4 years; white men, 16.3 years; and black men, 14.5 years.⁹ Today, if a person survives to age 85, he can expect to live another 5.6 years and she another 6.7 years.⁹ Given this increase in life expectancy, it is not surprising that the number of centenarians increased from 37,306 in 1990 to 50,454 in 2000.⁹ The Census Bureau has projected that this special population segment could number 834,000 by the middle of the next century.¹⁰

Along with changes in the life expectancy of future elders, there also will be changes in their racial/ethnic composition. In 2000, an estimated 84% of persons age 65 years and older were non-Hispanic white, 8% were non-Hispanic black, and 6% were Hispanic. By 2050, the percent of white elders will decline to 64%, and Hispanics and non-Hispanic blacks will account for 16% and 12% of the older population, respectively.¹¹

Contrary to popular thinking, most older persons are self-sufficient and live in the community. However, as they age in the community, the likelihood of living alone increases, more so for women than men. Only 4.5% of older persons reside in a long-term care facility, which has decreased since 1990 (5.1%). As expected, most of the older adults residing in nursing homes are 85 years of age and older (50%), followed by persons 75 to 84 years of age (16.9%) and those 65 to 74 years of age (13.5%).³

An important goal in the care of older adults is to maintain independence and avoid the need for institutionalization for as long as

possible. Functional loss or disability is often a final common pathway of most clinical problems in older persons, especially in those over age 75. In 2000, 28.6% of elders reported a physical disability (e.g., walking, climbing stairs, reaching, lifting, or carrying), and 9.5% reported disability with self-care or basic activities of daily living (ADLs) (e.g., dressing, bathing, getting around inside the home, feeding, toileting, and grooming).¹² Disability increases with increasing age and is higher in institutionalized older persons, where approximately 80% have some problems with mobility and 65% have difficulty controlling their bowels.¹³ Segments of the population that are especially vulnerable to disability include women, minorities, and those in lower socioeconomic classes. Recent data suggest that disability rates declined significantly during the 1990s. The decline in late-life disability was greatest for limitations in instrumental activities of daily living (IADLs) (e.g., housekeeping chores, shopping, going outside, medication management) and physical disability. Conflicting evidence exists for basic ADL disability, the most severe type of disability that often leads to institutionalization.¹⁴ Nonetheless, whether disability rates will continue to decline is debatable and depends on changes in the environment, changes in social roles, changes in the use of assistive devices, advancements in medicine and pharmacy, and changes in elders' education levels.⁸

A chronic condition, defined as an illness or impairment that cannot be cured, is often the cause of disability in the elderly. The older population compared with younger persons is more affected by chronic conditions for several reasons: (1) the types of chronic conditions common among older persons tend to be more disabling (e.g., arthritis, heart disease), (2) the conditions become more severe with aging, and (3) several conditions are likely to be present.¹⁵

The most common chronic conditions of older Americans depend on their residence status. For noninstitutionalized older Americans, the list has changed little in the past decade.¹⁶ These conditions, in rank order of prevalence, include arthritis (45%), high blood pressure (34%), hearing impairments (28%), heart disease (25%),

cataracts (16%), orthopedic impairments (15%), sinusitis (11%), diabetes (9%), tinnitus (8%), and visual impairments (8%).^{16,17} For elderly patients admitted to a nursing home, the common primary diagnoses are cardiovascular or cerebrovascular disease, mental disorders, nervous system or sensory impairment, and complications secondary to injuries.¹⁷ A national report released in 2000 noted that one-third of all elderly hospital admissions were due to cardiovascular disease, 14% were due to respiratory problems, 6.5% were due to fractures, and 6.3% were due to cancer.¹⁸

Figure 8–1 illustrates the top 10 causes of death in elders. The ranking of these causes has changed little over the last 20 years. Some important trends have emerged over the past two decades, however. First, there has been a decrease in the death rate for heart disease and stroke. This trend is secondary to the gains made in the prevention and treatment of these diseases. Second, death secondary to Alzheimer's disease has increased rapidly in recent years (9% from 1999 to 2000). This increase in rate may be because of the improvements in diagnosis and awareness in the medical community.⁹

Elders are avid consumers of medical and prescription drug resources. With older persons accounting for 36% of all hospital stays and 49% of all days of care in hospitals, elders consume almost one-third of total U.S. health care expenditures.¹⁹ By 2030, health care spending by the U.S. population is projected to increase by 25% simply because of aging demographics.¹⁹ Although older persons comprise 12.4% of the U.S. population, they account for 34% of all prescription drug expenditures.²⁰ Overall in 2002, prescription drug spending was estimated to be between \$91 and \$117 billion.²¹ For those over the age of 65, national estimates in 2000 indicated that elders fill nearly 20 prescriptions per year and that their average expenditure for prescription drugs was \$1102.²² Nearly one-half of adults have prescription drug coverage that is limited or intermittent, and one-third of elders have no prescription benefit.²⁰ Hopefully, this problem with prescription coverage for elders will be addressed in the near future with an additional Medicare benefit.

FIGURE 8–1. Leading causes of death in 2000: age-adjusted death rates. Rates per 100,000 population in specified age group. (Data from Miniño AM, Arias E, Kochanek KD, et al. Deaths: Final Data for 2000. *Natl Vital Stat Rep* 2002;50:1–120.)

HUMAN AGING AND CHANGES IN DRUG PHARMACOKINETICS AND PHARMACODYNAMICS

2 There is a progressive functional decline in many organ systems with advancing age. Table 8–1 reviews some common physiologic changes with an emphasis on those which can affect pharmacotherapy. For more detailed information, readers are referred to excellent reviews.^{23,24}

Age-associated physiologic changes may cause reductions in functional reserve capacity (i.e., the ability to respond to physiologic challenges or stresses) and the ability to preserve homeostasis, thus making an elder susceptible to decompensation in a stressful

situation.^{25,26} To deal with physiologic challenges or stresses, an older individual may require up to 95% of his or her remaining reserve capacity.^{23,24} The cardiovascular, musculoskeletal, and central nervous systems appear to be most affected.²⁴ Examples of impaired homeostatic mechanisms include postural or gait stability, orthostatic blood pressure responses, thermoregulation, cognitive reserve, and bowel and bladder function. An event resulting in functional impairment may involve an insult for which the body cannot compensate, and relatively small stresses may result in major morbidity and mortality.²⁵

A number of age-related physiologic changes occur that potentially could affect drug pharmacokinetics and pharmacodynamics

TABLE 8–1. Physiologic Changes with Aging^{23,24}

| Organ System | Manifestation |
|------------------------|--|

(see Table 8–1). Unfortunately, limited data are available regarding the pharmacokinetics and pharmacodynamics of individual drugs commonly used in the elderly. This information gap may improve with the implementation of Food and Drug Administration (FDA) guidelines calling for pharmacokinetic studies by pharmaceutical companies for new molecular entities likely to have significant use in the elderly.²⁷

ALTERED PHARMACOKINETICS

Table 8–2 and the following discussion summarize what is known about the effect of aging on each of the four major facets of pharmacokinetics.^{26,28,29}

ABSORPTION

Most drugs are given orally, and thus a number of the age-related changes in gastrointestinal physiology potentially could affect the absorption of medications. Fortunately, most drugs are absorbed via passive diffusion, and age-related physiologic changes appear to have little influence on drug bioavailability.³⁰ A few drugs require active transport for their absorption, and thus their bioavailability may be reduced (e.g., calcium in the setting of hypochlorhydria). However, there is evidence for a decreased first-pass effect on hepatic and/or gut wall metabolism that results in increased bioavailability and higher plasma concentrations of drugs such as propranolol and morphine.³⁰ Increased drug bioavailability also may be seen with the concurrent ingestion of grapefruit juice. Constituents of this product inhibit cytochrome P450 (CYP450) isoenzyme 3A4, thus decreasing first-pass metabolism and resulting in exaggerated pharmacologic effects.³¹

DISTRIBUTION

The distribution of medications in the body depends on factors such as blood flow, plasma protein binding, and body composition, each of which may be altered with age. For example, the volume of distribution of water-soluble drugs is decreased, whereas lipophilic drugs will exhibit an increased volume of distribution.^{26,28,29} Changes in the volume of distribution can have a direct impact on the amount of medication that needs to be given as a loading dose.

The two major plasma proteins to which medications can bind are albumin and α_1 -acid glycoprotein (AAG), and concentrations of these proteins may change with concurrent pathologies seen with increasing age.³² For acidic drugs such as naproxen, phenytoin, tolbutamide,

and warfarin, decreased serum albumin may lead to an increase in free fraction. An increase in AAG induced by burns, cancer, inflammatory disease, or trauma may lead to a decreased free fraction of basic drugs such as lidocaine, propranolol, quinidine, and imipramine. In the absence of compromise in excretory pathways, these potential changes are unlikely to have any deleterious clinical effect. However, they may be important to consider when interpreting serum concentrations of these drugs because usually only total drug concentrations (sum of free and protein-bound drug) are reported.

METABOLISM

The liver is the major organ responsible for drug metabolism, including phase I (oxidative) and phase II (conjugative) reactions.³³ The most remarkable characteristic of liver function in the elderly is the increase in interindividual variability compared with other age groups, a feature that may obscure true age-related changes.³³ Recent data suggest that age-related declines in phase I metabolism are more likely the result of reduced liver volume rather than reduced hepatic enzymatic activity.³⁴ Decreased phase I metabolism (e.g., hydroxylation, dealkylation) producing decreased drug clearance and increased terminal disposition half-life ($t_{1/2}$) has been reported in elders for medications such as diazepam, piroxicam, theophylline, and quinidine. Phase II metabolism (e.g., glucuronidation, acetylation) of medications such as lorazepam and oxazepam appears to be relatively unaffected by advancing age. Hepatic enzyme induction (e.g., by rifampin, phenytoin) or inhibition (e.g., by fluoroquinolone and macrolide antimicrobials, cimetidine) does not appear to be affected by the aging process.^{33,35}

Age-related decreases in liver blood flow also can decrease significantly the metabolism of high-hepatic-extraction-ratio drugs such as imipramine, lidocaine, morphine, and propranolol.³³ The effect of aging on polymorphic drug metabolism has not been well studied. Advancing age has been reported both to have no significant effect and to reduce significantly the activity of CYP450 3A4.^{36,37} Other available data suggest that advancing age has no significant effect on drug acetylation or CYP450 2D6 or 2C9 isoenzyme-mediated metabolism.^{38–41} Finally, a number of potential confounding factors, including race, sex, frailty, smoking, diet, and drug-drug interactions, may affect hepatic metabolism significantly in the elderly.³³

ELIMINATION

Renal excretion is the primary route of elimination for many drugs. Although age-related reductions in glomerular filtration are well

TABLE 8–2. Age-Related Changes in Drug Pharmacokinetics^{26,28,29}

| Pharmacokinetic Phase | Pharmacokinetic Parameters |
|-----------------------------|---|
| Gastrointestinal absorption | Unchanged passive diffusion and no change in bioavailability for most drugs ↓ Active transport and ↓ bioavailability for some drugs ↓ First-pass extraction and ↑ bioavailability for some drugs |
| Distribution | ↓ Volume of distribution and ↑ plasma concentration of water-soluble drugs ↑ Volume of distribution and ↑ terminal disposition half-life ($t_{1/2}$) for fat-soluble drugs |
| Hepatic metabolism | ↑ or ↓ Free fraction of highly plasma protein bound drugs ↓ Clearance and ↑ $t_{1/2}$ for some oxidatively metabolized drugs ↓ Clearance and ↑ $t_{1/2}$ of drugs with high hepatic extraction ratios |
| Renal excretion | ↓ Clearance and ↑ $t_{1/2}$ of renally eliminated drugs and active metabolites |

documented, as many as one-third of “normal” elderly subjects may have no reduction, as measured by creatinine clearance.^{26,28,29} Moreover, emerging information suggests that renal tubular secretion may not decline in proportion to other renal processes.⁴² The estimation of creatinine clearance, although not entirely accurate in individual patients, can serve as a useful screening approximation. One of the most commonly used equations for adults with stable renal function and whose actual weight is within 30% of their ideal body weight was created by Cockcroft and Gault⁴³:

$$\text{Creatinine clearance (males)} = \frac{(140 - \text{age in years})(\text{actual body weight in kg})}{72(\text{serum creatinine in mg/dL})}$$

For females, multiply this result by 0.85.

Medications whose excretion is primarily renal and for which there is evidence of age-related reduction in renal and total body clearance include (but are not limited to) amantadine, aminoglycosides, atenolol, captopril, cimetidine, digoxin, lithium, and vancomycin. Some hepatically metabolized medications can yield active, primarily renally excreted metabolites such as *N*-acetylprocainamide, normeperidine, and morphine-6-glucuronide, which can accumulate with advancing age owing to reduced renal function.

CLINICAL CONTROVERSY

When estimating creatinine clearance in the elderly using the Cockcroft and Gault equation, some clinicians choose to round the value up to 1 if the patient’s serum creatinine concentration is less than 1. Rounding the serum creatinine concentration may provide an underestimation of creatinine clearance and result in improper dose adjustment of renally eliminated medications. It is important to realize that the equation is merely an estimate, and attempts should be made to determine creatinine clearance accurately with certain medications (e.g., metformin).

ALTERED PHARMACODYNAMICS

There is some evidence in the elderly of altered drug response or “sensitivity.” Four possible mechanisms have been suggested: (1) changes in receptor numbers, (2) changes in receptor affinity, (3) postreceptor alterations, and (4) age-related impairment of homeostatic mechanisms.^{26,44,45} For example, muscarinic, parathyroid hormone, β -adrenergic, α_1 -adrenergic, and μ -opioid receptors exhibit reduced density with increasing age.^{26,44,45} Evidence from epidemiologic and experimental studies suggest that, independent of pharmacokinetic alterations, the elderly are more sensitive to the central nervous system effects of benzodiazepines.^{26,44,45} The elderly also exhibit a greater analgesic responsiveness to opioids when compared with their younger counterparts, even when pharmacokinetic parameters are similar in the two groups.^{26,44,45} In addition, the elderly demonstrate an enhanced responsiveness to anticoagulants such as warfarin and heparin, as well as thrombolytic therapy.^{26,44,45} In contrast, the elderly exhibit decreased responsiveness to certain drugs (e.g., β -agonists/antagonists).^{26,44,45} Also, reflex tachycardia, seen commonly with vasodilator therapy, is often blunted in the elderly, perhaps owing to dampened baroreceptor function. For some drugs (e.g., calcium channel blockers), both enhanced responsiveness (as demonstrated by greater reduction in blood pressure) and

decreased responsiveness (as demonstrated by reduced atrioventricular nodal blockade) can occur simultaneously in elders.^{26,44,45}

CLINICAL GERIATRICS

3 Maintenance of independence and prevention of disability are primary goals in the clinical care of persons 65 years of age or older. To achieve these goals, it is necessary that all health care professionals understand the concept of functional status. Functional status is a proxy measure of a patient’s ability to live independently and can be determined in part by inquiring about an elderly person’s ability to perform specific tasks. As mentioned previously, there are two types of functional measurements: ADLs and the more complex IADLs.^{46,47} However, to assess functional status fully, the patient’s psychological state, financial resources, physical function, and social circumstances must be considered as well.¹

One of the challenges of maintaining and improving functional status in geriatric individuals is recognizing and managing conditions frequently seen in older adults. Problems found more commonly in older persons sometimes are referred to as the “I’s of geriatrics”²³ (Table 8–3). These problems are often due to underlying disease processes that may or may not be diagnosed. Examples of diseases and syndromes that can present as common problems in the elderly include Parkinson’s disease, falls, hip fractures, benign prostatic hypertrophy, dementia, glaucoma, postherpetic neuralgia, and tuberculosis.

Another factor contributing to the challenge of clinical geriatrics is that approximately 50% of older patients present with atypical symptoms or complaints, making it difficult to use the classic medical model for diagnosis. For example, cardiac ischemia may present as syncope or weakness in an older person rather than the typical presentation of chest pain. Confusion may be the presenting symptom of an acute abdominal process rather than the expected severe pain, rigidity of the abdominal muscles, and leukocytosis. Serious adverse consequences may result if a diagnosis is delayed or missed because of these atypical presentations. Such unusual presentations may be due to age-related physiologic changes, the presence of multiple comorbid illnesses or compromised function, and the presence of psychological stressors.⁴⁸ Table 8–4 presents additional examples of medical illnesses that often present atypically in the elderly.^{48–50} For very frail older adults, delirium, falls, and nonspecific functional decline frequently are presenting problems.^{48–50}

Multiple coexisting chronic illnesses are another common threat to independence that distinguishes the elderly from younger patients. It is not unusual for elderly patients to have multiple comorbidities such as osteoarthritis, heart disease, and diabetes. Although multiple comorbidities can have a substantial impact on a patient’s functional status, the mere existence of multiple diseases alone does not determine functional impairment.

TABLE 8–3. The I’s of Geriatrics: Common Problems in the Elderly²³

| | |
|--------------------------|-------------------------|
| Immobility | Instability |
| Isolation | Intellectual impairment |
| Incontinence | Impotence |
| Infection | Immunodeficiency |
| Inanition (malnutrition) | Insomnia |
| Impaction | Iatrogenesis |
| Impaired senses | |

TABLE 8–4. Atypical Disease Presentation in the Elderly^{48–50}

| Disease | Presentation |
|-----------------------------|--|
| Acute myocardial infarction | Only about 50% present with chest pain. In general, the elderly present with weakness, confusion, syncope, and abdominal pain; however, electrocardiographic findings are similar to younger patients. |
| Congestive heart failure | Instead of dyspnea, the older patient may present with hypoxic symptoms, lethargy, restlessness, and confusion. |
| Gastrointestinal bleed | Although the mortality rate is about 10%, presenting symptoms are nonspecific, ranging from mental status change to syncope with hemodynamic collapse. Abdominal pain is often absent. |
| Upper respiratory infection | Older patients typically present with lethargy, confusion, anorexia, and decompensation of a preexisting medical condition. Fever, chills, and a productive cough may or may not be present. |
| Urinary tract infection | Dysuria, fever, and flank pain may be absent. More commonly, the elderly present with incontinence, confusion, abdominal pain, nausea/vomiting, and azotemia. |

DRUG-RELATED PROBLEMS IN THE ELDERLY

4 Although medications used by the elderly can lead to improvement in HRQOL, negative outcomes owing to drug-related problems are considerable.^{51,52} Three important and potentially preventable negative outcomes owing to drug-related problems that can occur in the elderly are adverse drug withdrawal events (ADWEs), which are clinically significant sets of symptoms or signs caused by the removal of a drug; therapeutic failure (inadequate or inappropriate drug therapy and not related to the natural progression of disease); and adverse drug reactions (ADRs), defined as a reaction that is noxious and unintended and which occurs at dosages normally used in humans for prophylaxis, diagnosis, or therapy.^{53–55}

Limited data are available about the prevalence of ADWEs and therapeutic failures in the elderly. Graves and colleagues⁵³ reported ADWEs in 38 of 124 male outpatients who had 238 medications discontinued. Grymonpre and coworkers⁵⁴ reported that 19% of drug-associated hospital admissions in a group of older Canadians were related to therapeutic failure. ADRs occur commonly in elders, with reported rates ranging from 2.5% to 50.6% depending on the study population and methodology employed.⁵² In a recent large study of more than 30,000 Medicare outpatients, Gurwitz and colleagues⁵⁶ reported that 5% experienced an ADR in a period of 1 year, with more serious reactions more likely to be preventable. ADRs and other drug-related problems (e.g., ADWEs, therapeutic failure) are major threats to the HRQOL of outpatient elders and account for billions of health care dollars per year.^{52,57,58} In the nursing home setting alone, a cost-of-illness study estimated that drug-related problems (including ADRs and therapeutic failure) cost \$4 billion per year.⁵⁹

RISK FACTORS

A number of factors are believed to increase the risk of drug-related problems in the elderly, including suboptimal prescribing (e.g., overuse of medications or polypharmacy, inappropriate use, and underuse), medication errors (both dispensing and administration problems), and patient medication nonadherence (both intentional and unintentional). The following subsections address suboptimal prescribing and medication nonadherence, the most common problems.

OVERUSE

Polypharmacy can be defined as either the concomitant use of multiple drugs or the administration of more medications than are indicated clinically.^{60,61} Polypharmacy is common and increasing among the elderly. Community-based surveys reveal that elders take an average of 2.7 to 4.2 prescription and nonprescription medications each day.^{61,62} A recent study of community-dwelling elders in Finland reported an increase in polypharmacy, growing most in the oldest old.⁶³ Increased use of dietary supplements, such as herbal products, vitamins, and minerals, may add to the increase in polypharmacy. Kaufman and colleagues⁶⁴ found in a nationwide survey that 59% of women and 46% of men older than age 65 used a vitamin or mineral supplement and that 14% of these women and 11% of these men used an herbal product. The use of drugs increases to an average of 5 medications in elders who are hospitalized.⁶² A recent nursing facility survey found that institutionalized elderly persons take an average of 6.69 routine medications and that 27.1% took 9 or more medications on a regular basis.⁶⁵ Drug-use studies that defined polypharmacy as use of one or more unnecessary medications showed that this occurs in 55% to 59% of elderly outpatients.^{66,67} Multiple medication use has been strongly associated with ADRs.⁵² Polypharmacy is also problematic for elderly patients because it may increase the risk of geriatric syndromes (e.g., falls, cognitive impairment), diminished functional status, and health care costs.^{60,61,68}

INAPPROPRIATE PRESCRIBING

Inappropriate prescribing can be defined as prescribing of medications outside the bounds of accepted medical standards.⁶⁸ This phenomenon occurs commonly in elderly outpatients, as exemplified by one study in which 74% of drugs had at least one inappropriate rating based on clinical review applying explicit criteria.⁶⁶ Studies using explicit drug-use review criteria have found that between 7% and 53% of community-dwelling elders take one or more medications that have a dose, duration, duplication, or drug-interaction problem.^{68,69}

Alternatively, *inappropriate prescribing* can be defined as prescribing of drugs whose use should be avoided because their risk outweighs their potential benefit.⁷⁰ Applying explicit criteria developed by Beers and colleagues, different investigators have found that between 14% and 27% of persons 65 years of age and older living in the community take one or more drugs whose use should be avoided.^{70,71}

CLINICAL CONTROVERSY

The Beers criteria were updated recently.⁷² At present, it is not clear what is the best way to measure inappropriate prescribing. Global measures for detecting polypharmacy or unnecessary drug use and underuse of essential medications are needed, as well as additional studies examining drug-disease interactions and other health outcomes. Moreover, we recommend further studies of the predictive validity of evidence-based standards for measuring inappropriate medications in the elderly.

Inappropriate prescribing may pose important health risks. Limited retrospective data suggest that inappropriate prescribing is associated with drug-related hospital admissions and readmissions.⁶⁸ Hanlon and colleagues^{73,74} reported on community-dwelling elderly taking any inappropriate drug as defined by drug utilization review explicit criteria from the Centers for Medicare and Medicaid Services. They found that elders with inappropriate drug use, especially those with potential drug-drug or drug-disease interactions, were more likely to report problems in basic self-care (e.g., toileting, dressing, eating, transferring, and grooming) and had more outpatient physician visits.

UNDERUSE

An important and increasingly recognized problem in elders is *underuse*, defined as the omission of drug therapy that is indicated for the treatment or prevention of a disease or condition.⁷⁵ One study found that 55% of 236 ambulatory elderly patients had one or more necessary drugs omitted because of lack of physician prescribing.⁷⁵ Another study of community-dwelling elders examined whether unrelated disorders are less likely to be treated in patients with chronic diseases.⁷⁶ They found that patients with diabetes mellitus were less likely to receive estrogen-replacement therapy, that patients with pulmonary emphysema were less likely to receive lipid-lowering medications, and that patients with psychotic syndromes were less likely to receive medications for arthritis.⁷⁶ Other investigators have focused on the omission of treatment of certain conditions such as asthma, cardiovascular disease, dyslipidemia, osteoporosis, pain, hypertension, cancer chemotherapy, and depression and underuse of angiotensin-converting enzyme (ACE) inhibitor medications in patients with congestive heart failure (CHF), anticoagulation in elderly patients with atrial fibrillation, and preventive therapy after myocardial infarction.^{68,75,77}

Underuse may have an important relationship with negative health outcomes in the elderly, including functional disability, death, and health services use.⁶⁸ The risk from underuse of medication in general owing to limiting Medicaid patients' access to medications resulted in a more than doubling of the risk of admission to a nursing home.⁷⁸ Tamblin and colleagues⁷⁹ studied the effects of a deductible and 25% coinsurance fee from medications taken by elders from Canada. This reform led to a decrease in the number of essential medications (e.g., furosemide, anticoagulants, ACE inhibitors) used by elderly patients and increasing costs owing to adverse events and emergency department visits.⁷⁹

MEDICATION NONADHERENCE

Medication nonadherence is a common problem in the elderly.^{80–82} The prevalence rate ranges from 40% to 80% of patients (mean of

approximately 50%).^{80–82} Overall, the elderly are adherent with about 75% of their medications.^{80–82} The elderly have similar adherence to younger patients when the number of drugs taken by both groups is similar.⁸³ In fact, there is some evidence that adherence may be better in elders for some conditions.^{84,85} What does seem to be different is that intentional nonadherence may be more common in the elderly.⁸⁶ This may be related to the occurrence of ADRs and may represent intelligent nonadherence. A study by Fincke and coworkers⁸⁷ found that elders who perceived that they were overmedicated were more likely to have decreased adherence.

Limited retrospective data suggest that nonadherence is associated with increased health services use and adverse drug reactions. A meta-analysis of studies published by Sullivan and associates⁸⁸ that included patients of all ages determined that the rate of hospital admissions owing to nonadherence was 5.5%. A study by Col and coworkers⁸⁹ evaluated 315 consecutive elderly patients admitted to a hospital and determined that 11.4% of admissions resulted from nonadherence. Gurwitz and colleagues⁵⁶ found that 21% of preventable ADRs in elderly outpatients were due to errors in patient adherence.

PROVISION OF COMPREHENSIVE GERIATRIC ASSESSMENT

5 Given that drug-related problems are common, costly, and clinically important, how can they be prevented/managed? A solution may lie in comprehensive geriatric assessment. The term *comprehensive geriatric assessment* has been applied to geriatric evaluation and management (GEM), in which GEM clinicians manage the patient, and to consultative geriatric assessment, in which the geriatric multidisciplinary team makes recommendations to other clinicians for management of the patient. Comprehensive geriatric assessment has become a cornerstone in the care of the elderly; its effectiveness was summarized recently in a meta-analysis of 28 controlled trials and a randomized, multicenter, controlled trial of frail elderly veterans.^{90,91}

Pharmacists can play a major role in optimizing pharmacotherapy for the elderly. A recent article summarized the results from 13 randomized, controlled studies that clinical pharmacy interventions can reduce drug-related problems and improve health outcomes in the elderly.⁹² The following subsections provide an approach to how pharmacists in any practice setting can optimize medication use through the provision of comprehensive geriatric assessment.

HISTORY TAKING

Several potential difficulties may occur while taking medication histories from the elderly. They include (1) communication problems (impaired hearing and vision), (2) underreporting (health beliefs, cognitive impairment), (3) vague or nonspecific symptoms (altered presentation), (4) multiple diseases and medications, (5) reliance on a caregiver for the history, and (6) lack of medical records to confirm findings. Despite these potential difficulties, health care professionals should find value in pursuing the collection of this vital medication history information. The importance of inquiry regarding nonprescription medication use in the elderly cannot be stressed enough because one-third of all medications used by the ambulatory elderly are sold without a prescription, especially analgesics and laxatives.⁹³ Moreover, with the passage of the Dietary Supplement Health and Education Act of 1994, it is important to probe about use of dietary supplements, including vitamins and minerals, herbal agents, and products such as glucosamine and chondroitin.

TABLE 8–5. Medication Appropriateness Index^{98,99}

Questions to ask about each individual medication:

1. Is there an indication for the medication?
2. Is the medication effective for the condition?
3. Is the dosage correct?
4. Are the directions correct?
5. Are the directions practical?
6. Are there clinically significant drug-drug interactions?
7. Are there clinically significant drug-disease/condition interactions?
8. Is there unnecessary duplication with other medication(s)?
9. Is the duration of therapy acceptable?
10. Is this medication the least expensive alternative compared with others of equal utility?

Asking elders and their caregivers about methods they use to keep track of medicines is also important. This will allow one to design solutions to the problems detected and prevent repeating ineffective and previously used methods.

Patients and caregivers also should be asked about risk factors for prescribing problems (e.g., multiple physicians and pharmacies) and for adherence problems (e.g., impaired hearing, vision, and cognition and ability to open safety caps, pay for medicines, and swallow medications).⁹⁴

ASSESSING AND MONITORING DRUG THERAPY

The appropriateness of each prescribed medication should be assessed using a variety of methods.^{95–97} One standardized measure that has demonstrated reliability and validity is the Medication Appropriateness Index (MAI).^{98,99} The MAI consists of 10 questions that should be asked about each medication (Table 8–5).

Several other factors that are not included in the MAI also should be assessed⁹⁵: (1) suboptimal medication choice (based on effectiveness, safety, cost, and effects on HRQOL), (2) allergy (especially for new prescriptions), (3) undertreatment, and (4) drug interactions with food or laboratory tests. Some additional factors to consider during drug regimen review include adherence, medication storage problems, laboratory monitoring, therapeutic end points, and ADRs.

CLINICAL CONTROVERSY

An increasing number of clinical trials are enrolling elderly patients. For example, we now have evidence to support the cardiac benefits of pravastatin in the elderly.¹⁰⁰ Clinicians must weigh the risks and benefits of adding drug therapy to a patient's drug regimen because increasing the number of drugs may decrease adherence and can lead to an increased risk of ADRs. Furthermore, a clinician must decide if it is ethical to add drug therapy in patients who may not live long enough to benefit from the medication.

DOCUMENTING PROBLEMS AND FORMULATING A THERAPEUTIC PLAN

The clinician must document the problems that have been detected, develop a therapeutic plan to resolve them, and establish reasonable therapeutic end points if these have not been set already. An important point to remember is that what may be a reasonable end point for a 40-year-old patient may not be as reasonable for an 80-year-old person

when comorbidities, functional status, and life expectancy are taken into consideration.

CONSULTING THE PHYSICIAN REGARDING PROBLEMS AND CONCERNS

In some cases, the pharmacist or other health care professional must contact a patient's physician regarding problems and concerns that have been detected and documented. In discussing the patient in this context, the importance of optimizing the prescribing for elderly patients before implementing strategies to enhance their adherence cannot be overstressed. Otherwise, the adherence intervention, if effective, may result in patient harm. Similarly, in institutional settings, strategies to reduce medication administration errors may not improve patient outcomes if prescribing is not improved beforehand.

COUNSELING AND ADHERENCE AIDS

Some general factors to consider, before medication dispensing, to enhance adherence in the elderly include modifying medication schedules to fit patients' lifestyles, considering generic agents to reduce costs, using easy-to-open bottles and easy-to-swallow dosage forms, and using larger-type direction labels and auxiliary labels.⁸⁰ When dispensing medications (in particular, new medications or old ones that have changed in appearance or directions for use), both written and oral drug information should be provided to the patient and caregiver.

To improve the likelihood of adherence, the health care professional also should recruit active patient and caregiver involvement, stress the importance of adherence, and consider the use of adherence-enhancing aids (e.g., special packaging, a medication record, a drug calendar, medication boxes, magnification for insulin syringes, dose-measuring devices, and spacers for metered-dose inhalers).^{101,102} In institutional settings, discussion of special considerations (e.g., medications that can be crushed and given via feeding tube) with health care professionals responsible for medication administration is also prudent.

DOCUMENTING INTERVENTIONS AND MONITORING PATIENT PROGRESS

All interventions must be documented, and the steps just outlined must be repeated over time with elderly patients. During follow-up contacts, minimum inquiry should include questions as to whether the patient has any questions or concerns regarding medicines and determining whether the therapeutic end points previously established have been achieved. Moreover, ask patients whether they are or have recently experienced any side effects, unwanted reactions, or other problems with their medications to assess potential ADRs.⁵²

TARGETING HIGH-RISK ELDERLY

In busy practices, the approach outlined here may not be feasible for every patient. Therefore, practitioners may consider targeting these activities to patients at high risk for developing drug-related problems. Geriatric experts have identified 18 risk factors for drug-related problems in elderly nursing home patients.¹⁰³ These include the following medication-related factors: (1) polypharmacy (e.g., 9 or more medications or 12 or more doses per day), (2) taking specific high-risk drugs (e.g., intermediate- and long-half-life benzodiazepines, sedative-hypnotic agents, antipsychotic drugs, anticholinergic medications,

opioid analgesics, and chlorpropamide), (3) certain patient characteristics (e.g., low body weight, age 85 years or older, and decreased renal function), (4) use of narrow-therapeutic-range drugs (e.g., lithium, digoxin, warfarin, and anticonvulsants), (5) a history of a prior ADR, and (6) presence of six or more illnesses. The applicability of these criteria to elderly persons in other care settings and the relationship between identification of elderly patients with these potential risk factors and actual health outcomes remain to be determined.⁵⁶

CONCLUSION

The number of people older than age 65 years is growing in the United States and around the world, and the fastest growing segment of the American population is those over age 85. A number of physiologic changes with age affect pharmacokinetics and pharmacodynamics of drugs, especially hepatic metabolism and renal excretion. Improving and maintaining functional status and managing comorbidities are hallmarks of clinical geriatrics. Certain medical conditions are restricted to the elderly, and drug-related problems represent a major concern for this group. Innovative approaches, such as the provision of comprehensive geriatric assessment by pharmacists and other health care professionals, are needed to decrease the occurrence of these drug-related problems.

ABBREVIATIONS

HRQOL: health-related quality of life

ADLs: activities of daily living (e.g., dressing, bathing, getting around inside the home, feeding, toileting, grooming)

IADLs: instrumental activities of daily living (e.g., housekeeping chores, shopping, going outside, medication management)

FDA: Food and Drug Administration

CYP450: cytochrome P450

AAG: α_1 -acid glycoprotein

ADRs: adverse drug reactions

ADWEs: adverse drug withdrawal events

ACE: angiotensin-converting enzyme

CHF: congestive heart failure

GEM: geriatric evaluation and management

MAI: Medication Appropriateness Index

PHARMACOEPIDEMIOLOGY

Andy Stergachis and Thomas K. Hazlet

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

1 Risks and benefits are commonly identified only after a drug is used widely by the general population.

2 Observational study designs are essential for the study of risks associated with marketed drugs.

3 Not all associations represent cause-effect relationships.

1 The practice of pharmacotherapy presents numerous challenges to clinicians as they apply knowledge of the benefits and risks of pharmaceuticals to individual and population-based patient care. A great deal of our understanding about the efficacy and short-term safety of drugs arises from well-controlled studies conducted during the drug development and approval process. However, many additional risks and, increasingly, additional benefits are only identified after the drug is used widely by the general population. Benefits and risks learned following a drug's approval may range from relatively minor to clinically important effects that seriously alter an individual drug's risk-benefit ratio. The association between certain appetite-suppressant drugs and primary pulmonary hypertension and valvular heart disease is an example where serious adverse effects were discovered only after these drugs had come into widespread use.^{1,2} This example highlights both the inherent limitations of the drug development process and the need to study populations receiving medications obtained through usual clinical practice. The liver toxicity seen with troglitazone is another example of the valuable contribution of close monitoring to drug safety. Introduced for treatment of type 2 diabetes mellitus in 1997, troglitazone was withdrawn from the market based on reports of serious hepatocellular injury. Medical products (drugs, biologicals, and medical devices) must be monitored closely following their introduction into the marketplace, and this information has value when applied to clinical practice. The purpose of this chapter is to describe the role of pharmacoepidemiology in drug development and therapeutics and to characterize the primary methods and contemporary issues in this field.

As illustrated in Fig. 9–1, pharmaceuticals and other medical products today are developed and used within a complex system involving contributions from numerous stakeholders, including manufacturers who develop and test products, the Food and Drug Administration (FDA) through its premarketing review and approval process and postmarketing surveillance programs, health care providers, and patients.

Pharmacoepidemiology is a discipline that provides valuable information about the health and cost outcomes of drugs, devices, and biologicals, particularly after their approval for clinical use. *Pharmacoepidemiology* is defined as the study of the use of and effects of drugs in large numbers of people.³ The field as applied to the period after a drug enters the market is referred to as *postmarketing drug*

surveillance (PMS). *Pharmacovigilance* is the science and activities relating to the detection, assessment, understanding, and prevention of adverse effects or any other drug-related problems and generally refers to the continual monitoring for unwanted effects and other safety-related aspects of marketed drugs. One of the noteworthy developments in the field of pharmacoepidemiology has been the use of automated, linked databases that permit efficient and rapid studies of drug effects, although Health Insurance Portability and Accountability Act of 1996 concerns about confidentiality of medical information may curtail future access to these data.

Epidemiologic study designs are also essential for evaluating drug safety and effectiveness in situations where it is either infeasible or unethical to assign patients randomly to active treatment or placebo. While the randomized, controlled, blinded trial (RCT) is the standard against which other designs are measured, it is often not suitable for safety questions within the domain of pharmacoepidemiology. Clinical trials conducted prior to drug approval cannot uncover every important health effect of a pharmaceutical agent. For example, the adverse health effects of drugs on the human fetus can be estimated only through observational but not experimental methods. The teratogenic effects of thalidomide and, more recently, isotretinoin were identified through observational methods. Epidemiologic studies of the patterns of drug prescribing and use are also essential to assess a drug's usefulness.⁴ As a discipline, pharmacoepidemiology traditionally has concerned itself with the study of adverse drug effects. Epidemiologic study designs such as case-control and cohort studies are also used to identify beneficial effects of drugs in populations. For example, to determine the relationship between patterns of use of inhaled corticosteroids and the risk of fatal or near-fatal asthma, Suissa and colleagues⁵ conducted an epidemiologic study of 30,569 residents of Saskatchewan who were dispensed three or more asthma drugs in any 1 year from September 1975 through December 1991. The authors found the death rate to be 21% lower among inhaled corticosteroid users for each additional canister used in the preceding year and an increased death rate in patients who had discontinued inhaled corticosteroid use. These findings support practice guidelines and quality performance measurements that recommend the use of inhaled anti-inflammatory agents in patients with moderate to severe asthma.

Whether or not a drug in fact achieves its desired effect in the real world, in contrast to RCTs, is referred to as its *effectiveness*,

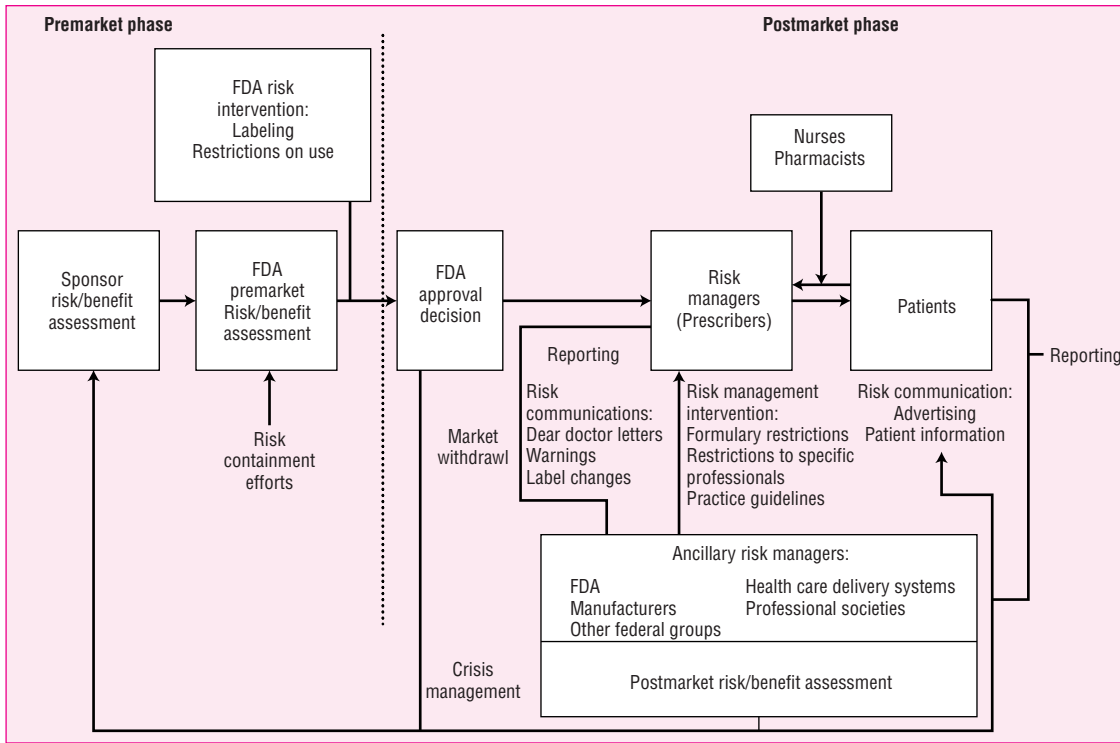

FIGURE 9-1. System for managing the risks of prescription drugs. (From U.S. Food and Drug Administration. *Managing the risks from medical product use: creating a risk management framework*; <http://www.fda.gov/oc/tfrm/executivesummary.html>; accessed May 10, 2004.)

not efficacy. Studies of drug effectiveness generally are conducted using observational study designs, although RCTs also play a role in determining a drug’s effectiveness.⁶ It is recognized widely that results from an RCT offer the best evidence that a drug will perform under ideal conditions, and it is likely that the “well controlled” design of RCTs will continue to be required for new drug applications (NDAs) to the FDA. As described in regulations governing NDAs, reports of adequate and well-controlled investigations provide the primary basis for determining whether there is “substantial evidence” to support the claims of effectiveness for new drugs.⁷

However, the rigorous circumstances surrounding the design and implementation of an RCT do not necessarily extrapolate to the individual patient. Fletcher and associates⁸ drew a distinction between *efficacy*—Does the treatment work?—and *effectiveness*—Does the treatment’s benefits outweigh its liabilities for those to whom it is offered in clinical practice?

The tension between the conflicting goals of validity in efficacy trials and generalizability in effectiveness trials is illustrated in Fig. 9-2. For example, in an efficacy trial, subjects are selected using narrowly defined eligibility criteria and are monitored closely to ensure that they use or are exposed to the intervention in the manner defined in the trial’s protocol and are cooperative with medical advice. In clinical practice, patients are not selected, and the manner in which the patient uses the intervention may vary widely from the intended use for which it was approved. Clinical outcomes among RCT subjects often are better than in nontrial patients.⁹ Trials to evaluate therapeutic effectiveness in clinical practice are difficult or expensive for researchers. If results from an effectiveness study are inconclusive, such results could be due to a lack of the intervention’s efficacy, patient behavior (such as lack of patient adherence), or both.

LIMITS OF KNOWLEDGE AT THE TIME OF NEW DRUG APPROVAL

The NDA process and the role of pharmacoepidemiology in the United States have evolved since the Food, Drug, and Cosmetic (FD&C) Act of 1938 was enacted into law. The FD&C Act was adopted following the deaths of more than 100 patients of renal failure from sulfanilamide prepared in a diethylene glycol vehicle.¹⁰ For the first time in U.S. history, the act required a drug to be proven safe under

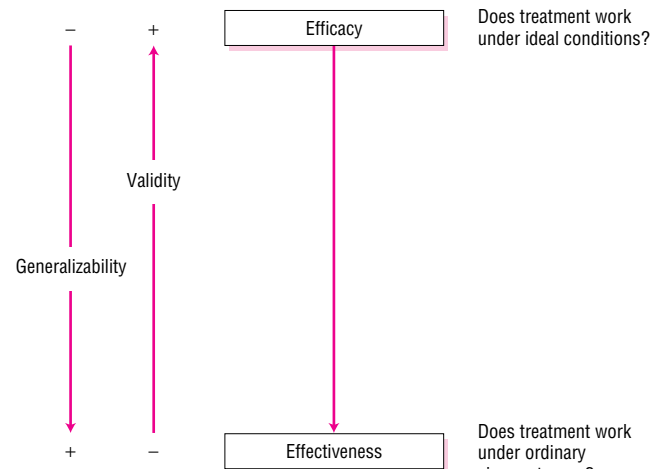

FIGURE 9-2. Schematic drawing showing the tension between conflicting goals of validity in efficacy trials and generalizability in effectiveness trials.

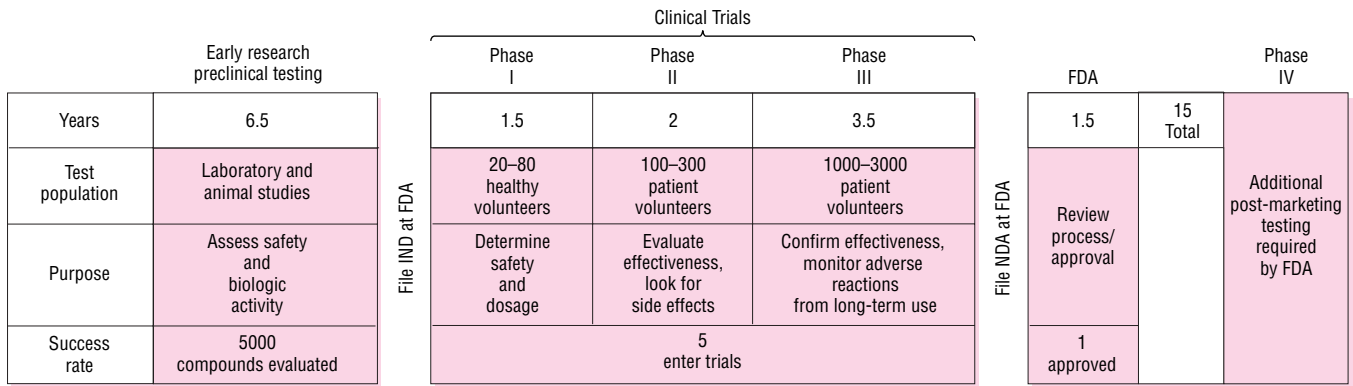

FIGURE 9-3. The drug development and approval process in the United States.

conditions of use intended by the manufacturer before marketing. The act also required manufacturers to conduct preclinical toxicity testing and gather and submit clinical data about drug safety to the FDA prior to drug marketing under an NDA. It also required new drugs to be labeled with adequate instructions and appropriate warnings for safe use. However, the FD&C Act required no proof of drug efficacy.

The FD&C Act was amended in 1962 following the epidemic of thalidomide-associated birth defects in Europe.¹¹ The Kefauver-Harris Amendments of 1962 strengthened the requirements for proof of drug safety and added a new requirement for demonstration of drug efficacy before marketing. Requiring “substantial evidence that the drug will have the effect it purports or is represented to have” resulted in the establishment of the RCT as the “gold standard” for proof of efficacy. The 1962 amendments also required manufacturers to report adverse drug events detected in the postmarketing setting to the FDA: Investigational new drug (IND) applications were required to be submitted to the FDA before clinical testing could begin. In 1985, requirements for manufacturers’ adverse drug event (ADE) reporting were clarified, and specific regulations and guidelines were published to define the manufacturers’ obligations in reviewing and reporting ADEs.

The Kefauver-Harris Amendments also identified explicit phases of preclinical animal testing followed by three phases of clinical testing (Fig. 9-3). In addition, a postapproval surveillance, phase IV of drug development, is now common. Today we are witnessing even more regulatory changes to the drug approval process as it pertains to pharmacoepidemiology. The Food and Drug Administration Modernization Act (FDAMA) of 1997 resulted in new provisions stating that substantial evidence of drug effectiveness may consist of data from one adequate and well-controlled clinical investigation plus confirmatory evidence. This indicates that two or more well-controlled trials (the previous standard) are not always necessary and that the FDA

should relate the number and type of trials to the specific product under development.

Phase III controlled clinical trials required by the FDA as part of the process of drug approval and labeling are the primary source of information about new drugs. Although these studies help to ensure that a drug is efficacious and does not cause unacceptable harm, premarketing studies fail to provide much of the information needed to make therapeutic decisions.¹² Table 9-1 describes the major limitations of premarketing controlled clinical trials, which lend support to the need for further evaluation of drugs after their approval for marketing by the FDA. Briefly, clinical trials performed during drug development cannot be depended on to detect rare adverse drug events and delayed adverse events. In addition, they cannot be used directly to address the performance of drugs in the populations that will use the drug in ways not studied in clinical trials because clinical trials restrict the complexity of the patients tested. Thus often not included in drug testing are many persons who are likely to receive new medicines eventually—the chronically ill, women of childbearing age, and pregnant women. Moreover, clinical trials are performed for patients with prespecified conditions. To improve the representativeness of populations included in clinical trials, the FDA has issued guidelines in support of inclusion of geriatric patients in phase II and phase III studies. Also, the FDA has issued guidelines and incentives to encourage manufacturers to provide efficacy, safety, pharmacokinetic, and pharmacodynamic information in support of the use of drugs and biologic products in pediatric and geriatric populations.

Despite the rigorous process for drug approval and regulation, several important medications have been removed from the market because of serious ADEs over the past 30 years. Examples of serious but uncommon effects include acute flank syndrome associated with suprofen,¹³ the gastrointestinal effects associated with nonsteroidal anti-inflammatory drugs (NSAIDs) in the elderly,¹⁴ troglitazone and the risk of hepatotoxicity,¹⁵ and the adverse effects of cisapride

TABLE 9-1. Limitations of Premarketing Clinical Trials

| | |
|-----------------------------|---|
| Short duration | Premarketing studies are limited in time Effects that develop following chronic use or those that have a long latency period cannot be detected |
| Small sample size | Few drugs are studied in more than 4000 subjects before FDA approval Effects that occur with a frequency of less than 1/1000 are difficult to detect |
| Narrowly defined population | Premarketing studies generally do not include special populations, such as children, women of childbearing age, or the elderly |
| Narrow set of indications | Manufacturers pursue specific indications for use during premarketing studies |
| Limited comparison groups | The comparison group is often limited to placebo |

(available only in the United States through a limited-use protocol from the manufacturer) when doses were too high or drug interactions resulted in QT-segment prolongation.¹⁶

Partially in response to concerns about ADEs, a number of epidemiology programs were developed beginning in the 1970s. An initial emphasis of early programs such as the Boston Collaborative Drug Surveillance Program was the estimation of drug use and adverse events among hospitalized patients.¹⁷ The Drug Epidemiology Unit, now the Slone Epidemiology Unit, also was formed in the early 1970s to perform hospital-based case-control studies.¹⁸ In the United Kingdom, the Drug Surveillance Research Unit established the Prescription Event Monitoring Program in 1980; it is now the Drug Safety Research Trust.¹⁹ Subsequent resources for pharmacoepidemiology evolved from the use of Medicaid data, followed by the use of databases from health maintenance organizations (HMOs) and other population-based data sources. Since the time of the 1980 report of the Joint Commission on Prescription Drug Use, there has been considerable interest in the use of HMO records for postmarketing drug surveillance.²⁰ Advantages to conducting PMS in an HMO setting include the availability of an identifiable population base for the estimation of rates, the presence of a relatively stable population base, and access to medical records and computerized databases.²¹ One evolution of the use of data from HMOs is the formation of the HMO Research Network, a group of 14 HMOs that facilitates health services and epidemiologic research in managed-care organizations.²²

CLINICAL CONTROVERSY

The FDA's proposed risk-assessment guidelines identify a sponsor's responsibilities to anticipate adverse events with medical products using survey methods and other techniques during product development: Generally, a sponsor determines its product's intended use and intended population(s) during product development. Decisions as to which interactions to either explore or specifically test in clinical trials could be based on these determinations and/or surveys and epidemiologic analyses. Missing from the guidelines is an acknowledgment that many medical products are used "off label" (e.g., recent experience with gabapentin and thalidomide, whose dominant use has been off-label). What is the sponsor's obligation to assess the risk of anticipated off-label usage during drug development?

Source: Guidance for Industry Premarketing Risk Assessment, May 2004, U.S. Food and Drug Administration, <http://www.fda.gov/cber/guidelines.htm>; accessed May 20, 2004.

ROLE OF THE FDA AND PHARMACOEPIDEMIOLOGY

Drug development should be viewed as a process that continues even after a drug is approved for marketing. As noted in the preceding section, it is not possible to detect all potential risks and benefits during premarketing studies. The FDA's PMS program provides important information on the clinical experience of medical products. The FDA's involvement in PMS includes monitoring approved drug use, monitoring the serious ADEs associated with the use of approved drugs, and the initiation of selected epidemiologic studies to estimate the risk or test specific hypotheses.²³ One of the primary uses of findings from PMS of drugs is modification of a drug's product labeling or package insert. Other methods used to communicate the results of

PMS efforts involve requiring the manufacturer to mail out a "Dear Doctor" letter, various listings on the FDA Web site (www.fda.gov), presentation of findings at professional meetings, and publication of findings in peer-reviewed journals. There is considerable debate on the best ways to communicate the findings from studies of the adverse effects of medications as the body of evidence grows on the limitations of the FDA's risk-management efforts.

As a condition of approval for marketing, drug manufacturers are required to notify the FDA of all adverse events of which they are aware. It is important for clinicians to report ADEs either to the manufacturer, the MedWatch system at the FDA, or the Medication Errors Reporting Program of the United States Pharmacopeia. These programs depend on health care professionals to report serious ADEs observed in the course of their practices as part of their professional responsibility and on the lay public to volunteer information about possible ADEs. The MedWatch form can be used to report ADEs or problems related to any medical product, with the exception of those occurring with vaccines. Reports concerning vaccines should be sent to the Vaccine Adverse Event Reporting System (VAERS), a joint program of the FDA and the Centers for Disease Control and Prevention. Table 9–2 describes the FDA's MedWatch program.

The FDA provides limited funding for investigators to use large, automated databases to study the adverse effects of drugs marketed in the United States and its territories. Through its cooperative-agreements program, the FDA has encouraged the use of large databases in pharmacoepidemiology. These agreements provide the FDA with access to data on the safety of pharmaceutical agents. The objectives of these programs include the rapid and efficient

TABLE 9–2. Characteristics of the FDA's MEDWATCH Program

Report experiences with:

- Medications (drugs or biologics)
- Medical devices (including in vitro diagnostics)
- Special nutritional products (dietary supplements, medical foods, infant formulas)
- Other products regulated by the FDA

Report SERIOUS adverse events. An event is serious when the patient outcome is:

- Death
- Life threatening (real risk of dying)
- Hospitalization (initial or prolonged)
- Disability (significant, persistent, or permanent)
- Congenital anomaly
- Required intervention to prevent permanent impairment or damage

Report even if:

- You're not certain that the product caused the event
- You don't have all the details

Report product problems—quality, performance, or safety concerns—such as:

- Suspected contamination
- Questionable stability
- Defective components
- Poor packaging or labeling
- Therapeutic failures

Important numbers:

- 1-899-FDA-0178 to fax report
- 1-800-FDA-7737 to report by modem
- 1-800-FDA-1088 to report by phone, for more information, or to obtain software for reporting by modem
- 1-800-822-7967 for a VAERS form for vaccines
- FDA MedWatch Web site: <http://www.fda.gov/medwatch/Download-reporting-forms> (PDF format) MedWatch information

conduct of pharmacoepidemiologic research designed to test hypotheses, particularly those arising from the MedWatch program. Current programs receiving funding for PMS from the FDA include Vanderbilt, Harvard-Pilgrim Health, and United HealthCare. The FDA also maintains agreements for pharmacoepidemiology with Kaiser Permanente, the Veterans Administration, and the Agency for Healthcare Research and Quality's Centers for Education and Research on Therapeutics (CERTs). Even though the FDA supports cooperative agreements for PMS, historically it has lacked regulatory authority to require phase IV studies for previously approved drugs. The Prescription Drug User Fee Act Amendments of 2002 will permit fee revenues to be used for some postapproval risk-management activities for the first time (<http://www.fda.gov/oc/pdufa3/2003plan/default.htm#update>; accessed April 5, 2004).

The Food and Drug Administration Modernization Act (FDAMA) does, however, require any sponsor of a drug that agreed to conduct a postmarketing study to report annually to the FDA on the progress of its postmarketing study commitments. The FDA uses postmarketing study commitments to gather additional information about a product's safety, efficacy, or optimal use. The FDA analyzed its data as of February 2002 on postmarketing commitments, and of the 2400 drug commitments, 882 had been categorized as completed. The FDA placed on its Web site a report on all postmarketing status reports received (<http://www.accessdata.fda.gov/scripts/cder/pmc/index.cfm>; accessed April 5, 2004).

The FDA has identified efficient risk management as the primary way to make the most effective use of agency resources and address these challenges. Efficient risk management requires using the best scientific data, developing quality standards, and using efficient systems and practices that provide clear and consistent decisions and communications for the American public and regulated industry. The FDA has long led the way in the science of risk management, and this ability is more important than ever given the expanding complexity of the agency's challenges and the need to reduce the health risks facing the public at the lowest possible cost to society (http://www.fda.gov/oc/mcclellan/strategic_risk.html; accessed April 5, 2004).

To assist in translating information about the risks and benefits of drugs into action, the federal Agency for Healthcare Research and Quality funds studies focused on patient outcomes associated with pharmaceutical therapy. The CERTs program is a national initiative to conduct research and provide education that advances the optimal use of medical products (i.e., drugs, medical devices and biological products) (<http://www.ahrq.gov/clinic/certsovr.htm>; accessed April 5, 2004). The program, which consists of seven centers and a coordinating center, is administered as a cooperative agreement by the Agency for Healthcare Research and Quality in consultation with the FDA.

CURRENT CONTROVERSY

Hormone-replacement therapy (HRT) is an example of a widely prescribed treatment among middle-aged women that was later found to have overall health risks that exceeded its benefits. The Women's Health Initiative showed that HRT did not reduce the risk of coronary artery disease, contrary to the results of most observational studies.

ADVERSE DRUG EVENTS

The field of pharmacoepidemiology concerns itself primarily with the study of adverse drug reactions (ADRs). According to the World

Health Organization, an *adverse drug reaction* is any noxious, unintended, and undesired effect of a drug that occurs at doses used in humans for prophylaxis, diagnosis, or therapy, and it implies a causal relationship between use of the drug and the noxious event.²⁴ ADEs, in contrast, describe an injury resulting from administration of a drug, but use of this term implies that the relationship may be coincidental or that the event is not caused solely by the drug itself but rather may relate to the circumstances surrounding use of the drug.

Virtually any drug can have adverse effects. Between 3% and 11% of hospital admissions have been attributed to adverse effects.²⁵ The likelihood that a patient will experience an ADE during hospitalization ranges from 1% to 44% depending on the type of hospital, the definition of an ADE, and the study methodology.²⁶ The economic impact of ADEs is substantial and potentially avoidable.^{27,28} The incidence of serious and fatal ADRs in hospital patients was reported to be as high as 6.7% and 0.32%, respectively.²⁹ More recently, ADEs among older persons in the ambulatory clinical setting were studied among all Medicare enrollees cared for by a multispecialty group practice during a 1-year study period. The researchers reported an overall rate of ADEs of 50.1 per 1000 person-years, with a rate of 13.8 preventable ADEs per 1000 person-years.³⁰

Although most ADEs can be anticipated, others are unpredictable, especially rare idiosyncratic reactions. ADRs have been separated into type A and B reactions. Type A reactions are expected exaggerations of a drug's known pharmacologic effects. Therefore, they usually are dose-dependent, predictable, and preventable. Type A reactions are responsible for most of the ADEs encountered. Examples include hypotension with antihypertensive agents and anticholinergic effects with tricyclic antidepressants. Type A reactions tend to occur in individuals who have one of three characteristics.³¹ First, the individual may have received more of a drug than is customarily required. Second, the individual may have received a conventional dose of the drug, but he or she may metabolize or excrete the drug unusually slowly, leading to drug levels that are too high, possibly owing to concomitant disease or drug interactions. Third, the individual may have normal drug levels but for some reason is overly sensitive to them. Most type A reactions are identified prior to drug marketing and are listed in a product's labeling.

Type B reactions are idiosyncratic and tend to be unrelated to the known pharmacologic action of a drug. They usually are not related to dose, are unpredictable and uncommon, and potentially are more serious than type A reactions. They may be due to what are known as *hypersensitivity reactions* or *immunologic reactions*. Type B reactions may be the consequence of some other idiosyncratic reaction to the drug, such as an inherited susceptibility. These reactions may concentrate in certain body systems, including the liver, blood, skin, kidney, and nervous system.³² Type B reactions represent a major focus of pharmacoepidemiologic studies of ADRs. Carcinogenic and teratogenic ADEs are considered type B reactions.

Because ADRs represent an important public health concern, institutions complying with the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) are required to perform numerous steps pertaining to the surveillance and management of ADRs. They must define significant ADRs, initiate intensive assessments for ADRs meeting the institution's definition, and be able to provide evidence during accreditation surveys of sufficiently detailed follow-up on the causes of ADRs.³³ The JCAHO recently has instituted an additional requirement for reporting of sentinel events, which are those involving the occurrence of risk of death or serious physical or psychological injury. In situations where the sentinel event indicates an ongoing possibility of threat to life or safety, the JCAHO may conduct an unscheduled survey and require that the institution undertake

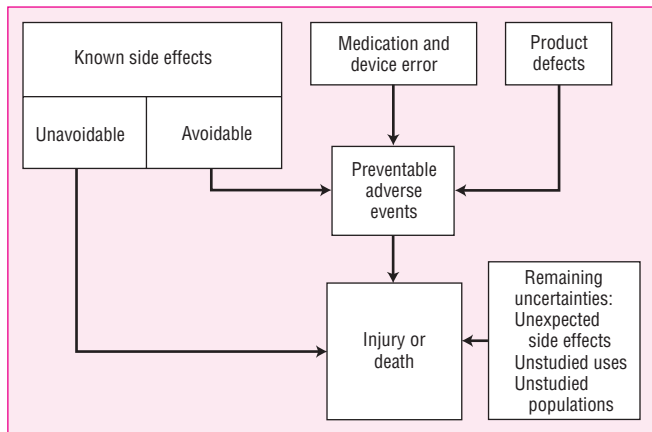

FIGURE 9-4. Sources of risk from medical products. (From *U.S. Food and Drug Administration. Managing the risks from medical product use: creating a risk management framework*; <http://www.fda.gov/oc/tfrm/executivesummary.html>; accessed May 10, 2004.)

extensive systems and process reviews and implement improvements to prevent recurrence of the sentinel event.

Risks from drugs and other medical products generally fall into four categories (Fig. 9-4). Most injuries and deaths associated with the use of medical products result from their known adverse effects. Some adverse effects are unavoidable, but others can be prevented or minimized by careful product choice and use. It is estimated that more than half the adverse effects from pharmaceuticals are avoidable.³⁴ Other sources of preventable adverse events are medication or device errors.

METHODOLOGIES FOR PHARMACOEPIDEMIOLOGIC STUDIES

2 A large number of study designs and methods are used to generate data on the uses and risks of new and older drugs. The types of study designs used in pharmacoepidemiology can be classified as experimental and observational. Experimental studies employ control in the assignment of individuals to exposure groups, usually through random assignment of individuals to the exposure under investigation, and then follow-up of individuals to detect the effects of exposure. For example, a recent clinical trial demonstrated that HRT does not prevent coronary heart disease in women. This randomized, controlled primary prevention trial, the Women's Health Initiative, studied 16,608 postmenopausal women aged 50 to 79 years with an intact uterus at baseline recruited by 40 U.S. clinical centers in 1993–1998. Overall health risks exceeded benefits from use of combined estrogen plus progestin for an average 5.2-year follow-up among healthy postmenopausal U.S. women.³⁵

Observational epidemiologic study designs, such as case-control, cohort, and cross-sectional studies, are used extensively. Large automated databases, meta-analyses, RCTs, and hybrid designs, such as nested case-control studies, also play an important role in pharmacoepidemiology. Epidemiologic studies typically do not use randomization to determine who will receive a particular drug exposure. Rather, associations between exposure(s) and disease(s) under study are determined through the use of observational study designs and statistical analyses. Observational methods are used in most situations because ethics and cost limit the use of experimentation. For example, one would not experimentally subject individuals to certain

drugs to determine if they develop cancer. A number of methods are used to study health events associated with drug exposures. The usual approach to studying ADEs begins with the collection of spontaneous reports of drug-related morbidity or mortality.

There has been a growing interest in using computerized databases containing medical care information for pharmacoepidemiologic studies.³⁶ These databases usually consist of patient-level data from two or more separate files (e.g., billing files for pharmacy and medical services reimbursement) that were developed originally for clinical or administrative applications.³⁷ Through record linkage, person-based longitudinal files can be created on an ad hoc basis. Multipurpose databases used for pharmacoepidemiologic studies include data from managed-care organizations, the Medicaid program, the Medicare program, and geographically defined populations. In general, these databases include information on patient demographics, outpatient drugs, hospital discharge diagnoses, and ambulatory care encounters. The advantages and disadvantages of linked databases for pharmacoepidemiologic studies have been the subject of numerous publications.^{38,39}

CASE REPORTS AND CASE SERIES

Case reports describe a single patient who was exposed to a drug and experienced a particular, usually adverse outcome. For example, within the first 3 months of marketing, hemolytic anemia and acute renal failure following use of the antibiotic temafloxacin were reported to the Spontaneous Report System, the predecessor of the MedWatch system. Case reports are useful for raising hypotheses about drug effects to be tested with more rigorous study designs. It is uncommon for a case report or a series of case reports to be used to make a statement about causation. Case series are collections of patients, all of whom have a single exposure, whose clinical outcomes are then evaluated and described. They are useful for quantifying the incidence of an adverse reaction, particularly for a newly approved drug. Further, case series can be useful for being certain that the incidence rate of any particular adverse effects of concern does not occur in a population that is larger than that studied prior to drug's marketing.

If the event is rare and the exposure combination is very specific, the cause of the adverse health event may be inferred from a case-series study. In most situations, however, it is necessary to compare cases with a group of controls to identify risk factors. Thus the major disadvantage of a case-series study is the lack of a comparison group. However, recent methodologic advances in the analysis of case-series data allow the estimation of relative incidence without the use of controls.⁴⁰

CASE-CONTROL STUDIES

A case-control study assembles a group of cases (people who have the disease of interest) and controls (people who do not). The exposure histories of the cases and the controls are determined to establish the extent of association between exposure(s) of interest and disease. Case-control studies compare patients with a specific disease with a control group composed of similar people but without the disease. Case-control studies attempt to identify risk factors for a disease by examining differences in antecedent exposure variables between cases and controls. For example, one can select cases of women of childbearing age with ovarian cysts and compare them with controls, looking for differences in prior use of oral contraceptives. Such a study was performed to determine if the then newly introduced triphasic oral contraceptives were associated with functional ovarian cysts.⁴¹

Case-control studies have been used extensively to assess the safety of pharmaceuticals. There are many examples of case-control studies that have identified important associations between drugs and adverse health events: vaginal cancer and diethylstilbestrol, Reye's syndrome and aspirin, peptic ulcer disease and nonsteroidal anti-inflammatory drugs, and venous thromboembolism and oral contraceptives. Data from case-control studies are used to calculate an odds ratio, which is the ratio of the odds of developing the disease for exposed patients to the odds of developing the disease for unexposed patients.

A classic example is a study of diethylstilbestrol given during pregnancy and the risk of vaginal adenocarcinoma among female offspring nearly a generation later.⁴² Recently, the association between use of antibiotics and the risk of breast cancer was studied in a case-control study among women enrolled in a large, nonprofit health plan. Controls were selected from health plan records and frequency matched to cases on age and length of enrollment. Cases were identified from the Surveillance, Epidemiology, and End Results Cancer Registry, whereas antibiotic use was ascertained from computerized pharmacy records.⁴³

A study of hip fracture risk in relation to the prescription of benzodiazepines exemplifies a nested case-control design.⁴⁴ Hip fracture cases and controls were chosen from a large existing database on health care use among Saskatchewan residents. The use of a nested case-control design to assess the role of potential confounding factors efficiently is further illustrated in the previously cited study of inhaled corticosteroids and the risk of fatal and near-fatal asthma.⁴⁵ A nested case-control study is an efficient variation of a case-control and a cohort study. In a nested case-control study, all cases (or a sample of all cases) and only a random sample of all controls are chosen for study from the same defined population.

An advantage of the case-control design for the study of drug-outcome relationships is its efficiency for the study of rare or delayed outcomes. Compared with other strategies, the case-control study is relatively inexpensive. One potential problem with case-control studies is their susceptibility to certain types of bias, including selection bias and information bias. *Selection bias* refers to systematic differences between those selected for study and those who are not, whereas *information bias* is systematic differences in the quality of information gathered for study and comparison groups.

COHORT STUDIES

A cohort study assembles a group of persons without the disease(s) of interest at the onset of the study, ascertains the exposure status of each person, and then follows the cohort over time to determine the development of disease in exposed and nonexposed persons. Cohort studies involve a comparison of the incidence of one or more outcome events among those who received a drug or some other exposure of interest compared with the incidence of the event(s) for a comparison group. For example, much information about the risk of fatal cardiovascular diseases among oral contraceptive users has come from the Royal College of General Practitioners Oral Contraception Study, in which 23,000 oral contraceptive users were compared with 23,000 nonusers chosen from the same British general practices.⁴² Death certificate records were used to ascertain instances of fatal events during the follow-up period.

Cohort studies can be prospective, as the Royal College of General Practitioners study illustrates, or retrospective. Some prospective cohort studies follow a large population over decades. For example, the Nurses Health Study was begun in 1976 to investigate the potential long-term consequences of the use of oral

contraceptives and was later expanded to include diet and nutrition and their relationship with the development of chronic diseases (<http://www.channing.harvard.edu/nhs/>). Prospective cohort studies are one of the most valid types of observational study designs because exposure is measured and recorded prior to the development of the health outcome(s) of interest. Using a prospective cohort study design, Hooton and colleagues⁴⁶ determined the association between contraceptive methods and symptomatic urinary tract infections in young women. The investigators recruited sexually active young women who were starting a new method of contraception and followed them for 6 months to determine the incidence of symptomatic urinary tract infections by contraceptive method.

An alternative to the prospective cohort design is the retrospective cohort study. Retrospective cohort studies are useful when comparison cohorts of persons exposed and not exposed to drugs of interest can be identified at some time in the past from large preexisting databases and followed from that time to the present with regard to the incidence of a given outcome. Recently, Soumerai and associates⁴⁷ used a retrospective cohort design to study the determinants and adverse health outcomes of β -blocker underuse in elderly patients with myocardial infarction. Controlling for other predictors of survival, the mortality rate among β -blocker recipients was 43% less than that for the comparison group, suggesting that use of β -blockers reduces the risk of death among elderly patients with myocardial infarction.

Prospective cohort studies can provide strong evidence of associations between drugs and diseases because the exposure is assessed before the outcome occurs. However, because many cohort studies require large numbers of people followed for long periods of time, they can be expensive and, in some instances, infeasible. Retrospective or historical cohort studies can overcome these limitations if high-quality data have been collected already.

QUASI-EXPERIMENTAL STUDY DESIGNS

One of the opportunities that has emerged with increased computerization in health care is the use of large, linked databases for exploring pharmaceutical outcomes. The ability to use transaction or claims data from an insurance company or state Medicaid agency and link these data to files containing diagnostic and other patient-specific information has allowed researchers to explore outcomes questions at relatively low expense. Because these studies do not rely on random assignment of subjects, they have been described as *quasi-experimental*.⁴⁸ The typical design includes a treatment (exposed) group, a control (unexposed) group, and some type of posttest assessment for both. Although efforts may be made to match treatment and control groups for important patient characteristics, the groups are not equivalent in the sense of an RCT. A refinement to this design is one where an analysis of underlying trends—factors that could influence study outcomes and progress independent of the study—is made using time-series methods. These studies often are used to evaluate the consequences of a change of policy, such as a prescription limit, or addition or removal of a drug from the marketplace. For instance, Soumerai and associates⁴⁹ studied the effect of a prescription cap on the use of psychotropic drugs and emergency mental health services using claims data. They used pharmacy claims data collected over a 42-month period, including the 11 months that the prescription cap was in effect, and found that drug use decreased while costs to the state Medicaid program increased during the period of the cap.

Recently, a quasi-experimental design was used to study British Columbia's reference pricing policy for five therapeutic classes of drugs to determine if a worsening of health outcomes could be detected after implementation of the reference pricing policy. The

TABLE 9–3. Criteria for the Causal Nature of an Association

1. **The association makes biologic sense.** In other words, the proposed association is consistent with our knowledge of the mechanism of disease. You can use data from other human or animal studies, or data from in vitro studies.
2. **The suspected cause precedes the disease.** Even though this is self-evident, it can be overlooked when interpreting findings from certain observational studies.
3. **The association is strong.** Associations with a relative risk of less than 2.0 are considered to be weak. Risks of 2.0 to 4.0 are considered moderate, while those greater than 4.0 are strong. You also need to consider the 95% confidence interval.
4. **The association is found consistently when studied using different methods or populations.** An important characteristic of science is that a finding is reproducible.
5. **There is a dose–response relationship.** For example, there is a higher risk among persons with greater exposure to a risk factor.

authors reported that there has been no worsening of health outcomes associated with implementing the reference pricing policy.⁵⁰

INTERPRETATION OF PHARMACOEPIDEMIOLOGIC STUDIES

3 Not all associations represent a cause–effect relationship. Because most epidemiologic studies of drug effects do not employ random allocation, it is important to determine if a legitimate cause–effect relationship exists. A central methodologic concern in observational studies is *confounding*—i.e., the possibility that the apparent effect of an exposure or intervention is due wholly or partly to other factors associated with it that have their own impact on the outcome of interest. Criteria have been proposed to help determine if an association is causal. The fewer criteria that are met, the less likely it is that an association is causal. Table 9–3 is adapted from the work of Hill and Stolly.^{51,52} Practitioners should ask the series of questions listed in the table to interpret findings from studies to determine if an association is likely to be causal.

CONCLUSION

Pharmacoepidemiologic studies conducted during the postapproval period provide important information to assist in optimizing therapeutic responses to drugs. The aging U.S. population, the introduction of new drugs, and reimbursement policies make pharmacoepidemiology an essential part of clinical practice. Studies can provide valuable information about the relationship between therapeutic agents and adverse and beneficial health outcomes. Information from pharmacoepidemiologic studies also contributes to population-based care and drug regulatory and reimbursement decisions. At the level of individual patient care, a combination of medical and epidemiologic knowledge leads to the choice to use a particular medication. Moreover, patient monitoring to optimize the therapeutic response to drugs also involves epidemiologic data and logic to balance likely benefits against potential risks. Epidemiologic information can provide vital information regarding safety, patterns of drug use, and effectiveness to assist in the provision of evidence-based health care. New data resources and methodologies are likely to expand the field of pharmacoepidemiology. There is an inherent tradeoff between the need for more information about a drug’s risks and the need to make a drug available for use. Because of limitations in the drug

development process, more information emerges about a drug after its approval through PMS. The challenge—articulated in the FDA’s recent “Innovation or Stagnation: Challenge and Opportunity on the Critical Path to New Medical Products”—will be to improve on this tradeoff through enhanced assessment methods for safety and utility and to better integration of these measures with manufacturing technology (<http://www.fda.gov/oc/initiatives/criticalpath/whitepaper.html>; accessed April 8, 2004).

CLINICAL TOXICOLOGY

Peter A. Chyka

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Poisoning can result from exposure to excessive doses of any chemical, with medicines being responsible for most childhood and adult poisonings.
- 2 The total number and rate of poisonings have been increasing, but preventive measures, such as child-resistant containers, have reduced mortality in young children.
- 3 Immediate first aid may reduce the development of serious poisoning, and consultation with a poison control center may indicate the need for further therapy.
- 4 The use of ipecac syrup, gastric lavage, and cathartics has fallen out of favor as routine therapies, whereas activated charcoal and whole-bowel irrigation are still useful for the gastric decontamination of appropriate patients.
- 5 Antidotes can prevent or reduce the toxicity of certain poisons, but symptomatic and supportive care is essential for all patients.
- 6 Acute acetaminophen poisoning produces severe liver injury and occasionally kidney failure. A determination of serum acetaminophen concentration may indicate whether there is risk of hepatotoxicity and the need for acetylcysteine therapy.
- 7 Anticholinesterase insecticides may produce life-threatening respiratory distress and paralysis by all routes of exposure and may be treated with symptomatic care, atropine, and pralidoxime.
- 8 Calcium channel antagonists will produce severe hypotension and bradycardia on overdose and can be treated with supportive care, calcium, glucagon, and insulin.
- 9 Poisoning with iron-containing drugs produces vomiting, gross gastrointestinal bleeding, shock, metabolic acidosis, and coma and can be treated with supportive care and deferoxamine.
- 10 Overdoses of tricyclic antidepressants can cause arrhythmias, such as prolonged QRS intervals and ventricular dysrhythmias, coma, respiratory depression, and seizures and are treated with symptomatic care and intravenous sodium bicarbonate.

Poisoning is an adverse effect from a chemical that has been taken in excessive amounts. The body is able to tolerate and, in some cases, detoxify a certain dose of a chemical, but once a critical threshold is exceeded, toxicity results. Poisoning can produce minor local effects that are treated readily in the outpatient setting or systemic life-threatening effects that require intensive medical intervention. This spectrum of toxicity is typical for many chemicals with which humans come in contact. Virtually any chemical can become a poison when taken in sufficient quantity, but the potency of some compounds leads to serious toxicity with small quantities¹ (Table 10–1). Poisoning by chemicals includes exposures to drugs, industrial chemicals, household products, plants, venomous animals, and agrochemicals. This chapter will describe some examples of this spectrum of toxicity, outline means to recognize poisoning risk, and present principles of treatment.

EPIDEMIOLOGY

Each year poisonings account for approximately 22,000 deaths and at least 875,000 emergency department visits in the United States.^{2,3} Young adults aged 25 to 44 years are at greatest risk of a poisoning death, and males have a twofold higher risk of death than females.

Nearly one-half of all poisoning deaths of adults are due to suicide. Poisoning deaths in adults most commonly involve motor vehicle exhaust (carbon monoxide), other gases or vapors, antidepressants, tranquilizers, barbiturates, alcohol, opioids, and local anesthetics, including cocaine.^{3–5} Approximately 0.3% of poisoning deaths involve children under the age of 5 years. The elderly, those 75 years old and older, children under 5 years of age, and adolescents and young adults 15 to 24 years of age have the highest risk for nonfatal poisonings requiring hospitalization. The number and rates of poisoning deaths (Fig. 10–1) have been increasing steadily, with a twofold increase from 1981 to 2001.³

1 There are several databases in the United States that provide different levels of insight into and documentation of the poisoning problem (Table 10–2). Poisonings documented by U.S. poison centers are compiled in the annual report of the American Association of Poison Control Centers-Toxic Exposure Surveillance System (AAPCC-TESS).⁶ Although it represents the largest database on poisoning, it is not complete because it relies on individuals voluntarily contacting a poison control center. The AAPCC-TESS data set captures approximately 5% of the annual number of deaths from poisoning tabulated in death certificates.⁴ Despite this shortcoming, AAPCC-TESS provides valuable insight into the characteristics and frequency of poisonings. In the 2003 AAPCC-TESS summary, 2,395,582 poisoning exposures

were reported by 64 participating poison centers that served a population of 295 million people.⁶ Children younger than 6 years of age accounted for 52% of the cases. The site of exposure was the home in 93% of the cases, and a single substance was involved in 92% of the cases. An acute exposure accounted for 92% of the cases, 85% of which were unintentional or accidental exposures. Only 12% were intentional. Fatalities accounted for 1106 (0.05%) cases, of which 3% were children younger than 6 years of age. The distribution of substances most frequently involved in pediatric and adult exposures differed; however, medicines were the most frequently involved (49%) substances (Table 10–3). Seventy-four percent of the poison exposures were treated at the scene, typically a home. In summary, children account for most of the reported poisonings with morbidity, but adults account for a greater proportion of mortality from poisoning.

ECONOMIC IMPACT OF POISONING

Poisoning, which ranks as the second leading cause of injury-related death, accounted for a total lifetime cost of \$8.5 billion in 1989 and, when adjusted for 2003, represented \$12.6 billion annually.⁷ Estimates of the lifetime cost of injury include related health care costs and lost lifetime earnings of the victim; however, they do not include the costs of suffering, reduced productivity of caregivers, or legal costs. The definition of poisoning for this economic estimate excluded poisoning from alcohol and other illicit drugs.

POISON PREVENTION STRATEGIES

2 The number of poisoning deaths in children has declined dramatically over the past three decades due, in part, to the implementation of several poison prevention approaches.^{7,8} These include

the Poison Prevention Packaging Act (PPPA) of 1970, the evolution of regional poison control centers, the application of prompt first-aid measures, improvements in overall critical care, development of less toxic product formulations, better clarity in the packaging and labeling of products, and public education on the risks and prevention of poisoning.⁹ Although all these factors play a role in minimizing poisoning dangers, particularly in children, the PPPA has perhaps had the most significant influence.⁸ The intent of the PPPA was to develop packaging that is difficult for children under 5 years of age to open or to obtain harmful amounts within a reasonable period of time. However, the packaging was not to be difficult for normal adults to use properly. There are a number of products and product categories for which safety packaging is required (Table 10–4). Child-resistant containers are not totally childproof and may be opened by children, which can result in poisoning. Despite the success of child-resistant containers, many adults disable the hardware or simply use no safety cap and thus place children at risk.¹⁰ Fatigue of the packaging materials also can occur, which underscores the need for new prescription ware for refills, as required in the PPPA.¹¹

Poison prevention requires constant vigilance because there are new generations of families where parents and grandparents need to be educated on poisoning risks and prevention strategies. New products and changes in product formulations also present different poisoning dangers and must be studied to provide optimal management. Strategies to prevent poisonings should consider the various psychosocial circumstances of poisoning (Table 10–5), prioritize risk groups and behaviors, and customize an intervention for specific situations.^{12,13}

RECOGNITION AND ASSESSMENT

The clinician’s initial responsibility is to determine whether a poisoning has occurred or if there is a potential for one to develop. Some patients provide a clear account of an exposure that has occurred with a known quantity of a specific agent. In other cases, the patient may appear with only an unexplained illness characterized by nonspecific signs and symptoms and no immediate history of ingestion. Exposure to folk remedies, dietary supplements, and environmental toxins also should be considered. Patients with suicide gestures can deliberately give an unclear history, and poisoning should be suspected routinely. Poisoning and drug overdoses should be suspected in any patient with a sudden, unexplained illness or with a puzzling combination of signs and symptoms, particularly in high-risk age groups. Nearly any

FIGURE 10–1. Deaths from all causes of poisoning and unintentional poisoning in the United States from 1981 to 2001. (Adapted from reference 2.)

TABLE 10–2. Strengths of Various Poisoning Databases

| Database (abbreviation) | Strength |
|---|---|
| Death certificates from state health departments compiled by the National Center for Health Statistics (NCHS) | Compiles all death certificates where the cause of death was by disease or external forces. Data typically verified by laboratory and clinical observations. |
| National Electronic Injury Surveillance System of U.S. Consumer Product Safety Commission (NEISS) | Surveys electronically all injuries, including poisonings, treated daily at a sample of approximately 100 emergency departments. Used to identify product-related injuries. |
| Drug Abuse Warning Network (DAWN) of the Federal Substance Abuse and Mental Health Services Administration | Identifies substance abuse–related episodes and deaths as reported to 400 hospitals and 150 medical examiners. |
| The American Association of Poison Control Centers-Toxic Exposure Surveillance System (AAPCC-TESS) | Represents largest database of poisonings with high representation of children based on voluntary reporting to poison control centers. |

symptom can be seen with poisoning, but some signs and symptoms are suggestive of a particular toxin exposure.¹⁴ Compounds that produce characteristic clinical pictures (toxicodromes), such as organophosphate poisoning with pinpoint pupils, rales, bradycardia, central nervous system depression, sweating, excessive salivation, and diarrhea, are most readily recognizable.¹⁵ The recognition of chemicals responsible for acute, mass emergencies due to industrial disasters, hazardous materials accidents, or acts of terrorism may be aided by evaluating characteristic signs and symptoms.¹⁶ Assessment of the patient may be aided by consultation with a poison control center. These centers can provide information on product composition, typical symptoms, range of toxicity, laboratory analysis, treatment options, and bibliographic references. Furthermore, the center will have specially trained physicians, pharmacists, nurses, and toxicologists on staff or on file to assist with difficult cases. Consultation with a poison control center also may identify changes in recommended therapy. A nationwide toll-free poison center access number (1-800-222-1222) routes callers to the local poison control center.

When the circumstances of a poison exposure indicate that it is minimally toxic, many poisonings can be managed successfully at the scene of the poisoning.⁶ Poison control centers typically monitor the victim by telephone during the first 2 to 6 hours of the exposure to assess the patient's status and outcome of first aid.

Once a poisoning is suspected and there is a need to confirm the diagnosis for medical or legal purposes, appropriate biologic material should be sent to the laboratory for analysis. Gastric contents may contain the greatest concentration of drug, but they are difficult

to analyze. Blood or urine may be tested by qualitative screening in order to detect a drug's presence.^{17,18} The results of a qualitative drug screen can be misleading owing to interfering or low-level substances (Table 10–6); it rarely guides therapy and thus has questionable value for nonspecific, general screening purposes.^{17,18} Consultation with the laboratory technician and review of the assay package insert will help to determine the sensitivity and specificity of the assay. Quantitative determination of serum concentrations may be important for the assessment of some poisonings, such as those with acetaminophen, ethanol, methanol, iron, theophylline, and digoxin.¹⁹

PHARMACOKINETICS OF OVERDOSE

The pharmacokinetic characteristics of drugs taken in overdose may differ from those observed following therapeutic doses^{20,21} (Table 10–7). These differences are due to dose-dependent changes in absorption, distribution, metabolism, or elimination; pharmacologic effects of the drug; or pathophysiologic consequences of the overdose. Dose-dependent changes may decrease the rate and extent of absorption, whereas the bioavailability of the agent may be increased due to saturation of first-pass metabolism. The distribution of a compound may be altered due to saturation of protein-binding sites. Metabolism and elimination of a compound may be retarded due to saturated biotransformation pathways leading to nonlinear elimination kinetics. Delayed gastric emptying by anticholinergic drugs or as the result of general central nervous system depression caused by many drugs may alter the rate and extent of absorption. The formation of concretions or bezoars of solid dosage forms may delay the onset, prolong the duration, or complicate the therapy of an acute overdose.²² A combination of pharmacokinetic and pharmacodynamic factors may lead to the delayed onset of toxicity of several toxins, such as thyroid hormones, oral

TABLE 10–3. Poison Exposure by Age Group and Fatal Outcome, Ranked in Decreasing Order

| Pediatric | Adult | Fatal Outcome |

| | |
|--|--|
| Acetaminophen | Kerosene |
| Aspirin | Methanol |
| Diphenhydramine | Oral prescription drugs ^a |
| Ethylene glycol | Permanent hair wave neutralizers containing sodium bromate |
| Glue removers containing acetone/nitrile | Sodium hydroxide |
| Ibuprofen | Sulfuric acid |
| Iron pharmaceuticals | Turpentine |

^aWith certain exceptions such as nitroglycerin and oral contraceptives.

TABLE 10–5. Psychosocial Characteristics of Poisoning Patients

| Children | Young Adults | Elderly |
|--|--|---|
| Act purposefully or are poisoned by caretaker or sibling | Intentional abuse or suicidal intent is possible | Suicidal intent or unintentional misuse |
| Act with developmentally appropriate curiosity | Disregard or cannot read directions | Confuse product identity and directions for use |
| Attracted by product appearance | Do not recognize poisoning risk | Do not recognize poisoning risk |
| Ingest substances that adults find unpleasant | Reluctant to seek assistance until ill | Comorbid conditions complicate toxicity |
| React to stressful and disrupted household | Exaggerate or misrepresent situation | Unable or unwilling to describe situation |
| Imitate adult behaviors (e.g., taking medicine) | Peer pressure to experiment with drugs | Multiple drugs may lead to adverse reactions |

TABLE 10–7. Examples of the Influence of Drug Overdosage on Pharmacokinetic and Pharmacodynamic Characteristics

| Effect of Overdosage ^a | Examples |
|--|---|
| Slowed absorption due to formation of poorly soluble concretions in the gastrointestinal tract | Aspirin, lithium, phenytoin, sustained-release theophylline |
| Slowed absorption due to slowed gastrointestinal motility | Benzotropine, nortriptyline |
| Slowed absorption due to toxin-induced hypoperfusion | Procainamide |
| Decreased serum protein binding | Lidocaine, salicylates, valproic acid |
| Increased volume of distribution associated with toxin-induced acidemia | Salicylates |
| Slowed elimination due to saturation of biotransformation pathways | Ethanol, phenytoin, salicylates, theophylline |
| Slowed elimination due to toxin-induced hypothermia (<35°C) | Ethanol, propranolol |
| Prolonged toxicity due to formation of longer-acting metabolites | Carbamazepine, dapson, glutethimide, meperidine |

^aCompared to characteristics following therapeutic doses or resolution of toxicity. From Bosse²³ and Vance.²⁴

TABLE 10–6. Considerations in Evaluating the Results of Some Common Immunoassays Used for Urine Drug Screening

| Drug | Detection After Stopping Use | Comments |
|--------------------------------------|--|--|
| Amphetamines | 2–5 days Up to 2 weeks with prolonged or heavy use | Many sympathomimetic amines such as pseudoephedrine, ephedra, phenylephrine, fenfluramine, and phentermine may cause positive results. Other drugs such as selegiline, chlorpromazine, trazodone, bupropion, and amantadine may cause false-positive results depending on the assay. |
| Benzodiazepines | Up to 2 weeks Up to 6 weeks with chronic use of some drugs | The ability to detect benzodiazepines varies by drug. |
| Cannabinoid metabolite (marijuana) | 7–10 days Up to 1–2 months with prolonged or heavy use | The extent and duration of use will affect detection time. Drugs such as ibuprofen and naproxen may cause false-positive results depending on the assay. |
| Cocaine metabolite (benzoylecgonine) | 12–72 hours Up to 1–3 weeks with prolonged or heavy use | Cocaine is metabolized rapidly, and specific metabolites are typically the substance detected. False-positive results from “-caine” anesthetics and other drugs are unlikely. |
| Opioids | 2–3 days typically Up to 6 days with sustained-release formulations Up to 1 week with prolonged or heavy use | Since the assay was made to detect morphine, detection of other opioids, such as codeine, oxycodone, hydrocodone, and other semisynthetic opioids, may be limited. Some synthetic opioids, e.g., fentanyl and meperidine, may not be detected. Drugs such as rifampin and some fluoroquinolones may cause false-positive results depending on the assay. |
| Phencyclidine | 2–10 days 1 month or more with prolonged or heavy use | Drugs such as ketamine, dextromethorphan, diphenhydramine, and sertraline may cause false positive results depending upon the assay. |

anticoagulants, acetaminophen, and drugs in sustained-release dosage forms.²³ Drug-induced hypoperfusion may affect drug distribution and result in reduced hepatic or renal clearance. Changes in blood pH may alter the distribution of weak acids and bases. Drug-induced renal or hepatic injury also can decrease clearance significantly. Implications of these changes for poisoning management include the delayed achievement of peak concentrations with a corresponding longer period of opportunity to remove the drug from the gastrointestinal tract. The expected duration of effects may be much greater than that ob-

served with therapeutic doses due to continued absorption and impaired clearance. The application of pharmacokinetic variables, such as percentage protein binding and volume of distribution, from therapeutic doses may not be appropriate in poisoning cases.²⁰ Data on toxicokinetics often are difficult to interpret and compare because the doses and times of ingestion are uncertain, the duration of sampling is inadequate, active metabolites may not be measured, protein binding typically is not assessed, and the severity of toxicity may vary dramatically.

▶ TREATMENT: Clinical Toxicology

GENERAL APPROACHES TO TREATMENT OF THE POISONED PATIENT

■ PREHOSPITAL CARE

■ FIRST AID

3 The presence of adequate airway, breathing, and circulation should be assessed, and cardiopulmonary resuscitation should be started if needed. The most important step in preventing a minor exposure from progressing to a serious intoxication is early decontamination of the poison. Basic poisoning first-aid and decontamination measures (Table 10–8) should be instituted immediately at the scene of the poisoning. If there is any question about the potential severity of the poison exposure, a poison control center should be consulted immediately (1-800-222-1222). While awaiting transport, placing the patient on the left side may afford easier clearance of the airway if emesis occurs and may slow absorption of drug from the gastrointestinal tract.²⁴

■ IPECAC SYRUP

4 Ipecac syrup, a nonprescription drug, has been used in the United States for the past 50 years as a means to induce vomiting for the treatment of ingested poisons. Despite its widespread use, concerns about its effectiveness and safety have been raised recently. An expert panel of North American and European toxicologists concluded that its routine use in the emergency department should be abandoned.²⁵ The American Academy of Pediatrics issued a policy statement in 2003 that indicated that ipecac syrup was no longer to be used rou-

tinely to treat poisonings at home and that parents should discard any ipecac.²⁶ The key reason for the policy change was that research failed to show benefits in those children who were treated with ipecac syrup. It likely will take several years for these recommendations to be adopted fully by parents and health care professionals, and rare exceptions may arise.

There are several contraindications to the use of ipecac syrup.²⁵ If the patient is without a gag reflex; is lethargic, comatose, or convulsing; or is expected to become unresponsive within the next 30 minutes, emesis should not be induced. If a fruitful emesis has occurred spontaneously shortly after ingestion, ipecac syrup may not be necessary. Ingestions of caustics, corrosives, ammonia, and bleach are definite contraindications to ipecac-induced emesis. The ingestion of aliphatic hydrocarbons (e.g., gasoline, kerosene, and charcoal lighter fluid) typically does not require emesis. When the agent is definitely known to be nontoxic, induction of emesis is purposeless and potentially dangerous. The rapid onset of coma or seizures or the potential to exaggerate the toxic effects of the poison may preclude the use of ipecac syrup. Some examples include poisonings with diphenoxylate, propoxyphene, clonidine, tricyclic antidepressants, hypoglycemic agents, nicotine, strychnine, β -blocking agents, and calcium channel blockers. Debilitated, pregnant, and elderly patients may be further compromised by the induction of emesis.

■ HOSPITAL TREATMENT

■ GENERAL CARE

Supportive and symptomatic care is the mainstay of treatment of a poisoned patient. In the search for specific antidotes and methods to increase excretion of the drug, attention to vital signs and organ functions should not be neglected. Establishment of adequate oxygenation and maintenance of adequate circulation are the highest priority. Other components of the acute supportive care plan include the management of seizures, arrhythmias, hypotension, acid-base balance, fluid status, electrolyte balance, and hypoglycemia. Placement of intravenous and urinary catheters is typical to ensure delivery of fluids and drugs when necessary and to monitor urine production, respectively.

■ GASTRIC LAVAGE

Gastric lavage involves the placement of an orogastric tube and washing out of the gastric contents through repetitive instillation and withdrawal of fluid. Gastric lavage may be considered only if a potentially toxic agent has been ingested within the past hour for most patients. If the patient is comatose or lacks a gag reflex, gastric lavage should be performed only after intubation with a cuffed or well-fitting endotracheal tube. The largest orogastric tube that can be passed (at least an

TABLE 10–8. First Aid for Poison Exposures

Inhaled Poison

Immediately get the person to fresh air. Avoid breathing fumes.

Open doors and windows. If victim is not breathing, start artificial respiration.

Poison on the Skin

Remove contaminated clothing and flood skin with water for 10 minutes. Wash gently with soap and water and rinse. Avoid further contamination of victim or first aid providers.

Poison in the Eye

Flood the eye with lukewarm or cool water poured from a glass 2 or 3 inches from the eye. Repeat for 10 to 15 continuous minutes.

Keep eye open, but do not force the eyelid open.

Swallowed Poison

Unless the patient is unconscious, having convulsions, or cannot swallow, give 2 to 4 ounces of water immediately and then seek further help.

external diameter of 12 mm in adults and 8 mm in children) should be used to ensure adequate evacuation, especially of undissolved tablets. Lavage should be performed with warm (37–38°C) normal saline or tap water until the gastric return is clear; this usually requires 2 to 4 L or more of fluid. Relative contraindications for gastric lavage include ingestion of a corrosive or hydrocarbon agent. Complications of gastric lavage include aspiration pneumonitis, laryngospasm, mechanical injury to the esophagus and stomach, hypothermia, and fluid and electrolyte imbalance.²⁷

■ SINGLE-DOSE ACTIVATED CHARCOAL

Reduction of toxin absorption can be achieved by the administration of activated charcoal. It is a highly purified, adsorbent form of carbon that prevents the gastrointestinal absorption of a drug by chemically binding (adsorbing) the drug to the charcoal surface. There are no toxin-related contraindications to its use, but it is generally ineffective for iron, lead, lithium, simple alcohols, and corrosives. It is not indicated for aliphatic hydrocarbons because of the increased risk of emesis and pulmonary aspiration. Activated charcoal is most effective when given within the first few hours after ingestion, ideally within the first hour.²⁸ The recommended dose of activated charcoal for a child (1–12 years old) is 25 to 50 g; for an adolescent or adult it is 25 to 100 g. Children under 1 year of age may receive 1 g/kg.⁹ Activated charcoal is mixed with water to make a slurry, shaken vigorously, and administered orally or by means of a nasogastric tube. Activated charcoal is contraindicated when the gastrointestinal tract is not intact. Activated charcoal is relatively nontoxic, but there are two identified risks: (1) emesis following administration and (2) pulmonary aspiration of charcoal and gastric contents leading to pneumonitis in patients with an unprotected airway or absent gag reflex.²⁸ Some activated charcoal products contain sorbitol, a cathartic that may be associated with an increased incidence of emesis following use.²⁹

■ CATHARTICS

Cathartics, such as magnesium citrate and sorbitol, were thought to decrease the rate of absorption by increasing gastrointestinal elimination of the poison and the poison-activated charcoal complex, but their value is unproven. Poisoned patients do not routinely require the administration of a cathartic, and it is rarely, if ever, given without concurrent activated charcoal administration.³⁰ If used, a cathartic should be administered only once and only if bowel sounds are present. Infants, the elderly, and patients with renal failure should be given saline cathartics cautiously, if at all.^{9,30}

CLINICAL CONTROVERSY

Activated charcoal has been promoted for use at home as a replacement for ipecac syrup, but some have contended that there is little evidence which indicates that it can be used safely and properly in this setting.

■ WHOLE-BOWEL IRRIGATION

Polyethylene glycol electrolyte solutions, such as GoLyte and Colyte, are used routinely as whole-bowel irrigants prior to colonoscopy and bowel surgery.³¹ These solutions also can be used as a means to decontaminate the gastrointestinal tract of ingested toxins.^{9,14,32} Large volumes of these osmotically balanced solutions

are administered continuously through a nasogastric or duodenal tube for 4 to 12 hours or more. They quickly cause gastrointestinal evacuation and are continued until the rectal discharge is relatively clear. This procedure may be indicated for certain patients in whom the ingestion occurred several hours prior to hospitalization and the drug still is suspected to be in the gastrointestinal tract, such as drug smugglers who swallow condoms filled with cocaine.³³ In addition, patients who have ingested delayed-release or enteric-coated drug formulations or have ingested substances such as iron that are not well adsorbed by activated charcoal may benefit from whole-bowel irrigation.³² It should not be used in patients with a bowel perforation or obstruction, gastrointestinal hemorrhage, ileus, or intractable emesis. Emesis, abdominal cramps, and intestinal bloating have been reported with whole-bowel irrigation.³²

CLINICAL CONTROVERSY

Some clinicians believe that whole-bowel irrigation should be used more routinely as a rapid means to evacuate the gastrointestinal tract. Others recognize that it does have a quick onset but point out that there is little proof that it makes a difference in patient outcome.

■ PERSPECTIVES ON GASTRIC DECONTAMINATION

Although there are a variety of options for gastric decontamination, two clinical toxicology groups (the American Academy of Clinical Toxicology and the European Association of Poison Centers and Clinical Toxicologists) have concluded that no means of gastric decontamination should be used routinely for a poisoned patient without careful consideration.^{25,27,28,30,32} They indicate that therapy is most effective within the first hour and that effectiveness beyond this time cannot be supported or refuted with the available data. A clinical policy statement by the American College of Emergency Physicians concludes that although no definitive recommendation can be made on the use of ipecac syrup, gastric lavage, cathartics, or whole-bowel irrigation, activated charcoal is advocated for most patients when appropriate.³⁴ The clinical policy also states that ipecac syrup is rarely of value in the emergency department and that the use of whole-bowel irrigation following ingestion of substances not well adsorbed by activated charcoal is not supported by evidence. Although gastric lavage can reduce drug absorption if performed within 1 hour of ingestion, its use is not recommended routinely.^{27,34,35} In recent years, the use of ipecac syrup has declined markedly in part because of its apparent lower efficacy compared with activated charcoal in minimizing drug absorption.^{6,25,28} The American Academy of Pediatrics has recommended that ipecac syrup no longer be used for the treatment of poisonings at home and has called for its removal from the home.²⁶ Recently, activated charcoal has been promoted for the treatment of poisonings at home, but issues of safety, patient compliance, and effectiveness have not been proven in the home setting.^{26,36} Poison control centers may be a source of guidance on the contemporary application of gastric decontamination techniques for a specific patient.

■ Enhanced Elimination

Numerous methods have been used to increase the rate of excretion of poisons from the body. Of these, only diuresis, multiple-dose activated charcoal, and hemodialysis are useful occasionally. These approaches should be considered only if the risks of the procedure are significantly outweighed by the expected benefits or if the recovery of

the patient is seriously in doubt and the method has been shown to be helpful.

■ Diuresis

Diuresis may be used for poisons excreted predominantly by the renal route; however, most drugs and poisons are metabolized, and only a good urine flow, such as 2–3 mL/kg per hour, needs to be maintained for most patients. Fluid and electrolyte balance should be monitored closely. Ionized diuresis by altering urinary pH may increase excretion of certain chemicals that are weak acids or bases by trapping ionized drug in the renal tubule and minimizing reabsorption.¹⁴ Alkalinization of the urine to achieve a urine pH of 7.5 or greater for poisoning by weak acids such as salicylates or phenobarbital can be achieved by the intravenous administration of sodium bicarbonate 1–2 mEq/kg over a 1- to 2-hour period. Complications of urinary alkalinization include alkalosis, fluid and electrolyte disturbances, and inability to achieve target urinary pH values.³⁷ Acid diuresis may enhance the excretion of weak bases, such as amphetamines, but it is rarely, if ever, used because it risks worsening rhabdomyolysis commonly associated with amphetamine overdose.¹⁴ Generally, ionized diuresis is rarely indicated for poisoned patients because it is inefficient relative to other methods of enhancing elimination, there is a risk of unacceptable adverse effects, and the renal elimination of most drugs is not enhanced dramatically.

■ Multiple-Dose Activated Charcoal

Multiple doses of activated charcoal can augment the body's clearance of certain drugs by enhanced passage from the bloodstream into the gastrointestinal tract and subsequent adsorption. This process, termed charcoal intestinal dialysis or charcoal-enhanced intestinal exsorption, describes the attraction of drug molecules across the capillary bed of the intestine by activated charcoal in the intestinal lumen and subsequent adsorption of the drug to the charcoal.³⁸ Furthermore, it may interrupt the enterohepatic recirculation of certain drugs.^{14,38} Once the drug is adsorbed to the charcoal, it is eliminated with the charcoal in the stool. The systemic clearance of several drugs has been shown to be enhanced up to severalfold.^{38,39} An international toxicology group's position statement on multiple-dose activated charcoal concluded that it should be considered only if a patient has ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline.³⁹ Although a prospective, randomized study of the effects of multiple-dose activated charcoal on phenobarbital-overdosed patients demonstrated increased drug elimination, no demonstrable effect on patient outcome was observed.⁴⁰

This approach provides a rapid onset of action that is limited by blood flow and a maximal "ceiling effect" related to the dose of charcoal present in the intestine. The response to multiple-dose activated charcoal is greatest for drugs with the following characteristics: good affinity for adsorption by activated charcoal, low intrinsic clearance, sufficient residence time in the body (long serum half-life), long distributive phase, and nonrestrictive protein binding. A small volume of distribution is also desirable, but it has a marginal influence as an isolated characteristic,⁴¹ particularly if multiple-dose activated charcoal is instituted during the toxin's distributive phase. A typical dosage schedule is 15–25 g activated charcoal every 2 to 6 hours until serious symptoms abate or the serum concentration of the toxin is below the toxic range. This procedure has been used in premature and full-term infants in doses of 1 g/kg every 1 to 4 hours. Serious complications, such as pulmonary aspiration, occur in less than 1% of patients.⁴² The

risks of aspiration pneumonitis in obtunded or uncooperative patients and of intestinal obstruction in patients prone to ileus following a period of bowel ischemia, for example, after cardiopulmonary arrest in the elderly may be higher.⁴³ Contraindications are the same as those for single-dose charcoal.

■ Hemodialysis

Hemodialysis may be necessary for certain severe cases of poisoning. Dialysis should be considered when the duration of symptoms is expected to be prolonged, other pathways of excretion are unavailable, clinical deterioration is present, the drug is dialyzable, and appropriate personnel and equipment are available. Drugs that are hemodialyzable usually have a low molecular weight, are not highly or tightly protein bound, and are not highly distributed to tissues. The principles of hemodialysis for acutely ill individuals are described in Chap. 45. Hemodialysis and charcoal hemoperfusion are the most efficient methods of dialysis, but both pose serious risks related to anticoagulation, blood transfusions, loss of blood elements, fluid and electrolyte disturbances, and infection.⁴⁴ Hemodialysis may be lifesaving for methanol and ethylene glycol poisoning and effective for other poisons, such as lithium, salicylates, ethanol, and theophylline.^{14,34} Charcoal hemoperfusion was popular in the 1970s and 1980s as a means to remove toxins quickly from the circulation, but this approach has fallen out of favor owing to poor results, inappropriate use for drugs with large volumes of distribution, and limited commercial availability of charcoal hemoperfusion columns. Continuous hemofiltration transports drugs across a semipermeable membrane by convection in response to hydrostatic pressure gradients.^{14,44} Limited experience is reported with the use of hemofiltration for poisonings, but it may be attractive for the hemodynamically unstable patient who cannot tolerate hemodialysis.

■ ANTIDOTES

5 The search for and use of an antidote should never replace good supportive care.³⁴ Specific systemic antidotes are available for many common poisonings^{45,46} (Table 10–9). Inadequate availability of antidotes at acute care hospitals has been noted throughout the United States and can complicate the care of a poisoned patient. An evidenced-based consensus of experts has recommended minimum stocking requirements for 16 antidotes for acute care hospitals.⁴⁷ These recommendations may provide guidance to pharmacy and therapeutics committees in establishing a hospital's antidote needs. Drugs used conventionally for nonpoisoning situations may act as antidotes to reverse acute toxicity, such as glucagon for β -adrenergic blocker or calcium channel antagonist overdose and octreotide for sulfonylurea-induced hypoglycemia.⁴⁸ As our understanding of drug toxicity increases, antidotes may have applications beyond contemporary indications, such as acetylcysteine, which has shown promise for treating approximately 25 different poisonings and adverse drug reactions.⁴⁹ The use of toxin-specific antibodies (e.g., Fab antibody fragments for digoxin⁵⁰ or crotalid snake venom⁵¹) has offered a new approach to the treatment of poisoning victims.

■ ASSESSING THE EFFECTIVENESS OF THERAPIES

Our knowledge of poisoning treatment is derived from case reports, clinical studies, human volunteer studies, animal investigations, and

TABLE 10–9. Systemic Antidotes Available in the United States

| Antidote | Toxic Agent |
|---|---|
| Acetylcysteine | Acetaminophen |
| Atropine | Anticholinesterase insecticides |
| Botulism antitoxin | Botulism |
| Calcium EDTA | Lead |
| <i>Crotalidae</i> polyvalent antivenin | Rattlesnakes, cottonmouth snakes, copperhead snakes |
| <i>Crotalidae</i> polyvalent immune Fab | Rattlesnakes, cottonmouth snakes, copperhead snakes |
| Cyanide antidote kit (Amyl nitrite, sodium nitrate, and sodium thiosulfate) | Cyanide |
| Deferoxamine | Iron |
| Digoxin immune Fab | Digoxin, digitoxin |
| Dimercaprol | Various heavy metals |
| Ethanol | Ethylene glycol, methanol |
| Flumazenil | Benzodiazepines |
| Fomepizole | Ethylene glycol, methanol |
| <i>Lactrodectus mactans</i> antivenin | Black widow spider |
| Methylene blue | Methemoglobinemia |
| <i>Micrurus fulvius</i> antivenin | Coral snake |
| Nalmefene | Opioids |
| Naloxone | Opioids |
| Oxygen | Carbon monoxide |
| Penicillamine | Various heavy metals |
| Phytonadione | Anticoagulants |
| Pralidoxime | Organophosphate insecticides |
| Succimer | Lead |

in vitro tests. Each of these approaches has limited applicability to the care of humans who have been poisoned. Case reports often are difficult to assess because they are uncontrolled, the histories are uncertain, and multiple therapies frequently are used. They can, however, be useful to describe unique or new toxicities or characterize adverse effects associated with a therapy. Although clinical studies may describe tens to hundreds of patients, they can exhibit serious shortcomings, such as weak randomization procedures, no laboratory confirmation or correlation with history, insufficient number of severe cases, no control group, and no quantitative measure of outcome. Extrapolation of data from human volunteer studies to patients who overdose is difficult because of potential or unknown variations in pharmacokinetics (e.g., differing dissolution, gastric emptying, and absorption rates) seen with toxic as opposed to therapeutic doses,^{20,21} differences in time to institute therapy in the emergency setting, and differences in absorption in fasted human volunteers compared with the full stomach of some patients who overdose. These studies, however, provide the most controlled and objective measures of the efficacy of a treatment. Experiences from animal studies cannot be applied directly to humans because of interspecies differences in toxicity and metabolism. In vitro tests serve to screen the efficacy of some approaches, such as activated charcoal adsorption, but they do not mimic physiologic conditions sufficiently to allow direct clinical application of the findings. Despite their limitations, these data comprise the basis for the therapy of poisoned patients and are tempered with the consideration of non-poisoning-related factors such as a particular patient's underlying medical condition, age, and need for concurrent supportive measures.

CLINICAL SPECTRUM OF POISONING

Poisoning and drug overdose with acetaminophen, anticholinesterase insecticides, calcium channel blockers, iron, and tricyclic antidepressants are the focus of the remainder of this chapter because they represent commonly encountered poisonings for which pharmacotherapy is indicated. These agents also were chosen because they represent common examples with different mechanisms of toxicity, and they illustrate the application of general treatment approaches as well as some agent-specific interventions.

ACETAMINOPHEN

CLINICAL PRESENTATION

6 Acute acetaminophen poisoning characteristically results in hepatotoxicity^{52,53} and is the leading cause of acute liver failure in the United States.⁵⁴ Clinical presentation (see below) is determined by the time required for hepatic necrosis to occur, presence of risk factors, and the ingestion of other drugs. During the first 12 to 24 hours after ingestion, nausea, vomiting, anorexia, and diaphoresis may be observed; however, many patients are asymptomatic. During the next 1 to 3 days, a latent phase of lessened symptoms, patients often have an asymptomatic rise in liver enzymes and bilirubin. Signs and symptoms of hepatic injury become manifest 3 to 5 days after ingestion and include right upper quadrant abdominal tenderness, jaundice, hypoglycemia, and encephalopathy. Prolongation of the prothrombin time worsens as hepatic necrosis progresses and may lead to disseminated intravascular coagulopathy. Patients with hepatic damage may develop hepatic coma, hepatorenal syndrome and death can occur.^{52,53,55} Even in patients with severe hepatotoxicity, there are usually no resid-

ual functional or histologic abnormalities of the liver noted within 1 to 6 months of the incident.⁵³

CLINICAL PRESENTATION OF ACUTE ACETAMINOPHEN POISONING

GENERAL

- No or mild nonspecific symptoms within 6 hours of ingestion

SYMPTOMS

- Nausea, vomiting, and abdominal discomfort within hours after ingestion
- Right upper abdominal quadrant tenderness typically within 1 to 2 days
- Jaundice, scleral icterus, bleeding within 3 to 10 days
- With severe poisoning, hepatic encephalopathy (delirium, coma) within 5 to 10 days

SIGNS

- Typically no signs present within first day
- Oliguria occasionally within 2 to 7 days
- Depressed reflexes and hypotension within 5 to 10 days with encephalopathy

LABORATORY TESTS

- Toxic serum acetaminophen concentration no earlier than 4 hours after ingestion by comparison with nomogram
- Elevated aspartate aminotransferase (AST), alanine aminotransferase (ALT), serum bilirubin, and international

normalization ratio (INR); hypoglycemia within 1 to 3 days

- Elevated serum creatinine and blood urea nitrogen (BUN) within 2 to 7 days

OTHER DIAGNOSTIC TESTS

- Ultrasound for hepatomegaly, if warranted

MECHANISM OF TOXICITY

Acetaminophen is metabolized in the liver primarily to glucuronide or sulfate conjugates, which are excreted into the urine with small amounts (<5%) of unchanged drug. Approximately 5% of a therapeutic dose is metabolized by the cytochrome P450 mixed-function oxygenase system, primarily CYP2E1, to a reactive metabolite, *N*-acetyl-*p*-benzoquinone-imine (NAPQI). This metabolite normally is conjugated with glutathione, a sulfhydryl-containing compound, in the hepatocyte and excreted in the urine as a mercapturate conjugate⁵⁵ (Fig. 10–2).

In an acute overdose situation, sulfate stores are depleted, shifting more drug through the cytochrome system, thereby depleting the available glutathione used to detoxify the reactive metabolite. The reactive metabolite, NAPQI, then reacts with other hepatocellular sulfhydryl compounds such as those in the cytosol, cell wall, and endoplasmic reticulum. This results in centrilobular hepatic necrosis.⁵⁵ Several other mechanisms, such as cytokine release or oxidative stress, also may be initiated by the initial cellular injury.⁵⁵

In many cases of severe hepatotoxicity, renal injury is also present and may range from oliguria to acute renal failure. The etiology of the renal injury may be a direct effect of a toxic metabolite of acetaminophen, *N*-acetyl-*p*-benzoquinone-imine (discussed in the next section), generated by renal cytochrome oxidase or a consequence of hepatic injury resulting in hepatorenal syndrome.⁵⁶ Isolated cases of myocardial injury have been reported rarely.⁵⁷

CAUSATIVE AGENTS

Acetaminophen, also known as paracetamol in other countries, is available widely without prescription as an analgesic and antipyretic. It is available in various oral dosage forms, including an extended-release preparation. Acetaminophen may be combined with other drugs, such as antihistamines or opioid analgesics, and marketed in cough and cold preparations, menstrual remedies, and allergy products.

FIGURE 10–2. Pathway of acetaminophen metabolism and basis for hepatotoxicity. (NAPQI, *N*-acetyl-*p*-benzoquinone-imine, a reactive acetaminophen metabolite.)

INCIDENCE

Acetaminophen is one of the most commonly ingested drugs by small children and is used commonly in suicide attempts by adolescents and adults. The 2003 AAPCC-TESS report documented 61,755 nonfatal exposures and 147 deaths from acetaminophen, with 48% of the exposures in children younger than 6 years of age.⁶

Age-based differences in the metabolism of acetaminophen appear to be responsible for major differences in the incidence of serious toxicity. Despite the common ingestion of acetaminophen by young children, few develop hepatotoxicity from acute overdosage.⁶ In children younger than 9 to 12 years of age, acetaminophen undergoes more sulfation and less glucuronidation. The reduced fraction available for metabolism by the cytochrome system may explain the rare development of serious toxicity in young children who take large overdoses. Earlier treatment intervention and spontaneous emesis also may reduce the risk of toxicity in children.

RISK ASSESSMENT

There is a risk of developing hepatotoxicity when adolescents or adults acutely ingest more than 7.5 g acetaminophen or when children acutely ingest more than 150 mg/kg.⁵² The least amount reported to produce death is 10 g in an adult, but others have survived much larger doses, particularly with early treatment. Initial symptoms, if present, do not predict how serious the toxicity eventually may become.

Chronic exposure to drugs that induce the cytochrome oxidase system—specifically isoenzyme CYP2E1, which is responsible for most of the formation of NAPQI—may increase the risk of acetaminophen hepatotoxicity. Poorer outcomes have been noted in patients who chronically ingest alcohol and those receiving anticonvulsants, both known to induce CYP2E1.^{53,58} Patients with chronic alcoholism have a 3.5 greater odds of mortality with acute acetaminophen poisoning.⁵⁹ Concurrent acute ingestion of alcohol and acetaminophen may decrease the risk of acetaminophen-induced hepatotoxicity by ethanol acting as a competitive substrate for CYP2E1, thus reducing NAPQI formation.⁶⁰ Ethanol co-ingestion is not advocated as a preventive measure, and it is difficult to account for its specific impact on care.

Chronic, excessive acetaminophen consumption, defined as doses exceeding the recommended daily doses of 4 g for an adult and 90 mg/kg for a child for several days, has been associated with hepatotoxicity.⁵³ The incidence is unknown, and the basis of this association is not well understood. Patients who are fasting or have ingested alcohol in the preceding 5 days appear to be at greater risk.⁶¹ Young children who receive acetaminophen in excess of the recommended total daily dose of 50–75 mg/kg have a risk of developing hepatotoxicity, particularly when they have been acutely fasting as the result of a febrile illness or gastroenteritis.^{62,63}

The risk of developing hepatotoxicity may be predicted from a nomogram (Fig. 10–3) based on the acetaminophen serum concentration and time after ingestion.⁵² The treatment line of the nomogram (150 mcg/mL at 4 hours), which allows a margin of error in laboratory analysis and time of ingestion, should be used to make treatment decisions. The other lines on the nomogram indicate differing levels of risk for hepatotoxicity based on a multicenter study of 11,195 patients.⁵²

If the plasma concentration plotted on the nomogram falls above the nomogram treatment line, indicating that hepatic damage is possible, a full course of treatment with acetylcysteine is indicated. When the results of the acetaminophen determination will be available later than 8 hours after the ingestion, acetylcysteine therapy should be

FIGURE 10-3. Nomogram for assessing hepatotoxic risk following acute ingestion of acetaminophen. (Adapted from reference 52.)

initiated based on the history and later discontinued if the results indicate nontoxic concentrations. The nomogram has not been evaluated and thus is not useful for assessing chronic exposure to acetaminophen. Some have advocated that patients with chronic alcoholism should be treated with acetylcysteine regardless of the risk estimation.⁵⁹

MANAGEMENT OF TOXICITY

Therapy of an acute acetaminophen overdose depends on the amount ingested, time after ingestion, and the serum concentration of acetaminophen. When adolescents or adults ingest excessive amounts, when the history is unclear, or when an intentional ingestion is suspected, the patient must be evaluated at an emergency department and acetaminophen serum concentrations obtained. No prehospital care generally is indicated, and ipecac syrup typically is avoided. If the patient presents to the emergency department within 4 hours of the ingestion or other drugs are suspected, one dose of activated charcoal may be administered.

Acetylcysteine (also known as *N*-acetylcysteine), a sulfhydryl-containing compound, replenishes the hepatic stores of glutathione by serving as a glutathione surrogate that combines directly with reactive metabolites or by serving as a source of sulfate, thus preventing hepatic damage.⁶⁴ It should be started within 10 hours of the ingestion to be most effective.⁵² Initiation of therapy 24 to 36 hours after the ingestion may be of value in some patients, particularly those with measurable serum acetaminophen concentrations.^{64,65} Patients with fulminant hepatic failure may benefit through other mechanisms by the administration or initiation of acetylcysteine several days after ingestion.⁶⁴

CLINICAL CONTROVERSY

The routine administration of acetylcysteine more than 24 hours after acetaminophen overdose has been proposed. Case reports and animal studies indicate that it is relatively safe and that its use may minimize hepatotoxicity. Although accepted criteria for its use are lacking, it may be considered for patients with fulminant hepatotoxicity, when acetaminophen is still measurable in the serum, or when the ingestion was not recognized within 24 hours and liver toxicity is apparent.

Therapy should be initiated with the oral or intravenous form of acetylcysteine within 10 hours of ingestion when indicated. The oral liquid was the only approved form of acetylcysteine in the United States until the Food and Drug Administration (FDA) approved an intravenous form in 2004. Besides the means of administration, there are several notable differences^{49,52,66,67} (Table 10-10). The 20-hour dosage regimen for the intravenous form is based on one used in Europe for two decades and has similar outcome to the 72-hour oral regimen.^{49,68} The preference for the oral or intravenous form of acetylcysteine will evolve during the next few years of experience.

When plasma concentrations are below the nomogram treatment line, there is little risk of toxicity, protective therapy with acetylcysteine is not necessary, and further medical therapy is unnecessary for the acetaminophen overdose.⁵² The acetaminophen blood sample should be drawn no sooner than 4 hours after the ingestion to ensure that peak acetaminophen concentrations have been reached.

TABLE 10-10. Comparison of Intravenous and Oral Regimens for Acetylcysteine in the Treatment of Acute Acetaminophen Poisoning

| Characteristic | Intravenous | Oral |
|---|--|--|
| Regimen (D ₅ W = 5% dextrose in water for injection) | 150 mg/kg in 200 mL D ₅ W infused over 15 minutes, then 50 mg/kg in 500 mL D ₅ W over 4 hours, followed by 100 mg/kg in 1000 mL D ₅ W over 16 hours | 140 mg/kg, followed 4 hours later by 70 mg/kg every 4 hours for 17 doses diluted to 5% with juice or soft drinks |
| Total dose (mg/kg) | 200 | 1330 |
| Duration (h) | 20 | 72 |
| Adverse effects | Anaphylactoid reactions (rash, hypotension, wheezing, dyspnea); acute flushing and erythema in first hour of the infusion that typically resolves spontaneously | Nausea, vomiting |
| Ancillary therapy, if needed | Antihistamines and epinephrine for severe anaphylactic reactions | Antiemetics, e.g., metoclopramide, ondansetron, or droperidol |
| Tradename | Acetadote | Mucomyst |
| Available strength | 20% | 10%, 20% |

If a concentration is obtained less than 4 hours after ingestion, it is uninterpretable, and a second determination should be done at least 4 hours after ingestion. Serial determinations of a serum concentration, 4 to 6 hours apart, typically are unnecessary unless there is some evidence of slowed gastrointestinal motility from other ingested drugs (e.g., opioids, antihistamines, or anticholinergic drugs) or unless an extended-release product is involved. Therapy with acetylcysteine is continued if any concentration is above the treatment line of the nomogram, and therapy is discontinued when both concentrations are below the treatment line.

Although young children have an inherently lower risk of acetaminophen-induced hepatotoxicity, these patients should be managed in the same manner as adults. When acetaminophen plasma concentrations predict that toxicity is probable, young children should receive acetylcysteine in the dosing regimen described previously.⁵⁸

If fulminant hepatic failure develops, the approaches described in Chap. 37 should be considered. In unresponsive patients, liver transplantation is a lifesaving option.⁵³

MONITORING AND PREVENTION

Baseline liver function tests (AST, ALT, bilirubin, prothrombin time), serum creatinine determination, and urinalysis should be obtained on admission and repeated at 24-hour intervals until at least 96 hours have elapsed for those at risk. Most patients with liver injury develop elevated transaminase concentrations within 24 hours of ingestion. Transaminase concentrations greater than 1000 IU/L commonly are associated with other signs of liver dysfunction and have been used as the threshold concentration in outcome studies to define severe liver toxicity.⁵² The extent of transaminase elevation is not correlated directly with severity of the hepatic injury, with nonfatal cases demonstrating peak concentrations as high as 30,000 IU/L between 48 and 72 hours after ingestion.⁵³

Prevention of acetaminophen poisoning is based on recognition of the maximum daily therapeutic doses, observance of general poison prevention practices, and early intervention in cases of suspected overdose.

ANTICHOLINESTERASE INSECTICIDES

CLINICAL PRESENTATION

7 The clinical manifestations of anticholinesterase insecticide poisoning include any or all of the following: pinpoint pupils, excessive lacrimation, excessive salivation, bronchorrhea, bronchospasm and expiratory wheezes, hyperperistalsis producing abdominal cramps and diarrhea, bradycardia, excessive sweating, fasciculations and weakness of skeletal muscles, paralysis of skeletal muscles (particularly those involved with respiration), convulsions, and coma.⁶⁹ Symptoms of anticholinesterase poisoning and their response to antidotal therapy depend on the action of excessive acetylcholinesterase at different receptor types (Table 10–11).

TABLE 10–11. Effects of Acetylcholinesterase Inhibition at Muscarinic, Nicotinic, and CNS Receptors

| | |
|-----------------------------------|--|
| Muscarinic Receptors | Nicotinic–Sympathetic Neurons |
| Diarrhea | Increased blood pressure |
| Urination | Sweating and piloerection |
| Miosis ^a | Mydriasis ^a |
| Bronchorrhea | Hyperglycemia |
| Bradycardia ^a | Tachycardia ^a |
| Emesis | Priapism |
| Lacrimation | Nicotinic–Neuromuscular Neurons |
| Salivation | Muscular weakness |
| CNS Receptors (Mixed Type) | Cramps |
| Coma | Fasciculations |
| Seizures | Muscular paralysis |

^aGenerally muscarinic effects predominate, but nicotinic effects can be observed.

The time of onset and severity of symptoms depend on the route of exposure, potency of the agent, and total dose received (see below). Toxic signs and symptoms develop most rapidly after inhalation or intravenous injection and slowest after skin contact. Anticholinesterase insecticides are absorbed through the skin, lungs, conjunctivae, and gastrointestinal tract. Severe symptoms can occur from absorption by any route. Within 6 hours, most patients are symptomatic, and without treatment, death may occur within 24 hours. Death typically is caused by respiratory failure owing to the combination of pulmonary and cardiovascular effects⁶⁹ (Fig. 10–4). Poisoning may be complicated by aspiration pneumonia, urinary tract infections, and sepsis.⁷⁰

CLINICAL PRESENTATION OF ANTICHOLINESTERASE INSECTICIDE POISONING

GENERAL

- Mild symptoms may resolve spontaneously; life-threatening toxicity may develop with 1 to 6 hours of exposure

SYMPTOMS

- Diarrhea, diaphoresis, urination, miosis, blurred vision, pulmonary congestion, dyspnea, emesis, lacrimation, salivation, and shortness of breath within 1 hour
- Muscle weakness, fasciculations, and respiratory paralysis within 1 to 6 hours
- Headache, confusion, coma, and seizures possible within 1 to 6 hours

SIGNS

- Increased bronchial secretions, tachypnea, rales, and cyanosis within 1 to 6 hours

FIGURE 10–4. Pathogenesis of life-threatening effects of organophosphate poisoning.

- Bradycardia, atrial fibrillation, atrioventricular block, and hypotension within 1 to 6 hours

LABORATORY TESTS

- Depressed erythrocyte cholinesterase activity (not readily available)
- Markedly depressed serum pseudocholinesterase activity below normal range
- Altered arterial blood gases, serum electrolytes, BUN, and serum creatinine in response to respiratory distress and shock within 1 to 6 hours

OTHER DIAGNOSTIC TESTS

- Chest radiographs for progression of pulmonary edema or hydrocarbon pneumonitis in symptomatic patients
- Electrocardiogram (ECG) with continuous monitoring and pulse oximetry for complications from toxicity and hypoxia

MECHANISM OF TOXICITY

Anticholinesterase insecticides phosphorylate the active site of cholinesterase in all parts of the body.^{69,71} Inhibition of this enzyme leads to accumulation of acetylcholine at affected receptors and results in widespread toxicity. Acetylcholine is the neurohormone responsible for physiologic transmission of nerve impulses from preganglionic and postganglionic neurons of the cholinergic (parasympathetic) nervous system, preganglionic adrenergic (sympathetic) neurons, the neuromuscular junction in skeletal muscles, and multiple nerve endings in the central nervous system (Fig. 10–5).

CAUSATIVE AGENTS

Anticholinesterase insecticides include organophosphate and carbamate insecticides. These insecticides are currently in widespread

TABLE 10–12. Commonly Used Organophosphate Insecticides

| Chemical Name | Product Name Examples |
|---|------------------------------|
| Agricultural Use: High Potency | |
| Disulfoton | Di-syston |
| Mevinphos | Phosdrin |
| Parathion | Niagara Phos Kil Dust |
| Animal Use: Intermediate Potency | |
| Coumaphos | Co-Ral, Baymix |
| Dichlorphos | Agridip, Muscatox |

use throughout the world for the eradication of insects in dwellings and crops. Carbamates typically are less potent and inactivate cholinesterase in a more reversible fashion through carbamylation compared with organophosphates.⁶⁹ The prototype anticholinesterase agent is the organophosphate, which will be the focus of this discussion. A large number of organophosphates are used as pesticides (Table 10–12), and several also have been used as potent chemical warfare or terrorist agents (e.g., sarin, tabun, and VX, which are known as nerve agents).^{72,74} The chemical warfare agents act like organophosphate insecticides, but as a group they are highly potent, absorbed quickly, and deadly to humans.^{73,74} An anticholinesterase insecticide typically is stored in a garage, chemical storage area, or living area. Anticholinesterase agents also can be found in occupational (e.g., pest exterminators) or agricultural (e.g., crop dusters or farm workers) settings. These agents also have been used as a means for suicide or homicide.

INCIDENCE

Anticholinesterase insecticides are among the most poisonous substances commonly used for pest control and are a frequent source of serious poisoning in children and adults in rural and urban settings. The 2003 AAPCC-TESS report documented 11,332 nonfatal exposures and 19 deaths from anticholinesterase insecticides alone or in combination with other pesticides, with 31% of the exposures in children younger than 6 years of age.⁶

RISK ASSESSMENT

The triad of miosis, bronchial secretions, and muscle fasciculations should suggest the possibility of anticholinesterase insecticide poisoning and warrants a therapeutic trial of the antidote atropine. In cases of low-level exposure, failure to develop signs within 6 hours indicates a low likelihood of subsequent toxicity.⁶⁹ Ruling out other chemical exposures may be guided initially by symptoms at presentations.¹⁶

Although the lethal dose for parathion is approximately 4 mg/kg, as little as 10–20 mg can be lethal to an adult and 2 mg (0.1 mg/kg) to a child. Small children may be more susceptible to toxicity because less pesticide is required per body weight to produce toxicity.^{69,73} Estimation of an exact dose is impossible in most cases of acute poisoning, and tabulated “toxic” doses thus generally are not helpful in assessing risk of toxicity. Generally, ingestion of a small mouthful (≈5 mL) of the concentrated forms of an organophosphate intended

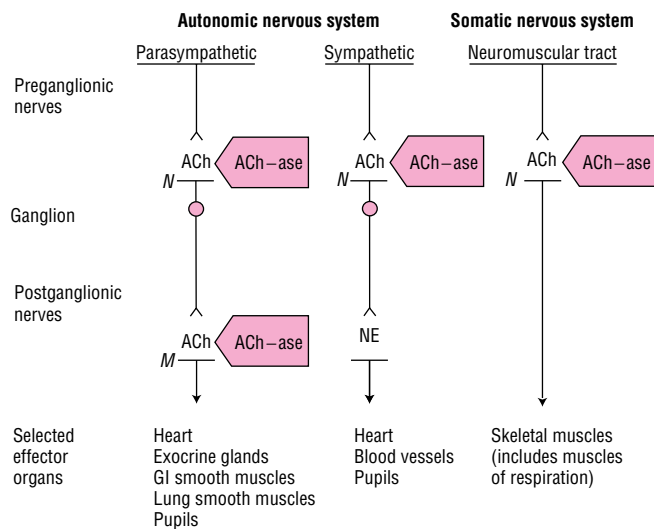

FIGURE 10–5. Organization of neurotransmitters of the peripheral nervous system and site of acetylcholinesterase action. (ACh, acetylcholine; ACh-ase, acetylcholinesterase; NE, norepinephrine; M, muscarinic receptor; N, nicotinic receptor.)

to be diluted for commercial or agricultural use will produce serious toxicity, whereas a mouthful of an already diluted household product such as an insecticide typically does not produce serious toxic effects.⁷³

Measurement of acetylcholinesterase activity at the neuronal synapse is not feasible clinically. Cholinesterase activity can be measured in the blood as the pseudocholinesterase (butylcholinesterase) activity of the plasma and acetylcholinesterase activity in the erythrocyte. Both cholinesterases will be depressed with anticholinesterase insecticide poisoning.^{69,75} Severity can be estimated roughly by the extent of depressed activity in relation to the low end of normal values. Because there are several methods to measure and report cholinesterase activity, each particular laboratory's normal range must be considered. Clinical toxicity usually is seen only after a 50% reduction in enzyme activity, and severe toxicity typically is observed with levels at 20% or less of the normal range.^{71,73,75} The intrinsic activity of acetylcholinesterase may be depressed in some individuals, but the absence of any manifestations in most people does not permit the recognition of the relative deficiency in the general population. Therapy should not be delayed pending laboratory confirmation when the clinical suspicion of poisoning is present.

MANAGEMENT OF TOXICITY

People handling the patient should wear gloves and aprons to protect themselves against contaminated clothing, skin, or gastric fluid of the patient.^{69,73} Because many insecticides are dissolved in a hydrocarbon vehicle, there is an additional risk of pulmonary aspiration of the hydrocarbon leading to pneumonitis. The risks and benefits of prehospital ipecac-induced emesis should be considered carefully and should involve consultation with a poison control center or clinical toxicologist. Symptomatic cases of anticholinesterase insecticide exposure typically are referred to an emergency department for evaluation and treatment.

If the poison has been ingested within the hour, gastric lavage should be considered and followed by the administration of activated charcoal. The patient with skin contamination should be washed with copious amounts of soap and water. An alcohol wash may be useful to remove residual insecticide due to its lipophilic nature. A surgical scrub kit for the hands, feet, and nails may be useful for exposure to those areas. Supportive therapy should include maintenance of an airway (including bronchotracheal suctioning), provision of adequate ventilation, and establishment of an intravenous line. Based on a history of an exposure and presence of typical symptoms, the anticholinesterase syndrome should be recognized without difficulty.

The pharmacologic management of organophosphate intoxication relies on the administration of atropine and pralidoxime.^{69,71,73} Atropine has no effect on inhibited cholinesterase, but it competi-

tively blocks the actions of acetylcholine on cholinergic and some central nervous system receptors. It thereby alleviates bronchospasm and reduces bronchial secretions. Although atropine has little effect on the flaccid muscle paralysis or the central respiratory failure of severe poisoning, it is indicated in all symptomatic patients and can be used as a diagnostic aid. It should be given intravenously and in larger than conventional doses of 0.05–0.1 mg/kg in children younger than 12 years of age and 2–5 mg in adolescents and young adults.⁷³ It should be repeated at 5- to 10-minute intervals until bronchial secretions and pulmonary rales resolve. Therapy may require large doses over a period of several days until all absorbed organophosphate is metabolized, and acetylcholinesterase activity is restored.

Restoration of enzyme activity is necessary for severe poisoning, characterized by reduction of cholinesterase activity to less than 20% of normal, profound weakness, and respiratory distress. Pralidoxime (Protopam), also called 2-PAM or pyridine aldoxamine methiodide, breaks the covalent bond between the cholinesterase and organophosphate and regenerates enzyme activity. Organophosphate-cholinesterase binding is reversible initially, but it gradually becomes irreversible. Therefore, therapy with pralidoxime should be initiated as soon as possible, preferably within 36 to 72 hours of exposure.⁷³ The drug should be given at a dose of 25–50 mg/kg up to 1 g intravenously over 5 to 20 minutes. If muscle weakness persists or recurs, the dose may be repeated after an hour and again if needed. A continuous infusion of pralidoxime has been shown to be effective in adults when administered at 3.2 mg/kg per hour preceded by a loading dose of 4 mg/kg⁷⁶ and in children at 10–20 mg/kg per hour with a loading dose of 15 to 50 mg/kg.⁷⁷ Both atropine and pralidoxime should be given together since they have complementary actions (Table 10–13). Carbamate insecticide poisonings typically do not require the administration of pralidoxime.

CLINICAL CONTROVERSY

Some references indicate that pralidoxime should be avoided in the treatment of carbamate (another type of anticholinesterase insecticide) poisoning because of reports of worsened toxicity in animals. Pralidoxime may be considered when exposure to carbamates is not known but an anticholinesterase is suspected based on symptoms or when respiratory paralysis due to nicotinic effects is not managed sufficiently by mechanical ventilation.

One of the pitfalls of therapy is the delay in administering sufficient doses of atropine or pralidoxime.^{69,73} The adverse effects of atropine and pralidoxime, predictable extensions of their anticholinergic actions, are minimally important compared with the life-threatening effects of severe anticholinesterase poisoning and can be minimized easily by decreasing the dose.

TABLE 10–13. Comparative Characteristics of Atropine and Pralidoxime for Anticholinesterase Poisoning

| Characteristic | Atropine | Pralidoxime |
|-------------------------|-----------------------------------|--|
| Interaction | Synergy with pralidoxime | Reduces atropine dose requirement |
| Indication | Any anticholinesterase agent | Typically needed for organophosphates |
| Primary sites of action | Muscarinic, CNS | Nicotinic > muscarinic > CNS |
| Adverse effects | Coma, hallucinations, tachycardia | Dizziness, diplopia, tachycardia, headache |
| Daily dose ^a | 2–1600 mg | 1–12 g |
| Total dose ^a | 2–11, 422 mg | 1–92 g |

^aRange of reported cases; higher doses may be required in rare cases.

MONITORING AND PREVENTION

Poisoned patients may require monitoring of vital signs, measurement of ventilatory adequacy such as blood gases and pulse oximetry, leukocyte count with differential to assess development of pneumonia, and chest radiographs to assess the degree of pulmonary edema or development of hydrocarbon pneumonitis. Workers involved in the formulation and application of pesticides should be monitored by periodic measurement of cholinesterase activity in their bloodstream. Untreated, anticholinesterase-depressed acetylcholinesterase activity returns to normal values in approximately 120 days.

Many anticholinesterase insecticide poisonings are unintentional as a result of misuse, improper storage, and failure to follow instructions for mixing or application, or inability to read directions for use. Training and vigilant adherence to directions may minimize some poisonings. Storing pesticides in original or labeled containers can minimize the risk of unintentional ingestion. Keeping pesticides out of children’s reach may decrease the risk of childhood poisoning.⁷⁸

CALCIUM CHANNEL BLOCKERS

CLINICAL PRESENTATION

8 Overdosage with calcium channel blockers typically results in bradycardia and hypotension (Fig. 10–6). Many patients become lethargic and may develop agitation and coma. If the degree of hypotension becomes severe or is prolonged, the secondary effects of seizures, coma, and metabolic acidosis usually develop. Pulmonary edema, nausea and vomiting, and hyperglycemia are frequent complications of calcium channel blocker overdoses. Paralytic ileus, mesenteric ischemia, and colonic infarction have been observed in patients with severe hypotension. Many symptoms become manifest within 1 to 2 hours of ingestion (see below). If a sustained-release formulation is involved, the onset of overt toxicity may be delayed by 6 to 18 hours from the time of ingestion. Severe poisoning can result in refractory shock and cardiac arrest. Death can occur within 3 to 4 hours of ingestion^{79–82}.

CLINICAL PRESENTATION OF CALCIUM CHANNEL BLOCKER POISONING

GENERAL

- Life-threatening cardiac toxicity within 1 to 3 hours of ingestion, delayed by 12 to 18 hours if a sustained-release product is involved
- Increased cardiovascular toxicity with concurrent ingestion of β -adrenergic blockers or digoxin

SYMPTOMS

- Nausea and vomiting within 1 hour
- Dizziness, lethargy, coma, and seizures within 1 to 3 hours

SIGNS

- Hypotension and bradycardia within 1 to 6 hours
- Unresponsiveness and depressed reflexes within 1 to 6 hours
- Atrioventricular block, intraventricular conduction defects, and ventricular dysrhythmias on electrocardiogram

LABORATORY TESTS

- Hyperglycemia typically resolves spontaneously
- Altered arterial blood gases (metabolic acidosis), serum electrolytes, BUN, and serum creatinine in response to shock within 1 to 6 hours

OTHER DIAGNOSTIC TESTS

- Electrocardiogram with continuous monitoring and pulse oximetry to monitor for toxicity and shock
- Monitor for complications of pulmonary aspiration such as hypoxia and pneumonia by physical findings and chest radiographs

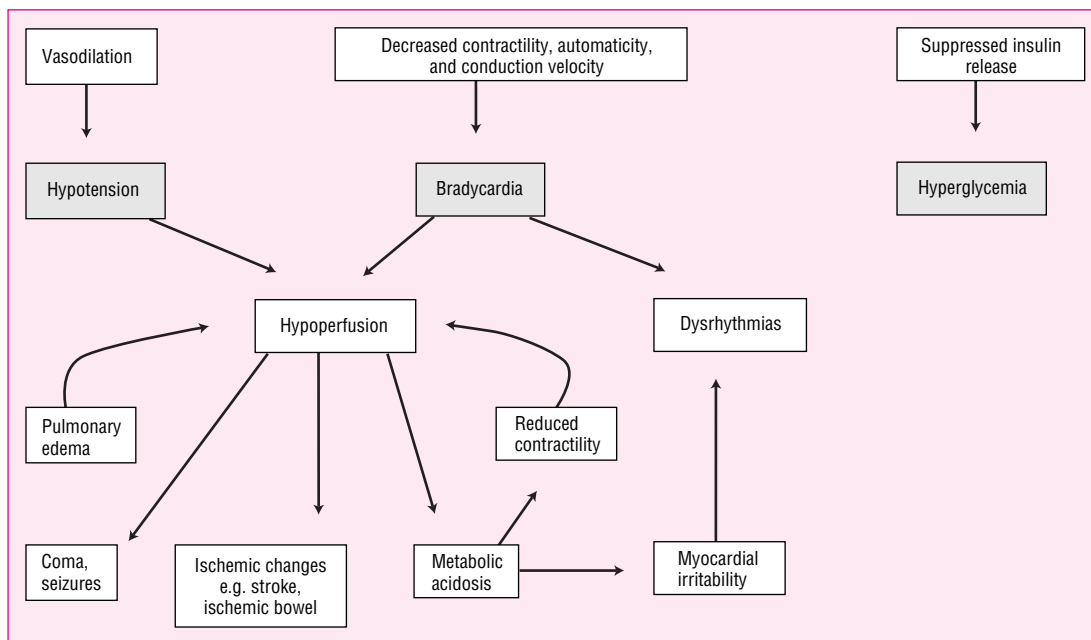

FIGURE 10–6. Pathophysiologic changes associated with calcium channel blocker poisoning.

MECHANISM OF TOXICITY

Most toxic effects of calcium channel blockers are produced by three basic actions on the cardiovascular system: vasodilation through relaxation of smooth muscles, decreased contractility by action on cardiac tissue, and decreased automaticity and conduction velocity through slow recovery of calcium channels. Calcium channel blockers interfere with calcium entry by inhibiting one or more of the several types of calcium channels and binding at one or more cellular binding sites.⁸³ Selectivity of these actions varies with the calcium channel blocker and provides some therapeutic distinctions (see Chap. 13), but these differences are less clear with overdose.⁸² Current experiences suggest that the signs and symptoms of calcium channel blocker toxicity are similar among the drugs in this class.

CAUSATIVE AGENTS

There are approximately a dozen calcium channel antagonists marketed in the United States for the treatment of hypertension, certain dysrhythmias, and some forms of angina (see Chaps. 13, 15, and 17). The calcium channel blockers are classified by their chemical structure as phenylalkylamines (e.g., verapamil), benzothiazines (e.g., diltiazem), and dihydropyridines (e.g., amlodipine, felodipine, nicardipine, and nifedipine). Several of these agents, namely, diltiazem, nicardipine, nifedipine, and verapamil, are formulated as sustained-release oral dosage forms or have a slow onset of action and longer half-life (e.g., amlodipine⁸⁴), allowing once-daily administration.

INCIDENCE

In 2003, the AAPCC-TESS report documented 9650 people with a toxic exposure to a calcium channel blocker, with 339 patients exhibiting and surviving major toxic effects.⁶ Fifty-seven people died. Poison control center reports have shown a steady increase in the number of cases of morbidity and mortality following calcium channel blocker overdose.

RISK ASSESSMENT

Ingestion of doses near or in excess of 1 g of diltiazem, nifedipine, or verapamil may result in life-threatening symptoms or death in an adult.^{79,85} Asymptomatic children who ingest less than 12 mg/kg of verapamil sustained release or 2.7 mg/kg of nifedipine sustained release may be monitored at home.⁸⁶ Doses associated with serious toxicity with the other agents have not been established. Patients on chronic therapy with these agents who acutely ingest an overdose may have a greater risk of serious toxicity. Elderly patients and those with underlying cardiac disease may not tolerate mild hypotension or bradycardia. Concurrent ingestion of β -adrenergic blocking drugs, digitalis, class I antiarrhythmics, and other vasodilators may worsen the cardiovascular effects of calcium channel blockers.^{80,82}

MANAGEMENT OF TOXICITY

There is no accepted specific prehospital care for calcium channel blocker poisoning except to summon an ambulance for symptomatic patients. Ipecac syrup should be avoided due to the risks of seizures and coma.^{82,85} The therapeutic options for the management of calcium channel blocker poisoning include supportive care, gastric decontamination, and adjunctive therapy for the cardiovascular and metabolic effects. Supportive care consists of airway protection, ventilatory

support, intravenous hydration to maintain adequate urine flow, and maintenance of electrolyte and acid-base balance. Maintaining vital organ perfusion is critical for successful therapy in order to allow time for calcium channel blocker toxicity to resolve.^{81,82}

Gastric lavage and a single dose of activated charcoal should be administered if instituted within 1 to 2 hours of ingestion. Besides exhibiting a slower onset of symptoms, sustained-release formulations also can form concretions in the intestine.^{82,85} Whole-bowel irrigation with polyethylene glycol electrolyte solution may accelerate rectal elimination of the sustained-release tablets and should be considered routinely for ingestion of sustained-release calcium channel antagonist formulations.^{32,87}

Adjunctive therapy is focused on treating hypotension, bradycardia, and resulting shock. Hypotension is treated primarily by correction of coexisting dysrhythmias (e.g., bradycardia, heart block) and implementation of conventional measures to treat decreased blood pressure. Infusion of normal saline and placement of the patient in the Trendelenburg position are initial therapy. Further fluid therapy should be guided by central venous pressure monitoring. Dopamine in conventional doses for cardiogenic shock should be considered next. If hypotension persists, dysrhythmias are present, or other signs of serious toxicity are present, calcium should be administered intravenously.^{79,82}

A calcium chloride bolus test dose (10–20 mg/kg up to 1 to 3 g) is the preferred therapy for patients with serious toxicity. In adults, calcium chloride 10% can be diluted in 100 mL normal saline and infused over 5 minutes through a central venous line. If a positive cardiovascular response is achieved with this test dose, a continuous infusion of calcium chloride (20–50 mg/kg per hour) should be started. Calcium gluconate is less desirable to use because it contains less elemental calcium per milligram of final dosage form. Intravenous calcium salts can produce vomiting and tissue necrosis on extravasation.^{48,82} Atropine also may be considered for treatment of bradycardia, but it is seldom sufficient as a sole therapy.⁸¹

If the bradycardia and hypotension are refractory to the foregoing therapy, a bolus infusion of glucagon (0.05–0.20 mg/kg) should be considered. Benefit typically is observed within 5 minutes of administration and can be sustained with a continuous intravenous infusion (0.05–0.1 mg/kg per hour) titrated to clinical response.⁸⁸ Glucagon possesses chronotropic and inotropic effects in part by stimulating adenylyl cyclase and increasing cyclic AMP, which may promote intracellular entry of calcium through calcium channels. It thereby may improve hypotension and bradycardia.⁴⁸ Vomiting is not uncommon with these large doses of glucagon, and the airway should be protected to avoid pulmonary aspiration. Hyperglycemia may occur or be exacerbated in those patients receiving glucagon therapy. Hyperglycemia from calcium channel blocker toxicity or glucagon therapy typically does not require treatment with insulin. Intravenous sodium bicarbonate, however, may be necessary to establish acid-base balance and correct the metabolic acidosis that is common with serious calcium channel blocker overdoses.

An insulin infusion should be considered for severe cases of calcium channel blocker toxicity.^{48,79,91} Case reports suggest that an intravenous bolus of regular insulin (0.5–1 units/kg) with 50 mL dextrose 50% (0.25 mg/kg for children) followed with a continuous infusion of regular insulin (0.5–1 units/kg per hour) may improve myocardial contractility. The effect of insulin is presently unclear, but it may improve myocardial metabolism that is adversely affected by calcium channel blocker overdoses, such as decreased cellular uptake of glucose and free fatty acids and a shift from fatty acid oxidation to carbohydrate metabolism.⁷⁹ This insulin regimen is titrated to improvement in systolic blood pressure over 100 mm Hg and heart rate

over 50 beats per minute. It is used for patients with serum glucose concentrations under 200 mg/dL. Serum glucose and potassium concentrations should be monitored closely. Patients with serum potassium concentrations below 2.5 mEq/L may need supplemental potassium (20 mEq intravenous infusion). The insulin infusion is reduced gradually as signs of toxicity resolve.

Therapies with glucagon and insulin are based on animal studies and case reports; clinical trials have not been performed to date to demonstrate effectiveness.^{48,79}

CLINICAL CONTROVERSY

Some clinicians believe that insulin or glucagon therapy for calcium channel antagonist poisoning should be used early in the course of therapy. Others reserve it for life-threatening symptoms not responsive to other therapy. More safety and effectiveness data are needed to define the place of these two agents in therapy.

Several lifesaving options may be warranted for patients with cardiogenic shock that is refractory to conventional therapy. Electrical cardiac pacing may restore an acceptable heart rate in patients with severe bradycardia.⁸² Intraaortic balloon counterpulsation or cardiopulmonary bypass may improve shock in patients unresponsive to other therapies.^{48,82,89,90}

Measures to enhance elimination from the bloodstream by hemodialysis or multiple-dose activated charcoal have not been shown to be effective and are not indicated for calcium channel blocker poisoning.^{39,80,82,92}

MONITORING AND PREVENTION

Regular monitoring of vital signs and electrocardiogram is essential in suspected calcium channel blocker poisoning. Determinations of serum electrolytes, serum glucose, arterial blood gases, urine output, and renal function are indicated to assess and monitor symptomatic patients. If serious toxicity is likely to develop, overt symptoms will manifest within 6 hours of ingestion.^{81,82} For ingestions of sustained-release products in toxic doses, observation for 24 hours in a critical care unit may be prudent because the onset of symptoms may be slow and delayed up to 12 to 18 hours after ingestion.^{79,87,92,93} Serum concentrations of these agents in overdose patients do not correlate well with the ingested dose, degree of toxicity, or outcome.⁸²

Poisonings owing to these agents are likely to increase as their therapeutic indications and use increase. These poisonings may be the result of an intentional suicide or unintentional ingestion by young children. Prevention of calcium channel blocker poisonings in children rests with the education of patients receiving these agents, particularly of grandparents and those who have children visit their homes infrequently, of their dangers on overdosage. Safe storage and use of child-resistant closures may reduce the opportunities for unintentional poisonings by children.⁸⁰

IRON

CLINICAL PRESENTATION

9 In the first few hours after the ingestion of toxic amounts of iron, symptoms of gastrointestinal irritation (e.g., nausea, vomiting, and diarrhea) are common (see below). In certain severe cases, acidosis and shock can become manifest within 6 hours of ingestion. Some have observed a quiescent phase between 6 and 48 hours after

ingestion where symptoms improve or abate, but this phenomenon is poorly characterized.⁹⁴ Continued gastrointestinal symptoms, poor perfusion, and oliguria should suggest the development of severe toxicity, with other effects still to become manifest. Generally, within 24 to 36 hours of the ingestion, central nervous system involvement with coma and seizures; hepatic injury characterized by jaundice, increased prothrombin time, increased bilirubin, and hypoglycemia; cardiovascular shock; and acidosis also develop.⁹⁴ Adult respiratory distress syndrome (ARDS) may develop in patients with severe cardiovascular shock and further compromise recovery.⁹⁵ Coagulopathy with decreased thrombin formation is one of the early direct effects of excessive iron concentrations, and later disturbances of coagulation (after 24 to 48 hours of ingestion) are a consequence of hepatotoxicity.⁹⁶ Mucosal injury, an iron-rich circulation, or deferoxamine therapy may promote septicemia with *Yersinia enterocolitica* during iron overdose; other bacteria or viruses also may cause septicemia.⁹⁴ Two to four weeks after the exposure, some patients experience persistent vomiting from gastric outlet obstruction as the result of pyloric and duodenal stenosis from the earlier gastric mucosal necrosis. Autopsy findings in children indicate prominent iron deposition in intestinal mucosa and periportal necrosis of the liver that correlate with the primary symptoms of serious iron poisoning.⁹⁷

CLINICAL PRESENTATION OF IRON POISONING

GENERAL

- Gastrointestinal symptoms shortly after ingestion with possible rapid progression to shock and coma

SYMPTOMS

- Vomiting, abdominal pain, and diarrhea within 1 to 6 hours
- Lethargy, coma, seizures, bloody vomiting, bloody diarrhea, and shock within 6 to 24 hours

SIGNS

- Hypotension and tachycardia within 6 to 24 hours
- Liver dysfunction and failure possible in 2 to 5 days

LABORATORY TESTS

- Toxic serum iron concentrations beyond 500 mcg/dL
- Altered arterial blood gases and serum electrolytes associated with a high anion gap metabolic acidosis within 3 to 24 hours
- Elevated BUN, serum creatinine, AST, ALT, and INR associated with systemic toxicity within 1 to 2 days

OTHER DIAGNOSTIC TESTS

- Guaiac test of stools for the presence of blood
- Abdominal radiograph to detect solid iron tablets in gastrointestinal tract

MECHANISM OF TOXICITY

The toxicity of acute iron poisoning includes local effects on the gastrointestinal mucosa and systemic effects induced by excessive iron in the body.^{94,95} Iron is irritating to the gastric and duodenal mucosa, which may result in hemorrhage and occasional perforations. Once

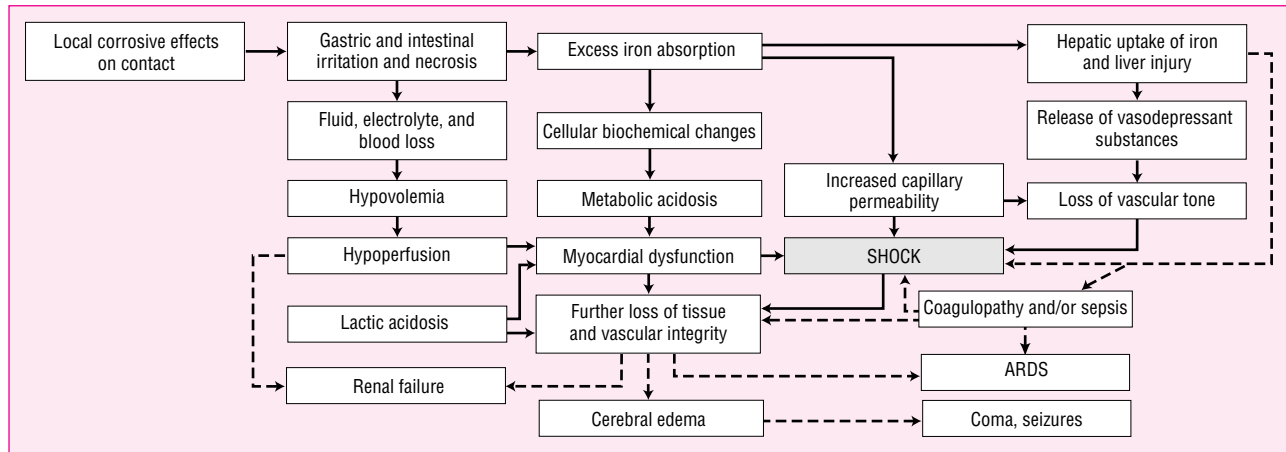

FIGURE 10-7. Pathophysiology of acute iron poisoning. Events indicated by dashed lines are not observed consistently in all serious poisonings. (ARDS, adult respiratory distress syndrome.)

absorbed, iron is taken up by tissues, particularly the liver, and acts as a mitochondrial poison. It occasionally causes hepatic injury. Iron may inhibit aerobic glycolysis and perturb the electron transport system. Further, iron may shunt electrons away from the electron transport system, thereby reducing the efficiency of oxidative phosphorylation. These biochemical factors, along with the cardiovascular effects of iron, lead to metabolic acidosis. The pathogenesis of shock is not well understood but may include the development of hypovolemia and lactic acidosis, release of endogenous vasodilators, and the direct vasodepressant effects of iron and ferritin on the circulation (see Fig. 10-7).

CAUSATIVE AGENTS

Iron poisoning results from the ingestion and absorption of excessive amounts of iron from iron tablets, multiple vitamins with iron, and prenatal vitamins. Different iron salts and formulations contain varying amounts of elemental iron (see Chap. 99). Generally, children's chewable vitamins are less likely to produce systemic iron poisoning due in part to lower iron content.

INCIDENCE

Acute iron poisoning can produce death in children and adults.^{97,98} An analysis by the Consumer Products Safety Commission concluded that iron poisoning remains a significant public health threat to young children based on injury and mortality data from 1980 through 1996.⁹⁸ The 2003 AAPCC-TESS report documented 32,991 nonfatal and 4 fatal cases, respectively, of iron poisoning, with 81% of the exposures in children younger than 6 years of age. In most cases (90%), multiple vitamins with iron were the source of iron.⁶

RISK ASSESSMENT

The minimum lethal and toxic doses for acute iron poisoning are not well established. The ingestion of 10–20 mg/kg elemental iron usually elicits mild gastrointestinal symptoms. The ingestion of 20–60 mg/kg is not likely to produce systemic toxicity, and typically these patients can be managed at home with observation and administration of a glassful of fluids. Ingestions of greater than 60 mg/kg usually are associated with serious systemic toxicity and require medical attention.

Immediate psychiatric and medical intervention is indicated for adults and adolescents who acutely ingest greater than 20 mg/kg elemental iron because this suggests that the overdose was intentional.^{94,95}

An abdominal radiograph (Fig. 10-8) may help to confirm the ingestion of iron tablets and indicate the need for aggressive gastrointestinal evacuation with whole-bowel irrigation. An abdominal radiograph is most useful within 2 hours of ingestion. The visualization

FIGURE 10-8. Abdominal radiograph of a 3-year-old boy who had ingested ferrous sulfate tablets.

of radiopaque iron tablets is confounded by the presence of other hard-coated tablets and some extended-release tablets that are also radiopaque. Furthermore, the radiopacity of iron tablets diminishes as the tablets disintegrate, and chewable and liquid formulations typically are not radiopaque.⁹⁹

Iron poisoning causes vomiting and diarrhea, but these symptoms are poor indicators of later serious toxicity. The presence of a combination of findings such as coma, radiopacities, leukocytosis, and increased anion gap, however, is associated with dangerously high serum concentrations greater than 500 mcg/dL. The presence of single signs and symptoms, such as vomiting, leukocytosis, or hyperglycemia, is not a reliable indicator of the severity of iron poisoning in adults or children.^{100,101}

Once iron is absorbed, it is eliminated only as the result of blood loss or sloughing of the intestinal and epidermal cells. Thus iron kinetics essentially represent a closed system with multiple compartments. The serum iron concentration represents a small fraction of the total-body content of iron and is at its greatest concentration in the postabsorptive and distributive phases, typically 2 to 10 hours after ingestion.¹⁰² Serum iron concentrations in excess of 500 mcg/dL have been associated with severe toxicity, whereas concentrations below 350 mcg/dL typically are not associated with severe toxicity; however, exceptions have been reported for both thresholds.¹⁰² Serious toxicity is best determined by assessing the development of gross gastrointestinal bleeding, metabolic acidosis, shock, and coma regardless of the serum iron concentration.⁹⁵ The serum iron concentration serves as a guide for further assessment and treatment options. The ratio of the serum iron concentration to the total iron-binding capacity previously has been advocated to assess acute iron poisoning, but it is no longer used. This procedure is unreliable, insensitive, and has little relationship to toxicity.¹⁰¹

MANAGEMENT OF TOXICITY

Many patients vomit spontaneously, and generally, ipecac syrup should be avoided. Asymptomatic patients who ingested 10–60 mg/kg can be managed on the scene with follow-up contact over 6 hours to ascertain that no symptoms have developed. If symptoms such as persistent vomiting, bloody emesis, diarrhea, or unresponsiveness develop; if the patient ingested greater than 60 mg/kg; or if intentional overdosage is suspected, immediate referral to an emergency department is indicated.^{94,95}

At the emergency department, gastric lavage with normal saline can be considered. Lavage with normal saline may remove iron tablet fragments and dissolved iron, but because the lumen of the tube is often smaller than some whole tablets, effective removal is unlikely.⁹⁴ Activated charcoal administration is not warranted routinely because it adsorbs iron poorly. If abdominal radiographs reveal a large number of iron tablets, whole-bowel irrigation with polyethylene glycol electrolyte solution typically is necessary.³² Although removal by gastrostomy has been used in a few cases,⁹⁵ early and aggressive decontamination and evacuation of the gastrointestinal tract usually will be adequate to minimize iron absorption and thereby reduce the risk of systemic toxicity.

Patients with systemic symptoms (e.g., shock, coma, or gross gastrointestinal bleeding or metabolic acidosis) should receive deferoxamine as soon as possible. If the serum iron concentration exceeds 500 mcg/dL, deferoxamine is also indicated because serious systemic toxicity is likely.^{94,95} Its use is less clear in patients with serum iron concentrations in the range of 350–500 mcg/dL because many of these patients do not develop systemic symptoms.¹⁰²

Deferoxamine is a highly selective chelator of iron that theoretically binds ferric (Fe^{3+}) iron in a 1:1 molar ratio (100 mg deferoxamine to 8.5 mg ferric iron) that is more stable than the binding of iron to transferrin. Deferoxamine removes excess iron from the circulation and some iron from transferrin by chelating ferric complexes in equilibrium with transferrin. The resulting iron-deferoxamine complex, ferrioxamine, is then excreted in the urine. Its action on intracellular iron is unclear, but it may have a protective intracellular effect or may chelate extramitochondrial iron.⁹⁵ The parenteral administration of deferoxamine produces an orange-red-colored urine within 3 to 6 hours because of the presence of ferrioxamine in the urine.⁹⁴ For mild to moderate cases of iron poisoning, where its use is unclear, the presence of discolored urine indicates the persistent presence of chelatable iron and the need to continue deferoxamine. The reliance on discolored urine as a therapeutic end point has been challenged because it is not sensitive and is difficult to detect.¹⁰³

An initial intravenous infusion of 15 mg/kg per hour generally is indicated, although some have used up to 30 mg/kg per hour for life-threatening cases. In these situations, the dose must be titrated carefully to minimize deferoxamine-induced hypotension.^{94,95,104} The rapid intravenous infusion of deferoxamine (> 15 mg/kg per hour) has been associated with tachycardia, hypotension, shock, generalized erythema, and urticaria.^{94,105} Anaphylaxis has been reported rarely. The use of deferoxamine for greater than 24 hours at doses used for the treatment of acute poisoning has been associated with the exacerbation or development of ARDS.^{105–107} Although the manufacturer states that the total dose in 24 hours should not exceed 6 g, the basis for this recommendation is unclear, and daily doses as high as 37.1 g have been administered without incident.^{104,106} Good hydration and urine output may moderate some of the secondary physiologic effects of iron toxicity and ensure urinary elimination of ferrioxamine. In the patient who develops renal failure, hemodialysis or hemofiltration does not remove excess iron, but it will remove ferrioxamine.⁹⁴

CLINICAL CONTROVERSY

There is little evidence on how much deferoxamine should be given for iron poisoning or for how long to administer it. The dosage regimen should balance the benefits of increased iron removal in patients with exceedingly high serum iron concentrations versus the risk of developing ARDS when therapy lasts for more than 1 to 3 days.

The desired end point for deferoxamine therapy is not clear. Some have suggested that deferoxamine therapy should cease when the serum iron concentration falls below 150 mcg/dL.⁹⁵ The decline of serum iron concentrations, however, may not account for the potential cellular action of deferoxamine irrespective of its effect on iron elimination. The cessation of orange-red urine production that is indicative of ferrioxamine excretion is also not reliable because many individuals cannot distinguish its presence in the urine.¹⁰³ Considering these shortcomings, deferoxamine therapy should be continued for 12 hours after the patient is asymptomatic and the urine returns to normal color or until the serum iron concentration falls below 350 mcg/dL and approaches 150 mcg/dL.

OTHER THERAPIES

Lavage solutions of phosphate or deferoxamine have been proposed previously as a means to render iron insoluble, but they were found ineffective and dangerous.⁹⁵ Administering deferoxamine orally with activated charcoal has been shown in volunteers to decrease iron

absorption, but its application to the poisoned patient requires further evaluation.¹⁰⁸ Deferiprone, an oral iron chelating agent, is available for the management of chronic iron overload states, but its role in the treatment of acute iron poisoning remains to be determined.¹⁰⁹

MONITORING AND PREVENTION

Once a poisoning has occurred, acid-base balance (anion gap and arterial blood gases), fluid and electrolyte balance, and perfusion should be monitored. Other indicators of organ toxicity such as ALT, AST, bilirubin, prothrombin time, serum glucose and creatinine concentrations, as well as markers of physiologic stress or infection such as leukocytosis, also should be monitored.

Iron poisoning often is not recognized as a potentially serious problem by parents or victims until symptoms develop, and thus valuable time to institute treatment is lost. Parents should be made aware of the potential risks and asked to observe basic poison prevention measures. Many chewable vitamins with iron are shaped like animal or cartoon characters that can be attractive to children and can lead to poisoning. Some hard-coated iron tablets resemble candy-coated chocolates and are confused easily by children. Based on these considerations and the frequency of this poisoning, iron tablets are packaged in child-resistant containers.

TRICYCLIC ANTIDEPRESSANTS

CLINICAL PRESENTATION

▶ Patients may deteriorate rapidly and progress from no symptoms to life-threatening cardiotoxicity or seizures within 1 hour.^{110,111} Major symptoms of tricyclic antidepressant overdose typically are manifest within 6 hours of ingestion.¹¹⁰ The principal effects of tricyclic antidepressant poisoning involve the cardiovascular system and the central nervous system and can result in arrhythmias, hypotension, coma, and seizures (see below).

CLINICAL PRESENTATION OF TRICYCLIC ANTIDEPRESSANT POISONING

GENERAL

- Sedating and cardiovascular effects observed within 1 hour of ingestion, quickly leading to life-threatening symptoms; death is possible within 1 to 2 hours

SYMPTOMS

- Lethargy, coma, and seizures occur within 1 to 6 hours
- Anticholinergic symptoms, such as dry mouth, mydriasis, urinary retention, and hypoactive bowel sounds, develop within 1 to 6 hours

SIGNS

- Tachycardia within 1 to 3 hours
- Mild hypertension early will change to severe hypotension and shock within 1 to 6 hours
- Unresponsiveness and depressed reflexes within 1 to 3 hours
- Depressed respiratory rate and depth depending on the degree of coma
- Common arrhythmias, such as prolonged QRS and QT intervals to ventricular dysrhythmias, within 1 to 6 hours

LABORATORY TESTS

- Altered arterial blood gases associated with metabolic acidosis from hypoxia and seizures
- Altered serum electrolytes, BUN, and serum creatinine in response to seizures and shock within 3 to 12 hours

OTHER DIAGNOSTIC TESTS

- Electrocardiogram with continuous monitoring and pulse oximetry to monitor for toxicity and shock
- Monitor for complications of pulmonary aspiration, such as hypoxia and pneumonia, by physical findings and chest radiograph

Prolongation of the QRS complex on electrocardiogram indicating nonspecific intraventricular conduction delay or bundle-branch block is the most distinctive feature of tricyclic antidepressant overdose.¹¹¹ Sinus tachycardia with rates typically under 160 beats per minute is common and does not cause serious hemodynamic changes in most patients. Ventricular tachycardia is a common ventricular arrhythmia, but it may be difficult to distinguish from sinus tachycardia in the presence of QRS complex prolongation and the apparent absence of P waves. It often occurs in patients with marked QRS complex prolongation or hypotension and may be precipitated by seizures.^{111,112} High rates of mortality are associated with ventricular tachycardia; ventricular fibrillation is the terminal rhythm. Torsades de pointes is observed infrequently with tricyclic antidepressant poisoning. With massive tricyclic antidepressant overdose, slow ventricular rhythms may be observed. Hypotension is a significant factor in most cases of tricyclic antidepressant poisoning. Refractory hypotension leading to death is due to vasodilation and impaired cardiac contractility.¹¹¹ Other factors, such as extreme heart rates, intravascular volume depletion, hypoxia, hyperthermia, seizures, and acidosis, may contribute to refractory hypotension.

Coma usually is present in patients with tricyclic antidepressant poisoning and may or may not be associated with QRS complex prolongation. In severe cases, coma is sufficient to depress respirations. Delirium, manifest as agitation or disorientation, may occur early in the course of severe poisoning or with poisoning of moderate severity. Seizures often occur within 2 hours of ingestion and usually are generalized, single, and brief. Seizures may result in acidosis, hyperthermia, or rhabdomyolysis, and 10% to 20% of patients may abruptly develop cardiovascular deterioration.¹¹¹ Myoclonus also may be observed with tricyclic antidepressant overdose.

Hyperthermia often results from seizure and myoclonic activity in the presence of decreased sweating and is associated with a high incidence of neurologic sequelae and mortality. Anticholinergic symptoms, such as urinary retention, ileus, and dry mucous membranes, often are observed with tricyclic antidepressant overdose.^{110,111} Pupil size is variable. Tricyclic antidepressant overdose can be staged based on the patient's symptoms and recovery time. In stage 1, patients are responsive to pain, have sinus tachycardia, and recover within 24 hours. In stage 2, seizures, coma, and cardiac conduction problems are evident; respiratory support typically is needed. Patients recover within 24 to 48 hours of ingestion. Stage 3 is characterized by the features of stage 2 with the addition of respiratory arrest, hypotension, ventricular dysrhythmias, and asystole, which may occur within 1 to 24 hours of ingestion.

Amoxapine, bupropion, and maprotiline are atypical antidepressants associated with a higher incidence of seizures on overdose; amoxapine produces minimal cardiotoxicity,^{111,113} but

venlafaxine has been associated with greater mortality.¹¹⁴ The selective serotonin reuptake inhibitors (SSRIs) generally produce a common toxicity profile on overdose despite their structural and pharmacologic distinctions.¹¹⁵ The SSRIs inhibit the presynaptic neuronal uptake of serotonin, resulting in increased synaptic serotonin levels. When ingested in excess, SSRIs rarely cause death and typically produce nausea, vomiting, diarrhea, tremor, and decreased level of consciousness.¹¹⁵ Tachycardia and seizures are infrequent.^{111,113,116} Serotonin syndrome is associated with the coingestion of drugs increasing serotonin levels and develops within minutes to hours of the inciting action. It is characterized by a collection of neurobehavioral (e.g., confusion, agitation, coma, seizures), autonomic (e.g., hyperthermia, diaphoresis, tachycardia, hypertension), and neuromuscular (e.g., myoclonus, rigidity, tremor, ataxia, shivering, nystagmus) signs and symptoms.^{117,118} Most cases are mild and resolve spontaneously within 24 to 72 hours. Cardiac arrest, coma, and multiple-organ-system failure have been reported as consequences of serotonin syndrome.¹¹⁷ Recognition of the syndrome is based on a high index of suspicion and identification of risk factors.

MECHANISM OF TOXICITY

Many of the toxic effects of tricyclic antidepressants are associated with an exaggeration of their pharmacologic action. The tricyclic antidepressants, such as type Ia antiarrhythmic drugs, inhibit the fast sodium channel so that phase zero depolarization of the myocardium is slowed.¹¹¹ This action leads to QRS complex prolongation, atrioventricular block, ventricular tachycardia, and decreased myocardial contractility. Tricyclic antidepressants also block vascular α -adrenergic receptors, resulting in vasodilation, which contributes to hypotension. Sinus tachycardia is related to the inhibition of norepinephrine reuptake and anticholinergic effects. Other anticholinergic effects include urinary retention, ileus, dry mucous membranes, and impaired sweating. Inhibition of norepinephrine reuptake also may account for the early, transient, and self-limiting elevation of blood pressure observed in some patients. The central nervous system toxicity of tricyclic antidepressants is not well understood.

CAUSATIVE AGENTS

Tricyclic antidepressants and SSRIs are used to treat a variety of behavioral conditions (see Chaps. 68 and 69). The tricyclic antidepressants include drugs such as amitriptyline, desipramine, doxepin, imipramine, and nortriptyline. Atypical agents include amoxapine, bupropion, maprotiline, nefazodone, trazodone, and venlafaxine. The SSRIs include fluoxetine, paroxetine, and sertraline. The tricyclic antidepressants are generally highly protein bound, exhibit a large volume of distribution, and possess elimination half-lives of 8 to 24 hours or more. Virtually none of the drug is eliminated unchanged in the urine. Metabolism of the parent drug produces active metabolites in most cases (e.g., amitriptyline to nortriptyline) that may contribute to toxicity after the first 12 to 24 hours.¹¹¹ Genetic polymorphism at CYP2D6 may lead to slower recovery in patients who are slow hydroxylators.¹¹⁹

INCIDENCE

Tricyclic antidepressant poisoning is a common cause of death from drug overdose.^{111,112} The 2003 AAPCC-TESS report documented 12,710 patients with exposures to tricyclic antidepressants, of whom 62% were intentional overdoses. A total of 1373 people experienced

a major effect, and 93 people died.⁶ The SSRIs accounted for 55,871 nonfatal exposures and 106 deaths.

RISK ASSESSMENT

Ingestion of greater than 1 g of a tricyclic antidepressant (>10 mg/kg in children) typically results in life-threatening toxicity.¹¹¹ Because serious toxicity may occur within 1 to 2 hours of ingestion, prompt transport to an emergency department is crucial for overdoses. A QRS complex greater than 160 ms or progressive prolongation of the QRS complex is an indicator of toxicity such as seizures or ventricular arrhythmias and often precedes more serious symptoms.^{110,112,120} The QRS complex duration should not be used as the sole indicator of risk for tricyclic antidepressant poisoning.¹²⁰ Although urine drug analyses routinely screen for tricyclic antidepressant, the qualitative result can only suggest or confirm a potential risk for the development of toxicity.

Patients with coexisting cardiovascular and pulmonary conditions (e.g., ARDS, pulmonary infection, pulmonary aspiration) may be more susceptible to the toxic effects or complications of tricyclic antidepressant poisoning. The influence of chronic exposure to tricyclic antidepressants on the risks of an acute overdose is unclear. Tricyclic antidepressants interact with other central nervous system depressant drugs, which together may lead to increased central nervous system and respiratory depression.

The risk of serotonin syndrome may be increased shortly after dosage increases of SSRIs or when drug interactions increase serotonin activity.¹²¹ Concomitant or proximal use of SSRIs, tricyclic antidepressants, or monoamine oxidase inhibitors may cause serotonin syndrome. Further, the addition of certain drugs, such as tryptophan, dextromethorphan, cocaine, or sympathomimetics, to SSRI therapy may increase the risk of developing serotonin syndrome.^{117,121}

MANAGEMENT OF TOXICITY

Once the ingestion of an overdose of tricyclic antidepressant is suspected or for any intentional ingestions, medical evaluation and treatment should be sought promptly. If the patient is symptomatic, it may be prudent to call for an ambulance owing to the rapid progression of some cases. At the emergency department, the patient should be monitored carefully, have vital signs assessed regularly, and have an intravenous line started. Supportive and symptomatic care includes oxygen, intravenous fluids, and other treatments as indicated. Prompt administration of activated charcoal may decrease the absorption of any remaining tricyclic antidepressant. It also may be useful beyond the first hour of ingestion owing to decreased gastrointestinal motility from the anticholinergic action of tricyclic antidepressants. Gastric lavage may be considered if the time of the ingestion is unknown or if it occurred within the past 1 to 2 hours. Some practitioners avoid gastric lavage altogether.¹¹¹ Ipecac syrup should be avoided in patients who ingest tricyclic antidepressants because the rapid onset of toxicity limits its usefulness. Multiple-dose activated charcoal has been shown to increase the elimination of some tricyclic antidepressants in human volunteers³⁹ and has been used in poisoned patients.^{110,111} It may be most useful during the first 12 hours of ingestion while the drug is distributing to tissue compartments. Because the tricyclic antidepressants possess such a large volume of distribution and so little of the drug is present in the bloodstream, hemodialysis is not useful for the extracorporeal removal of tricyclic antidepressants.

Intravenous sodium bicarbonate is part of the first-line treatment of QRS complex prolongation, ventricular arrhythmias, and

hypotension caused by tricyclic antidepressant overdose.^{48,111,122} Typically 1–2 mEq/kg sodium bicarbonate (1 mEq/mL) is administered as a bolus infusion (usually a 50-mEq ampule in an adult) and repeated as necessary to achieve an arterial blood pH of 7.50 to 7.55 or abatement of toxicity.^{110,111} A therapeutic effect usually is observed within minutes. Excessive use of sodium bicarbonate may produce dangerous alkalemia, which is by itself associated with ventricular arrhythmias.¹¹¹ The mechanism of action of sodium bicarbonate is unclear. Although some practitioners have proposed that sodium bicarbonate increases protein binding of tricyclic antidepressants, this has been discounted. Sodium may play an important role by stabilizing tricyclic antidepressant–induced changes to the sodium gradient of the myocardium.^{111,123} Regardless of its action, it is effective and generally safe. Hyperventilation to produce a mild state of respiratory alkalosis has been used to treat some dysrhythmias, but it is used less widely than sodium bicarbonate.^{110,111}

CLINICAL CONTROVERSY

Since intravenous sodium bicarbonate is used as therapy for certain arrhythmias and hypotension caused by tricyclic antidepressant poisoning, some practitioners have advocated its prophylactic use. There is little evidence to indicate which patients would benefit from prophylactic use. The risks of potentially producing alkalosis in a patient who is not seriously toxic should be considered.

Treatment of the complications of tricyclic antidepressant poisoning is outlined in Table 10–14 and includes pharmacologic and nonpharmacologic approaches.^{110,111} Several agents generally should be avoided in the treatment of tricyclic antidepressant poisoning. Other drugs that inhibit the fast sodium channel, such as procainamide and quinidine, are contraindicated. Phenytoin has limited usefulness in treating tricyclic antidepressant seizures and has questionable efficacy in managing cardiotoxicity.¹¹⁰ Physostigmine was used in the past as a treatment of tricyclic antidepressant

cardiotoxicity and seizures because it antagonizes anticholinergic actions. However, physostigmine has been associated with bradycardia and asystole^{111,124} and has been avoided in the contemporary treatment of tricyclic antidepressant cardiovascular or central nervous system toxicity. Flumazenil is used to antagonize the effects of benzodiazepines, but its use in the presence of a tricyclic antidepressant has been associated with the development of seizures and should be avoided.¹²⁵

Treatment of an overdose of the atypical antidepressants and SSRIs is directed primarily toward decontamination of the gastrointestinal tract with activated charcoal, symptomatic treatment, and general supportive care. Management of the serotonin syndrome involves discontinuation of the serotonergic agent and supportive therapy. Benzodiazepines, propranolol, and cyproheptadine, a serotonin antagonist, have been used successfully.¹¹⁷

MONITORING AND PREVENTION

Measurement of vital signs, electrolytes, and blood urea nitrogen and a urinalysis are indicated for initial assessment. Patients should be monitored continuously by electrocardiogram, and a 12-lead electrocardiogram should be obtained if QRS complex prolongation is noted. If patients start to show signs of cardiotoxicity, arterial blood gases should be determined. Patients who show no signs of toxicity during 6 hours of observation and have received activated charcoal promptly require no further medical monitoring. Psychiatric evaluation is indicated for adolescents and adults. When signs of tricyclic antidepressant are present in a patient, cardiac monitoring generally is recommended for at least 24 hours after the patient is without findings.¹¹¹

Prevention of tricyclic antidepressant poisoning poses unique challenges. Many of the dosage forms are small in size, and adults and children can consume large numbers easily. In the course of treating depression, several antidepressant agents may be tried to achieve results. By not discarding unused medicines, a storehouse of potentially deadly drugs may be available for children to discover or for the

TABLE 10–14. Treatment Options for Acute Tricyclic Antidepressant Toxicity

| Toxicity | Treatment |
|---|--|
| Cardiovascular | |
| QRS prolongation, if progressive or greater than 0.16 s | Intravenous sodium bicarbonate to a blood pH of 7.5 even in the absence of acidosis; generally avoid other antiarrhythmic drugs |
| Hypotension | Intravascular fluids; intravenous sodium bicarbonate; consider norepinephrine or dopamine; treat hyperthermia, acidosis, seizures, hypokalemia; if present |
| Ventricular tachycardia | Intravenous sodium bicarbonate; lidocaine, overdrive pacing; treat hyperthermia, acidosis, seizures, hypokalemia; if present |
| Ventricular bradycardia | Epinephrine drip; cardiac pacemaker |
| Atrioventricular block type II, second or third degree | Cardiac pacemaker |
| Cardiac arrest | Advanced cardiac life support, prolonged resuscitation may be needed |
| Neurologic | |
| Seizures, agitation | Benzodiazepines (physical restraints for agitation); neuromuscular blockade may be needed if hyperthermia or acidosis are present |
| Coma | Endotracheal intubation; mechanical ventilation if needed |
| Homeostatic | |
| Hyperthermia | Treat seizures and agitation; consider cooling blanket, ice water lavage, and cool water mist of body |
| Acidosis | Intravenous sodium bicarbonate; treat hypotension, hypoventilation, seizures |

despondent patient to use to attempt suicide. Although patients take tricyclic antidepressants for therapeutic relief of depression, they are also a group likely to contemplate suicide with tricyclic antidepressants. Strategies that would limit the amount of tricyclic antidepressant prescribed at one time also potentially would impair adherence to a dosage regimen and thereby compromise the therapeutic potential of these agents.^{111,122} Patients with a history of suicidal gestures may be candidates for the atypical antidepressants or SSRIs, which possess less cardiotoxicity. General poison prevention measures may limit childhood poisonings, and monitoring depressed patients for suicidal ideation may identify patients at risk.¹²⁶

CARDIOVASCULAR TESTING

Robert L. Talbert

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 A careful patient history and physical examination are extremely important in diagnosing cardiovascular disease and should be done prior to any test.
- 2 Heart sounds and heart murmurs are important in identifying heart valve abnormalities and other structural cardiac defects.
- 3 Elevated jugular venous pressure is an important sign of heart failure and may be used to assess severity and response to therapy.
- 4 Electrocardiography is useful for determining rhythm disturbances (tachy- or bradyarrhythmias) and changes in ventricular and atrial size.
- 5 Exercise stress testing provides important information concerning the likelihood and severity of coronary artery disease; changes in the electrocardiogram, blood pressure, and heart rate are used to assess the response to exercise.
- 6 Cardiac catheterization and angiography are used to assess coronary anatomy and ventricular performance.
- 7 Echocardiography is used to assess valve structure and function as well as ventricular wall motion; transesophageal echocardiography is more sensitive for detecting thrombus and vegetations than transthoracic echocardiography.
- 8 Radionuclides such as technetium-99m and thallium-201 are used to assess wall motion and myocardial viability in patients with coronary artery disease and heart failure.
- 9 Pharmacologic stress testing is used when patients cannot perform physical exercise to assess the likelihood of coronary artery disease.

Cardiovascular disease (CVD) is present in more than 64 million Americans, and CVD has been the number one killer of men and women in the United States every year since 1900 except for 1918.¹ CVD kills nearly 2600 Americans each day and accounts for more deaths than the next five leading causes of death. Following the initial myocardial infarction (MI), 25% of men and 38% of women will die within 1 year. Also, 50% of men and 64% of women who died suddenly of CVD had no previous symptoms of this disease.¹ Although it may seem prudent to screen the population for CVD with the goal of reducing disease development, progression, and associated morbidities and mortality, currently, there are no tests with adequate sensitivity or specificity or that have been shown to have an impact on disease outcomes. An awareness of symptoms of CVD and aggressive prevention and management of risk factors are more cost-effective than expensive diagnostic tests.

A plethora of tests exist to evaluate CVD. Four properties of the CVD system can be evaluated to provide diagnostic, prognostic, and therapeutic management information. These include (1) electrical conduction, (2) pump function, (3) myocardial perfusion and vasculature competence, and (4) anatomy.² Multiple test modalities are available to evaluate each of these functions. Selection of the most appropriate test is complex owing to overlap in available information from different tests, paucity of comparative data between tests, and “gold standards” that may not have been challenged by new

technologies and drug therapies, making extrapolation of data difficult.^{2,3} For example, myocardial perfusion can be evaluated using the “gold standard” angiography but also can be measured using echocardiography (ECHO), positron-emission tomography (PET), computed tomographic (CT) scans, magnetic resonance imaging (MRI), and nuclear imaging, and it can be inferred from the exercise stress test (ET) and electrocardiogram (ECG). There is considerable debate as to how best to evaluate new tests, but for cost-effective use of tests, comparative head-to-head trials are essential. This chapter will outline each of the main groups of CVD testing modalities, highlight their advantages and disadvantages, give basic interpretation of results, and where possible, provide some comparative information. Tables 11–1 and 11–2 outline the use of different tests in CVD.

PATIENT INTERVIEW AND PHYSICAL EXAMINATION

- 1 In CVD, patient interview, history taking, and physical examination are the most important elements of patient assessment.^{4–6} Technologically advanced tests can be used effectively only in conjunction with a complete physical examination and history.

The history and patient interview provide valuable insight into the patient’s condition and help in the planning and interpretation of

TABLE 11–1. Types of Tests Used to Evaluate the Cardiovascular System

| | Cardiac Function ^a | | | |

^aNot all tests for any one cardiac function are used to evaluate all parameters listed. MUGA = multigated acquisition; ECG = electrocardiogram.

tests performed at a later date. History taking enables the examiner to establish a relationship with the patient and develop an awareness of the patient’s perception of problems and quality of life and an assessment of problem acuity and severity. History taking covers elements such as chief complaint, present problems, past medical history, review of systems, and social and family history.

Primary signs and symptoms of CVD disease include chest pain, dyspnea with or without orthopnea, paroxysmal nocturnal dyspnea, cyanosis, fatigue, palpitations, cough, edema, and syncope.^{4–6} During the interview and physical examination, identification and elucidation of the characteristics of and modulating factors for cardiac-related signs and symptoms are obtained.

3. Measurement of parameters of CVD function (pulse, blood pressure)
4. Auscultation, percussion, and palpation of the chest and related cardiac structures^{4–6}

The initial part of the physical examination consists of inspection of the precordium for normal patterns of rise and fall and any abnormal markings or shape. The chest is then palpated for normal pulses, thrills (humming vibrations like the throat of a purring cat), and heaves (lifting of the chest wall). Thrills may indicate murmurs, and heaves may indicate enlargement of one of the heart chambers or an abnormal vessel such as an aneurysm. The apical pulse (also known as the *point of maximum impulse* [PMI]) is helpful to estimate heart size and rotation. This is usually located in the fifth intercostal space in the midsternal line and radiates in an arc of 1 to 2 cm. Heightened intensity and/or displacement laterally suggests left or right ventricle enlargement, and reduced intensity may be a sign of fluid overload or pericardial effusion. Factors such as obesity, large breasts, muscularity, and pulmonary disease can interfere with determination of the apical pulse. The carotid pulse is examined for its intensity and, concurrently with the apical pulse, for concordance within the cardiac cycle. Decreased carotid pulsations may be due to reduced stroke volume or atherosclerotic narrowing of the carotid artery.

PHYSICAL EXAMINATION

The cardiovascular physical examination is divided into four categories:

1. Global examination of the patient for signs of CVD and a review of all body systems
2. Observation and assessment of physical findings (e.g., jugular venous pressure)

TABLE 11–2. Types of Tests for Various Cardiac Disorders or Features

| Feature/Disorder | CXR | Echo | Angiography | Nuclear Scan | CT | MRI | ET | ECG | PET |

CXR = chest x-ray; echo = echocardiography; CT = computed tomography; MRI = magnetic resonance imaging; ET = exercise testing; ECG = electrocardiogram; PET = positron emission tomography; CA = coronary artery.

^aUltrafast or cine-CT may be very useful in detecting ischemia based on calcium deposition.

^bTransesophageal echocardiography is superior to transthoracic echocardiography.

FIGURE 11-1. Schematic illustrations of topographic areas on the precordium for cardiac auscultation. Auscultatory areas do not correspond to anatomic locations of the valves but to the sites at which particular valves are heard best. (Redrawn from Kinney MR, Packa DR (eds). *Andreoli's Comprehensive Cardiac Care*, 8th ed. St. Louis, Mosby, 1996, with permission.)

HEART SOUNDS

2 Auscultation with a stethoscope is used to characterize heart sounds. Auscultation is conducted in a systematic manner to ensure that all sites where normal and abnormal sounds are heard are reviewed (Fig. 11-1). Respiratory pattern, various maneuvers such as handgrip and the Valsalva maneuver, sitting versus standing, and pharmacologic agents (e.g., amyl nitrate) also may be used in the evaluation of heart sounds to accentuate or diminish the intensity of these sounds. Auscultation is an acquired art and requires considerable practice to become competent.

The normal heart sounds include S_1 (first heart sound) and S_2 (second heart sound) and occur with closure of the mitral and tricuspid valves and the pulmonic and aortic valves, respectively. The sound of S_1 is thought to be generated by closure of the valvular leaflet. Other sounds, such as S_3 (third heart sound) and S_4 (fourth heart sound) and murmurs, are not considered normal but provide important diagnostic information.⁴⁻⁶ Initially, the patient is examined lying partially on the left side to accentuate left-sided S_3 and S_4 and mitral murmurs, with the bell on the PMI. To identify S_1 and S_2 , the patient can be examined lying or sitting. The other areas that are auscultated are the apex or base of the heart (mitral sounds), the lower left sternal border (tricuspid sounds), the second left interspace (pulmonic sounds), and the second right interspace (aortic sounds). At each of these locations, S_1 and S_2 should be heard.

Heart sounds are characterized by location, pitch, intensity, duration, and timing within the cardiac cycle. High-pitched sounds such as S_1 and S_2 , murmurs of aortic and mitral regurgitation, and pericardial friction rubs are best heard with the diaphragm. The bell is preferred for low-pitched sounds such as S_3 and S_4 . S_1 is heard as a click at the end of diastole and usually is synchronous with the apical pulse. The intensity of S_1 can be increased if systole begins prior to the mitral valve closing, which may occur in high-output states (e.g., exercise, tachycardia, anemia, or hyperthyroidism) and mitral valve stenosis. S_1 intensity is decreased in first-degree heart block, mitral regurgitation, states of reduced myocardial contractility (such as heart failure or coronary artery disease), obesity (difficult to hear), and systemic or pulmonary hypertension. S_2 is heard at the end of systole and is best heard at the tricuspid and mitral areas. Most of the sound arises from aortic valve closure. Heart sounds may be “split” if the two valves do not close synchronously. Physiologic splitting of S_1 or S_2 is

accentuated by inspiration and may disappear with expiration. Splitting of S_2 creates a pulmonic (P_2) and aortic (A_2) sound. S_2 frequently is heard as a split sound and is most predominant at the height of inspiration. Although S_1 also may be split, this is often difficult to hear.

Pathologic splitting of S_2 during expiration is described as *wide splitting*, *fixed splitting*, and *paradoxical splitting* and may be indicative of both stenosis and regurgitation. With right-sided heart failure, right bundle-branch block, pulmonic stenosis, or atrial septal defects, S_2 may be split owing to delayed closure of the pulmonic valve. Fixed splitting of S_2 is associated with large atrial septal defects and right ventricular failure. Increased intensity of P_2 is seen in pulmonary hypertension and dilated pulmonary arteries and with atrial septal defects. Decreased or absent P_2 occurs with aging and in pulmonic stenosis. Extra heart sounds in systole include early systolic ejection sounds and clicks and midsystolic clicks. Early ejection sounds such as aortic or pulmonic ejection sounds often are associated with valvular disease. Midsystolic to late systolic clicks usually are due to mitral valve prolapse (MVP). MVP is best heard at or medial to the apex but also may be heard at the left lower sternal border.

The S_3 heart sound, or ventricular gallop, is an abnormal low-pitched sound usually heard at the apex of the heart. It is thought to be due to rapid filling and stretching of the left ventricle when the left ventricle is somewhat noncompliant. This heart sound is characteristic of volume overloading such as in congestive heart failure (especially left-sided heart failure), tricuspid or mitral valve insufficiency, and atrial and/or ventricular septal defects. A physiologic S_3 is heard commonly in children and may persist into young adulthood. Localization of S_3 is helpful for determining heart rotation within the chest cavity.

The S_4 diastolic sound is a dull, low-pitched postsystolic atrial gallop (rapid blood flow) usually due to reduced ventricular compliance. It is best heard at the apex in the left lateral position. Like S_3 , it occurs with reduced ventricular compliance and is present in conditions such as aortic stenosis, hypertension, hypertrophic cardiomyopathies, and coronary artery disease. It is less specific for congestive heart failure than S_3 .

HEART MURMURS

Murmurs are auditory vibrations heard on auscultation, and they occur because of turbulent blood flow within the heart chambers or through the valves.^{5,6} They are classified by timing and duration within the cardiac cycle (systolic, diastolic, and continuous), location, intensity, shape (configuration or pattern), pitch (frequency), quality, and radiation (Table 11-3).

Some murmurs are considered innocent or physiologic and result from rapid, turbulent flow of blood into the left ventricle during atrial systole and through the aorta during ventricular systole. Fever, anxiety, anemia, hyperthyroidism, and pregnancy exacerbate physiologic murmurs, and these murmurs need to be distinguished from those suggestive of valvular abnormalities.

As with heart sounds, accurate determination of murmurs requires practice. The intensity or loudness of a murmur is graded using a scale of I to VI. Grade I is so faint that it is heard only with special effort. Grade VI may be heard with the stethoscope just off the chest wall. Determinants of the grade include the amount of blood ejected across a valve, severity of the lesion, and chest anatomy.

Systolic murmurs begin with or after S_1 and end at or before S_2 depending on the origin of the murmur. They are classified based on time of onset and termination within systole: midsystolic, holosystolic (pansystolic), early, or late. Pathologic midsystolic murmurs are associated with pulmonic stenosis, aortic stenosis, and hypertrophic

TABLE 11–3. Characteristics of Heart Sounds

| Type of Murmur | Examples | Location | Pitch | Radiation | Quality |
|----------------|-----------------------------|---------------------------|----------------|-----------------------------|-------------|
| Midsystolic | Aortic stenosis | 2nd RICS | Medium | Neck, left sternal border | Harsh |
| | Pulmonic stenosis | 2nd and 3rd LICS | Medium | Left shoulder and neck | Harsh |
| | Hypertrophic cardiomyopathy | 3rd and 4th LICS | Medium | Left sternal border to apex | Harsh |
| Pansystolic | Mitral regurgitation | Apex | Medium to high | Left axilla | Blowing |
| | Tricuspid regurgitation | Lower left sternal border | Medium | Right sternum, xiphoid | Blowing |
| | Ventricular septal defect | 3rd, 4th, and 5th LICS | High | | Often harsh |
| Diastolic | Aortic regurgitation | 2nd to 4th LICS | High | Apex | Blowing |
| | Mitral stenosis | Apex | Low | Little or none | |

RICS = right intercostal space; LICS = left intercostal space.

cardiomyopathy. Midsystolic murmurs include obstruction to ventricular outflow, dilatation of the aortic root or pulmonary trunk, an increased flow in the great arteries, anatomic changes in the semilunar valves, and some forms of regurgitation. Holosystolic murmurs occur when blood flows from a chamber of higher pressure to one of lower pressure, such as with mitral or tricuspid regurgitation and ventricular septal defects. Early systolic murmurs are decrescendo and may be associated with ventricular septal defects, mitral regurgitation, or tricuspid regurgitation. A late systolic murmur preceded by one or more midsystolic to late systolic clicks is the hallmark of MVP. Atherosclerotic obstruction of the carotid, subclavicular, or iliofemoral artery can give rise to a crescendo-decrescendo extracardiac systolic arterial murmur.

Early diastolic murmurs are heard commonly with aortic regurgitation. This murmur begins with A_2 and generally is decrescendo, reflecting the progressive decline in volume and rate of regurgitant flow during diastole. Aortic regurgitation is best heard by having the patient lean forward while holding his or her breath and listening with the diaphragm at the midleft sternal border. Pulmonary hypertension (Graham Steell's murmur) also may cause an early diastolic murmur. Middiastolic murmurs occur across the atrioventricular valves during rapid filling and are consistent with pure mitral stenosis or mitral stenosis along with a ventricular septal defect or tricuspid regurgitation with an atrial septal defect. The Austin Flint murmur may be middiastolic or presystolic and results from antegrade flow across the mitral valve that is closing rapidly because of simultaneous left ventricular filling from aortic regurgitation. Continuous murmurs begin in systole and continue without interruption into all or part of diastole. Such murmurs are due mainly to aortopulmonary connections (e.g., patent ductus arteriosus), arteriovenous connections (e.g., arteriovenous fistula, coronary artery fistula), and disturbances of flow patterns in arteries or veins.

Anatomic correlation of murmurs may require cardiac catheterization or ECHO, where direct visualization of the blood flow abnormality and calculation of flow and chamber pressures can be obtained. PET and MRI are also possible options to evaluate flow patterns and gradients of murmurs across heart valves.

JUGULAR VENOUS PRESSURE

3 The jugular venous pressure (JVP) is used as a measure of right atrial pressure.^{5,6} The JVP is measured in centimeters from the sternal angle and is best visualized with the patient's head rotated to the left. The JVP is described for its quality and character, effects of respiration, and patient position–induced changes. When reporting a JVP, both the measure and the patient position must be reported. The JVP can be reported as actual centimeters above the manubrium, or

this value plus 5 to 7 cm to indicate the rise of the JVP above the right ventricle. For persons in whom the central venous pressure (CVP) is normal, JVP is observed in the right internal jugular vein with the patient supine at 30 degrees or less. In the presence of an elevated CVP, the JVP is measured at 60 to 90 degrees. In patients with poor myocardial function, the accuracy of the JVP as a measure of CVP is reduced, and CVP is best measured directly by means of a Swan-Ganz catheter.

The normal JVP is a v wave 1 to 2 cm above the sternal ridge. If it is greater than halfway to the jaw angle, there is elevated CVP. Both the degree of elevation of the JVP and its wave flow in conjunction with the heartbeat are noted. The first wave, or a wave, represents atrial contraction and occurs just prior to S_1 , giving rise to increased pressure. It is seen as an undulating pulsation in the internal jugular vein. The second and much larger wave, the v wave, represents the increased venous pressure that occurs during venous filling. To interpret the JVP accurately, the carotid pulse is palpated concurrently. The a wave occurs just before the pulse and the v wave just after. Jugular venous pressure is often elevated in heart failure, and the degree of elevation can be used to assess the severity of heart failure, and diminution of JVP can be used to assess therapy.

PERIPHERAL CIRCULATION AND ARTERIAL PULSES

Arterial pulses are evaluated and characterized bilaterally by observation, palpation, and auscultation for presence, character, pattern, and rhythm.^{4–6} Various arterial pulse patterns are described: pulsus alterans (variation in amplitude beat to beat), bisferens pulse (increased arterial pulse with a double systolic peak), bigeminal pulse (reduced amplitude associated with premature ventricular beats), and paradoxical pulse (decrease in amplitude with inspiration). Although each may be associated with certain disorders (e.g., bigeminal pulse in premature ventricular contractions), none is sensitive or specific enough to be diagnostic. The status of the patient's overall peripheral circulation is recorded, especially the presence and degree of edema or skin changes suggestive of venous or arterial insufficiency. Color, condition, and integrity of the skin are also recorded, including signs of thrombophlebitis, tenderness, or swelling. Capillary refill (normal less than 2 seconds) is assessed by depressing the nail bed until it blanches and then releasing pressure and watching for the return of color, indicating blood flow.

HEART RATE

Heart rate is described by both rate and rhythm.^{5,6} The arterial pulse usually is taken at the radius, but carotid or other arterial pulses may be used. In healthy individuals, the heart rate is usually assessed by

counting the pulse for 15 seconds and multiplying by 4. In patients with irregular rhythms, the pulse should be taken over an extended period, approximately 1 to 2 minutes, to try to determine the patient's average pulse and rhythm.

Arterial pulses are an accurate measure of the ventricular rate in healthy persons with good ventricular function. In patients with a rapid ventricular rate—because of supraventricular tachyarrhythmias such as atrial flutter or fibrillation or rapid ventricular rates (e.g., ventricular tachycardia or premature ventricular beats)—extremity pulses (e.g., radial pulse) may be considerably slower than the true ventricular rate. A more accurate ventricular rate is determined by listening to the ventricles with the stethoscope (usually at the apex) or counting from an ECG. In patients with atrial fibrillation and a fast ventricular rate, a pulse deficit (measure of the difference in true ventricular rate and peripheral pulse rate) may exist. This may be as much as 10 to 20 beats per minute. Thus the location of the pulse (radial or apical) should be recorded. The pulse deficit will be reduced as the ventricular rate is controlled with drug therapy or normal sinus rhythm is restored.

PRACTICE GUIDELINES FOR DIAGNOSTIC AND PROGNOSTIC TESTING IN CVD TESTING

The American Heart Association (AHA) and American College of Cardiology (ACC) task force on practice guidelines publishes guidelines as to the recommended uses for many diagnostic testing methods. Such guidelines were first developed in the 1980 and are updated as more information is available. These are evidence-based recommendations that rank the indications and uses of tests into three primary classes. Class I indications are those where there is evidence or agreement that the specific procedure is useful and effective. Class II indications are those situations where there is divergence of opinion as to the usefulness of the method. Class III indications are those where there is evidence or agreement that a diagnostic test is not useful. Each class (usually class II) may be broken down into two to three subcategories. Class IIa indications are those where there is evidence or opinion in favor of the test, whereas class IIb indications are those where there is less evidence. With each class of recommendation for a specific clinical scenario, the guidelines will indicate the level of evidence for the recommendation. Level A evidence is given if the recommendation is based on the availability of multiple randomized clinical trials. Level B evidence is given if only a single randomized trial or multiple nonrandomized trials exist. Level C evidence is given if the recommendation is afforded based on expert opinion only.

Each guideline provides a preamble to indicate how it was constructed and the peer review process. These documents provide the clinician with an extensive database on the testing methodologies and are endorsed by both organizations as acceptable standards of practice.

TESTING MODALITIES

CHEST X-RAY

The chest x-ray (CXR) provides supplemental information to the physical examination and is usually the first diagnostic test in a cardiac work-up.^{4–6} It does not provide details of internal cardiac structures but gives global information about position and size of the heart and chambers and surrounding anatomy. The standard CXRs for evaluation of lungs and heart are standing posteroanterior (PA) and lateral

views taken at maximal inspiration. Portable CXRs usually are less satisfactory because of penetration difficulties, patient rotation, and poor inspiratory effort.

Initial assessment of the CXR evaluates the quality of the film for patient rotation, inspiratory effort, and penetration. Rotation is assessed by evaluating symmetry of the clavicles and central placement of the carina. Inspiratory effect is considered adequate if the diaphragms are pulled below the ninth rib. Lack of inspiratory effort and obesity lead to a poor-quality CXR, which makes it more difficult to assess the presence of pleural effusions and fluid in the costophrenic angles. Where possible, comparison with previous or baseline films is done to determine the quality of film and comparison of structures.

The PA view CXR outlines the superior vena cava, right atrium on the right and left sides, aortic knob, main pulmonary artery, left atrial appendage (especially if enlarged), and left ventricle. In the lateral view, the CXR visualizes the right ventricle, inferior vena cava, and left ventricle. These structures are visualized as shadows of differing density rather than discrete structures (Fig. 11–2).

The CXR is approached from two perspectives: (1) observation and (2) clinical correlation. Observation notes gross anatomic features such as size and placement of the cardiac silhouette, definition of the cardiac border, chamber enlargement, pulmonary vasculature, air-fluid levels, and diaphragm. Cardiac enlargement is determined by the cardiothoracic (CT) ratio, which is the maximal transverse diameter of the heart divided by the maximal transverse diameter of the thorax of a PA view. Normal averages 0.45, but it may be up to 0.55 in subjects with large stroke volumes (e.g., highly trained athletes). Heart conditions such as congestive heart failure and hypertension may enlarge the heart and so the CT ratio. Individual chamber enlargement can be seen on the CXR. Right ventricle enlargement is best seen on the lateral film, where the heart appears to occupy the retrosternal space. Left atrial enlargement is suspected if there is elevation of the left bronchus or an increase in the atrial appendage bulge. Left ventricular enlargement is the most common feature identified on CXR and is seen as an elongation and downward displacement of the apex of the heart. Sometimes a characteristic “boot” or “water bottle”

FIGURE 11–2. Schematic illustration of the parts of the heart. (AO = aorta; SVC = superior vena cava; RA = right atrium; PA = pulmonary artery; LA = left atrium; RV = right ventricle; LV = left ventricle.)

outline is seen with left ventricular enlargement, as in congestive heart failure (CHF).

The pulmonary vessels are examined for plumpness and definition of vessel walls. Decreased pulmonary flow (e.g., tetralogy of Fallot) causes central and peripheral vessels to be decreased in size. Increased pulmonary flow is associated with high-output states such as hyperthyroidism and atrial septal defects. This may lead to enlargement and tortuosity of the central and peripheral vessels. Pulmonary arterial hypertension (increased pulmonary resistance) is identified by enlargement of the central vessels and diminished peripheral vessels. Pulmonary venous hypertension usually is due to mitral stenosis or left ventricular failure. This is characterized by larger than normal vessels in the upper lung zones owing to recruitment of upper vessels from blood diverted from the lower constricted vessels (cephalization of flow).

Heart failure causes Kerley's B lines (edema of interlobular septa), which appear as thin, horizontal reticular lines in the costophrenic angles. At higher pressures, alveolar edema and pleural effusions appear in the pleural space or as blunting of the costophrenic angles. Pericardial effusions also may appear as a large heart, but because it usually occurs rapidly, there is no evidence of pulmonary venous congestion.

ELECTROCARDIOGRAM (ECG)

4 Measurement of electrical activity in the heart, now known as the *electrocardiogram* (ECG), was introduced about 75 years ago by Willem Einthoven. The ECG is simple to perform and is the most frequently used, least invasive, and cheapest cardiovascular test.^{7–10} It remains the procedure of first choice for evaluation of chest pain, dizziness, or syncope. In its simplest interpretation, the ECG characterizes rhythms and conduction abnormalities. However, the ECG also provides, by inference, information about the anatomy and structures of the heart, pathophysiologic changes, and hemodynamics of the CVD system.^{3,8} ECG abnormalities are often the earliest sign of adverse drug effects, ischemia, and electrolyte abnormalities.

Although few ECG recordings are highly specific or sensitive to a disease state, correlation of findings with clinical and pathologic states affords the ECG significant diagnostic and prognostic capabilities. Sensitivity and specificity of ECG changes depend primarily on the clinical setting, recording technique, and skill of interpreters. Sensitivity and specificity of findings are increased by interpretation in conjunction with patient information such as age, gender, medical history, and medications. Additionally, prior and/or serial ECGs should be obtained for comparison prior to identifying new findings on a current ECG as diagnostic. This is particularly important in patients with significant cardiac disease or on medications that alter the ECG (Table 11–4). The ECG is sensitive in detecting rhythm abnormalities, but it does not record the actual activity of the conduction tissue.^{7–9}

The ECG can be used to evaluate ischemia following angioplasty or other surgical interventions and to monitor responses to

FIGURE 11–3. The torso with the six limb leads in a single frontal plane.

antiarrhythmic agents or in patients receiving drugs with potential cardiac effects. Refer to Table 11–5 for examples of conditions for which the ECG is a recommended evaluation tool.

Electrocardiography is based on the measurement of change in summated three-dimensional electrical vectors or forces that result from depolarization and repolarization of cells in the conduction system and heart muscle. The standard external 12-lead ECG uses two sets of leads: limb and chest (Fig. 11–3). The six limb leads look at the heart in a single frontal plane. Limb lead nomenclature is as follows: lead I, right arm/left arm; lead II, right arm/left leg; lead III, left arm/left leg. Altering resistances create the augmented limb leads, which are called aVR, aVL, and aVF. Unipolar chest leads are positioned across the chest and labeled V₁ to V₆. V₁ is positioned slightly to the right of the midline, and V₆ is positioned in the left midaxillary line (Fig. 11–4). Leads aVR and V₁ are considered right-sided leads, so they appear inverted, and leads aVL, I, II, V₅ and V₆ are left-sided leads, so they appear upright on the ECG. Leads II, III, and aVF are inferior leads. Leads V₁ to V₄ are anterior wall leads. Single-lead ECGs or ECG monitors frequently use lead II.

Recording of the ECG has several standard features. The paper is divided into squares of 1 mm; each 10 mm (10 small boxes) is equivalent to 1 mV. Paper speed is 25 mm/s. Each small box on the tracing paper equals 0.04 second (40 ms), and each big box is 0.2 second. If there is one QRS complex per six big boxes (6 × 0.20 second), the patient has a heart rate of 50 beats per minute, whereas one QRS per big box indicates a heart rate of 300 beats per minute.

The ECG pattern is named alphabetically and is read from left to right, beginning with the P wave. Electrical activation (depolarization) of the right and then the left atrium owing to discharge from the sinoatrial (SA) nodes causes an upward or positive deflection in lead II called the *P wave*. The normal duration of the P wave is up to 0.12 second, and it has an amplitude of 0.25 mV (i.e., 2.5 small boxes). The *PR segment* is created by passage of the impulse through the atrioventricular (AV) node and the bundle of His and its branches, and it has a duration of 0.12 to 0.21 second. The *QRS complex* primarily traces the electrical depolarization of the ventricles. Initially, there is

TABLE 11–4. Drugs That May Affect the Electrocardiogram

|------------------------------|--|
| Digoxin | Pentamidine |
| Antiarrhythmics—classes I–IV | Lithium |
| Tricyclic antidepressants | Catecholamines (e.g., dopamine, albuterol) |
| H ₁ antagonists | Diuretics (electrolyte abnormalities) |
| Methylxanthines | |
| Doxorubicin | |

FIGURE 11-4. A. Electrode positions of the precordial leads (V_1 = fourth intercostal space at the right sternal border; V_2 = fourth intercostal space at the left sternal border; V_3 = halfway between V_2 and V_4 ; V_4 = fifth intercostal space at the midclavicular line; V_5 = anterior axillary line directly lateral to V_4 ; V_6 = anterior axillary space directly lateral V_5). B. The precordial reference figure. Leads V_1 and V_2 are called right-sided precordial leads; leads V_3 and V_4 , midprecordial leads; and leads V_5 and V_6 , left-sided precordial leads. (Redrawn from Kinney MR, Packa DR (eds). *Andreoli's Comprehensive Cardiac Care, 8th ed.* St. Louis, Mosby, 1996, with permission.)

a negative deflection, the *Q wave*, followed by a positive deflection, the *R wave*, and finally a negative deflection, the *S wave*. Q-wave duration is normally 0.4 second or less, and the amplitude is 25% or less of the overall height of the QRS complex. Normal duration of the QRS complex is 0.12 second. The QRS complex is positive in left-sided leads and negative in right-sided leads because the left ventricle is much thicker than the right, and the forces going left during depolarization dominate.

Following the QRS complex is a plateau phase called the *ST segment*, which extends from the end of the QRS complex (called the *J point*) to the beginning of the T wave. The ST segment is evaluated from its position relevant to the baseline, configuration, and leads where changes occur. The ST segment is normally on or slightly above the baseline. Configuration changes, convexity upward or downward, identify the presence of myocardial ischemia. Lead localization of ST-segment changes indicates the area of ischemia. The *QT interval* is measured from the start of the QRS complex to the end of the T wave. This varies with heart rate and is corrected (*QTc*) for heart rates greater than 60 beats per minute. The normal *QTc* is less than 0.42 second in men and 0.43 second in women.

Repolarization of the ventricle leads to the *T wave*. The T wave usually goes in the same direction as the QRS complex. The normal axis of the ECG is 30 degrees (above the horizontal) to +110 degrees (away from the horizontal) (Fig. 11-5). The six frontal plane (A) and the six horizontal plane (B) leads provide a three-dimensional representation of cardiac electrical activity.

The ECG is evaluated in a systematic manner to avoid omission of important characteristics. All ECGs are interpreted for the

following elements: rate, general rhythm, intervals, voltage, axis, waveforms, abnormal features (e.g., Q waves), and technical aspects such as adequacy of lead placement and calibration.⁸ The number of P waves and QRS complexes (*RR interval*) is also used to determine rate. QRS complexes may be more useful if heart block exists. The rhythm from the ECG is identified by the following features:

1. The rate of the QRS (>100/min is tachycardia and <60/min is bradycardia)
2. The regularity of the QRS [The presence or absence of the QRS complex with each P wave helps to identify if the rhythm is atrial or ventricular in origin and if each atrial beat (P wave) is being conducted to the ventricles. The regularity of the QRS identifies conditions such as atrial fibrillation and extra beats.]
3. Configuration of the QRS—wide or narrow—indicating if it is generated from electrical activity that arose in the atria or ventricles

Always reported are the RR, PR, QRS, and QT intervals and the duration, magnitude, and configuration of the P waves, QRS complexes, ST segments, T waves, and U waves. Computer interpretation of the ECG provides a standardized reading and records and calculates basic rhythm patterns, heart rate, and intervals but does not interpret arrhythmias. Independent review of the ECG is necessary for accurate translation of findings.⁸

In epidemiologic studies, the ECG is used to assess physical fitness, document the prevalence of ischemic heart disease (IHD),

FIGURE 11-5. The six frontal plane (A) and six horizontal plane (B) leads provide a three-dimensional representation of cardiac electrical activity. (Redrawn from ref. 7 with permission.)

and identify subclinical heart disease. The sensitivity and specificity of ECG changes are highly dependent on the pretest probability of heart disease. As the pretest probability of heart disease increases, the sensitivity and specificity of ECG findings increase. The use and value of the ECG as a screening tool are controversial. It is only used where the diagnosis of heart disease would preclude active employment, such as in airline pilots. The ECG frequently is used in conjunction with other diagnostic tests to provide additional data, to monitor the patient, and to identify if abnormalities detected during tests correlate with ECG changes.^{7,8,10}

Gating, or linkage of and simultaneous recording of an ECG and other diagnostic tests, such as ECHO and CT scans, allows for correlation of images with the cardiac cycle. Gating is either prospective, where a certain portion of the cardiac cycle is predetermined as the time during which the images are obtained, or retrospective, where the ECG and image are recorded simultaneously but independently and later matched for concurrent events. This allows multiple cardiac cycles to be overlaid, thus increasing the sensitivity to detect abnormalities.

Anomalies on the ECG include abnormal intervals, altered waveform configurations, and rate variability. Other findings give evidence for various forms of heart block, ischemia, infarction, atrial and ventricular enlargement and hypertrophy, atrial and ventricular rhythm disorders, pericarditis, metabolic abnormalities, drug-induced changes, and pacemaker-related changes. ECG patterns found on consecutive leads can help to identify where a particular conduction defect or impulse generation is occurring or anatomic problem is located. For example, ST-segment elevation in V₂ to V₆ is indicative of anterior wall myocardial infarction from occlusion of the left anterior descending coronary artery. Single-lead abnormalities most frequently are attributed to poor lead placement, position of the patient, or recording artifacts.

Examples of some common findings will be discussed briefly.^{7,8} Short PR intervals are associated with the Wolff-Parkinson-White and Lown-Ganong-Levine syndromes and reflect the presence of accessory pathways. Long PR intervals are measures of heart block. The presence of a Q wave is a marker for loss of electrically functioning myocardium and suggests a prior myocardial infarction. It also may be present in congenital heart disorders, hypertrophic cardiomyopa-

thy, left ventricular hypertrophy, conduction defects such as Wolff-Parkinson-White syndrome, and intraventricular conduction defects. U waves are relatively nonspecific, the most common cause being hypertension. Bundle-branch blocks are frequent findings and indicate conduction defects in one of the bundles of His. Their presence confounds the interpretation of important ECG findings such as ischemia. Right bundle-branch block is associated with an R wave and the following abnormalities: QRS complex greater than or equal to 12 ms, delayed right ventricular forces resulting in terminal R waves in the right-sided leads and S wave in the left-sided lead, and right-sided ST-segment depression and T-wave inversion. Left bundle-branch block is characterized by the following: QRS complex greater than or equal to 12 ms, delayed left ventricular activation, loss of the normal “septal Q wave” in the left-sided leads, and left-sided ST-segment depression and T-wave inversion. Intraventricular conduction delay usually causes a wide QRS complex, and generally there are ST-segment-T-wave abnormalities.

Myocardial ischemia, ranging from injury to necrosis, results in T-wave changes, ST-segment abnormalities, and changes in the QRS complex.^{7,10} Myocardial infarction results in a typical pattern of ECG changes that begins with tall peaked T waves persisting up to several hours, followed by ST-segment elevation with a coved (convexity upward) configuration, and inverted T waves. Development of a new Q wave has a high specificity but low sensitivity for acute myocardial ischemia. Q waves that are 4 ms or longer in duration and 25% or greater of the overall QRS height are considered diagnostic and occur within minutes to hours of occlusion. Although Q waves usually evolve within hours of infarction, they may not become evident for several days. The finding of new and significant Q waves on an ECG is indicative of a previous infarction. Q waves persist indefinitely in 80% to 90% of myocardial infarctions. The location of Q waves identifies the region of myocardium affected and the coronary artery blocked (e.g., inferior infarction will result in Q waves in II, III, and aVF associated with blockage in the right coronary artery). Non-Q-wave (subendocardial) myocardial infarction implies that the Q wave does not meet the diagnostic criteria for Q-wave infarction. ST-segment depression may be present.

ST-segment changes are very common and always should be compared with a previous ECG. ST-segment elevation may be seen

in persons with no known coronary disease but is usually indicative of hyperacute ischemia. ST-segment depression is never considered a normal finding. ST-segment scooping (convexity downward) may be normal, but coving (convexity upward) is abnormal. Depression of the ST segment that does not return quickly to normal and changes in multiple leads suggests clinically significant heart disease. Diffuse ST-segment elevation in all leads except V_1 and aVR suggests the diagnosis of pericarditis. Exertion in normal individuals may cause J-point depression with a rapid rise of the ST segment, and this may be confused with ST-segment depression owing to the configuration. Poor R-wave progression (usually increase in size moving from V_1 to V_6) suggests anterior myocardial infarction, but smaller R waves also can occur in diseases such as chronic obstructive pulmonary disease (COPD). T-wave changes are the most frequent and most sensitive abnormality on the ECG but are also the least specific and frequently are found in persons with no heart disease.

Left atrial enlargement is characterized by a P wave that is 12 mV in lead II, or the negative component of the biphasic P wave is 4 mV in duration and 0.1 mV in depth in lead V_1 . In right atrial enlargement, the P wave in lead II can exceed 0.25 mV and usually has a vertical axis. Ventricular hypertrophy results in increased deflection of the QRS complex because of the increased muscle mass. Left ventricular hypertrophy (LVH) is diagnosed from the ECG using several different sets of criteria; none are considered highly sensitive or specific. LVH often is indicative of hypertension and resulting ventricular enlargement and strain. Commonly used voltage criteria indicating LVH are summation of the S wave in V_1 and the R wave in V_5 or the S wave in V_2 and the R wave in V_6 that exceeds 3.5 mV (35 small boxes) or the R wave in lead aVL that exceeds 1.1 mV (11 small boxes). Right ventricular hypertrophy (RVH) is characterized by an R wave in V_1 that is equal to or greater than the S wave in that lead. In persons who are obese, increased voltage may not be apparent, making voltage criteria a less useful tool to identify hypertrophy. LVH also may be assessed using ECHO.

Electrolyte abnormalities have characteristic signs on the ECG and can be used as monitoring parameters. Hypokalemia may increase ventricular ectopy and causes ST-segment depression, T-wave flattening, and the appearance of a U wave (usually when the serum potassium concentration is less than 3.0 mEq/L). Hyperkalemia results in very characteristic changes in the ECG. Potassium concentrations above 6.0 mEq/L produce tall, peaked T waves. As the concentration rises further, intraventricular conduction becomes blocked, with widening of the QRS complex, and ultimately, a sine wave develops. Hypercalcemia causes a short QT interval and, occasionally, ST-segment depression, sinus arrest, and AV conduction blocks. Hypocalcemia causes a long QT interval and some broadening of the T wave. A number of drugs cause characteristic changes in the ECG that may mask interpretation of other findings. A list of commonly used drugs that may alter the ECG is given in Table 11-4. Pericardial effusion, obesity, and large breasts limit the amount of voltage that is measured on the skin surface and reduce the QRS voltage. In the presence of large pericardial effusions, rapid changes in the positive to negative deflection of the QRS complex or electrical alternans may occur because the heart is swinging on a beat-to-beat basis.

Signal-averaged ECG (SAECG) may be used to help elucidate the presence of low-amplitude bioelectrical potentials.¹¹ Derangements of ventricular activation and late potentials can be detected on the ECG after the QRS and ST segments and are thought to be associated with increased risk of ventricular arrhythmias. Traditional ECGs are unable to detect these potentials because they are “lost” in the noise of the ECG recording. SAECG improves the signal-to-noise ra-

tio, enabling the low-amplitude potentials to be interpreted. SAECG can be used to identify patients at risk for developing sustained ventricular tachycardia after myocardial infarction. Patients with IHD and unexplained syncope who are at risk for sustained ventricular tachycardia also may be candidates for SAECG. Other potential uses of SAECG include patients with nonischemic cardiomyopathy with sustained ventricular tachycardia, detection of acute rejection of heart transplant, and assessment of the proarrhythmia potential of antiarrhythmic drug therapy.

AMBULATORY ECG MONITORING

Ambulatory ECG monitoring (AEM), or Holter monitoring, named for its inventor, is an aid to detect, document, characterize, and evaluate arrhythmias and other ECG abnormalities over extended periods of time.¹²⁻¹⁷ AEM provides information regarding random abnormal cardiac electrical activity during daily activity and helps relate altered electrical activity to precipitating factors and patient symptomatology. Additionally, some findings on AEM have been used to determine prognostic implications.

Although controversial, AEM is used as a diagnostic and screening tool for asymptomatic ischemia. It is difficult to interpret changes in the ST segment recorded during AEM owing to amplitude, and definitions of significant changes recorded with AEM are still in evolution. As a prognostic tool, it is used primarily to evaluate patients with known CVD who have symptoms that may be associated with an arrhythmia. It is also used in clinical trials to evaluate the efficacy of drug therapy.

Guidelines as to the recommended uses of AEM are available from AHA/ACC. The major class I indications for AEM include diagnosis in patients with symptoms suggestive of arrhythmias, prognostic delineation in patients with cardiac disease considered at risk for arrhythmia-related events, and measurement of efficacy of interventions in patients with known and characterized arrhythmias. Examples of clinical rhythm disturbances are listed in Table 11-5.

A major limitation of AEM is the amount of data collected with ECG abnormalities that are of unknown clinical significance. High day-to-day variability of frequency and type of arrhythmias means that repeat AEM may demonstrate as much as a 90% difference in

TABLE 11-5. Indications for AECG to Assess Symptoms Possibly Related to Rhythm Disturbances

Class I

Patients with unexplained syncope, near syncope, or episodic dizziness in whom the cause is not obvious
Patients with unexplained recurrent palpitation

Class IIb

Patients with episodic shortness of breath, chest pain, or fatigue that is not otherwise explained
Patients with neurological events when transient atrial fibrillation or flutter is suspected
Patients with symptoms such as syncope, near syncope, episodic dizziness, or palpitation in whom a probable cause other than an arrhythmia has been identified but in whom symptoms persist despite treatment of this other cause

Class III

Patients with symptoms such as syncope, near syncope, episodic dizziness, or palpitation in whom other causes have been identified by history, physical examination, or laboratory tests
Patients with cerebrovascular accidents, without other evidence of arrhythmia

the number of premature ventricular contractions. Little correlation of arrhythmia suppression and clinical outcomes is available. No AEM study has shown a mortality advantage when used in conjunction with antiarrhythmic drugs or devices. Following an intervention (drugs or device), at least a 63% to 95% reduction in arrhythmia frequency is required for AEM to be considered a valuable arrhythmia detection and evaluation tool. Compared with electrophysiology testing (EPS) in the Electrophysiologic Study Versus Electrocardiographic Monitoring (ESVEM) study, AEM was equivalent but not superior to EPS in the ability to select initial drug therapy.¹⁶ The Asymptomatic Cardiac Ischemia Pilot (ACIP) study found that 75% of patients with asymptomatic evidence of ischemia on AEM had multivessel coronary artery disease on angiography.¹⁷

During AEM, the patient wears a portable ECG recorder that weighs about 8 to 16 oz. The recorder uses two to four chest leads (V₅ and V₃ most commonly). Additional leads do not improve the sensitivity of AEM significantly. If ST-segment changes are known to occur in certain leads, these can be used during AEM. Most AEM recordings are for 24 to 48 hours, but they can extend to weeks or months where the frequency of events related to ECG abnormalities is low. Implantable devices are used when long periods of monitoring are necessary. Currently used equipment is able to detect and analyze arrhythmias, ST-segment deviations, QRS complexes, RR intervals, and late potentials.

Three types of monitors are available: (1) continuous monitors, which record an ECG strip over the duration of the test, (2) event or intermittent recorders, which continuously monitor the ECG but only record preprogrammed abnormal ECG events or are patient-activated based on occurrence of symptoms, and (3) real-time analytical recorders, which record throughout the monitoring period and analyze each beat as it occurs. Monitors digitize, encode, and store the information in a solid-state memory or on magnetic tape. Event monitors are preprogrammed to record parameters such as the number of premature ventricular contractions and heart rate. During monitoring, the patient maintains a diary in which the occurrence, duration, and severity of symptoms (e.g., light-headedness, chest pain) are recorded, plus any specific activities undertaken, development of symptoms with the activity, and any interventions such as the taking of medication. A clocking device in the recorder allows later correlation of the patient's diary with the recorded ECG.

Evaluation and analysis of the ECG record are complex. Computer-assisted interpretation is used to scan the ECG and identify irregular rhythms, rates, and specific preprogrammed changes. The main advantage of computer analysis is to reduce interpretation of artifact recordings. Each beat recorded during AEM is evaluated for its arrhythmia potential and classified as normal or abnormal. The morphology of each QRS-T section is examined for ischemia potential, although, as indicated previously, baseline ST-segment abnormalities and adjustments in amplitude of the recording may preclude interpretation of these segments. The new ACC/AHA guidelines provide detail as to the suitability of using ST segments for analysis of ischemia.¹² Various drugs such as digoxin and the tricyclic antidepressants that cause baseline ECG abnormalities may preclude patients from being evaluated with AEM.

Sections identified by the computer as abnormal or those correlating with patient symptoms are then evaluated and characterized further (e.g., potentially pathologic rhythms) by technical personnel and physicians. Confounding factors when using AEM can arise from the patient and the device (Table 11–6). AEM is evolving rapidly, primarily related to improved technology with respect to data interpretation, signal quality, and improved understanding of the implications of ECG changes.

TABLE 11–6. Confounding Factors in Ambulatory ECG Monitoring

| Patient Factors | Equipment Factors |
|--|---|
| Electrolyte abnormalities | Battery failure |
| Hyperventilation | Loose lead |
| Lead interference by patient | Mechanical failure of recorder |
| Medications | Motor failure |
| Physiologic variations in waveforms | Overrecording |
| Medications | Computer inability to detect arrhythmia |
| Patient activities (e.g., sudden exercise) | |
| Presence of atrial fibrillation | |

EXERCISE STRESS TESTING (ET)

ET is a noninvasive test used to evaluate clinical and cardiovascular responses to exercise.^{19–23} ET is used frequently as an initial test, in conjunction with physical examination and patient symptoms, to aid in the selection of additional testing modalities. It is a simple test that can be conducted in a physician's office and is about 20 times less expensive than an angiogram and almost three times less expensive than stress ECHO. Almost two-thirds of ETs billed to Medicare in 1996 were conducted in physicians' offices, and one-third were conducted by noncardiologists.

5 The ET provides diagnostic information in patients with known or suspected IHD and prognostic information in patients after myocardial infarction or revascularization. However, there are no data that support its use as a screening tool for coronary artery disease (CAD) or for detection of early CAD in asymptomatic subjects.

The principle behind ET is to increase myocardial oxygen demand above myocardial oxygen supply and coronary reserve, thereby provoking ischemia (inadequate myocardial perfusion), using exercise as a stressor. Ischemia is detected by patient symptoms, ECG changes, and/or hemodynamic changes. The type of ECG changes, leads affected, and patient performance are used as an index of severity and location of disease. ET is a very practical test in that it can assess patients' functional capacity.

Some examples of class I, II, and III indications from the ACC/AHA guidelines on ET are presented here.²⁰ The major class I indications are evaluation of males older than 40 years who have symptoms suggestive of CAD and risk factors for CAD or atypical symptoms suggestive of CAD. Another class I indication is to help assess prognosis and functional capacity in patients with confirmed CAD.²¹ Frequently, the ET is performed following an acute myocardial infarction (AMI) for this purpose. Class II indications are patients with variant angina or women with a history of typical or atypical chest pain. Examples of class III indications are patients with simple premature ventricular contractions on a resting ECG with no other signs or symptoms of CAD. Additionally, ET is used to assess symptoms such as chest pain or breathlessness. The ET should be used only if the results are able to alter patient management or to assess patient function.

Guidelines for conducting and interpreting the tests and details of testing equipment and environment are outlined in the ACC/AHA guidelines on ET standards. ET is conducted on a treadmill or bicycle ergometer or by means of a handgrip. These dynamic methods are used to assess exercise tolerance because they induce both a volume and pressure load on the heart. Both modalities also allow the degree of stress to be delivered in a graded and calibrated manner. Treadmill walking is preferred over the ergometer because it involves more

muscle mass and the $\dot{V}O_{2,max}$ achieved with cycle ergometer is 10% to 15% lower than with the treadmill.

Many protocols have been designed and validated for use with ET, but the two used most commonly are the Bruce and Naughton protocols. Protocols help to decrease inter- and inpatient variability and allow for standardization in the interpretation of the tests. Protocols may be customized for individual patients to ensure an exercise time of 6 to 12 minutes and a heart rate of 85% to 90% of maximum predicted (adjusted for age and gender). Protocols detail gradient, speed, and rates of change of these parameters during the test.

In preparation for ET, patients fast prior to the test for a minimum of 3 hours, may not exercise 12 hours prior to the test, and must dress suitably for exercise. Baseline evaluation consists of history and physical examination, blood pressure, heart rate, and ECG. The test begins with a 1-minute warmup period to orient the patient to the equipment. Each stage of the test is maintained for at least 3 minutes. Continuous blood pressure, heart rate, and ECG recordings are obtained, with definitive readings 2 minutes into each stage. Patients are questioned 2 to 3 minutes into each stage of the test about symptoms such as headache, dizziness, and chest pain. Clinical symptoms assessed include color of skin, level of perspiration, and evidence of peripheral cyanosis and light-headedness. Patients are encouraged to exercise as vigorously as they can to ensure an optimal test result. Onset, nature, and duration of all changes in symptoms, hemodynamics, and ECG are noted. Following the test there is a cool-down period during which the patient is seated or lying and is observed for changes as described earlier.

The ET requires considerable effort, with many patients requiring encouragement to perform to the best of their ability. Some patients use the test as a personal challenge and perform better on repeated attempts. This is referred to as a *training effect* and may be a confounding factor in using ET to assess the effect of drug therapy or after interventions for IHD in clinical trials.

Interpretation of the ET requires correlation of clinical, ECG, and other parameters measured during the test with the patient's history (e.g., age, gender, concurrent risk factors, and medical history) and concomitant therapy. Results of the ET can be used as a guide to future patient management, including suitability for interventional cardiology and selection of pharmacotherapy. A positive ET is defined as 1 mm of horizontal or downsloping depression or elevation of the ST segment for 60 to 80 ms after the QRS complex. For patients with baseline ST-segment depression, combinations of abnormal responses (e.g., 2 mm of ST-segment depression with hemodynamic abnormalities) would be necessary to call a test positive. ST-segment depression of 2 mm or more, especially in conjunction with heart rates of less than 120 beats per minute, low levels of stress, or depression persisting for up to 6 minutes after the cessation of the ET, is associated with a poor prognosis. Depression of the ST segment in multiple leads is also significant. Other ECG changes include development of U waves and increased complexity and/or frequency of premature ventricular contractions or beats, especially if associated with bigeminy or periods of ventricular tachycardia.

Although ECG changes and heart rate responses are used as objective end points of an ET, patient and clinical end points are actually preferred. The use of the 85% to 90% maximally predicted heart rate is highly variable among patients and often is not achieved because of concomitant drug therapy and different levels of fitness. Symptom-limited or patient-directed tests are continued to the predetermined end point(s) unless the patient tires or certain characteristics are noted. Clinical symptoms, exhaustion, chest pain, and changes in blood pressure, heart rate, and the ECG (rhythm, configuration, and

rate) are used as end points for such *open-ended tests*. Also, patient performance, measured as exercise duration, time until symptoms, stress at which symptoms occur, and hemodynamic parameters, is a better indicator of an adequate test than heart rate response. *Close-ended testing* is the use of fixed end points such as time on the treadmill or maximal heart rate.

The product of blood pressure and heart rate (*double product*) is a measure of myocardial oxygen demand. In patients with stable angina, the double product is reproducible on repeat ETs; thus it is used as an objective parameter to follow an individual patient's disease. Inappropriate or inadequate responses in blood pressure and/or heart rate to exercise suggest heart disease. A reduction in heart rate or a flat response (failure to increase heart rate above 120 beats per minute) with increasing levels of stress has a poor prognosis. Likewise, failure to increase the systolic blood pressure or the finding of a sustained decrease of more than 10 mm Hg is also associated with a worse prognosis. Such responses indicate that the heart has an inadequate reserve to respond to stress. Patients who are unable to progress beyond stage II of the Bruce protocol have a poor prognosis and more severe IHD. Other rating scales (e.g., Borg, which measures perceived exertion) may be used in conjunction with the objective results from the ET to classify patients into high- and low-risk groups. Silent ischemia may confound the interpretation of ET because blood pressure and ECG changes may occur in the absence of symptoms.

To provide standardized comparability between tests and patients, metabolic equivalents (METs) are used as a measure of $\dot{V}O_{2,max}$. A MET is a measure of resting oxygen uptake. Activity energy demands then can be calculated in terms of METs. For example, 4 METs is equivalent to walking at 4 mi/h. The number of METs a patient can undertake without symptoms of ischemia correlates with prognosis and helps to guide appropriate management strategies. Refer to Table 11–7 for examples of METs and activity correlations. Exercise capacities of less than 5 METs are associated with a poor prognosis; those greater than 13 METs have a good prognosis despite the presence of disease.

Meta-analysis of more than 24,000 patients in 147 studies showed a mean sensitivity of 68% and specificity of 77% for ET as a diagnostic test. The specificity of ET to detect the presence of CAD, compared with angiography, is 84%. Sensitivity ranges from 40% to 90% depending on the number of vessels affected, with a mean of 66%.

As a prognostic test, ET is very popular after myocardial infarction and can be conducted within 3 days of an acute event. It can be used to determine functional capacity, assess the degree of rehabilitation, and identify patients at risk for further cardiovascular events. Immediately after myocardial infarction, a modified protocol is used; the test is terminated when a heart rate of 70% to 75% of age- and gender-predicted maximum is reached (e.g., 140 beats per minute for those under age 40 and 130 for those older than age 40) or a MET level of 5 for patients older than 40 or 7 for those younger than 40. Tests usually are done prior to discharge or within 6 weeks of infarction.

TABLE 11–7. MET Relationship to Activity and Function

| METs | Level of Activity | ET Result |
|------|-------------------------|---|
| 1 | Resting | < 6 METs |
| 2 | Level walking at 2 mi/h | Symptom-limited lifestyle |
| 4 | Level walking at 4 mi/h | Sedentary lifestyle tolerated |
| 13 | Cycling 9–10 mi/h | Little or no activity-limited lifestyle |
| 20 | Shoveling heavy snow | No limitations on lifestyle |

TABLE 11–8. Contraindications for Exercise Testing

| Absolute | Relative |
|-------------------------------|-----------------------------------|
| Unstable angina | Left main coronary artery disease |
| Syncope | Tachy- or bradyarrhythmias |
| <72 hours after AMI | Electrolyte abnormalities |
| Uncontrolled CHF | Hypertension (SBP >220 mm Hg) |
| Uncontrolled arrhythmias | High-degree AV block |
| Acute systemic illness | |
| Acute pulmonary embolism | |
| Acute myocarditis | |
| Thrombosis of lower extremity | |

In the peri-infarction period, mortality and reinfarction rates are 0.02% and 0.09%, respectively. Patients may be stratified into low-, intermediate-, and high-risk categories depending on the evidence for ischemia and the level of exercise tolerance.

ET is relatively safe, with an estimated risk of AMI or death of 10 per 10,000 tests overall. Most adverse effects are cardiac in nature, including arrhythmias (primarily bradyarrhythmias), sudden death, hypotension, and myocardial infarction. Patients in whom ET is contraindicated are those who are unable or who should not exercise because of physiologic or psychological limitations (Table 11–8). Unstable angina is usually a contraindication to ET because of the instability of the patient's disease state and because patients cannot exercise to a satisfactory level for the test to be considered adequate. However, once such a patient is stable, ET is excellent for prognostic evaluation. In patients with untreated life-threatening arrhythmias or CHF, ET is also contraindicated. Patients with comorbid diseases such as COPD or peripheral vascular disease (PVD) may be limited in their exercise capacity, whereas lower limb amputees are unable to perform the standard treadmill test. For patients with disabilities or other medical conditions that limit their exercise capacity independent of heart disease, pharmacologic stress testing with dipyridamole, adenosine, or dobutamine is an alternative (see "Pharmacologic Stress Testing" below).

Drug therapy rarely is discontinued for the test primarily because few data exist to support better test results off drug therapy. Patients on β -blockers or calcium channel blockers may not achieve maximal heart rates, but ET helps to demonstrate patients' exercise capacity on drug therapy. Nitrates do not alter exercise capacity directly and theoretically may improve patient response because they relieve or prevent symptoms of ischemia. Digoxin interferes with interpretation of ST-segment changes, and patients rarely achieve ST-segment changes greater than 1 mm even in the face of significant ischemia. Owing to its long half-life, digoxin need not be discontinued prior to the test.

CARDIAC CATHETERIZATION AND ANGIOGRAPHY

Development of the cardiac catheterization technique was a major milestone in the diagnosis and management of CVD because it provided a physiologic and anatomic approach to assess patency of coronary vessels and hemodynamic parameters of cardiac function.^{24–34} Cardiac catheterization is the technique used to gain vascular access to the coronary arteries by intravascular catheters and heart chambers. Once cardiac catheterization is complete, other diagnostic and therapeutic procedures, such as angiography, ventriculography, and percutaneous transluminal angioplasty (PTCA), and drug administration (e.g., thrombolytics) may be undertaken.

Following interventional procedures such as PTCA, catheterization with angiography can be used to evaluate efficacy of the intervention. In recurrent clinical syndromes, following a procedure, catheterization is used to help delineate a new management strategy. Catheterization is also now used commonly with PTCA and/or drug therapy in the management of acute coronary syndromes.

Additionally, catheterization allows assessment of valvular function and computation of various cardiac performance parameters such as cardiac output, stroke volume, systemic vascular resistance, cardiac chamber pressures, and blood flow. It also allows for placement of cardiac pacemakers. Drug administration during cardiac catheterization is used primarily for assessment of end points in clinical trials (e.g., thrombolytics to assess coronary artery patency), for management of events (e.g., chest pain) during catheterization, or for diagnostic purposes (e.g., ergonovine to evaluate coronary spasm). Further applications of cardiac catheterization include aortic root angiography, pulmonary angiography, retrieval of foreign bodies, and atherectomy.

More than 1 million cardiac catheterizations are performed in the United States each year, making it the second most frequent in-hospital procedure. Images obtained during catheterization are stored on 35-mm cineradiographic film or are digitized, allowing comparison of studies at a later date. The ACC/AHA guidelines on angiography and PTCA describe the class I, II, and III indications for each of these procedures; examples are given in Table 11–9.^{27,28} The guidelines for angiography, PTCA, and catheterization also include recommendations regarding technique, procedures, facilities, personnel, and training.

The cardiac catheterization procedure requires vascular access, usually obtained percutaneously at brachial or femoral arteries or veins. Left-sided catheterization provides access to the aorta, left ventricle, and left atrium. Right-sided catheterization enables the right side of the heart, coronary sinus, pulmonary arteries, and pulmonary wedge position to be reached. Left-sided catheterization is used for coronary angiography and ventriculography, whereas right-sided catheterization is used for determination of cardiac performance parameters.

Prior to an elective procedure, the patient is given nothing by mouth (after midnight) except for oral medications. It is not necessary to stop any medications except warfarin prior to catheterization. Patients receiving warfarin may be transitioned to low-molecular-weight

TABLE 11–9. Indications for Coronary Angiography

Class I

Patients with class III–IV angina or high risk for adverse outcomes not responding to medical therapy
 Patients who have high-risk findings on noninvasive testing
 Suspected abrupt closure or stent thrombosis following PTCA
 Recurrent angina within 9 months of PTCA
 Alternative to thrombolytic therapy in patients less than 12 hours from AMI

Class II

Patients with class III–IV angina who improve on medical therapy
 Patients with CAD who fail to respond to medical therapy
 Patients with CAD who cannot be risk stratified by other methodologies
 Recurrent angina within 12 months of PTCA
 Recurrent angina not controlled by medical therapy post PTCA

Class III

Patients after interventional procedure with no evidence of ischemia
 Patients who are not candidates for or do not wish interventional procedures for revascularization
 Assessment of atypical chest pain

or unfractionated heparin or anticoagulation may be discontinued depending on the clinical scenario about 3 days prior to the procedure. Heparin products are stopped about 6 hours before the procedure to allow normalization of coagulation. There are no data to support low-molecular-weight heparin during catheterization procedures because its longer half-life may increase the risk of intra- and postprocedural bleeding. Patients who require anticoagulation prior to angiography (e.g., those with acute coronary syndromes) usually are treated with unfractionated heparin or low-molecular-weight heparin.

Patients frequently develop chest pain and/or vasospasm during introduction and manipulation of catheters and injection of angiographic dyes. Nitroglycerin and/or morphine may be given for chest pain. Nitroglycerin also is used to prevent vasospasm and is given sublingually or by intravenous infusion. Sedatives, such as midazolam or other short-acting benzodiazepines, frequently are given to ensure patient comfort and safety, but the patient is awake and aware of the procedure. Patient cooperation is necessary to obtain the angiographic views and assess symptoms. The patient will be required to remain still for about 6 to 8 hours to reduce the risk of bleeding from the catheter entry site(s). Depending on the procedure, patients may be discharged the same day or within 24 hours, if stable.

Heparin products are used during procedures such as angiography, left-sided heart catheterization, and PTCA to prevent thrombotic complications. Depending on the procedure undertaken, heparin is either discontinued almost immediately following the procedure or continued for 12 to 24 hours. Heparin administration during the procedure is measured with the activated clotting time (ACT), not the partial thromboplastin time (PTT). For patients undergoing PTCA, aspirin, clopidogrel, or ticlopidine and calcium channel blockers are used prior to and following the procedure. Despite the invasive nature of the procedure, there is no consensus as to the need for prophylactic antibiotics in patients at risk for bacterial endocarditis because of valvular prostheses or a prior history of rheumatic fever. With the advent of class IIb/IIIa receptor antagonists such as tirofiban, eptifibatid, and abciximab, which have been shown to improve short- and long-term coronary artery patency rates with PTCA, patients who receive a stent also will receive one of these agents prior to, during, and/or after the procedure.

During the procedure, hemodynamic parameters, blood pressure, and heart rate are monitored continuously. ECG monitoring and intermittent 12-lead ECGs are also maintained. Measurements taken during catheterization are obtained only after hemodynamic stabilization: at baseline, following catheter movement, or during pharmacologic intervention. Information obtained during catheterization is in real time and is assumed to reflect the ongoing status of the coronary circulation. Procedurally related vasospasm may be misleading because the catheter itself is a powerful stimulus for spasm.

Complications associated with cardiac catheterization procedures and attending angiographic or interventional activities are related to the expertise and experience of the operator, with case load being a good indicator of the latter. The incidence of significant complications related to catheterization with angiography is reported to be less than 2%, with mortality about 0.11%. Patient factors such as hemodynamic stability and renal function increase risk. There are no absolute contraindications to coronary angiography, and the relative contraindications are not well substantiated (Table 11–10). In essence, clinical stability of the patient and potential benefit of the procedure in terms of future patient management predicate the importance of relative contraindications. Complication rates, especially those of a thrombotic nature, increase with the dwell time of the catheters, duration of catheterization, catheter type, and operator technique. Bleeding complications can be reduced by ensuring that patients have normal

TABLE 11–10. Contraindications of Cardiac Catheterization and Other Procedures^a

| | |
|--|------------------------------------|
| Recent stroke | Patient noncompliance ^b |
| Advanced physiologic age | Digoxin intoxication |
| Severe anemia | Anaphylaxis to radiographic dyes |
| Severe hypertension | Active infection |
| Active gastrointestinal bleed | Severe electrolyte imbalances |
| Fever | Unstable condition |
| Other comorbid illnesses, e.g., COPD ^{c,d} | |

^aPrimarily contraindications to procedures such as arteriography and PTCA.

^bPatient not willing to undergo further treatment (e.g., surgery based on results of catheterization).

^cCOPD = chronic obstructive pulmonary disease.

^dDisease states that may prohibit or increase risk of other interventions (e.g., surgery).

^ePatients in whom emergency cardiac surgery would pose a high risk (e.g., during acute asthma or acute exacerbation of COPD).

coagulation studies prior to the procedure and remain at bed rest for several hours after the procedure and that the nursing staff undertakes good care of the catheter entry and exit sites. In the event of bleeding complications, direct pressure is required with sandbags, followed by emergency surgery if there is no resolution, to prevent further complications. Heart perforation is an uncommon but potentially lethal complication requiring emergency surgical intervention. Other complications such as a vagal reflex with hypotension, bradycardia, and nausea can occur. These occur most frequently in conjunction with patient anxiety and can be prevented or treated with atropine. An increased predisposition to myocardial infarction during and after the procedure is seen in patients with unstable angina, recent subendocardial infarction, and type 1 diabetes mellitus. After catheterization, patients may have elevated creatine phosphokinase and troponins owing to tissue damage during the procedure. There is some controversy as to how to interpret these values with respect to what they indicate regarding myocardial damage. Acute closure of a coronary vessel or myocardial ischemia is managed by return to the catheterization laboratory or cardiac surgery. All facilities should be in close liaison with a cardiothoracic surgery unit.

Angiography, which accompanies most cardiac catheterization procedures, is defined as the “radiographic visualization of coronary vessels after injection of radiopaque contrast medium.” Despite the expanding role of cardiac catheterization, angiography is used most frequently to describe the presence and extent of CAD and to allow planning for medical or surgical intervention. Cardiac catheterization with angiography is the “gold standard” in the diagnosis and assessment of CAD, against which all new invasive and noninvasive tests are measured. Unlike most other procedures, angiography determines the morphology of a stenotic lesion and the degree of luminal obstruction. However, this does not relate well to physiologic or functional significance of the lesion.³⁴ For example, a 50% luminal occlusion not considered significant by radiologic standards may still be the lesion producing symptomatic chest pain, and a diabetic patient with significant microvascular CAD may appear to have unaffected larger arteries at angiography and yet still be at risk of a cardiac event. Angiography also assesses the presence of collateral circulation and dynamic abnormalities such as vasospasm.

The extent of disease by angiography is defined as the number of vessels, and the vessels affected are named. Angiography is able to detect lesions that occlude the vessel by as little as 20%. Occlusions of 75% or more are almost always seen on angiography. Significant

narrowing is usually assumed to be 50% or more, although some studies use 70% narrowing as the cutoff point. The lesion can be measured in several ways. Considerable controversy exists as to the best methodology. During angiography, the lesion is compared visually with surrounding vessels. Inherent difficulties include individual evaluator variability and also the assumption that surrounding vessels are normal. Calipers can be used to document physical size, but generally, the degree of stenosis is reported as a percentage of narrowing. Various grading scales, such as the coronary artery score and myocardial jeopardy scores, are used, and these scores have been shown to predict long-term outcomes. Coronary artery lesions most prone to rupture and thrombosis are those with 40% to 60% narrowing, so lesions with less than 50% narrowing are not benign.

Multiple views are required to obtain a good image of the vessel; the right anterior oblique planes are used most commonly (two views at 90 degrees to each other). Lesions may be described as concentric and smooth (simple lesions) or eccentric and broad with a rough surface (complicated lesions). The number of lesions is also considered of importance to the severity and prognosis of IHD, although there is considerable variation in the accuracy of such predictions because angiographic and pathologic correlation of lesions is imperfect. The occurrence of spasm, variants in anatomy, and collateral filling also complicate interpretation of the angiogram.

Angiographic films are used to plan interventions, in particular coronary artery bypass grafting (CABG) and PTCA. They are also used during both surgery and PTCA to guide the procedure.^{35,36} Ventriculographic studies may be performed during cardiac catheterization to obtain information about the contours of the heart and to assess global and segmental function. Regional wall motion, filling defects, and the presence of mural thrombi also may be visualized. During this procedure, radiopaque dye is injected into the heart chambers, and serial films are taken to follow the dye passage. Left ventricular ventriculography is a routine part of left-sided catheterization unless ventricular function information is already available from other noninvasive studies or there are specific contraindications to the procedure.

Cardiac performance is also best assessed during catheterization procedures as direct visualization of performance along with calculated parameters that can be obtained simultaneously and represent real-time values. Measured and observed parameters obtained during catheterization are used to determine cardiac performance. Contractility, as judged by wall motion and ejection fraction, can be used to assess global cardiac performance and to plan and evaluate or assess therapy.

Invasive cardiology is growing rapidly not only in terms of the numbers of patients undergoing such procedures but also in terms of the diversity of procedures. The development of electrophysiologic studies for the assessment and treatment of arrhythmias was made possible because of catheterization. The diversity of techniques is "limited only by the imagination of the physician and inventiveness of the microtechnologist."

COMPUTED TOMOGRAPHY

CT scanning is used rarely as a primary diagnostic procedure in the evaluation of CVD and function because it provides similar information as other diagnostic procedures (e.g., ECHO) and is significantly more expensive. Enhanced definition and spatial resolution of structures are possible with CT scanning, which is useful in some specific indications such as to evaluate aortic and pericardial disease and assess paracardiac and cardiac masses. More accurate determination of chamber volume and size and mass calculations of myocardial wall thickness can be obtained from CT scanning than with other methods

such as ECHO or angiography. Additionally, CT scanning acquires three-dimensional images.³⁷

New techniques such as ultrafast CT (cine-CT) scanning have resolved the problems of cardiac motion that distorted conventional CT images.³⁸ With cine-CT scanning, complete tomograms are assembled within one cardiac cycle (50 ms), thus providing real-time images. For ultrafast CT scanners, a set event within the cardiac cycle (determined by ECG) usually is used as initiator for imaging to ensure standardization. Conventional CT scanning requires that images be correlated with the cardiac cycle by gating the CT to the ECG. Cine-CT scans examine the heart at 10 to 14 tomographic levels in 10-mm slices.

Although still in its infancy, cine-CT scanning has been proposed as a screening tool for evaluating the risk of developing obstructive CAD and as a diagnostic tool for CAD. Recent AHA/ACC guidelines address the current state of practice with this methodology. The CT scan will show localized areas of infarction and abnormal perfusion and allows quantification of the extent and density of coronary artery calcification.⁴⁰ Cine-CT scanning is more sensitive and specific than fluoroscopy in identifying the extent and density of coronary artery calcification. The calcium score (calcium density and volume of calcium) in patients older than 30 to 70 years with known CAD is significantly higher than in subjects with no CAD and appears to correlate well with the degree of coronary artery occlusion.⁴¹

CT scanning is more definitive and accurate in the diagnosis of aortic dissection and evaluation of the pericardium than ECHO. Diagnostic accuracy of aortic dissections with CT scanning is at least 90%. CT scanning affords definition of the edges of the intimal flap of the dissection, and true and false channels can be seen. It also demarcates the components of the myocardial wall from the inner endocardial wall through to the epicardial surface and pericardium, allowing visualization of abnormalities, such as aneurysms and thrombin. Detection of the presence of a thrombus on a CT scan is comparable in accuracy with two-dimensional ECHO. The pericardium appears as a distinct entity and can be evaluated for thickening and calcification. CT scanning is the most sensitive technique to differentiate types of pericarditis and estimate pericardial fluid volume. Compared with ECHO, CT scanning is equivocal to define loculated and hemorrhagic effusions.

In the evaluation of cardiac masses, CT scanning shows the mass as a distinct space-occupying entity. Tissue density differentiation as seen on a CT scan allows characterization of density, aiding in determination of the nature of masses. Masses as small as 0.5 to 1 cm can be identified on CT scans.

Like radionuclide assessment, contrast angiography, and ECHO, CT scanning can be used to calculate ejection fraction, left ventricular volume, and stroke volume. The blood pool is defined with intravenous iodinated contrast material. Ventricular volumes, ejection fraction, and stroke volume are determined directly from the blood pool on each image. Values obtained with CT scanning are more accurate and reproducible than those obtained on angiography and ECHO. The three-dimensional image of a CT scan also allows determination of the extent and distribution of LVH in patients with hypertrophic or congestive cardiomyopathy.

CT scanning has proven to be an effective noninvasive method to visualize congenital heart disease, but its role is challenged by the higher-resolution capacity of MRI.⁴² For measuring parameters in some congenital disorders, such as evaluation of ventricular function and estimation of the volume of cardiac shunts, CT scanning still remains the evaluation method of choice.

In summary, CT scanning, especially cine-CT scanning, is a rapidly evolving technique for evaluation of CVD.⁴³⁻⁴⁶ It remains an

expensive alternative to other methodologies in many instances, but the high resolution and spatial capabilities mean that CT scanning offers unique properties.

POSITRON-EMISSION TOMOGRAPHY (PET)

PET is a relatively new modality for diagnostic imaging in CVD medicine.^{47–54} PET has found a niche to characterize myocardial physiologic and metabolic activity, perfusion, and viability. PET can measure regional myocardial uptake of exogenous glucose and fatty acids, quantitate free fatty acid metabolism, define perfused myocardium energy source(s), and evaluate myocardial chemoreceptor sites.⁵⁰ Although many other techniques can be used similarly to evaluate myocardial function, PET images are superior in definition. The primary advantages of PET are its noninvasive nature, the ability to do repeat scans within a short period of time, such as before and after PTCA, and the reproducibility of images over time. PET is very expensive owing to the need for on-site cyclotrons for many of the radiotracers, and there is limited availability of sites that offer the technique. Cheaper forms of PET-like scanning are in development, but image resolution is less.

PET uses positron-emitting isotopes such as oxygen-15, nitrogen-13, carbon-11, and fluoride-18. These are incorporated into substances such as water, glucose analogs, or fatty acids, the metabolic substrates for myocardial tissue. For myocardial perfusion studies, rubidium-82 (⁸²Rb), nitrogen-13 ammonia ([¹³N]H₃), and ¹⁵O₂-labeled water are used. For myocardial substrate metabolism studies, [¹¹C]palmitate, [¹¹C]acetate, and [¹⁸F]2-deoxyglucose (FDG) are used. All these substances have very short half-lives (<10 minutes). In the fasted state, perfused myocardium primarily uses fatty acids as energy source. Postprandially, glucose is the preferred substrate. Ischemic myocardium primarily metabolizes glucose because mitochondrial fatty acid oxidation is impaired. Hence, with PET using either a fatty acid or glucose substrate, ischemic versus nonischemic areas can be defined. Frequently, PET is used in conjunction with pharmacologic stress testing to provoke ischemia, with images obtained before and after stress application.

Uptake of ⁸²Rb occurs via the Na⁺,K⁺-ATPase pump and occurs preferentially in viable tissue. Net uptake into tissue resolving from an ischemic insult and infarcted tissue is reduced. With a half-life of 1.26 minutes, serial images of myocardial perfusion can be taken as frequently as every 5 minutes, and a dobutamine stress test is completed within 45 minutes. Comparative studies with ET, single-photon-emission computed tomography (SPECT), and stress ECHO show PET to be more accurate in the detection of IHD. The substrate [¹³N]H₃ rapidly crosses capillary membranes and is trapped in the myocardium by glutamate-glutamine reactions. This product produces high-contrast images with a sensitivity of 88% to 97% and a specificity of 90% to 100% to detect IHD. Oxygen-15–labeled water has a high extraction ratio into myocardial tissue, which appears to be independent of blood flow or the metabolic state of the myocardium. Oxygen-15–labeled water studies are done in conjunction with [¹⁵O]carbon monoxide (labels red blood cells in the vascular space) studies to help eliminate some of the background activity that occurs as a result of the high extraction ratio.⁵⁴

Tracers used for assessment of myocardial metabolism are selected based on the type of metabolism of interest: FDG traces glucose metabolism, [¹¹C]palmitate traces mitochondrial fatty acid metabolism, and [¹¹C]acetate is an indirect marker for myocardial oxygen consumption, allowing assessment of ventricular performance. [¹¹C]Palmitate is a useful marker for normal myocardial oxygen consumption because baseline energy needs of the myocardium

are met through fatty acid oxidation. Clearance of [¹¹C]palmitate is biexponential, and studies in animals and in healthy men have shown clearance to be proportional to cardiac workload and myocardial oxygen consumption. In acute ischemia, the first component of clearance is reduced and the second is increased. The use of [¹¹C]palmitate to assess myocardial metabolism in ischemic tissue is limited because there is altered transport and storage of the compound and significant backdiffusion of the agent into the vascular space.

FDG accumulates in the heart proportional to glucose use by the myocardial cell and so is a marker of cell viability. FDG studies help to identify the affected vascular bed and allow evaluation as to whether angioplasty or surgery might be used.⁵⁰ Detection of hibernating myocardium is possible because it predominantly uses glucose and can be seen readily on PET scans. Patients with a significant degree of jeopardized or hibernating myocardium identified on PET scanning then could be candidates for revascularization procedures. In contrast, a perfusion study would not show as good differentiation of infarcted versus hibernating tissue, and revascularization may not be considered. In studies of recovery of left ventricular function following revascularization, PET has a positive predictive value of 72% and a negative predictive value of 83%. PET with FDG has been used in the assessment of cardiomyopathies. In ischemic cardiomyopathy, discrete regional ischemia is seen as a patchy, nonhomogeneous uptake of the tracers; dilated cardiomyopathies show global decreased uptake of tracers.

In CAD, PET is used to assess and follow the physiologic significance of stenotic lesions. After infarction, PET myocardial substrate metabolism studies are used to evaluate the amount and activity of viable tissue around the infarcted area and the site and extent of infarction. Myocardial perfusion studies with PET identify more accurately the viable and nonviable myocardium compared with technetium and thallium. PET also quantifies regional myocardial perfusion more accurately than other modalities. When linked with physiologic or pharmacologic stress tests, PET enables evaluation of the myocardium under stress conditions. Studies in patients with more than 50% stenosis on angiography suggest that dipyridamole stress SPECT and [¹³N]ammonia PET are comparable tests to assess coronary artery perfusion, with respective sensitivities of 98% and 96% and specificities of 88% and 81%.⁵¹ SPECT analysis using FDG compared with PET with FDG shows comparable accuracy for the detection of CAD. Comparative studies with SPECT thallium in conjunction with bicycle ergometer or dipyridamole versus PET perfusion scanning showed comparative sensitivities (76% to 79%) but improved specificity (90% versus 82%, *p* < .005).^{53,54}

The future of PET appears promising. Improved tomographic scanners, development of new radiopharmaceuticals, and improved understanding of substrate metabolism and its relationship to myocardial tissue viability will provide new dimensions to assess and evaluate myocardial function. Research enterprises are developing agents to label receptors as a tool to determine cardiovascular physiology and how altered receptor function, biochemical abnormalities, substrate metabolism, or other as yet unrecognized abnormalities impair cardiac function.

ECHOCARDIOGRAM

7 ECHO is the use of ultrasound to visualize anatomic structures such as the valves within the heart and to describe wall motion.^{55–60} Clinically, ECHO is the most frequently used noninvasive cardiovascular test, aside from the ECG. It competes well with invasive techniques such as cardiac catheterization with angiography for the evaluation of ischemia and valvular abnormalities. ECHO is

relatively cheap to perform and can be done at the bedside, in the operating room, or in the physician's office. The major disadvantages of ECHO relate to technical limitations of operator-dependent images and competition from other noninvasive technologies such as MRI and CT scanning that provide similar information with superior tissue-type resolution. ECHO is used often as an initial evaluative tool following auscultation detection of an abnormality, thus providing a baseline visual characterization. Serial determinations in a given patient, especially following a change in clinical condition or a procedure, allow evaluation of progression of disease over time.

ECHO remains the procedure of choice in the diagnosis and evaluation of a number of conditions such as valvular dysfunction (aortic and mitral stenosis and regurgitation and endocarditis), wall motion abnormalities associated with ischemia, and congenital abnormalities, such as ventricular or atrial septal defects. Images obtained from ECHO are used to estimate chamber wall thickness and left ventricle ejection fraction, assess ventricular function, and detect abnormalities of the pericardium such as effusions or thickening.

ECHO is based on the principle of differential acoustic impedance (or tissue density) and the laws of reflection and refraction. Sound waves directed across tissues from a transducer will reflect back sound waves of different frequencies. The ability of the ultrasonic beam to penetrate chest wall structures is inversely proportional to the frequency of the signal. With transthoracic ECHO, frequencies of 2.0 to 5.0 MHz are used commonly in adults, and frequencies of 3.5 to 10.0 MHz are used in children. Serial determinations in a given patient using the same conditions and ECHO images (windows) provide the best form of internal control to allow comparisons of test results. In clinical trials, echocardiograms are read and interpreted independently by two or three clinicians to provide a means of control.

Two primary approaches to ECHO are used in clinical practice. Transthoracic echocardiography (TTE) is conducted with the transducer on the chest wall, whereas transesophageal echocardiography (TEE) is conducted with the transducer in the esophagus. In TTE, several modes of operation are possible, the most common being M-mode (motion) and two-dimensional (2D) imaging. Both M-mode and 2D ECHO provide visualization of heart structures and can indicate numerous structural abnormalities such as aneurysms, wall thickness abnormalities, chamber collapse (e.g., tamponade), and valvular stenosis. TEE is used primarily for assessment of valvular anatomy and function or to image intracardiac masses such as tumors or thrombi and valvular vegetations.^{59,60}

In M-mode ECHO, the transducer is placed at a single site on the chest (usually along the sternal border), and the ultrasound is directed posteriorly. M-mode ECHO records only static objects in one plane, producing a single picture of a small region of the heart, or an "icepick view." Results depend on the exact placement of the transducer with respect to the underlying structures. Conventional M-mode ECHO provides visualization of the right ventricle, left ventricle, and posterior left ventricular wall and pericardium. If the transducer is swept in an arc from the apex to the base of the heart, virtually the whole heart can be visualized, including the valves and left atrium. Images are displayed as "windows."

Two-dimensional ECHO employs multiple windows of the heart, and each view provides a wedge-shaped image. Windows most commonly used include parasternal long- and short-axis and apical two- and four-chamber views (Fig. 11-6). These views are processed onto a videotape to produce a motion picture of the heart. 2D ECHO renders increased accuracy in calculating ventricular volumes, wall thickness, and degree of valvular stenosis compared with M-mode ECHO. Patient-specific calculated parameters such as ejection fraction and wall thickness are compared with standardized values (population-

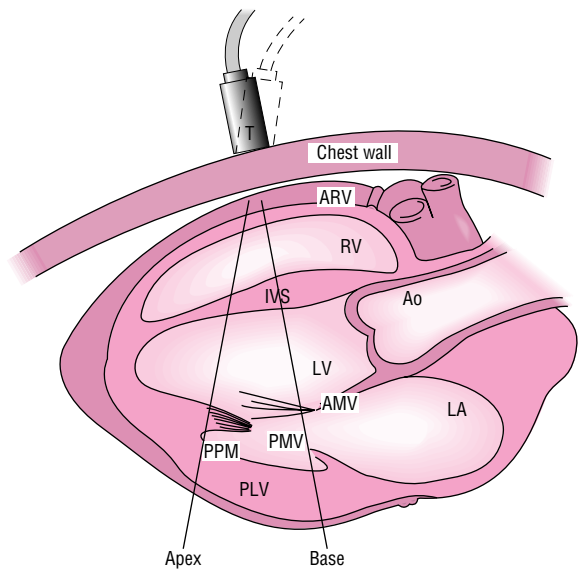

FIGURE 11-6. Schematic drawing of two-dimensional echocardiography to illustrate location of cardiac structures as "seen" by the transducer. The transducer is swept in an arc so that several pictures of the heart are obtained to generate the final electrocardiogram. (Redrawn from Coryu BC, et al. *Application of electrocardiography in acute myocardial infarction. Cardiovasc Clin* 1995;2:113, with permission.)

based) or with previously obtained values from the patient. Although ejection fraction is still commonly obtained with ECHO, it is a derived number, so it is considered subjective. Other tests to determine ejection fraction provide different numbers and highlight the difficulty of comparing results between tests. Ejection fraction from ECHO is also limited by the diminished views of total ventricular volume able to be visualized, especially in persons with distorted ventricles. Despite these limitations, ECHO remains the most common modality for ejection fraction determination.

ECHO can be used for diagnosis and prognosis and as a serial evaluation tool to assess acute and chronic ischemic heart disease and regional left ventricular function.⁵⁷ Areas of ischemic myocardium are seen on ECHO as aberrations in wall motion. Wall motion abnormalities are seen as altered thicknesses of various segments of the heart. Wall motion abnormalities are graded using descriptive terms such as *akinetic*, *hypokinetic*, *dyskinetic*, and *hyperkinetic*. It is possible to visualize the complete ventricle (in segments), allowing both global and regional left ventricular function to be assessed. Studies have shown that the locations of segmental ventricular wall motion abnormalities correspond with areas of CAD. ECHO can be linked with the various stress tests (ET, dipyridamole) to assess stress-induced structural or functional abnormalities (e.g., changes in wall motion). As a serial monitoring test, ECHO is comparable with angiography as a prognostic tool and can be used as a treatment planning tool. After myocardial infarction, ECHO is a useful noninvasive diagnostic tool for detection of ventricular aneurysms, thrombi, and pericardial effusions and can be used serially for diagnostic and prognostic information.

In TEE, the transducer is advanced into the esophagus and rests just behind the heart. The transducer also can be passed into the fundus of the stomach to obtain better images of the ventricles. Images are obtained in either the horizontal or vertical plane.⁵⁸ This is a low-risk invasive procedure and does not require routine antibiotic prophylaxis for patients at risk of developing endocarditis. Complications such as esophageal tears or perforation, esophageal burns, transient

ventricular tachycardia, minor throat irritation, and transient vocal cord paralysis have been reported rarely.⁵⁹ In one series of 10,218 studies, only 1 death (0.0098%) was reported, comparable with that with esophageal gastroduodenoscopy (0.004%).⁵⁸ TEE is contraindicated in patients with esophageal abnormalities, in whom passage of the transducer might be limited (e.g., esophageal strictures or varices).

TEE yields higher resolution and improved visualization of structures, especially pulmonary veins and valves, compared with TTE. Interference of ribs, lungs, and subcutaneous tissues is reduced, enabling TEE to be more useful in patients in whom TTE is limited because of pulmonary disease, mechanical ventilation, or obesity. A high-frequency transducer (5 MHz for adults) is used, thus producing better image resolution. TEE is used for the same indications as TTE. Visualization of the heart valves—in particular, the mitral valve—is superior, allowing more accurate evaluation of both native and prosthetic valves. Clinical studies have shown that it is possible to visualize valvular vegetations as small as 5 mm with TEE. The ACC/AHA guidelines recommend TEE if the TTE is equivocal and the patient has staphylococcal bacteremia.⁵⁷ In a study comparing vegetation visualization, TEE detected vegetations in 90% of patients compared with 58% with TTE. It also can help to define complications of endocarditis such as thrombosis or valve leakage. In aortic dissection, TEE is able to identify the initial flap and origin of dissection and has an overall sensitivity and specificity of 97% and 100%, respectively. CT remains the diagnostic method of choice for aortic dissection, but TEE offers a sensitive and fast test that can be conducted in the emergency room.

Other uses of TEE include identification of cardiac thrombus, especially thrombi in the left atrium, and assessment of atrial dilation. After transient ischemic attacks or cerebrovascular accidents, TEE may enable identification of the site of cardiac emboli by providing excellent images of likely sources of such, namely, ventricular or atrial thrombus, valvular vegetation, cardiac shunts, cardiac tumors, or atrial and ventricular septal defects. In a study of almost 1500 patients with cerebral ischemia or nonvalvular atrial fibrillation, atrial thrombi were seen in 183 patients when evaluated by TEE versus only 2 patients using TTE. TEE can be used for intraoperative cardiac imaging to ascertain development of ischemia.

Another advance with ECHO has been the addition of Doppler and color-flow Doppler technology. The Doppler principle involves reflecting sound off a moving object—in the case of ECHO, the red blood cell. As the red cell moves in relation to the transducer, a frequency shift occurs in the reflected wave. Assessment with Doppler ECHO combines structural images and hemodynamic monitoring. Thus it is possible to evaluate the impact of structural disease on cardiac function and quantify the associated hemodynamics. Color enhancement allows flow direction to be visualized; different colors are used for antegrade and retrograde flow. These improve resolution of structures, identify patterns of blood flow, and allow calculation of flow gradients.

Doppler ECHO is used primarily in conjunction with traditional ECHO for analysis of valvular function or blood flow patterns. It allows measurement of transvalvular pressure gradients, valve area, and pressure changes on either side of the valve. Doppler ECHO is either continuous or pulsed; the former is used to assess pressure changes, whereas the latter is used to localize points of origin and creation of turbulent and high blood flow. Color Doppler is used to visualize blood flow (e.g., regurgitation). Turbulence associated with valvular and wall motion abnormalities can be visualized and quantified clearly. In aortic regurgitation, Doppler ECHO is the best noninvasive technique to assess the pressure and severity of regurgitation. Color-flow mapping allows tracing of the jet direction and an indication

of its volume, point of wall contact, and width. Because Doppler ECHO distinguishes different types of turbulence, it can simultaneously identify more than one type of valvular abnormality (e.g., aortic regurgitation and mitral stenosis) and the source of concomitant heart murmur.

NUCLEAR CARDIOLOGY

Nuclear cardiology continues to be a major advance as a noninvasive testing method.^{61–70} Radionuclides with short half-lives, which can be used either alone or combined with other substances to form agents with particular properties, such as technetium-99m pyrophosphate, have expanded the role for nuclear imaging in cardiology.

8 Nuclear imaging techniques have demonstrated equal sensitivity and specificity to many of the invasive “gold standard” testing modalities. The major limitations of nuclear cardiology are the availability of suitable radionuclides and correlation of nuclear images with cardiovascular function.

Despite the availability of new radionuclides, technetium-99m (^{99m}Tc) and thallium-201 (²⁰¹Tl) remain the two most commonly used radionuclides. ^{99m}Tc is ideal for clinical imaging, with a half-life of about 6 hours, a single 140-keV photon peak suitable for available imaging systems, primarily γ -ray emission, and the ability to be combined with multiple pharmaceuticals. It is generated in-house by a benchtop generator that reduces transportation costs and provides immediate availability. The short half-life means high doses and repeat injections can be given to evaluate efficacy of interventional therapy over a relatively short period of time. ²⁰¹Tl has a much longer half-life of 73 hours, which prevents the use of multiple doses close together but does mean that delayed imaging is possible following administration of the agent. Uptake into cells depends on blood flow. The energy from ²⁰¹Tl is x-ray, with an energy level of 69 to 83 keV. Production of thallium requires a cyclotron. Images are obtained with a conventional gamma camera.

TECHNETIUM SCANNING

Technetium scanning is used for the evaluation of blood pool and myocardial perfusion and as an infarct-avid agent to identify damaged myocardium. Analysis of the blood pool, as in a multigated angiography (MUGA), uses technetium either alone or as a red blood cell complex. The former obtains images following a bolus of technetium and traces its passage from the venous system through the heart to the aorta and is known as *first-pass angiography*. Equilibrium tests where technetium is bound to red blood cells provide an imaging time of several hours, which allows serial images to be obtained. These tests are used to determine right and left ventricular ejection fractions, detect cardiac shunts, estimate ventricular volumes, and view wall motion.⁶⁴

Infarct-avid radionuclides such as technetium-pyrophosphate (^{99m}Tc-PYP) are used to describe the presence and extent of damaged myocardium after myocardial infarction, in suspected myocardial contusion, and following chest wall injuries. Imaging with ^{99m}Tc-PYP is applicable when myocardial infarction is suspected clinically, but patient history, ECG changes, and laboratory evidence are not definitive. Uptake of ^{99m}Tc-PYP into infarcted tissue depends on regional blood flow, myocardial calcium concentration, the degree of irreversible myocardial injury, and time after infarction. ^{99m}Tc-PYP attaches to calcium deposited in the infarcted area, so the approach is known as *hot spot scanning*. False hot spots may occur where there is necrotic myocardial tissue, as in myocarditis, myocardial abscesses, old infarctions, and myocardial trauma. Additionally, uptake has been seen during unstable angina and ventricular dyskinesia and at sites of

ventricular aneurysms, suggesting that these are associated with transient low blood flow. In infarcted tissue, ^{99m}Tc -PYP levels can be as high as 18 to 20 times that of normal myocardium, which gives rise to very distinct borders between the infarcted and normal myocardium. Uptake of ^{99m}Tc -PYP into necrotic myocardium is delayed and not measurable until after about 4 hours of coronary occlusion. Scans prior to this time are usually negative and become positive about 12 hours after occlusion. Peak intensity of ^{99m}Tc -PYP is reached at 48 hours. Washout occurs over 5 to 7 days, so ^{99m}Tc -PYP is a useful late marker of infarction, especially in patients who present late or with a silent infarction. Images are viewed by comparing sternum and rib uptake with that seen in the myocardium. This type of imaging also can be used to assess graft patency after coronary artery bypass. Certain characteristics of the images obtained have been linked with various prognostic values but await confirmation in comparative and long-term prognostic trials.

Other technetium-labeled agents used include technetium-*t*-butyl isonitrile (^{99m}Tc -TIBI); technetium-carboxy isopropyl isonitrile (^{99m}Tc -CPI); technetium-sestamibi, also known as methoxy-isobutyl isonitrile (Tc-MIBI); and technetium-teboroxime. Technetium-sestamibi has a similar myocardial uptake pattern to thallium and produces similar results but with improved image quality because it generates a much higher photon yield. This is now popular as an alternative perfusion imaging agent to thallium. Technetium-teboroxime is still primarily an investigational agent. The main advantage of the newer technetium compounds is the lack of redistribution perfusion, allowing for delayed imaging. This is particularly useful in acute clinical settings; the radiopharmaceutical can be injected during the acute event and imaging undertaken when the patient is more stable.

THALLIUM SCANNING

Thallium is a potassium analog taken up into normal myocardium by passive diffusion and possibly by active transport via the Na^+, K^+ -ATPase pump. Uptake depends on regional blood flow and in a linear fashion up to very high blood flow rates. It is used primarily for the analysis of coronary and myocardial perfusion. High thallium uptake occurs in perfused myocardium; in ischemic myocardium, uptake is reduced significantly. Scans taken during acute ischemia or following infarction show areas of poor or nil distribution of thallium corresponding to the site of ischemia. A scan repeated 4 to 6 hours after the initial scan may show a redistribution of the thallium into areas that previously had little to no thallium uptake. These defects are referred to as *partial defects*, demonstrating areas hypoperfused during “stress” but viable myocardium at rest. Redistribution occurs because there is delayed washout of thallium from poorly perfused myocardium, resulting in less contrast between the density of thallium in different areas of the heart. This gives the appearance of “redistribution” of the radionuclide into the previously ischemic area. To enhance evaluation of potential partial defects, a second injection of thallium can be used. Areas of nil distribution are called *cold spots* or *fixed defects* and reflect infarcted myocardium.

Thallium scanning with the aid of computer analysis segregates the images into anatomic regions and specifically localizes areas of dead or necrotic myocardial tissue. In conjunction with ECHO or SPECT,⁶⁶ thallium scans can correlate areas of abnormal wall motion with areas of poor perfusion. Sensitivity and specificity of thallium scanning to detect IHD disease are comparable with those of ET (75% and 80%, respectively). When used in conjunction with exercise ECG, sensitivity increases to about 80%. Thallium scanning also can be used in conjunction with ET to allow detection of lower levels of ischemia than may be determined from ECG abnormalities or patient

symptoms. Thallium is injected at the peak of the ET, and exercise continues for another 30 to 60 seconds, when the initial images are taken. Repeat images are taken at 3 to 4 hours.

Thallium scanning is useful in patients with atypical chest pain and ambiguous or false-positive ET to determine if IHD is the cause of symptoms and the ET abnormalities. Thallium scanning is also used for postoperative evaluation of revascularization or angioplasty procedures and for preoperative evaluation for prognostic stratification for persons with IHD. A normal thallium scan heralds a benign outcome, even in patients who have angiographically evident CAD. The finding of redistribution is a marker of jeopardized but viable myocardium and has been shown to have important prognostic value. Major cardiac events such as MI in patients with normal ^{201}Tl studies average less than 1% per year. The best predictor of coronary events, which correlates thallium scans with clinical significance, is the number of myocardial segments with transient (redistribution) defects.

A number of other radiopharmaceuticals have found some use in cardiovascular testing, such as labeled antimyosin antibodies.⁶⁷ Theoretically, these antibodies should be more specific markers of myocyte necrosis. The currently used antibodies are a murine Fab fragment. Phase I, II, and III trials suggest that these are highly specific for irreversibly injured myocytes, but they have limitations in terms of pharmacokinetic properties. Uptake into myocardial tissues is very slow, with a prolonged blood pool activity seen for at least 24 hours. In clinical use, the antibody is given within 24 hours of the infarction, and planar or SPECT imaging is undertaken 24 to 48 hours later. Despite the supposed specificity of the antibody to myosin, localization is more dependent on blood flow than on myosin concentration, so measurement of infarction size is not as accurate as expected. Another investigational agent, [^{123}I]phenylpentadecanoic acid, is able to assess both myocardial perfusion and metabolism by virtue of its affinity for fatty acid metabolism.⁶⁷

PHARMACOLOGIC STRESS TESTING

9 Pharmacologic stress testing is an alternative to ET and ET with thallium in patients who are unable or unwilling to undergo ET.^{70–77} Additionally, pharmacologic stress testing is now used more than 50% of the time to assess coronary perfusion. The pharmacologic agent produces stress by a hyperemic (vasodilator) response or by increasing myocardial oxygen demand (heart rate and myocardial contractility). Agents currently used include dipyridamole and adenosine (hyperemic stress) and dobutamine (myocardial stress). Pharmacologic stress tests can be linked to various imaging techniques such as thallium planar scanning, SPECT, MRI, and ECHO. Dobutamine is linked most frequently to ECHO, allowing quantification of wall motion abnormalities, which have been shown to correlate well with areas of ischemia.

The principle of dipyridamole and adenosine thallium imaging is related to their coronary arteriolar vasodilator properties. Dipyridamole inhibits adenosine cellular reuptake, resulting in increased concentrations of adenosine in the blood and tissues. Adenosine is a potent coronary artery vasodilator and can increase perfusion four to five times over baseline. Areas distal to a coronary artery obstruction will show a relative hypoperfusion compared with normal coronary arteries because there is reduced perfusion pressure owing to preferential perfusion of normal segments over stenotic segments. Acutely, these areas will appear as cold spots, but on the redistribution scans, the defects will fill, indicating viable but jeopardized myocardium.

Dipyridamole is given intravenously in a dose of 0.142 mg/kg per minute over 4 minutes. This dose has been shown to increase baseline coronary blood flow in the normal tissues up to four to five

times over control. Some studies have used doses up to 0.84 mg/kg to enhance the vasodilator response. At the higher dose, acute adverse effects such as chest pain are more common. Adenosine for stress testing is an unlabeled use of this drug. Adenosine is given over 6 minutes at a dose of 0.140 mcg/kg per minute. At the end of infusion (dipyridamole) or after 3 minutes (adenosine), a 2.5- to 4-mCi dose of thallium is given. The maximum effect of dipyridamole occurs at 5 to 7 minutes and adenosine at about 30 seconds after the end of infusion. Imaging follows immediately and can be repeated at 24 hours (thallium scanning) to heighten the redistribution defects from fixed or partial defects.

Like exercise thallium scanning, dipyridamole and adenosine scanning or ECHO is used to detect IHD, evaluate the prognosis of patients with known disease, assess patients after MI, and as a risk-stratification method prior to vascular, cardiac, and noncardiac surgery. Pharmacologic stress testing evaluates wall motion abnormalities and perfusion defects under stress and has been shown in numerous studies to have comparable sensitivity and specificity with the traditional ET. Using planar scanning and dipyridamole, sensitivity to detect IHD ranges from 67% to 95% with a 67% to 100% specificity. A summary of 13 studies in almost 900 patients gave a pooled sensitivity of 85% and specificity of 87%. SPECT scanning has at least comparable sensitivity and slightly lower specificity to planar imaging but produces higher-quality imaging, which may enhance quantitative interpretation.

Dipyridamole testing has been shown to be safe and effective in the elderly and in those with unstable angina immediately after MI (within days). It also may be used to assess the status of revascularization procedures.⁷⁰ As a prognostic test, dipyridamole testing is very useful. In several studies, abnormal scans have shown about a 10-fold increase in event rates over 1 to 2 years of follow-up. Abnormal scans also have been shown to be an independent risk factor for myocardial infarction and death with a relative risk of 3.1. Reversible defects correlate best with events, with one study demonstrating a 4.41 relative risk for cardiac events.

Adverse effects with dipyridamole thallium testing are minimal, the main adverse effects being chest pain (with or without ischemic changes on the ECG), headache, dizziness, and nausea. Adverse effects are related to the increased adenosine activity and can be ameliorated by xanthine compounds because they are direct competitive antagonists of adenosine. Caffeine products must be avoided for about 24 hours prior to the test. Adenosine is associated with a higher incidence of adverse effects (80% versus 50%), but these are very transient, and some studies have shown that patients prefer it over dipyridamole. Both agents are relatively contraindicated in patients with a history of bronchospasm.

Dobutamine, a synthetic catecholamine, increases heart rate and cardiac output, resulting in an increase in myocardial oxygen demand. Ischemia develops in areas where stenosis prevents the increase in oxygen demand from being met with increased blood flow. Ischemia is detected by ECHO as regional wall motion abnormalities or with thallium scanning.

Dobutamine, when used as a stress test, is given in doses of 20–40 mcg/kg per minute. The dose is titrated at 3-minute intervals in increments of 10 mcg/kg per minute. If thallium is used, it is given 2 to 3 minutes before the end of infusion. Atropine 0.5–1 mg may be given to augment the heart rate response to 85% of the patient's calculated maximum. ECG and blood pressure are recorded continuously throughout the test, and ECHO recordings are made during the last minute of each dose level and during recovery.

β -Blocker and calcium channel blocker therapy may interfere with the heart rate response to dobutamine stress tests and is

recommended to be discontinued prior to the test. Dobutamine stress testing is relatively well tolerated. Reasons to discontinue the test include development of severe chest pain, extensive new wall motion abnormalities, ST-segment elevation and depression suggestive of significant ischemia, tachyarrhythmias, and symptomatic reductions in blood pressure.^{64,74} β -Blockers can be used to reverse most adverse effects if they persist. Dobutamine stress tests are contraindicated in patients with aortic stenosis, uncontrolled hypertension, and severe ventricular arrhythmias. Ventricular fibrillation and myocardial infarction occur at a rate of about 0.05%.

Dobutamine stress testing has been studied as a diagnostic, prognostic, and therapy assessment tool after MI and for unstable and chronic angina. One study compared dobutamine, dipyridamole, and ET with coronary angiography for diagnostic accuracy in patients with IHD and showed an overall accuracy of 87% for ET, 82% for dobutamine, and 77% for dipyridamole. A recent review of 14 studies of 942 patients for the detection of IHD with dobutamine stress testing calculated the sensitivity to be about 80% (70% to 100%) with a 75% (64% to 100%) specificity. Sensitivity is highest for detection of three-vessel disease (92%). Dobutamine-sestamibi stress testing seems to be less sensitive than thallium even for multivessel disease. Comparative studies with ET and dipyridamole ECHO show dobutamine to be more sensitive. After MI, dobutamine stress testing identifies patients at high risk of subsequent cardiac events. For patients with suspected or known IHD, a positive dobutamine stress test is an independent predictor of cardiac events, and a negative test affords protection from cardiac death.

INTRAVASCULAR ULTRASOUND

Intravascular ultrasound (IVUS) combines braided polyethylene catheter technology with miniaturized ultrasound transducers that can be inserted into a variety of vascular beds within the body, including the coronary artery vasculature.^{78–81} Catheter configuration varies and may include over-the-wire, monorail, and fixed-guidewire tip configurations, resulting in different torqueability, steerability, and pushability characteristics for each type of catheter. There are two basic types of transducers, the solid-state phased array and a rotating mechanical transducer. In general, the phased-array transducers are smaller and may be mounted on more flexible catheters so that smaller vessels (such as coronary arteries) can be visualized, but they require a more complex system for image reconstruction and show more artifacts in imaging.

In contrast to angiography, IVUS provides quantitative information from within the vessel on diameter, circumference, luminal diameter, plaque volume, and percent stenosis. Qualitative information regarding the amount of plaque elevation, plaque composition (e.g., calcific, fibrous, or fatty plaque), and the presence of plaque versus thrombus, thrombus versus tumor, and aneurysm and hematoma can be provided with IVUS. IVUS is also used as a therapeutic adjunct with PTCA, atherectomy, stent or graft placement, and fibrinolysis, although routine use may not be justified.⁸⁰ These combination procedures may be monitored in real time as the procedure (e.g., atherectomy) is being performed.

CORONARY ANGIOSCOPY

Percutaneous coronary angiography permits direct visualization of the luminal surface of the coronary blood vessels.⁸² The coronary angiogram is composed of a flexible catheter with a fiberoptic imaging bundle coupled with a video monitor and video recorder for live and archival viewing. Because a blood-free field is necessary for viewing,

an occlusion catheter on the end of the catheter can be inflated for 45 to 90 seconds in a disease-free portion of the artery of interest and flushed with saline or lactated Ringer's solution to view diseased segments.

Although the role of angiography is still being developed, the recognized uses include guiding saphenous vein bypass graft interventions, postinterventional evaluation of lesions, identification of culprit and borderline lesions, stent deployment, and directing of procedures to achieve better outcomes with fewer complications. The limitations of angiography include lack of cross-sectional information, large fluid boluses to clear the field, large introducer size, and length of the procedure. Currently, this technology is not widely available, but it holds promise for future applications.

CARDIOPULMONARY RESUSCITATION

Jeffrey F. Barletta

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 For patients in ventricular fibrillation/pulseless ventricular tachycardia (VF/PVT), rapid defibrillation is the single most important intervention that affects survival.
- 2 The purpose of using vasopressors following cardiac arrest is to increase both coronary and cerebral perfusion pressure.
- 3 Either epinephrine or vasopressin is an appropriate drug of first choice in patients with VF/PVT; if vasopressin is used, only one dose is administered.
- 4 The primary reason for the use of antiarrhythmic agents following cardiac arrest is to raise the fibrillation threshold.
- 5 Amiodarone is the only antiarrhythmic drug that has shown benefit over placebo in patients with out-of-hospital cardiac arrest.
- 6 Electrolyte abnormalities always should be assessed as a cause of refractory arrhythmias.
- 7 For pulseless electrical activity (PEA) and asystole, the primary focus should be diagnosis and identification of a reversible cause.

Cardiopulmonary arrest is the abrupt cessation of spontaneous and effective ventilation and circulation following a cardiac or respiratory event.¹ Cardiopulmonary resuscitation (CPR) provides artificial ventilation and circulation until it is possible to provide advanced cardiac life support (ACLS) and reestablish spontaneous circulation. In the United States, there are more than 450,000 victims of sudden cardiac arrest each year, with 60% to 70% occurring outside the hospital.²

Early attempts at resuscitation date back to the biblical era.³ Modern-day resuscitation began in the late 1950s when it was discovered that expired air delivered via a mouth-to-mouth technique can maintain adequate oxygenation of blood.⁴ Later, in 1960, Kouwenhoven and colleagues described “closed chest cardiac massage,” and together with mouth-to-mouth ventilation, modern-day CPR was born.⁵

EPIDEMIOLOGY

In an adult patient, cardiopulmonary arrest usually results from the development of an arrhythmia.^{2,6} Most cardiac arrests take place outside the hospital shortly after the onset of symptoms, and most patients have coronary artery disease (CAD).⁷ The most common arrhythmia is either ventricular fibrillation (VF) or pulseless ventricular tachycardia (PVT).^{8,9} The number of patients with out-of-hospital cardiac arrests presenting with VF as the initial rhythm, however, has changed dramatically.^{10–12} In one study, the number of patients with VF was 61% in 1980 compared with only 41% in 2000, a reduction of greater than 30%.¹⁰ This change may be due to the aggressive treatment strategies aimed at CAD, the growing awareness of the symptoms of cardiac ischemia (shifting the occurrence of VF to in-hospital rather than out of hospital), or the overall decline in CAD-related mortality. Hospital survival for VF or PVT is approximately 3% to 40%, with higher mortality rates being observed in communities that do not have a rapid response system.^{6,10,13,14}

CLINICAL PRESENTATION OF CARDIOPULMONARY ARREST

SYMPTOMS

- Anxiety, change in mental status, or unconscious
- Cold, clammy extremities
- Dyspnea, shortness of breath, or no respiration
- Chest pain
- Diaphoresis
- Nausea and vomiting

SIGNS

- Hypotension
- Tachycardia, bradycardia, irregular or no pulse
- Cyanosis
- Hypothermia
- Distant or absent heart and lung sounds

ETIOLOGY

Cardiopulmonary arrest is much less common in pediatric patients than in adults.⁸ In pediatric patients, cardiopulmonary arrest is often the terminal event of progressive shock or respiratory failure.⁸ The cause of cardiac arrest varies with age, the underlying health of the child, and the location of the event. Out-of-hospital arrests frequently are associated with events such as trauma, sudden infant death syndrome, drowning, poisoning, choking, severe asthma, and pneumonia. In-hospital arrests, on the other hand, are associated with sepsis, respiratory failure, drug toxicity, metabolic disorders, and arrhythmias. Pediatric out-of-hospital arrest generally presents with hypoxia and hypercarbia progressing to respiratory arrest and bradycardia and

finally to asystolic cardiac arrest. In contrast to adult patients, only 10% of pediatric patients present with VF or PVT as the initial rhythm.⁸ Unfortunately, survival following pediatric out-of-hospital cardiopulmonary arrest ranges only from 3% to 17%, with most survivors having a poor neurologic status.⁸

PATHOPHYSIOLOGY

There are two proposed theories describing the mechanism of blood flow during CPR.^{1,15,16} The first theory, known as the *cardiac pump theory*, states that the active compression of the heart between the sternum and vertebrae creates an “artificial systole” in which intraventricular pressure increases, the atrioventricular valves close, the aortic valve opens, and blood is forced out of the ventricles. When ventricular compression ends, the decline in intraventricular pressure causes the mitral and tricuspid valves to open, and ventricular filling begins. The second, more recent theory is the *thoracic pump theory*.

The basis for this theory is the belief that blood flow results from intrathoracic pressure alterations induced by chest compressions. During compression or systole, a pressure gradient develops between the intrathoracic arteries and the extrathoracic veins, causing forward blood flow from the lungs into the systemic circulation. The heart merely acts as a passive conduit for flow. After compression ends, or diastole, intrathoracic pressure declines, and blood flow returns to the lungs.

The concept of cough CPR supports the importance of changes in intrathoracic pressure as a means of generating forward blood flow.^{15,16} During vigorous coughing, intrathoracic pressures increase secondary to contractions of the diaphragm, abdominal muscles, and intracostal muscles. These pressure changes occur without direct chest compression and are sufficient to maintain consciousness. The observation that cough alone can maintain consciousness led many investigators to question the cardiac pump theory and accept the thoracic pump theory. In reality, it is likely that both models apply to the mechanism of blood flow during CPR.¹⁶

► TREATMENT: Cardiopulmonary Resuscitation

■ DESIRED OUTCOME

The goal of CPR is to return effective ventilation and circulation as quickly as possible to minimize hypoxic damage to vital organs. It is not sufficient to restore spontaneous circulation if the patient is left neurologically devastated or incurs severe morbidity in the process. Factors proved to enhance prehospital survival include the occurrence of a witnessed arrest, rapid implementation of bystander CPR, presence of VF as the initial rhythm, and early defibrillation therapy for VF.¹⁷ In one report, the rate of survival to hospital discharge was 74% when defibrillation was performed within 3 minutes of a witnessed cardiac arrest compared with 49% when defibrillation was performed after 3 minutes ($p = .02$).¹⁸

Considerable controversy surrounds the identification of patient-specific factors that affect resuscitation survival. Proposed risk factors are age, concomitant diseases, initial pH, duration of resuscitation, and end-tidal carbon dioxide. The accuracy of these predictors has not been consistent in clinical studies, however.⁶

■ GENERAL APPROACH TO TREATMENT

National conferences and organized committees have played a major role in encouraging widespread competency in CPR technique. The first national conference took place in 1966 and recommended the training of health care professionals in the techniques of CPR.³ Since then, the American Heart Association (AHA) has organized six additional national conferences to update philosophies for providing CPR and emergency cardiovascular care (ECC) to the general population. The most recent conference was the Guidelines 2000 Conference, which provided the latest set of recommendations for CPR and ECC.⁸ The resuscitation guidelines are now internationally developed, as well as evidence-based, and a new intervention category has been added to the three categories originally established at the 1992 conference.⁷ Class I interventions are considered to be appropriate and efficacious. Class II interventions are subdivided into those in class IIa, meaning that they are probably beneficial and efficacious, and those in class IIb, meaning that they are possibly beneficial

without causing harm. Class III interventions are considered inappropriate and potentially harmful. The Guidelines 2000 Conference added class indeterminate, meaning there is insufficient evidence to support a final class decision.

In an effort to highlight the crucial components for successful CPR, the National Council on CPR and ECC has orchestrated a “chain of survival.”⁷ Based on the concept that “a chain is only as strong as its weakest link,” each element in the chain is essential for a successful resuscitation outcome. If one of these critical actions is neglected or delayed, survival is unlikely. The four links of the chain of survival are

1. Early access, which encompasses the events initiated after the patient’s collapse to promote the arrival of paramedic personnel. Rapid emergency medical dispatch is a critical component of this link.
2. Early bystander basic life support and CPR. Basic life support is based on the assessment and application of the ABCs: airway, breathing, and circulation.
3. Early defibrillation. Because this is the most likely to improve survival, automatic external defibrillators (AED) have become more common in community settings. Public-access defibrillation (PAD), which places AEDs in the hands of trained laypersons, has the potential to become the greatest advance in the treatment of cardiac arrest since the discovery of CPR.⁸ Evidence supports the value of PAD programs in locations either where the frequency of cardiac arrests is greater than 1 arrest per 1000 patient-years or where conventional paramedic services cannot ensure a call-to-shock time of less than 5 minutes.⁸
4. Early ACLS, the final link in the “chain of survival.”

The idea of a team approach to cardiac resuscitation has existed since the early 1960s,¹⁹ but it was not until the late 1960s that pharmacists began participating as cardiac resuscitation team members.²⁰ Defining roles for specific health care professionals, it is hoped, will make resuscitation attempts more efficient and consequently more effective. Team composition may vary among institutions, but a code team generally consists of a physician-in-charge, a surgeon, an anesthesiologist, a respiratory therapist, a nurse, and a pharmacist.²¹ Table 12–1 lists the typical roles for each team member.²¹

TABLE 12–1. Responsibilities of Cardiac Resuscitation Team Members

| Team Member | Responsibilities |
|-----------------------|--|
| Physician-in-charge | Team leader; determines appropriate therapy; directs and oversees order implementation including provision of CPR, electrical therapy, endotracheal intubation, intravenous access, ECG monitoring, and drug administration; arranges postresuscitation care |
| Surgeon | Identifies surgically correctable causes for arrest |
| Anesthesiologist | Performs endotracheal intubation; provides adequate oxygenation; may assist with obtaining vascular access |
| Respiratory therapist | Maintains adequate oxygenation and ventilation |
| Nurse | Records timing and outcome of therapeutic interventions; may assist with chest compressions, obtaining peripheral venous access, administering fluids and medications, acquiring blood samples for laboratory determination |
| Pharmacist | Prepares medications for administration; provides drug information; documents medication administration and outcomes of interventions |

VENTRICULAR FIBRILLATION AND PULSELESS VENTRICULAR TACHYCARDIA

NONPHARMACOLOGIC THERAPY

Because electrical defibrillation is the only effective method of restoring a perfusing cardiac rhythm,²² electrical defibrillation is the most crucial link in the “chain of survival.” The probability of successful defibrillation is directly related to the time interval between the onset of VF and the delivery of the first shock.⁸ Generally, with each passing minute, the rate of survival decreases by 8% to 10%.²³ In one study, a 23% relative improvement in survival was observed with each 1-minute reduction in the time to defibrillation (odds ratio [OR] 0.77, 95% confidence interval [CI] 0.73–0.81).²⁴

Although early defibrillation is crucial for survival following cardiac arrest, several animal studies have suggested that CPR prior to defibrillation may lead to more successful outcomes.²³ Two clinical trials have evaluated the impact of delaying defibrillation to allow for CPR in patients with out-of-hospital VF.^{25,26} In the first, the provision of roughly 90 seconds of CPR prior to defibrillation was associated with an increased rate of hospital survival (compared with a historical control group) when response intervals were 4 minutes or longer (27% versus 17%; $p < .007$).²⁵ In the second, hospital survival rates were higher in patients with response intervals greater than 5 minutes when 3 minutes of CPR was administered prior to defibrillation (22% versus 4%; $p = .006$).²⁶ These trials support the theory of a three-phase time-sensitive model for resuscitation after cardiac arrest.²³ This model suggests that the optimal treatment of cardiac arrest is time-specific based on three distinct phases. These phases are the electrical phase (cardiac arrest until about 4 minutes), the

circulatory phase (approximately 4 minutes to approximately 10 minutes), and the metabolic phase (after approximately 10 minutes). Successful defibrillation most likely will occur when cardiac arrest victims are in the electrical phase. On the other hand, when cardiac arrest victims are in the circulatory phase (4 to 10 minutes following cardiac arrest), global ischemia has already occurred, and immediate defibrillation may be detrimental. It may be more important to first provide some blood flow and cardiac perfusion via CPR to flush out the deleterious metabolic factors that have accumulated during ischemia.²³ Further trials are needed to evaluate this resuscitation technique.

Persons in VF or PVT should receive electrical defibrillation with at least three shocks.⁸ The initial defibrillation attempt should begin with 200 J. The second and third shocks can be either the same or as high as 360 J. Repeated shocks, even at the same energy level, increase the probability of successful defibrillation. Following three unsuccessful attempts of defibrillation, the patient should receive roughly 1 minute of CPR. Endotracheal intubation and intravenous (IV) access should be obtained at this time. Once an airway is achieved, patients should be ventilated with 100% oxygen. Pharmacologic agents, such as sympathomimetics and antiarrhythmics, play a secondary role and are not recommended until an airway has been established and IV access attempted (Fig. 12–1).

PHARMACOLOGIC THERAPY

SYMPATHOMIMETICS

The use of sympathomimetics is a major part of drug therapy in CPR. The goal of using these agents is to augment both coronary and cerebral perfusion pressures during the low-flow state seen with CPR. Coronary perfusion pressures of at least 15 mm Hg are associated with a higher rate of return of spontaneous circulation (ROSC).²⁷ Animal studies have shown that coronary perfusion pressure averages between 10 and 15 mm Hg with CPR alone following 10 minutes of ventricular fibrillation.²⁸ Sympathomimetics work primarily by increasing systemic arteriolar vasoconstriction, thus improving coronary and cerebral perfusion pressure. In addition, they also maintain vascular tone, decreasing arteriolar collapse, and shunt blood to the heart and brain.

Epinephrine continues to be a drug of first choice for the treatment of VF, PVT, asystole, and pulseless electrical activity (PEA). Epinephrine is both an α - and β -receptor agonist, although its effectiveness is thought to be due to its α effects. One study evaluated the importance of α -adrenergic, β -adrenergic, and any nonadrenergic activity mediated by epinephrine in dogs.²⁹ The first group received epinephrine along with phenoxybenzamine (an α -blocker), whereas a second group received epinephrine along with propranolol (a β -blocker). When α -receptors were blocked, epinephrine was not successful in restoring circulation. When β -receptors were blocked, epinephrine was successful in restoring circulation in six of eight animals ($p \leq .01$). It was concluded that the efficacy of epinephrine is due to the α -adrenergic receptor stimulation and that β -stimulation is not important. It is unclear, however, whether β effects are useful or harmful during CPR. It has been shown that β -stimulation lowers the defibrillation threshold, whereas β -blockade increases it.³⁰ This would make epinephrine, a drug with both α and β properties, an ideal agent. Conversely, β -stimulation increases myocardial oxygen demand and can increase the severity of postresuscitation myocardial dysfunction.^{31,32}

Several studies have compared the effects of pure α_1 -agonists, such as phenylephrine and methoxamine, with epinephrine to

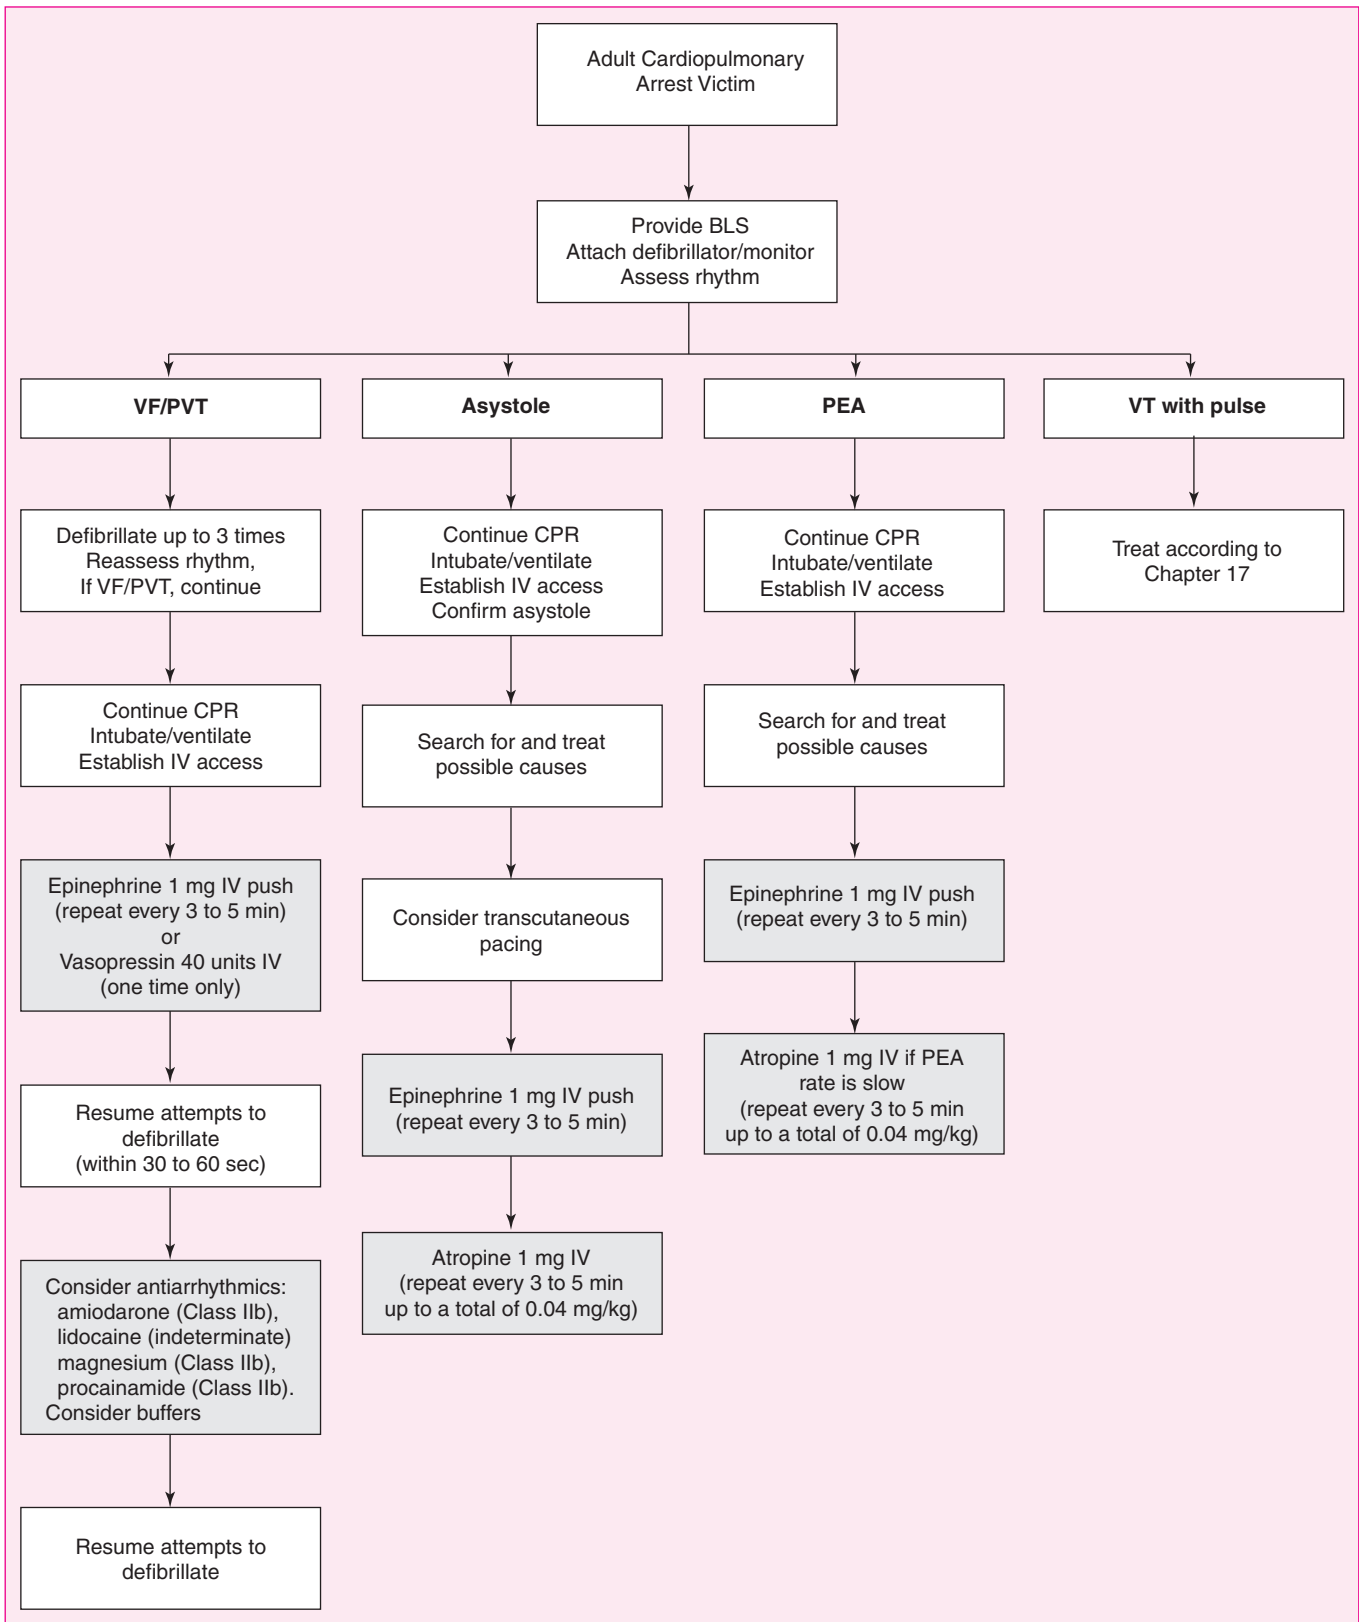

FIGURE 12-1. Treatment algorithm for adult cardiopulmonary arrest.

determine whether the β effects have a negative impact on cardiac arrest outcome. These studies have shown the use of α_1 -agonists to have no long-term survival advantage over epinephrine.³³ One study found that both epinephrine (50 mcg/kg) and phenylephrine (50 mcg/kg) increased arterial blood pressure in dogs, but only epinephrine increased coronary and cerebral blood flows.³⁴ This study has been criticized, however, because doses were not equipotent. The primary reason that selective α_1 -agonists are not superior to epinephrine is related to the α_2 effects. Agents that have potent α_2 effects (e.g., epinephrine and norepinephrine) may be more effective because the α_2 -adrenergic receptors lie extrajunctionally in the intima of the blood vessels, making them more accessible to circulating catecholamines—even in low-flow states that occur during CPR.³³ Furthermore, during ischemia, the number of postsynaptic α_1 -receptors decreases, which suggests a greater role for α_2 -agonist activity during CPR.³⁵

Another agent possessing α_2 -agonist activity is norepinephrine (an α_1 , α_2 , β_1 -agonist). Since it has been hypothesized that β_2 -agonist-induced vasodilation may counteract the efficacy of α -agonist-induced vasoconstriction, investigators have compared the effects of the exogenous administration of epinephrine with those of norepinephrine in order to determine the impact of β_2 -agonist activity during CPR. Callahan and associates conducted the only large-scale randomized, double-blind, prospective trial comparing the efficacy of norepinephrine with that of epinephrine in the prehospital cardiac arrest setting.³⁶ In this trial, 816 adults were randomized to receive standard-dose epinephrine (1 mg), high-dose epinephrine (15 mg), or high-dose norepinephrine (11 mg) after initial defibrillation attempts failed. Study end points were ROSC (i.e., measurable blood pressure or pulse for at least 5 minutes), hospital discharge rate, and neurologic status. Thirteen percent (35 of 260) of patients who received norepinephrine achieved ROSC prior to reaching the hospital. Thirteen percent (37 of 286) of patients received 15 mg epinephrine achieved ROSC compared with 8% (22 of 270) of patients randomized to receive 1 mg epinephrine ($p = .01$). Return of spontaneous circulation was not statistically different between norepinephrine and epinephrine ($p = .19$). Overall, only 1.8% (15 of 816) of all patients enrolled survived to hospital discharge. The percentages of patients discharged from the standard-dose epinephrine, high-dose epinephrine, and high-dose norepinephrine groups were not statistically different; they were 1.2%, 1.7%, and 2.6%, respectively. Neurologic survival was most favorable in the standard-dose epinephrine group; however, these differences were not statistically significant. The low number of surviving patients made it impossible to detect a meaningful difference in these two areas. Lindner and colleagues compared the efficacy of norepinephrine (1 mg) with repeated doses of epinephrine (1 mg) on the ROSC and hospital discharge rate in 50 patients.³⁷ In this study, there was an increase in ROSC with norepinephrine, but there was no difference in the hospital discharge rate.

A study using a swine model compared the effects of epinephrine (200 mcg/kg) and norepinephrine (80, 120, and 160 mcg/kg) on VF.²⁸ Compared with epinephrine, there was a trend toward improved myocardial blood flow and successful defibrillation with the two highest doses of norepinephrine. A second study, in a swine model, examined the effects of epinephrine (45 mcg/kg) and norepinephrine (45 mcg/kg) on myocardial oxygen delivery and consumption.³⁸ In this trial, norepinephrine reduced myocardial oxygen consumption, thereby creating a more favorable profile between myocardial oxygen supply and demand than did epinephrine. Similarly, Brown and colleagues compared the effect of epinephrine (200 mcg/kg) and three doses of norepinephrine (80, 120, and 160 mcg/kg) on cerebral blood flow in a swine model.³⁹ Statistically significant increases in aortic diastolic pressure and coronary perfusion pressure occurred with

epinephrine and the two highest doses of norepinephrine (120 and 160 mcg/kg). Increased blood flow to the left cerebral cortex, mid-brain, pons, medulla, and cervical spinal cord also was evident with the two highest doses of norepinephrine. Epinephrine, however, improved only flow to the medulla and cervical cord compared with 80 mcg/kg norepinephrine. Although norepinephrine has demonstrated beneficial effects over epinephrine on myocardial oxygen balance and ROSC, there is no difference in survival to hospital discharge. Consequently, epinephrine remains the first-line sympathomimetic for CPR until more definitive data become available.

Considerable controversy surrounds the optimal dose of epinephrine for CPR. The standard epinephrine dose is 1 mg administered by IV push every 3 to 5 minutes.⁸ This epinephrine dose was derived from animal studies (0.1 mg/kg in a 10-kg dog) and equates to approximately 0.015 mg/kg for a 70-kg human.⁴⁰ Both animal and human studies have demonstrated a positive dose-response relationship with epinephrine.^{41–44} Animal studies have suggested that higher doses were necessary to improve hemodynamics and achieve successful resuscitation. These results, however, have not been replicated in human studies.^{36,45–52} Collectively, these studies (Table 12–2) have shown that high-dose epinephrine may increase the initial resuscitation success rate but that overall survival is not significantly different. One study demonstrated an unfavorable neurologic outcome in patients treated with high-dose epinephrine.⁵³ Many of these patients would not have survived if given only standard-dose epinephrine, however, so this result may wrongfully discredit high-dose epinephrine.

The discrepancy between animal and human studies may be due to the fact that most victims of cardiac arrest have CAD, a condition not present in an animal model. In a human model, however, atherosclerotic plaques can aggravate the balance between myocardial oxygen supply and demand. Moreover, the interval from arrest to treatment in animal studies is shorter than the interval frequently reported in human studies. Since time to CPR and defibrillation are crucial variables for success, prolonging this time period can lower resuscitation rates. Because of the lack of evidence supporting high-dose epinephrine, the current guidelines recommend 1 mg IV push every 3 to 5 minutes or vasopressin as initial drug therapy for VF or PVT.⁸ Tolerance to adrenergic stimulation can occur, especially when catecholamine levels are high. Therefore, if the standard dose of epinephrine is not successful, higher doses (up to 0.2 mg/kg) can be considered.

■ VASOPRESSIN

3 The algorithm for the treatment of VF/PVT now includes vasopressin. Also known as *antidiuretic hormone*, vasopressin is a potent vasoconstrictor that increases blood pressure and systemic vascular resistance. Although it acts on various receptors throughout the body, its vasoconstrictive properties are due primarily to its effects on the V_1 receptor.⁵⁴ Measurement of vasopressin levels in patients undergoing CPR has shown a high correlation between the levels of endogenous vasopressin released and the potential for ROSC.⁵⁵ In fact, in one study, plasma vasopressin concentrations were approximately three times as high in survivors compared with nonsurvivors, suggesting that vasopressin is released as an adjunct vasopressor to epinephrine in life-threatening events such as cardiac arrest.⁵⁵ Vasopressin may have several advantages over epinephrine. First, the metabolic acidosis that frequently accompanies cardiopulmonary arrest can blunt the vasoconstrictive effect of adrenergic agents such as epinephrine. This effect does not occur with vasopressin. Second, the

stimulation of β -receptors caused by epinephrine can increase myocardial oxygen demand and complicate the postresuscitative phase of CPR. Because vasopressin does not act on β -receptors, this effect does not occur with its use.

Several animal studies have demonstrated the beneficial effect of vasopressin on coronary and cerebral blood flow.^{56–58} Although vasopressin improves vital organ perfusion during VF, myocardial oxygen consumption is lower with vasopressin than with epinephrine.⁵⁹ Vasopressin also may have a beneficial effect on renal blood flow by stimulating V₂ receptors in the kidney, causing vasodilation and increased water reabsorption. With regard to splanchnic blood flow, however, most studies have shown that vasopressin has a detrimental effect compared with epinephrine.^{59,60}

Unfortunately, there are limited data on vasopressin in humans. Lindner and associates evaluated the use of vasopressin in eight patients following in-hospital cardiac arrest.⁶¹ After standard ACLS had failed, 40 units of vasopressin was administered intravenously. Spontaneous circulation returned in all eight patients, but only three survived until hospital discharge. Following these results, Lindner and colleagues conducted a prospective, randomized, controlled trial comparing vasopressin with epinephrine.⁶² Forty patients who experienced out-of-hospital VF resistant to electrical defibrillation were randomized to receive either 40 units of vasopressin or 1 mg of epinephrine as the initial drug for the treatment of cardiac arrest. In the vasopressin group, 16 patients (80%) achieved ROSC, compared with 11 patients (55%) in the epinephrine group ($p = .18$). Fourteen

patients (70%) in the vasopressin group survived to hospital admission, and 12 patients (60%) survived more than 24 hours. Seven patients in the epinephrine group (35%) survived to hospital admission ($p = .06$), and 4 (20%) survived more than 24 hours ($p = .02$). There was no difference in hospital discharge rates between the groups—8 patients (40%) in the vasopressin group and 3 patients (15%) in the epinephrine group ($p = .16$). Following administration of the study drug alone (i.e., no further ACLS), ROSC was achieved in 7 (35%) vasopressin patients compared with 2 (10%) epinephrine patients ($p < .001$). No adverse drug events secondary to vasopressin were observed. This trial showed a trend toward survival with vasopressin; however, statistical significance was evident only with survival longer than 24 hours and ROSC following use of the study drug alone.

Stiell and colleagues evaluated vasopressin and epinephrine in 200 patients with in-hospital cardiac arrest.⁶³ In contrast to Lindner and colleagues, no advantage was noted with vasopressin in either ROSC (60% versus 59%; $p = .97$), short-term (1-hour) survival (39% versus 35%; $p = .66$), or survival to hospital discharge (12% versus 14%; $p = .67$) compared with epinephrine. When only patients with VF were evaluated, short-term survival rates were 54% and 61% for vasopressin and epinephrine, respectively, whereas survival rates to hospital discharge were 25% and 33%. Major differences between the two trials (Stiell and colleagues⁶³ and Lindner and colleagues⁶²) include the setting in which cardiac arrest was evaluated (in-hospital versus out of hospital), the average time from collapse to study drug administration (6.1 versus 14.5 minutes), and the

TABLE 12–3. Initial Doses of Drugs Used in Cardiac Arrest

| Drug | Initial Dose | Comments |
|--------------------|--|--|
| Epinephrine | 1 mg IV every 3 to 5 minutes. | If a 1-mg dose is not successful, then high-dose epinephrine (up to 0.2 mg/kg) is acceptable. |
| Vasopressin | 40 units IV | A single dose of vasopressin may be used in place of epinephrine following the initial three unsuccessful defibrillation attempts. If there is no response to vasopressin after 5 to 10 minutes, epinephrine therapy may resume. |
| Amiodarone | VF or PVT: 300 mg diluted in a volume of 20 to 30 mL of saline or D ₅ W by rapid infusion | Supplementary doses of 150 mg by rapid infusion may be administered for recurrent or refractory VF/VT, followed by an infusion of 1 mg/min for 6 hours and then 0.5 mg/min, to a maximum daily dose of 2 grams |
| Lidocaine | VF or PVT: 1.5 mg/kg IV | A continuous infusion at 2–4 mg/min is reasonable if the drug was associated with the restoration of a stable rhythm. Reappearance of an arrhythmia during a constant infusion should be treated with a small bolus dose (0.5 mg/kg) of lidocaine with an increase in the infusion rate. |
| Magnesium | VF or PVT: 1 to 2 grams diluted in 100 mL D ₅ W administered over 1 to 2 min | For treatment of torsades de pointes, a loading dose of 1 to 2 grams mixed in 50–100 mL of D ₅ W given over 5–60 min, followed by an infusion of 0.5–1 gram per hour. |
| Sodium bicarbonate | 1 mEq/kg IV | Therapy should be guided by the bicarbonate concentration or calculated base deficit obtained from blood gas analysis or laboratory measurement. Complete correction of the base deficit should be avoided to minimize the risk of iatrogenically induced alkalosis. |
| Atropine | 1 mg IV repeated as needed every 3 to 5 minutes | Maximum dose is 0.04 mg/kg. Doses less than 0.5 mg should be avoided. |

Abbreviations: IV = intravenous; VF = ventricular fibrillation; PVT = pulseless ventricular tachycardia; D₅W = dextrose in water.

number of patients presenting with VF as the initial rhythm (21% versus 100%). The superior effects of vasopressin may be evident only when response times are prolonged and the effect of catecholamines is blunted.

In the largest comparative trial conducted to date, 1186 patients with out-of-hospital cardiac arrest were randomized to receive two doses of either vasopressin 40 units or epinephrine 1 mg.⁶⁴ Most patients presented with asystole (45%) or VF (40%) as their initial cardiac rhythm, and the average time to the administration of study drug was about 18 minutes. Overall, there were no significant differences between vasopressin and epinephrine in ROSC (25% versus 28%; $p = .19$), hospital admission rate (36% versus 31%; $p = .06$), or discharge rate (10% versus 10%; $p = .99$). When patients were stratified according to their initial presenting rhythm, no significant differences were noted for patients with VF or PEA. Patients with asystole, on the other hand, had a significantly higher rate of hospital admission (29% versus 20%; $p = .02$) and discharge (4.7% versus 1.5%; $p = .04$) when vasopressin was administered compared with epinephrine. In addition, a subgroup analysis of 732 patients who required additional epinephrine therapy despite the two doses of study drug revealed significant benefits in ROSC (37% versus 26%; $p = .002$), hospital admission rate (26% versus 16%; $p = .002$), and discharge rate (6.2% versus 1.7%; $p = .002$) with vasopressin. There was a trend, however, toward a poorer neurologic state or coma among the patients who survived to discharge and received vasopressin. It appears that combined therapy using both vasopressin and epinephrine was effective in restoring cardiac function but not brain function in some patients. Further research is needed in this area.

Overall, these studies suggest that vasopressin has a beneficial effect in out-of-hospital cardiac arrests or arrests secondary to asystole, situations when the effect of catecholamines may be diminished because of profound acidosis. Its usefulness for in-hospital cardiac arrest secondary to VF or PVT remains questionable. The doses for vasopressin and other agents used for cardiac arrest are listed in Table 12–3.

ANTIARRHYTHMICS

4 The primary reason for the use of antiarrhythmic agents following unsuccessful defibrillation and vasopressor administration is to prevent the development or recurrence of VF and PVT by raising the fibrillation threshold. There is, however, conflicting evidence and a divergence of opinion regarding the efficacy of these drugs and their place in CPR. These agents, therefore, receive either a class indeterminate or class IIb intervention classification according to the 2000 guidelines for CPR and ECC.⁸

With drugs used as a secondary intervention, there is no recommendation for a specific antiarrhythmic. Many experts feel that amiodarone, the newest antiarrhythmic added to the VF/PVT algorithm (class IIb), should be the agent of choice. Lidocaine remains on the algorithm, although its classification has been changed from a class IIb to an indeterminate intervention. Bretylium, previously the second antiarrhythmic on the VF/PVT algorithm, has been dropped from the guidelines because of the difficulty in obtaining the raw materials necessary for production. Magnesium is a class IIb intervention for polymorphic VT (torsades de pointes) and suspected hypomagnesemia. Procainamide is considered acceptable for refractory or recurrent VF/PVT (class IIb); however, its usefulness is limited by the need for a prolonged administration time, which makes it unsuitable for cardiac arrest.

Amiodarone

Although officially classified as a class III antiarrhythmic, amiodarone possesses electrophysiologic characteristics of all four Vaughn Williams classifications. Acutely, intravenous amiodarone displays mainly antiadrenergic (class II) and calcium channel blocking (class IV) properties. Consequently, hypotension, which occurs in roughly 20% of clinical trials, is a concern. This hypotension is more dependent on the rate of administration than on the amount of drug

administered. A decrease in the infusion rate generally reverses hypotension induced by amiodarone.⁶⁵ The diluent used for the amiodarone solution, polysorbate 80, also may contribute to the hypotensive effect because it is known to have vasodilatory actions.⁶⁶ Amiodarone has mild negative inotropic actions as well, but its vasodilatory action usually offsets this effect, resulting in a minimal change in cardiac output.⁶⁷ Other adverse effects noted acutely include fever, elevated values on liver function tests, confusion, nausea, and thrombocytopenia.

Kudenchuk and colleagues conducted a large randomized, double-blind, placebo-controlled study evaluating amiodarone for out-of-hospital cardiac arrest (also known as the ARREST trial).⁶⁸ After receiving epinephrine 1 mg, 504 patients with cardiac arrest secondary to VF or PVT were randomized to receive either amiodarone 300 mg or placebo. Conventional ACLS was then followed. The primary end point was admission to the hospital with a spontaneously perfusing rhythm. Secondary end points included the number of precordial shocks required after administration of amiodarone or placebo, the total duration of resuscitative efforts, and the need for additional antiarrhythmics. Survival to discharge and neurologic status at discharge also were evaluated, although the trial did not have sufficient statistical power to demonstrate differences in these outcomes. Recipients of amiodarone were more likely to be resuscitated and survive to hospital admission than were recipients of placebo (44% and 34%, respectively; $p = .03$) for a relative improvement of 29%. A subgroup analysis revealed that patients whose cardiac arrest was due to VF were more likely to survive to hospital admission than those with asystole or PEA (44% and 14%, respectively; $p < .001$). There were no significant differences in number of precordial shocks, total duration of resuscitative efforts, or need for additional antiarrhythmics.

5 This is the first trial to demonstrate the benefit of an antiarrhythmic agent over placebo in patients with out-of-hospital cardiac arrest.

The ALIVE trial compared amiodarone with lidocaine in patients with out-of-hospital VF.⁶⁹ Following three unsuccessful defibrillation attempts, IV epinephrine, and an additional defibrillation attempt, 347 patients were randomized to receive either amiodarone 5 mg/kg or lidocaine 1.5 mg/kg. A second dose of amiodarone 2.5 mg/kg or lidocaine 1.5 mg/kg was administered if needed. As in the ARREST trial, the primary end point was survival to hospital admission; survival to hospital discharge was a secondary outcome. Amiodarone was associated with a relative improvement of 90% in survival to hospital admission compared with lidocaine (22.8% versus 12%; OR 2.17; 95% CI 1.21–3.83; $p = .009$). Among patients who presented with either VF or PVT as their initial rhythm, survival to hospital admission was higher with amiodarone (24.8% versus 14.2%; $p = .03$). This benefit was less evident in patients who presented with a rhythm other than VF or PVT; 15.8% and 3.2% ($p = .08$) for amiodarone- and lidocaine-treated patients, respectively. Survival to hospital discharge was only 5% for patients receiving amiodarone and 3% for those receiving lidocaine ($p = .34$). The initial rhythm for all long-term survivors was VF. Amiodarone therefore has become the antiarrhythmic of first choice among many experts.⁸

Lidocaine

For many years lidocaine has been used for the treatment of ventricular arrhythmias in the setting of acute myocardial infarction (AMI). The efficacy seen in cardiac arrest, however, has not mirrored that seen in AMI. In the only published case-control trial where patients were classified according to whether they received lidocaine, no significant

difference was noted in ROSC, admission to the hospital, or survival to hospital discharge between groups.⁷⁰ Similarly, a prospective study comparing the effectiveness of lidocaine with that of standard-dose epinephrine showed not only a lack of benefit with lidocaine but also a higher tendency to promote asystole.⁷¹ In contrast, a retrospective analysis in patients with VF indicated that lidocaine was associated with a higher rate of ROSC and hospitalization ($p < .01$) but not an increase in the hospital discharge rate.⁷²

Lidocaine has been shown to increase VF threshold in both the CPR and non-CPR settings.⁷³ Furthermore, it benefits the defibrillation threshold or the amount of energy required to convert VF to a more stable rhythm.⁷⁴ Although controversial, some studies show that lidocaine has a detrimental effect on defibrillation threshold.⁷⁵ These conflicting results may be related to drug interactions with lidocaine and the agents used for anesthesia.⁷⁵

Lidocaine pharmacokinetics have not been studied extensively during cardiac arrest. Animal studies suggest that plasma lidocaine concentrations of at least 6 mcg/mL are necessary to achieve antifibrillatory effects, but concentrations greater than 12 mcg/mL may result in toxicity.⁷⁶ Because lidocaine metabolism depends on hepatic blood flow, lidocaine clearance may decrease following the reduction in cardiac output seen in cardiac arrest, thereby yielding toxic lidocaine concentrations.⁷⁷ Clinical trials in humans indicate that lidocaine levels are highly variable and unpredictable during cardiac arrest,⁷⁸ but they are nontoxic following ROSC and return of cardiac output.⁷⁹ In fact, a physiologically based pharmacokinetic model suggested that a 2 mg/kg dose of lidocaine may be more appropriate than the current AHA recommended dose because this dosing regimen will achieve a therapeutic concentration more rapidly.⁷⁶ Clinical trials in humans are necessary to validate this particular dosing regimen.

THERAPEUTIC ALTERNATIVES FOR REFRACTORY VF OR PVT

6 Patients with persistent or recurrent VF or PVT following antiarrhythmic administration should be assessed for underlying electrolyte abnormalities as a cause for their refractory arrhythmia. The primary electrolyte abnormalities associated with refractory ventricular arrhythmias include hyperkalemia, hypokalemia, and hypomagnesemia.

In one study of prehospital cardiac arrests, 49% of resuscitated patients were found to be hypokalemic ($[K^+] < 3.6$ mEq/L) on hospital admission.⁸⁰ Although frequently debated, it is not yet known whether the hypokalemia most often precedes cardiac arrest or is a consequence of cardiac resuscitation.^{80–82} Hypokalemia identified during cardiac arrest also may result from conditions that arise during resuscitation. For example, intracellular potassium shifts may occur secondary to metabolic derangements or to elevated circulating catecholamine concentrations.^{80–82} Similarly, hypomagnesemia has been associated with ventricular arrhythmias.⁸³ Investigators have found that in hospitalized patients, approximately 40% of hypokalemic patients have coexisting hypomagnesemia.⁸⁴ This is important because uncorrected hypomagnesemia may prevent successful potassium repletion.⁸³ The value of magnesium in cardiac arrest has not been demonstrated in randomized, controlled trials, but anecdotal evidence is supportive. Therefore, the administration of magnesium is recommended only when a low level of magnesium is the suspected cause of an arrhythmia or when the patient experiences torsades de pointes.⁸ Large doses of magnesium may produce hypotension but do not compromise coronary perfusion pressure because of coronary artery dilatation.⁷

■ THERAPEUTIC HYPOTHERMIA

Restoration of blood flow following cardiac arrest can lead to several chemical cascades and destructive enzymatic reactions that can result in cerebral injury. These reactions include free-radical production, excitatory amino acid release, and calcium shifts, leading to mitochondrial damage and apoptosis (programmed cell death).⁸⁵ Hypothermia can protect from cerebral injury by suppressing these chemical reactions, thereby reducing the production of free radicals. Various animal models have demonstrated improved functional recovery and reduced cerebral deficits with the induction of mild therapeutic hypothermia.⁸⁵ Recently, there have been two clinical trials in humans evaluating this technique.^{86,87}

The first trial was conducted in nine centers in five European countries.⁸⁶ In this study, patients who had been resuscitated after cardiac arrest due to VF but remained comatose were assigned randomly to undergo therapeutic hypothermia, targeting a temperature of 32 to 34°C, for 24 hours. The primary end point was neurologic outcome within 6 months of cardiac arrest. Secondary end points were mortality (within 6 months) and complication rate within 7 days. A favorable neurologic outcome (defined as a cerebral performance category score of 1 or 2; see Table 12–4) was achieved in 55% of patients in the hypothermia group as opposed to 39% in the normothermia group ($p = .009$). Additionally, mortality rates were improved significantly in the hypothermia group (41% versus 55%; $p = .02$). Based on this difference, seven patients would need to be treated with hypothermia to prevent one death. The rate of complications (e.g., bleeding, pneumonia, sepsis, and renal failure) did not differ between the two groups (73% for the hypothermia group and 70% for the normothermia group; $p = .70$).

The second trial was conducted in four hospitals in Melbourne, Australia.⁸⁷ Entry criteria were similar to the previous trial, but the target temperature for hypothermia was 33°C, which was maintained for 12 hours. The primary outcome measure was survival to hospital discharge with good neurologic function. Forty-nine percent of

patients in the hypothermia group had good neurologic function on discharge (to either home or a rehabilitation facility) compared with 26% of patients in the normothermia group ($p = .046$). Mortality rates were similar between the two groups (51% for the hypothermia group and 68% for the normothermia group; $p = .145$). Hypothermia was associated with a lower cardiac index, higher systemic vascular resistance, and hyperglycemia.

In light of these trials, the Advanced Life Support Task Force of the International Liaison Committee on Resuscitation has recommended that unconscious adult patients with spontaneous circulation after out-of-hospital cardiac arrest be cooled to 32 to 34°C for 12 to 24 hours when the initial rhythm was VF.⁸⁵ Such cooling also may be of benefit for other rhythms or in-hospital cardiac arrest. There is insufficient evidence to make a recommendation on the use of therapeutic hypothermia in children.

NON-VF/PVT RHYTHMS: PEA AND ASYSTOLE

■ NONPHARMACOLOGIC THERAPY

Pulseless electrical activity (PEA) is defined as the absence of a detectable pulse and the presence of some type of electrical activity other than VF or PVT. *Asystole* is defined as the presence of a flat line on the ECG monitor. Although PEA is still classified as a “rhythm of survival,” the success rate of treatment is much lower than the rates seen with VF/PVT.^{10,13} The rate of survival among patients with asystole is a dismal 1% to 2%.^{8,10} Successful treatment of both PEA and asystole depends almost entirely on diagnosis of the underlying cause (Table 12–5). The treatment of PEA is relatively similar to the treatment of asystole. Both conditions require CPR, intubation, and IV access. Emphasis, once again, should be placed on identifying a correctable cause. Asystole should be reconfirmed by checking a second lead on the cardiac monitor. Defibrillation should be avoided in patients with asystole because the parasympathetic discharge that occurs with defibrillation may reduce the chance of ROSC and worsen the chance of survival. If available, transcutaneous pacing can be attempted. Asystole often represents confirmation of death rather than a rhythm to be treated; therefore, withdrawal of efforts must be strongly considered.

■ PHARMACOLOGIC THERAPY

The primary pharmacologic agents used in the treatment of asystole are epinephrine and atropine. The recommended epinephrine dose is identical to that used for the treatment of VF/PVT.

Atropine is an antimuscarinic agent that blocks the depressant effect of acetylcholine on both the sinus and atrioventricular nodes, thus decreasing parasympathetic tone. During asystole, parasympathetic tone may increase because of the vagal stimulation that occurs secondary to intubation, the effects of hypoxia and acidosis, or alterations in the balance of parasympathetic and sympathetic control.⁸⁸ Unfortunately, there are no large randomized trials showing benefit from atropine for the treatment of asystole. Evidence is limited to small case series or retrospective reviews.^{89–91}

Earlier small observational reports found some response to atropine in asystole or pulseless idioventricular rhythm but little evidence to suggest that long-term outcomes were altered.⁸⁹ In a retrospective case-control study, Stueven and colleagues found a 14% (6 of 43) success rate with atropine compared with a 0% (0 of 41) rate

with a control; as in previous trials, no patients survived to hospital discharge.⁸⁹ Ornato and associates published a retrospective study of 24 patients with asystole as the presenting rhythm; of the 22 patients who received atropine, asystole was abolished in 4.⁹⁰ Once again, none survived to hospital discharge. Finally, Tortolani and associates retrospectively reviewed the case histories of 123 patients with asystole.⁹¹ Of the 101 patients who had received atropine, 24 were alive 24 hours after resuscitation. It is unclear how many survived to hospital discharge. These results show that although atropine may achieve ROSC in some instances, asystolic arrest is almost always fatal. Thus the use of atropine for this indication is not harmful, but the beneficial effect is limited.

■ ACID-BASE MANAGEMENT DURING CPR

Acidosis seen during cardiac arrest results from decreased blood flow and inadequate ventilation. Chest compressions generate approximately 20% to 30% of normal cardiac output, leading to inadequate organ perfusion, tissue hypoxia, and metabolic acidosis. In addition, the lack of ventilation causes retention of carbon dioxide, leading to respiratory acidosis. This combined acidosis produces not only reduced myocardial contractility and negative inotropic effect but also the appearance of arrhythmias because of a lower fibrillation threshold. In early cardiac arrest, adequate alveolar ventilation is the mainstay of control to limit the accumulation of carbon dioxide and control the acid-base imbalance.⁸ With arrests of long duration, buffer therapy often is necessary.

Although sodium bicarbonate was once given routinely to reduce the detrimental effects associated with acidosis (e.g., reduced myocardial contractility), enhance the effect of epinephrine, and improve the rate of defibrillation, its use for cardiac arrest has been extremely controversial over the past several years. Unfortunately, there are few clinical data supporting sodium bicarbonate use.⁹² Furthermore, sodium bicarbonate may have some detrimental effects.^{92–94} The effect of sodium bicarbonate can be described by the following reaction:

When sodium bicarbonate is added to an acidic environment, this reaction will shift to the right, thereby increasing tissue and venous

hypercarbia. The carbon dioxide generated by this reaction will diffuse into the cell and decrease intracellular pH. The accumulation of intracellular carbon dioxide, specifically within the myocardium, is inversely correlated with coronary perfusion pressure produced by CPR. Intracellular acidosis also will decrease myocardial contractility, further complicating the low-flow state associated with CPR.⁹² Furthermore, treatment with sodium bicarbonate often overcorrects extracellular pH because sodium bicarbonate has a greater effect when the pH is closer to normal.⁹³ Alkalosis, created by overcorrection, causes an increase in the affinity of oxygen to hemoglobin, thus interfering with oxygen release into the tissues.

Recommendations for sodium bicarbonate vary (from class I to class III) depending on the clinical situation.⁸ Sodium bicarbonate use is acceptable for patients with known, preexisting hyperkalemia (class I), preexisting bicarbonate-responsive acidosis (class IIa), overdoses of tricyclic antidepressants (class IIa), and to alkalinize the urine in aspirin and other drug overdoses (class IIa). In addition, sodium bicarbonate may be of benefit in intubated and ventilated patients with a long arrest interval (class IIb). Sodium bicarbonate may be harmful in hypercarbic acidosis, and patients with this condition should not receive it (class III).

GUIDELINES FOR DRUG ADMINISTRATION DURING EMERGENCY SITUATIONS

Several routes of administration are available for drug delivery during CPR. The routes chosen represent a compromise between the practicality of access and their apparent efficacy in introducing the necessary drug into the central circulation. The most efficacious method, obviously, is administration through a central venous catheter. Compared with peripheral administration, drug delivery via a central venous catheter results in a faster and higher peak concentration.⁹⁵ Central lines located above the diaphragm are preferable to those located below the diaphragm because of poor blood flow during CPR.^{95,96} It is not practical, however, to interrupt CPR for an invasive procedure such as central line placement. Thus, if a central line is not already present, it is necessary to use a peripheral venous line. The antecubital vein is the first target for IV access.⁷ Peripheral drug administration

yields a peak concentration in the major systemic arteries in 1.5 to 3 minutes.⁹⁵ Circulation time is shortened by up to 40% if the drug is followed by a 20-mL fluid bolus with elevation of the extremity.⁹⁵

In the event that neither central nor venous IV access is available, then a few drugs can be administered endotracheally. These drugs are atropine, lidocaine, and epinephrine remembered by the AHA mnemonic *ALE*.⁷ Animal studies have shown that endotracheal administration mimics the effects of IV administration.⁹⁶ Human studies, on the other hand, show that drugs administered endotracheally have a lower plasma concentration with a delayed peak but a longer duration of action.⁹⁵ The endotracheal dose, therefore, should be 2 to 2.5 times larger than the IV dose.⁹ Clinical trials evaluating outcomes, however, such as ROSC or survival, have failed to show any benefit using this dosing regimen.^{97,98} Further trials are needed evaluating larger doses.

The technique of endotracheal drug administration markedly influences the pattern of absorption.⁹⁶ The dose first should be diluted with 10 mL sterile water or normal saline to permit distribution over the largest possible surface area. CPR should be interrupted and the dose administered beyond the tip of the endotracheal tube. Immediately, three to five forceful insufflations should follow using a bag-valve device to aerosolize the drug and enhance bioavailability.

In pediatric patients, the intraosseous route can be used temporarily if no other route is available. Lastly, the intracardiac route is no longer recommended for patients of any age because of potential complications such as myocardial laceration, coronary artery laceration, hemopericardium, and pneumopericardium.

ETHICAL AND ECONOMIC CONSIDERATIONS IN CPR

The primary objective of CPR is to obtain *neurologic survival*. Since this is often unobtainable, many health care professionals are

attempting to identify patients unlikely to benefit from cardiac resuscitation. One difficulty in accomplishing this task is defining *medical futility*. The two major determinants of medical futility are length of life and quality of life.⁸ An intervention that cannot increase length or quality of life is considered futile. Key factors in CPR are the disease underlying the cardiac arrest and the expected state of health after resuscitation. One important question that is debated often is how low should the chance of survival be before medical therapy is considered futile? Should it be 0.1%, 1%, or 2%? Is the chance of 1 or 2 months of life for a patient an acceptable goal? These are important questions that must be addressed when determining resuscitation status.

Unfortunately, there is no scientific evidence or scoring system that can predict the outcome following CPR. Therefore, all patients in cardiac arrest should receive resuscitation unless the patient has a “do not resuscitate” order, signs of irreversible death, or vital organ function deterioration that makes it impossible to expect any benefit from CPR—despite maximum therapy.⁸ Withholding CPR attempts in these futile cases not only would decrease the number of patients left in a vegetative state with poor neurologic status but also would improve the cost-effectiveness of CPR programs. CPR is of minimal economic benefit if the only outcome following ROSC is a prolonged, expensive hospital stay.

CLINICAL CONTROVERSIES

Animal studies have suggested that higher doses of epinephrine are beneficial in improving resuscitation outcomes. Human studies, on the other hand, have not shown an advantage with higher dosing regimens.

A recommendation for a specific antiarrhythmic agent of first choice does not exist. Amiodarone, lidocaine, and procainamide are the available options.

EVALUATION OF THERAPEUTIC OUTCOMES

To gauge the success of resuscitation outcomes, therapeutic outcome monitoring should occur both during the resuscitation attempt and in the postresuscitation phase. The optimal outcome following CPR is an awake, responsive, spontaneously breathing patient. Patients must remain neurologically intact with minimal morbidity following the resuscitation if it is to be truly classified as a success. Heart rate, cardiac rhythm, and blood pressure should be assessed and documented throughout the resuscitation attempt and subsequent to each intervention. Determination of the presence or absence of a pulse is paramount to deciding which interventions may be appropriate. In addition, nonresponse to an array of suitable interventions may indicate that resuscitation is impossible.

The primary goal of resuscitation is the complete reestablishment of regional organ and tissue perfusion. Simple restoration of blood pressure and improvement in tissue gas exchange do not necessarily improve the patient's chance of survival.⁸ Clinicians should consider the precipitating cause of the cardiac arrest, such as an AMI, electrolyte imbalance, or primary arrhythmia. They should review prearrest status carefully, particularly if the patient was receiving drug therapy. Laboratory investigations, including a 12-lead ECG, portable chest x-ray, measurement of arterial blood gases, and blood chemistry determinations, are necessary. Altered cardiac, hepatic, and renal function resulting from ischemic damage during the cardiopulmonary arrest warrant special attention. Neurologic function should be assessed by means of the Cerebral Performance Category and the Glasgow Coma Scale (see Table 12–4).

ABBREVIATIONS

ACLS: advanced cardiac life support
 AED: automatic external defibrillator
 AMI: acute myocardial infarction
 CPC: cerebral performance category
 CPR: cardiopulmonary resuscitation
 D₅W: dextrose 5% in water
 ECC: emergency cardiovascular care
 ECG: electrocardiogram
 GCS: Glasgow Coma Scale
 IV: intravenous
 PAD: public-access defibrillation
 PEA: pulseless electrical activity
 PVT: pulseless ventricular tachycardia
 ROSC: return of spontaneous circulation
 VF: ventricular fibrillation

HYPERTENSION

Joseph J. Saseen and Barry L. Carter

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The risk of cardiovascular morbidity and mortality is directly correlated with blood pressure (BP). Starting at a BP of 115/75 mm Hg, risk of cardiovascular disease doubles with every 20/10-mm Hg increase. Even patients with prehypertension have an increased risk of cardiovascular disease. Outcome trials have shown that antihypertensive drug therapy substantially reduces the risks of cardiovascular events and death.
- 2 Essential hypertension is usually an asymptomatic condition. A diagnosis cannot be made based on one elevated BP measurement. An elevated value from the average of two or more measurements on two or more clinical encounters is needed to diagnose hypertension.
- 3 The overall goal of treating hypertension is to reduce hypertension-associated morbidity and mortality. The selection of specific drug therapy is based on evidence that demonstrates risk reduction.
- 4 A goal BP of less than 140/90 mm Hg is appropriate for most patients. Achieving lower BP values has not been proven to provide additional risk reduction, except in patients with diabetes or chronic kidney disease. These patients have a goal BP of less than 130/80 mm Hg.
- 5 Lifestyle modifications should be prescribed in all patients with hypertension and prehypertension. However, they should never be used as a replacement for antihypertensive drug therapy in patients with hypertension.
- 6 Thiazide diuretics are first-line agents for the management of hypertension in most patients. This recommendation is supported by clinical trials showing reduced morbidity and mortality with these agents. Comparative data from the landmark clinical trial, the ALLHAT, confirm the first-line role of thiazide diuretics.
- 7 Compelling indications are comorbid conditions where specific drug therapies have been shown in outcome trials to provide unique long-term benefits. Drug therapy recommendations for compelling indications are either in combination with or in place of a thiazide diuretic.
- 8 Patients with diabetes are at very high risk for cardiovascular disease. All patients with diabetes and hypertension should be managed with either an angiotensin-converting enzyme (ACE) inhibitor or an angiotensin II receptor blocker (ARB), typically in combination with one or more other antihypertensive agents. Multiple agents frequently are needed to control BP.
- 9 Older patients with isolated systolic hypertension are often at risk for orthostatic hypotension when drug therapy is started. This is particularly prevalent with diuretics, ACE inhibitors, and ARBs. Although overall treatment should be the same, initial doses should be very low and dose titrations gradual to minimize risk of orthostatic hypotension.
- 10 Most patients require combination therapy to achieve goal BP values. Combination regimens should include a diuretic, preferably a thiazide. If a diuretic was not the first drug, it should be the second drug add-on therapy.

Hypertension is a common disease that is defined simply as persistently elevated arterial blood pressure (BP). Although elevated BP was perceived to be necessary for adequate perfusion of essential organs during the early and middle 1900s, it is now identified as one of the most significant risk factors for cardiovascular disease in the United States. Increasing awareness and diagnosis of hypertension and improving control of BP with appropriate treatment are considered critical public health initiatives to reduce cardiovascular morbidity and mortality.

The Seventh Report of the Joint National Committee on the Detection, Evaluation, and Treatment of High Blood Pressure (JNC7) is the national clinical guideline that was developed to aid clinicians in the management of hypertension.¹ This chapter reviews relevant components of this evidence-based guideline with a focus on the pharmacotherapy of hypertension. Data from the National

Health and Nutrition Examination Survey from 1999 to 2000 indicate that of the population of Americans with hypertension, 68.9% are aware that they have hypertension, and only 58.4% are on some form of antihypertensive treatment.² Moreover, only 34% of all patients have controlled BP, which increases to only 53.1% when only those on treatment are evaluated.² Therefore, there are ample opportunities for clinicians to improve the care of hypertensive patients.

EPIDEMIOLOGY

It is estimated that approximately 30% of the population (50 million Americans) has high BP ($\geq 140/90$ mm Hg).^{2,3} Estimates from the National Health and Nutrition Examination Survey from 1999–2000

indicate that the prevalence is 30.1% and 27.1% among men and women, respectively.² This represents a significant increase of 5.6% in women from 1988 to 2000, whereas the prevalence in men has remained unchanged. Prevalence rates are highest in non-Hispanic blacks (33.5%), followed by non-Hispanic whites (28.9%) and Mexican-Americans (20.7%).

BP values increase with age, and hypertension is very common in the elderly. The lifetime risk of developing hypertension among those 55 years of age and older who are normotensive is 90%.¹ Most patients have prehypertension BP values before they are diagnosed with hypertension, and most hypertension diagnoses occur between the third and fifth decades of life. Up to the age of 55 years, more men than women have hypertension. From the ages of 55 to 74 years, slightly more women have hypertension than men, with this sex difference becoming greater in the very elderly (≥ 75 years). In the older population (age ≥ 60 years), the prevalence of hypertension is 65.4% (estimated in 2000), which is significantly higher than the 57.9% prevalence estimated in 1988.²

ETIOLOGY

Hypertension is a heterogeneous medical condition. In most patients it results from unknown pathophysiologic etiology (essential or primary hypertension). While this form of hypertension cannot be cured, it can be controlled. A small percentage of patients have a specific cause of their hypertension (secondary hypertension). There are many potential secondary causes that are either concurrent medical conditions or are endogenously induced. If the cause of secondary hypertension can be identified, hypertension in these patients potentially can be cured.

ESSENTIAL HYPERTENSION

Over 90% of individuals with hypertension have essential hypertension (primary hypertension).¹ Numerous mechanisms have been identified that may contribute to the pathogenesis of this form of hypertension, so identifying the exact underlying abnormality is not possible. Hypertension often runs in families, indicating that genetic factors may play an important role in the development of essential hypertension. Data suggest that there are monogenic and polygenic forms of BP dysregulation that may be responsible for essential hypertension.^{4,5} Many of these genetic traits feature genes that affect sodium balance,⁵ but genetic mutations altering urinary kallikrein excretion, nitric oxide release, aldosterone excretion, other adrenal steroids, and angiotensinogen are also documented.⁴ In the future, identifying individuals with these genetic traits could lead to alternative approaches to preventing or treating hypertension; however, this is not currently recommended.

SECONDARY HYPERTENSION

Fewer than 10% of patients have secondary hypertension, where either a comorbid disease or a drug is responsible for elevating BP¹ (see Table 13–1). In most of these cases, renal dysfunction resulting from chronic kidney disease or renovascular disease is the most common secondary cause.⁶ Certain drugs, either directly or indirectly, can cause hypertension or exacerbate hypertension by increasing BP. The most common agents are listed in Table 13–1. Some of these agents are herbal products. Although these are not technically drugs, they have been identified as causes of elevated BP and secondary hypertension. When a secondary cause is identified, removing the offending agent or treating/correcting the underlying comorbid condition should be the first step in management.

TABLE 13–1. Secondary Causes of Hypertension

| Disease | Drugs Associated with Hypertension in Humans |
|--------------------------|---|
| Chronic kidney disease | Prescription drugs |
| Cushing’s syndrome | Corticosteroids, ^a ACTH |
| Coarctation of the aorta | Estrogens ^a (usually oral contraceptives with high estrogenic activity) |
| Obstructive sleep apnea | Nonsteroidal anti-inflammatory drugs, ^a COX-2 inhibitors ^a |
| Parathyroid disease | Phenylpropanolamine ^a and analogues ^a |
| Pheochromocytoma | Cyclosporine ^a and tacrolimus ^a |
| Primary aldosteronism | Erythropoetin ^a |
| Renovascular disease | Sibutramine ^a |
| Thyroid disease | Antidepressants (especially venlafaxine), bromocriptine, buspirone, carbamazepine, clozapine, desfulrane, ketamine, metoclopramide Clonidine/ β -blocker combination Pheochromocytoma: β -blocker without α -blocker first |
| | Street Drugs and Other Natural Products |
| | Cocaine ^a and cocaine withdrawal ^a |
| | Ma huang, ^a “herbal ecstasy,” ^a other phenylpropanolamine analogues ^a |
| | Nicotine and withdrawal, anabolic steroids, narcotic withdrawal, methylphenidate, phencyclidine, ketamine, ergotamine and other ergot-containing herbal products, St. John’s wort |
| | Food Substances |
| | Sodium ^a |
| | Ethanol ^a |
| | Licorice |
| | Tyramine-containing foods if taking a monoamine oxidase inhibitor |
| | Chemical Elements and Other Industrial Chemicals |
| | Lead, mercury, thallium and other heavy metals, lithium |

^aAgents of most clinical importance.

PATHOPHYSIOLOGY^{4,7}

A clear understanding of arterial BP and regulation is needed to manage hypertension appropriately and to understand antihypertensive drug therapy mechanistically. Multiple factors that control BP are potential contributing components in the development of hypertension. These include malfunctions in either humoral (i.e., the renin-angiotensin-aldosterone system [RAAS]) or vasodepressor mechanisms, abnormal neuronal mechanisms, defects in peripheral autoregulation, and disturbances in sodium, calcium, and natriuretic hormone. Many of these factors are cumulatively affected by the multifaceted RAAS, which ultimately regulates arterial BP. It is probable that none of these factors is solely responsible for hypertension; however, most antihypertensives specifically target these mechanisms and components of the RAAS.

ARTERIAL BLOOD PRESSURE

Arterial BP is the measured pressure in the arterial wall in millimeters of mercury. Two arterial BP values are typically measured, systolic BP (SBP) and diastolic BP (DBP). SBP is achieved during cardiac contraction and represents the peak value. DBP is achieved after contraction when the cardiac chambers are filling and represents the nadir value. The difference between SBP and DBP is called the *pulse pressure* and indicates arterial wall tension. Mean arterial pressure (MAP) is the average pressure throughout the cardiac cycle of contraction. It is sometimes used clinically to represent overall arterial BP. During a cardiac cycle, two-thirds of the time is spent in diastole and one-third in systole. Therefore, the MAP can be estimated by using the following equation:

$$\text{MAP} = \frac{1}{3}(\text{SBP}) + \frac{2}{3}(\text{DBP})$$

Arterial BP is generated hemodynamically by the interplay between blood flow and the resistance to blood flow. It is defined mathematically as the product of cardiac output (CO) and total peripheral resistance (TPR) according to the following equation:

$$\text{BP} = \text{CO} \times \text{TPR}$$

CO is the major determinant of SBP, whereas TPR largely determines DBP. In turn, CO is a function of stroke volume, heart rate, and venous capacitance. Table 13–2 lists physiologic causes of increased CO and TPR and correlates them with potential mechanisms of pathogenesis.

Under normal physiologic conditions, arterial BP fluctuates throughout the day. It typically follows a circadian rhythm, where it decreases to its lowest daily values during sleep.⁸ This is followed by a sharp rise starting a few hours prior to awakening, with the high-

est values occurring midmorning. BP is also increased acutely during physical activity or emotional stress.

CLASSIFICATION

The JNC7 classification of BP in adults (age ≥ 18 years) is based on the average of two or more properly measured BP readings from two or more clinical encounters¹ (Table 13–3). It includes four categories, with normal values considered to be an SBP of less than 120 mm Hg and a DBP of less than 80 mm Hg. Prehypertension is not considered a disease category but identifies patients whose BP is likely to increase into the classification of hypertension in the future. There are two stages of hypertension, and all patients in these categories warrant drug therapy.

Hypertensive crises are clinical situations where BP values are greater than 180/120 mm Hg.^{7,9} They are categorized as either a hypertensive emergency or hypertensive urgency. *Hypertensive emergencies* are extreme elevations in BP that are accompanied by acute or progressing target-organ damage. Examples of acute target-organ injury include encephalopathy, intracranial hemorrhage, acute left ventricular failure with pulmonary edema, dissecting aortic aneurysm, unstable angina, and eclampsia or severe hypertension during pregnancy. Hypertensive emergencies require an immediate but gradual

TABLE 13–3. Classification of Blood Pressure in Adults (Age ≥ 18 Years)^a

| Classification | Systolic Blood Pressure (mm Hg) | | Diastolic Blood Pressure (mm Hg) |
|------------------------------|---------------------------------|-----|----------------------------------|
| Normal | Less than 120 | and | Less than 80 |
| Prehypertension ^b | 120–139 | or | 80–89 |
| Stage 1 hypertension | 140–159 | or | 90–99 |
| Stage 2 hypertension | Greater than or equal to 160 | or | Greater than or equal to 100 |

^aClassification determined based on the average of two or more properly measured seated BP measurements from two or more clinical encounters. If systolic and diastolic blood pressure values yield different classifications, the highest category is used for the purpose of determining a classification.

^bFor patients with diabetes mellitus or chronic kidney disease, values $\geq 130/80$ mm Hg are considered above goal.

reduction in BP over a period of several minutes to several hours using intravenous antihypertensive agents. A reasonable goal is to gradually lower DBP to <110 mm Hg.⁷ Abrupt BP reductions should be avoided. *Hypertensive urgencies* are high elevations in BP without acute or progressing target-organ injury. These situations require BP reductions with oral antihypertensive agents to stage 1 values over a period of several hours to several days.

CARDIOVASCULAR RISK AND BLOOD PRESSURE

◀ Epidemiologic data clearly indicate a strong correlation between BP and cardiovascular morbidity and mortality.¹⁰ Risk of stroke, myocardial infarction, angina, heart failure, kidney failure, or early death from a cardiovascular cause are directly correlated with BP. Starting at a BP of 115/75 mm Hg, risk of cardiovascular disease doubles with every 20/10 mm Hg increase.¹ Even within the prehypertension BP category, an increased risk of cardiovascular disease is associated with higher BP values.¹¹ Moreover, large-scale placebo-controlled outcome trials have shown that the increased risks of cardiovascular events and death associated with elevated BP are reduced substantially by antihypertensive therapy.^{12–15}

SBP is a stronger predictor of cardiovascular disease than DBP in adults 50 years of age and older and is the most important clinical BP parameter for most patients.^{1,16} Patients with DBP values less than or equal to 90 mm Hg and SBP values greater than or equal to 140 mm Hg have *isolated systolic hypertension*. Isolated systolic hypertension is believed to result from pathophysiologic changes in the arterial vasculature consistent with aging. These changes decrease the compliance of the arterial wall and portend an increased risk of cardiovascular morbidity and mortality.

Cardiovascular risk, especially in those with isolated systolic hypertension, may be projected by calculating the pulse pressure.¹⁷ Pulse pressure is the difference between SBP and DBP. It is believed to reflect extent of atherosclerotic disease in the elderly and is a measure of increased arterial stiffness. Higher pulse pressure values are correlated with an increased risk of cardiovascular mortality.¹⁷

HUMORAL MECHANISMS

Several humoral abnormalities may be involved in the development of essential hypertension. These abnormalities may involve the RAAS, natriuretic hormone, and hyperinsulinemia.

THE RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM (RAAS)

The RAAS is a complex endogenous system that is involved with most regulatory components of arterial BP. Activation and regulation are governed primarily by the kidney (Fig. 13–1). The RAAS regulates sodium, potassium, and fluid balance. Therefore, this system significantly influences vascular tone and sympathetic nervous system activity and is the most influential contributor to the homeostatic regulation of BP.

Renin is an enzyme that is stored in the juxtaglomerular cells, which are located in the afferent arterioles of the kidney. The release of renin is modulated by several factors: intrarenal factors (e.g., renal perfusion pressure, catecholamines, and angiotensin II) and extrarenal factors (e.g., sodium, chloride, and potassium).

Juxtaglomerular cells function as a baroreceptor-sensing device. Decreased renal artery pressure and kidney blood flow are sensed by these cells and stimulate secretion of renin. The juxtaglomerular apparatus also includes a group of specialized distal tubule cells

referred to collectively as the *macula densa*. A decrease in sodium and chloride delivered to the distal tubule stimulates renin release. Catecholamines increase renin release probably by directly stimulating sympathetic nerves on the afferent arterioles that, in turn, activate the juxtaglomerular cells. Decreased serum potassium and/or intracellular calcium is detected by the juxtaglomerular cells, resulting in renin secretion.

Renin catalyzes the conversion of angiotensinogen to angiotensin I in the blood. Angiotensin I is then converted to angiotensin II by angiotensin-converting enzyme (ACE). After binding to specific receptors (classified as either AT₁ or AT₂ subtypes), angiotensin II exerts biologic effects in several tissues. The AT₁ receptor is located in brain, kidney, myocardium, peripheral vasculature, and the adrenal glands. These receptors mediate most responses that are critical to cardiovascular and kidney function. The AT₂ receptor is located in adrenal medullary tissue, uterus, and brain. Stimulation of the AT₂ receptor does not influence BP regulation.

Circulating angiotensin II can elevate BP through pressor and volume effects. The pressor effects include direct vasoconstriction, stimulation of catecholamine release from the adrenal medulla, and centrally mediated increases in sympathetic nervous system activity. Angiotensin II also stimulates aldosterone synthesis from the adrenal cortex. This leads to sodium and water reabsorption that increases plasma volume, total peripheral resistance, and ultimately, BP. Clearly, any disturbance in the body that leads to activation of the RAAS could explain chronic hypertension.

The heart and brain contain a local RAAS. In the heart, angiotensin II is also generated by a second enzyme, angiotensin I convertase (human chymase). This enzyme is not blocked by ACE inhibition. Activation of the myocardial RAAS increases cardiac contractility and stimulates cardiac hypertrophy. In the brain, angiotensin II modulates the production and release of hypothalamic and pituitary hormones and enhances sympathetic outflow from the medulla oblongata.

Peripheral tissues can locally generate biologically active angiotensin peptides, which may explain the increased vascular resistance seen in hypertension. Some evidence suggests that angiotensin produced by local tissue may interact with other humoral regulators and endothelium-derived growth factors to stimulate vascular smooth muscle growth and metabolism. These angiotensin peptides may, in fact, instigate increased vascular resistance in low plasma renin forms of hypertension. Components of the tissue RAAS also may be responsible for the long-term hypertrophic abnormalities seen with hypertension (left ventricular hypertrophy, vascular smooth muscle hypertrophy, and glomerular hypertrophy).

NATRIURETIC HORMONE

Natriuretic hormone inhibits sodium and potassium ATPase and thus interferes with sodium transport across cell membranes. Inherited defects in the kidney's ability to eliminate sodium can cause an increased blood volume. A compensatory increase in the concentration of circulating natriuretic hormone theoretically could increase urinary excretion of sodium and water. However, this same hormone is also thought to block the active transport of sodium out of arteriolar smooth muscle cells. The increased intracellular concentration of sodium ultimately would increase vascular tone and BP.

INSULIN RESISTANCE AND HYPERINSULINEMIA

Evidence has linked insulin resistance and hyperinsulinemia with the development of hypertension, sometimes referred to as the *metabolic*

FIGURE 13-1. Diagram representing the renin-angiotensin-aldosterone system. The interrelationship between the kidney, angiotensin II, and regulation of blood pressure is depicted. Renin secretion from the juxtaglomerular cells in the afferent arteriole is one of the major regulators of this system. Sites of action for major antihypertensive agents are included (①, ACE inhibitors; ②, angiotensin II receptor blockers; ③, β -blockers; ④, calcium channel blockers; ⑤, diuretics; ⑥, aldosterone antagonists).

syndrome.¹⁸ Hypothetically, increased insulin concentrations may lead to hypertension because of increased renal sodium retention and enhanced sympathetic nervous system activity. Moreover, insulin has growth hormone–like actions that can induce hypertrophy of vascular smooth muscle cells. Insulin also may elevate BP by increasing intracellular calcium, which leads to increased vascular resistance. The exact mechanism by which insulin resistance and hyperinsulinemia occur in hypertension is unknown. However, this association is strong because many of the criteria used to define this population (elevated blood pressure, obesity, dyslipidemia, and elevated blood glucose) are often present in hypertensive patients.¹⁸

NEURONAL REGULATION

The central and autonomic nervous systems are intricately involved in the regulation of arterial BP. A number of receptors that either enhance or inhibit norepinephrine release are located on the presynaptic surface of sympathetic terminals. The α and β presynaptic receptors play a role in negative and positive feedback to the norepinephrine-containing vesicles located near the neuronal ending. Stimulation

of presynaptic α -receptors (α_2) exerts a negative inhibition on norepinephrine release. Stimulation of presynaptic β -receptors facilitates further release of norepinephrine.

Sympathetic neuronal fibers located on the surface of effector cells innervate the α - and β -receptors. Stimulation of postsynaptic α -receptors (α_1) on arterioles and venules results in vasoconstriction. There are two types of postsynaptic β -receptors, β_1 and β_2 . Both are present in all tissue innervated by the sympathetic nervous system. However, in some tissues, β_1 -receptors predominate, and in other tissues, β_2 -receptors predominate. Stimulation of β_1 -receptors in the heart results in an increase in heart rate and contractility, whereas stimulation of β_2 -receptors in the arterioles and venules causes vasodilation.

The baroreceptor reflex system is the major negative-feedback mechanism that controls sympathetic activity. Baroreceptors are nerve endings lying in the walls of large arteries, especially in the carotid arteries and aortic arch. Changes in arterial pressure rapidly activate baroreceptors, which then transmit impulses to the brain stem through the ninth cranial nerve and vagus nerves. In this reflex system, a decrease in arterial BP stimulates baroreceptors, causing reflex vasoconstriction and increased heart rate and force of cardiac contraction.

These baroreceptor reflex mechanisms may be blunted in the elderly and in those with diabetes.

Stimulation of certain areas within the central nervous system (e.g., nucleus tractus solitarius, vagal nuclei, vasomotor center, and the area postrema) can either increase or decrease BP. For example, α_2 -adrenergic stimulation within the central nervous system decreases BP through an inhibitory effect on the vasomotor center. However, angiotensin II increases sympathetic outflow from the vasomotor center, which increases BP.

The purpose of these neuronal mechanisms is to regulate BP and maintain homeostasis. Pathologic disturbances in any of the four major components (autonomic nerve fibers, adrenergic receptors, baroreceptors, or central nervous system) conceivably could lead to chronically elevated BP. These systems are physiologically interrelated. A defect in one component may alter normal function in another, and such cumulative abnormalities then may explain the development of essential hypertension.

PERIPHERAL AUTOREGULATORY COMPONENTS

Abnormalities in renal or tissue autoregulatory systems could cause hypertension. It is possible that a renal defect in sodium excretion may develop first, which can then cause resetting of tissue autoregulatory processes, resulting in a higher arterial BP.

The kidney usually maintains normal BP through a volume-pressure-adaptive mechanism. When BP drops, the kidneys respond by increasing retention of sodium and water. These changes lead to plasma volume expansion, which increases BP. Conversely, when BP rises above normal, renal sodium and water excretion are increased to reduce plasma volume and cardiac output. This ultimately will maintain homeostatic BP conditions.

Local autoregulatory processes maintain adequate tissue oxygenation. When tissue oxygen demand is normal to low, the local arteriolar bed remains relatively vasoconstricted. However, increases in metabolic demand trigger arteriolar vasodilation that lowers peripheral vascular resistance and increases blood flow and oxygen delivery through autoregulation.

Intrinsic defects in these renal adaptive mechanisms could lead to plasma volume expansion and increased blood flow to peripheral tissues, even when BP is normal. Local tissue autoregulatory processes that vasoconstrict then would be activated to offset the increased blood flow. This effect would result in increased peripheral vascular resistance and, if sustained, also would result in thickening of the arteriolar walls. This pathophysiologic component is plausible because increased total peripheral vascular resistance is a common underlying finding in patients with essential hypertension.

VASCULAR ENDOTHELIAL MECHANISMS

Vascular endothelium and smooth muscle play important roles in regulating blood vessel tone and BP. These regulating functions are mediated through vasoactive substances that are synthesized by endothelial cells. It has been postulated that a deficiency in the local synthesis of vasodilating substances (e.g., prostacyclin and bradykinin) or excess vasoconstricting substances (e.g., angiotensin II and endothelin I) contribute to essential hypertension, atherosclerosis, and other diseases.

Nitric oxide is produced in the endothelium, relaxes the vascular epithelium, and is a very potent vasodilator. The nitric oxide system is an important regulator of arterial BP. Hypertensive patients may have

an intrinsic deficiency in nitric oxide release, resulting in inadequate vasodilation. Although the exact role of nitric oxide in hypertension is unclear, it may be a pharmacologic target in the future.

ELECTROLYTES AND OTHER CHEMICALS

Epidemiologic and clinical data have associated excess sodium intake with hypertension. Population-based studies indicate that high-salt diets are associated with a high prevalence of stroke and hypertension. Conversely, low-salt diets are associated with a low prevalence of hypertension. Clinical studies have shown consistently that dietary sodium restriction lowers BP in many (but not all) patients with elevated BP. The exact mechanisms by which excess sodium leads to hypertension are not known. However, they may be linked to increased circulating natriuretic hormone, which would inhibit intracellular sodium transport, causing increased vascular reactivity and increased BP.

Altered calcium homeostasis also may play an important role in the pathogenesis of hypertension. A lack of dietary calcium hypothetically can disturb the balance between intracellular and extracellular calcium, resulting in an increased intracellular calcium concentration. This imbalance can alter vascular smooth muscle function by increasing peripheral vascular resistance. Some studies have shown that dietary calcium supplementation results in a modest BP reduction in hypertensive patients.

The role of potassium fluctuations is also inadequately understood. Potassium depletion may increase peripheral vascular resistance, but the clinical significance of small serum potassium concentration changes is unclear. Furthermore, data demonstrating reduced cardiovascular risk with dietary potassium supplementation are very limited. This issue requires further investigation before potassium supplementation can be endorsed.

Hyperuricemia has been associated with an increased risk of cardiovascular events in hypertensive patients but remains controversial because of inconsistent data. Uric acid has no physiologic function and is considered a biologic waste product. Therefore, there is no rational explanation describing why uric acid would cause cardiovascular harm. However, elevated uric acid may be viewed as a supplemental risk marker in hypertensive patients.

CLINICAL PRESENTATION

CLINICAL PRESENTATION OF HYPERTENSION

GENERAL

The patient may appear very healthy or may have the presence of additional cardiovascular risk factors:

- Age (≥ 55 years for men to 65 years for women)
- Diabetes mellitus
- Dyslipidemia (elevated low-density lipoprotein [LDL] cholesterol, total cholesterol or triglycerides; low high-density lipoprotein [HDL] cholesterol)
- Microalbuminuria
- Family history of premature cardiovascular disease
- Obesity (body mass index ≥ 30 kg/m²)
- Physical inactivity
- Tobacco use

SYMPTOMS

- Most patients are asymptomatic

SIGNS

- Previous blood pressure values measured in the prehypertension or hypertension category

LABORATORY TESTS

The patient may have normal values and still have hypertension. However, some may have abnormal values consistent with either additional cardiovascular risk factors or hypertension-related damage.

- Blood urea nitrogen (BUN) and serum creatinine
- Fasting lipid panel
- Fasting blood glucose
- Serum potassium
- Urinalysis

OTHER DIAGNOSTIC TESTS

- 12-lead electrocardiogram (to detect LVH)
- Highly sensitive C-reactive protein (high concentrations are associated with increased cardiovascular risk)

TARGET-ORGAN DAMAGE

The patient may have a previous medical history or diagnostic findings that indicate the presence of hypertension-related target-organ damage:

- Brain (stroke, transient ischemic attack, dementia)
- Eyes (retinopathy)
- Heart (left ventricular hypertrophy, angina or prior myocardial infarction, prior coronary revascularization, heart failure)
- Kidney (chronic kidney disease)
- Peripheral vasculature (peripheral arterial disease)

DIAGNOSTIC CONSIDERATIONS

2 Hypertension is termed the “silent killer” because patients with essential hypertension are usually asymptomatic. The primary physical finding is elevated BP. The diagnosis of hypertension cannot be made based on one elevated BP measurement. The average of two or more measurements taken during two or more clinical encounters should be used to diagnose hypertension.¹ Thereafter, this BP average can be used to establish a diagnosis and then to classify the stage of hypertension present using Table 13–3.

MEASURING BLOOD PRESSURE**Sphygmomanometry**

Indirect measurement of BP using a sphygmomanometer is a common routine medical screening tool that should be conducted at every health care encounter.¹ The appropriate procedure to measure BP has been described by the American Heart Association (AHA).¹⁹ It is imperative that the measurement equipment (inflation cuff, stethoscope, manometer) meet certain national standards.²⁰ These standards use criteria to ensure maximum quality and precision with measurement.

The following stepwise technique is recommended^{1,19}:

- Patients should refrain from smoking or caffeine ingestion for 30 minutes and be seated with the lower back supported in a chair and with their bare arm resting near heart level. Legs should be flat on the floor (not crossed). Measuring BP in the supine or standing position may be required under special circumstances (e.g., suspected orthostatic hypotension, volume depletion, or dehydration). The measurement environment should be relatively quiet and should provide privacy.
- Measurement should begin only after a 5-minute period of rest.
- A properly sized cuff (pediatric, small, regular, large, or extra large) should be used. Overestimating the actual BP can occur if the cuff is too small. The inflatable rubber bladder inside the cuff should encircle at least 80% of the arm, and the width of the cuff should be at least two-thirds the length of the upper arm.
- The palpatory method should be used to estimate the SBP:
 - Place the cuff on the upper arm, and attached it to the manometer (either a mercury or aneroid).
 - Close the inflation valve with the thumb and index finger, and inflate the cuff to 70 mm Hg, and then inflate in increments of 10 mm Hg by pumping the inflation bulb (as it is resting in the palm of your hand) with the last three fingers.
 - Simultaneously palpate the radial pulse with the first and second fingers of the opposite hand.
 - Note the pressure at which the radial pulse disappears; this is the estimated SBP.
 - Release pressure from the cuff by turning the valve counterclockwise.
- The bell (not the diaphragm) of the stethoscope should be placed on the skin of the antecubital fossa, directly over where the brachial artery is palpated. The stethoscope earpieces should be inserted appropriately. The valve should be closed with the cuff then inflated rapidly to about 30 mm Hg above the estimated SBP from the palpatory method. The valve should be opened only slightly to release pressure at a rate of 2 to 3 mm Hg/s.
- The clinician should listen for Korotkoff sounds with the stethoscope. The first phase of Korotkoff sounds is the initial presence of clear tapping sounds. Note the pressure at the first recognition of these sounds. This is the SBP. As pressure continues to deflate, note the pressure when all sounds disappear (also known as the fifth Korotkoff phase). This is the DBP.
- A second measurement should be obtained after 2 minutes, and the average should be documented. If these values differ by more than 5 mm Hg, additional measurements should be collected and averaged.

In all instances, using the stethoscope bell rather than the diaphragm is recommended. Low-frequency Korotkoff sounds may not be heard clearly and accurately with the diaphragm. This is especially problematic in patients with faint or “distant” sounds.

Inaccuracies with indirect measurements result from inherent biologic variability of blood pressure, inaccuracies related to suboptimal technique, and the white coat effect.²¹ BP varies with environmental temperature, the time of day and year, meals, physical activity, posture, smoking, and emotions.^{8,19,22} Some patients have *white coat hypertension*, where BP values rise in a clinical setting but return to normal in nonclinical environments using home or ambulatory blood

pressure measurements.²³ Interestingly, the rise in BP dissipates gradually over several hours after leaving the clinical setting. It may or may not be precipitated by other stresses in the patient's daily life. Aggressive treatment of white coat hypertension is controversial. However, patients with white coat hypertension may have increased cardiovascular risk compared with those without such BP changes.²⁴

Several additional factors can result in erroneous BP measurements. *Pseudohypertension* is a falsely elevated BP measurement that is seen in elderly patients with a rigid, calcified brachial artery.²⁵ In these patients, the true arterial BP when measured directly intraarterially (the most accurate measurement of BP) is much lower than that measured using the indirect cuff method. The Osler's maneuver can be used to test for pseudohypertension. In this maneuver, the BP cuff is inflated above peak SBP. If the radial artery remains palpable, the patient has a positive Osler's maneuver (rigid artery), which indicates pseudohypertension.

Patients with an *auscultatory gap* may have either underestimated SBP or overestimated DBP measurements. In this situation, as the cuff pressure falls from the true SBP value, the Korotkoff sound may disappear (indicating a false DBP measurement), reappear (a false SBP measurement), and then disappear again at the true DBP value. This is often identified by using the palpatory method to estimate SBP and then inflating the cuff an additional 30 mm Hg above this estimate because the "gap" is usually less than 30 mm Hg. When an auscultatory gap is present, Korotkoff sounds usually are heard when pressure in the cuff first starts to decrease after inflation.

Patients with irregular ventricular rates (e.g., atrial fibrillation or atrial flutter) may have misleading BP values when measured indirectly. In this situation, SBP and DBP values may vary from one heartbeat to the next.

Ambulatory and Self Blood Pressure Monitoring

Twenty-four-hour ambulatory BP monitoring can document BP at frequent time intervals throughout the day.²³ Ambulatory BP values usually are lower than clinic-measured values because hypertensive patients have average values greater than 135/85 mm Hg during the day and greater than 120/80 mm Hg during sleep. Home BP measurements are collected by patients, preferably in the morning, using home monitoring devices. Either of these may be warranted in patients with suspected white coat hypertension (without hypertension-related target-organ damage) to differentiate white coat from essential hypertension.¹ Moreover, ambulatory BP monitoring may be helpful in patients with apparent drug resistance, hypotensive symptoms while on antihypertensive therapy, episodic hypertension, and autonomic dysfunction.¹

Some data suggest that 24-hour and home BP measurements correlate better with cardiovascular risk than do conventional office-based measurements.^{26,27} However, one controlled study found that ambulatory and self BP monitoring are complementary to conventional clinic-based measurements.²⁸ Limitations of these measurements that prohibit routine use of such technology include complexity of use, availability of devices, costs, and lack of prospective outcomes data describing normal ranges for these measurements. Although self-monitoring of BP at home is less complicated than ambulatory monitoring, patients may fail to record some high values and then actually may add lower "ghost" values that were never measured.²³

CLINICAL EVALUATION

Frequently, the only sign of essential hypertension is elevated BP. The rest of the physical examination may be completely normal. However, a complete medical evaluation (a comprehensive medical

history, physical examination, and laboratory and/or diagnostic tests) is recommended after diagnosis to (1) identify secondary causes, (2) identify other cardiovascular risk factors or comorbid conditions that may define prognosis and/or guide therapy, and (3) assess for the presence or absence of hypertension-associated target-organ damage.¹ All hypertensive patients should have the following measured prior to initiating therapy: 12-lead electrocardiogram; urinalysis; blood glucose and hematocrit; serum potassium, creatinine (with estimated glomerular filtration rate [GFR]), and calcium; and a fasting lipid panel.¹ A urinary albumin excretion or albumin/creatinine ratio is considered an optional test.

SECONDARY CAUSES

The most common secondary causes of hypertension are listed in Table 13–1. A complete medical evaluation may provide clues for diagnosing secondary hypertension. For example, patients with coarctation of the aorta may have diminished or even absent femoral pulses, and patients with renal artery stenosis may have an abdominal systolic-diastolic bruit.

Patients with secondary hypertension may complain of symptoms suggestive of the underlying disorder, but some are asymptomatic. Patients with pheochromocytoma may have a history of paroxysmal headaches, sweating, tachycardia, and palpitations. Over half these patients suffer from episodes of orthostatic hypotension. In primary aldosteronism, symptoms related to the hypokalemia usually include muscle cramps and muscle weakness. Patients with Cushing's syndrome may complain of weight gain, polyuria, edema, menstrual irregularities, recurrent acne, or muscular weakness and have several classic physical features (e.g., moon face, buffalo hump, hirsutism, and abdominal striae).

Routine laboratory tests may help to identify secondary hypertension. Baseline hypokalemia may suggest mineralocorticoid-induced hypertension. Protein, blood cells, and casts in the urine may indicate renovascular disease. Some laboratory tests are used specifically to diagnose secondary hypertension. These include: plasma norepinephrine and urinary metanephrine concentrations for pheochromocytoma, plasma and urinary aldosterone concentrations for primary aldosteronism, and plasma renin activity, captopril stimulation test, renal vein renins, and renal artery angiography for renovascular disease.

Certain medications and herbal products can result in drug-induced hypertension. The most common of these are listed in Table 13–1. For some patients, the addition of these agents can be the cause of hypertension or can exacerbate underlying hypertension. Identifying a temporal relationship between starting the suspected agent and developing elevated BP is most suggestive of drug-induced BP elevation.

NATURAL COURSE OF THE DISEASE

Essential hypertension usually is preceded by elevated BP values that are in the prehypertension category. BP values may fluctuate between elevated and normal values for an extended period of time. These changes may begin as early as the second decade of life. During this stage, many patients have a hyperdynamic circulation with increased cardiac output and normal or even low peripheral vascular resistance. As the disease progresses, peripheral vascular resistance increases, and BP elevation is sustained to the point where essential hypertension is diagnosed.

TARGET-ORGAN DAMAGE

As hypertension progresses, target-organ damage may appear. The primary organs involved are the eye, brain, heart, kidneys, and peripheral blood vessels. Cardiovascular events, cerebrovascular accidents, and kidney failure are the primary causes of morbidity and mortality in patients with hypertension. These clinical events are often preceded by the development of hypertension-association target-organ damage (see Clinical Presentation above). The probability of morbidity and mortality in hypertension is directly correlated with the severity of BP elevation.

Hypertension accelerates atherosclerosis and stimulates left ventricular and vascular hypertrophy. These pathologic changes are thought to be secondary to both a chronic pressure overload and a variety of nonhemodynamic stimuli. Some of the nonhemodynamic disturbances that have been implicated in these effects include the adrenergic system, RAAS, increased synthesis and secretion of endothelin I, and a decreased production of prostacyclin and nitric oxide. Accelerated atherogenesis in hypertension is accompanied by proliferation of smooth muscle cells, lipid infiltration into the vascular endothelium, and an enhancement of vascular calcium accumulation.

Cerebrovascular disease is a consequence of hypertension. A neurologic assessment can detect either gross neurologic deficits or a slight hemiparesis with some incoordination and hyperreflexia that are indicative of cerebrovascular disease. Stroke can result from lacunar infarcts caused by thrombotic occlusion of small vessels or intracerebral hemorrhage resulting from ruptured microaneurysms. Transient ischemic attacks secondary to atherosclerotic disease in the carotid arteries are common in hypertensive individuals.

Retinopathies can occur in hypertension and may manifest as a variety of different findings. A fundoscopic examination can detect hypertensive retinopathy, which manifests as arteriolar narrowing, focal arteriolar constrictions, arteriovenous crossing changes (nicking), retinal hemorrhages and exudates, and disc edema. Accelerated arteriosclerosis, a long-term consequence of essential hypertension, can cause nonspecific changes such as increased light reflex, increased tortuosity of vessels, and arteriovenous nicking. Focal arteriolar narrowing, retinal infarcts, and flame-shaped hemorrhages usually are

suggestive of an accelerated or malignant phase of hypertension. Papilledema is a swelling of the optic disc and is caused by a breakdown in autoregulation of capillary blood flow in the presence of high pressure. It is usually only present in very severe hypertension or in hypertensive emergencies.

Heart disease is the most well-identified form of target-organ damage. A thorough cardiac and pulmonary examination can identify cardiopulmonary abnormalities. Clinical manifestations include left ventricular hypertrophy, coronary heart disease (e.g., angina, prior myocardial infarction, and prior coronary revascularization), and heart failure. These complications may lead to cardiac arrhythmias, angina, myocardial infarction, and sudden death. Coronary heart disease and associated cardiac events are the most common causes of death in hypertensive patients.

The kidney damage caused by hypertension is characterized pathologically by hyaline arteriosclerosis, hyperplastic arteriosclerosis, arteriolar hypertrophy, fibrinoid necrosis, and atheroma of the major renal arteries. Glomerular hyperfiltration and intraglomerular hypertension are early stages of hypertensive nephropathy. Microalbuminuria is followed by a gradual decline in renal function. The primary renal complication in hypertension is nephrosclerosis, which is secondary to arteriosclerosis. Atheromatous disease of a major renal artery may give rise to renal artery stenosis. Although overt kidney failure is an uncommon complication of essential hypertension, it is an important cause of end-stage kidney disease, especially in African-Americans, Hispanics, and Native Americans. It is not completely understood why these ethnic groups are more at risk for kidney decline than other races.

The peripheral vasculature is considered a target organ. Physical examination of the systemic vasculature can detect evidence of atherosclerosis, which may present as bruits (in the aortic, abdominal, and peripheral arteries), distended veins, diminished or absent peripheral arterial pulses, or lower extremity edema. Peripheral arterial disease is a clinical condition that can result from atherosclerosis, which is accelerated in hypertension. Other cardiovascular risk factors (e.g., smoking) can increase the likelihood of peripheral arterial disease as well as all other forms of target-organ damage.

▶ TREATMENT: Hypertension

■ DESIRED OUTCOMES

■ OVERALL GOAL OF THERAPY

3 The overall goal of treating hypertension is to reduce hypertension-associated morbidity and mortality.¹ This morbidity and mortality are related to target-organ damage (e.g., cardiovascular events, cerebrovascular events, heart failure, and kidney disease). Reducing risk remains the primary purpose of hypertension therapy, and the choice of drug therapy is influenced significantly by evidence demonstrating such risk reduction.

■ SURROGATE GOAL OF THERAPY

4 Treating hypertensive patients to achieve a desired target BP value is simply a surrogate goal of therapy. Reducing BP to target does not guarantee that target-organ damage will not occur. However, attaining target BP values is associated with a lower risk of cardiovascular disease and target-organ damage.^{1,16,29,30} Targeting a goal BP value is a tool that clinicians can use easily to evaluate

response to therapy and is the primary method used to determine the need for titration and regimen modification.

Most patients have a goal BP of less than 140/90 mm Hg. However, this goal is lowered to less than 130/80 mm Hg for patients with diabetes or chronic kidney disease.

GOAL BP VALUES RECOMMENDED BY THE JNC7

- Most patients < 140/90 mm Hg
- Patients with diabetes < 130/80 mm Hg
- Patients with chronic kidney disease < 130/80 mm Hg (estimated GFR < 60 mL/min, serum creatinine > 1.3 mg/dL in women or > 1.5 mg/dL in men, or albuminuria > 300 mg/day or ≥ 200 mg/g creatinine)

Some clinicians advocate attaining BP goal values that are lower than what is recommended as a modality to further reduce cardiovascular risk following the myth that “lower is better.” Contrary to this, a J-curve hypothesis where lowering BP too much might increase the risk of cardiovascular events has been described.^{31,32} However, these

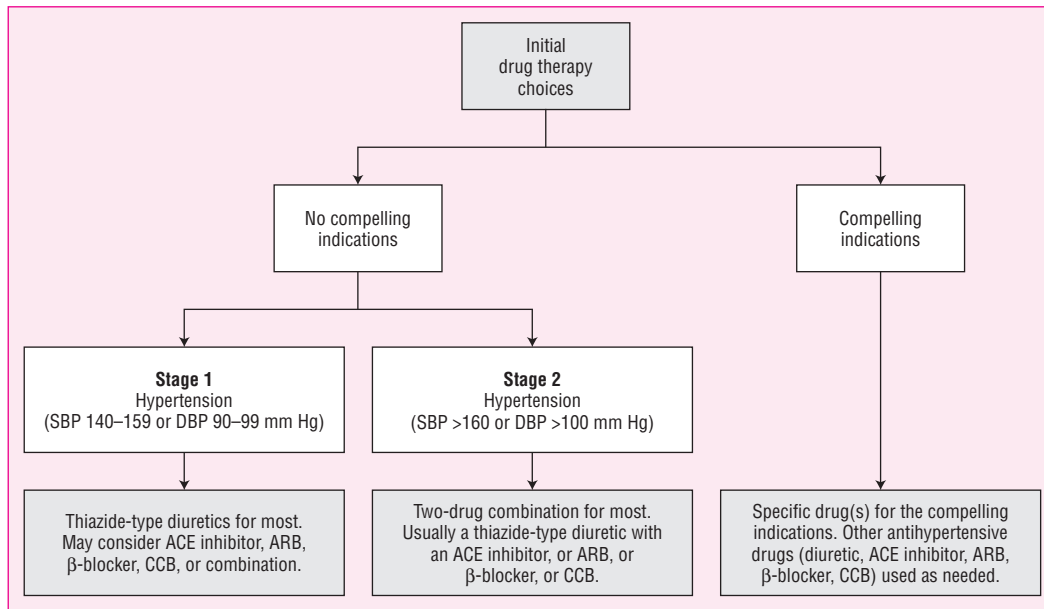

FIGURE 13–2. Algorithm for treatment of hypertension when patients are not at their goal blood pressure. (Adapted from the JNC7.¹)

data are based on observational studies and cannot establish a cause-and-effect relationship owing to confounding variables.

Lower-goal BP values have been evaluated prospectively in the Hypertension Optimal Treatment (HOT) trial.²⁹ In this study, over 18,700 patients were randomized to target DBP values of 90, 85, or 80 mm Hg or less. Although the actual DBP values achieved were 85.2, 83.2, and 81.1 mm Hg, respectively, the risk of major cardiovascular events was the lowest with a BP of 139/83 mm Hg, and lowest risk of stroke was with a BP of 142/80 mm Hg. Risk of events in subjects with either diabetes or ischemic heart disease was lowest at DBP values of less than 80 mm Hg. No J-curve relationship was seen. The HOT trial results provide evidence that support the JNC recommended goal value of less than 140/90 mm Hg for most patients and the more aggressive goal of less than 130/80 mm Hg in patients with diabetes.

■ GENERAL APPROACH TO TREATMENT

Although hypertension is one of the most common medical conditions, BP control rates are poor. Many hypertensive patients are at goal DBP values but continue to have elevated SBP values. It has been estimated that of the hypertensive population that is treated yet not controlled, 76.9% have an SBP greater than or equal to 140 mm Hg with DBP values less than 90 mm Hg.³³ For most hypertensive patients, attaining the SBP goal almost always ensures achievement of the DBP goal. When coupled with the fact that SBP is a better predictor of cardiovascular risk than DBP, SBP must be used as the primary clinical marker of disease control in hypertension.

After a definitive diagnosis of hypertension is made, patients should be placed on both lifestyle modifications and drug therapy concurrently. Lifestyle modification alone is considered appropriate therapy for patients with prehypertension. However, lifestyle modifications alone are not considered adequate for patients with hypertension or patients with BP goals of less than 130/80 mm Hg (those with diabetes and chronic kidney disease) who have BP values above their goal.

The choice of initial drug therapy depends on the degree of BP elevation and the presence of compelling indications (discussed later). Most patients with stage 1 hypertension should be treated initially with a thiazide-type diuretic. For most patients with more severe BP elevation (stage 2 hypertension), combination drug therapy, with one of the agents preferably being a thiazide type-diuretic, is recommended. This general approach is outlined in Fig. 13–2. There are six compelling indications where specific antihypertensive drug classes have shown evidence of unique benefits (Fig. 13–3).

■ NONPHARMACOLOGIC THERAPY

5 All patients with prehypertension and hypertension should be prescribed lifestyle modifications. Modifications that have been shown to lower BP are listed in Table 13–4. These approaches are recommended by the JNC7¹ and provide small to moderate reductions in SBP. Aside from lowering BP in patients with known hypertension, lifestyle modification can decrease the progression to hypertension in patients with prehypertension BP values.³⁴ In a number of hypertensive patients with relatively good BP control while on single antihypertensive drug therapy, sodium reduction and weight loss may allow withdrawal of drug therapy.^{35,36}

A sensible dietary program is one that is designed to reduce weight gradually for overweight and obese patients and one that restricts sodium intake with only moderate alcohol consumption. Successful implementation of dietary lifestyle modifications by clinicians requires aggressive promotion through reasonable patient education, encouragement, and continued reinforcement. Patients may better understand the rationale for dietary intervention in hypertension if they are provided the following observations and facts:

1. Hypertension is two to three times more prevalent in overweight as compared with lean persons.
2. Over 60% of hypertensive persons are overweight.

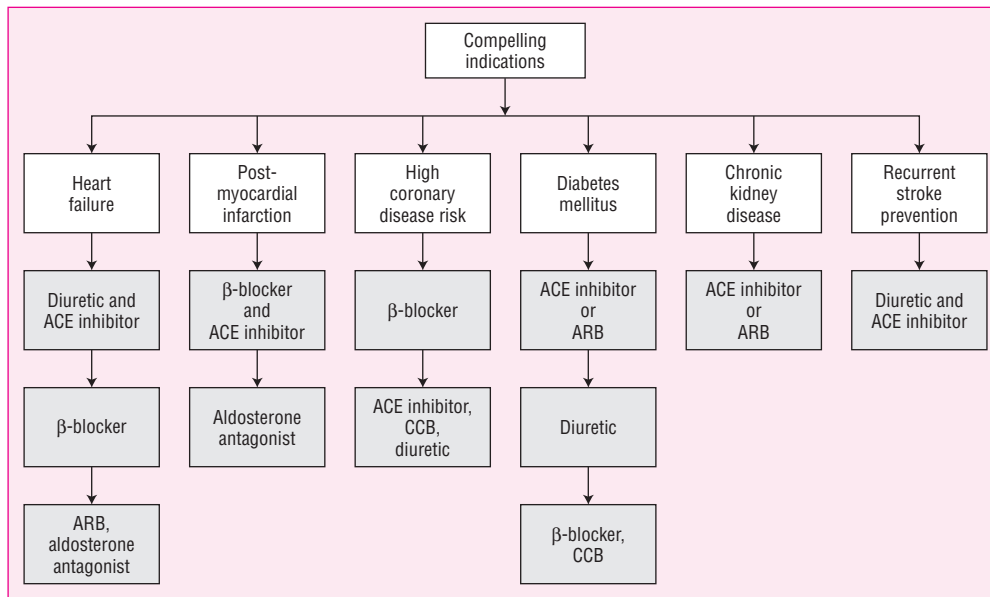

FIGURE 13-3. Compelling indications for individual drug classes. Compelling indications for specific drugs are evidenced-based recommendations from outcome studies or existing clinical guidelines. The order of drug therapies serves only as a general guidance that should be balanced with clinical judgment and patient response. Blood pressure control should be managed concurrently with the compelling indication. (Adapted from the JNC7.¹)

3. Weight loss, even as little as 10 pounds, can decrease BP significantly in hypertensive overweight individuals.³⁷
4. Abdominal obesity is associated with the metabolic syndrome, which is a precursor to hypertension and insulin-resistance syndrome that may progress to type 2 diabetes, dyslipidemia, and ultimately, cardiovascular disease.¹⁸
5. Diets rich in fruits and vegetables and low in saturated fat have been shown to lower BP in hypertensive individuals.^{38,39}
6. Although some hypertensive patients are not salt-sensitive, most people experience some degree of SBP reduction with sodium restriction.^{40,41}

The DASH eating plan is a diet that is rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated and total fat. It is advocated by the JNC7 as a reasonable and feasible

diet that is known to lower BP. The recommended restriction is less than 2.4 g (100 mEq) sodium per day. Patients should be aware of the multiple sources of dietary sodium (e.g., processed meats, soups, and table salt) so that they may follow this restriction. Excessive alcohol use can either cause or worsen hypertension. Hypertensive patients who drink alcoholic beverages should restrict their daily intake (see Table 13-4). Patients should be counseled about how much 80-proof whiskey, wine, and beer servings correlate with a drink equivalent.

Carefully designed programs of physical activity can lower BP. Regular aerobic exercise for at least 30 minutes a day most days of the week is ideal for most patients. Studies have shown that aerobic exercise, such as jogging, swimming, walking, and bicycling, can reduce BP. These benefits can occur even in the absence of weight loss. Patients should consult their physicians before starting an exercise program, especially those with target-organ disease.

Cigarette smoking is a major independent, modifiable risk factor for cardiovascular disease. Hypertensive patients who smoke should be thoroughly counseled regarding the additional risks that smoking

TABLE 13-4. Lifestyle Modifications to Prevent and Manage Hypertension

| Modification | Recommendation | Approximate Systolic Blood Pressure Reduction (mm Hg) ^a |
|------------------------------|---|--|
| Weight reduction | Maintain normal body weight (body mass index, 18.5–24.9 kg/m ²) | 5–20 per 10-kg weight loss |
| Adopt DASH eating plan | Consume a diet rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated and total fat | 8–14 |
| Dietary sodium restriction | Reduce daily dietary sodium intake to less than or equal to 100 mEq (2.4 g sodium or 6 g sodium chloride) | 2–8 |
| Physical activity | Regular aerobic physical activity (at least 30 minutes/day, most days of the week) | 4–9 |
| Moderate alcohol consumption | Limit consumption to less than or equal to 2 drinks/day (1 oz or 30 mL ethanol [e.g., 24 oz beer, 10 oz wine, 3 oz 80-proof whiskey] in most men and less than or equal to 1 drink/day in women and lighter-weight persons) | 2–4 |

^a Effects of implementing these modifications are time- and dose-dependent and could be greater for some patients.

incurs. Moreover, the potential benefits that cessation can provide should be explained to encourage quitting. Several smoking-cessation programs, pharmacotherapy options, and aids are available to assist patients.

■ PHARMACOLOGIC THERAPY

There are nine different antihypertensive drug classes. Diuretics, β -blockers, ACE inhibitors, angiotensin II receptor blockers, and calcium channel blockers are considered primary antihypertensive agents (Table 13–5). These agents, either alone or in combination, should be used to treat the majority of hypertensive patients because evidence from outcomes data have demonstrated benefits with these classes. Several of these classes (i.e., diuretics, β -blockers, and calcium channel blockers) have subclasses where significant differences in mechanism of action, clinical use, or side effects or evidence from outcomes studies exist. α -Blockers, central α_2 -agonists, adrenergic inhibitors, and vasodilators are considered alternative drug classes that may be used in select patients after primary agents (Table 13–6).

Evidence-based medicine is a conscientious, explicit, and judicious use of current best evidence to make decisions about the care of individual patients.⁴² Evidence-based practice in hypertension involves selecting specific agents based on outcomes data demonstrating a reduction in hypertension-associated target-organ damage or cardiovascular morbidity and mortality. Scientific evidence demonstrating simply BP lowering, tolerability, or costs never should be the sole justification for selecting drug therapy. When considering these factors, the most useful agents are diuretics, ACE inhibitors, angiotensin II receptor blockers, β -blockers, and calcium channel blockers. The JNC7 drug therapy recommendations are discussed throughout this section and are founded based on evidence-based medicine principles.

■ FIRST-LINE TREATMENT FOR MOST PATIENTS

6 JNC7 guidelines recommend thiazide-type diuretics whenever possible as first-line therapy for most patients.¹ Figure 13–2 displays the algorithm for the treatment of hypertension. This recommendation is specifically for those without compelling indications and is based on the best available evidence demonstrating reductions in morbidity and mortality. However, diuretics are also useful agents in hypertensive patients with compelling indications, but they are not always the first agent recommended based on the compelling indication present.

Three landmark placebo-controlled clinical trials have established the benefits of both hypertension treatment and diuretic therapy. The Systolic Hypertension in the Elderly Program (SHEP),¹² the Swedish Trial in Old Patients with Hypertension (STOP-Hypertension),¹³ and the Medical Research Council (MRC) trial¹⁴ showed significant reductions in stroke, myocardial infarction, and all-cause cardiovascular disease and mortality with thiazide diuretic-based therapy versus placebo. These trials allowed for β -blockers as add-on therapy for BP control. Newer agents (i.e., ACE inhibitors, angiotensin II receptor blockers [ARBs], and calcium channel blockers [CCBs]) were not available at the time of these studies. However, subsequent clinical trials have compared these newer antihypertensive agents (ACE inhibitors, ARBs, and CCBs) to diuretics.^{43–48} These data show similar effects, but most trials used a prospective, open-label, blinded end point (PROBE) study methodology that is

not double-blinded and limited their ability to prove equivalence of newer drugs to diuretics.

■ The ALLHAT Study⁴⁶

The results of the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) was the deciding evidence that the JNC7 used to justify thiazide diuretics as first-line therapy.⁴⁶ It was designed to test the hypothesis that newer antihypertensive agents (an α -blocker, ACE inhibitor, and dihydropyridine CCB) would be superior to thiazide diuretic therapy. The primary objective was to compare the combined end point of fatal coronary heart disease and nonfatal myocardial infarction. Other hypertension-related complications (e.g., heart failure and stroke) were evaluated as secondary end points. This was the largest hypertension trial ever conducted and included 42,418 patients aged 55 years and older with hypertension and one additional cardiovascular risk factor. This prospective, double-blind trial randomized patients to chlorthalidone (a thiazide diuretic), amlodipine (dihydropyridine CCB), doxazosin (α -blocker), or lisinopril (ACE inhibitor) for a mean follow-up of 4.9 years.

The doxazosin arm was terminated early when a significantly higher risk of heart failure compared with chlorthalidone was observed.⁴⁹ The other arms were continued as scheduled, and no significant differences in the primary end point were seen between chlorthalidone and either lisinopril or amlodipine. However, chlorthalidone had statistically fewer secondary end points than amlodipine (heart failure) and lisinopril (combined cardiovascular disease, heart failure, and stroke). The study conclusions were that chlorthalidone was superior in preventing one or more major forms of cardiovascular disease and was less expensive than amlodipine and lisinopril.

The ALLHAT was double-blinded and provided the most scientific rigor when compared with other comparative trials that were open label. While the JNC7 recommendations follow the ALLHAT results, the 2003 European Society of Hypertension/European Society of Cardiology guidelines for the management of arterial hypertension do not support thiazide diuretics over other primary antihypertensive classes.⁵⁰ These guidelines are founded on the principle that target-organ disease and cardiovascular risk reduction are functions of BP control that are largely independent of specific drug(s).⁵⁰ These guidelines criticize the ALLHAT, stating limitations such as lower BP values (1 to 4 mm Hg) with chlorthalidone versus other agents, especially in African-Americans; β -blockers, clonidine, and reserpine as unrealistic add-on therapies; and an overreliance on the end point of heart failure that was not systematically evaluated throughout the study.

ALLHAT was designed as a superiority study with the hypothesis that amlodipine, doxazosin, and lisinopril would be better than chlorthalidone.⁵¹ It did not prove this hypothesis because the primary end point was not different among chlorthalidone, amlodipine, and lisinopril. Therefore, thiazides remain unsurpassed in their ability to reduce hypertension-related morbidity and mortality. A meta-analysis in 2003 supports this statement. In this analysis of 42 clinical trials representing 192,478 patients, low-dose diuretics were found to be the most effective first-line agent for preventing cardiovascular mortality.⁵² The preponderance of evidence supports the JNC7 recommendation of using a thiazide-type diuretic in most patients unless there are contraindications or a compelling indication for another agent is present. Since most patients require two or more agents to control BP, a thiazide diuretic should be one of these agents unless contraindicated.

TABLE 13–5. Primary Antihypertensive Agents

| Class | Subclass | Drug (Brand Name) | Usual Dose Range, mg/day | Daily Frequency | Comments |
|--|--------------------------------|--|--------------------------|-----------------|---|
| Diuretics | Thiazides | Chlorthalidone (Hygroton) | 6.25–25 | 1 | Dose in the morning to avoid nocturnal diuresis; thiazides are more effective antihypertensives than loop diuretics except in patients with severely decreased glomerular filtration rate (Estimated creatinine clearance < 30 mL/min); use usual doses to avoid adverse metabolic effects; hydrochlorothiazide and chlorthalidone are generally preferred, with 25 mg/day generally considered the maximum effective dose; chlorthalidone is nearly twice as potent as hydrochlorothiazide; have additional benefits in osteoporosis; may require additional monitoring in patients with a history of gout or hyponatremia |
| | | Hydrochlorothiazide (Esidrix, HydroDiuril, Microzide, Oretic) | 12.5–50 | 1 | |
| | | Indapamide (Lozol) | 1.25–2.5 | 1 | |
| | | Metolazone (Mykrox) | 0.5 | 1 | |
| | | Metolazone (Zaroxolyn) | 2.5 | 1 | |
| | Loops | Bumetanide (Bumex) | 0.5–4 | 2 | |
| | | Furosemide (Lasix) | 20–80 | 2 | |
| | | Torsemide (Demadex) | 5 | 1 | |
| | Potassium sparing | Amiloride (Midamor) | 5–10 | 1 or 2 | |
| | | Amiloride/hydrochlorothiazide (Moduretic) | 5–10/50–100 | 1 | |
| | | Triamterene (Dyrenium) | 50–100 | 1 or 2 | |
| | | Triamterene/hydrochlorothiazide (Dyazide) | 37.5–75/25–50 | 1 | |
| | Aldosterone Antagonists | Eplerenone (Inspra) | 50–100 | 1 or 2 | |
| | | Spironolactone (Aldactone) | 25–50 | 1 or 2 | |
| | | Spironolactone/hydrochlorothiazide (Aldactazide) | 25–50/25–50 | 1 | |
| Angiotensin-converting enzyme inhibitors | Benazepril (Lotensin) | 10–40 | 1 or 2 | | |
| | Captopril (Capoten) | 12.5–150 | 2 or 3 | | |
| | Enalapril (Vasotec) | 5–40 | 1 or 2 | | |
| | Fosinopril (Monopril) | 10–40 | 1 | | |
| | Lisinopril (Prinivil, Zestril) | 10–40 | 1 | | |
| | Moexipril (Univasc) | 7.5–30 | 1 or 2 | | |
| | Perindopril (Aceon) | 4–16 | 1 | | |
| | Quinapril (Accupril) | 10–80 | 1 or 2 | | |
| | Ramipril (Altace) | 2.5–10 | 1 or 2 | | |
| | Trandolapril (Mavik) | 1–4 | 1 | | |
| Angiotensin II receptor blockers | Candesartan (Atacand) | 8–32 | 1 or 2 | | |
| | Eprosartan (Teveten) | 600–800 | 1 or 2 | | |
| | Irbesartan (Avapro) | 150–300 | 1 | | |
| | Losartan (Cozaar) | 50–100 | 1 or 2 | | |
| | Olmesartan (Benicar) | 20–40 | 1 | | |
| | Telmisartan (Micardis) | 20–80 | 1 | | |
| | Valsartan (Diovan) | 80–320 | 1 | | |
| β -Blockers | Cardioselective | Atenolol (Tenormin) | 25–100 | 1 | |
| | | Betaxolol (Kerlone) | 5–20 | 1 | |
| | | Bisoprolol (Zebeta) | 2.5–10 | 1 | |
| | | Metoprolol (Lopressor) | 50–200 | 2 | |
| | | Metoprolol extended release (Toprol XL) | 50–200 | 1 | |
| | | Abrupt discontinuation may cause rebound hypertension; inhibit β_1 receptors at low to moderate dose, higher doses also stimulate β_2 receptors; may exacerbate asthma when selectivity is lost; have additional benefits in patients with atrial tachyarrhythmia or preoperative hypertension | | | |

TABLE 13–5. (Continued)

| Class | Subclass | Drug (Brand Name) | Usual Dose Range, mg/day | Daily Frequency | Comments | |
|--|---|--|--------------------------|------------------------|---|--|
| Calcium channel blockers | Nonselective | Nadolol (Corgard) | 40–120 | 1 | Abrupt discontinuation may cause rebound hypertension; inhibit β_1 and β_2 receptors at all doses; can exacerbate asthma; have additional benefits in patients with essential tremor, migraine headache, thyrotoxicosis | |
| | | Propranolol (Inderal) | 160–480 | 2 | | |
| | | Propranolol long-acting (Inderal LA, InnoPran XL) | 80–320 | 1 | | |
| | | Timolol (Blocadren) | 10–40 | 1 | | |
| | Intrinsic sympathomimetic activity | Acebutolol (Sectral) | 200–800 | 2 | | |
| | | Carteolol (Cartrol) | 2.5–10 | 1 | | |
| | | Penbutolol (Levitol) | 10–40 | 1 | | |
| | | Pindolol (Visken) | 10–60 | 2 | | |
| | Mixed α - and β -blockers | Carvedilol (Coreg) | 12.5–50 | 2 | | |
| | | Labetolol (Normodyne, Trandate) | 200–800 | 2 | | |
| | Dihydropyridines | Amlodipine (Norvasc) | 2.5–10 | 1 | | Short-acting dihydropyridines should be avoided, especially immediate-release nifedipine and nicardipine; dihydropyridines are more potent peripheral vasodilators than nondihydropyridines and may cause more reflex sympathetic discharge (tachycardia), dizziness, headache, flushing, and peripheral edema; have additional benefits in Raynaud's syndrome |
| | | Felodipine (Plendil) | 5–20 | 1 | | |
| | | Isradipine (DynaCirc) | 5–10 | 2 | | |
| Isradipine SR (DynaCirc SR) | | 5–20 | 1 | | | |
| Nicardipine sustained release (Cardene SR) | | 60–120 | 2 | | | |
| Nifedipine long-acting (Adalat CC, Procardia XL) | | 30–90 | 1 | | | |
| Nisoldipine (Sular) | | 10–40 | 1 | | | |
| Non-Dihydropyridines | | Diltiazem sustained-release (Cardizem SR) | 180–360 | 2 | | |
| | | Diltiazem sustained-release (Cardizem CD, Cartia XT, Dilacor XR, Diltia XT, Tiazac, Taztia XT) | 120–480 | 1 | | |
| | | Diltiazem extended-release (Cardizem LA) | 120–540 | 1 (morning or evening) | | |
| | Verapamil sustained-release (Calan SR, Isoptin SR, Verelan) | 180–480 | 1 or 2 | | | |
| | Verapamil controlled-onset extended-release (Covera HS) | 180–420 | 1 (in the evening) | | | |
| Verapamil chronotherapeutic oral drug absorption system (Verelan PM) | 100–400 | 1 (in the evening) | | | | |

COMPPELLING INDICATIONS

The JNC7 report identifies six compelling indications. *Compelling indications* represent specific comorbid conditions where evidence from clinical trials supports using specific antihy-

pertensive classes to treat both the compelling indication and hypertension. Drug therapy recommendations for compelling indications are either in combination with or in place of a thiazide diuretic (see Fig. 13–3). Data from these clinical trials have demonstrated reduction in morbidity and/or mortality that justify use in hypertensive

TABLE 13–6. Alternative Antihypertensive Agents

| Class | Drug (Brand Name) | Usual Dose Range, mg/day | Daily Frequency | Comments |
|----------------------------------|--------------------------------|--------------------------|-----------------|---|
| α_1 -Blockers | Doxazosin (Cardura) | 1–8 | 1 | First dose should be given at bedtime; counsel patients to rise from sitting or laying down slowly to minimize risk of orthostatic hypotension; have additional benefits in men with benign prostatic hyperplasia |
| | Prazosin (Minipress) | 2–20 | 2 or 3 | |
| | Terazosin (Hytrin) | 1–20 | 1 or 2 | |
| Central α_2 -agonists | Clonidine (Catapres) | 0.1–0.8 | 2 | Abrupt discontinuation may cause rebound hypertension; most effective if used with a diuretic to diminish fluid retention; clonidine patch is replaced once per week |
| | Clonidine patch (Catapres-TTS) | 0.1–0.3 | 1 weekly | |
| | Methyldopa (Aldomet) | 250–1000 | 2 | |
| Peripheral adrenergic antagonist | Reserpine (generic only) | 0.05–0.25 | | A very useful agent that has been used in many of the major clinical trials; should be used with a diuretic to diminish fluid retention |
| Direct arterial vasodilators | Minoxidil (Loniten) | 10–40 | 1 or 2 | Should be used with diuretic and β -blocker to diminish fluid retention and reflex tachycardia |
| | Hydralazine (Apresoline) | 20–100 | 2 to 4 | |

patients with such a compelling indication. Some compelling indications have recommendations provided by other national treatment guidelines that are complimentary to the JNC7 guidelines.

■ Heart Failure⁵³

Five drug classes are listed as compelling indications for heart failure. These recommendations specifically refer to systolic heart failure, where the primary physiologic abnormality is decreased cardiac contractility. ACE inhibitors are recommended as the first drugs of choice based on numerous outcome studies showing reduced morbidity and mortality.⁵³ Diuretics are also a part of first-line therapy because they provide symptomatic relief of edema by inducing diuresis. Loop diuretics often are needed, especially in patients with more advanced systolic heart failure. Evidence from clinical trials has shown that ACE inhibitors significantly modify disease progression by reducing morbidity and mortality. Although systolic heart failure was the primary disease in these studies, ACE inhibitor therapy also will control BP in patients with heart failure and hypertension. ACE inhibitors should be started with low doses in patients with heart failure, especially those in acute exacerbation. Heart failure induces a compensatory high-renin condition, and starting ACE inhibitors under this circumstance can cause a pronounced first-dose effect and possible orthostatic hypotension.

β -Blocker therapy is appropriate to further modify disease in systolic heart failure. In patients on a standard regimen of a diuretic and ACE inhibitor, β -blockers have been shown to reduce morbidity and mortality.^{54,55} It is of paramount importance that β -blockers be dosed appropriately because of the risk of inducing an acute exacerbation of heart failure. They must be started in very low doses, doses much lower than those used to treat hypertension, and titrated slowly to high doses based on tolerability.

After diuretics, ACE inhibitors and β -blockers (collectively considered standard therapy), other agents may be added to further reduce cardiovascular morbidity and mortality and reduce BP if needed. Early data suggested that ARBs may be better than ACE inhibitors in systolic heart failure.⁵⁶ However, when directly compared in a well-designed prospective trial, ACE inhibitors were found to be better.⁵⁷ ARBs are acceptable as an alternative therapy for patients who cannot tolerate ACE inhibitors and possibly as add-on therapy to those already on a standard three-drug regimen.^{58,59}

The addition of aldosterone antagonists can reduce morbidity and mortality in systolic heart failure.^{60,61} Spironolactone has been studied in severe heart failure and has shown benefit in addition to diuretic and ACE inhibitor therapy.⁶⁰ Eplerenone, the newest aldosterone antagonist, has been studied in patients with symptomatic systolic heart failure within 3 to 14 days after an acute myocardial infarction in addition to a standard three-drug regimen.⁶¹ Collectively, both these agents should be considered in the specific heart failure population studied but only in addition to diuretics, ACE/ARBs, and β -blockers.

■ Post Myocardial Infarction⁶²

Hypertension is a strong risk factor for myocardial infarction. Once a patient experiences a myocardial infarction, controlling BP is essential for secondary prevention to reduce the risk of recurrent cardiovascular events. β -Blocker therapy (agents without intrinsic sympathomimetic activity [ISA]) and ACE inhibitor therapy are recommended in the American College of Cardiology/American Heart Association post-myocardial infarction guidelines.⁶² β -Blockers decrease cardiac adrenergic stimulation and have been shown in clinical trials to reduce the risk of a subsequent myocardial infarction or sudden cardiac death.^{63,64} ACE inhibitors have been shown to improve cardiac remodeling and cardiac function and to reduce cardiovascular events after myocardial infarction.^{65,66} These two drug classes, with β -blockers first, are considered the first drugs of choice for patients who have experienced a myocardial infarction.

Eplerenone has been shown recently to reduce morbidity and mortality in patients soon after experiencing an acute myocardial infarction (within 3 to 14 days).⁶¹ However, this supporting evidence was in patients with symptoms of acute left ventricular dysfunction (systolic heart failure). Considering that this drug has a propensity to cause significant hyperkalemia, and given the patient population studied, eplerenone should be used only in selected patients following a myocardial infarction.

■ High Coronary Disease Risk^{62,67}

Chronic stable angina, unstable angina, and myocardial infarction are all forms of coronary disease (also known as coronary artery disease or ischemic heart disease). These are the most common forms of hypertension-associated target-organ disease. β -Blocker therapy

has the most evidence demonstrating benefits in these patients. β -Blockers are first-line therapy in chronic stable angina and have the ability to reduce BP, improve myocardial oxygen consumption, and decrease demand.¹

Long-acting CCBs traditionally have been viewed as alternatives to β -blockers in chronic stable angina. The INVEST study has compared β -blocker with diuretic therapy with nondihydropyridine CCB with ACE inhibitor therapy in this population and has shown no difference in cardiovascular risk reduction.⁶⁸ Nonetheless, the preponderance of data are with β -blockers, and they remain therapy of choice.^{1,62}

For acute coronary syndromes (non-ST-segment elevation myocardial infarction and unstable angina), first-line therapy should consist of a β -blocker and an ACE inhibitor.⁶² This regimen will lower BP, control acute ischemia, and reduce cardiovascular risk. Diuretics can be added thereafter if the goal BP is not achieved with first-line therapy.

CCBs (especially the nondihydropyridines diltiazem and verapamil) and β -blockers lower BP and reduce myocardial oxygen demand in patients with hypertension and high coronary disease risk. However, cardiac stimulation may occur with dihydropyridine CCBs or β -blockers with intrinsic sympathomimetic activity, making these agents less desirable. Therefore, β -blockers with intrinsic sympathomimetic activity should be avoided, and CCBs (especially dihydropyridines) should be reserved as second- or third-line therapy.

There has been concern that overtreating high BP in patients with coronary artery disease may bring about more harm than good (termed the *J-curve phenomenon*). Since coronary blood flow occurs during diastole, the rate of flow is directly influenced by the DBP. Therefore, excessively reducing DBP may compromise coronary perfusion, especially in patients with fixed coronary artery stenosis, and lead to myocardial infarction. This concern has been theoretical based on retrospective analyses, and prospective studies have not found a J-curve until DBPs were very low (<60 mm Hg). However, this controversy has resurfaced because a post-hoc subgroup analysis of the INVEST study has shown a J-curve in patients with DBP less than 84 mm Hg.

■ Diabetes Mellitus^{1,29,30,69-72}

The primary cause of mortality in diabetes is cardiovascular disease, and hypertension management is a very important risk-reduction strategy. The BP goal in diabetes is less than 130/80 mm Hg, and five antihypertensive agents have evidence supporting their compelling indications in diabetes (see Fig. 13-3). All these agents have been shown to reduce cardiovascular events in patients with diabetes. However, risk reduction may not be equal when comparing these agents.

8 All patients with diabetes and hypertension should be treated with an antihypertensive regimen that includes either an ACE inhibitor or an ARB.⁷⁰ Pharmacologically, both these agents should provide nephroprotection owing to vasodilation in the efferent arteriole of the kidney. Moreover, ACE inhibitors have overwhelming data demonstrating cardiovascular risk reduction in patients with established forms of heart disease. Evidence from outcome studies has demonstrated reductions in both cardiovascular risk (mostly with ACE inhibitors) and the risk of progressive kidney dysfunction (mostly with ARBs) in patients with diabetes. There is controversy surrounding which agent is better because data support both drug classes. Nonetheless, either drug class should be used to control BP as one of the drugs in the antihypertensive regimen for patients with diabetes because multiple agents often are needed to attain goal BP values, and a thiazide diuretic is recommended as the second agent.

Some evidence indicates that ACE inhibitors and ARBs may increase insulin sensitivity. A few case reports have associated hypoglycemia with ACE inhibitor use in patients with diabetes taking oral hypoglycemic agents. While such effects could be problematic in some patients, the fact that ACE inhibitors improve insulin sensitivity is of limited clinical significance in diabetes.

β -Blockers have been shown to reduce cardiovascular risk in patients with diabetes, and these agents should be used when needed. β -Blockers have been shown in at least one study to be as effective as ACE inhibitors in protection against morbidity and mortality in patients with diabetes.⁷¹ They are especially indicated in patients with diabetes who have suffered a myocardial infarction or have high coronary disease risk. However, β -blockers (especially nonselective agents) may mask the signs and symptoms of hypoglycemia in patients with tightly controlled diabetes because most of the symptoms of hypoglycemia (i.e., tremor, tachycardia, and palpitations) are mediated through the sympathetic nervous system. Sweating, a cholinergically mediated symptom of hypoglycemia, still should occur during a hypoglycemic episode despite β -blocker therapy. Patients also may have a delay in hypoglycemia recovery time because compensatory recovery mechanisms need the catecholamine input that is antagonized by β -blocker therapy. Finally, unopposed α -receptor stimulation during the acute hypoglycemic recovery phase (owing to endogenous epinephrine release intended to reverse hypoglycemia) may result in acutely elevated BP from vasoconstriction. Despite these potential problems, β -blockers are highly beneficial in diabetes after ACE inhibitors/ARBs and diuretics.

CCBs are useful add-on agents for BP control in hypertensive patients with diabetes. Several studies have compared an ACE inhibitor with either a dihydropyridine CCB or a β -blocker. In the studies comparing a dihydropyridine with an ACE inhibitor, the ACE inhibitor group had significantly lower rates of cardiovascular end points, including myocardial infarctions and all cardiovascular events.⁷³ These data do not suggest that CCBs are harmful in diabetic patients but indicate that they are not as protective as ACE inhibitors. While data are limited, nondihydropyridine CCBs (diltiazem and verapamil) appear to provide more kidney protection than the dihydropyridines.³⁰

Based on the weight of all evidence, ACE inhibitors/ARBs are preferred first-line agents for controlling hypertension in diabetes. The need for combination therapy should be anticipated, and thiazide diuretics should be the second agent added in most patients to lower BP. Based on scientific evidence, β -blockers and CCBs are useful evidenced-based agents in this population but are considered add-on therapies to the aforementioned agents.

■ Chronic Kidney Disease^{30,74}

Patients with hypertension may develop damage to either the renal tissue (parenchyma) or the renal arteries. Chronic kidney disease presents initially as microalbuminuria (30–299 mg albumin in a 24-hour urine collection) that can progress to macroalbuminuria and overt kidney failure.⁷⁵ The rate of kidney function deterioration is accelerated when both hypertension and diabetes are present.^{30,75} Once patients have an estimated glomerular filtration rate (GFR) of less than 60 mL/m² per minute or macroalbuminuria, they have chronic kidney disease, and the risk of cardiovascular disease and progression to severe chronic kidney disease increases.¹ Strict BP control to a goal of less than 130/80 mm Hg can slow the decline in kidney function. This strict control often requires two or more antihypertensive agents.

In addition to lowering BP, ACE inhibitors and ARBs reduce intraglomerular pressure, which can provide additional benefits in

further reducing the decline in renal function. ACE inhibitors and ARBs have been shown to reduce progression of chronic kidney disease in patients with diabetes^{76–80} and in those without diabetes.^{30,81} One of these two agents should be used as first-line therapy to control blood pressure and preserve kidney function in patients with chronic kidney disease. Some data indicate that the combination of an ACE inhibitor and an ARB may be more effective than either agent alone.⁸² However, routine use of this combination in all patients with chronic kidney disease is controversial. Since these patients typically require multiple antihypertensive agents, diuretics and a third antihypertensive drug class (β -blocker or CCB) often are needed. Thiazide diuretics can be used but may not be as effective as loop diuretics when creatinine clearances are below 30 mL/min.

Patients may experience a rapid and profound drop in BP or acute kidney failure when given an ACE inhibitor or ARB. The potential to produce acute kidney failure is particularly problematic in patients with bilateral renal artery stenosis or a solitary functioning kidney with stenosis. Patients with renal artery stenosis are usually older, and the condition is more common in patients with diabetes or those who smoke. Patients with renal artery stenosis do not necessarily have evidence of renal disease unless sophisticated tests are performed. Starting with low dosages and evaluating renal function shortly after starting the drug (in 2 to 4 weeks) can minimize this risk.

■ Recurrent Stroke Prevention

Attaining goal BP values in patients who have experienced a stroke is considered a primary modality to reduce the risk of a second stroke. However, BP lowering should be attempted only after patients have stabilized following an acute cerebrovascular event. One clinical trial, the PROGRESS trial, showed that an ACE inhibitor in combination with a thiazide diuretic reduces the incidence of recurrent stroke in patients with a history of stroke or transient ischemic attacks.⁴⁷ Reduction in recurrent stroke was seen with this combination therapy, even in those with BP values less than 140/90 mm Hg. These data are consistent with other evidence demonstrating reduced cardiovascular risk with ACE inhibitor therapy in high-risk patients at goal BP values.^{66,83}

■ ALTERNATIVE DRUG TREATMENTS

It is necessary to use other agents such as α -blockers, central α_2 -agonists, adrenergic inhibitors, and vasodilators in some patients. Although these agents are potent, they have a much greater incidence of adverse effects. Moreover, they do not have compelling outcomes data showing reduced morbidity and mortality in hypertension. They generally are reserved for patients with resistant hypertension and ideally should be used only in combination with other primary antihypertensive agents, especially diuretics.

■ SPECIAL POPULATIONS¹

Selection of drug therapy should follow the guidelines provided by the JNC7, which are summarized in Figs. 13–2 and 13–3. These should be maintained as the guiding principles of drug therapy. However, there are some patient populations where the approach to drug therapy may be slightly different or use recommended agents with tailored dosing strategies. In some cases this is so because other agents have unique properties that benefit a coexisting condition but may not be based on evidence from outcomes studies in hypertension.

■ Hypertension in Older People

Hypertension often presents as isolated systolic hypertension in the elderly. Epidemiologic data indicate that cardiovascular morbidity and mortality are more closely related to SBP than to DBP in patients aged 50 years and older, so this population is at high risk for hypertension-related target-organ damage.^{1,16} Although several placebo-controlled trials have specifically demonstrated risk reduction in this form of hypertension, many older people with hypertension are either not treated or treated yet not controlled.³³

The SHEP was a landmark double-blind, placebo-controlled trial that evaluated active treatment (chlorthalidone-based, with atenolol or reserpine as add-on therapy) for isolated systolic hypertension.¹² A 36% reduction in total stroke, a 27% reduction in coronary artery disease, and 55% reduction in heart failure were demonstrated versus placebo. The Systolic Hypertension–Europe (Syst-Eur) was another placebo-controlled trial that evaluated treatment with a long-acting dihydropyridine CCB.¹⁵ Treatment resulted in a 42% reduction in stroke, 26% reduction in coronary artery disease, and 29% reduction in heart failure. Similar findings were observed in a Chinese population with isolated systolic hypertension.⁸⁴ These data clearly demonstrate reductions in cardiovascular morbidity and mortality in older patients with isolated systolic hypertension, especially with thiazide diuretics and long-acting dihydropyridine CCBs.

The very elderly population, those 80 years of age and older, has been underrepresented in clinical trials, including the SHEP and Syst-Eur studies. This population often is not treated to goal either because of a fear of lowering BP too much or because of limited data demonstrating benefit. The best available data in the very elderly come from meta-analyses.^{85,86} Although these data do not show reductions in mortality, they consistently show fewer strokes with active antihypertensive treatment.

Thiazide diuretics or β -blockers have been compared with either ACE inhibitors or CCBs in elderly patients with either systolic or diastolic hypertension or both.⁸⁷ In a Swedish trial, no significant differences were seen between conventional drugs and either ACE inhibitors or CCBs. However, there were significantly fewer myocardial infarctions and cases of heart failure in the ACE inhibitor group compared with the CCB group. These data suggest that overall treatment may be more important than specific antihypertensive agents in this population.

Elderly patients are more sensitive to volume depletion and sympathetic inhibition than younger individuals. This may lead to orthostatic hypotension (see next section). In the elderly, this can increase the risk of falls because of the associated dizziness and risk of fainting. Antihypertensives such as the centrally acting agents and α -blockers should be used with caution in the elderly because they are frequently associated with dizziness and postural hypotension. Diuretics and ACE inhibitors provide significant benefits and can be used safely in the elderly, but smaller-than-usual initial doses must be used. Most authorities agree that a thiazide should be the initial antihypertensive agent in most elderly patients, especially in those with isolated systolic hypertension, and that the starting dose should be low (e.g., 12.5 mg hydrochlorothiazide).

The JNC7 goal BP recommendations are independent of age; in the elderly, they are less than 140/90 mm Hg or less than 130/80 mm Hg (for diabetes or chronic kidney disease).¹ Age-adjusted goals are not appropriate.¹⁶ Moreover, the JNC7 recommends that treatment follow the same principles that are outlined for general care of hypertension (e.g., diuretics for most and specific drug therapies to treat compelling indications). However, initial drug doses may be lower and dosage titrations should occur over a longer period of time

to minimize the risk of hypotension. An interim goal of an SBP of below 160 mm Hg may be necessary for those with a very high initial SBP, but the ultimate goal should still be an SBP of less than 140 mm Hg.

Patients at Risk for Orthostatic Hypotension

g *Orthostatic hypotension* is a significant drop in BP when standing and can be associated with dizziness and/or fainting. It is defined as an SBP decrease of greater than 20 mm Hg or a DBP decrease of greater than 10 mm Hg when changing from supine to standing.¹ Older patients (especially those with isolated systolic hypotension) and patients with diabetes, severe volume depletion, baroreflex dysfunction, autonomic insufficiency, and those using venodilators (α -blockers, mixed α/β -blockers, nitrates, and phosphodiesterase inhibitors for erectile dysfunction) all are at increase risk of orthostatic hypotension. In patients with these risks, antihypertensive agents should be started in low doses, especially diuretics and ACE inhibitors.

Hypertension in Children and Adolescents⁸⁸

Detecting hypertension in children requires special attention to BP measurement, and detection is based on age-determined percentiles for excessive BP.⁸⁸ Hypertensive children often have a family history of high BP, and many are overweight. Unlike hypertension in adults, secondary hypertension is much more common in children and adolescents. An appropriate work-up for secondary causes is essential if elevated BP is identified. Kidney disease (e.g., pyelonephritis, glomerulonephritis, renal artery stenosis, and renal cysts) is the most common cause of secondary hypertension in children. Pheochromocytoma and coarctation of the aorta also can produce secondary hypertension. Medical or surgical management of the underlying disorder usually normalizes BP.

Treatment recommendations are provided in the 1996 National High Blood Pressure Education Program Working Group on Hypertension Control in Children and Adolescents.⁸⁸ Nonpharmacologic treatment is the cornerstone of therapy for essential hypertension. The goal is to reduce the BP to below the 95th percentile for age. Diuretics, β -blockers, and ACE inhibitors are very effective. ACE inhibitors and ARBs are contraindicated in sexually active girls owing to potential teratogenic effect and in those who might have bilateral renal artery stenosis or unilateral stenosis in a solitary kidney. Long-acting dihydropyridine CCBs have been successfully used in children, but long-term safety is unknown.

Women

Younger women generally have a lower prevalence of hypertension than younger men. However, after the fifth decade of life, prevalence rises sharply to the point that it actually exceeds men in the sixth decade.¹ Many women on oral contraceptives have a very small but detectable increase in BP. Women with a family history of hypertension, pregnancy-induced hypertension, obesity, age greater than 35 years, kidney disease, and extended duration of use have increased susceptibility to hypertension. It appears as though BP increases are related to the progestin, not the estrogen, component of oral contraceptives. BP increases in postmenopausal women treated with hormone-replacement therapy are modest and do not preclude use in

hypertensive women. Regardless, all women on oral contraceptives or hormone-replacement therapy should have their BP monitored at least every 6 months.¹

Women receive the same benefits from antihypertensive therapy as men. However, ACE inhibitors and ARBs are contraindicated in women who intend to become pregnant because they are teratogenic. Thiazide diuretics may be especially beneficial in postmenopausal women with osteoporosis because they cause retention of calcium and have been shown to positively affect bone mineral density. Women tend to have higher rates of drug-related adverse effects than men.

Pregnancy⁸⁹

The National High Blood Pressure Education Program Working Group Report on High Blood Pressure in Pregnancy was updated in 2000.⁸⁹ It is important to differentiate preeclampsia from chronic, transient, and gestational hypertension. Preeclampsia can lead rapidly to life-threatening complications for both mother and fetus and usually presents after 20 weeks' gestation in primigravid women. The diagnosis of preeclampsia is based on the appearance of hypertension (>140/90 mm Hg) after 20 weeks' gestation with proteinuria. Chronic hypertension presents before 20 weeks' gestation. It is controversial whether treating elevated BP in patients with chronic hypertension in pregnancy is beneficial. Women with chronic hypertension prior to pregnancy can develop preeclampsia.

Definitive treatment of preeclampsia is delivery. Delivery is clearly indicated if pending or frank eclampsia (preeclampsia plus convulsions) is present. Otherwise, management consists of restricting activity, bed rest, and close monitoring. Salt restriction or any other measures that contract blood volume should not be employed. Antihypertensive agents are used prior to induction of labor if the DBP is greater than 105 or 110 mm Hg, with a target DBP of 95 to 105 mm Hg. Intravenous hydralazine is used most commonly, and intravenous labetalol is also effective. Immediate-release oral nifedipine has been used, but it is not approved by the Food and Drug Administration (FDA) for hypertension, and untoward fetal and maternal effects (hypotension with fetal distress) have been reported.

Many agents can be used to treat chronic hypertension in pregnancy (Table 13–7). Methyldopa is considered the drug of choice.¹ Data indicate that uteroplacental blood flow and fetal hemodynamics are stable with methyldopa. Moreover, it is viewed as very safe based on long-term follow-up data (7.5 years) that have not demonstrated adverse effects on childhood development. β -Blockers, labetalol, and

TABLE 13–7. Treatment of Chronic Hypertension in Pregnancy

| Drug/Class | Comments |
|--|---|
| Methyldopa | Preferred agent based on long-term follow-up data supporting safety |
| β -Blockers | Generally safe, but intrauterine growth retardation reported |
| Labetolol | Increasingly preferred over methyldopa because of fewer side effects |
| Clonidine | Limited data available |
| Calcium channel blockers | Limited data available; no increase in major teratogenicity with exposure |
| Diuretics | Not first-line agents but probably safe in low doses |
| ACE inhibitors, angiotensin II receptor blockers | Contraindicated; major teratogenicity reported with exposure (fetal toxicity and death) |

CCBs are also reasonable alternatives. ACE inhibitors and ARBs are absolutely contraindicated. Although they are pregnancy category C in the first trimester, they are category D in the second and third trimesters owing to potential teratogenicity.

■ African-Americans^{1,3,90}

Hypertension affects African-American patients at a disproportionately higher rate, and hypertension-related target-organ damage is more prevalent than in other populations. The reasons for these differences are not fully understood. Differences in electrolyte homeostasis, GFR, sodium excretion and transport mechanisms, plasma renin activity, and BP response to plasma volume expansion may explain the higher prevalence but do not account for the increased severity. The African-American population has comparatively low plasma renin activity and increased BP response to sodium and fluid loading.

African-Americans have an increased need for combination therapy to attain and maintain BP goals.⁹⁰ The Hypertension in African American Working Group of the International Society on Hypertension in Blacks has published treatment guidelines that are similar to the JNC7.⁹⁰ Lifestyle modifications are recommended to augment drug therapy. The guidelines also support thiazide diuretics as first-line therapy for most patients and selecting specific drug therapy to treat compelling indications, if present. These guidelines aggressively promote combination therapy and recommend starting with two drugs in patients with SBP values greater than or equal to 15 mm Hg from goal. These recommendations are more stringent than the JNC7 cutoff of greater than or equal to 20 mm Hg. This more aggressive approach is reasonable considering that overall goal BP attainment rates are low in African-Americans.

BP-lowering effects of antihypertensive classes vary in African-Americans. Monotherapy with β -blockers, ACE inhibitors, or ARBs results in less BP lowering compared with Caucasian patients. This may be due to the low-renin pattern of hypertension. Even within these three drug classes, data suggest that β -blockers may have better effects on target-organ disease than ARBs.⁹¹ Conversely, thiazide diuretics and CCBs seem to be particularly effective at lowering BP in African-Americans. When either of these two classes (especially thiazides) is used in combination with a β -blocker, ACE inhibitor, or ARB, antihypertensive response is increased significantly. Interestingly, African-Americans have a higher risk of angioedema and cough from ACE inhibitors compared with Caucasians.⁹⁰

Despite differences in antihypertensive effects, drug therapy selection should be based on evidence, as outlined in the JNC7 guidelines. Thiazide diuretics are first-line therapy based on the preponderance of evidence. These agents just so happen to also be very effective at controlling BP in this population. Other drug therapies should be used if a compelling indication is present, even if antihypertensive effect may not be as great as with another drug class (i.e., a β -blocker is first-line therapy for BP control in an African-American patient who has suffered a myocardial infarction). Combination therapy is needed frequently in this population, and a thiazide diuretic ideally should be one of the agents used.

■ OTHER CONCOMITANT CONDITIONS

Most patients with hypertension have some other coexisting conditions that may influence selection or use of drug therapy. Under most circumstances, these are helpful in deciding on a particular antihypertensive agent when more than one agent is recommended to

treat a compelling indication(s). In some cases, an agent should be avoided because it may aggravate a concomitant disorder. In other cases, an antihypertensive agent can be used to treat hypertension, a compelling indication, and another concomitant condition. The influence of concomitant conditions only should be complementary to and never in replacement of drug therapy choices indicated by compelling indications.

■ Pulmonary Disease and Peripheral Arterial Disease

Nonselective β -blockers should be avoided in hypertensive patients with asthma, chronic obstructive pulmonary disease (COPD), and peripheral vascular disease. α/β -Blockers (carvedilol and labetalol) will not result in unopposed α constriction like pure β -blockers can and may be used in peripheral arterial disease. However, similar to nonselective β -blockers, they should be avoided in patients with asthma and COPD. If a hypertensive patient with mild to moderate asthma or COPD requires a β -blocker to treat a compelling indication, a β_1 -selective agent should be selected, and the lowest effective dose should be used.⁹²

■ Dyslipidemia

Dyslipidemia (high low-density lipoprotein [LDL] cholesterol, high triglycerides, and/or low high-density lipoprotein [HDL] cholesterol) is considered a major cardiovascular risk factor. Therefore, controlling dyslipidemia is important to the overall care of hypertensive patients. Thiazide diuretics and β -blockers without intrinsic sympathomimetic activity may adversely affect serum cholesterol values, but these effects generally are transient and of no clinical consequence.⁹³

α -Blockers, on the other hand, have been shown to have favorable effects (decreased LDL cholesterol and increased HDL cholesterol). However, because data from the ALLHAT show that α -blockers do not reduce cardiovascular risk as much as thiazide diuretics, this benefit is not clinically applicable.⁴⁹ ACE inhibitors and CCBs have no effect on serum cholesterol.

■ Left Ventricular Hypertrophy

Left ventricular hypertrophy (LVH) is an independent risk factor for cardiovascular disease and is considered a form of target-organ damage. LVH is present in about 50% of hypertensive patients. Most classes of antihypertensive agents, except vasodilators, prevent or regress LVH. Attaining goal BP values also should improve LVH. ACE inhibitors and ARBs are considered the most effective agents for regressing LVH, but data suggest that long-term diuretic use leads to the most regression. While prevention or regression of LVH is an important objective in the overall management of hypertension, it is merely a surrogate marker of reducing cardiovascular risk. Drug selections should not be made based on the potential to improve LVH at this time.

The Losartan Intervention For Endpoint (LIFE) trial was a prospective study that compared losartan versus atenolol in patients with LVH and hypertension.⁴⁵ Losartan was more effective than atenolol in reducing the combined end point of stroke, myocardial infarction, and death. When patients with diabetes from the LIFE trial were evaluated in a subanalysis, there was a significant reduction in both cardiovascular morbidity and mortality with losartan versus atenolol.⁹⁴ Despite this evidence, LVH is not considered a compelling indication for ARBs in the JNC7.

■ Erectile Dysfunction⁹⁵

Most antihypertensive agents have been associated with erectile dysfunction in men. Diuretics and β -blockers traditionally have been labeled as more problematic than ACE inhibitors, ARBs, and CCBs. However, prospective long-term data from the Treatment of Mild Hypertension Study (TOMHS) and the VA Cooperative trial show no difference in the incidence of erectile dysfunction between diuretics and β -blockers versus ACE inhibitors and CCBs.^{96,97} Nonetheless, if a β -blocker is necessary to treat a compelling indication, a cardioselective agent should be used. Centrally acting agents (e.g., clonidine, methyldopa, and guanethidine) are associated with higher rates of sexual dysfunction and should be avoided in men with erectile dysfunction.

Hypertensive men frequently have arterial dysfunction, which can result in erectile dysfunction. Therefore, erectile dysfunction may be associated mostly with chronic arterial changes resulting from elevated BP, and lack of control may increase the risk of erectile dysfunction. These changes are even more pronounced in hypertensive men with diabetes.

■ INDIVIDUAL ANTIHYPERTENSIVE AGENTS^{1,7}

■ Diuretics^{12-14,46,52,98}

Diuretics, preferably a thiazide, are first-line agents for most patients with hypertension.¹ The best available evidence justifying this recommendation is from ALLHAT.⁴⁶ Moreover, when combination therapy is needed in hypertension to control BP, a diuretic is recommended as one of the agents used.¹ Four subclasses of diuretics are used in the treatment of hypertension: thiazides, loops, potassium-sparing agents, and aldosterone antagonists (see Table 13-5). Potassium-sparing diuretics are weak antihypertensive agents when used alone but provide an additive effect when used in combination with a thiazide or loop diuretic. Moreover, they counteract the potassium- and magnesium-losing properties of the other diuretic agents. Aldosterone antagonists (spironolactone) technically may be considered potassium-sparing agents but are more potent antihypertensives with a slow onset of activity (up to 6 weeks with spironolactone). However, they are viewed by the JNC7 as an independent class because of evidence supporting compelling indications.

The exact hypotensive mechanism of action of diuretics is not known but has been well hypothesized. The drop in BP seen when diuretics are first started is caused by an initial diuresis. Diuresis causes reductions in plasma and stroke volume, which decreases cardiac output and BP. This initial drop in cardiac output causes a compensatory increase in peripheral vascular resistance. With chronic diuretic therapy, extracellular fluid and plasma volume return to near pretreatment values. However, peripheral vascular resistance decreases to values that are lower than the pretreatment baseline. This reduction in peripheral vascular resistance is responsible for chronic antihypertensive effects.

Thiazide diuretics have additional actions that may further explain their antihypertensive effects. Thiazides mobilize sodium and water from arteriolar walls. This effect would lessen the amount of physical encroachment on the lumen of the vessel created by excessive accumulation of intracellular fluid. As the diameter of the lumen relaxes and increases, there is less resistance to the flow of blood, and peripheral vascular resistance drops further. High dietary sodium intake can blunt this effect, and a low salt intake can enhance this effect. Thiazides also are postulated to cause direct relaxation of

vascular smooth muscle. This theory is based on the known mechanism of action of diazoxide, which is a direct vasodilator that is structurally related to thiazide diuretics.

Thiazides are the preferred type of diuretic for treating hypertension. In patients with adequate kidney function (estimated GFR > 30 mL/min), thiazides are the most effective diuretics for lowering BP. As kidney function declines, a more potent diuretic is needed to counteract the associated increase in sodium and water retention. In this case, a loop diuretic (e.g., furosemide dosed twice daily) should be considered. Diuretics ideally should be dosed in the morning if given once daily and in the morning and afternoon if dosed twice daily to minimize the risk of nocturnal diuresis. However, with chronic use, thiazides, potassium-sparing diuretics, and aldosterone antagonists rarely cause a pronounced diuresis.

The major pharmacokinetic differences between the various thiazides are serum half-life and duration of diuretic effect. The clinical relevance of these differences is unknown because the serum half-life of most antihypertensive agents does not correlate with the hypotensive duration of action. Moreover, diuretics may lower BP primarily through extrarenal mechanisms. Hydrochlorothiazide and chlorthalidone are the two most frequently used thiazide diuretics in landmark clinical trials that have demonstrated reduced morbidity and mortality. It was once thought that these agents were equipotent on a milligram-per-milligram basis. However, chlorthalidone appears to be 1.5 to 2.0 times more potent than hydrochlorothiazide.⁹⁹ This has been attributed to a longer half-life (45–60 hours versus 8–15 hours) and longer duration of effect (48–72 hours versus 16–24 hours) with chlorthalidone. When looking at both agents, a dose of 25 mg daily results in a mean decrease in SBP of 18 and 12 mm Hg for chlorthalidone and hydrochlorothiazide, respectively. Again, since a difference in outcomes has not been demonstrated in outcomes trials, the significance of these differences is unknown, and it is well accepted that either of these agents is reasonable to use.

Diuretics are very effective in lowering BP when used in combination with most other antihypertensive agents. This additive response is explained by two independent pharmacodynamic effects. First, when two drugs cause the same overall pharmacologic effect (BP lowering) through different mechanisms of action, their combination usually results in an additive or synergistic effect. This is especially relevant when a β -blocker or ACE inhibitor is indicated in an African-American but does not elicit sufficient antihypertensive effect. Adding a diuretic in this situation often can lower BP significantly. Second, a compensatory increase in sodium and water retention may be seen with antihypertensive agents. This problem is counteracted with the concurrent use of a diuretic.

The side effects of thiazide diuretics include hypokalemia, hypomagnesemia, hypercalcemia, hyperuricemia, hyperglycemia, hyperlipidemia, and sexual dysfunction. Loop diuretics may cause the same side effects, although the effect on serum lipids and glucose is not as significant, and hypocalcemia may occur. Short-term studies indicate that indapamide does not adversely affect lipids or glucose tolerance or cause sexual dysfunction. These side effects are all dose-related. Many of these side effects were identified when high doses of thiazides were used in the past (e.g., hydrochlorothiazide 100 mg/day). Current guidelines suggest limiting the dose of hydrochlorothiazide or chlorthalidone to 12.5–25 mg/day, which markedly reduces the risk for most metabolic side effects.

Hypokalemia and hypomagnesemia may cause muscle fatigue or cramps. However, serious cardiac arrhythmias can occur in patients with significant degrees of hypokalemia and hypomagnesemia. Patients at greatest risk are those with LVH, high coronary disease risk, previous myocardial infarction, a history of arrhythmia, or

concurrently receiving digoxin. Low-dose thiazide diuretic therapy (i.e., 25 mg hydrochlorothiazide or 12.5 mg chlorthalidone daily) rarely causes significant electrolyte disturbances. Every effort should be made to keep potassium in the therapeutic range by careful monitoring because severe hypokalemia also may negate the beneficial effects of the diuretic (reducing cardiovascular events).

Diuretic-induced hyperuricemia can precipitate gout, either acute gouty arthritis or uric acid nephrolithiasis. This side effect may be especially problematic in patients with a previous history of gout. However, attacks are unlikely in patients with no previous history of gout. If gout does occur in a patient who requires diuretic therapy, allopurinol can be given to prevent gout and will not compromise the antihypertensive effects of the diuretic. High doses of thiazide and loop diuretics may increase fasting glucose and serum cholesterol values. These effects, however, usually are transient and often inconsequential.¹⁰⁰ Low-dose diuretic therapy is much less likely to produce these metabolic abnormalities.

Potassium-sparing diuretics can cause hyperkalemia, especially in patients with chronic kidney disease or diabetes and in patients receiving concurrent treatment with an ACE inhibitor, ARB, nonsteroidal anti-inflammatory drugs, or potassium supplements. Hyperkalemia is especially problematic for the newest aldosterone antagonist eplerenone. Since this agent is a very selective aldosterone antagonist, its propensity to cause hyperkalemia is believed to be greater than the other potassium-sparing agents and even spironolactone (the other aldosterone antagonist). Because of an increased risk of hyperkalemia, eplerenone is contraindicated in patients with impaired renal function or type 2 diabetes with proteinuria (see Table 13–5). While spironolactone may cause gynecomastia in up to 10% of patients, this occurs rarely with eplerenone.

Diuretics can be used safely with most other agents. However, concurrent administration with lithium may result in increased lithium serum concentrations. This interaction can predispose patients to lithium toxicity.

■ Angiotensin-Converting Enzyme Inhibitors^{43,48,69,87,101}

ACE inhibitors are considered second-line therapy to diuretics in most patients with hypertension.¹ The ALLHAT demonstrated less heart failure and stroke with chlorthalidone versus lisinopril.⁴⁶ This difference in stroke is consistent with another outcomes trial, the Captopril Prevention Project (CAPPP).¹⁰¹ However, other outcome studies have demonstrated similar, if not better, outcomes with ACE inhibitors versus thiazide diuretics.^{43,48} In the elderly, one study found that they were at least as effective when compared with diuretics and β -blockers,⁸⁷ and another study found that they were more effective.⁴⁸ In addition, ACE inhibitors have many roles for patients with hypertension and coexisting conditions. Nonetheless, most clinicians will agree that if ACE inhibitors are not first-line therapy in most patients with hypertension, they are a very close second to diuretics.

ACE facilitates the production of angiotensin II, which has a major role in the regulation of arterial BP, as depicted in Fig. 13–1. ACE is distributed in many tissues and is present in several different cell types, but its principal location is in endothelial cells. Therefore, the major site for angiotensin II production is in the blood vessels, not the kidney. ACE inhibitors block the conversion of angiotensin I to angiotensin II. This latter substance is a potent vasoconstrictor that also stimulates aldosterone secretion. ACE inhibitors also block the degradation of bradykinin and stimulate the synthesis of other vasodilating substances, including prostaglandin E₂ and prostacyclin. The observation that ACE inhibitors lower BP in patients with normal plasma renin

activity suggests that bradykinin and perhaps tissue production of ACE are important in hypertension. Increased bradykinin enhances the BP-lowering effects of ACE inhibitors but also is responsible for the side effect of dry cough. ACE inhibitors effectively prevent or regress LVH by reducing the direct stimulation by angiotensin II on myocardial cells.

The JNC7 lists six compelling indications for ACE inhibitors, indicating many evidence-based uses for this drug class (see Fig. 13–3). Several studies have shown that ACE inhibitors may be more effective at reducing cardiovascular risk than other antihypertensives. In type 2 diabetes, two studies showed that ACE inhibitors were superior to CCBs.^{69,70} However, one of the U.K. Prospective Diabetes Study Group (UKPDS) trials found captopril equivalent to atenolol in preventing cardiovascular events in patients with type 2 diabetes.⁷¹ ACE inhibitors reduce cardiovascular morbidity and mortality in patients with heart failure⁵³ and decrease progression of chronic kidney disease.³⁰ They should be first-line disease-modifying therapy in all these patients unless absolutely contraindicated.⁵³ In addition to β -blocker therapy, evidence shows that ACE inhibitors further reduce cardiovascular risk in chronic stable angina (the EUROPA trial)⁸³ and in patients after myocardial infarction (the HOPE trial).^{62,66} Finally, data from the PROGRESS trial have shown reduced risk of secondary stroke with the combination of an ACE inhibitor and thiazide diuretic.⁴⁷

There are 10 ACE inhibitors on the U.S. market (see Table 13–5). All can be dosed once daily for hypertension except captopril, which has a shorter half-life than the others. It is usually dosed two or three times daily. In addition to captopril, enalapril and lisinopril are the most frequently used ACE inhibitors. Enalapril is a prodrug that is converted to the active metabolite enalaprilat, which has a longer half-life than the parent drug, extends the duration of action, and usually allows for once-daily dosing. In some patients, especially when higher doses are used, twice-daily dosing is needed to maintain 24-hour effects. Lisinopril has an even longer duration of action and does not require metabolic conversion to exert its effect. All three are excreted in the urine, and therefore, an adjustment in dosage may be necessary in patients with severe chronic kidney disease. The absorption of captopril, but not enalapril or lisinopril, is reduced by 30% to 40% when given with food. Benazepril, captopril, fosinopril, moexipril, quinapril, ramipril, and trandolapril can provide 24-hour BP reduction with once daily dosing. Similar to enalapril, benazepril, moexipril, quinapril, and ramipril may need twice daily dosing in some patients.

ACE inhibitors are well tolerated in most patients but are not absent of side effects. ACE inhibitors decrease aldosterone and can increase potassium serum concentrations. Usually the increase in potassium is small, but hyperkalemia is possible. It is seen primarily in patients with chronic kidney disease or diabetes mellitus and in those on concomitant ARBs, nonsteroidal anti-inflammatory drugs, potassium supplements, or potassium-sparing diuretics. Judicious monitoring of potassium and serum creatinine values within 4 weeks of starting or increasing the dose of an ACE inhibitor often can identify these abnormalities before they evolve into more serious complications.

The most worrisome adverse effects of ACE inhibitors are neutropenia and agranulocytosis, proteinuria, glomerulonephritis, and acute kidney failure. Fortunately, these serious adverse effects are rare, occurring in less than 1% of patients. Preexisting kidney or connective tissue diseases increase the risk of these side effects. Bilateral renal artery stenosis or unilateral stenosis of a solitary functioning kidney renders patients dependent on the vasoconstrictive effect of angiotensin II on the efferent arteriole of the kidney, thus explaining

why these patients are particularly susceptible to acute kidney failure from ACE inhibitors. Slowly titrating the dose of ACE inhibitor and judicious kidney function monitoring can minimize risk and allow for early detection of those with renal artery stenosis.

It is important to note that GFR does decrease in patients placed on ACE inhibitors or ARBs.³⁰ This is attributed to the inhibition of angiotensin II vasoconstriction on the efferent arteriole. This decrease in GFR often increases serum creatinine concentration, and small increases should be anticipated when monitoring patients on ACE inhibitors. Modest elevations of either up to a 35% (for baseline creatinine values of less than or equal to 3 mg/dL) or absolute increases of less than 1 mg/dL do not warrant changes.³⁰ If larger increases occur, ACE inhibitor therapy should be stopped or the dose reduced.

Angioedema is a serious potential complication of ACE inhibitor therapy. Although it occurs in less than 2% of the population, it is more likely in African-Americans and smokers. Symptoms include lip and tongue swelling and possibly difficulty breathing. Drug withdrawal is appropriate for all patients with angioedema, but laryngeal edema and pulmonary symptoms occur occasionally and also require epinephrine, corticosteroids, antihistamines, and/or emergent intubation to support respiration. A history of angioedema, even if not from an ACE inhibitor, precludes use of another ACE inhibitor. Cross-reactivity between ACE inhibitors and ARBs has been reported, but the exact incidence of cross-reactivity is unknown. Therefore, it is controversial whether patients with ACE inhibitor–induced angioedema should be given an ARB.

A persistent dry cough develops in up to 20% of patients and is explained pharmacologically by the inhibition of bradykinin breakdown. This cough does not cause clinical illness but is annoying to patients. It should be clearly differentiated from a wet cough associated with pulmonary edema, which may be a sign of uncontrolled heart failure. Cromolyn and sulindac have been used to treat the cough, but these options are not recommended. If an ACE inhibitor is indicated for the compelling indications of heart failure, diabetes, or chronic kidney disease, then patients with a dry cough should be switched to an ARB. Otherwise, other antihypertensive alternatives, including ARBs, should be considered.

ACE inhibitors are absolutely contraindicated in pregnancy (see “Pregnancy” section under “Special Populations”) and in patients with a history of angioedema. Similar to diuretics, ACE inhibitors can increase lithium serum concentrations in patients on lithium therapy. Concurrent use of an ACE inhibitor with a potassium-sparing diuretic (including aldosterone antagonists), potassium supplements, or an ARB may result in excessive increases in potassium.

Starting doses of ACE inhibitors should be low, with even lower doses started in patients at risk for orthostatic hypotension. Acute hypotension may occur at the onset on ACE inhibitor therapy. Patients who are sodium- or volume-depleted, in heart failure exacerbation, very elderly, or on concurrent vasodilators or diuretics are at high risk for this effect (see the “Hypertension in Older People” and “Patients at Risk for Orthostatic Hypotension” sections under “Special Populations”). It is important to start with half the normal dose of an ACE inhibitor for all patients with these risk factors and to use slow dose titration. The risk of serious adverse reactions overall can be decreased approximately 50% by using a 6-week time interval between dose increases versus a 2-week interval.¹⁰²

■ Angiotensin II Receptor Blockers^{45,56–59,78–80,103–106}

Angiotensin II is generated by two enzymatic pathways: the RAAS, which involves ACE, and an alternative pathway that uses other

enzymes such as chymases. ACE inhibitors inhibit only the effects of angiotensin II produced through the RAAS, whereas ARBs inhibit angiotensin II from all pathways. It is unclear how these differences affect tissue concentrations of ACE. Because of these differences, ACE inhibitors only partially block the effects of angiotensin II. ARBs directly block the angiotensin II type 1 (AT₁) receptor that mediates the known effects of angiotensin II in humans: vasoconstriction, aldosterone release, sympathetic activation, antidiuretic hormone release, and constriction of the efferent arterioles of the glomerulus. They do not block the angiotensin II type 2 (AT₂) receptor. Therefore, beneficial effects of AT₂ receptor stimulation (i.e., vasodilation, tissue repair, and inhibition of cell growth) remain intact when ARBs are used. Unlike ACE inhibitors, ARBs do not block the breakdown of bradykinin. Therefore, some of the beneficial effects of bradykinin such as vasodilation (which can enhance BP lowering), regression of myocyte hypertrophy and fibrosis, and increased levels of tissue plasminogen activator are not present with ARB therapy.

ARBs have outcomes data showing long-term reductions in progression of target-organ damage in patients with hypertension and certain compelling indications. In patients with type 2 diabetes and nephropathy, progression of nephropathy has been shown to be reduced significantly with ARB therapy.^{78–80} Some benefits appear to be independent of BP lowering, suggesting that the unique benefits of ARBs are explained pharmacologically by effects on the efferent arteriole. For patients with systolic heart failure, the CHARM studies showed that ARB therapy reduces the risk of cardiovascular events when added to a stable regimen of a diuretic, ACE inhibitor, and β -blocker or as alternative therapy in ACE inhibitor–intolerant patients.^{58,59} However, the ELITE studies also have shown that losartan is not superior to captopril in systolic heart failure when compared head to head.^{56,57} This finding is consistent with other data in post-myocardial infarction patients (the OPTIMAAL study).¹⁰⁵

Seven ARBs are marketed for the treatment of hypertension. Data from pooled analyses and direct comparisons have demonstrated that all these drugs are effective in lowering BP. They have a fairly flat dose-response curve, suggesting that increasing the dose above low or moderate levels is unlikely to result in a large degree of BP lowering. The addition of low doses of a thiazide diuretic to an ARB significantly increases antihypertensive efficacy. Similar to ACE inhibitors, most ARBs have long enough half-lives to allow for once daily dosing. However, candesartan, eprosartan, and losartan have the shortest half-lives and may require twice daily dosing for sustained BP lowering.

ARBs seem to have the lowest incidence of side effects compared with other antihypertensive agents. Since they do not affect bradykinin, they do not have an associated dry cough like ACE inhibitors. While these drugs often have been considered to be “ACE inhibitors without the cough,” pharmacologic differences highlight that they could have very different effects on vascular smooth muscle and myocardial tissue that can correlate with different effects on target-organ damage and cardiovascular risk reduction when compared with ACE inhibitors. It is possible that their effects may be superior to ACE inhibitors in patients with type 2 diabetic nephropathy but may be inferior to ACE inhibitors in patients with more advanced heart disease (e.g., heart failure and after myocardial infarction). Unfortunately, there are no direct comparisons that look at long-term effects in patients with just hypertension. Regardless, their role in patients with type 2 diabetic nephropathy is well established, and they also are very reasonable alternatives in patients requiring an ACE inhibitor but who experience an intolerable cough. Using the combination of an ACE inhibitor with an ARB has not been well studied in hypertension despite demonstrated benefits of this combination in patients with heart failure and nephrotic syndrome.

Like ACE inhibitors, ARBs may cause kidney insufficiency, hyperkalemia, and orthostatic hypotension. The same precautions that apply to ACE inhibitors for patients with suspected bilateral renal artery stenosis, those on drugs that can raise the potassium level, and those on drugs that increase the risk of hypotension apply to ARBs. Cough is very uncommon. Angioedema is also less likely to occur than with ACE inhibitors, but cross-reactivity has been reported. ARBs should be used cautiously in patients with a history of angioedema but, unlike ACE inhibitors, are not contraindicated. ARBs should not be used in pregnancy.

■ **β -Blockers**^{43,44,46,53,62,67,71}

β -Blockers have been used in several large outcome trials in hypertension. They were recommended previously as first-line agents along with diuretics in most patients. However, in most of these trials, diuretics were the primary agents, and β -blockers were added on for additional BP lowering. Therefore, they are now considered appropriate first-line agents when there are compelling indications (after myocardial infarction or high coronary disease risk) and are evidenced-based as additional therapy for other compelling indications (heart failure and diabetes). Numerous trials have shown reduced cardiovascular risk when β -blockers are used following a myocardial infarction, during acute coronary syndrome, or in chronic stable angina. Although once considered contraindicated in heart failure, multiple studies have shown that carvedilol and metoprolol succinate reduce mortality in patients with systolic heart failure who are treated with a diuretic and an ACE inhibitor. Atenolol was even used in type 2 diabetes in the UKPDS studies and showed comparable, if not better, cardiovascular risk reduction when compared with captopril.

Several mechanisms of action have been proposed for β -adrenoceptor blockers (β -blockers), but none of them alone has been shown to be associated consistently with a reduction in arterial BP. β -Blockers have negative chronotropic and inotropic cardiac effects that reduce cardiac output, which explains some of the antihypertensive effect. However, cardiac output falls equally in patients treated with β -blockers regardless of BP lowering. Additionally, β -blockers with intrinsic sympathomimetic activity (ISA) do not reduce cardiac output, yet they lower BP and decrease peripheral resistance.

β -Adrenoceptors are also located on the surface membranes of juxtaglomerular cells, and β -blockers inhibit the release of renin. However, there is a weak association between plasma renin concentrations and antihypertensive efficacy of β -blocker therapy. Some patients with low plasma renin concentrations do respond to β -blockers. Therefore, additional mechanisms also must account for the antihypertensive effect of β -blockers. However, the ability of β -blockers to reduce plasma renin and thus angiotensin II concentrations may play a major role in their ability to reduce cardiovascular risk.

There are important pharmacodynamic and pharmacokinetic differences among the various β -blockers, but all agents provide a similar degree of BP lowering. There are three pharmacodynamic properties of the β -blockers that differentiate this class: cardioselectivity, ISA, and membrane-stabilizing effects. β -Blockers that possess a greater affinity for β_1 -receptors than β_2 -receptors are *cardioselective*.

Both β_1 - and β_2 -adrenoceptors are distributed throughout the body, but they concentrate differently in certain organs and tissues. There is a preponderance of β_1 -receptors in the heart and kidney and a preponderance of β_2 -receptors in the lungs, liver, pancreas, and arteriolar smooth muscle. β_1 -Receptor stimulation increases heart rate, contractility, and renin release. β_2 -Receptor stimulation results in bronchodilation and vasodilation. Cardioselective β -blockers are

less likely to provoke bronchospasm and vasoconstriction. Also, both insulin secretion and glycogenolysis are adrenergically mediated by β_2 -receptors. Blocking β_2 -receptors may reduce these processes and cause hyperglycemia or blunt recovery from hypoglycemia.

Atenolol, betaxolol, bisoprolol, and metoprolol are cardioselective β -blockers. Therefore, they are safer than nonselective β -blockers in patients with asthma, COPD, peripheral arterial disease, and diabetes who have a compelling indication for a β -blocker. However, cardioselectivity is a dose-dependent phenomenon. At higher doses, cardioselective agents lose their relative selectivity for β_1 -receptors and block β_2 -receptors as effectively as they block β_1 -receptors. The dose at which cardioselectivity is lost varies from patient to patient. In general, cardioselective β -blockers are preferred when using a β -blocker to treat hypertension.

Some β -blockers have *intrinsic sympathomimetic activity (ISA)*. Acebutolol, carteolol, penbutolol, and pindolol are ISA β -blockers that act as partial β -receptor agonists. When they bind to the β -receptor, they stimulate it, but far less than a pure β -agonist. If sympathetic tone is low, as it is during resting states, β -receptors are partially stimulated by ISA β -blockers. Therefore, resting heart rate, cardiac output, and peripheral blood flow are not reduced when these types of β -blockers are used. Theoretically, ISA agents would appear to have advantages over β -blockers in patients with heart failure, sinus bradycardia, or perhaps even peripheral arterial disease. Unfortunately, they do not appear to reduce cardiovascular events as well as other β -blockers. In fact, they may increase risk after myocardial infarction or in those with high coronary disease risk. Thus agents with ISA are rarely needed.

Finally, all β -blockers exert a *membrane-stabilizing action* on cardiac cells when large enough doses are given. This activity is important when antiarrhythmic properties of the β -blockers are needed.

Pharmacokinetic differences among β -blockers relate to first-pass metabolism, serum half-lives, degree of lipophilicity, and route of elimination. Propranolol and metoprolol undergo extensive first-pass metabolism, so the dose needed to attain β -blockade with either drug varies from patient to patient. Atenolol and nadolol have relatively long half-lives and are excreted renally. The dose of these agents may need to be reduced in patients with moderate to severe chronic kidney disease. Even though the half-lives of the other β -blockers are much shorter, once daily administration may be effective because serum half-life does not correlate well with the hypotensive duration of action.

β -Blockers also vary in terms of their lipophilic properties and thus central nervous system penetration. All β -blockers cross the blood-brain barrier, but lipophilic agents penetrate to a greater extent than hydrophilic agents. Propranolol is the most lipophilic drug, and atenolol is the least lipophilic. Therefore, much higher brain concentrations of propranolol compared with atenolol are seen after equivalent doses are given. This can result in more central nervous system side effects (e.g., dizziness and drowsiness) with lipophilic agents such as propranolol. However, the lipophilic properties can provide better effects for noncardiovascular conditions such as migraine headache prevention, essential tremor, and thyrotoxicosis. BP lowering is equal among β -blockers regardless of lipophilicity.

Most side effects of β -blockers are an extension of their ability to antagonize β -adrenoceptors. β -Blockade in the myocardium can be associated with bradycardia, atrioventricular conduction abnormalities (e.g., second- or third-degree heart block), and the development of acute heart failure. The decreases in heart rate actually may benefit certain patients with atrial arrhythmias (e.g., atrial fibrillation and atrial flutter) and hypertension by both providing rate control and lowering BP. β -Blockers usually only produce heart failure if

they are used in high initial doses in patients with preexisting left ventricular dysfunction (systolic heart failure) or if started in these patients during an acute heart failure exacerbation. Blockade of β_2 -receptors in the lung may cause acute exacerbations of bronchospasm in patients with asthma or COPD. Blocking β_2 -receptors in arteriolar smooth muscle may cause cold extremities and may aggravate intermittent claudication or Raynaud's phenomenon as a result of decreased peripheral blood flow. In addition, there is an increase of sympathetic tone during periods of hypoglycemia that may result in a significant increase in BP because of unopposed α -receptor-mediated vasoconstriction.

Abrupt cessation of β -blocker therapy can produce unstable angina, myocardial infarction, and even death in patients with high coronary disease risk. Abrupt cessation also may lead to rebound hypertension (a sudden increase in BP to the pretreatment values) or overshoot hypertension (increase in BP above pretreatment values). To avoid this, β -blockers always should be tapered gradually over 1 to 2 weeks before eventually discontinuing the drug. This acute withdrawal syndrome is believed to be secondary to progression of underlying coronary artery disease, hypersensitivity of β -adrenergic receptors because of upregulation, and increased physical activity after withdrawal of a drug that decreases myocardial oxygen requirements. In patients without coronary artery disease, abrupt discontinuation may present as sinus tachycardia, increased sweating, and generalized malaise, in addition to increased BP.

Like diuretics, β -blockers have been shown to increase serum cholesterol and glucose values, but these effects are transient and of little clinical significance. In patients with diabetes or dyslipidemia, the reduction in cardiovascular events was as great with β -blockers as with an ACE inhibitor in the UKPDS trial⁷¹ and far superior to placebo in the SHEP trial.¹² β -Blockers can increase serum triglycerides and decrease HDL cholesterol slightly. β -Blockers with α -blocking properties (carvedilol and labetalol) produce no changes in these lipid values. Moreover, ISA β -blockers do not adversely affect these values and may even increase HDL cholesterol. However, since these are of questionable clinical significance, cardioselective agents remain the β -blockers of choice for most patients.

■ Calcium Channel Blockers^{15,43,107,108}

CCBs are not first-line agents but are very effective antihypertensive agents, especially in African-American patients. They have compelling indications in high coronary disease risk and in diabetes. However, with these compelling indications, they are in addition to or in replacement of other antihypertensive drug classes. Some data indicated that dihydropyridines may not provide as much protection against cardiac events when compared with "conventional" therapy (diuretics and β -blockers) or ACE inhibitors in uncomplicated hypertension.⁴³ Since only heart failure was higher with amlodipine versus chlorthalidone in ALLHAT, differences between agents are small.⁴⁶ In patients with hypertension and diabetes, ACE inhibitors appear to be more cardioprotective than dihydropyridines.⁶⁹ Studies with the nondihydropyridine CCBs diltiazem and verapamil are limited, but the NORDIL study found diltiazem to be equivalent to diuretics and β -blockers in reducing cardiovascular events.⁴³ It is possible that these differences (beneficial with diltiazem and neutral with dihydropyridines) may relate to the sympathetic stimulation that can occur with dihydropyridines.

Dihydropyridine CCBs are very effective in older patients with isolated systolic hypertension. The Syst-Eur was a placebo-controlled

trial that demonstrated that a long-acting dihydropyridine CCB reduced the risk of cardiovascular events markedly in isolated systolic hypertension.¹⁵ In previous guidelines, isolated systolic hypertension was a compelling indication for a long-acting dihydropyridine CCB. The JNC7 does not list isolated systolic hypertension differently from any other form of hypertension, and diuretics remain first-line therapy. However, a long-acting dihydropyridine CCB may be considered as add-on therapy if a thiazide diuretic is not controlling BP in a patient with isolated systolic hypertension and no other compelling indications. This is especially relevant if the patient is older with SBP elevation.

Contraction of cardiac and smooth muscle cells requires an increase in free intracellular calcium concentrations from the extracellular fluid. When cardiac or vascular smooth muscle is stimulated, voltage-sensitive channels in the cell membrane are opened, allowing calcium to enter the cells. The influx of extracellular calcium into the cell releases stored calcium from the sarcoplasmic reticulum. As intracellular free calcium concentration increases, it binds to a protein, calmodulin, which then activates myosin kinase, enabling myosin to interact with actin to induce contraction. CCBs work by inhibiting influx of calcium across the cell membrane. There are two types of voltage-gated calcium channels: a high-voltage channel (L-type) and a low-voltage channel (T-type). Currently available CCBs only block the L-type channel, which leads to coronary and peripheral vasodilation.

There are two subclasses of calcium channel blockers, dihydropyridines and nondihydropyridines (see Table 13–5). They are pharmacologically very different from each other. They are all similar in their antihypertensive effectiveness, but they differ somewhat in other pharmacodynamic effects. Nondihydropyridines (verapamil and diltiazem) decrease heart rate and slow atrioventricular nodal conduction. Similar to β -blockers, these drugs also may treat supraventricular tachyarrhythmias. Verapamil produces a negative inotropic and chronotropic effect that is responsible for its propensity to precipitate or cause heart failure in high-risk patients. Diltiazem also has these effects but to a lesser extent than verapamil. All CCBs (except amlodipine) have negative inotropic effects. Dihydropyridines cause a baroreceptor-mediated reflex tachycardia because of their potent peripheral vasodilating effects, although this varies among agents within this subclass. Dihydropyridines do not alter conduction through the atrioventricular node and thus are not effective agents in supraventricular tachyarrhythmias.

Within the dihydropyridines, nifedipine rarely may cause an increase in the frequency, intensity, and duration of angina in association with acute hypotension. This effect is most likely due to a reflex sympathetic stimulation and likely is obviated by using sustained-release formulations of nifedipine. For this reason, all other dihydropyridines have an intrinsically long half-life or are provided in sustained-release formulations. Immediate-release nifedipine has been associated with an increased incidence of adverse cardiovascular effects, and it is not approved for treatment of hypertension. It should not be used to treat hypertension. Other side effects with dihydropyridines include dizziness, flushing, headache, gingival hyperplasia, peripheral edema, mood changes, and various gastrointestinal complaints. The side effects due to vasodilation such as dizziness, flushing, headache, and peripheral edema occur more frequently with all dihydropyridines than with the nondihydropyridines verapamil and diltiazem because they are less potent vasodilators.

Diltiazem and verapamil can cause cardiac conduction abnormalities such as bradycardia or atrioventricular block, but this occurs mostly with high doses. Heart failure has been reported in otherwise

healthy patients secondary to negative inotropic effects. These problems occur at increased frequency in those with preexisting abnormalities in the cardiac conduction system. Both drugs can cause anorexia, nausea, peripheral edema, and hypotension. Verapamil causes constipation in about 7% of patients. This side effect also occurs with diltiazem, but to a lesser extent.

Verapamil and, to a lesser extent, diltiazem can cause drug interactions because of their ability to inhibit the cytochrome P450 3A4 isoenzyme system. This inhibition can increase the serum concentrations of other drugs that are metabolized by this isoenzyme system. Agents such as cyclosporine, digoxin, lovastatin, simvastatin, tacrolimus, and theophylline are examples of these drugs. Verapamil and diltiazem should be given very cautiously with a β -blocker for treating hypertension because there is an increased risk of heart block with these combinations. If a CCB is needed in combination with a β -blocker, a dihydropyridine should be selected because it will not increase the risk of heart block. The hepatic metabolism of CCBs, especially nifedipine, may be inhibited by ingesting large quantities of grapefruit juice and can increase pharmacologic effects.

Many different formulations of verapamil and diltiazem are currently available (see Table 13–5). Although certain sustained-release verapamil and diltiazem products may contain the same active drug (i.e., Calan SR and Verelan; both contain verapamil), they are usually not AB rated by the FDA as interchangeable on a milligram-per-milligram basis because of different biopharmaceutical release mechanisms.

Two sustained-release verapamil products (Covera HS and Verelan PM) and one diltiazem product (Cardizem LA) are chronotherapeutically designed to target the circadian changes in BP rhythm. These agents are dosed primarily in the evening so that drug is released during the morning when BP first starts to increase. The rationale behind chronotherapy in hypertension is that blunting the early-morning BP surge may result in more reduction in cardiovascular events than conventional dosing of regular antihypertensive products in the morning. However, evidence from the CONVINCE trial showed that chronotherapeutic verapamil was similar to but not better than a thiazide diuretic/ β -blocker–based regimen with respect to cardiovascular events.⁴⁴

■ α_1 -Blockers⁴⁹

Prazosin, terazosin, and doxazosin are selective α_1 -receptor blockers. They work in the peripheral vasculature and inhibit the uptake of catecholamines in smooth muscle cells, resulting in vasodilation and BP lowering.

Doxazosin was one of the original treatment arms of the ALLHAT. However, it was stopped prematurely when statistically more secondary end points of stroke, heart failure, and cardiovascular events were seen with doxazosin compared with chlorthalidone.⁴⁹ There were no differences in the primary end point of fatal coronary heart disease and nonfatal myocardial infarction. These data suggest that thiazide diuretics are superior to doxazosin (and probably other α_1 -blockers) in preventing cardiovascular events in patients with hypertension. Therefore, α_1 -blockers are alternative agents that should be used in combination with one or more primary antihypertensive agent(s). α_1 -Blockers can provide symptomatic benefits in men with benign prostatic hypertrophy. These agents block postsynaptic α_1 -adrenergic receptors located on the prostate capsule, causing relaxation and decreased resistance to urinary outflow. However, they

should be used only in addition to other standard antihypertensive agents.

A potentially severe side effect of α_1 -blockers is a first-dose phenomenon that is characterized by transient dizziness or faintness, palpitations, and even syncope within 1 to 3 hours of the first dose. This adverse reaction also can occur after dose increases. These episodes are accompanied by orthostatic hypotension and can be obviated by taking the first dose and subsequent first increased doses at bedtime. Orthostatic hypotension and dizziness may persist with chronic administration. For these reasons, these agents should be used very cautiously in elderly patients. Even though antihypertensive effects are achieved through a peripheral α_1 -receptor antagonism, these agents cross the blood-brain barrier and may cause central nervous system side effects such as lassitude, vivid dreams, and depression. α_1 -Blockers also may cause priapism. Sodium and water retention can occur with higher doses and sometimes even with chronic administration of low doses. Therefore, these agents are most effective when given in combination with a diuretic to maintain the hypotensive efficacy and minimize potential edema.

■ Central α_2 -Agonists

Clonidine, guanabenz, guanfacine, and methyldopa lower BP primarily by stimulating α_2 -adrenergic receptors in the brain. This stimulation reduces sympathetic outflow from the vasomotor center in the brain and increases vagal tone. It is also believed that peripheral stimulation of presynaptic α_2 -receptors may further reduce sympathetic tone. Reduced sympathetic activity, together with enhanced parasympathetic activity, can decrease heart rate, cardiac output, total peripheral resistance, plasma renin activity, and baroreceptor reflexes. Although guanabenz and guanfacine are used rarely in clinical practice, clonidine is often used in resistant hypertension, and methyldopa is a first-line agent for hypertension in pregnancy.

Chronic use of centrally acting α -agonists results in sodium and water retention, which is most prominent with methyldopa. Low doses of clonidine (and guanfacine or guanabenz) can be used to treat hypertension without the addition of a diuretic. However, methyldopa should be given with a diuretic to avoid the blunting of antihypertensive effect that happens with prolonged use, except in pregnancy. Sedation and dry mouth are common side effects that typically improve with chronic use of low doses. As with other centrally acting antihypertensives, depression can occur. The incidence of orthostatic hypotension and dizziness is higher than with other antihypertensive agents, so they should be used very cautiously in the elderly. Lastly, clonidine has a relatively high incidence of anticholinergic side effects such as sedation, dry mouth, constipation, urinary retention, and blurred vision.

Abrupt cessation of central α_2 -agonists may lead to rebound hypertension or overshoot hypertension. This effect is thought to be secondary to a compensatory increase in norepinephrine release after abrupt discontinuation. Methyldopa can cause hepatitis or hemolytic anemia, although this is rare. Transient elevations in serum hepatic transaminases are seen occasionally with methyldopa therapy but are clinically irrelevant unless they are greater than three times the upper limit of normal. Methyldopa should be discontinued quickly if persistent increases in serum hepatic transaminases or alkaline phosphatase are detected because this may indicate the onset of a fulminant hepatitis, which is life-threatening. A Coombs'-positive hemolytic anemia occurs in less than 1% of patients receiving methyldopa, although 20% exhibit a positive direct Coombs' test without anemia. For these

reasons, methyldopa has limited use in the routine management of hypertension.

Transdermal clonidine may be associated with fewer side effects and thus better adherence than oral clonidine. This patch is applied to the skin and replaced once a week. It possesses the same BP-lowering effects as oral clonidine but avoids the high peak serum drug concentrations seen with oral dosing, which contribute to the high incidence of adverse effects. Hypertensive patients on clonidine should be taking other primary oral antihypertensive medications because clonidine is an alternative antihypertensive. Therefore, the potential advantage of improved adherence with a transdermal product is mostly hypothetical. Disadvantages of this system are cost, a 20% incidence of local skin rash or irritation, and delayed onset 2 to 3 days that requires an overlapping period of using the oral formulation if the transdermal product is replacing oral clonidine. A similar delay in offset of action is also seen when the patch is removed, so BP returns to pretreatment values over a 2- to 3-day period.

■ Reserpine

Reserpine lowers BP by depleting norepinephrine from sympathetic nerve endings and blocking transport of norepinephrine into its storage granules. Norepinephrine release into the synapse following nerve stimulation is reduced and results in reduced sympathetic tone, peripheral vascular resistance, and BP. Reserpine also depletes catecholamines from the brain and the myocardium, which may lead to sedation, depression, and decreased cardiac output.

Reserpine has a slow onset of action and long half-life that allows for once daily dosing. However, it may take 2 to 6 weeks before the maximal antihypertensive effect is seen. Reserpine can cause significant sodium and water retention. It should be given in combination with a diuretic (preferably a thiazide). Reserpine's strong inhibition of sympathetic activity results in increased parasympathetic activity. This effect explains why side effects such as nasal stuffiness, increased gastric acid secretion, diarrhea, and bradycardia can occur. Depression has been reported, which is a consequence of central nervous system depletion of catecholamines and serotonin. Depression may manifest as sadness, loss of appetite or self-confidence, gradual loss of energy, erectile dysfunction, or early-morning awakening. The initial reports of depression with reserpine were in the 1950s and are not consistent with current definitions of depression. Regardless, reserpine-induced depression is likely dose-related, and very high doses (above 1 mg daily) were used frequently in the 1950s. Depression is minimal when doses between 0.05 and 0.25 mg daily are used. With these low doses, the rate of depression is equal to that seen with β -blockers, diuretics, or placebo.¹²

Reserpine was used as a third-line agent in many of the landmark clinical trials that have documented its benefit in treating hypertension, including the VA Cooperative trials and, most important, the SHEP trial.¹² An analysis of the SHEP data found that reserpine was very well tolerated. The combination of a diuretic and reserpine is very effective at lowering BP, and this is a very inexpensive antihypertensive regimen.

■ Direct Arterial Vasodilators

The antihypertensive effects of hydralazine and minoxidil are caused by direct arteriolar smooth muscle relaxation. They exert little to

no venous vasodilation. By decreasing arterial BP, they also reduce impedance to myocardial contractility. Both agents cause potent reductions in perfusion pressure that activates the baroreceptor reflexes. Activation of baroreceptors results in a compensatory increase in sympathetic outflow, which leads to an increase in heart rate, cardiac output, and renin release. Consequently, tachyphylaxis can develop, resulting in a loss of hypotensive effect, with continued use. This compensatory baroreceptor response can be counteracted by concurrent use of a β -blocker.

All patients receiving these drugs long term for hypertension generally should receive both a diuretic and a β -blocker first. Direct arterial vasodilators can precipitate angina in patients with underlying coronary artery disease unless the baroreceptor reflex mechanism is completely blocked with a β -blocker. Clonidine can be used in patients who have contraindications to β -blockers. The side effect of sodium and water retention is significant with these drugs and can be minimized with diuretic therapy (preferably thiazides).

One side effect unique to hydralazine is a dose-dependent drug-induced lupus-like syndrome. Hydralazine is eliminated by hepatic *N*-acetyltransferase. This enzyme displays genetic polymorphism, and slow acetylators are especially prone to develop drug-induced lupus with hydralazine. This syndrome is more common in women and is reversible on discontinuation. Drug-induced lupus may be avoided by using less than 200 mg hydralazine daily. Other side effects of hydralazine include dermatitis, drug fever, peripheral neuropathy, hepatitis, and vascular headaches. For these reasons, hydralazine has limited usefulness in the treatment of hypertension. However, it is still used with isosorbide dinitrate in patients with heart failure (especially African-Americans) and is useful in patients with severe chronic kidney disease and kidney failure.

Minoxidil is a more potent vasodilator than hydralazine. Therefore, the compensatory increases in heart rate, cardiac output, renin release, and sodium retention are even more dramatic. Sodium and water retention can be so severe with minoxidil that heart failure can be precipitated. It is even more important to coadminister a β -blocker and a diuretic with minoxidil. A loop diuretic is often more effective than a thiazide diuretic in patients treated with minoxidil. A troublesome side effect of minoxidil is hypertrichosis. Increased hair growth occurs on the face, arms, back, and chest. This drug-induced hirsutism ceases with discontinuation of the drug. Other minoxidil side effects include pericardial effusion and a nonspecific T-wave change on the electrocardiogram. Minoxidil generally is reserved for very difficult to control hypertension and patients requiring hydralazine that experience drug-induced lupus.

■ Other Agents

Guanethidine and guanadrel are postganglionic sympathetic inhibitors. They deplete norepinephrine from postganglionic sympathetic nerve terminals and inhibit the release of norepinephrine in response to sympathetic nerve stimulation, thus resulting in reduced cardiac output and peripheral vascular resistance. Orthostatic hypotension is common because reflex-mediated vasoconstriction is blocked. Other common side effects include erectile dysfunction, diarrhea, and weight gain. Long-term norepinephrine depletion leads to postsynaptic receptor supersensitivity. Therefore, concomitant use of tricyclic antidepressants and sympathomimetics may provoke acute severe hypertensive episodes. Because of these complications, these drugs have little to no role in the current management of hypertension.

PHARMACOECONOMIC CONSIDERATIONS

The cost of effectively treating hypertension is substantial. However, these costs can be offset by savings that would be realized by reducing cardiovascular morbidity and mortality. Cost related to treating other forms of target-organ damage (e.g., myocardial infarction and end-stage kidney failure) can drive health care costs up substantially. The cost per life-year saved from treating hypertension has been estimated to be \$40,000 for younger adults and even less for older adults.¹⁰⁹ Treatments that cost less than \$50,000 per life-year saved generally are considered favorable by health economists.

Drug costs can account for over 70% of the total cost of hypertensive care. One model for calculating the cost-effectiveness of various initial monotherapies for mild to moderate hypertension found that the cost of life-year saved ranged from \$10,900 with a generic β -blocker to \$72,100 with a brand-name ACE inhibitor.¹⁰⁹

In a cost-minimization study that included the cost of drug acquisition, supplemental drugs, laboratory tests, clinic visits, and complications, the total costs of treating hypertension were \$895 for β -blockers, \$1043 for diuretics, \$1165 for α -agonists, \$1243 for ACE inhibitors, \$1288 for α -blockers, and \$1425 for CCBs.¹¹⁰ Another cost-minimization analysis found that 86 middle-aged or 29 elderly hypertensive patients would need to be treated to prevent one myocardial infarction, stroke, or death.¹¹¹ The excess cost of preventing one event with a CCB or ACE inhibitor instead of a diuretic or β -blocker was \$89,000 to \$341,000 for a middle-aged patient and \$30,000 to \$115,000 for an elderly patient. Depending on the agent chosen, the added cost would be \$200 to \$800 per year.

A comparative analysis in 133,624 hypertensive patients aged 65 and older from a state prescription drug assistance program demonstrated that 40% of patients were prescribed pharmacotherapy that was not necessarily recommended by the JNC7 guidelines.¹¹² If these 40% had drug therapy modifications made to follow evidence-based treatment, a reduction in costs of \$11.6 million would have been realized in the 2001 calendar year based on discounted prices. This was projected to increase to \$20.5 million using usual Medicaid pricing limits.

It therefore is crucial to identify ways to reduce the cost of care without increasing the morbidity and mortality associated with uncontrolled hypertension. Using evidence-based pharmacotherapy will save costs not only by using the most effective agents. Thiazide diuretics are recommended as first-line therapy in most patients and are very inexpensive. Just using thiazides, either as monotherapy or in combination, is appropriate under almost all circumstances and aspects of hypertension management. When needed, using other generic primary antihypertensive agents (e.g., atenolol or metoprolol for β -blockers and lisinopril or enalapril for ACE inhibitors) that can be administered once daily should be considered.

CLINICAL CONTROVERSIES

Hydrochlorothiazide is used more frequently to treat hypertension than chlorthalidone despite the fact that chlorthalidone was the thiazide used in the majority of outcome trials. Chlorthalidone also is twice as potent in BP lowering on a milligram-per-milligram basis.⁹⁹ However, the clinical impact of these differences on cardiovascular morbidity and mortality is unknown.

Patients with angioedema from an ACE inhibitor also can experience this with an ARB, but the exact incidence of cross-reactivity is not known. The ACC/AHA guidelines for

the management of systolic heart failure recommend ARBs as alternative therapy in patients with angioedema from an ACE inhibitor. The best available data are from the CHARM-Alternative study, where only 1 of 39 patients with ACE inhibitor-associated angioedema experienced the same reaction when treated with candesartan.⁵⁸

Over 90% of ACE is localized in tissues and organs, and benazepril, lisinopril, quinapril, and ramipril are ACE inhibitors that have a high degree of tissue penetration. In vitro studies show that high-penetration ACE inhibitors have greater improvements in endothelial function compared with low-penetration ACE inhibitors.^{113,114} However, multiple outcome trials using low- or medium-penetration ACE inhibitors have shown reduced cardiovascular morbidity and mortality, thus questioning the clinical significance of tissue penetration.

HYPERTENSIVE URGENCIES AND EMERGENCIES^{1,7,9,107}

Hypertensive urgencies and emergencies both are characterized by the presence of very elevated BP, greater than 180/120 mm Hg (see “Classification” in the “Arterial Blood Pressure” section). However, the need for urgent or emergent antihypertensive therapy should be determined based on the presence of acute or immediately progressing target-organ injury but not elevated BP alone. Urgencies are not associated with acute or immediately progressing target-organ injury, whereas emergencies are.

A common error with hypertensive urgency is overly aggressively antihypertensive therapy. This treatment likely has been perpetrated by the classification terminology *urgency*. Hypertensive urgencies ideally are managed by adjusting maintenance therapy by adding a new antihypertensive and/or increasing the dose of a present medication. This is the preferred approach to these patients because it provides a more gradual reduction in BP. Very rapid reductions in BP to goal values should be discouraged because of potential risks. Since autoregulation of blood flow in chronically hypertensive patients occurs at a much higher range of pressures than in normotensive persons, the inherent risks of reducing BP too precipitously include cerebrovascular accidents, myocardial infarction, and acute kidney failure. All patients with hypertensive urgency should be reevaluated within no more than 7 days (preferably after 1 to 3 days).

Acute administration of a short-acting oral antihypertensive agent (captopril, clonidine, or labetalol), followed by careful observation for several hours to ensure a gradual reduction in BP, is an option for hypertensive urgency. However, there are no data supporting this approach as being absolutely needed. Oral captopril is one of the agents of choice and can be used in doses of 25–50 mg at 1- to 2-hour intervals. The onset of action of oral captopril is 15 to 30 minutes, and a marked fall in BP is unlikely to occur if no hypotensive response is observed within 30 to 60 minutes. For patients with hypertensive rebound following withdrawal of clonidine, 0.2 mg clonidine can be given initially, followed by 0.2 mg hourly until the DBP falls below 110 mm Hg or a total of 0.7 mg clonidine has been administered. A single dose may be all that is necessary. Labetalol can be given in a dose of 200–400 mg, followed by additional doses every 2 to 3 hours.

Oral or sublingual immediate-release nifedipine has been used in the office setting, nursing homes, and hospitals for acute BP lowering but is potentially dangerous. This approach produces a rapid reduction in BP. Immediate-release nifedipine should never be used for hypertensive urgencies because of reports of severe adverse events such as myocardial infarctions and strokes.¹⁰⁷

TABLE 13–8. Parenteral Antihypertensive Agents for Hypertensive Emergency

| Drug | Dose | Onset (minutes) | Duration (minutes) | Adverse Effects | Special Indications |
|---------------------------|---|-----------------|-----------------------|--|--|
| Sodium nitroprusside | 0.25–10 mcg/kg/min intravenous infusion (requires special delivery system) | Immediate | 1–2 | Nausea, vomiting, muscle twitching, sweating, thiocyanate and cyanide intoxication | Most hypertensive emergencies; caution with high intracranial pressure, azotemia, or in chronic kidney disease |
| Nicardipine hydrochloride | 5–15 mg/h intravenous | 5–10 | 15–30; may exceed 240 | Tachycardia, headache, flushing, local phlebitis | Most hypertensive emergencies except acute heart failure; caution with coronary ischemia |
| Fenoldopam mesylate | 0.1–0.3 mcg/kg/min intravenous infusion | <5 | 30 | Tachycardia, headache, nausea, flushing | Most hypertensive emergencies; caution with glaucoma |
| Nitroglycerin | 5–100 mcg/min intravenous infusion | 2–5 | 5–10 | Headache, vomiting, methemoglobinemia, tolerance with prolonged use | Coronary ischemia |
| Enalaprilat | 1.25–5 mg intravenous every 6 h | 15–30 | 360–720 | Precipitous fall in pressure in high-renin states; variable response | Acute left ventricular failure; avoid in acute myocardial infarction |
| Hydralazine hydrochloride | 12–20 mg intravenous 10–50 mg intramuscular | 10–20 20–30 | 60–240 240–360 | Tachycardia, flushing, headache vomiting, aggravation of angina | Eclampsia |
| Labetalol hydrochloride | 20–80 mg intravenous bolus every 10 min; 0.5–2.0 mg/min intravenous infusion | 5–10 | 180–360 | Vomiting, scalp tingling, bronchoconstriction, dizziness, nausea, heart block, orthostatic hypotension | Most hypertensive emergencies except acute heart failure |
| Esmolol hydrochloride | 250–500 mcg/kg/min intravenous bolus, then 50–100 mcg/kg/min intravenous infusion; may repeat bolus after 5 minutes or increase infusion to 300 mcg/min | 1–2 | 10–20 | Hypotension, nausea, asthma, first-degree heart block, heart failure | Aortic dissection; perioperative |

Hypertensive emergencies are those rare situations that require immediate BP reduction to limit new or progressing target-organ damage (see “Classification” in the “Arterial Blood Pressure” section). Hypertensive emergencies generally require parenteral therapy, at least initially, with one of the agents listed in Table 13–8. The goal in hypertensive emergencies is not to lower BP to less than 140/90 mm Hg; rather, a reduction in mean arterial pressure (MAP) of up to 25% within minutes to hours is the initial target. If the BP is then stable, BP can be reduced toward 160/100–110 mm Hg within the next 2 to 6 hours. Precipitous drops in BP may lead to end-organ ischemia or infarction. If patients tolerate this reduction well, additional gradual reductions toward goal BP values can be attempted after 24 to 48 hours. The exception to this guideline is for patients with an acute ischemic stroke, in whom maintaining an elevated BP is needed for a much longer period of time.

The clinical situation should dictate which intravenous medication is used to treat hypertensive emergencies. Regardless, therapy should be provided in a hospital or emergency room setting with intraarterial BP monitoring. Table 13–8 lists special indications for agents that can be used. Some of these agents are discussed in further detail below.

Nitroprusside is widely considered the agent of choice for most cases but can be problematic in patients with chronic kidney disease. It is a direct-acting vasodilator that decreases peripheral vascular resistance but does not increase cardiac output unless left ventricular failure is present. Nitroprusside can be given to treat most hypertensive emergencies, but in aortic dissection, propranolol should be given first to prevent reflex sympathetic activation. Since nitroprusside is metabolized to cyanide and then to thiocyanate, which is eliminated by the kidneys, serum thiocyanate levels should be monitored when infusions are continued longer than 72 hours. Nitroprusside should

be discontinued if the concentration exceeds 12 mg/dL. The risk of thiocyanate accumulation and toxicity is increased in patients with impaired kidney function.

Fenoldopam is a dopamine-1 agonist that is a popular alternative to nitroprusside. It is used often for perioperative hypertension. Similar to nitroprusside, it has a very quick onset of action and can be titrated easily by adjusting the continuous infusion rate. Conversely, it can improve renal blood flow and is especially useful in patients with kidney insufficiency.

Intravenous nitroglycerin dilates both arterioles and venous capacitance vessels, thereby reducing both cardiac afterload and preload, which can decrease myocardial oxygen demand. It also dilates collateral coronary blood vessels and improves perfusion to ischemic myocardium. These properties make intravenous nitroglycerin ideal for the management of hypertensive emergency in the presence of myocardial ischemia. Intravenous nitroglycerin is associated with tolerance when used over 24 to 48 hours and can cause severe headache.

The hypotensive response of hydralazine is less predictable than with other parenteral agents. Therefore, its major role is in the treatment of eclampsia or hypertensive encephalopathy associated with renal insufficiency.

EVALUATION OF THERAPEUTIC OUTCOMES

ACHIEVING GOALS

The most important strategy to prevent cardiovascular morbidity and mortality in hypertension is BP control to goal values (<140/90 mm Hg for most). Modifying other cardiovascular risk factors, such as

TABLE 13–9. Fixed-Dose Combination Products

| Combination | Drugs (Brand Name) | Strengths (mg/mg) | Daily Frequency |
|---|---|---------------------------------|-----------------|
| ACE inhibitor with a thiazide diuretic | Benazepril/hydrochlorothiazide (Lotensin HCT) | 5/6.25, 10/12.5, 20/12.5, 20/25 | 1 |
| | Captopril/hydrochlorothiazide (Capozide) | 25/15, 25/25, 50/15, 50/25 | 1 to 3 |
| | Enalapril/hydrochlorothiazide (Vaseretic) | 5/12.5, 10/25 | 1 |
| | Lisinopril/hydrochlorothiazide (Prinidex, Zestoretic) | 10/12.5, 20/12.5, 20/25 | 1 |
| | Moexipril/hydrochlorothiazide (Uniretic) | 7.5/12.5, 15/25 | 1 or 2 |
| | Quinapril/hydrochlorothiazide (Accuretic) | 10/12.5, 20/12.5, 20/25 | 1 |
| Angiotensin-receptor blocker with a thiazide diuretic | Candesartan/hydrochlorothiazide (Atacand HCT) | 16/12.5, 32/12.5 | 1 |
| | Eprosartan/hydrochlorothiazide (Teveten HCT) | 600/12.5, 600/25 | 1 |
| | Irbesartan/hydrochlorothiazide (Avalide) | 75/12.5, 150/12.5, 300/12.5 | 1 |
| | Losartan/hydrochlorothiazide (Hyzaar) | 50/12.5, 100/25 | 1 |
| | Olmesartan/hydrochlorothiazide (Benicar HCT) | 20/12.5, 40/12.5, 40/25 | 1 |
| | Telmisartan/hydrochlorothiazide (Micardis HCT) | 40/12.5, 80/12.5 | 1 |
| β -Blocker with a thiazide diuretic | Valsartan/hydrochlorothiazide (Diovan HCT) | 80/12.5, 160/12.5 | 1 |
| | Atenolol/chlorthalidone (Tenoretic) | 50/25, 100/25 | 1 |
| | Bisoprolol/hydrochlorothiazide (Ziac) | 2.5/6.25, 5/6.25, 10/6.25 | 1 |
| | Propranolol/hydrochlorothiazide (Inderide) | 40/25, 80/25 | 2 |
| | Propranolol LA/hydrochlorothiazide (Inderide LA) | 80/50, 120/50, 160/50 | 1 |
| | Metoprolol/hydrochlorothiazide (Lopressor HCT) | 50/25, 100/25 | 1 or 2 |
| ACE inhibitor with calcium channel blocker | Nadolol/bendroflumethazide (Corzide) | 40/5, 80/5 | 1 |
| | Timolol/hydrochlorothiazide (Timolide) | 10/25 | 1 or 2 |
| | Amlodipine/benazepril (Lotrel) | 2.5/10, 5/10, 10/20 | 1 |
| | Enalapril/pelodipine (Lexxel) | 5/5 | 1 |
| | Trandolapril/verapamil (Tarka) | 2/180, 1/240, 2/240, 4/240 | 1 or 2 |

smoking, dyslipidemia, and diabetes mellitus, is also important. Lowering BP to less than 130/80 mm Hg should be targeted in patients with diabetes or chronic kidney disease. For these patients, BP lowering should be done cautiously if high-risk coronary disease risk is present to avoid precipitation of ischemic myocardial events. Moreover, routine goal BP values should be attained in elderly patients with isolated systolic hypertension, but actual BP lowering can occur at a very gradual pace over a period of several months to avoid orthostatic hypotension.

COMBINATION ANTIHYPERTENSIVE THERAPY

Starting therapy with a combination of two drugs is now recommended in patients far from their BP goal, for patients in whom goal achievement may be difficult (i.e., those with diabetes or chronic kidney disease and African-Americans), or in patients with multiple compelling indications for different antihypertensive agents. However, combination therapy is often needed to control BP in patients already on therapy, and most patients require two or more agents.^{1,30,33,50}

Combination regimens for hypertension should include a diuretic, preferably a thiazide. If a diuretic was not the first drug added, it should be the second agent as add-on therapy. This method will provide additional BP lowering because most patients respond well to a two-drug regimen that includes a diuretic. Clinicians should anticipate the need for three drugs to control BP in patients with aggressive BP goals (diabetes and chronic renal disease).³⁰

Diuretics, when combined with several agents (especially an ACE inhibitor, ARB, or β -blocker), can result in additive antihypertensive effects that are independent of reversing fluid retention. BP lowering from certain antihypertensive agents can activate the RAAS as a compensatory mechanism to counteract BP changes and regulate fluid loss. Most alternative antihypertensive agents (e.g., reserpine, arterial vasodilators, and centrally acting agents) need to be given with a diuretic to avoid sodium and water retention.

Many fixed-dose combination products are available commercially, and some are generic (Table 13–9). Most of these products contain a thiazide diuretic and have multiple dose strengths available. Individual dose titration is more complicated with fixed-dose combination products, but this strategy can reduce the number of daily tablets/capsules and can simplify regimens to improve adherence. This alone may increase the likelihood of achieving or maintaining goal BP values. Depending on the product, some may be less expensive to patients and to health systems.

RESISTANT HYPERTENSION

Resistant hypertension is the failure to achieve goal BP in patients who are adhering to full doses of an appropriate three-drug regimen that includes a diuretic.¹ Several causes of resistant hypertension are listed in Table 13–10. These highlight the importance of diuretic therapy in the management of hypertension. Patients should be evaluated closely to see if any of these causes can be reversed. If nothing is identified, the principle of drug therapy selection from the JNC7 still should apply.

TABLE 13–10. Causes of Resistant Hypertension

| |
|--|
| Improper BP measurement |
| Volume overload |
| • Excess sodium intake |
| • Volume retention from kidney disease |
| • Inadequate diuretic therapy |
| Drug-induced or other causes |
| • Nonadherence |
| • Inadequate doses |
| • Agents listed in Table 13–1 |
| Associated conditions |
| • Obesity, excess alcohol intake |
| Disease causing secondary hypertension |

Compelling indications, if present, should guide selection, assuming that these patients are on a diuretic. If additional therapy is needed, spironolactone and reserpine are agents with unique mechanisms of action that can be particularly effective in augmenting BP lowering.

CLINICAL MONITORING

Patients should be monitored for signs and symptoms of progressive target-organ disease (see p. 191). A careful history for chest pain (or tightness), palpitations, dizziness, dyspnea, orthopnea, headache, sudden change in vision, one-sided weakness, slurred speech, and loss of balance should be taken to assess the likelihood of cardiovascular and cerebrovascular hypertensive complications. Other clinical monitoring parameters that may be used to assess target-organ disease includes changes in funduscopic findings, LVH regression on electrocardiogram or echocardiogram, proteinuria, and changes in kidney function. These parameters should be monitored periodically because any sign of deterioration requires immediate assessment and follow-up.

Clinic-based BP monitoring remains the standard for managing hypertension. BP response should be evaluated 2 to 4 weeks after initiating or making changes in therapy. With some agents, monitoring BP 4 to 6 weeks later may better represent steady-state BP values (reserpine) or in the case of ACE inhibitors may minimize the risk of adverse effects. Once goal BP values are attained, assuming no symptoms of acute target-organ disease, BP monitoring can be done every 3 to 6 months. More frequent evaluations are required in patients with a history of poor control, nonadherence, progressive target-organ damage, or symptoms of adverse drug effects. Self-measurements of BP or automatic ambulatory BP monitoring can be useful clinically to establish effective 24-hour control. This type of monitoring may become the standard of care in the future, but the JNC7 recommends that ambulatory BP monitoring only be used in select situations such as suspected white coat hypertension. If patients are measuring their BP at home, it is important that they measure during the early morning hours for most days and then at different times of the day on alternative days of the week.

Patients should be monitored routinely for adverse drug effects. The most common side effects that attend each class of antihypertensive agents are discussed in the treatment section of this chapter, and laboratory parameters for primary agents are listed in Table 13–11. These side effects typically should occur 2 to 4 weeks after starting a new agent or increasing the dose, and laboratory tests should be

TABLE 13–11. Select Monitoring for Antihypertensive Drug Therapy

| Class | Parameters |
|----------------------------------|--|
| Diuretics | Blood pressure, BUN/serum creatinine, serum electrolytes (potassium, magnesium, sodium), uric acid (for thiazides) |
| Aldosterone antagonists | Blood pressure, BUN/serum creatinine, serum potassium |
| β -Blockers | Blood pressure, heart rate |
| ACE inhibitors | Blood pressure, BUN/serum creatinine, serum potassium |
| Angiotensin II receptor blockers | Blood pressure, BUN/serum creatinine, serum potassium |
| Calcium channel blockers | Blood pressure; heart rate |

repeated every 6 to 12 months in stable patients. Additional monitoring may be needed for other concomitant diseases, if present (e.g., diabetes, dyslipidemia, and gout). The occurrence of an adverse drug event may require dosage reduction or substitution with an alternative antihypertensive agent.

ADHERENCE

Hypertension is a relatively asymptomatic disease, and antihypertensive agents are not without adverse side effects. Therefore, it is imperative to assess patient adherence on a regular basis. Identification of nonadherence should be followed up with appropriate patient education and counseling. Once daily regimens are preferred in most patients to improve adherence. Although some practitioners may believe that aggressive treatment will have a negative impact on quality of life, several studies have found that most patients actually feel better once their BP is controlled. Patients on antihypertensive therapy should be questioned periodically about changes in their general health perception, energy level, physical functioning, and overall satisfaction with their treatment. At the present time, there is inadequate information to recommend any herbal therapy as a treatment strategy for hypertension. Lifestyle modifications always should be recommended and encouraged continually in patients engaging in such endeavors.

ABBREVIATIONS

ACE: angiotensin-converting enzyme
 ARB: angiotensin II receptor blocker
 BP: blood pressure
 BUN: blood urea nitrogen
 CCB: calcium channel blocker
 COPD: chronic obstructive pulmonary disease
 DBP: diastolic blood pressure
 GFR: glomerular filtration rate
 JNC7: Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure
 ISA: intrinsic sympathomimetic activity
 LVH: left ventricular hypertrophy
 RAAS: renin-angiotensin-aldosterone system
 SBP: systolic blood pressure

Review Questions and other resources can be found at www.pharmacotherapyonline.com.

HEART FAILURE

Robert B. Parker, J. Herbert Patterson, and Julie A. Johnson

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Heart failure is a clinical syndrome caused by the inability of the heart to pump sufficient blood to meet the metabolic needs of the body. Heart failure can result from any disorder that reduces ventricular filling (diastolic dysfunction) and/or myocardial contractility (systolic dysfunction). The leading causes of heart failure are coronary artery disease and hypertension. The primary manifestations of the syndrome are dyspnea, fatigue, and fluid retention.
- 2 Heart failure is a progressive disorder that begins with myocardial injury. In response to the injury, a number of compensatory responses are activated in an attempt to maintain adequate cardiac output, including the sympathetic nervous system, increased preload, vasoconstriction, and ventricular hypertrophy/remodeling. These compensatory mechanisms are responsible for the symptoms of heart failure and contribute to disease progression.
- 3 Our current understanding of heart failure pathophysiology is best described by the neurohormonal model. Activation of endogenous neurohormones, including norepinephrine, angiotensin II, aldosterone, vasopressin, and numerous proinflammatory cytokines, play an important role in ventricular remodeling and the subsequent progression of heart failure. Importantly, pharmacotherapy targeted at antagonizing this neurohormonal activation has slowed the progression of heart failure and improved survival.
- 4 Most patients with symptomatic heart failure should be treated routinely with four medications: an angiotensin-converting enzyme (ACE) inhibitor, a β -blocker, a diuretic, and digoxin. The benefits of these medications on slowing heart failure progression, reducing morbidity and mortality, and improving symptoms are clearly established.
- 5 In patients with heart failure, ACE inhibitors improve survival, slow disease progression, reduce hospitalizations, and improve quality of life. The doses for these agents should be targeted at those shown in clinical trials to improve survival. When ACE inhibitors are contraindicated or not tolerated, an angiotensin II receptor blocker or the combination of hydralazine and isosorbide dinitrate are reasonable alternatives. Patients with asymptomatic left ventricular dysfunction and/or a previous myocardial infarction (stage B of the American College of Cardiology/American Heart Association (ACC/AHA) classification scheme) also should receive ACE inhibitors, with the goal of preventing symptomatic heart failure and reducing mortality.
- 6 The β -blockers carvedilol, metoprolol CR/XL, and bisoprolol have been shown to prolong survival, decrease hospitalizations and the need for transplantation, and cause “reverse remodeling” of the left ventricle. These agents are recommended for all patients with symptomatic heart failure. Therapy must be instituted at low doses, with slow upward titration to the target dose.
- 7 Although chronic diuretic therapy frequently is used in heart failure patients, it is not mandatory and is required only in patients with peripheral edema and/or pulmonary congestion.
- 8 Digoxin does not improve survival in patients with heart failure but does provide symptomatic benefits, particularly in patients with moderate and severe heart failure and those with supraventricular tachyarrhythmias (e.g., atrial fibrillation). Digoxin doses should be adjusted to achieve plasma concentrations of 0.5 to 1 ng/mL; higher plasma concentrations are not associated with additional benefits but may be associated with increased risk of toxicity.
- 9 Aldosterone antagonism with low-dose spironolactone has been shown to reduce mortality in patients with New York Heart Association (NYHA) class III and IV heart failure and thus should be strongly considered in these patients. Given its low cost and safety profile at the doses studied, it may be reasonable to consider in other patients with symptomatic heart failure, especially those taking potassium supplementation, in whom the aldosterone antagonist might allow dose reduction or discontinuation of the potassium supplement, and should be considered strongly in patients with severe heart failure.
- 10 No therapy for advanced/decompensated heart failure studied to date has been shown conclusively to influence mortality. Treatment goals are directed toward restoration of systemic oxygen transport and tissue perfusion, relief of pulmonary edema, and limitation of further cardiac damage. Maximizing oral therapy and using combinations of short-acting intravenous medications with different cardiovascular actions often are needed to optimize cardiac output, relieve pulmonary edema, and limit myocardial ischemia. Invasive hemodynamic monitoring usually is required to provide immediate feedback on treatment efficacy and adverse effects.
- 11 Pharmacists should play an important role as part of a multidisciplinary team to optimize therapy in heart

failure. The pharmacist should be responsible for such activities as optimizing regimens for heart failure drug therapy (namely, ensuring that appropriate drugs at appropriate doses are used), educating patients about the importance

of adherence to their heart failure regimen (including pharmacologic and dietary interventions), screening for drugs that may exacerbate or worsen heart failure, and monitoring for adverse drug effects and drug interactions.

1 **2** Heart failure is a clinical syndrome that can result from any disorder that impairs the ability of the ventricle to fill with or eject blood, thus rendering the heart unable to pump blood at a rate sufficient to meet the metabolic demands of the body.¹ Heart failure is the final common pathway for numerous cardiac disorders, including those affecting the pericardium, heart valves, and myocardium. Diseases that adversely affect ventricular diastole (filling), ventricular systole (contraction), or both can lead to heart failure. For many years it was believed that reduced myocardial contractility, or systolic dysfunction, was the sole disturbance in cardiac function responsible for heart failure. However, it is now recognized that disturbances in relaxation (lusitropic) properties of the heart, or diastolic dysfunction, cause heart failure in 20% to 50% of patients.² However, regardless of the etiology of heart failure, the underlying pathophysiologic process and principal clinical manifestations (i.e., fatigue, dyspnea, and volume overload) are similar and appear to be independent of the initial cause. Historically, this disorder was commonly referred to as *congestive heart failure*; the preferred nomenclature now is *heart failure* because a patient can have the clinical syndrome of heart failure without having symptoms of congestion. This chapter will focus on treatment of patients with systolic dysfunction (with or without concurrent diastolic dysfunction), whereas Chap. 18 will focus on the treatment of heart failure with normal ejection fraction (isolated diastolic dysfunction).

EPIDEMIOLOGY

Heart failure is an epidemic public health problem in the United States. Approximately 5 million Americans have heart failure, with an additional 550,000 cases diagnosed each year.³ Unlike most other cardiovascular diseases, the prevalence of heart failure is increasing and is expected to continue to increase over the next few decades as the population ages.³ A large majority of patients with heart failure are elderly, with multiple comorbid conditions that influence morbidity and mortality.² The incidence of heart failure doubles with each decade of life and affects nearly 10% of individuals over age 75.³ Heart failure is more common in men than in women until age 65, reflecting the greater incidence of coronary artery disease.³ Recent results from the Framingham Heart Study showed that the incidence of heart failure in men has not changed over the last 40 years but has decreased by approximately one-third in women.⁴ These differences in heart failure incidence may be due to sex-based differences in the cause of heart failure because myocardial infarction is the leading cause in men, whereas hypertension is the leading etiology in women.

Heart failure is the most common hospital discharge diagnosis in individuals over age 65.³ Annual hospital discharges for heart failure now total nearly 1 million, a 165% increase over the last two decades.³ Heart failure also exacts a tremendous economic impact, with this expected to increase markedly as the baby-boom generation ages. Estimates of annual expenditures for heart failure range from \$24 to \$50 billion, with most of these costs spent on hospitalized patients.^{3,5} Thus heart failure is a major medical problem with substantial economic impact that is expected to become even more significant as the population ages.

Despite prodigious advances in our understanding of the etiology, pathophysiology, and pharmacotherapy of heart failure, the prognosis for patients with this disorder remains grim. Although the mortality rates have declined over the last 50 years, the overall 5-year survival remains approximately 50% for all patients with a diagnosis of heart failure, with mortality increasing with symptom severity.⁴ For heart failure patients under age 65, 80% of men and 70% of women will die within 8 years.³ Death is classified as sudden in about 40% of patients,^{1–3} implicating serious ventricular arrhythmias as the underlying cause of death in many patients with heart failure.

ETIOLOGY

1 Heart failure can result from any disorder that affects the ability of the heart to contract (systolic function) and/or relax (diastolic dysfunction); common causes of heart failure are shown in Table 14–1.⁶ Systolic heart failure is the classic, more familiar form of the disorder, but current estimates suggest that 20% to 50% of patients with heart failure have preserved left ventricular systolic function and suffer from diastolic dysfunction.² In contrast to systolic heart failure that is usually caused by previous myocardial infarction (MI), patients with diastolic heart failure typically are elderly, female, and have hypertension and diabetes.² However, systolic and diastolic dysfunction frequently coexist. The common cardiovascular diseases such as MI and hypertension can cause both systolic and diastolic dysfunction; thus many patients have heart failure as a result of reduced myocardial contractility and abnormal ventricular filling.

1 Coronary artery disease is the most common cause of systolic heart failure, accounting for nearly 70% of cases.⁷ MI leads to

TABLE 14–1. Causes of Heart Failure

Systolic Dysfunction (Decreased Contractility)

- Reduction in muscle mass (e.g., myocardial infarction)
- Dilated cardiomyopathies
- Ventricular hypertrophy
 - Pressure overload (e.g., systemic or pulmonary hypertension, aortic or pulmonic valve stenosis)
 - Volume overload (e.g., valvular regurgitation, shunts, high-output states)

Diastolic Dysfunction (Restriction in Ventricular Filling)

- Increased ventricular stiffness
- Ventricular hypertrophy (e.g., hypertrophic cardiomyopathy, other examples above)
- Infiltrative myocardial diseases (e.g., amyloidosis, sarcoidosis, endomyocardial fibrosis)
- Myocardial ischemia and infarction
- Mitral or tricuspid valve stenosis
- Pericardial disease (e.g., pericarditis, pericardial tamponade)

Data from Colucci W, Braunwald E. Pathophysiology of heart failure. In: Braunwald E, Zipes DP, Libby P, eds. *Heart Disease: A Textbook of Cardiovascular Medicine*, 6th ed. Philadelphia, Saunders, 2001:503–533; and Wynne J, Braunwald E. The cardiomyopathies and myocarditides. In: Braunwald E, Zipes DP, Libby P, eds. *Heart Disease: A Textbook of Cardiovascular Medicine*, 6th ed. Philadelphia, Saunders, 2001:1751–1806.

a reduction in muscle mass owing to death of affected myocardial cells. The degree to which contractility is impaired will depend on the size of the infarction. In an attempt to maintain cardiac output, the surviving myocardium undergoes a compensatory remodeling, thus beginning the maladaptive process that initiates the heart failure syndrome. This is discussed in greater detail in the “Pathophysiology” section. Myocardial ischemia and infarction also affect the diastolic properties of the heart by slowing ventricular relaxation and increasing ventricular stiffness. Thus MI frequently results in systolic and diastolic dysfunction.

Systolic contractile dysfunction is a cardinal feature of dilated cardiomyopathies. Although the cause of reduced contractility frequently is unknown, abnormalities such as interstitial fibrosis, cellular infiltrates, cellular hypertrophy, and myocardial cell degeneration are seen commonly on histologic examination.⁸

Pressure or volume overload causes ventricular hypertrophy, which attempts to return contractility to a near-normal state. However, if the pressure or volume overload persists, the remodeling process results in alterations in the geometry of the hypertrophied myocardial cells and is accompanied by increased collagen deposition in the extracellular matrix. Thus both systolic and diastolic function may be impaired.⁶ Examples of pressure overload include systemic or pulmonary hypertension and aortic or pulmonic valve stenosis. Hypertension remains an important cause and/or contributor to heart failure in many patients, particularly women, the elderly, and African-Americans.⁴ The role of hypertension should not be underestimated because hypertension is an important risk factor for ischemic heart disease and thus is also present in a high percentage of the patients with this disorder. Volume overload may occur in the presence of valvular regurgitation, shunts, or high-output states such as anemia or pregnancy. Less common causes of diastolic dysfunction are listed in Table 14-1 and include infiltrative myocardial diseases, mitral or tricuspid valve stenosis, and pericardial disease.

Since ischemic heart disease and/or hypertension contribute so significantly to the development of heart failure in the majority of patients, it is important to emphasize that heart failure is a largely preventable disorder. Thus recent evidence that obesity and salt intake are important risk factors for heart failure is not surprising.^{9,10} Moreover, control of blood pressure and appropriate management of other risk factors for cardiovascular disease (e.g., smoking cessation, treatment of lipid disorders, diabetes management, dietary modification, etc.) are important strategies for clinicians to implement to reduce their patients' risk of heart failure.

PATHOPHYSIOLOGY

NORMAL CARDIAC FUNCTION

To understand the pathophysiologic processes in heart failure, a basic understanding of normal cardiac function is necessary. *Cardiac output* (CO) is defined as the volume of blood ejected per unit time (L/min) and is the product of heart rate (HR) and stroke volume (SV):

$$CO = HR \times SV$$

The relationship between CO and mean arterial pressure (MAP) is

$$MAP = CO \times \text{systemic vascular resistance (SVR)}$$

Heart rate is controlled by the autonomic nervous system. Stroke volume, or the volume of blood ejected during systole, depends on preload, afterload, and contractility.⁶ As defined by the Frank-Starling mechanism, the ability of the heart to alter the force of contraction

FIGURE 14-1. Relationship between stroke volume and systemic vascular resistance. In an individual with normal left ventricular (LV) function, increasing systemic vascular resistance has little effect on stroke volume. As the extent of LV dysfunction increases, the negative inverse relationship between stroke volume and systemic vascular resistance becomes more important (B to A).

depends on changes in preload. As myocardial sarcomere length is stretched, the number of cross-bridges between thick and thin myofilaments increases, resulting in an increase in the force of contraction. The length of the sarcomere is determined primarily by the volume of blood in the ventricle; therefore, left ventricular end-diastolic volume (LVEDV) is the primary determinant of preload. In normal hearts, the preload response is the primary compensatory mechanism such that a small increase in end-diastolic volume results in a large increase in cardiac output. Because of the relationship between pressure and volume in the heart, left ventricular end-diastolic pressure (LVEDP) is often used in the clinical setting to estimate preload. The hemodynamic measurement used to estimate LVEDP is the pulmonary artery occlusion pressure (PAOP). Afterload is a more complex physiologic concept that can be viewed pragmatically as the sum of forces preventing active forward ejection of blood by the ventricle. Major components of global ventricular afterload are ejection impedance, wall tension, and regional wall geometry. In patients with left ventricular systolic dysfunction, an inverse relationship exists between afterload (or SVR) and stroke volume such that increasing afterload causes a decrease in stroke volume (Fig. 14-1). Contractility is the intrinsic property of cardiac muscle describing fiber shortening and tension development.

COMPENSATORY MECHANISMS IN HEART FAILURE

Heart failure is a progressive disorder initiated by an event that impairs the ability of the heart to contract and/or relax. The index event may have an acute onset, as with MI, or the onset may be slow, as with long-standing hypertension. Regardless of the index event, the decrease in the heart's pumping capacity results in the heart having to rely on compensatory responses to maintain an adequate cardiac output.¹¹ These compensatory responses are (1) tachycardia and increased contractility through sympathetic nervous system (SNS) activation, (2) the Frank-Starling mechanism, whereby an increase in preload results in an increase in stroke volume, (3) vasoconstriction, and (4) ventricular hypertrophy and remodeling. Teleologically, these compensatory responses are intended to be short-term responses to maintain circulatory homeostasis after acute reductions in blood pressure or renal perfusion. However, the persistent decline in cardiac output in heart failure results in long-term activation of these compensatory responses, resulting in the complex functional, structural, biochemical, and molecular changes important for the initiation

TABLE 14–2. Beneficial and Detrimental Effects of the Compensatory Responses in Heart Failure

| Compensatory Response | Beneficial Effects of Compensation | Detrimental Effects of Compensation |
|---|--|---|
| Increased preload (through Na ⁺ and water retention) | Optimize stroke volume via Frank-Starling mechanism | Pulmonary and systemic congestion and edema formation Increased MVO ₂ |
| Vasoconstriction | Maintain BP in face of reduced cardiac output Shunt blood from nonessential organs to brain and heart | Increased MVO ₂ Increased afterload decreases stroke volume and further activates the compensatory responses |
| Tachycardia and increased contractility (due to SNS activation) | Helps maintain cardiac output | Increased MVO ₂ Shortened diastolic filling time β ₁ -Receptor downregulation, decreased receptor sensitivity Precipitation of ventricular arrhythmias |
| Ventricular hypertrophy and remodeling | Helps maintain cardiac output Reduces myocardial wall stress Decreases MVO ₂ | Increased risk of myocardial cell death Diastolic dysfunction Systolic dysfunction Increased risk of myocardial cell death Increased risk of myocardial ischemia Increased arrhythmia risk Fibrosis |

Abbreviations: SNS = sympathetic nervous system; BP = blood pressure; MVO₂ = myocardial oxygen demand.

and progression of the heart failure syndrome. The benefits and detrimental consequences of these compensatory responses are described below and are summarized in Table 14–2.

TACHYCARDIA AND INCREASED CONTRACTILITY THROUGH SNS ACTIVATION

The change in heart rate and contractility that occurs in response to a drop in cardiac output is due primarily to release of norepinephrine (NE) from adrenergic nerve terminals, although parasympathetic nervous system activity is diminished. Because cardiac output equals the product of heart rate and stroke volume, one might expect cardiac output to change linearly with heart rate, but the relationship is much more complex. Since systolic time intervals change comparatively little with changing heart rate, almost all cardiac cycle shortening occurs during diastole. Cardiac output continues to increase with heart rate until diastolic filling becomes compromised, which in the normal heart is at 170 to 200 beats per minute. When preexisting or acute diastolic dysfunction is present, however, the ventricle’s need for more complete (longer) diastolic filling results in reduction of effective preload at significantly lower heart rates. Loss of atrial contribution to ventricular filling also can occur (e.g., atrial fibrillation or ventricular tachycardia), reducing ventricular performance even more. Because ionized calcium is sequestered into the sarcoplasmic reticulum and pumped out of the cell during diastole, shortened diastolic time also results in a higher average intracellular calcium concentration during diastole, increasing actin-myosin interaction, augmenting the active resistance to fibril stretch, and reducing lusitropy. Conversely, the higher average calcium concentration translates into greater filament interaction during systole, generating more tension.⁶

Increasing heart rate greatly increases myocardial oxygen demand. If ischemia is induced or worsened, both diastolic and systolic function may become impaired, and stroke volume can drop precipitously.

INCREASED PRELOAD

Augmentation of preload is another compensatory response that is activated rapidly in response to decreased cardiac output. Renal perfusion in heart failure is reduced owing to both depressed cardiac output and redistribution of blood away from nonvital organs. The kidney interprets the reduced perfusion as an ineffective blood volume, resulting in activation of the renin-angiotensin-aldosterone (RAA) system. Reduced renal perfusion and increased sympathetic tone also stimulate renin release from juxtaglomerular cells in the kidney. As shown in Fig. 14–2, renin is responsible for conversion of angiotensinogen to angiotensin I. Angiotensin I is converted to angiotensin II by angiotensin-converting enzyme (ACE). Angiotensin II also may be generated via non-ACE-dependent pathways. Angiotensin II feeds back on the adrenal gland to stimulate aldosterone release, thereby providing an additional mechanism for sodium and water retention in the kidney. As intravascular volume increases secondary to sodium and water retention, left ventricular volume and pressure (preload) increase, sarcomeres are stretched, and the force of contraction is enhanced.⁶ While the preload response is the primary compensatory mechanism in normal hearts, the chronically failing heart usually has exhausted its preload reserve.⁶ As shown in Fig. 14–3, increases in preload will increase stroke volume only to a certain point. Once the flat portion of the curve is reached, further increases in preload will only lead to pulmonary or systemic congestion, a detrimental result.⁶ Figure 14–3 also shows that the curve is flatter in patients with left ventricular dysfunction. Consequently, a given increase in preload in a patient with heart failure will produce a smaller increment in stroke volume than in an individual with normal ventricular function.

In addition to causing symptoms of congestion, augmentation of preload in the heart failure patient will increase afterload because increasing the radius of the ventricle elevates wall tension. Because the failing ventricle is highly afterload-dependent, increases in performance augmented by preload at times may be offset by the attendant increase in afterload. Additionally, the effects of increased preload on force of contraction and afterload will increase myocardial

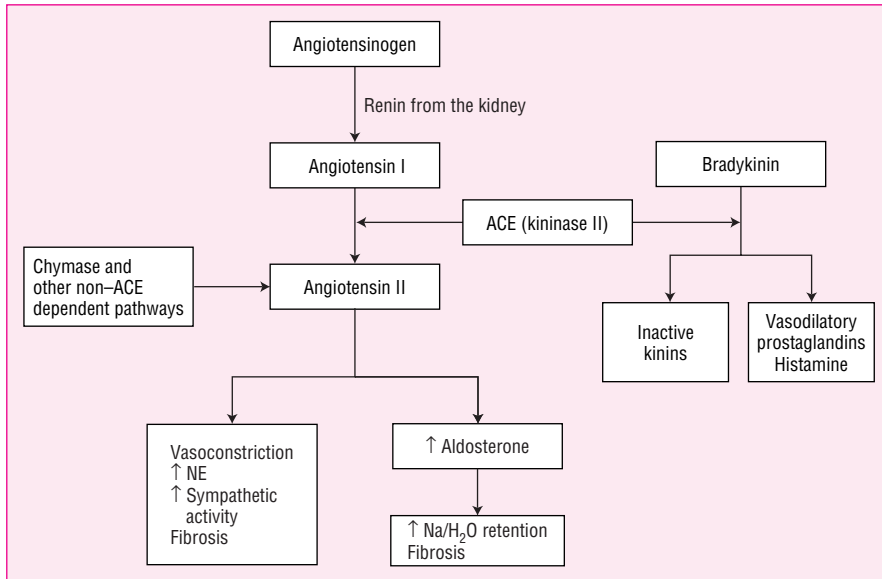

FIGURE 14–2. Physiology of the renin-angiotensin-aldosterone system. Renin produces angiotensin I from angiotensinogen. Angiotensin I is cleaved to angiotensin II by angiotensin-converting enzyme (ACE). Angiotensin II has a number of physiologic actions that are detrimental in heart failure. Note that angiotensin II can be produced in a number of tissues, including the heart, independent of ACE activity. ACE is also responsible for the breakdown of bradykinin. Inhibition of ACE results in accumulation of bradykinin, which, in turn, enhances the production of vasodilatory prostaglandins.

oxygen consumption. Thus an increase in preload can induce ischemia in the coronary patient, with subsequent lusitropic and inotropic compromise.

VASOCONSTRICTION

Vasoconstriction occurs in patients with heart failure to help redistribute blood flow away from nonessential organs to coronary and cerebral circulations to support blood pressure, which may be reduced secondary to a decrease in cardiac output ($MAP = CO \times SVR$).⁶ A number of neurohormones likely contribute to the vasoconstriction, including NE, angiotensin II, endothelin-1, and arginine vasopressin (AVP).⁶ Vasoconstriction impedes forward ejection of blood from the ventricle, further depressing cardiac output and heightening the compensatory responses. Because the failing ventricle usually has exhausted its preload reserve (unless the patient is depleted intravascularly), its performance is exquisitely sensitive to changes in afterload (see Fig 14–1). Thus, increases in afterload often potentiate a vicious

cycle of continued worsening and downward spiraling of the heart failure state.

VENTRICULAR HYPERTROPHY AND REMODELING^{6,11}

3 While the signs and symptoms of heart failure are associated closely with the items just described, the progression of heart failure appears to be independent of the patient’s hemodynamic status. It is now recognized that ventricular hypertrophy and remodeling are key components in the pathogenesis of progressive myocardial failure. *Ventricular hypertrophy* is a term used to describe an increase in ventricular muscle mass. *Cardiac or ventricular remodeling* is a broader term describing changes in both myocardial cells and extracellular matrix that result in changes in the size, shape, structure, and function of the heart. Ventricular hypertrophy and remodeling can occur in association with any condition that causes myocardial injury, including MI, cardiomyopathy, hypertension, and valvular heart disease.

Cardiac remodeling is a complex process that affects the heart at the molecular and cellular levels. Key elements in the process are shown in Fig. 14–4. Collectively, these events result in progressive changes in myocardial structure and function, such as cardiac hypertrophy, myocyte loss, and alterations in the extracellular matrix. The progression of the remodeling process leads to reductions in myocardial systolic and/or diastolic function that, in turn, lead to further myocardial injury, perpetuating the remodeling process and the decline in ventricular function. Angiotensin II, NE, endothelin, aldosterone, vasopressin, and numerous inflammatory cytokines, as well as substances under investigation, that are activated both systemically and in the heart play an important role in initiating the signal-transduction cascade responsible for ventricular remodeling.

Pressure overload (and probably hormonal activation) associated with hypertension produces a concentric hypertrophy (an increase in ventricular wall thickness without chamber enlargement). Eccentric left ventricular hypertrophy (myocyte lengthening with increased chamber size and a minimal increase in wall thickness) characterizes the hypertrophy seen in patients with systolic dysfunction or previous MI. As the myocytes undergo change, so do various

FIGURE 14–3. Relationship between cardiac output (shown as cardiac index, which is CO/BSA) and preload (shown as pulmonary artery occlusion pressure).

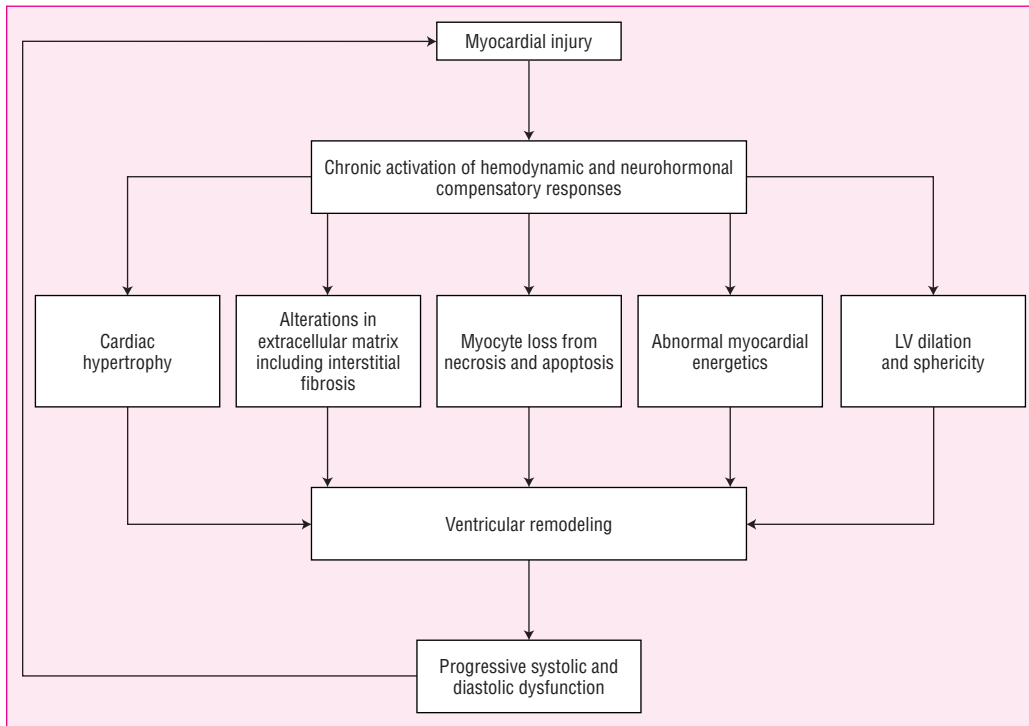

FIGURE 14–4. Key components of the pathophysiology of cardiac remodeling. Myocardial injury (e.g., myocardial infarction) results in the activation of a number of hemodynamic and neurohormonal compensatory responses in an attempt to maintain circulatory homeostasis. Chronic activation of the neurohormonal systems results in a cascade of events that affect the myocardium at the molecular and cellular levels. These events lead to the changes in ventricular size, shape, structure, and function known as *ventricular remodeling*. The alterations in ventricular function result in further deterioration in cardiac systolic and diastolic function, which further promotes the remodeling process.

components of the extracellular matrix. For example, there is evidence for collagen degradation, which may lead to slippage of myocytes, fibroblast proliferation, and increased fibrillar collagen synthesis, resulting in fibrosis and stiffening of the entire myocardium. Thus a number of important ventricular changes that occur with remodeling include changes in the geometry of the heart from elliptical to spherical, increases in ventricular mass (from myocyte hypertrophy), and changes in ventricular composition (especially the extracellular matrix) and volume, all of which likely contribute to the impairment of cardiac function. If the event that produces cardiac injury is acute (e.g., MI), the ventricular remodeling process begins immediately. However, it is the progressive nature of this process that results in continual worsening of the heart failure state and thus is now the major focus for identification of therapeutic targets. In fact, it is believed that all the heart failure therapies that have been associated with decreased mortality and/or slowing of the progression of the disease produce this effect largely through their ability to slow or reverse the ventricular remodeling process. Thus, while ventricular hypertrophy and remodeling may have some beneficial effects by helping to maintain cardiac output, they also are believed to play an essential role in the progressive nature of heart failure.

THE NEUROHORMONAL MODEL OF HEART FAILURE AND THE THERAPEUTIC INSIGHTS IT PROVIDES^{6,11}

2 3 Over the years, several different paradigms have guided the therapy of heart failure. The early paradigm is often called the *cardiorenal model*, in which the problem was viewed as excess

sodium and water retention, and diuretic therapy was the main therapeutic approach to combating the problem. The next paradigm was the *cardiocirculatory model*, which focused on impaired cardiac output (viewed as being due to both inadequate contractility and systemic vasoconstriction). This paradigm focused on positive inotropes and, later, vasodilators as the primary therapies to overcome the problems associated with heart failure. The inadequacy of this model to explain the progressive nature of heart failure is pointed out by the detrimental effects of positive inotropic drugs (e.g., amrinone, milrinone, enoximone, vesnarinone, xamoterol, and dobutamine) on survival.¹² The first studies with ACE inhibitors were initiated with the thought that they might be effective owing to their balanced (arterial and venous) vasodilation. While the therapeutic approaches associated with these paradigms provided some symptomatic benefits to patients with heart failure, they did little to slow progression of the disease (with the exception of ACE inhibitors). Subsequent realization that ACE inhibitors were providing benefit beyond their vasodilating effects, followed by the positive results with β -adrenergic receptor blockers and aldosterone antagonists, has led to the current paradigm used to describe heart failure: the *neurohormonal model*. This model recognizes that there is an initiating event (e.g., MI or long-standing hypertension) that leads to decreased cardiac output and begins the “heart failure state,” but then the problem moves beyond the heart, and it essentially becomes a systemic disease whose progression is mediated largely by neurohormones and autocrine/paracrine factors. While the former paradigms still guide us to some extent in the symptomatic management of the disease (e.g., diuretics and digoxin), it is the latter paradigm that helps us understand disease progression and, more

important, the ways to slow disease progression. In the sections that follow, important neurohormones and autocrine/paracrine factors are described with respect to their role in heart failure and its progression. The benefits of current and investigational drug therapies can be better understood through a solid understanding of the neurohormones they regulate/affect.

ANGIOTENSIN II^{6,11}

Of the neurohormones and autocrine/paracrine factors that play an important role in the pathophysiology of heart failure, angiotensin II is probably the best understood. Angiotensin II has multiple actions that contribute to its detrimental effects in heart failure. Angiotensin II increases systemic vascular resistance in heart failure through direct, potent vasoconstriction. Its ability to cause release of AVP and endothelin-1 also may contribute to vasoconstriction. Angiotensin II also facilitates release of NE from adrenergic nerve terminals, heightening SNS activation. It promotes sodium retention through direct effects on the renal tubules and by stimulating aldosterone release. Its vasoconstriction of the efferent glomerular arteriole helps to maintain perfusion pressure in patients with severe heart failure or impaired renal function. Thus, in patients dependent on angiotensin II for maintenance of perfusion pressure, initiation of an ACE inhibitor or angiotensin II receptor type I blocker (ARB) causes efferent arteriole vasodilation, decreased perfusion pressure, and decreased glomerular filtration. This explains the risk of transient impairment in renal function associated with initiation of ACE inhibitor or ARB therapy. Finally, angiotensin II, as well as many of the neurohormones whose release/production is stimulated by angiotensin II, plays a central role in stimulating ventricular hypertrophy, remodeling, myocyte apoptosis (programmed cell death), and alterations in the extracellular matrix. Clinical data suggest that blocking these effects contributes substantially to the prolonged survival of ACE inhibitor- and ARB-treated heart failure patients.^{13,14} The favorable effects of ACE inhibitors (and presumably ARBs) on hemodynamics, symptoms, quality of life, and survival in heart failure highlight the importance of angiotensin II in the pathophysiology of heart failure.

NOREPINEPHRINE^{6,15,16}

Many of the detrimental effects of NE in heart failure were described earlier. NE plays a central role in the tachycardia, vasoconstriction, and increased contractility observed in heart failure. Plasma NE concentrations are elevated in correlation with the degree of heart failure, and patients with the highest plasma NE concentrations have the poorest prognosis. In addition to the detrimental effects described, excessive SNS activation causes downregulation of β_1 -receptors, with a subsequent loss of sensitivity to receptor stimulation. Recent evidence suggests that genetic variations in the β_1 - and α_{2c} -receptors, which are targets for NE's actions, may increase the risk of heart failure.¹⁷ Excess catecholamines increase the risk of arrhythmias and can cause myocardial cell loss by stimulating both necrosis and apoptosis. Finally, NE contributes to ventricular hypertrophy and remodeling. The detrimental effects of SNS activation are further highlighted by the clinical trials of chronic therapy with β -agonists, phosphodiesterase inhibitors, or other drugs that cause SNS activation because they have been shown uniformly to increase mortality in heart failure.¹² Additionally, β -blockers, ACE inhibitors, and digoxin all help to decrease SNS activation through various mechanisms and are beneficial in heart failure. Thus it is clear that NE plays a critical role in the pathophysiology of the heart failure state.

ALDOSTERONE^{18,19}

Aldosterone-mediated sodium retention and its key role in volume overload and edema have long been recognized as important components of the heart failure syndrome. Circulating aldosterone is increased in heart failure due to stimulation of its synthesis and release from the adrenal cortex by angiotensin II and to decreased hepatic clearance secondary to reduced hepatic perfusion. Although its enhancement of sodium retention is an important component of heart failure symptoms, recent studies indicate that direct effects of aldosterone on the heart may be even more important in heart failure pathophysiology. Chief among these is the ability of aldosterone to produce interstitial cardiac fibrosis through increased collagen deposition in the extracellular matrix of the heart. This cardiac fibrosis may decrease systolic function and also impair diastolic function by increasing the stiffness of the myocardium. Current research shows that extraadrenal production of aldosterone in the heart, kidneys, and vascular smooth muscle also contributes to the progressive nature of heart failure through target-organ fibrosis and vascular remodeling. Aldosterone also may increase the risk of ventricular arrhythmias through a number of mechanisms, including creation of reentrant circuits as a result of fibrosis, inhibition of cardiac NE reuptake, depletion of intracellular potassium and magnesium, and impairment of parasympathetic traffic. Recent studies with the aldosterone antagonists spironolactone²⁰ and eplerenone²¹ produced significant reductions in mortality in patients with heart failure without appreciable effects on diuresis or hemodynamics, providing substantial evidence that the direct cardiac effects of aldosterone play an important role in heart failure pathophysiology.

NATRIURETIC PEPTIDES^{22,23}

The natriuretic peptide family has three members, atrial natriuretic peptide (ANP), B-type natriuretic peptide (BNP), and C-type natriuretic peptide (CNP). ANP is stored mainly in the right atrium, whereas BNP is found mainly in the ventricles. Both are released in response to pressure or volume overload. CNP is found mainly in the brain and has very low plasma concentrations. ANP and BNP plasma concentrations are elevated in patients with heart failure and are thought to balance the effects of the RAA system by causing natriuresis, diuresis, vasodilation, decreased aldosterone release, decreased hypertrophy, and inhibition of the SNS and the RAA system.

The role of BNP as a biomarker for prognostic, diagnostic, and therapeutic use has received much recent attention. In patients with chronic heart failure, the degree of elevation in BNP levels is closely associated with increased mortality, risk of sudden death, symptoms, and hospital readmission. Current data indicate that BNP is more sensitive than NE in predicting morbidity and mortality in heart failure patients. Accurate diagnosis of decompensated heart failure in acute care settings is often difficult because many of the symptoms (e.g., dyspnea) mimic those of other disorders such as pulmonary disease or obesity. The development of a rapid bedside BNP assay has proven helpful for discriminating decompensated heart failure from these other disorders. Although larger prospective trials are needed, initial evidence indicates that BNP may be a useful marker to guide titration of heart failure therapy. Patients whose heart failure therapy was titrated to achieve lower BNP concentrations had improved outcomes (defined as a composite of death, hospital admission, or heart failure decompensation) compared with traditionally treated patients.²⁴ Finally, administration of recombinant human BNP (nesiritide) for short-term management of acute heart failure resulted in

hemodynamic and symptomatic improvement, further supporting the role of BNP in heart failure pathophysiology.

ARGININE VASOPRESSIN²⁵

AVP is a pituitary peptide hormone that plays an important role in regulation of renal water and solute excretion. AVP secretion is linked directly to changes in plasma osmolality, thus attempting to maintain body fluid homeostasis. The physiologic effects of AVP are mediated through the V_{1a} and V_2 receptors. V_{1a} receptors are located in vascular smooth muscle and in myocytes, where their stimulation by AVP results in vasoconstriction and increased cardiac contractility, respectively. V_2 receptors are located in the collecting duct of the kidney, where AVP stimulation causes reabsorption of free water.

Plasma concentrations of AVP are elevated in patients with heart failure, with the magnitude of elevation correlating with symptom severity. Importantly, current research suggests that AVP also may play a role in the pathophysiology of heart failure. Important effects associated with increased circulating AVP concentrations include (1) increased renal free water reabsorption in the face of plasma hyposmolality, resulting in volume overload and hyponatremia, (2) increased arterial vasoconstriction, which contributes to reduced cardiac output, and, (3) stimulation of remodeling by cardiac hypertrophy and extracellular matrix collagen deposition.

Given the importance of AVP in heart failure, recent efforts have focused on the development of AVP antagonist drugs for treatment of acute and chronic heart failure. Although still investigational, the oral V_2 -receptor antagonist tolvaptan reduced edema and body weight and increased urine output and serum sodium concentration without affecting heart rate, blood pressure, or renal function in volume-overloaded heart failure patients.²⁶ Similar effects have been reported with agents that are V_{1a}/V_2 antagonists. These results suggest that AVP antagonists may be useful in the treatment of heart failure patients with volume overload. Unlike diuretics, they appear to reduce excess fluid volume without affecting heart rate, blood pressure, renal function, or electrolytes. Thus these agents may offer a new therapeutic approach to currently available drug therapies, although additional clinical trials are needed to establish long-term efficacy and safety.

OTHER CIRCULATING MEDIATORS^{27,28}

In addition to neurohormones, several proinflammatory cytokines are under extensive investigation for their role in heart failure pathophysiology. Tumor necrosis factor α (TNF- α), interleukin-6 (IL-6), and IL-1 β all have been shown to be elevated in heart failure, with a direct relationship between the degree of elevation and the severity of heart failure. Of these cytokines, TNF- α is best studied for its pathophysiological role in heart failure. TNF- α produces multiple deleterious actions, including negative inotropic effects, uncoupling β -adrenergic receptors from adenylyl cyclase (thus reducing β -receptor-mediated responses), increasing myocardial cell apoptosis, and stimulating remodeling via several mechanisms. Although these findings clearly imply a role for TNF- α in the pathophysiology of heart failure, clinical trials evaluating anti-TNF- α therapies (e.g., etanercept) have been disappointing, with no improvement in outcomes demonstrated.

The endothelin peptides are potent vasoconstrictors that may be involved in heart failure pathophysiology through a number of mechanisms. Endothelin-1 (ET-1), the best characterized of these peptides, is synthesized by endothelial and vascular smooth muscle cells, with the release of ET-1 enhanced by NE, angiotensin II, and inflammatory cytokines. Like other peptides and hormones described earlier, ET-1 plasma concentrations are elevated in heart failure and

have been correlated directly with the severity of hemodynamic abnormality, symptoms, and mortality. Its arterial and venous constrictive effects increase preload and afterload, and its vasoconstriction of both efferent and afferent renal arterioles may decrease renal plasma flow and induce sodium retention. ET-1 has direct cardiotoxic effects, is a potent stimulator of cardiac myocyte hypertrophy, and has arrhythmogenic effects. It is also a positive inotrope and, like the β -agonists, over the long-term may be harmful owing to the increased myocardial energy utilization. Finally, ET-1 also appears to modulate production of many other neurohormones involved in heart failure pathophysiology, including angiotensin II, aldosterone, and NE. These findings suggest that endothelin-receptor antagonists may be beneficial in patients with heart failure. Clinical trials with several agents have shown improvements in hemodynamics and symptoms, although the more important long-term effects of endothelin-receptor blockade on heart failure progression and mortality remain unknown.

PRECIPITATING FACTORS IN HEART FAILURE DECOMPENSATION

Although significant advancements have been made in treatment, exacerbations of symptoms to the point that hospitalization is required is a common and growing problem in patients with heart failure. Hospitalization for heart failure exacerbation consumes large amounts of health care dollars and significantly impairs the patient's quality of life. Thus there is great interest in identifying and then remedying factors that increase the risk of decompensation. In patients with heart failure, appropriate therapy often can maintain them in a "compensated" state, indicating that they are relatively symptom-free. However, there are many aggravating or precipitating factors that may cause a previously compensated patient to decompensate, resulting in worsened symptoms and necessitating hospitalization. Precipitants of heart failure decompensation typically increase preload or afterload and/or decrease cardiac contractility. The resulting symptoms are typically those associated with volume overload, but in more severe cases, hypoperfusion also may be present.

Factors involved in precipitating decompensation have been evaluated prospectively in patients admitted to the hospital with heart failure.^{29,30} These studies consistently show that noncompliance with drugs or diet is a common cause of heart failure exacerbation. For example, 43% of patients admitted with an acute decompensation of chronic heart failure were assessed as having dietary sodium excess, 34% had excess fluid intake (defined as >2.5 L/day), and about 24% had drug noncompliance that may have contributed to their decompensation (although not necessarily defined as the primary cause of decompensation).³⁰ Use of inappropriate medications such as antiarrhythmic agents or calcium channel blockers also was an important precipitant of exacerbations.

Cardiac events also may precipitate heart failure exacerbations. Myocardial ischemia and infarction are potentially reversible causes that must be considered carefully because nearly 70% of heart failure patients have coronary artery disease. It should be noted that myocardial ischemia can be either a cause or a consequence of heart failure decompensation. Revascularization should be considered in appropriate patients. Atrial fibrillation occurs in up to 10% to 30% of patients with heart failure and is associated with increased morbidity and mortality.³¹ Atrial fibrillation can exacerbate heart failure through rapid ventricular response and loss of atrial contribution to ventricular filling. Conversely, decompensated heart failure can precipitate atrial fibrillation by atrial distension resulting from ventricular volume overload. Control of ventricular response, maintenance of sinus rhythm in appropriate patients, and prevention of thromboembolism

are important elements in the treatment of heart failure patients with atrial fibrillation.

A number of noncardiac events may also be associated with heart failure decompensation. Pulmonary infections frequently cause worsening of heart failure. At least some of these events would be preventable with more widespread use of the pneumococcal and influenza vaccines in these patients. Recent studies suggest that anemia occurs frequently in patients with heart failure and that it is associated with reduced survival and functional status and increased risk of hospitalization.³² Although correction of anemia with agents such as epoetin- α may improve symptoms, the effect on prognosis awaits the results of ongoing clinical trials.

What should be evident is that many of the precipitating factors are preventable, particularly through appropriate pharmacist intervention. Specifically, patient education and counseling by a pharmacist should help to decrease the most common reason for heart failure exacerbation—noncompliance with dietary sodium and water restrictions, drug therapy, or both. Pharmacists also should be able to identify and address inadequate heart failure therapy, poorly controlled hypertension, and administration of drugs that may worsen heart failure owing to their negative inotropic, cardiotoxic, or sodium-retaining properties. Specific examples of drugs that can worsen heart failure are given in Table 14–3. It should be noted that while the cyclooxygenase-2 (COX-2) inhibitors may differ from the traditional nonsteroidal anti-inflammatory drugs (NSAIDs) in their gastric ulceration effects, their effects on renal function are similar to those of NSAIDs.³³ Thus both NSAIDs and COX-2 inhibitors should be used judiciously in heart failure patients. The thiazolidinedione hypoglycemic drugs rosiglitazone and pioglitazone are associated with weight gain and the development of edema that may exacerbate heart failure. Current guidelines indicate these agents should not be used in patients with NYHA class III or IV heart failure.¹ It can be argued that heart failure exacerbations owing to noncompliance, inadequate/inappropriate drug therapy, and poorly controlled hypertension are all preventable and amenable to pharmacist intervention. Thus the value of the pharmacist's role in careful and repeated education of patients and monitoring of the drug regimen should not be underestimated. Attention to these factors may make an important contribution

TABLE 14–3. Drugs that May Precipitate or Exacerbate Heart Failure

Negative Inotropic Effect

Antiarrhythmics (e.g., disopyramide, flecainide, and others)
 β -Blockers (e.g., propranolol, metoprolol, atenolol, and others)
 Calcium channel blockers (e.g., verapamil and others)

Itraconazole

Terbinafine

Cardiotoxic

Doxorubicin

Daunomycin

Cyclophosphamide

Sodium and Water Retention

NSAIDs

COX-2 inhibitors

Rosiglitazone and pioglitazone

Glucocorticoids

Androgens

Estrogens

Salicylates (high dose)

Sodium-containing drugs (e.g., carbenicillin disodium, ticarcillin disodium)

to reducing the risk of hospitalization and improving the quality of life of patients.

CLINICAL PRESENTATION³⁴

SIGNS AND SYMPTOMS

The primary manifestations of heart failure are dyspnea and fatigue, which lead to exercise intolerance, and fluid overload, which can result in pulmonary congestion and peripheral edema. The presence of these signs and symptoms may vary considerably from patient to patient such that some patients have dyspnea but no signs of fluid retention, and others may have marked volume overload with few complaints of dyspnea or fatigue. However, many patients may have both dyspnea and volume overload. It is also important to note that these symptoms can vary considerably over time in a given patient. Historically, these signs and symptoms have been classified as being due to left ventricular failure, LVF (pulmonary congestion) or right ventricular failure, RVF (systemic congestion). Although most patients initially have LVF, the ventricles share a septal wall, and because LVF increases the workload of the right ventricle, both ventricles eventually fail and contribute to the heart failure syndrome. Because of the complex nature of this syndrome, it has become exceedingly more difficult to attribute a specific sign or symptom as caused by either RVF or LVF. Therefore, the numerous signs and symptoms associated with this disorder are collectively attributed to heart failure rather than to dysfunction of a specific ventricle.

CLINICAL PRESENTATION OF HEART FAILURE

GENERAL

Patient presentation may range from asymptomatic to cardiogenic shock.

SYMPTOMS

- Dyspnea, particularly on exertion
- Orthopnea
- Paroxysmal nocturnal dyspnea
- Exercise intolerance
- Tachypnea
- Cough
- Fatigue
- Nocturia
- Hemoptysis
- Abdominal pain
- Anorexia
- Nausea
- Bloating
- Ascites
- Mental status changes

SIGNS

- Pulmonary rales
- Pulmonary edema
- S₃ gallop
- Pleural effusion
- Cheyne-Stokes respiration
- Tachycardia

- Cardiomegaly
- Peripheral edema
- Jugular venous distension
- Hepatojugular reflux
- Hepatomegaly

LABORATORY TESTS

- BNP >100 pg/mL.
- Electrocardiogram: May be normal or could show numerous abnormalities including acute ST-T-wave changes from myocardial ischemia, atrial fibrillation, bradycardia, and left ventricular hypertrophy.
- Serum creatinine: May be increased owing to hypoperfusion. Preexisting renal dysfunction can contribute to volume overload.
- Complete blood count: Useful to determine if heart failure due to reduced oxygen-carrying capacity.
- Chest x-ray: Useful for detection of cardiac enlargement, pulmonary edema, and pleural effusions.
- Echocardiogram: Used to assess LV size, valve function, pericardial effusion, wall motion abnormalities, and ejection fraction.

Pulmonary congestion arises as the left ventricle fails and is unable to accept and eject the increased blood volume that is delivered to it. Consequently, pulmonary venous and capillary pressures rise, leading to interstitial and bronchial edema, increased airways resistance, and dyspnea. The associated signs and symptoms may include: (1) dyspnea (with or without exertion), (2) orthopnea, (3) paroxysmal nocturnal dyspnea (PND), and (4) pulmonary edema. Exertional dyspnea occurs when there is a reduction in the level of exertion that causes breathlessness. This is typically described as more breathlessness than was associated previously with a specific activity (e.g., vacuuming or stair climbing). As heart failure progresses, many patients eventually have dyspnea at rest.

Orthopnea is dyspnea that occurs with assumption of the supine position. It occurs within minutes of recumbency and is due to reduced pooling of blood in the lower extremities and abdomen. Orthopnea is relieved almost immediately by sitting upright and typically is prevented by elevating the head with pillows. A change in the number of pillows required to prevent orthopnea (e.g., a change from “two-pillow” to “three-pillow” orthopnea) suggests worsening heart failure. Attacks of PND typically occur after 2 to 4 hours of sleep; the patient awakens from sleep with a sense of suffocation. The attacks are due to severe pulmonary and bronchial congestion, leading to shortness of breath and wheezing. The reasons these attacks occur at night are unclear but may include: (1) reduced pooling of blood in the lower extremities and abdomen (as in orthopnea), (2) slow resorption of interstitial fluid from sites of dependent edema, (3) normal reduction in sympathetic activity that occurs with sleep (e.g., less support for the failing ventricle), and (4) the normal depression in respiratory drive that occurs with sleep.

Pulmonary edema is the most severe form of pulmonary congestion and is caused by accumulation of fluid in the interstitial spaces and alveoli. In heart failure patients, it is the result of increased pulmonary venous pressure. The patient experiences extreme breathlessness and anxiety and may cough pink, frothy sputum. Pulmonary edema can be terrifying for the patient, causing a feeling of suffocation or drowning.

Rales (crackling sounds heard on auscultation) are present in the lung bases owing to transudation of fluid into alveoli. The rales typically are bibasilar, but if they are heard unilaterally, they are usually right-sided. A third heart sound, or S₃ gallop, is heard frequently in patients with LVF and may be due to elevated atrial pressure and altered distensibility of the ventricle.

Systemic congestion is associated with a number of signs and symptoms. Jugular venous distension (JVD) is the simplest and most reliable sign of fluid overload. Examination of the right internal jugular vein with the patient at a 45-degree angle is the preferred method for assessing JVD. The presence of JVD more than 4 cm above the sternal angle suggests systemic venous congestion. In patients with mild systemic congestion, JVD may be absent at rest, but application of pressure to the abdomen will cause an elevation of JVD (hepatojugular reflux).

Peripheral edema is a cardinal finding in heart failure. Edema usually occurs in dependent parts of the body and thus is seen as ankle or pedal edema in ambulatory patients, although it may be manifested as sacral edema in bedridden patients. Adults typically have a 10-lb fluid weight gain before trace peripheral edema is evident; therefore, patients with acute heart failure may have no clinical evidence of systemic congestion except weight gain.

DIAGNOSIS¹

No single test is available to confirm the diagnosis of heart failure. Because the syndrome of heart failure can be caused or worsened by multiple cardiac and noncardiac disorders, accurate diagnosis is essential for development of therapeutic strategies. Heart failure often is suspected initially in a patient based on the symptoms. These frequently will include dyspnea, exercise intolerance, fatigue, and/or fluid retention. However, it must be emphasized that signs and symptoms lack sensitivity for diagnosing heart failure because these symptoms are found frequently with other disorders such as pulmonary disease. Even in patients with known heart failure, there is poor correlation between the presence or severity of symptoms and hemodynamic abnormality.

A complete history and physical examination are essential in the initial evaluation of a patient suspected of having heart failure. Particular attention should be paid to cardiovascular risk factors and to other disorders that can cause or exacerbate heart failure. Since coronary artery disease is the cause of heart failure in nearly 70% of patients, careful attention to and evaluation of the possibility of coronary disease is essential, especially in men. The patient's volume status should be documented by assessing the body weight, JVP, and presence or absence of pulmonary congestion and peripheral edema. Laboratory testing may assist in identification of disorders that cause or worsen heart failure. The initial evaluation should include a complete blood count, serum electrolytes (including magnesium), tests of renal and hepatic function, urinalysis, lipid profile, chest x-ray, and a 12-lead electrocardiogram (ECG). There are no specific ECG findings associated with heart failure. Measurement of BNP also may assist in differentiating dyspnea caused by heart failure from other causes.²³

Although the history, physical examination, and laboratory tests can provide important clues to the underlying cause of heart failure, imaging is required to identify any structural abnormality of the heart. In most patients, an echocardiogram is used to detect any valvular, pericardial, or myocardial abnormalities. The echocardiogram also can determine the presence of systolic and/or diastolic dysfunction and the left ventricular ejection fraction (LVEF).

► TREATMENT: Chronic Heart Failure

■ DESIRED OUTCOMES

For many years, the goals of therapy in the management of chronic heart failure were to improve the patient's quality of life, reduce symptoms, reduce hospitalizations, slow progression of the disease process, and prolong survival. Although these goals are still important, identification of risk factors for heart failure development and recognition of its progressive nature have led to increased emphasis on preventing the development of this disorder. With this in mind, the most recent ACC/AHA guidelines for the evaluation and management of chronic heart failure developed a new staging system that not only recognizes the evolution and progression of the disorder but also emphasizes risk-factor modification and preventive treatment strategies.¹ This system consists of four stages (Fig. 14–5). This staging system differs from the NYHA functional classification (Table 14–4) that most clinicians are familiar with. The NYHA system is intended primarily to classify *symptomatic* heart failure according to the clinician's subjective evaluation and does not recognize preventive measures or the progression of heart failure. A patient's symptoms can change frequently over a short period of time owing to changes in medications, diet, intercurrent illnesses, etc. For example, a patient with NYHA class IV symptoms with marked volume overload could improve rapidly to class II–III with aggressive diuretic therapy. Despite these limitations, this system can be useful for monitoring patients and is used widely in heart failure studies. However, the ACC/AHA staging system provides a more comprehensive framework for evaluation, prevention, and treatment of heart failure.

■ GENERAL MEASURES

The complexity of the heart failure syndrome necessitates a comprehensive approach to management that includes accurate diagnosis, identification and treatment of risk factors (e.g., diabetes, hypertension, and coronary artery disease), elimination or minimization of precipitating factors such as NSAIDs, and appropriate pharmacologic and nonpharmacologic therapy.

The first step in the management of chronic heart failure is to determine the etiology (see Table 14–1) and/or any precipitating factors. Treatment of underlying disorders such as anemia or hyperthyroidism may obviate the need for treatment of heart failure. Patients with valvular diseases may derive significant benefit from valve replacement or repair. Revascularization or anti-ischemic therapy in patients with coronary disease may reduce heart failure symptoms. Drugs that aggravate heart failure (see Table 14–3) should be discontinued, if possible.

Restriction of physical activity reduces cardiac workload and is recommended for virtually all patients with acute congestive symptoms. However, once the patient's symptoms have stabilized and excess fluid is removed, restrictions on physical activity are discouraged. In fact, current guidelines indicate that exercise training programs in stable heart failure patients improve exercise tolerance and functional capacity and may slow heart failure progression.¹

Because a major compensatory response in heart failure is sodium and water retention, restriction of fluid intake and dietary sodium is an important nonpharmacologic intervention. Fluid intake

TABLE 14-4. New York Heart Association Functional Classification

| Functional Class | Description |
|------------------|--|
| I | Patients with cardiac disease but without limitations of physical activities. Ordinary physical activity does not cause undue fatigue, dyspnea, or palpitations. |
| II | Patients with cardiac disease that results in slight limitations of physical activity. Ordinary physical activity results in fatigue, palpitations, dyspnea, or angina. |
| III | Patients with cardiac disease that results in marked limitation of physical activity. Although patients are comfortable at rest, less than ordinary activity will lead to symptoms. |
| IV | Patients with cardiac disease that results in an inability to carry on physical activity without discomfort. Symptoms of congestive heart failure are present even at rest. With any physical activity, increased discomfort is experienced. |

typically is limited to a maximum of about 2 L/day from all sources. The typical American diet contains 3 to 6 g sodium per day, and this should be reduced by about half (1.5 to 2 g sodium per day). This can be accomplished by not adding salt to prepared foods and eliminating foods high in sodium (e.g., salt-cured meats, salted snack foods, pickles, soups, delicatessen meats, and processed foods). Further reductions in dietary sodium can be achieved by eliminating salt from cooking. However, this is not recommended for most heart failure patients because excessive sodium restriction produces an unpalatable

diet, which leads to poor dietary compliance or compromised nutritional status. Additionally, the availability of potent diuretics makes excessive sodium restriction unnecessary in most cases. Although dietary sodium and water restriction should be instituted in all heart failure patients, pharmacologic therapy is required for slowing disease progression and prolonging survival and usually is necessary for control of symptoms. Thus all patients with systolic heart failure should be on pharmacologic therapy in addition to the nonpharmacologic therapies discussed earlier.

GENERAL APPROACH TO TREATMENT

4 Current ACC/AHA treatment guidelines are organized around the four identified stages of heart failure¹ (Figs 14-6 and 14-7). This staging system emphasizes the progressive nature of the disorder and targets treatment to prevent and/or slow the progression of heart failure.

TREATMENT OF STAGE A HEART FAILURE (SEE FIG. 14-6)

Patients in stage A do not have structural heart disease or symptoms but are at high risk for developing heart failure because of the presence of risk factors. The emphasis here is on identification and modification of these risk factors to prevent the development of structural heart disease and subsequent heart failure. Commonly encountered risk factors include hypertension, diabetes, and coronary artery disease. Although each of these disorders individually increases risk, they frequently co-exist in many patients and act synergistically to foster the development of heart failure. Effective control of blood pressure reduces the risk

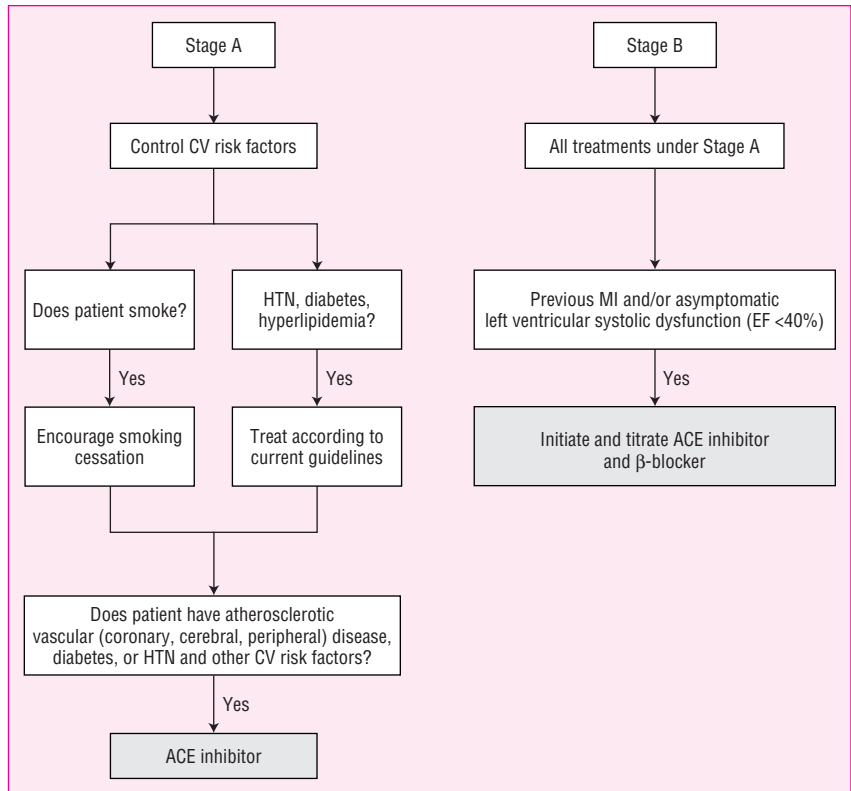

FIGURE 14-6. Treatment algorithm for patients with ACC/AHA stages A and B heart failure. (Adapted with permission from *Circulation* 2001;104:2996-3007.)

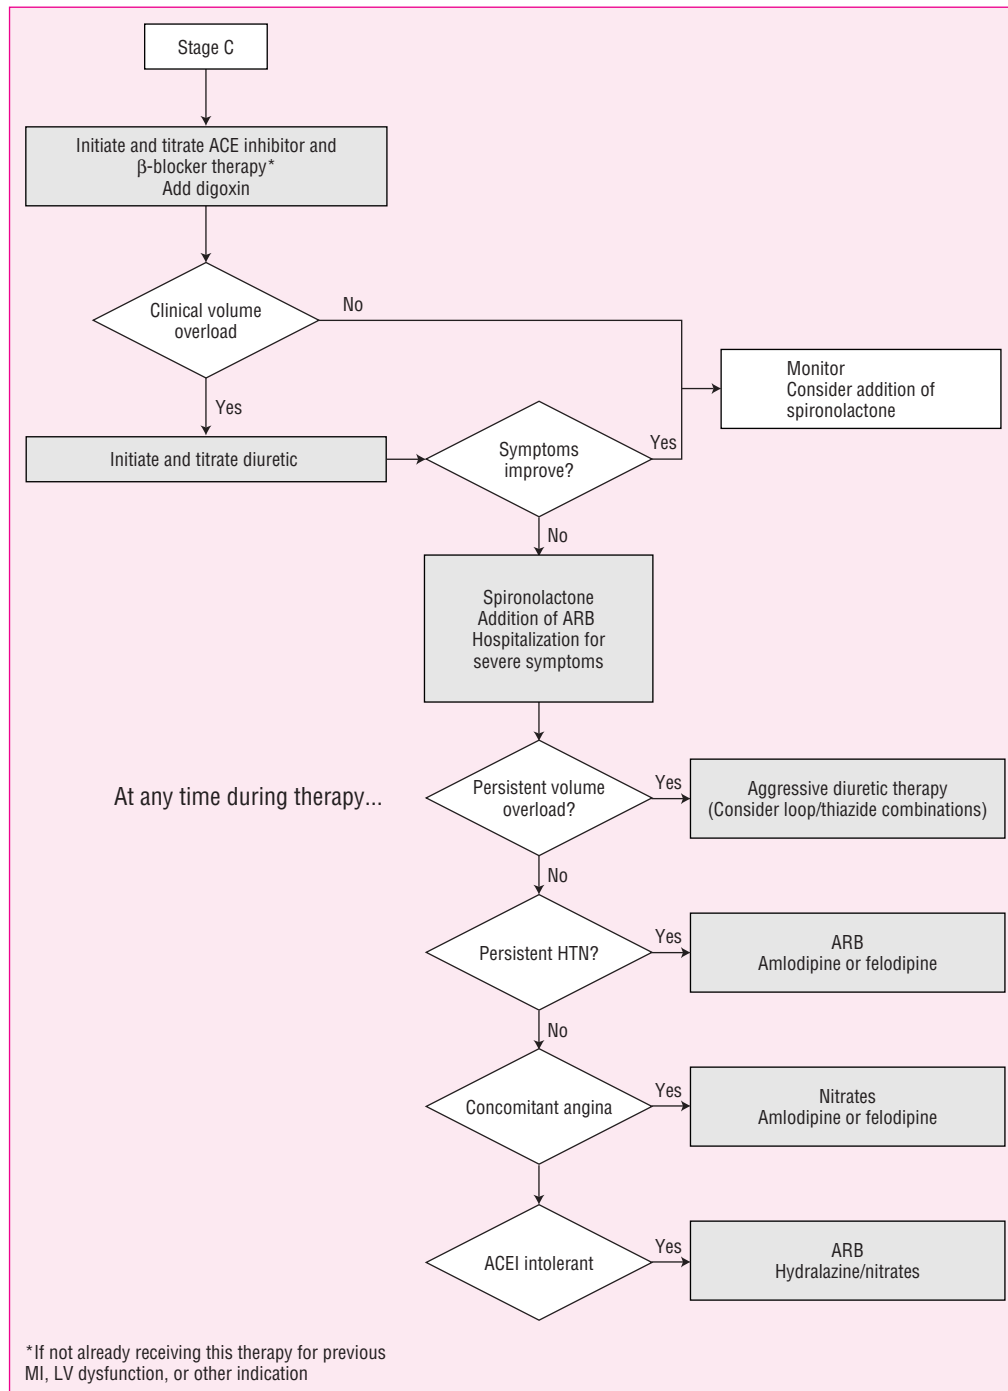

FIGURE 14-7. Treatment algorithm for patients with ACC/AHA stage C heart failure. (Adapted with permission from *Circulation* 2001;104:2996–3007.)

of developing heart failure by approximately 50%.³⁵ Control of hyperglycemia reduces the risk of end-organ damage and may decrease the risk of heart failure. Appropriate management of coronary artery disease and its associated risk factors is also important, including treatment of hyperlipidemia according to published guidelines and smoking cessation. Although treatment must be individualized, ACE inhibitors should be strongly considered for antihypertensive therapy in patients with multiple vascular risk factors.^{1,36,37} Diuretics and β -blockers also are useful in this setting.

■ TREATMENT OF STAGE B HEART FAILURE (SEE FIG. 14-6)

Patients in stage B have structural heart disease but do not have heart failure symptoms. This group includes patients with left ventricular hypertrophy or fibrosis, previous MI, valvular disease, or left ventricular systolic dysfunction. These individuals are at risk for developing heart failure, and treatment is targeted at minimizing additional injury and preventing or slowing the remodeling process. In addition to the treatment measures outlined in stage A, ACE inhibitors and

β -blockers are important components of therapy. Patients with a previous MI should receive both ACE inhibitors and β -blockers regardless of the ejection fraction (EF).¹ Similarly, patients with reduced EFs also should receive both these agents, whether or not they have had a MI.¹

■ TREATMENT OF STAGE C HEART FAILURE (SEE FIG. 14–7)

4 Patients with structural heart disease and previous or current heart failure symptoms are classified as stage C. It should be noted that stage C patients may have their symptoms classified as NYHA class I, II, III, or IV. Most patients in stage C should be treated routinely with four medications: an ACE inhibitor, a diuretic, a β -blocker, and digoxin (see “Standard First-Line Therapies” below). The benefits of these medications on slowing heart failure progression, reducing morbidity and mortality, and improving symptoms are clearly established. Aldosterone receptor antagonists, ARBs, and hydralazine-isosorbide dinitrate are also useful in selected patients. Other general measures also are important, including moderate sodium restriction, daily weight measurement, immunization against influenza and pneumococcus, modest physical activity, and avoidance of medications that can exacerbate heart failure. Recent evidence suggests that careful follow-up and patient education that reinforces dietary and medication compliance can prevent clinical deterioration and reduce hospitalization.¹

■ TREATMENT OF STAGE D HEART FAILURE

Stage D heart failure includes patients with symptoms at rest that are refractory despite maximal medical therapy. This includes patients who undergo recurrent hospitalizations or cannot be discharged from the hospital without special interventions. These individuals have the most advanced form of heart failure and should be considered for specialized therapies, including mechanical circulatory support, continuous positive inotropic therapy, cardiac transplantation, or hospice care. The approach to treatment of patients with stage D heart failure is discussed in more detail in the section “Treatment: Advanced/Decompensated Heart Failure.”

■ NONPHARMACOLOGIC THERAPY

Recent studies demonstrate that cardiac resynchronization therapy (CRT) offers a promising approach to selected patients with chronic heart failure.^{38,39} Delayed electrical activation of the left ventricle, characterized on the ECG by a QRS duration that exceeds 120 ms, occurs in approximately one-third of patients with moderate to severe systolic heart failure. Since the left and right ventricles normally activate simultaneously, this delay results in asynchronous contraction of the left and right ventricles, which contributes to the hemodynamic abnormalities of this disorder. Implantation of a specialized biventricular pacemaker to restore synchronous activation of the ventricles can improve ventricular contraction and hemodynamics. Recent trials show improvements in exercise capacity, NYHA classification, quality of life, hemodynamic function, and hospitalizations.^{38,39} A device that combined CRT with an implantable cardioverter-defibrillator (ICD) improved survival in addition to functional status.³⁹ CRT is currently indicated only in NYHA class III–IV patients receiving optimal medical therapy (ACE inhibitors, diuretics, β -blockers, and digoxin) and

with a QRS duration of 120 ms or greater and an ejection fraction of 35% or less.

Sudden cardiac death, primarily due to ventricular tachycardia and fibrillation, is responsible for 40% to 50% of the mortality in heart failure patients. In general, patients in the earlier stages of heart failure with milder symptoms are more likely to die from sudden death, whereas death from pump failure is more frequent in those with advanced heart failure. Most of these patients have complex and frequent ventricular ectopy, although it remains unknown whether these ectopic beats contribute to the risk of malignant arrhythmias or merely serve as markers for individuals at higher risk for sudden death. What is clear is that empirical treatment with class I antiarrhythmic agents, although they can suppress ventricular ectopy, adversely affects survival.⁴⁰ Unlike the class I drugs, the class III antiarrhythmic agent amiodarone has a low proarrhythmic potential, but it has not been shown consistently to prevent sudden death in patients with heart failure. Because of its lack of benefit, in addition to its multiple adverse effects and drug interactions, amiodarone is not recommended for the prevention of sudden death.¹ In cardiac arrest survivors with a reduced ejection fraction, the ICD is superior to antiarrhythmic drug therapy for improving survival.⁴¹ The role of the ICD in primary prevention of sudden death is less certain. Compared with antiarrhythmic drugs, an ICD improves survival in patients with coronary artery disease and an ejection fraction of 30% or less.⁴¹ However, the role of the ICD in patients with nonischemic cardiomyopathy and those with ejection fractions of 30% or greater remains an unsettled issue and hopefully will be clarified by the results on ongoing clinical trials. A thorough review of ICD therapy can be found in Chap. 17.

■ PHARMACOLOGIC THERAPY

■ STANDARD FIRST-LINE THERAPIES

4 A treatment algorithm for management of chronic (i.e., stage C) heart failure is shown in Fig. 14–7. It should be noted that patients with symptomatic systolic heart failure should be on all the drugs described in this section.¹

■ ACE Inhibitors

5 ACE inhibitors are the cornerstone of pharmacotherapy of patients with heart failure. By blocking the conversion of angiotensin I to angiotensin II by ACE, the production of angiotensin II and, in turn, aldosterone is decreased but not completely eliminated.^{42–44} This decrease in angiotensin II and aldosterone attenuates many of the deleterious effects of these neurohormones, including reducing ventricular remodeling, myocardial fibrosis, myocyte apoptosis, cardiac hypertrophy, NE release, vasoconstriction, and sodium and water retention.^{42,45} Thus ACE inhibitor therapy appears to play an important role in preventing angiotensin II–mediated progressive worsening of myocardial function. The endogenous vasodilator bradykinin, which is inactivated by ACE, is also increased by ACE inhibitors, along with the release of vasodilatory prostaglandins and histamine.^{42,45} The precise contribution of the effects of ACE inhibitors on bradykinin and vasodilatory prostaglandins is unclear. However, the persistence of clinical benefits with ACE inhibitors despite the fact that angiotensin II and aldosterone levels return to pretreatment levels suggests that this is a potentially important effect.^{43,44}

Numerous placebo-controlled trials have documented the favorable effects of ACE inhibitor therapy on hemodynamic variables,

clinical status, and symptoms in heart failure.^{5,45,46} Hemodynamic effects observed with long-term therapy include significant increases in cardiac index, stroke work index, and stroke volume index, as well as significant reductions in left ventricular filling pressure, SVR, MAP, and heart rate. Significant improvements in clinical status, functional class, exercise tolerance, and left ventricular size also are well documented. When compared with placebo, patients treated with ACE inhibitors have fewer treatment failures, fewer hospitalizations, and fewer increases in diuretic dosages.^{1,5,46} The acute response to ACE inhibitor therapy is greater in patients with high levels of plasma renin activity. However, long-term hemodynamic and clinical responses to ACE inhibition cannot be predicted from the plasma renin activity or from response to the initial dose of ACE inhibitor.

The beneficial effect of ACE inhibitors on mortality has been documented conclusively, with numerous trials showing a 20% to 30% relative reduction in mortality with ACE inhibitor therapy compared with placebo.⁴⁶ A long-term (12-year) follow-up of the Studies of Left Ventricular Dysfunction (SOLVD) prevention and treatment trials demonstrated sustained survival benefits in patients treated with enalapril.⁴⁷ In addition to improving survival, ACE inhibitors also reduce the combined risk of death or hospitalization, slow the progression of heart failure, and reduce the rates of reinfarction.⁴⁶ The benefits of ACE inhibitor therapy are independent of the etiology of heart failure (ischemic versus nonischemic) and are observed in patients with mild, moderate, or severe symptoms. ACE inhibitors clearly are superior to vasodilator therapy with hydralazine-isosorbide dinitrate.⁴⁸

The most common cause of heart failure is ischemic heart disease, where MI results in loss of myocytes, followed by ventricular dilatation and remodeling. Captopril, ramipril, and trandolapril all have been shown to benefit post-MI patients whether they are initiated early (within 36 hours) and continued for 4 to 6 weeks⁴⁹ or started later and administered for several years.⁴⁶ Collectively, these studies indicate that ACE inhibitors after MI improve overall survival, decrease the development of severe heart failure, and reduce reinfarction and heart failure hospitalization rates.^{46,49} The benefit occurs within the first few days of therapy and persists during long-term treatment. The effects are most pronounced in higher-risk patients, such as those with symptomatic heart failure or reduced EFs, with 20% to 30% reductions in mortality reported in these patients.^{46,49} Post-MI patients without heart failure symptoms or decreases in EF also benefit from ACE inhibitors, but the magnitude of this effect is less pronounced, with all-cause mortality reduced by 7% to 11%.⁴⁹

In addition to their benefits in patients with established heart failure, ACE inhibitors also are effective for prevention of heart failure. The SOLVD prevention trial showed that enalapril decreased the risk of hospitalization for worsening heart failure and reduced the composite end point of death and heart failure hospitalization in patients with asymptomatic left ventricular dysfunction.^{50,51} The development of diabetes mellitus, an important risk factor for cardiovascular disease that also increases morbidity and mortality in heart failure patients, is reduced by enalapril in patients with chronic heart failure.⁵² In a post-hoc analysis of the Heart Outcomes Prevention Evaluation (HOPE) trial, ramipril reduced the development of new-onset heart failure by nearly 25% in patients with normal EFs and no symptoms of heart failure.³⁶

Despite the overwhelming benefit demonstrated with ACE inhibitors, there is substantial evidence that these agents are underused and underdosed in patients with heart failure.^{53–55} These data indicate that significant numbers of heart failure patients do not receive ACE inhibitors, and of those who are receiving these agents, many may be taking lower than recommended doses.^{53–55} The most common reasons cited for underuse or underdosing are concerns about

safety and adverse reactions to ACE inhibitors, especially in patients with underlying renal dysfunction or hypotension. The use of ACE inhibitors in patients with renal insufficiency is particularly relevant because it occurs in 25% to 50% of heart failure patients and is associated with an increased risk of mortality.^{56,57} Recent evidence indicates that ACE inhibitors in post-MI patients with decreased left ventricular function may be more effective in patients with renal insufficiency.⁵⁸ In this retrospective cohort study, nearly 21,000 Medicare patients with confirmed MIs and EFs of less than 40% on hospital discharge were studied. In patients receiving an ACE inhibitor at hospital discharge, those with a serum creatinine level of greater than 3 mg/dL had a 37% increase in 1-year survival compared with only a 16% increase in patients with a serum creatinine level of less than 3 mg/dL. Since many heart failure patients have concomitant disorders (e.g., diabetes, hypertension, or previous MI) that also may be affected favorably by ACE inhibitors, renal dysfunction should not be a contraindication to ACE inhibitor use in patients with left ventricular dysfunction. However, these patients should be monitored carefully for the development of acute renal failure and/or hyperkalemia, with special attention to risk factors associated with this complication of ACE inhibitor therapy.^{56,57}

No dose-dependent differences in mortality have been reported for ACE inhibitors. In the ATLAS trial, over 3000 patients with NYHA class II–IV heart failure and an EF of 30% or less were randomized to receive either low-dose (2.5–5 mg/day) or high-dose (32.5–35 mg/day) lisinopril for a median of 45 months.⁵⁹ No differences in mortality were found between the high- and low-dose groups. However, the composite end point of death or hospitalization for any cause was reduced significantly by 12% and heart failure hospitalizations decreased by 24% in the high-dose group. In many positive trials of other heart failure therapies (e.g., β -blockers, aldosterone antagonists), intermediate ACE inhibitor doses generally were used as background therapy. These results emphasize that clinicians should attempt to use ACE inhibitor doses proven to be beneficial in clinical trials, but if these doses are not tolerated, lower doses can be used with the knowledge that there are likely only small differences in efficacy between the high and low doses.

In summary, the evidence that ACE inhibitors improve symptoms, slow disease progression, and decrease mortality in heart failure is unequivocal. As such, all patients with documented left ventricular dysfunction, irrespective of symptomatology, should receive ACE inhibitors unless there are contraindications or intolerance is present.¹

■ β -Blockers

6 It may seem paradoxical that within this chapter β -blockers are listed as drugs that may exacerbate or worsen heart failure (see Table 14–3) and as standard therapy for the management of chronic heart failure, but both are true. Initiation of β -blocker therapy at normal doses in patients with heart failure has the potential to lead to symptomatic worsening or decompensation owing to the drug's negative inotropic effect. However, there is also overwhelming evidence that if stable patients are initiated on low doses of a β -blocker, with slow upward dose titration over several weeks, they can expect to derive significant benefits. As such, the ACC/AHA guidelines on the management of heart failure recommend that β -blockers should be used in all patients with stable systolic heart failure unless they have a contraindication or have been shown clearly to be unable to tolerate β -blockers.¹ Patients should receive a β -blocker even if their symptoms are well controlled with diuretic and ACE inhibitor therapy because

they remain at risk for progression of disease. Additionally, it is not essential that ACE inhibitor doses are optimized prior to initiation of β -blocker therapy because patients are more likely to accrue benefit from addition of a β -blocker than from an increase in their ACE inhibitor dose.¹

β -Blockers have been studied extensively, with data on more than 10,000 participants of placebo-controlled trials. Carvedilol, metoprolol controlled release/extended release (CR/XL), and bisoprolol are the best studied of the β -blockers in heart failure. Each has been studied in large populations, with a primary study end point of mortality, and each has been shown to reduce mortality significantly compared with placebo. The CIBIS-II trial studied bisoprolol in over 2600 patients, most of whom had class III heart failure. The study was stopped prematurely because of the 34% reduction in mortality associated with bisoprolol.⁶⁰ Post-hoc analyses showed a 44% reduction in sudden death and a 26% reduction in death due to worsening heart failure. The data from the largest β -blocker mortality trial to date, Metoprolol CR/XL Randomised Intervention Trial in Congestive Heart Failure (MERIT-HF), were very similar to those with bisoprolol. In this study, nearly 4000 patients were randomized to metoprolol CR/XL (Toprol XL) or placebo.⁶¹ Most of the patients had class II or III heart failure. Again, the study was halted prematurely because of a 34% reduction in total mortality, with a 41% reduction in sudden death and a 49% reduction in death from worsening heart failure. Multiple post-hoc subgroup analyses suggested that all analyzed subgroups benefited from the therapy.

Following publication of these trials, the value of β -blockers in class II and III heart failure patients was clear, and they became standard therapy in these patients. However, there remained questions about their value or safety in patients with class IV heart failure. The Carvedilol, Prospective, Randomized, Cumulative Survival (COPERNICUS) trial was designed to test carvedilol in the severe heart failure population and, like the other studies, was stopped prematurely because of the drug's significant survival benefit.⁶² Specifically, carvedilol produced a 35% relative reduction in mortality and an impressive 7.1% absolute reduction in mortality (from 18.5% to 11.4%). Thus there is now clear evidence of benefit with β -blockers in all patients with symptomatic systolic heart failure.

In addition to data on the effects of β -blockers on survival, there are data showing improvements in numerous other end points. All the large clinical trials have shown β -blockers to produce 15% to 20% reductions in all-cause hospitalization and 25% to 35% reductions in hospitalizations for worsening heart failure.^{60,63,64} The positive effects of β -blockers on the left ventricle systolic function also have been very consistent across studies. Following several weeks to months of therapy, β -blockers have been documented consistently to increase EFs by 5 to 10 units (e.g., from an EF of 20% to 25% or 30%), to decrease ventricular mass, to improve the sphericity of the ventricle, and to reduce systolic and diastolic volumes (LVESV and LVEDV).^{65,66} These effects are often collectively called *reverse remodeling*, referring to the fact that they return the heart toward more normal size, shape, and function.

While the effects of β -blockers on survival prolongation and left ventricular reverse remodeling could be argued to be greater than those of any other drugs used in heart failure, this is not the case for their symptomatic benefits. Many, but not all studies, have shown improvements in the NYHA functional class, patient symptom scores or quality-of-life assessments (such as the Minnesota Living with Heart Failure Questionnaire), and exercise performance, as assessed by the 6-minute walk test.^{63–66} Thus it is important to educate patients that they will not necessarily notice dramatic symptomatic improvements with β -blocker therapy. However, even in the absence of symptomatic

improvement, positive effects on disease progression and survival are still anticipated.

A number of potential mechanisms have been suggested to explain the beneficial effects of β -blockers in heart failure patients. Although not clearly elucidated, it seems likely that the mechanisms of benefit include antiarrhythmic effects, slowing or reversing the detrimental ventricular remodeling caused by sympathetic stimulation, decreased myocyte death from catecholamine-induced necrosis or apoptosis, and prevention of fetal gene expression and the other detrimental effects of SNS activation described earlier.^{1,67}

■ **Use of β -Blockers in Heart Failure.** An important aspect to the safe use of β -blockers in heart failure is initiation of therapy at a low dose, with slow upward dose titration. Current guidelines recommend initiation of therapy once patients have been relatively stable for several weeks. However, a recent study indicated that initiation of carvedilol therapy before discharge in patients hospitalized for decompensated heart failure increased the number of patients treated with β -blockers compared with usual care and did not increase the risk of serious adverse effects.⁶⁸ Typically, starting doses have been 1/10 to 1/20 the final dose, with doses doubling no more frequently than every 2 weeks until the target dose is reached. The starting and target doses are described in Table 14–5. As shown in the table, the starting dose for bisoprolol is 1.25 mg/day. However, the smallest commercially available tablet of bisoprolol is a scored 5-mg tablet. Since the starting dosage of bisoprolol is not readily available, this drug is the least commonly used of the three agents, and it is not approved by the Food and Drug Administration (FDA) for use in heart failure.

Clinical questions about how high the dose should be are also common. There is strong evidence with carvedilol and metoprolol CR/XL that decreases in hospitalization depend on β -blocker dose, with greater benefit seen at higher doses.^{69,70} The data suggest that lower doses may prolong survival but that the benefits may be greater with higher doses.⁶⁹ It appears that an important guide to therapy is the patient's heart rate, and lower doses might be judged reasonable if the heart rate provides evidence of β -blockade.⁶⁹ Thus it seems important to make every effort to titrate patients to target doses when possible, although there are benefits over placebo at lower doses; thus any dose of β -blocker is likely to provide some benefit.

Education of patients about β -blocker therapy is also particularly important to ensure the greatest likelihood for success. It is essential that patients understand that there will be a long, slow upward titration of dose to attempt to get them to a specific target. They also need to be aware of the benefits of β -blocker therapy and that the β -blocker may make them feel worse during the initiation phase. If they understand the benefits, they are less likely to discontinue

TABLE 14–5. Initial and Target Doses for β -Blockers Used in Treatment of Heart Failure

| Drug | Initial Dose ^a | Target Dose |
|---|----------------------------|------------------------|
| Bisoprolol ^b | 1.25 mg qd | 10 mg qd |
| Carvedilol ^b | 3.125 mg bid | 25 mg bid ^d |
| Metoprolol succinate CR/XL ^b | 12.5–25 mg qd ^c | 200 mg qd |

^aDoses should be doubled approximately every 2 weeks or as tolerated by the patient until the highest tolerated or target dose is reached.

^bRegimens proven in large trials to reduce mortality.

^cIn MERIT-HF, the majority of class II patients were given 25 mg/day, whereas the majority of class III patients were given 12.5 mg/day as their starting dose.

^dTarget dose for patients >85 kg is 50 mg bid.

therapy if they do have some worsening of heart failure symptoms during the dose-titration phase. Nearly all patients can tolerate some dose of a β -blocker, and with good communication between the patient and health care provider(s), initiation of β -blocker therapy is likely to be successful.

Details regarding selection of a specific β -blocker are contained in the “Drug Class” section of this chapter. Based on the clinical trial data to date, there is some clarity on this issue. First, it seems clear that any assumptions about class effect should not be made and that therapy should be limited to carvedilol, metoprolol CR/XL, or bisoprolol. Additionally, the data provide reasonable evidence that it is inappropriate to assume that the cheaper immediate-release formulation of metoprolol tartrate will provide benefits equivalent to those of metoprolol CR/XL. And given that bisoprolol is not available in the necessary starting doses, the choice typically is limited to either carvedilol or metoprolol CR/XL. Many clinicians consider carvedilol to be the agent of choice, but there is no compelling evidence that it is superior to metoprolol CR/XL or bisoprolol. Please see the “Drug Class” section of this chapter for a more detailed discussion on the Carvedilol Or Metoprolol European Trial (COMET) comparing carvedilol with immediate-release metoprolol.

In summary, the data provide clear evidence that β -blockers slow the progression of heart failure, evidenced by reductions in mortality and hospitalizations. Many patients also will have improvements in quality of life associated with β -blocker therapy, although this is not a universal finding. Based on these data, β -blockers are recommended as standard therapy for all patients with systolic dysfunction, irrespective of the severity of their symptoms.

■ Diuretics^{71–73}

7 The compensatory mechanisms in heart failure stimulate excessive sodium and water retention, often leading to signs and symptoms of systemic and pulmonary congestion. Consequently, diuretic therapy is recommended for all patients with clinical evidence of fluid retention. Among the drugs used for management of heart failure, the diuretics are most rapid in producing symptomatic benefits. The majority of patients with heart failure will require chronic diuretic therapy to control their fluid status, and as such, diuretics represent a cornerstone of heart failure therapy. However, because they do not alter disease progression (or prolong survival), they are not considered mandatory therapy. Thus patients who do not have fluid retention would not require diuretic therapy.

The primary goal of diuretic therapy is to reduce symptoms associated with fluid retention and pulmonary congestion, improve quality of life, and reduce hospitalizations from heart failure. They accomplish this by decreasing edema and pulmonary congestion through reduction of preload. Although preload is a determinant of cardiac output, the Frank-Starling curve (see Fig. 14–3) shows that patients with congestive symptoms have reached the flat portion of the curve. A reduction in preload improves symptoms but has little effect on the patient’s stroke volume or cardiac output until the steep portion of the curve is reached. However, diuretic therapy must be used judiciously because overdiuresis can lead to a reduction in cardiac output and symptoms of dehydration.

Once diuretic therapy is initiated, dosage adjustments are based on symptomatic improvement and daily body weight. Change in body weight is a sensitive marker of fluid retention or loss, and it is recommended that patients monitor their status by taking daily morning body weights. Patients who gain a pound per day for several consecutive days or 3 to 5 lb in a week should contact their health care

provider for instructions (which often will be to increase the diuretic dose temporarily). Such action often will allow patients to prevent a decompensation that requires hospitalization.

■ **Thiazide Diuretics.** Thiazide diuretics such as hydrochlorothiazide block sodium and chloride reabsorption in the distal convoluted tubule (approximately 5% to 8% of filtered sodium). The thiazides therefore are relatively weak diuretics and infrequently are used alone in heart failure. However, as is reviewed in detail in the section “Treatment: Advanced/Decompensated Heart Failure” under “Diuretic Resistance,” thiazides or the thiazide-like diuretic metolazone can be used in combination with loop diuretics to promote a very effective diuresis.

■ **Loop Diuretics.** Loop diuretics are the most widely used diuretics in heart failure. They act in the thick ascending limb of the loop of Henle, where 20% to 25% of filtered sodium normally is reabsorbed. Because loop diuretics are highly bound to plasma proteins, they are not highly filtered at the glomerulus. They reach the tubular lumen by active transport via the organic acid transport pathway. Competitors for this pathway (probenecid or organic by-products of uremia) can inhibit delivery of loop diuretics to their site of action and decrease effectiveness. Loop diuretics also induce a prostaglandin-mediated increase in renal blood flow, which contributes to their natriuretic effect. Coadministration of NSAIDs and COX-2 inhibitors blocks this prostaglandin-mediated effect and can diminish diuretic efficacy. Unlike thiazides, loop diuretics maintain their effectiveness in the presence of impaired renal function, although higher doses are necessary to obtain adequate delivery of the drug to the site of action.

Heart failure is one of the disease states in which the maximal response to loop diuretics is reduced. This is believed to be the result of increased proximal or distal tubule reabsorption of sodium, which might occur owing to increased expression and activity of the Na-K-2Cl transporter.⁷¹ As a consequence, doses above the recommended ceiling doses produce no additional diuresis. Thus, once these doses are reached, it is recommended to give the diuretic more frequently for additional effect rather than to give progressively higher doses. The appropriate chronic dose is that which maintains the patient at a stable dry weight without symptoms of dyspnea. Ranges of doses of loop diuretics and recommended ceiling doses are shown in Table 14–6.

■ Digoxin

8 In 1785, William Withering was the first to report extensively on the use of foxglove, or *Digitalis purpurea*, for the treatment of dropsy (i.e., edema). Although digitalis glycosides have been in clinical use for more than 200 years, not until the 1920s were they clearly demonstrated to have a positive inotropic effect on the heart. Furthermore, it was not until the late 1980s that clinical trials were conducted to critically evaluate the role of digoxin in the therapy of chronic heart failure. The results of the Digitalis Investigation Group (DIG) trial helped to clarify the role of digoxin in this setting.⁷⁴ The view of digoxin also has shifted over the past decade. While historically it was considered to be useful in heart failure because of its positive inotropic effects, it now seems clear that its real benefits in heart failure are related to its neurohormonal modulating effects.

■ **Clinical Efficacy and Role in Therapy.** The efficacy of digoxin in patients with heart failure and supraventricular tachyarrhythmias such as atrial fibrillation is well established and widely accepted.^{75,76}

TABLE 14–6. Loop Diuretics: Use in Heart Failure

| | Furosemide | Bumetanide | Torsemide |
|---------------------------------|---------------|--------------|--------------|
| Usual daily dose (PO) | 20–160 mg/day | 0.5–4 mg/day | 10–80 mg/day |
| Ceiling dose ^a | | | |
| Normal renal function | 80–160 mg | 1–2 mg | 20–40 mg |
| CL _{CR} : 20–50 mL/min | 160 mg | 2 mg | 40 mg |
| CL _{CR} : <20 mL/min | 400 mg | 8–10 mg | 100 mg |
| Bioavailability | 10–100% | 80–90% | 80–100% |
| | Average, 50% | | |
| Affected by food | Yes | Yes | No |
| Half-life | 0.3–3.4 h | 0.3–1.5 h | 3–4 h |

^aCeiling dose: single dose above which additional response is unlikely to be observed.

Adapted from *Am J Med Sci.* 2000; 319:38–50.

Its role in heart failure patients with normal sinus rhythm has been considerably more controversial. Until the 1980s, most data supporting efficacy of digoxin in these patients came from anecdotal evidence and seriously flawed or uncontrolled studies. Since then, a number of clinical trials have shown that digoxin improves LVEF, quality of life, exercise tolerance, and heart failure symptoms.^{75,76} However, these studies involved small numbers of patients followed for short time periods, with many of the patients being withdrawn from preexisting digoxin treatment on entering the trial. Although these trials demonstrated hemodynamic and symptomatic improvement in heart failure patients receiving digoxin, an unresolved issue was the unknown effect of digoxin on mortality. This was of particular concern given the increased mortality seen with other positive inotropic drugs and finally led to organization and performance of the DIG trial to determine the effects of digoxin on survival in patients with heart failure in sinus rhythm.⁷⁴

The DIG trial was a double-blind, randomized, placebo-controlled trial with the primary end point of all-cause mortality.⁷⁴ Patients ($n = 6800$) with heart failure symptoms and an EF of 45% or less were eligible and followed for a mean of 37 months. Most patients received background therapy with diuretics and ACE inhibitors. The mean serum digoxin concentration achieved was 0.8 ng/mL after 12 months of therapy. No significant difference in all-cause mortality was found between patients receiving digoxin and placebo (34.8% and 35.1%, respectively). A trend toward lower mortality due to worsening heart failure was observed in the digoxin group, although this was offset by a trend toward an increased mortality from other cardiovascular causes (presumably arrhythmias) in patients receiving digoxin. Hospitalizations for worsening heart failure were reduced 28% by digoxin compared with placebo ($p < .001$), whereas hospitalizations for other cardiovascular causes were increased in the digoxin group. In all, 64.3% of digoxin-treated patients were hospitalized compared with 67.1% of patients receiving placebo ($p = .006$). Therefore, DIG is the first trial to show that a positive inotropic agent does not increase mortality in patients with heart failure.

Although digoxin does not improve survival in heart failure patients, multiple post-hoc analyses of data from studies evaluating the effect of digoxin withdrawal have helped to clarify the role of digoxin use for patients in sinus rhythm.^{75,76} Collectively, these studies suggested that the drug produces important symptomatic benefits and that digoxin withdrawal increased the risk of treatment failure and deterioration of exercise capacity and EF. Furthermore, the risk of symptomatic exacerbation of heart failure after digoxin discontinuation was highest in patients with the most severe symptoms.^{75,76} Based on this evidence, digoxin is now recommended for use in patients with

stage C heart failure, along with ACE inhibitors, β -blockers, and diuretics, to improve symptoms and clinical status.¹

The appropriate dose or target plasma concentration for digoxin also has been clarified by recent trials. One reported that an increase in the digoxin plasma concentration from a mean of 0.67 to 1.22 ng/mL resulted in only a minor increase in EF (23.7% to 27.1%) but no improvement in symptoms, exercise tolerance, or neurohormone levels.⁷⁷ Another study found that an increase in digoxin plasma concentration from 0.8 to 1.5 ng/mL produced no additional effect on EF and likewise did not improve other hemodynamic variables or indices of neurohormonal function.⁷⁸ Two recent retrospective analyses of the combined PROVED/RADIANCE database⁷⁹ and the DIG trial database⁸⁰ offer additional insights as to the clinical benefit of low serum digoxin concentrations in heart failure patients. While all patients in the PROVED and RADIANCE trials who continued to take digoxin did significantly better than those who were withdrawn, those who had plasma digoxin concentrations between 0.5 and 0.9 ng/mL were just as likely to be free of worsening heart failure as those with higher plasma concentrations. Retrospective analysis of the DIG trial database suggests that a serum digoxin concentration of 0.5 to 0.8 ng/mL may be associated with a reduction in mortality, whereas higher concentrations may increase mortality.⁸⁰ In another post-hoc analysis of the DIG trial, digoxin therapy was associated with an increased risk of death in women but not men.⁸¹

These results suggest that most of the benefit from digoxin is achieved at low plasma concentrations and that little additional effect is achieved with higher doses. Thus, for most patients, the target digoxin plasma concentration should be 0.5 to 1 ng/mL. This more conservative target also would be expected to decrease the risk of adverse effects from digoxin toxicity. In most patients with normal renal function, this plasma concentration range can be achieved with a daily dose of 0.125 mg. Patients with decreased renal function, the elderly, or those receiving interacting drugs (e.g., amiodarone) should receive 0.125 mg every other day. In patients with atrial fibrillation and a rapid ventricular response, the historic practice of increasing digoxin doses (and plasma concentrations) until rate control is achieved is no longer recommended. Digoxin alone is often ineffective to control ventricular response in patients with atrial fibrillation, and increasing the dose only increases the risk of toxicity. A recent study showed that digoxin combined with carvedilol is superior to either agent alone for controlling ventricular response in patients with atrial fibrillation and heart failure.⁸² Therefore, it should be dosed similarly irrespective of whether the patient is in sinus rhythm or atrial fibrillation. Adequate rate control can be achieved by adding a β -blocker or amiodarone. Several equations and nomograms have been proposed to estimate digoxin maintenance doses based on estimated renal function

for a particular patient and population pharmacokinetic parameters. These methods are reviewed extensively elsewhere.⁸³ In the absence of supraventricular tachyarrhythmias, a loading dose is not indicated because digoxin is a mild inotropic agent that will produce gradual effects over several hours, even after loading.

Digoxin's place in the pharmacotherapy of chronic heart failure therefore can be summarized for two patient groups. In patients with heart failure and supraventricular tachyarrhythmias such as atrial fibrillation, it should be considered early in therapy to help control ventricular response rate. For patients in normal sinus rhythm, although digoxin does not improve survival, its effects on symptom reduction and quality-of-life improvement are evident in patients with mild to severe heart failure. Therefore, it should be used together with other standard heart failure therapies, including diuretics, ACE inhibitors, and β -blockers, in patients with symptomatic heart failure. Clinicians may want to consider adding digoxin after instituting β -blocker therapy so that the potential bradycardic effect of digoxin does not preclude the use of a β -blocker.

■ OTHER HEART FAILURE THERAPIES

■ Aldosterone Antagonists

9 Spironolactone has long been recognized as an inhibitor of aldosterone that produces a weak, potassium-sparing diuretic effect. However, only recently have the cardiovascular effects of aldosterone been understood. As discussed in detail under "Pathophysiology" above, aldosterone is now recognized as a neurohormone that plays an important role in ventricular remodeling, particularly by causing increased collagen deposition in the extracellular matrix and thus causing cardiac fibrosis. Based on this knowledge, the effects of aldosterone antagonism by spironolactone were studied in 1600 patients with class III (with recent hospitalization) or class IV heart failure. This study (called RALES) tested addition of spironolactone 25 mg daily versus placebo to standard heart failure therapy, which included ACE inhibitor, a diuretic, and digoxin.²⁰ Owing to the timing of this trial, the benefits of β -blockers were not appreciated fully, and only 10% of patients were taking β -blockers. Patients with a serum creatinine concentration above 2.5 mg/dL or a serum potassium concentration above 5 mEq/L were excluded. The study was stopped prematurely after an average of 24 months of follow-up because of the significant reduction in mortality associated with spironolactone. Specifically, spironolactone was associated with a 30% reduction in total mortality, a 36% reduction in death due to progressive heart failure, and a 29% reduction in sudden deaths. Spironolactone also produced significant reductions in hospitalizations for cardiac causes and hospitalizations for heart failure. Active therapy also was associated with significant improvements in symptoms, as assessed by changes in NYHA functional class.

The low dose of spironolactone in the RALES study was well tolerated. The most common adverse effect was gynecomastia, which occurred in 10% of men on spironolactone and 1% of men on placebo, although only 10 patients (1.7% of men) in the spironolactone group discontinued therapy because of gynecomastia. It also produced statistically significant, although probably clinically unimportant, increases in serum creatinine and serum potassium levels of 0.05 to 0.10 mg/dL and 0.30 mEq/L, respectively. Serious hyperkalemia was not different between groups, occurring in 1% on placebo and 2% on spironolactone.

More recently, the EPHEsus trial evaluated the effect of an aldosterone-selective receptor antagonist eplerenone in patients with

left ventricular dysfunction after MI.²¹ Eplerenone or placebo was added to usual therapy (ACE inhibitor, β -blocker, aspirin, and diuretics in the majority) in 6642 patients, and similar to the RALES trial, patients were excluded who had serum creatinine concentrations of greater than 2.5 mg/dL or serum potassium concentrations of greater than 5 mEq/L. In this study, eplerenone was associated with a 13% reduction in death from any cause, with the greatest survival benefit appearing to be a reduction in sudden death from cardiac causes. And while there was no evidence for a reduction in hospitalizations from all causes, there was a 23% reduction in the risk of hospitalization from heart failure. Owing to the receptor-selective nature of eplerenone, it was not associated with gynecomastia. However, there was a significant difference in the incidence of serious hyperkalemia, occurring in 5.5% of eplerenone- and 3.9% of placebo-treated patients.

While the clinical trial evidence suggests minimal risk associated with aldosterone antagonists in the setting of heart failure, the data from clinical practice suggest a different picture. Several studies have highlighted that the risk of serious hyperkalemia and worsening renal function are much higher than observed in the clinical trials.^{84,85} These data suggest that 25% to 40% of patients develop hyperkalemia (>5 mEq/L) and that 10% to 12% develop serious hyperkalemia (>6 mEq/L). This may be due, in part, to failure of clinicians to consider the patient's renal function, to reduce or stop the patient's potassium supplementation, or to monitor renal function and potassium concentration closely once the aldosterone antagonist is initiated. However, even in closely monitored patients, the risk of hyperkalemia may remain high, particularly in the elderly and those with very low EFs.⁸⁴ Thus, if a clinician is to use an aldosterone antagonist, it must be done cautiously, with careful monitoring of renal function and potassium concentration and with avoidance of use in patients with significant renal impairment or high-normal potassium levels.

The benefits of aldosterone antagonists in heart failure appear to be due largely to their neurohormonal inhibition, namely, inhibition of aldosterone's actions in the heart. Specifically, the benefits are believed to be due to the ability of these agents to inhibit aldosterone-mediated cardiac fibrosis and thus ventricular remodeling.⁸⁶ And while spironolactone historically has been viewed as a diuretic, this is believed to contribute little to its benefits in heart failure in part because the doses used have minimal diuretic effect.²⁰ Thus, as with ACE inhibitors and β -blockers, the data on aldosterone antagonists also support the neurohormonal model of heart failure.

Taken together, the RALES and EPHEsus trials provide evidence of benefit from aldosterone antagonists at the two extremes of the heart failure spectrum, namely, after MI (NYHA class I) and NYHA class IV. While the benefits of aldosterone antagonists in patients with class II or stable class III heart failure have not been studied, it would be reasonable to speculate that benefit might exist. The place of aldosterone antagonists in therapy remains to be fully elucidated; however, it seems reasonable to consider their addition to standard therapy in patients who are similar to those enrolled in the RALES and EPHEsus trials. For patients who fall outside the populations studied in these clinical trials, there are no clear guidelines on aldosterone antagonist use. For such patients, it might be reasonable to consider use of an aldosterone antagonist if the patient requires potassium supplementation. The premise for use in this setting would be that reduction or elimination of the potassium supplement might be possible and that there also would be potential for additional benefit with respect to altering the disease course. Addition of spironolactone to class II or III heart failure patients who remain symptomatic despite optimal therapy is also a reasonable consideration.

TABLE 14–7. Clinical Trials of Candesartan in Heart Failure

| Trial | Drug | Patient Population | Primary End Point | Results (%) | | Adjusted Hazard Ratio | p Value |
|-------------------|-------------------------|---|---------------------------------------|-------------|---------|-----------------------|---------|
| | | | | Drug | Placebo | | |
| CHARM-Added | Candesartan vs. placebo | Symptomatic HF and EF ≤ 40% on ACE inhibitors | CV death or hospital admission for HF | 37.9 | 42.3 | 0.85 | 0.01 |
| CHARM-Alternative | Candesartan vs. placebo | Symptomatic HF and EF ≤ 40%, ACE inhibitor intolerant | CV death or hospital admission for HF | 33.0 | 40.0 | 0.70 | <0.0001 |
| CHARM-Preserved | Candesartan vs. placebo | Symptomatic HF and EF ≥ 40% | CV death or hospital admission for HF | 22.0 | 24.3 | 0.86 | 0.051 |
| CHARM-Overall | Candesartan vs. placebo | Combined from preceding three trials | All-cause mortality | 23.0 | 25 | 0.90 | 0.032 |

■ Angiotensin II Receptor Blockers

51 The use of angiotensin II receptor blockers (ARBs) in heart failure has generated great interest and controversy. The crucial role of the RAA system in heart failure development and progression is well established, as are the benefits of RAA system inhibition with ACE inhibitors. However, chronic administration of ACE inhibitors can result in *ACE escape*, with increased circulating angiotensin II, NE, and aldosterone.^{20,43,44} In addition, angiotensin II can be formed in a number of tissues, including the heart, through non-ACE-dependent pathways (e.g., chymase, cathepsin, and kallikrein).^{14,87} Therefore, blockade of the detrimental effects of angiotensin II by ACE inhibition is incomplete. In addition, troublesome adverse effects of ACE inhibitors such as cough are linked to accumulation of bradykinin associated with these agents.¹³ The ARBs block the angiotensin II receptor subtype AT₁, preventing the deleterious effects of angiotensin II, regardless of its origin. They do not appear to affect bradykinin.^{14,87} By inhibiting both the formation of angiotensin II and its effects on the AT₁ receptor, combination therapy with an ACE inhibitor and an ARB offers a theoretical advantage over either agent used alone by more complete blockade of the deleterious effects of angiotensin II. Also, by directly blocking AT₁ receptors, ARBs would allow unopposed stimulation of AT₂ receptors, causing vasodilation and inhibition of ventricular remodeling.^{14,87} Because the bradykinin-related adverse effects of ACE inhibitors such as angioedema and cough lead to drug discontinuation in some patients, the potential for an ARB to produce similar clinical benefits with fewer side effects is of great interest. Whether ARBs add incremental benefit to current established therapies or are superior (or equivalent) to ACE inhibitors is the focus of several clinical trials.

Initial studies indicate that ARBs and ACE inhibitors produce similar hemodynamic effects and that combination therapy improves exercise capacity, ventricular function, quality of life, and neurohormones in heart failure patients.^{14,87} The ELITE II trial was the first to compare the effects of an ARB (losartan) with those of an ACE inhibitor (captopril) on all-cause mortality in patients with NYHA class II–IV heart failure.⁸⁸ No significant difference in mortality between the two groups was observed, although losartan was better tolerated than captopril. The Val-HeFT trial evaluated whether the addition of valsartan to standard background heart failure therapy (which included an ACE inhibitor in 93% and a β -blocker in 35% of patients) improved survival.⁸⁹ The addition of valsartan had no effect on all-cause mortality but produced a 13% reduction in morbidity and mortality (principally due to reductions in heart failure hospitalizations). Subgroup analysis showed that the benefits were greatest in

patients not receiving background ACE inhibitor therapy, and detrimental effects were found in those who had valsartan added to ACE inhibitor and β -blocker. Based on these results, valsartan is now approved for use in patients intolerant to ACE inhibitors. Although this study suggests a benefit of combined ARB-ACE inhibitor therapy, it does not provide clear support for use of the combination, especially in patients receiving β -blocker therapy.

The Candesartan in Heart Failure: Assessment of Reduction in Mortality and Morbidity (CHARM) trials were designed as three studies to compare candesartan with placebo in patients with symptomatic heart failure⁹⁰ (Table 14–7). Both the CHARM-Added⁹¹ and the CHARM-Alternative⁹² trials found significant reductions in the primary end point of cardiovascular death or hospitalization for heart failure in patients receiving candesartan, although the benefit was modest in CHARM-Added. By the end of the CHARM-Added trial, over 60% of patients were receiving β -blocker therapy, but unlike the Val-HeFT trial, no adverse interaction with β -blockers was detected. No significant benefit of candesartan was observed in the CHARM-Preserved trial.⁹³ Overall, candesartan was well tolerated, but its use was associated with an increased risk of hypotension, hyperkalemia, and renal dysfunction.

The Valsartan in Acute Myocardial Infarction Trial (VALIANT) compared the effects of valsartan, captopril, and the combination of the two agents in post-MI patients with symptomatic heart failure, left ventricular dysfunction, or both.⁹⁴ The primary end point of total mortality occurred in 19.3% of patients receiving valsartan and captopril, 19.5% of captopril-treated patients, and 19.9% of the valsartan-treated group. Thus, in this high-risk post-MI population, valsartan was as effective as captopril in reducing the risk of death, but combination therapy only increased the risk of adverse effects and did not improve survival compared with monotherapy with either agent.

The ACC/AHA guidelines, developed before the Val-HeFT, CHARM, and VALIANT trials were completed, indicate that ARBs should not be considered equivalent or superior to ACE inhibitors and that they should be considered in patients who are intolerant of ACE inhibitors.¹ Collectively, the results of these trials clearly support this recommendation. For patients unable to tolerate an ACE inhibitor, usually due to intractable cough or angioedema, an ARB is a safe and effective alternative, although caution still should be exercised when it is used in patients with angioedema from ACE inhibitors. ARBs are not an alternative in patients with hypotension, hyperkalemia, or renal insufficiency secondary to ACE inhibitors because they are as likely to cause these adverse effects. The specific drugs and doses proven to be effective in clinical trials should be used. The role of ARBs as an adjunct to ACE inhibitors remains controversial.

The CHARM-Added trial found that the addition of candesartan to ACE inhibitor and β -blocker therapy produced incremental reductions in cardiovascular death and hospitalizations for heart failure but did not improve overall survival.⁹¹ In contrast, VALIANT found no benefit from the addition of valsartan to ACE inhibitor treatment in post-MI patients, and post-hoc analysis of Val-HeFT suggested potential harm in patients receiving both ACE inhibitors and β -blockers.^{89,94} These results suggest that the addition of an ARB to optimal heart failure therapy (ACE inhibitors, β -blockers, diuretics, etc.) offers, at best, marginal benefits with increased risk of adverse effects. Thus, until additional data are available, ACE inhibitor and β -blocker therapy should be optimized first before considering the addition of an ARB.

■ Nitrates and Hydralazine

5 Nitrates and hydralazine were combined originally in the treatment of heart failure because of their complementary hemodynamic actions. Nitrates, by activating guanylate cyclase to increase cyclic guanosine monophosphate (cGMP) in vascular smooth muscle, are primarily venodilators, thus producing reductions in preload.⁴² Hydralazine is a direct-acting vasodilator that acts predominantly on arterial smooth muscle to reduce SVR and increase stroke volume and cardiac output (see Fig 14–1); its effects on preload are minimal.⁴² Recent evidence suggests that these agents also may have beneficial effects in heart failure beyond their hemodynamic actions by inhibiting the ventricular remodeling process, preventing nitrate tolerance, and attenuating cellular mechanisms associated with heart failure progression.^{1,5}

Compared with placebo, the combination of hydralazine and isosorbide dinitrate (ISDN) reduced mortality in patients receiving diuretics and digoxin (but not ACE inhibitors or β -blockers).⁹⁵ However, another trial comparing the combination with an ACE inhibitor found that mortality was lower in the ACE inhibitor group.⁴⁸ Adverse effects (primarily headache and gastrointestinal complaints) with combined hydralazine-ISDN were common, limiting their use in many patients. Patient compliance also was an important issue because hydralazine-ISDN therapy was given four times daily in these trials. Whether less frequent administration provides equivalent benefit is unknown.

Current guidelines recommend that hydralazine-ISDN should not be used instead of ACE inhibitors as standard therapy in heart failure or substituted for ACE inhibitors in patients who are tolerating an ACE inhibitor.¹ The combined use of hydralazine-ISDN may be considered a therapeutic option in patients unable to take an ACE inhibitor or an ARB because of renal insufficiency, hyperkalemia, or possibly hypotension. However, it should be anticipated that compliance with this regimen will be poor and the risk of adverse effects high. Therefore, given the proven benefits and low risk of adverse effects, many clinicians now prefer ARBs in patients who cannot tolerate an ACE inhibitor. There are no controlled trials evaluating the benefits of adding hydralazine-ISDN therapy to patients who remain symptomatic despite ACE inhibitor and/or β -blocker treatment.

■ TREATMENT OF CONCOMITANT DISORDERS

Heart failure is often accompanied by other disorders whose natural history or therapy may affect morbidity and mortality. In selected patients, optimal management of these concomitant disorders may have a profound impact on heart failure symptoms and outcomes.

■ Hypertension

Although ischemic heart disease has replaced hypertension as the most common cause of heart failure, still nearly two-thirds of heart failure patients currently have hypertension or a previous history of hypertension.¹ Hypertension can contribute directly to the development of heart failure and also contributes indirectly by increasing the risk of coronary artery disease. Pharmacotherapy of hypertension in patients with heart failure initially should involve agents that can treat both disorders, such as ACE inhibitors, β -blockers, and diuretics. If control of hypertension is not achieved after optimizing treatment with these agents, the addition of an ARB or a second-generation calcium channel blocker such as amlodipine (or possibly felodipine) should be considered. Medications that should be avoided include the calcium channel blockers with negative inotropic effects (e.g., verapamil, diltiazem, and most dihydropyridines) and direct-acting vasodilators (e.g., minoxidil) that cause sodium retention.

■ Angina

Coronary artery disease is the most common heart failure etiology. Appropriate management of coronary artery disease and its risk factors is thus an important strategy for the prevention and treatment of heart failure. Coronary revascularization should be strongly considered in patients with both heart failure and angina.¹ Pharmacotherapy of angina in patients with heart failure should use drugs that can treat both disorders successfully. Nitrates and β -blockers are effective antianginal agents and are the preferred agents for patients with both disorders because they may improve hemodynamics and clinical outcomes.¹ It should be noted that the antianginal effectiveness of these agents may be significantly limited if fluid retention is not controlled with diuretics. Similar to their use in hypertension, both amlodipine and felodipine appear to be safe to use in this setting.

■ Atrial Fibrillation

Atrial fibrillation is the most frequently encountered arrhythmia, and it is found commonly in patients with heart failure, affecting 10% to 50% of patients.⁹⁶ The high incidence of atrial fibrillation in the heart failure population is not surprising because each of these two disorders predisposes to the other, and they share many risk factors, including coronary artery disease and hypertension. The presence of atrial fibrillation in patients with heart failure is associated with a worse long-term prognosis. The combination of atrial fibrillation and heart failure may exert a number of detrimental effects that include increased risk of thromboembolism secondary to stasis of blood in the atria, a reduction in cardiac output owing to loss of the atrial contribution to ventricular filling, and hemodynamic compromise from the rapid ventricular response. Moreover, heart failure exacerbations and atrial fibrillation are linked closely, and it is often difficult to determine which disorder caused the other. For example, worsening heart failure results in volume overload, which, in turn, causes atrial distension and increases the risk of atrial fibrillation. Similarly, atrial fibrillation with a rapid ventricular response can reduce cardiac output and lead to heart failure exacerbation. Thus optimal management of both conditions is required, with careful attention paid to control of ventricular response and anticoagulation for stroke prevention (see Chap. 17).

Because of the close association between atrial fibrillation, heart failure exacerbations, and hospitalizations, many clinicians prefer

maintenance of sinus rhythm with antiarrhythmic drugs to the rate-control approach in the treatment of patients with both disorders. However, it must be noted that the benefits of restoring and maintaining sinus rhythm remain unclear in this population and is not without risk. Although the recently completed AFFIRM study showed no difference in outcomes between the rhythm-control and rate-control approaches, less than 10% of the patients in this study had significant left ventricular dysfunction.⁹⁷ An ongoing clinical trial should help to clarify the best approach to these difficult to manage patients.⁹⁶ In general, amiodarone is the preferred agent if the rhythm-control approach is taken. Although it has many noncardiac toxicities, amiodarone does not have cardiodepressant or significant proarrhythmic effects. Dofetilide also appears to be safe and effective in this population. Class I antiarrhythmics should be avoided.

■ Diabetes Mellitus

Diabetes is highly prevalent in the heart failure population, with current estimates indicating that it is present in approximately one-third of heart failure patients.^{1,98} Diabetes may contribute directly to systolic or diastolic dysfunction, as well as indirectly by contributing to the development of coronary artery disease. Diabetes is an independent risk factor for developing heart failure, and its presence is associated with a hastened progression of heart failure and worse prognosis.

Pharmacotherapy of diabetes in heart failure patients is complicated by concerns about adverse effects with metformin and the thiazolidinedione (TZD) drugs (rosiglitazone and pioglitazone). The beneficial effects of these agents on glucose control and cardiovascular risk factors lead to their widespread use in patients with heart failure despite the warnings in the product labeling against their use in heart failure.⁹⁹ Metformin is contraindicated for use in patients with heart failure requiring pharmacologic treatment because of the risk of lactic acidosis. Although the mechanisms are presently unclear, the TZDs are associated with weight gain, peripheral edema, and heart failure. The TZD package insert indicates that these agents should not be used in patients with class III or IV heart failure because they may cause intravascular volume expansion and heart failure exacerbation. Most clinical trials with these drugs excluded patients with moderate to severe heart failure; thus the evidence supporting this precaution comes mainly from retrospective analyses and case reports. Because of the potential risk, a recent consensus statement indicates that TZDs should not be used in patients with NYHA class III or class IV heart failure.⁹⁸ TZDs should be used cautiously in patients with class I or

II symptoms, and close observation is needed to detect weight gain, edema formation, or heart failure exacerbation.⁹⁸

■ DRUG CLASS INFORMATION

■ ACE Inhibitors

◀ A number of ACE inhibitors are available currently in the United States; those approved for use in heart failure are summarized in Table 14–8. The major differences in the ACE inhibitors are not in their pharmacologic properties but in their pharmacokinetic properties. Although it appears that mortality reduction with ACE inhibitors is probably a drug class effect, not all ACE inhibitors FDA approved for treatment of heart failure have been tested for their effects on mortality in heart failure. Thus it seems most prudent to use those agents which have been documented to prolong survival because the dose required for this effect has been documented. Table 14–8 also contains a summary of the target doses for survival benefit.

To minimize the risk of hypotension and renal insufficiency, ACE inhibitor therapy should be started with low doses, followed by gradual titration to the target doses as tolerated.¹ Asymptomatic hypotension should not be considered a contraindication to initiation of an ACE inhibitor. Renal function and serum potassium concentration should be evaluated within 1 to 2 weeks after therapy is started with periodic assessments, especially after dose increases. Careful attention to appropriate doses of diuretics is important because fluid overload may blunt the beneficial effects of ACE inhibitors, and overdiuresis increases the risk of hypotension and renal insufficiency. After titration of the drug to the target dose, most patients tolerate chronic therapy with few complications. Although symptoms may improve within a few days of initiating therapy, it may take weeks to months before the full benefits are apparent. Even if symptoms do not improve, long-term ACE inhibitor therapy should be continued to reduce the risk of mortality and hospitalization.

Because of the high prevalence of coronary artery disease in patients with heart failure, aspirin frequently is coadministered with ACE inhibitors. Several retrospective cohort analyses suggest that aspirin may attenuate the hemodynamic and mortality benefits of ACE inhibitors.¹⁰⁰ The postulated mechanism of this interaction involves opposing effects on synthesis of vasodilatory prostaglandins. The ACE inhibitor–mediated increase in bradykinin increases the synthesis of vasodilatory prostaglandins that have favorable hemodynamic benefits in heart failure. Because of aspirin's effect

TABLE 14–8. ACE Inhibitors Approved for Use in Heart Failure

| Generic Name | Brand Name | Initial Dose | Target Dosing Survival Benefit ^a | Prodrug | Elimination ^b |
|--------------|-------------------|-----------------|---|---------|--------------------------|
| Captopril | Capoten | 6.25 mg tid | 50 mg tid | No | Renal |
| Enalapril | Vasotec | 2.5–5 mg bid | 10 mg bid | Yes | Renal |
| Lisinopril | Zestril, Prinivil | 2.5–5 mg qd | 20–40 mg qd ^c | No | Renal |
| Quinapril | Accupril | 10 mg bid | 20–40 mg bid ^d | Yes | Renal |
| Ramipril | Altace | 1.25–2.5 mg bid | 5 mg bid | Yes | Renal |
| Fosinopril | Monopril | 5–10 mg qd | 40 mg qd ^d | Yes | Renal/hepatic |
| Trandolapril | Mavik | 0.5–1 mg qd | 4 mg qd | Yes | Renal/hepatic |

^aTarget doses associated with survival benefits in clinical trials.

^bPrimary route of elimination.

^cNote that in the ATLAS trial,⁵⁷ no significant difference in mortality was found between low dose (~5 mg/day) and high dose (~35 mg/day) lisinopril therapy.

^dEffects on mortality have not been evaluated.

Abbreviations: tid = three times daily; bid = twice daily; qd = once daily.

on prostaglandin synthesis, this potentially beneficial action of ACE inhibitors may be negated. However, in contrast with studies that showed an ACE inhibitor–aspirin interaction, other investigators have found no interaction^{101,102} or that the effect of aspirin is dose-related.¹⁰³ Since there is no prospective evidence confirming an interaction between these agents, it is currently recommended that the decision to use each of these medications be made based on whether an individual patient has indications for each drug. Use of aspirin doses of 160 mg/day or less may be considered.

■ **Adverse Effects of ACE Inhibitors.** The primary adverse effects of ACE inhibitor therapy are secondary to their major pharmacologic effects of angiotensin II suppression and increased bradykinin. The reductions in angiotensin II are associated with hypotension and functional renal insufficiency, which are the most common adverse effects observed with ACE inhibitors. Hypotension may be asymptomatic or manifested as dizziness, light-headedness, presyncope, or syncope. It occurs most commonly early in therapy or after an increase in dose, although it may occur at any time during treatment. Risk factors for hypotension include hyponatremia (serum sodium concentration <130 mEq/L), hypovolemia, and overdiuresis.¹ The occurrence of hypotension may be minimized by initiating therapy with lower ACE inhibitor doses and/or temporarily withholding or reducing the dose of diuretic and liberalizing salt intake.¹ An often-overlooked solution to hypotension is to space the administration times of vasoactive medications (e.g., diuretics and β -blockers) throughout the day so that these medications are not all administered at or near the same time. Many patients who experience symptomatic hypotension early in therapy are still good candidates for long-term treatment if risk factors for low blood pressure are addressed.

Functional renal insufficiency is manifested as increases in serum creatinine and blood urea nitrogen. As cardiac output and renal blood flow decline, renal perfusion is maintained by the vasoconstrictor effect of angiotensin II on the efferent arteriole. Patients most dependent on this system for maintenance of renal perfusion (and therefore most likely to develop functional renal insufficiency with ACE inhibitors) are those with severe heart failure, hypotension, hyponatremia, volume depletion, and concomitant use of NSAIDs.^{56,57} Sodium depletion (usually secondary to diuretic therapy) is the most important factor in the development of functional renal insufficiency with ACE inhibitor therapy. Renal insufficiency therefore can be minimized in many cases by reduction in diuretic dosage or liberalization of sodium intake. In some patients, the serum creatinine concentration will return to baseline levels without a reduction in ACE inhibitor dose.⁵⁶ Since renal dysfunction with ACE inhibitors is secondary to alterations in renal hemodynamics, it is almost always reversible on discontinuation of the drug.^{56,57}

Careful dose titration can minimize the risks of hypotension and transient worsening of renal function. Thus usual initial doses should be about one-fourth the final target dose, with slow upward dose titration over several days based on blood pressure and serum creatinine concentration. In certain patients, especially hospitalized patients who seem at high risk for hypotension or worsening of renal function, it also may be advisable to initiate therapy with a short-acting agent such as captopril. This will help to minimize the duration of adverse effects should they occur. Once the patient is stabilized on ACE inhibitor therapy with captopril, he or she then can be switched to a longer-half-life drug.

Retention of potassium with ACE inhibitor therapy can occur and is due to the reduced feedback of angiotensin II to stimulate aldosterone release. Hyperkalemia is most likely to occur in patients with renal insufficiency and in those taking concomitant

potassium supplements, potassium-containing salt substitutes, or potassium-sparing diuretic therapy, especially if they have diabetes.⁵⁷ The more widespread use of aldosterone antagonists (e.g., spironolactone) in patients with heart failure may increase the risk of hyperkalemia.¹⁰⁴

A dry, hacking cough occurs with a similar frequency (5% to 15% of patients) with all the agents and is related to bradykinin accumulation. The cough is usually nonproductive, occurs within the first few months of therapy, resolves within 1 to 2 weeks of drug discontinuation, and reappears with rechallenge. Cough occurs in up to 40% of patients with heart failure independent of ACE inhibitor use, although ACE inhibitors increase its incidence significantly. However, in large clinical trials, only about 1% of participants discontinued ACE inhibitor therapy because of cough. Because cough is a bradykinin-mediated effect, replacement of ACE inhibitor therapy with an ARB would be reasonable in patients who cannot tolerate the cough. Angioedema is a rare but potentially life-threatening complication that is also believed to be related to bradykinin accumulation. Use of ACE inhibitors is contraindicated in patients with a history of angioedema. Rash and dysgeusia are troublesome side effects of ACE inhibitor therapy that appear to be more common with high doses; the rash may resolve with continued therapy.

■ β -Blockers

6 Metoprolol CR/XL, carvedilol, and bisoprolol all have been shown to reduce mortality in heart failure and are the β -blockers discussed here. The initial and target doses are shown in Table 14–5. Metoprolol is a lipophilic β_1 -selective blocker, bisoprolol is a hydrophilic β_1 -selective blocker, and carvedilol is a nonselective β -blocker with α_1 -blocker and antioxidant effects. Despite some studies aimed at addressing the issue, there is no clear evidence that these pharmacologic differences have any important effects on the outcomes associated with β -blockers in heart failure. However, their pharmacologic differences may aid in selection of a specific agent. For example, the α_1 -blockade of carvedilol causes more hypotension and dizziness than metoprolol or bisoprolol.¹⁰⁵ Thus metoprolol or bisoprolol may be preferred in patients with low blood pressure or in whom dizziness would be especially problematic. Conversely, carvedilol may be preferred in patients whose blood pressure is poorly controlled because it would be expected to have a greater antihypertensive effect than the others.

Bisoprolol is eliminated about 50% by renal elimination, whereas metoprolol and carvedilol are essentially completely metabolized and undergo extensive hepatic first-pass metabolism. Both metoprolol and carvedilol are also substrates for the cytochrome P450 2D6, which is known to be polymorphic. Thus the 7% of the white population and 1% to 2% of the Asian-American and African-American populations who are CYP2D6 poor metabolizers would be expected to have more pronounced effects than anticipated at the usual doses of carvedilol and metoprolol.

An important issue regarding use of β -blockers in heart failure is whether the benefits seen represent a class effect, and if not, which drug(s) should be used. The evidence that benefits of β -blockers in heart failure should not be viewed as a class effect is fairly strong. Specifically, a study powered for mortality reduction showed that bucindolol was no different from placebo.¹⁰⁶ There has been much debate since publication of this trial about why this particular β -blocker failed to show benefit, but most practitioners now believe it relates to ancillary properties of the drug that were counterproductive in heart failure, namely, intrinsic sympathomimetic activity or

central sympatholytic effects.^{107,108} Unlike many other drug classes, the various β -blockers have differing receptor selectivities and other ancillary properties. As such, it is even more critical for β -blockers than other drug classes to confine use to agents that have proven efficacy in clinical trials.

There also has been much debate about whether carvedilol is superior to metoprolol or bisoprolol and whether immediate-release metoprolol has equivalent efficacy to metoprolol CR/XL, the formulation studied in the MERIT-HF trial. Despite the differing properties of carvedilol versus metoprolol or bisoprolol, the clinical trials data provided little evidence for superiority of one drug over another. Specifically, mortality reduction versus placebo for each of these drugs was identical (34% to 35%). Yet questions persist about potential superiority of carvedilol, in part because it appears to be superior in its effects on certain parameters, such as change in EF, and certain hemodynamic responses at peak exercise.^{65,66}

To address the issue of superiority of carvedilol, a head-to-head clinical trial (COMET) of carvedilol versus immediate-release metoprolol tartrate was undertaken.¹⁰⁹ Consistent with the hypothesis that carvedilol tartrate has superior effects, this trial showed that mortality was 17% lower in patients treated with carvedilol 25 mg twice daily than in those treated with immediate-release metoprolol 50 mg twice daily. While this trial may have been expected to settle the debate, there were several concerns with the design of the study. First, the study did not use metoprolol CR/XL, the formulation that had been shown previously to be superior to placebo. It had long been thought that the pharmacokinetic profile of metoprolol CR/XL, which provides more sustained β -blockade, might make this formulation superior to immediate-release metoprolol. More significant were the concerns that the doses used in COMET did not provide equivalent β -blockade.¹¹⁰ Specifically, it was felt that the dosing of carvedilol was much more aggressive than that of metoprolol. This is supported in part by the fact the target metoprolol dose in COMET was 100 mg/day (50 mg twice daily), whereas the target metoprolol dose in the MERIT-HF trial was 200 mg/day. While there are differences in the first-pass effects of the CR/XL and immediate-release formulations, it still seems likely that the degree of β -blockade achieved in COMET with immediate-release metoprolol 50 mg twice daily is less than that achieved in the MERIT-HF trial with metoprolol CR/XL 200 mg/day or that achieved by carvedilol 25 mg twice daily. Thus the question about whether carvedilol is superior to metoprolol CR/XL at similar β -blocking doses remains and is one that is not likely to be answered by a subsequent clinical trial.

Thus the clinical trial data suggest that we should only use drugs that have been shown superior to placebo in large mortality trials. And while some clinicians would argue superiority of carvedilol, it seems clear that what is most important is that one of the three proven β -blockers is used in all heart failure patients.

Diuretics⁷³

Loop diuretics, as described earlier, represent the typical diuretic therapy for patients with heart failure due to their potency and, as such, are the only diuretics discussed here. There are currently three loop diuretics available that are used routinely: furosemide, bumetanide, and torsemide. They share many similarities in their pharmacodynamics, with their differences being largely pharmacokinetic in nature. Relevant information on the loop diuretics is shown in Table 14–6. Following oral administration, the peak effect with all the agents occurs in 30 to 90 minutes, with duration of 2 to 3 hours (slightly longer for torsemide). Following intravenous administration, the diuretic effect begins within minutes. All three drugs are

highly (>95%) bound to serum albumin and enter the nephron by active secretion in the proximal tubule. The magnitude of effect is determined by the peak concentration achieved in the nephron, and there is a threshold concentration that must be achieved before any diuresis is seen.

The biggest difference between the agents is bioavailability. Bioavailability of bumetanide and torsemide is essentially complete (80% to 100%), whereas furosemide bioavailability exhibits marked intra- and interpatient variability. Furosemide bioavailability ranges from 10% to 100%, with an average of 50%. Thus, if bioequivalent intravenous and oral doses are desired, oral furosemide doses should be approximately double that of the intravenous dose, whereas intravenous and oral doses are the same for torsemide and bumetanide. Coadministration of furosemide and bumetanide with food can decrease bioavailability significantly, whereas food has no effect on bioavailability of torsemide. The intraabdominal congestion that can occur in heart failure also may slow the rate (and thus decrease the peak concentration) of furosemide, which can reduce the diuretic's efficacy. Thus furosemide is most problematic with respect to rate and extent of absorption and the factors that influence it, whereas torsemide has the least variable bioavailability.

Recent data suggest that these differences in bioavailability and variability may have clinical implications. For example, several studies have suggested that torsemide is absorbed reliably and is associated with better outcomes than the more variably absorbed furosemide.^{111,112} And while the costs of torsemide exceed those of furosemide, pharmacoeconomic analyses suggest that the costs of care are similar or less with torsemide.¹¹² These data require confirmation in controlled, double-blinded clinical trials but provide preliminary evidence that the more reliably absorbed loop diuretics may be superior to furosemide.

As noted in the previous section on diuretics, the loop diuretics exhibit a ceiling effect in heart failure, meaning that once the ceiling dose is reached, no additional response is achieved by increasing the dose. Thus, when this dose is reached, additional diuresis is achieved by giving the drug more often or by giving combination diuretic therapy. The ceiling doses are listed in Table 14–6. While some heart failure patients take their diuretic once per day, many will take it twice per day and a small percentage three times per day. Multiple daily dosing is somewhat common in heart failure because of the ceiling-dose effects and to achieve a more sustained diuresis throughout the day. When dosed two or three times daily, the first dose is usually given first thing in the morning and the final dose in late afternoon/early evening.

Diuretics cause a variety of metabolic abnormalities, with severity related to the potency of the diuretic. The reader is referred to Chap. 13 for a detailed discussion on the adverse effects of diuretic therapy. The most common metabolic disturbance associated with both thiazide and loop diuretics is hypokalemia, which in heart failure patients may be exacerbated by hyperaldosteronism. Hypokalemia in these patients also is accompanied frequently by hypomagnesemia, and since adequate magnesium is necessary for entry of potassium into the cell, magnesium supplementation also is necessary sometimes in order to correct the hypokalemia. Hypokalemia is especially worrisome in the setting of heart failure because it can precipitate ventricular arrhythmias, a common mode of death for these patients. Digoxin-associated arrhythmias are also more common with concurrent hypokalemia. Concomitant ACE inhibitor and/or aldosterone antagonist therapy may help to minimize diuretic-induced hypokalemia because these drugs tend to increase serum potassium concentration through their effects on aldosterone. Nonetheless, the serum potassium concentration should be monitored closely in heart failure patients and supplemented appropriately when needed.

Data from Reuning RH, Geraets DR, Rocci ML, Vlasses PH. Digoxin. In: Evans WE, Schentag JJ, Jusko WJ, eds. *Applied Pharmacokinetics: Principles of Therapeutic Drug Monitoring*, 3d ed. Spokane, WA, Applied Therapeutics, 1992: 20-1–20-48.

Digoxin

Pharmacology. Digoxin exerts its positive inotropic effect by binding to sodium- and potassium-activated adenosine triphosphatase (Na⁺,K⁺-ATPase or sodium pump).^{75,76} Inhibition of Na⁺,K⁺-

ATPase decreases outward transport of sodium and leads to increased intracellular sodium concentrations. Higher intracellular sodium concentrations favor calcium entry and reduce calcium extrusion from the cell through effects on the sodium-calcium exchanger.⁷⁵ The result is increased storage of intracellular calcium in the sarcoplasmic reticulum and, with each action potential, a greater release of calcium to activate contractile elements. Digoxin also has beneficial neurohormonal actions. These effects occur at low plasma concentrations, where little inotropic effect is seen, and are independent of inotropic activity.^{75,76} Unlike other positive inotropes that increase intracellular cAMP, digoxin attenuates the excessive SNS activation present in heart failure patients.^{75,76} Although the precise mechanism is unknown, a digoxin-mediated reduction in central sympathetic outflow and improvement in impaired baroreceptor function appear to play an important role.^{75,76} Because mortality and progression of heart failure are linked to the extent of SNS activation, these sympathoinhibitory effects may be an important component of the clinical response to the drug. Chronic heart failure is also marked by autonomic dysfunction, most notably suppression of the parasympathetic (vagal) system.⁷⁵ Digoxin increases parasympathetic activity in heart failure patients and leads to a decrease in heart rate, thus enhancing diastolic filling.^{75,76} The vagal effects also result in slowed conduction and prolongation of atrioventricular node refractoriness, thus slowing the ventricular response in patients with atrial fibrillation. Because atrial fibrillation is a common complication of heart failure, the combined positive inotropic, neurohormonal, and negative dromotropic effects of digoxin can be particularly beneficial for such patients. The overall

TABLE 14–10. Digoxin Drug Interactions

| Drug | Mechanism/Effect | Suggested Clinical Management |
|--|---|---|
| Amiodarone | Inhibits P-glycoprotein resulting in decrease in renal and nonrenal clearance; can increase SDC by 70–100% | Monitor SDC and adverse effects; anticipate the need to reduce the dose by 50% |
| Antacids | Concurrent administration may decrease digoxin bioavailability by 20–35% | Space doses at least 2 h apart or avoid concurrent use if possible |
| Cholestyramine, colestipol | Bind digoxin in gut and decrease bioavailability 20–35%; also may decrease enterohepatic recycling | Space doses at least 2 h apart or avoid concurrent use if possible |
| Diuretics | Thiazides or loop diuretics may cause hypokalemia and hypomagnesemia, thereby increasing the risk of digitalis toxicity | Monitor and replace electrolytes if necessary |
| Erythromycin, clarithromycin, tetracycline | Alter gut bacterial flora; bioavailability and SDC increase 40–100% in about 10% of patients who extensively metabolize digoxin in the gut, also may be due to inhibition of P-glycoprotein by macrolides | Monitor SDC and anticipate the need to reduce the dose; avoid concurrent use if possible |
| Ketoconazole, itraconazole | Decrease in renal and nonrenal clearance by inhibition of P-glycoprotein; SDC may increase by 50–100% | Monitor SDC and anticipate the need to reduce the dose by 50% |
| Kaolin-pectin | Large dose (30–60 mL) may decrease digoxin bioavailability by about 60% | Space doses at least 2 h apart or avoid concurrent use if possible |
| Metoclopramide | Increase in gut mobility may decrease bioavailability of slowly dissolving tablets; unknown significance | Effect is minimized by administration of digoxin capsules |
| Neomycin, sulfasalazine | Decrease in bioavailability by 20–25% | Space doses at least 2 h apart or avoid concurrent use if possible |
| Propafenone | Decrease in renal clearance; SDC may increase 30–40% | Monitor SDC and anticipate the need to reduce the dose |
| Quinidine | Inhibits P-glycoprotein resulting in decrease in renal and nonrenal clearance; also displacement of digoxin from tissue binding sites with decrease in the volume of distribution; SDC generally increases about twofold. | Monitor SDC and anticipate the need to reduce dose by 50% |
| Spironolactone | Decrease in renal and nonrenal clearance; also interference with some digoxin assays thus increasing apparent SDC | Monitor SDC and anticipate the need to reduce dose; check assay for interference |
| Verapamil | Inhibits P-glycoprotein resulting in decrease in renal and nonrenal clearance, SDC may increase 70–100% | Monitor SDC and anticipate the need to reduce the dose by 50%; consider using another calcium channel blocker |

SDC = serum digoxin concentration.

response to digoxin is usually an increase in cardiac index, a decrease in SVR, PAOP, and plasma NE, but relatively little change in arterial blood pressure.^{75,76}

■ **Pharmacokinetics.** Numerous studies of digoxin pharmacokinetics have been published and are summarized in Table 14–9.⁸³ Digoxin has a large volume of distribution and is extensively bound to various tissues, most notably to Na⁺,K⁺-ATPase in skeletal and cardiac muscles. Because it does not distribute appreciably to body fat, loading doses of digoxin (when necessary) should be calculated based on estimates of lean body weight. There is a long “distribution phase” after administration of oral or intravenous digoxin, resulting in a lag time before maximum pharmacologic response is observed (see Table 14–9). Transiently elevated serum digoxin concentrations (SDCs) during the distribution phase are not associated with increased therapeutic or adverse effects, although they can mislead the clinician who is unaware of the timing of blood sampling relative to the previous digoxin dose. Consequently, blood samples for measurement of SDCs should be collected at least 6 hours and preferably 12 hours or more after the last dose.

In patients with normal renal function, 60% to 80% of a dose of digoxin is eliminated unchanged in urine via glomerular filtration and tubular secretion. The terminal half-life of digoxin is approximately 1.5 days in subjects with normal renal function but approximately 5 days in anuric patients (see Table 14–9). Recent evidence indicates that the drug efflux transporter P-glycoprotein (P-gp) plays an important role in the bioavailability, renal and nonrenal clearance, and drug interactions with digoxin.¹¹³ Clinically important pharmacokinetic/pharmacodynamic drug interactions are summarized in Table 14–10. An extensive review of the pharmacokinetics and pharmacodynamics of digoxin is available.⁸³

■ **Adverse Effects.** Digoxin can produce a variety of cardiac and noncardiac adverse effects, but it is usually well tolerated by most patients^{75,76} (Table 14–11). Noncardiac adverse effects frequently involve the central nervous system or gastrointestinal system but also may be nonspecific (e.g., fatigue or weakness). Cardiac manifestations include numerous different arrhythmias that are believed to be caused by multiple electrophysiologic effects (see Table 14–11). Cardiac arrhythmias may be the first evidence of toxicity in a patient (before any noncardiac symptoms occur). Rhythm disturbances are of particular concern because patients with chronic heart failure are already at increased risk for sudden cardiac death presumably owing

TABLE 14–11. Signs and Symptoms of Digoxin Toxicity

Noncardiac (Mostly CNS) Adverse Effects

Anorexia, nausea, vomiting, abdominal pain
Visual disturbances, such as halos, photophobia, problems with color perception (i.e., red-green or yellow-green vision), scotomata
Fatigue, weakness, dizziness, headache, neuralgia, confusion, delirium, psychosis

Cardiac Adverse Effects^{a,b}

Ventricular arrhythmias
Premature ventricular depolarizations, bigeminy, trigeminy, ventricular tachycardia, ventricular fibrillation
Atrioventricular (AV) block
First degree, second degree (Mobitz type I), third degree
AV junctional escape rhythms, junctional tachycardia
Atrial arrhythmias with slowed AV conduction or AV block
Particularly paroxysmal atrial tachycardia with AV block
Sinus bradycardia

^aSome adverse effects may be difficult to distinguish from the signs/symptoms of heart failure.

^bDigoxin toxicity has been associated with almost every known rhythm abnormality (only the more common manifestations are listed).

Compiled from *Circulation* 1999;99:1265–1270; *Prog Cardiovasc Dis*. 2002;44:251–266; and from Reuning RH, et al: *Digoxin*. In: Evans WE, Schentag JJ, Jusko WJ, eds. *Applied Pharmacokinetics: Principles of Therapeutic Drug Monitoring*, 3rd ed. Spokane, WA, Applied Therapeutics, 1992:20–1–20–48.

to ventricular arrhythmias. Patients at increased risk of toxicity include those with impaired renal function, decreased lean body mass, the elderly, and those taking interacting drugs. Hypokalemia, hypercalcemia, and hypomagnesemia will predispose patients to cardiac manifestations of digoxin toxicity. Thus concomitant therapy with diuretics may lead to electrolyte abnormalities and increase the likelihood of cardiac arrhythmias. Similarly, hypothyroidism, myocardial ischemia, and acidosis also will increase the risk of cardiac adverse effects. Although digoxin toxicity is associated commonly with plasma concentrations greater than 2 ng/mL, clinicians should remember that digoxin toxicity is based on the presence of symptoms rather than a specific plasma concentration. Usual treatment of digoxin toxicity includes drug withdrawal or dose reduction and treatment of cardiac arrhythmias and electrolyte abnormalities. In patients with life-threatening digoxin toxicity, purified digoxin-specific Fab antibody fragments provide reversal of adverse effects within 1 hour in over 90% of patients.

► **TREATMENT: Advanced/Decompensated Heart Failure^{114,115}**

10 As discussed previously, the number of patients with heart failure is substantial and continues to increase. Although mortality from heart failure has improved, the growing number of patients with the disorder and the progressive nature of the syndrome have led to substantial increases in hospitalizations for heart failure.³ Recent data indicate that nearly 1 million patients are hospitalized annually for heart failure, resulting in significant morbidity, reduced quality of life, and consumption of large quantities of health care resources.³ In fact, the majority of costs for the treatment of heart failure are attributed to patients admitted to the hospital. Inpatient admission for heart failure exacerbations is associated with an increased risk of subsequent hospitalization and decreased long-term survival.¹¹⁴

A number of descriptive terms have been used to identify this group of patients. Patients with *advanced*, *end-stage*, or *refractory heart failure* are those with persistent symptoms despite optimal therapy with ACE inhibitors, β -blockers, diuretics, and digoxin (i.e., stage

D in the ACC/AHA classification scheme).^{114,115} The terms *decompensated heart failure* and *exacerbation of heart failure* refer to patients with acute worsening of their baseline symptoms that is usually caused by volume overload and/or hypoperfusion. Irrespective of the term used, these forms of severe heart failure may be caused by progression of the underlying disorder or by other intercurrent events that result in worsening of the patient’s symptoms. Early identification and aggressive management of patients with advanced heart failure hopefully will reduce morbidity, mortality, and cost of care.

■ **PATHOPHYSIOLOGY AND CLINICAL PRESENTATION**

Patients requiring intensive therapy for advanced heart failure may present via several pathways. Patients with chronic progressive heart

failure can become refractory to available oral therapy and decompensate following a relatively mild insult (e.g., dietary indiscretion), from medical noncompliance, from a noncardiac concurrent illness (e.g., infection), or simply from a progressive reduction in cardiac output (*low-output syndrome*). A new cardiac event, such as recurrent MI, atrial fibrillation, myocarditis, or acute valvular insufficiency, also can cause a stable patient to decompensate. A third group of patients consists of those with acute massive MI whose initial presentation is severe heart failure. Regardless of their presentation, these patients represent the most advanced stage of heart failure.

The general pathophysiologic determinants of myocardial systolic (preload, afterload, or inotropy) and diastolic function (ventricular compliance or lusitropic function) in these patients are essentially the same as described earlier in this chapter. However, the severity of their symptoms, lack of cardiopulmonary reserve, and potential for adverse responses to intervention make successful treatment of these patients a challenge.

■ GENERAL APPROACH TO TREATMENT

◀ The overall goals of therapy in the patient with advanced/decompensated heart failure are to relieve symptoms of congestion and edema and improve the hemodynamic profile so that the patient can be discharged in a compensated (euvolemic) state on oral drug therapy. Although diuretic, vasodilator, and positive inotrope therapy can be very effective at achieving these goals, their efficacy must be balanced against the potential for serious toxicity. Thus another important goal is to minimize the risks of pharmacologic therapy. Maintenance of vital organ perfusion to preserve renal function and prevent additional myocardial injury is as important a goal as is prevention of diuretic-induced electrolyte depletion, hypotension from vasodilators, and myocardial ischemia and arrhythmias from positive inotropes.

A careful history and physical examination are key components in the diagnosis of decompensated heart failure. The history should focus on the potential etiologies of heart failure; the presence of any precipitating factors; onset, duration, and severity of symptoms; and a careful medication history. Important elements of the physical examination include vital signs, cardiac auscultation for heart sounds and murmurs, pulmonary examination for the presence of rales, the presence of peripheral edema, and weight. The JVP is a reliable indicator of the patient's volume status and should be evaluated carefully on admission and followed closely as an indicator of the efficacy of diuretic therapy.

The development of a bedside assay for plasma BNP has focused considerable attention on the use of BNP as an aid in the diagnosis of suspected heart failure. Plasma BNP concentration is positively correlated with the degree of left ventricular dysfunction and heart failure, and this assay is now used frequently in acute care settings to assist in the differential diagnosis of dyspnea [heart failure versus asthma, chronic obstructive pulmonary disease (COPD), or infection]. Recent studies found that an elevated BNP concentration is an independent predictor of heart failure as the cause of dyspnea and that in patients with decompensated heart failure, an elevated pre-hospital discharge BNP concentration is associated with an increased risk of death or readmission.^{116,117} Additional research is ongoing to better characterize the role of BNP measurement in the diagnosis and treatment of heart failure.

Patients should be admitted to an intensive care unit (ICU) for decompensated heart failure when they show signs of significant systemic hypoperfusion (e.g., severe fatigue, shortness of breath at rest,

hypotension, altered mental status, or decreased renal function), develop pulmonary vascular congestion requiring mechanical ventilation, manifest symptomatic sustained tachyarrhythmias, or require potent intravenous vasoactive or inotropic drugs or mechanical ventricular assistance. However, most patients do not require ICU admission and are admitted to a monitored unit or general medical floor. Reversible or treatable causes of the patient's decompensation, such as a thyroid disorder or anemia, should be addressed and corrected. The need for drugs that may aggravate heart failure (e.g., calcium channel blocking drugs, antiarrhythmics, and NSAIDs) should be evaluated carefully and discontinued when possible.

The first step in the management of advanced heart failure is to ascertain that optimal treatment with oral medications has been achieved. If fluid retention is evident on physical examination, aggressive diuresis should be accomplished. Although increasing the dose of oral diuretic may be effective in some cases, the use of intravenous diuretics frequently is necessary. Most patients should be receiving digoxin at a low dose prescribed to achieve a trough serum concentration of 0.5 to 1 ng/mL.¹ Additionally, every effort should be made to optimally treat the patient with an ACE inhibitor. Although β -blockers generally should not be started during this period of instability, it is desirable to continue their administration, if possible, in patients who are receiving them on a chronic basis. However, discontinuation occasionally may be necessary because some patients with advanced heart failure may not be able to tolerate target doses of both ACE inhibitors and β -blockers.

There are two general approaches to maximize therapy in the advanced/decompensated heart failure patient. One is to use simple clinical parameters (i.e., signs and symptoms, blood pressure, and renal function), and the other is to use invasive hemodynamic monitoring. However, it is frequently necessary to combine the two approaches.

■ PRINCIPLES OF THERAPY BASED ON CLINICAL PRESENTATION^{114,115,118}

Appropriate medical management of the patient presenting with advanced heart failure is aided by determination of whether the patient has signs and symptoms of fluid overload ("wet" heart failure) or low cardiac output ("dry" heart failure).^{115,118} Most patients present with congestion (or the wet profile). Symptoms of an elevated filling pressure include orthopnea and dyspnea with minimal exertion and can lead to systemic symptoms such as gastrointestinal discomfort, ascites, and peripheral edema. Patients with no or minimal fluid overload (or the dry category of advanced heart failure) may have symptoms that are more difficult to distinguish. This is a syndrome of low cardiac output and is characterized principally by fatigue and other symptoms not commonly attributed to cardiac causes, such as poor appetite, nausea, and early satiety. Moreover, these patients frequently exhibit worsening renal function and a decline in serum sodium level. Many patients will present with signs and symptoms of both types of advanced heart failure. In these patients, low-output symptoms may not be obvious until congestion is treated. Based on the assessment of wet versus dry heart failure, the algorithm in Fig. 14–8 may be considered.

■ PRINCIPLES OF THERAPY BASED ON HEMODYNAMIC SUBSETS

Patients with severe heart failure may have critically reduced cardiac output, usually with low arterial blood pressure and systemic hypoperfusion resulting in organ system dysfunction (i.e., cardiogenic

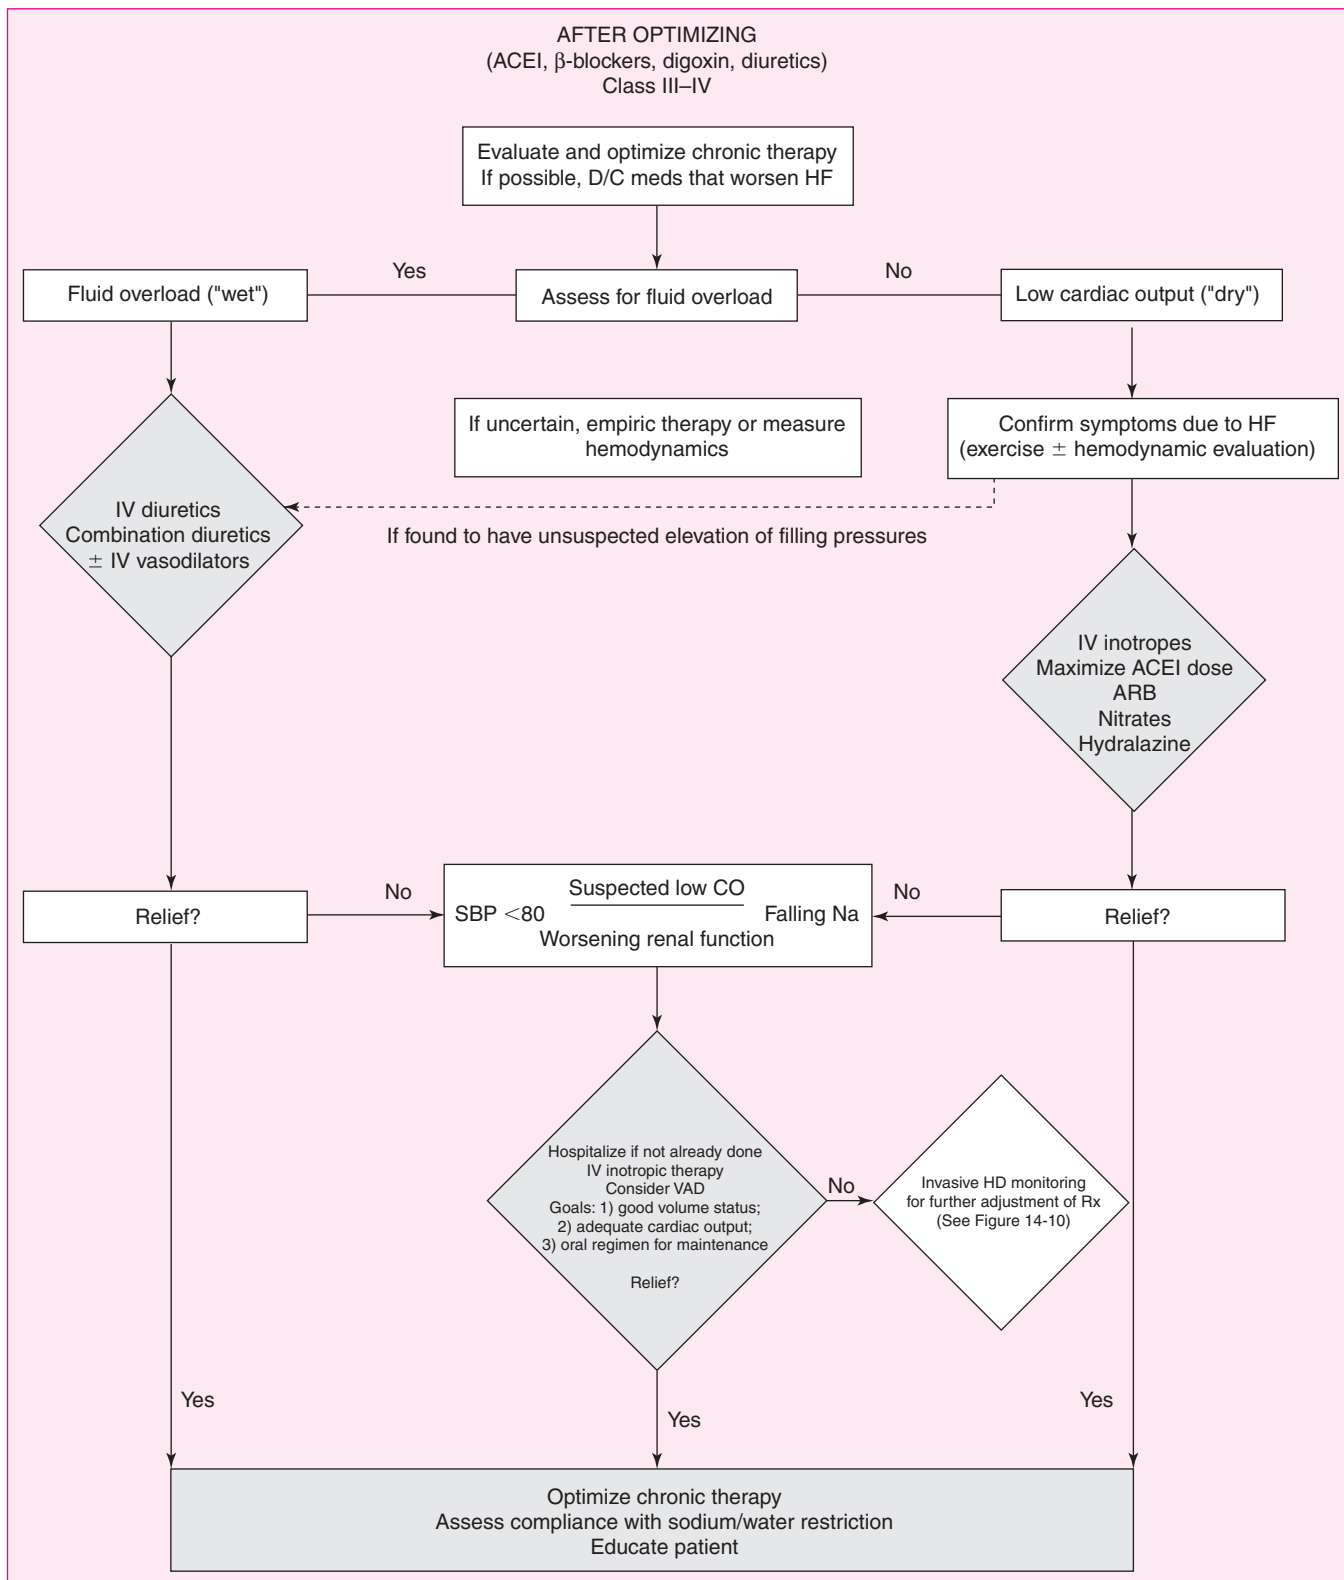

FIGURE 14-8. General treatment algorithm for advanced/decompensated heart failure based on clinical presentation. Intravenous vasodilators that may be used include nitroglycerin, nesiritide, and nitroprusside. (Adapted with permission from *Am Heart J* 1998;135:S293-309.)

shock). They also may demonstrate pulmonary edema with hypoxemia, respiratory acidosis, and markedly increased work of breathing. Since cardiopulmonary support must be instituted and adjusted rapidly, immediate assessment of the results of an intervention limits risks and makes adjustments in therapy more prompt. ECG monitoring, continuous pulse oximetry, urine flow monitoring, and automated sphygmomanometric blood pressure recording are now the minimal noninvasive standard of care for critically ill patients with cardiopulmonary decompensation. Peripheral or femoral arterial catheters provide continuous and accurate assessment of arterial pressure.

■ Hemodynamic Monitoring

The role of invasive hemodynamic monitoring for improving outcomes in patients with severe heart failure remains controversial. No guidelines or consensus statements are available to identify optimal hemodynamic end points or which patients may benefit from invasive monitoring. Although the routine use of invasive monitoring has come under scrutiny, its efficacy and safety in individual patients with advanced heart failure seem well established. Hemodynamic monitoring often provides essential information necessary to achieve optimal drug therapy in patients with a confusing or complicated clinical picture and during dose titration of rapidly acting medications. Invasive monitoring should be considered in patients with cardiogenic shock, refractory hypotension or heart failure symptoms, uncertain volume status, or declining renal function.

Invasive hemodynamic monitoring usually is performed with a flow-directed pulmonary artery (PA) or Swan-Ganz catheter placed percutaneously through a central vein and advanced through the right side of the heart and into the PA. Inflation of a balloon proximal to the end port allows the catheter to “wedge,” yielding the PAOP, which estimates the pulmonary venous (left atrial) pressure and, in the absence of intracardiac shunt or mitral valve or pulmonary disease, left ventricular diastolic pressure. Additionally, cardiac output may be measured and systemic vascular resistance (SVR) calculated. Normal values for hemodynamic parameters are listed in Table 14–12.

In addition to the clinical presentation, invasive hemodynamic monitoring helps in the selection of appropriate medical therapy, as well as in the classification of patients into specific subsets. These *hemodynamic subsets* were first proposed for patients with left ventricular dysfunction following an acute MI but also are applicable

TABLE 14–12. Hemodynamic Monitoring: Normal Values

| | |
|--|---------------------------------|
| Central venous (right atrial) pressure, mean | <5 mm Hg |
| Right ventricular pressure | 25/0 mm Hg |
| Pulmonary artery pressure | 25/10 mm Hg |
| PAP, mean | <18 mm Hg |
| Pulmonary artery occlusion pressure, mean | <12 mm Hg |
| Systemic arterial pressure | 120/80 mm Hg |
| Mean arterial pressure | 90–110 mm Hg |
| Cardiac index | 2.8–4.2 L/min/m ² |
| Stroke volume index | 30–65 mL/beat/m ² |
| Systemic vascular resistance | 900–1400 dyn·s·cm ⁻⁵ |
| Pulmonary vascular resistance | 150–250 dyn·s·cm ⁻⁵ |
| Arterial oxygen content | 20 mL/dL |
| Mixed venous oxygen content | 15 mL/dL |
| Arteriovenous oxygen content difference | 3–5 mL/dL |

FIGURE 14–9. Hemodynamic subsets of heart failure based on cardiac index and pulmonary artery occlusion pressure. (Adapted with permission from *N Engl J Med* 1976;295:1356–1362.)

to patients with acute or severe heart failure from other causes¹¹⁹ (Fig. 14–9). This hemodynamic classification has four subsets and is based on a cardiac index above or below 2.2 L/m² per minute and a PAOP above or below 18 mm Hg. A treatment algorithm, based on hemodynamic subsets, is shown in Fig. 14–10.

■ Subset I

Patients in hemodynamic subset I have a cardiac index and PAOP within generally acceptable ranges and have the lowest mortality of any subset. These patients do not need immediate specific interventions other than maximizing oral therapy and monitoring. It should be emphasized that patients with significant left ventricular dysfunction still may present in subset I because normal compensatory mechanisms and/or appropriate drug therapy at least partially may correct an otherwise abnormal hemodynamic profile.

■ Subset II

As shown in Fig. 14–9, patients in subset II have an adequate cardiac index but a PAOP greater than 18 mm Hg. These patients are likely to have pulmonary congestion (i.e., wet heart failure) secondary to increased hydrostatic pressure in the pulmonary capillaries but no evidence of peripheral hypoperfusion. The primary goal of therapy in these patients is to reduce pulmonary congestion by lowering PAOP. However, it is critically important that PAOP not be decreased excessively so as to cause a significant decrease in cardiac index. Although the normal range of PAOP is 5 to 12 mm Hg for individuals without cardiac dysfunction, higher pressures of 15 to 18 mm Hg frequently are necessary for heart failure patients to optimize cardiac index while avoiding pulmonary congestion. Generally, the PAOP can be lowered to the range of 15 to 18 mm Hg with relatively little decrease in cardiac index because the Frank-Starling curve is flatter at higher PAOP values, particularly in patients with heart failure. Intravenous administration of agents that reduce preload (i.e., loop diuretics, nitroglycerin, or nesiritide) is the most appropriate acute therapy to achieve the therapeutic goal for patients in subset II. These agents will produce a very

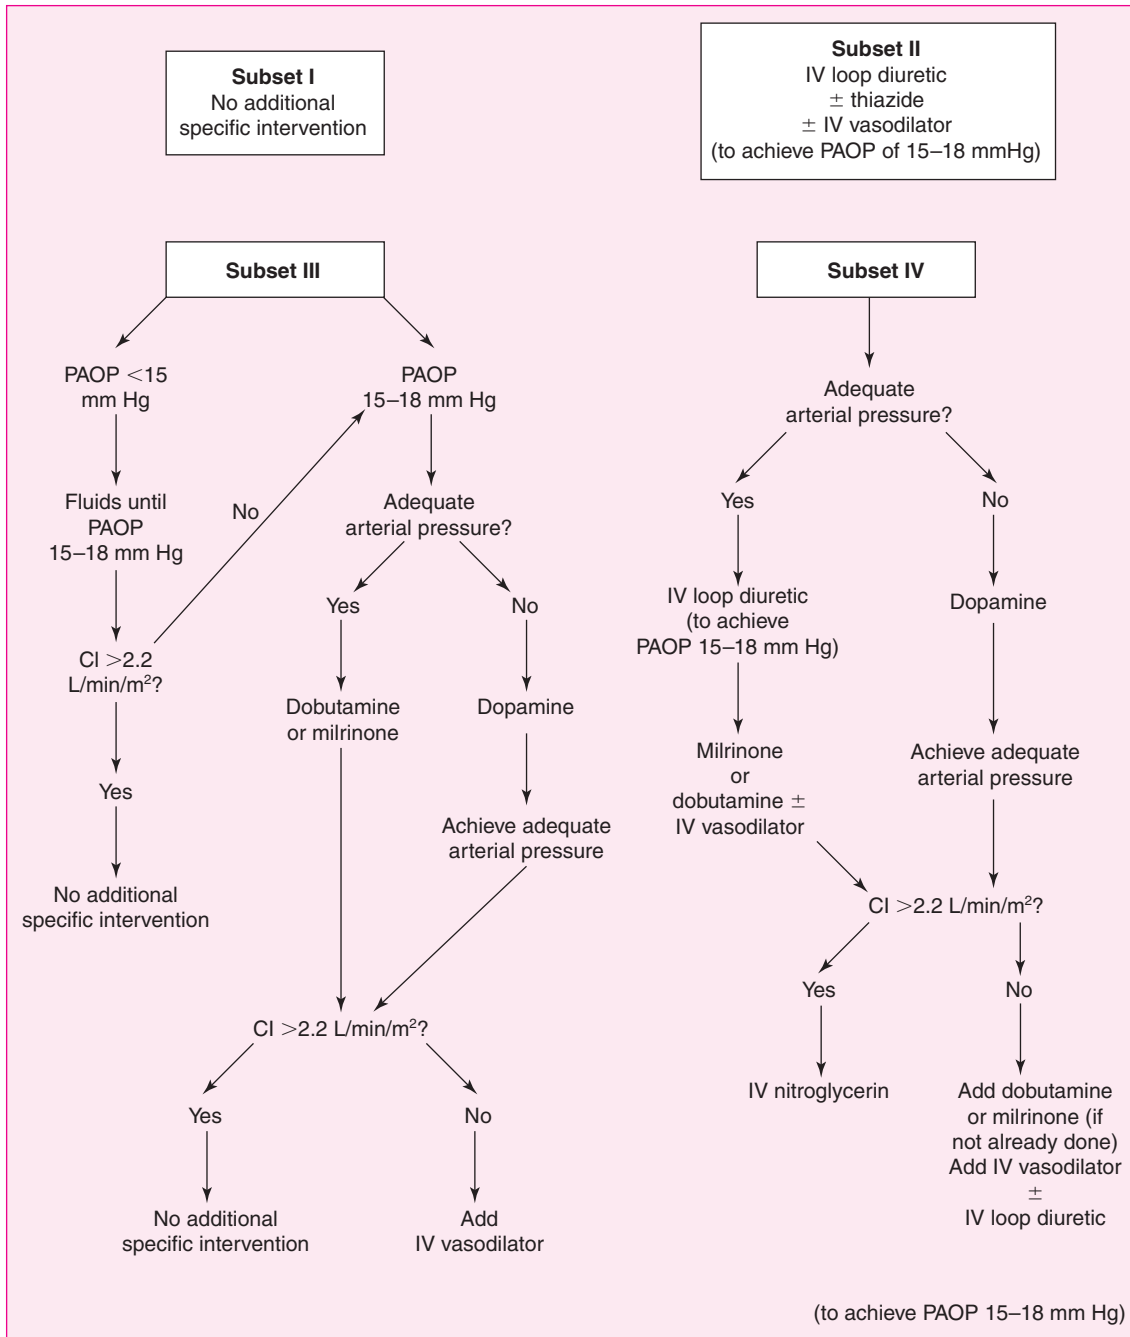

FIGURE 14–10. General treatment algorithm for patients with advanced/decompensated heart failure based on hemodynamic monitoring and hemodynamic subsets. Intravenous vasodilators that may be used include nitroglycerin, nesiritide, and nitroprusside.

rapid decrease in preload, although signs and symptoms of pulmonary congestion may take longer to resolve.

■ **Subset III**

Patients in hemodynamic subset III have a cardiac index of less than 2.2 L/m² per minute but without an abnormally elevated PAOP (see Fig 14–9). These patients usually will present without evidence of

pulmonary congestion, but the low cardiac index will result in signs and symptoms of peripheral hypoperfusion (i.e., decreased urine output, weakness, peripheral vasoconstriction, and weak pulses). The mortality rate of subset III patients is reported to be four times higher than that of patients without hypoperfusion.¹¹⁹ Although the treatment goal is to alleviate the signs and symptoms of hypoperfusion by increasing cardiac index and perfusion to essential organs, therapy will differ among patients. If the PAOP is significantly below 15 mm Hg, initial therapy will be to administer intravenous fluids to

provide a more optimal left ventricular filling pressure of 15 to 18 mm Hg and consequently improve cardiac index. When there is only mild left ventricular dysfunction, intravenous fluid administration may be all that is necessary to achieve a cardiac index above 2.2 L/m² per minute. However, many patients will have significant left ventricular dysfunction and a depressed Frank-Starling relationship despite adequate preload (i.e., PAOP of 15 to 18 mm Hg). In these patients, intravenously administered positive inotropic agents (e.g., dobutamine or milrinone) and/or arterial vasodilators (e.g., nitroprusside or nitroglycerin) often are necessary to achieve an adequate cardiac index. It is noteworthy that many positive inotropic drugs also will have arterial vasodilating activity (see specific drug classes that follow).

■ Subset IV

Patients with a cardiac index of less than 2.2 L/m² per minute and a PAOP higher than 18 mm Hg are in hemodynamic subset IV. These patients have the worst prognosis of any subset and illustrate the typical hemodynamic profile for the patient hospitalized for severe heart failure.

Because of severe pump failure, these patients cannot maintain an adequate cardiac index despite the elevated left ventricular filling pressure and increased myocardial fiber stretch. These patients will present with signs and symptoms of both wet and low-output heart failure. The treatment goals are to alleviate these signs and symptoms by increasing cardiac index above 2.2 L/m² per minute and reducing PAOP to 15–18 mm Hg while maintaining an adequate mean arterial pressure. Thus therapy will involve a combination of agents used for subset II and subset III patients to achieve these goals (i.e., combination of diuretic plus positive inotrope). These targets may be difficult to achieve and will necessitate careful monitoring and individualization of drug therapy. Nitroprusside is a particularly useful agent in this setting because of its mixed arterial-venous vasodilating effects. In the presence of significant hypotension, inotropic agents with vasopressor activity may be required initially to achieve an adequate perfusion pressure to essential organs and then can be combined, if necessary, with diuretics and/or vasodilators to obtain the desired hemodynamic effects and clinical response.

■ PHARMACOLOGIC THERAPY OF ADVANCED OR DECOMPENSATED HEART FAILURE

Unfortunately, the treatment of advanced heart failure has not improved substantially in the past decade owing in large part to the lack of clinical trial data in this population. The pharmacotherapeutic agents used to treat patients with decompensated heart failure rarely, if ever, produce a single cardiovascular action. Even when intended for a single purpose (e.g., a positive inotrope), other drug effects (e.g., tachycardia, vasodilation, or vasoconstriction) may either add to the therapeutic effect or cause adverse events that negate or even outweigh the intended therapeutic benefit. It often can be difficult to anticipate how an individual patient will respond to a given intervention. For this reason, hemodynamic monitoring can be useful, and many drugs are considered first-line therapy owing in part to their short half-lives and ease of titration. The description of expected drug actions outlined below should be viewed as a general guide to the clinician, who must reassess the patient continuously for desired outcomes. Table 14–13 contains a summary of the expected hemodynamic effects of the various drugs discussed below.

■ DIURETICS

Intravenous loop diuretics, including furosemide, bumetanide, and torsemide, are used in the management of advanced heart failure, with furosemide the most widely studied and used agent in this setting. Bolus administration of diuretics decreases preload by functional venodilation within 5 to 15 minutes and later (>20 minutes) via sodium and water excretion, thereby improving pulmonary congestion.^{73,120} However, the acute reduction in venous return may severely compromise effective preload in patients with significant diastolic dysfunction or intravascular depletion. This results in a reflex increase in sympathetic activation, renin release, NE, and AVP elevations and the expected consequences of arteriolar and coronary constriction, tachycardia, and increased PAOP and myocardial oxygen consumption.⁷³ Unlike arterial dilators and positive inotropic agents, diuretics do not cause an upward shift in the Frank-Starling curve or increase

TABLE 14–13. Usual Hemodynamic Effects of Intravenous Agents Commonly Used for Treatment of Acute/Severe Heart Failure^a

| Drug | Dose | HR | MAP | PAOP | CO | SVR |
|---------------|---|-----|-----|------|-----|-----|
| Dopamine | 0.5–3 mcg/kg/min | 0 | 0 | 0 | 0/+ | – |
| Dopamine | 3–10 mcg/kg/min | + | + | 0 | + | 0 |
| Dopamine | >10 mcg/kg/min | + | + | + | + | + |

+ = increase; – = decrease; 0 = no change; HR = heart rate; MAP = mean arterial pressure; PAOP = pulmonary artery occlusion pressure; CO = cardiac output; SVR = systemic vascular resistance.

cardiac index significantly in most patients (see Table 14–13). Excessive preload reduction with diuretics can lead to a decline in cardiac output (see Fig 14–3). Thus diuretics must be used judiciously to obtain the desired improvement in symptoms of congestion while avoiding a reduction in cardiac output.

■ **Diuretic Resistance**

Occasionally, patients respond poorly to large doses of loop diuretics, and heart failure is the most common clinical setting in which diuretic resistance is observed.¹²⁰ The mechanisms responsible for diuretic resistance in heart failure patients appear to be both pharmacokinetic and pharmacodynamic. The bioavailability of furosemide is relatively normal in heart failure patients, but the rate of absorption is prolonged approximately twofold, and peak concentrations are about half of normal. Because loop diuretics have a sigmoid-shaped urine concentration-response curve, prolonged absorption may result in concentrations that fail to reach the steep portion of this curve, resulting in diminished responsiveness. Thus diuretic resistance with oral therapy may be overcome by giving larger oral doses, converting to intravenous administration, or combining a thiazide diuretic with the loop diuretic.¹²⁰

Despite normal pharmacokinetics following intravenous administration, diuretic resistance is also observed with this route, suggesting an important pharmacodynamic component to diuretic resistance. The decreased responsiveness in heart failure patients is explained in part by the high concentrations of sodium reaching the distal tubule as a result of the blockade of sodium reabsorption in the loop of Henle. As a consequence, the distal tubule hypertrophies, increasing its ability to reabsorb sodium.¹²⁰ In addition, low cardiac output, reduced renal perfusion, and subsequent decreased delivery of drug to the kidney also may contribute to resistance.

Several maneuvers can be attempted to overcome diuretic resistance. Treatment of heart failure by other agents (e.g., positive inotropes or afterload reducers) may improve diuresis by increasing cardiac output and renal perfusion. Administration of low doses of dopamine with the hope of enhancing diuresis is also a common practice. However, recent data suggest that the addition of dopamine to furosemide provides no additional diuresis.¹²¹ Larger intravenous bolus doses may achieve concentrations closer to the top of the concentration-response curve, or a continuous intravenous infusion may be used to maintain more constant concentrations in the steep portion of the concentration-response curve. Recent studies of continuous-infusion furosemide suggest a greater natriuretic effect and no difference in metabolic adverse effects when compared with the same total daily dose given by intravenous bolus.¹²² Infusions also may limit adverse hemodynamic events.

Another approach to improving diuresis is addition of a second diuretic with a different mechanism of action. Combining a

loop diuretic with a distal tubule blocker such as metolazone or hydrochlorothiazide can produce a synergistic diuretic effect.¹²⁰ The synergism is not a pharmacokinetic interaction but is related to the increased delivery of sodium to the distal convoluted tubule. Enhanced sodium delivery to (and reabsorption in) the distal tubule then can be blocked by the thiazide-type diuretic. Thus, when thiazide-type diuretics are added to a loop diuretic, they block more than their normal 5% to 8% of filtered sodium, and the combination results in synergistic natriuresis.¹²⁰

The loop diuretic–thiazide combination generally should be reserved for the inpatient setting, where the patient can be monitored closely, because it can induce a profound diuresis with severe sodium, potassium, and volume depletion. When used in the outpatient setting, very low doses or only occasional doses of the thiazide-type diuretic should be used along with close follow-up (weight, vital signs, dizziness) to avoid serious adverse events.

■ **POSITIVE INOTROPIC AGENTS^{114,123}**

Drugs that increase intracellular cAMP are the only positive inotropic agents currently approved for the treatment of acute heart failure. β -Agonists activate adenylate cyclase through stimulation of β -adrenergic receptors, with the enzyme then catalyzing the conversion of ATP to cAMP. Phosphodiesterase inhibitors raise cAMP concentrations by reducing its degradation. Thus both drug classes increase intracellular cAMP, which enhances phospholipase (and subsequently phosphorylase) activity, increasing the rate and extent of calcium influx during systole and enhancing contractility. Additionally, cAMP enhances reuptake of calcium by the sarcoplasmic reticulum during diastole, improving active relaxation. The receptor activities of the β -agonists are summarized in Table 14–14. Although rarely used in management of heart failure, the receptor effects of epinephrine, NE, and isoproterenol are provided for reference.

Digoxin has little, if any, place in the acute treatment of patients with advanced heart failure who are hemodynamically unstable. The delay in peak inotropic effect, limited inotropic effect, long duration of action, and potential toxicity (arrhythmic, vasoconstrictive, neurologic) are disadvantages in the acute setting. However, in patients with acute decompensation who are taking digoxin as part of their chronic therapy, it is generally unnecessary to adjust the dose or discontinue its use unless changes in renal function increase the risk of toxicity.

Although a number of parenteral agents have been used for the treatment of patients with advanced heart failure, dobutamine and milrinone have emerged as the two drugs administered most commonly. These drugs differ in their mechanisms of action and resulting pharmacologic effects and provide advantages and disadvantages in any given patient.

TABLE 14–14. Relative Effects of Adrenergic Drugs on Receptors

| Drug | α_1 | β_1 | β_2 | Dopamine ₁ |

■ Dobutamine¹²³

Dobutamine, a synthetic catecholamine, is a β_1 - and β_2 -receptor agonist with some α_1 -agonist effects (see Table 14–14). Unlike dopamine, dobutamine does not cause release of NE from nerve terminals. The overall hemodynamic effects of dobutamine are the result of its effects on adrenergic receptors and reflex-mediated actions. Its β_2 -receptor-mediated effects are greater than those of dopamine, and β_2 -receptor-mediated vasodilation will tend to offset some of the α_1 -receptor-mediated vasoconstriction. Thus the net vascular effect is usually vasodilation. The positive inotropy is primarily a β_1 -receptor-mediated effect. Cardiac β_1 -receptor stimulation by dobutamine causes an increase in contractility but generally no significant change in heart rate and may provide an explanation for the apparently more modest chronotropic actions of dobutamine compared with dopamine.

The overall hemodynamic effects of dobutamine are those of a potent inotropic agent with vasodilating action. Initial doses of 2.5–5 mcg/kg per minute can be increased progressively to 20 mcg/kg per minute or higher based on clinical and hemodynamic responses. Cardiac index is increased because of inotropic stimulation, arterial vasodilation, and a variable increase in heart rate. Because of the offsetting changes in arteriolar resistance and cardiac index, dobutamine usually will cause relatively little change in mean arterial pressure compared with the more consistent increase observed with dopamine. This smaller effect on blood pressure is beneficial in patients with heart failure and ischemic heart disease because it will minimize the increase in myocardial oxygen demand. More important, dobutamine appears to improve coronary blood flow by augmenting coronary perfusion pressure, increasing diastolic filling time, vasodilating coronary vessels, and unloading the left ventricle. However, the absence of a consistent hypertensive effect with dobutamine is a disadvantage in patients with heart failure and significant hypotension. Dobutamine's vasodilating action usually will decrease PAOP, making it particularly useful in the presence of low cardiac index and an elevated left ventricular filling pressure.

Attenuation of dobutamine's hemodynamic effects has been reported after 72 hours of continuous infusion and may be a consequence of downregulation of β_1 -adrenergic receptors or uncoupling of β_2 -adrenergic receptors from adenylate cyclase. However, it is unlikely that total loss of effect occurs with chronic administration. The evidence for this, although anecdotal, is the large number of patients (especially those awaiting transplant) who are "dobutamine-dependent" and experience hemodynamic deterioration when discontinuation is attempted. Thus, when dobutamine therapy is discontinued, it should be tapered off rather than stopped abruptly to prevent decompensation. Receptor downregulation should occur during long-term therapy with any β -agonist, and cross-tolerance with dopamine would be predicted. Full sensitivity to β -agonists should be restored 7 to 10 days after drug withdrawal. The maximum inotropic effects of dobutamine are diminished in patients with severe heart failure compared with those without heart failure. The mechanism of this tolerance is decreased myocardial β -receptor density and uncoupling from G-protein, which is caused by chronically elevated circulating catecholamine concentrations in heart failure patients.

In some patients, dobutamine (or milrinone) dose reduction or discontinuation results in acute decompensation, and these patients then may require placement of an indwelling intravenous catheter for continuous therapy. This approach may be used to "bridge" patients awaiting cardiac transplantation and also may be used to facilitate the discharge of patients who are not transplant candidates but who cannot be weaned from inotropic therapy. The use of continuous

outpatient dobutamine therapy should be considered only after multiple unsuccessful attempts to maximize oral therapy. Although effective for symptom palliation, it should be realized that the risk of mortality is likely increased. In contrast, the use of regularly scheduled intermittent dobutamine infusions at home or in an outpatient clinic is not recommended in the current guidelines.¹

■ Milrinone and Amrinone¹²³

Both milrinone and amrinone are bipyridine derivatives that inhibit phosphodiesterase III, an enzyme responsible for the breakdown of cAMP to AMP. The subsequent increase in intracellular cAMP levels leads to an increase in intracellular calcium concentration and increased myocardial contractility. These agents produce similar pharmacologic and hemodynamic effects during intravenous administration. Amrinone was the prototype drug in this group, but its use has been supplanted largely by milrinone owing to the more frequent occurrence of thrombocytopenia with amrinone. Both positive inotropic and arterial and venous vasodilating effects contribute to the therapeutic response in heart failure patients; hence these drugs have been referred to as *inodilators*. The relative balance of these pharmacologic effects may vary in a particular patient with dose and underlying cardiovascular pathology.

During intravenous administration, there is an increase in stroke volume (and therefore cardiac output) with little change in heart rate (see Table 14–13). Despite the increase in cardiac index, mean arterial pressure generally remains constant because of the concomitant decrease in arteriolar resistance. However, the vasodilating effects may predominate in certain patients and lead to a decrease in blood pressure and a reflex tachycardia. The drugs lower PAOP by venodilation and thus are particularly useful in patients with a low cardiac index and an elevated left ventricular filling pressure. Such a reduction in preload, however, can be hazardous for patients without excessive filling pressure (especially those with symptoms of dry heart failure), leading to a decrease in cardiac index. Such an effect would blunt the improvement in cardiac output that otherwise would be produced by the positive inotropic and arterial dilating actions. These drugs should be used cautiously as single agents in severely hypotensive heart failure patients because they will not increase and may even decrease arterial blood pressure. The results of controlled studies comparing dobutamine with amrinone or milrinone indicate that these agents produce generally similar hemodynamic effects to dobutamine. A clinically insignificant but greater increase in heart rate with dobutamine is the most consistent difference in these studies.

Milrinone and amrinone have longer terminal elimination half-lives than adrenergic agonists. The average milrinone half-life in healthy subjects is about 1 hour and for amrinone is 2 to 4 hours. This roughly doubles in patients with heart failure.¹²⁴ These long elimination half-lives may be a disadvantage in this patient population because a loading dose may be necessary to obtain a prompt initial response, minute-to-minute titrations in dose cannot be made based on response, and adverse effects (arrhythmias or hypotension) will persist longer after drug discontinuation. The usual loading dose for milrinone is 50 mcg/kg administered over 10 minutes and for amrinone is 0.75 mg/kg administered over 2 to 3 minutes. However, if rapid hemodynamic changes are not necessary, the loading dose should be eliminated owing to the risk of hypotension and patients simply started on the maintenance infusion. The maintenance infusion for milrinone is 0.5 mcg/kg per minute (range 0.375 to 0.75 mcg/kg per minute) and for amrinone it is 5 to 10 mcg/kg per minute. Over 80% of a dose of milrinone is excreted unchanged in urine, and unlike

amrinone, its infusion rate should be decreased by 50% to 70% in patients with significant renal impairment.

In addition to undesirable hemodynamic effects, the most notable adverse events associated with inodilators are arrhythmias, hypotension, and thrombocytopenia. Thrombocytopenia is reported to occur in 2.4% of patients who have received intravenous amrinone, with decreased platelet survival from nonimmunologic platelet damage as the postulated mechanism. This adverse effect is dose-dependent and generally completely reversible within 5 to 7 days of drug discontinuation. The incidence of thrombocytopenia associated with milrinone therapy is very low (<0.5%). Milrinone therefore is preferable to amrinone because of its better side-effect profile. Patients who receive either drug should be monitored for signs of bleeding and have platelet counts determined before and during therapy.

Well-designed studies comparing clinical outcomes of milrinone treatment with those of other inotropes are limited. A recent retrospective analysis in patients with decompensated heart failure found no differences in clinical end points between dobutamine and milrinone, although the cost of dobutamine therapy was significantly less than milrinone.¹²⁵ In a prospective, randomized trial comparing milrinone and dobutamine as a pharmacologic “bridge” to cardiac transplantation, these agents produced similar hemodynamic and clinical outcomes, but again, drug costs favored dobutamine.¹²⁶ The combination of dobutamine and a bipyridine produces additive effects on cardiac index and PAOP reduction, suggesting this regimen as an option in patients who have dose-limiting adverse effects with either class of drugs. It is unclear, however, if this combination provides a therapeutic advantage over the combination of a positive inotrope and a traditional pure vasodilator such as nitroprusside.

A recent study with milrinone points out the risk of routine administration of inotropic therapy to patients admitted to the hospital with an acute exacerbation of heart failure. Although this approach is not supported by clinical trial data, many patients without signs or symptoms of hypoperfusion receive milrinone or other inotropic therapy with the belief that the hemodynamic effects may shorten hospitalization and improve clinical outcomes. Designed to evaluate this strategy, the OPTIME CHF trial was a randomized, double-blind trial that compared the effects of milrinone and placebo in patients hospitalized with an acute exacerbation of chronic heart failure who, in the investigator’s opinion, did not require inotropic therapy.¹²⁷ The 949 patients received a 48-hour infusion of milrinone 0.5 mcg/kg per minute with no loading dose or placebo. No difference between milrinone and placebo was found in the primary end point of the number of days patients were hospitalized for cardiovascular causes within 60 days of randomization. However, adverse events were more common in the milrinone group. Sustained hypotension requiring intervention (10.7% versus 3.2%; $p < .001$) and new onset of atrial fibrillation or flutter (4.6% versus 1.5%; $p = .004$) occurred more frequently in patients receiving milrinone. These results add to the growing concern about the use of inotropic drugs in patients with decompensated heart failure and strongly suggest that milrinone, and probably other inotropes, should not be used routinely for the treatment of acute heart failure exacerbations. Although the routine use of milrinone should be discouraged, clinicians should be aware that inotropic therapy may be needed in selected patients, such as those with low cardiac output states with organ hypoperfusion or with cardiogenic shock. Generally, milrinone should be considered for patients who are receiving chronic β -blocker therapy because its positive inotropic effect does not involve stimulation of β -receptors. Although it appears that β -agonists such as dobutamine still exert some beneficial effects in patients on β -blocker therapy, it is expected that higher than normal doses of these drugs would be needed to achieve the desired pharmacologic

effect. Therefore, milrinone may provide a theoretical advantage in β -blocker-treated patients.

■ Dopamine¹²³

Although dopamine generally should be avoided in the treatment of advanced heart failure, there are two clinical scenarios where its pharmacologic actions may be preferable to dobutamine or milrinone. The first is a patient with marked systemic hypotension or cardiogenic shock in the face of elevated ventricular filling pressures, where dopamine in doses greater than 5 mcg/kg per minute may be necessary to raise central aortic pressure. The second use, although somewhat controversial, is to directly attempt to improve renal function in a patient with inadequate urine output despite volume overload and high ventricular filling pressures. Low doses (1 to 3 mcg/kg per minute) traditionally have been administered for this indication. As discussed earlier, however, there are no data to support this commonly employed practice.

Dopamine, the endogenous precursor of NE, exerts its effects by directly stimulating adrenergic receptors as well as causing release of NE from adrenergic nerve terminals. Dopamine produces dose-dependent hemodynamic effects because of its relative affinity for α_1 -, β_1 -, β_2 -, and D_1 -receptors (vascular dopaminergic) (see Table 14–14). The following dose-dependent actions are intended as a general guide to the clinician.

Positive inotropic effects mediated primarily by β_1 -receptors become more prominent with dopamine doses of 3 to 10 mcg/kg per minute. Cardiac index is increased because of an increase in stroke volume and a variable increase in heart rate, which is partially dose-dependent. There is usually little change in SVR, presumably because neither vasodilation (D_1 - and β_2 -receptor-mediated) nor vasoconstriction (α_1 -receptor-mediated) predominates. Renal effects of dopamine still may be evident at these higher doses and are caused by a combination of D_1 -mediated renovascular effects, increased cardiac index, and altered sodium tubular reabsorption. At doses above 10 mcg/kg per minute, chronotropic and α_1 -receptor-mediated vasoconstricting effects become more prominent. Mean arterial pressure usually increases because of an increase in both cardiac index and SVR (see Table 14–13). The vasoconstricting effects of higher doses could indirectly limit the increase in cardiac index by increasing afterload and PAOP, thus complicating the management of patients with preexisting high afterload. In such patients, alternative agents (e.g., dobutamine or milrinone) or the addition of diuretics and/or vasodilators may be necessary.

Dopamine, particularly at higher doses, may alter several parameters that increase myocardial oxygen demand (increased heart rate, contractility, and systolic pressure) and potentially decrease myocardial blood flow (coronary vasoconstriction and increased wall tension), worsening ischemia in some patients with coronary artery disease. Arrhythmogenesis is also more common at higher doses.

■ VASODILATORS

Activation of the SNS, the RAA system, AVP, and other mediators all cause vasoconstriction and increased SVR. In patients with heart failure, stroke volume varies inversely with SVR such that an increase in peripheral resistance leads to a severe decline in stroke volume and cardiac output (see Fig. 14–1).

Vasodilators typically are described by their prominent site of action (arterial or venous). Arterial vasodilators act as

impedance-reducing agents and usually cause an increase in cardiac output. Venodilators act as preload reducers by increasing venous capacitance, reducing symptoms of pulmonary congestion in patients with high cardiac filling pressures. Mixed vasodilators act on both resistance and capacitance vessels, reducing congestive symptoms while increasing cardiac output. Nitroprusside, nitroglycerin, and nesiritide are the most widely studied and commonly used intravenous vasodilating agents in acute/severe heart failure. Other vasodilators have shown either tachyphylaxis, excessive reflex tachycardia, or refractory hypotension compromising coronary blood flow; they are rarely, if ever, used in this setting.

■ Nitroprusside¹²⁴

Sodium nitroprusside, a mixed arterial-venous vasodilator, acts on vascular smooth muscle, increasing synthesis of nitric oxide to produce its balanced vasodilating action. As such, it both increases cardiac index and decreases venous pressure. Nitroprusside's effects on these parameters are qualitatively similar to those produced by dobutamine and phosphodiesterase inhibitors despite the fact that it has no direct inotropic activity (see Table 14–13). However, nitroprusside generally causes a greater decrease in PAOP, SVR, and blood pressure than these agents. Mean arterial pressure may remain fairly constant but often decreases depending on the relative increase in cardiac output and reduction in arteriolar tone. Hypotension is an important dose-limiting adverse effect of nitroprusside and other vasodilators. Therefore, this drug is used primarily in patients who have a significantly elevated SVR.

Patients with normal left ventricular function will not have an increase in stroke volume when SVR falls because the normal ventricle is fairly insensitive to small changes in afterload. Consequently, these patients experience a significant decrease in blood pressure after administration of arterial vasodilators. This explains why nitroprusside is a potent antihypertensive agent in patients without heart failure but causes less hypotension and reflex tachycardia in patients with left ventricular dysfunction. Nonetheless, even a modest increase in heart rate could have adverse consequences in patients with underlying ischemic heart disease and/or resting tachycardia, and close monitoring is necessary during therapy.

Nitroprusside has been studied extensively and shown to be effective in the short-term management of patients with severe heart failure in a variety of settings (i.e., acute MI, valvular regurgitation, after coronary bypass surgery, decompensated chronic heart failure). Generally, nitroprusside will not worsen and may improve the balance between myocardial oxygen demand and supply. This is mainly due to a decrease in oxygen demand caused by the lowering of left ventricular wall tension and a possible increase in subendocardial blood flow resulting from decreased LVEDP. However, an excessive decrease in systemic arterial pressure can reduce coronary perfusion and worsen ischemia, leading to increased risk of coronary steal.

Nitroprusside has a rapid onset of action and a duration of action of less than 10 minutes, necessitating its administration by continuous intravenous infusion. This allows for precise dose titration based on measured clinical and hemodynamic parameters. It, like other vasodilators used in heart failure, should be initiated at a low dose (0.1 to 0.2 mcg/kg per minute) to avoid excessive hypotension and then increased by small increments (0.1 to 0.2 mcg/kg per minute) every 5 to 10 minutes as needed and tolerated. Usually effective doses range from 0.5 to 3 mcg/kg per minute. A rebound phenomenon has been reported after abrupt withdrawal of nitroprusside in patients with heart failure and is apparently due to reflex neurohormonal

activation during therapy. If renal perfusion pressure is compromised by the drug, salt and water retention can contribute to volume expansion and tachyphylaxis; this is seen typically only in patients with chronic hypertension, baseline azotemia, or when therapeutic augmentation of cardiac output during therapy is minimal. When stopping nitroprusside and switching to oral drugs, it is usually advisable to taper doses slowly. Nitroprusside can cause cyanide and thiocyanate toxicity, but these are very unlikely when doses of less than 3 mcg/kg per minute are administered for less than 3 days, except in patients with a serum creatinine level greater than 3 mg/dL.

■ Nitroglycerin

Intravenous nitroglycerin is often considered the preferred agent for preload reduction in patients with severe heart failure. Because of its short half-life, intravenous nitroglycerin is administered by continuous infusion. Its major hemodynamic actions are reductions in preload and PAOP via functional venodilation and mild arterial vasodilation that is particularly evident in patients with heart failure and elevated SVR or when given in doses approaching 200 mcg/min (see Table 14–13). Intravenous nitroglycerin is used primarily as a preload reducer for patients with pulmonary congestion and low-normal cardiac output or in combination with inotropic agents for patients with severely depressed systolic function and pulmonary edema. Combination therapy with nitroglycerin and dobutamine or dopamine produces complementary effects to increase cardiac index and decrease PAOP. In higher doses, nitroglycerin displays potent coronary vasodilating properties and beneficial effects on myocardial oxygen demand and supply, making it the vasodilator of choice for patients with severe heart failure and ischemic heart disease.

Nitroglycerin should be initiated at a dose of 5 to 10 mcg/min (0.1 mcg/kg per minute) and increased every 5 to 10 minutes as necessary and tolerated. Hypotension and an excessive decrease in PAOP are important dose-limiting side effects. Maintenance doses usually vary from 35 to 200 mcg/min (0.5 to 3 mcg/kg per minute), although doses over 1000 mcg/min (15 mcg/kg per minute) have been used in rare cases. Tolerance to the hemodynamic effects of nitroglycerin may develop over 12 to 72 hours of continuous administration, but some patients have a sustained response. Neither nitroglycerin nor nitroprusside should be used in the presence of elevated intracranial pressure because either may worsen cerebral edema in this setting.

■ Nesiritide^{22,128}

Nesiritide is the first new drug approved for the treatment of decompensated heart failure since milrinone. Manufactured by recombinant techniques, it is identical to the endogenous human BNP secreted by the ventricular myocardium in response to volume overload. Exogenous administration of nesiritide mimics the vasodilatory and natriuretic actions of the endogenous peptide by stimulating natriuretic peptide receptor A, which leads to increased levels of cGMP in target tissues. In small clinical trials, nesiritide produces venous and arterial vasodilation, increases natriuresis and diuresis, and decreases cardiac filling pressures, blood pressure, and SNS and RAA system activity. Unlike nitroglycerin or dobutamine, tolerance does not develop to nesiritide's pharmacologic actions. It does not affect cAMP or stimulate β -receptors, mechanisms that are thought to contribute to the myocardial toxicity associated with the positive inotropic drugs. Thus, as shown in a recent comparative trial, nesiritide does

not have the proarrhythmic effects associated with dobutamine.¹²⁹ Nesiritide is eliminated by several pathways, including the natriuretic peptide receptor C on target tissues, proteolytic cleavage by neutral endopeptidase, and renal filtration. Its elimination half-life of 18 minutes is considerably longer than that of other vasodilators or β -agonists.

The VMAC trial was a randomized, double blind trial that compared the effects of nesiritide, intravenous nitroglycerin, or placebo in patients with decompensated heart failure and dyspnea receiving standard background therapy.¹³⁰ Patients received pulmonary artery catheterization at the discretion of the investigators. The primary end points were the patient's self-assessment of dyspnea (all patients) and the change in PAOP at 3 hours after the start of the study drug infusion (only in patients with a pulmonary artery catheter). Although nesiritide reduced dyspnea at 3 hours compared with placebo, no difference between nesiritide and nitroglycerin was found. In patients with a pulmonary artery catheter, nesiritide reduced PAOP by a mean of 5.8 mm Hg, which was significantly greater than the reduction with nitroglycerin (3.8 mm Hg) or placebo (2 mm Hg). This small but statistically significant difference between nesiritide and nitroglycerin was maintained for 24 hours, although this did not result in differences in dyspnea. The most frequently reported adverse effect was headache, which occurred more often with nitroglycerin (20%) than with nesiritide (8%). A similar frequency of asymptomatic and symptomatic hypotension was reported with nesiritide and nitroglycerin. However, because the elimination half-life of nesiritide is longer than that of nitroglycerin (18 versus 2–3 minutes), the duration of hypotensive episodes with nesiritide was significantly longer than those with nitroglycerin (2.2 versus 0.7 hours). Although not the primary end point of the trial, 30-day follow-up of the patients found no differences between the nesiritide and nitroglycerin groups in hospital readmissions, death, or other serious adverse events.

The precise role of nesiritide in the pharmacotherapy of decompensated heart failure remains controversial. Much of this controversy centers on the marginal hemodynamic benefits and the lack of improvement in mortality or other clinical outcomes with nesiritide compared with nitroglycerin (or nitroprusside) balanced against nesiritide's significantly greater costs (~\$450 for a 24-h nesiritide infusion compared with \$10 to \$15 for nitroglycerin). Nesiritide does offer several potential therapeutic advantages, including beneficial neurohormonal effects, use without invasive hemodynamic monitoring, administration in outpatient settings (e.g., emergency departments) with the goal of preventing hospital admission, and low proarrhythmic potential compared with inotropes. Disadvantages of nesiritide include the risk of sustained hypotension, the cost, and the lack of improvement in important clinical outcomes. Given these questions on the role of nesiritide, the use of this medication varies considerably among institutions, with many developing specific criteria for its use. Nesiritide may be most useful in the treatment of patients with volume overload (i.e., warm and wet) and systolic blood pressure greater than 90 mm Hg who fail to respond adequately to intravenous diuretics and/or vasodilators such as nitroglycerin.

MECHANICAL CIRCULATORY SUPPORT¹³¹

INTRAAORTIC BALLOON PUMP

The intraaortic balloon pump (IABP) is a frequently used form of mechanical circulatory assistance and typically is employed in patients with advanced heart failure who do not respond adequately to

drug therapy, those with intractable myocardial ischemia, or patients in cardiogenic shock. The IABP consists of a polyethylene balloon mounted on a catheter that is usually inserted percutaneously into the femoral artery, and the balloon is then advanced into the descending thoracic aorta. During counterpulsation, the balloon is synchronized with the ECG so that it inflates during diastole and displaces aortic blood, thus increasing aortic diastolic pressure and coronary perfusion. The balloon deflates just prior to opening of the aortic valve during systole and causes a sudden decrease in aortic pressure, allowing the left ventricle to pump against reduced arterial impedance. IABP support results in increased cardiac index, coronary artery perfusion, and myocardial oxygen supply, accompanied by decreased myocardial oxygen demand. Thus it is particularly useful for short-term use in patients with decompensated heart failure in the setting of myocardial ischemia (evolving infarction, patients awaiting emergency coronary bypass surgery). It is also used in hemodynamically unstable patients to stabilize them prior to insertion of a left ventricular assist device that will serve as a bridge to cardiac transplantation when inotropic drugs are no longer effective. Intravenous vasodilators and inotropic agents generally are used in conjunction with the IABP to maximize hemodynamic and clinical benefits.

VENTRICULAR ASSIST DEVICES

A number of different ventricular assist devices (VADs) are available or under investigation. These pumps are surgically implanted and assist, or in some cases replace, the pumping functions of the right and/or left ventricles. VADs are currently used to provide short-term hemodynamic support in patients experiencing an acute event (e.g., acute MI accompanied by cardiogenic shock or patients who cannot be weaned from cardiopulmonary bypass after cardiac surgery) in which ventricular recovery is anticipated. There is also strong interest in longer-term use of these devices in patients whose ventricular function is unlikely to recover. Here, VADs are being used as a bridge to cardiac transplantation and for palliative therapy (so-called destination therapy) in lieu of continuous inotropic therapy in patients who are not transplant candidates. Also, several models of total artificial hearts are currently under investigation for use as a bridge to transplant or for destination therapy.

SURGICAL THERAPY

Orthotopic cardiac transplantation remains the best therapeutic option for patients with chronic, irreversible NYHA class IV heart failure, with a 5-year survival of approximately 60% to 70% in well-selected patients. Unfortunately, the shortage of acceptable donor hearts has resulted in an average waiting time for transplant of more than 6 months, with only about one in five approved potential recipients receiving a heart before succumbing to their disease. Another large percentage of patients is rejected from consideration for transplant because of age, concurrent illnesses, psychosocial factors, and other reasons. See Chap. 87 for additional details on cardiac transplantation. The shortage of donor hearts has prompted development of new surgical techniques, including ventricular aneurysm resection, mitral valve repair, and myocardial cell transplantation, which have resulted in variable degrees of symptomatic improvement. Further development of these and other techniques may offer additional options in patients who are not transplant candidates.

PHARMACOECONOMIC CONSIDERATIONS

Heart failure imposes a tremendous economic burden on the health care system. In patients over age 65, it is the most common reason for hospitalization, with hospital admission rates for this disorder continuing to increase. Heart failure is also associated with 30% to 50% readmission rates during the 3 to 6 months after initial discharge. Current estimates of costs of heart failure treatment in the United States exceed \$40 billion, with most of the costs associated with hospitalization.^{1,3} The prevalence of heart failure and the costs associated with patient care are expected to increase as the population ages and as survival from ischemic heart disease is improved. Thus approaches to improve the quality and cost-effectiveness of care for these patients may have a significant impact on health care costs.

Studies to assess the cost-effectiveness of drug therapy for heart failure have been reviewed recently.¹³² Carvedilol reduced the number of heart failure–related hospital admissions compared with placebo, resulting in a significant savings in hospital costs. The cost per life-year saved with carvedilol was \$12,799, which is similar to that of other medical therapies.¹³² β -Blockers reduced Medicare costs by approximately \$6000 per patient, primarily owing to a reduction in the rates of hospitalization, and resulted in reduced hospital and physician revenue.¹³³ In the DIG trial, patients treated with digoxin had fewer hospitalizations for heart failure, but digoxin produced an absolute decrease of only 2.8% in hospitalizations for any cause.⁷⁴ Although no prospective economic analyses have been performed, studies using decision-analysis techniques indicate that ACE inhibitors are cost-effective.¹³² While not providing direct cost estimates, number needed to treat (NNT) is often a useful index that provides a sense of the cost-effectiveness of a given therapy. In the case of the ACE inhibitors and β -blockers, the NNT to prevent one death has ranged from 7 to 20 patients for the ACE inhibitor studies (including most of the post-MI studies) and from 14 to 26 patients for the β -blocker studies. These numbers compare favorably with and in fact are superior to most other cardiovascular therapies. In the case of both drug classes, the benefits are greater (NNT lower) for the patients with more severe heart failure.

As the management of heart failure has become increasingly complex, the development of disease-management program approaches that use multidisciplinary teams has attracted significant interest.^{132,134} These programs use several broad approaches, including heart failure specialty clinics and/or home-based interventions. Most are multidisciplinary and may include physicians, advanced practice nurses, dietitians, and pharmacists. In general, the programs focus on optimization of drug and nondrug therapy, patient and family education and counseling, exercise and dietary advice, intense follow-up by telephone or home visits, and monitoring and management of signs and symptoms of decompensation. Collectively, studies evaluating this disease-management approach have reported fewer hospitalizations, improved functional capacity and symptoms, reduced health care costs, and improved patient satisfaction and quality of life compared with usual care.^{132,134} The improvement in outcome in these studies may be related to better adherence to heart failure treatment guidelines by cardiologists compared with other physicians.¹³⁵

11 Pharmacists can play an important role in the multidisciplinary team management of heart failure.^{136,137} Compared with conventional treatment, pharmacist intervention that included medication evaluation and therapeutic recommendations, patient education, and follow-up telephone monitoring reduced hospitalizations for heart failure. Adherence to guideline-recommended therapy was improved by pharmacist intervention. Thus the role and cost benefits of pharmacist involvement in the multidisciplinary care of heart failure

patients are now apparent and should include optimizing doses of heart failure drug therapy, screening for drugs that exacerbate heart failure, monitoring for adverse drug effects and drug interactions, educating patients, and patient follow-up.

CLINICAL CONTROVERSIES

There is now reasonable evidence that immediate-release metoprolol tartrate is inferior to carvedilol, but controversy remains about the equivalency of metoprolol succinate CR/XL (Toprol-XL) and carvedilol. Some practitioners believe that the evidence suggests that carvedilol is superior, whereas others believe that any of the drugs (bisoprolol, carvedilol, or metoprolol CR/XL) are appropriate for management of chronic heart failure.

Some clinicians advocate the use of aldosterone antagonists in essentially all patients with symptomatic heart failure or post-MI left ventricular dysfunction. Others believe that they should be reserved for those who remain symptomatic with NYHA class IIIb or IV heart failure.

The role of nesiritide in patients with acute decompensated heart failure remains controversial. The debate focuses primarily on the efficacy and increased cost of nesiritide compared with other vasodilators (i.e., nitroglycerin). Although a more rapid improvement in hemodynamics was observed with nesiritide therapy compared with nitroglycerin, this advantage was not apparent after 24 hours of treatment. Because of the marginal efficacy advantage over nitroglycerin, coupled with the substantially higher cost of nesiritide, many institutions restrict the use of nesiritide to patients failing to respond to nitroglycerin or other vasodilators. Others advocate nesiritide as the treatment of choice in this patient population.

EVALUATION OF THERAPEUTIC OUTCOMES

CHRONIC HEART FAILURE

Although mortality is an important end point, it does not give a complete measure of the overall effects of the disease on patient outcomes because many patients are hospitalized repeatedly for heart failure exacerbations and continue to survive. Thus some of the more important therapeutic outcomes in heart failure management, such as prolonged survival or prevention or slowing of the progression of heart failure, cannot be quantified in an individual patient. However, after appropriate diagnostic evaluation to determine the etiology of heart failure, ongoing clinical assessment of patients typically focuses on three general areas: (1) evaluation of functional capacity, (2) evaluation of volume status, and (3) laboratory evaluation.

The evaluation of functional capacity should focus on the presence and severity of symptoms the patient experiences during activities of daily living and how those symptoms affect these activities. Questions directed toward the patient's ability to perform specific activities may be more informative than general questions about what symptoms the patient may be experiencing. For example, ask patients if they can participate in exercise, climb stairs, get dressed without stopping, check the mail, or clean the house. Another important component of assessment of functional capacity is to ask patients what activities they would like to do but are now unable to perform.

Assessment of volume status is a vital component of the ongoing care of patients with heart failure. This evaluation provides the clinician with important information about the adequacy of diuretic

therapy. Since the cardinal signs and symptoms of heart failure are caused by excess fluid retention, the efficacy of diuretic treatment is readily evaluated by the disappearance of these signs and symptoms. The physical examination is the primary method for the evaluation of fluid retention, and specific attention should be focused on the patient's body weight, extent of jugular venous distension, presence of hepatojugular reflux, presence and severity of pulmonary congestion, and peripheral edema. Specifically, in a patient with pulmonary congestion, monitoring is indicated for resolution of rales and pulmonary edema and improvement or resolution of dyspnea on exertion (DOE), orthopnea, and PND. For patients with systemic congestion, a decrease or disappearance of peripheral edema, JVD, and hepatojugular reflux is sought. Other therapeutic outcomes include an improvement in exercise tolerance and fatigue, decreased nocturia, and a decrease in heart rate. Clinicians also will want to monitor blood pressure and ensure that the patient does not develop symptomatic hypotension as a result of drug therapy. Body weight is a sensitive marker of fluid loss or retention, and patients should be counseled to weigh themselves daily, reporting changes to their health care provider so that adjustments can be made in diuretic doses. It should be noted that, particularly with β -blocker therapy, symptoms may worsen initially and that it may take weeks to months of treatment before patients notice improvement in symptoms. Also, patients and health care providers should be aware that heart failure progression may be slowed even though symptoms have not resolved.

Routine monitoring of serum electrolytes and renal function is required in patients with heart failure. Assessment of serum potassium is especially important because hypokalemia is a common adverse effect of diuretic therapy and is associated with an increased risk of arrhythmias and digoxin toxicity. Serum potassium monitoring is also required because of the risk of hyperkalemia associated with ACE inhibitors, ARBs, and aldosterone antagonists. A serum potassium concentration of 4 mEq/L or greater should be maintained, with some evidence suggesting that it should be 4.5 mEq/L or greater.¹³⁸ Assessment of renal function (BUN and serum creatinine) is also an important end point for monitoring diuretic and ACE inhibitor therapy. Common causes of worsening renal function in patients with heart failure include overdiuresis, adverse effects of ACE inhibitor or ARB therapy, and hypoperfusion.

ADVANCED/DECOMPENSATED HEART FAILURE

Assessment of adequacy of therapy in the advanced heart failure patient can be separated into two general categories: initial improvement of physiologic parameters and safe discharge from the ICU following conversion to a chronic oral therapeutic regimen. Both goals must be achieved because hemodynamic improvement has not correlated with prolonged symptom improvement or enhanced survival.

Initial stabilization requires achievement of adequate arterial oxygen saturation and content. Cardiac index and blood pressure must be sufficient to ensure adequate organ perfusion, as assessed by alert mental status, creatinine clearance sufficient to prevent metabolic azotemic complications, hepatic function adequate to maintain synthetic and excretory functions, a stable heart rate (generally between 50 and 110 beats per minute) and rhythm (predominately sinus rhythm, rate-stabilized atrial fibrillation or flutter, or paced rhythm), absence of ongoing myocardial ischemia or infarction, skeletal muscle and skin blood flow sufficient to prevent ischemic injury, and normal arterial pH (7.34 to 7.47) with a normal serum lactate concentration. Although these goals are achieved most often with a cardiac index greater than 2.2 L/m² per minute, a mean arterial blood pressure greater than 60 mm Hg, and a PAOP of 25 mm Hg or greater, the absolute values are highly variable and depend on chronicity of ill-

ness, efficacy of chronic compensatory mechanisms, previous chronic therapy, and concurrent illness.

Discharge from the ICU requires maintenance of the preceding parameters in the absence of ongoing intravenous infusion therapy, mechanical circulatory support, or positive-pressure ventilation. Some patients may achieve this goal with markedly lower blood pressure or higher filling pressure than suggested earlier; hence numerical goals cannot always be substituted for clinical status. Nonpharmacologic treatments aimed at the precipitants of a patient's heart failure exacerbation include permanent pacing, CRT with or without ICD, coronary angioplasty or valvuloplasty, pericardial drainage, cardiac surgery (coronary bypass, valve replacement or reconstruction, closure of intracardiac shunts), or even cardiac transplantation to achieve initial stabilization, definitive therapy, or both.

Note Added in Proof. The European Society of Cardiology released new treatment guidelines in February 2005 for the diagnosis and treatment of acute heart failure. (Niemenen MS, Bohm M, Cowie MR, et al. Executive summary of the guidelines on the diagnosis and treatment of acute heart failure. The Task Force on Acute Heart Failure of the European Society of Cardiology. *Eur Heart J* 2005;26:384–416.)

ADDENDUM

Since the final preparation of this chapter, the results from two recently published clinical trials provide important information for clinicians involved in the pharmacotherapy of heart failure. The first trial examined prescribing rates for spironolactone and hospital admission rates for hyperkalemia in approximately 1.3 million elderly patients in the Ontario Drug Benefit Program before and after publication of the RALES trial.¹³⁹ Immediately after publication of RALES, the spironolactone prescription rate increased nearly fivefold. Similarly, the rates of hospitalization for hyperkalemia and hyperkalemia-associated deaths increased by threefold. These results indicate that the use of spironolactone was widely embraced and that important clinical trial results can be rapidly translated into clinical practice. However, these findings also confirm earlier case reports that spironolactone-induced hyperkalemia occurs more frequently in clinical practice than in clinical trials. Risk factors for hyperkalemia with aldosterone antagonists include the elderly, renal insufficiency, diabetes, concomitant use of ACE inhibitors, potassium supplements, NSAIDs, or β -blockers, high doses of aldosterone antagonists, and inadequate laboratory monitoring. Appropriate patient selection and monitoring are keys to minimizing the risk of hyperkalemia with the aldosterone antagonists.

Post-hoc analyses of several clinical trials collectively suggested African-Americans with heart failure responded better to the combination of isosorbide dinitrate plus hydralazine than to ACE inhibitors. These findings served as the basis for the African-American Heart Failure Trial (A-HeFT) that compared the effects of isosorbide dinitrate combined with hydralazine, when added to standard background heart failure pharmacotherapy (ACE inhibitors or ARBs, β -blockers, diuretics, and digoxin), to placebo in patients self-identified as African-Americans.¹⁴⁰ The investigational study medication was a fixed-dose combination of isosorbide and hydralazine (BiDiI) containing 20 mg of isosorbide and 37.5 mg of hydralazine in one tablet that was administered three times daily. The dose could be increased to two tablets three times daily if no drug-related adverse effects were present. The trial was terminated early due to a 40% reduction in all-cause mortality in patients receiving isosorbide and hydralazine compared to placebo. Hospitalizations for heart failure were reduced and quality of life was improved by the combination

product. However, patients receiving isosorbide plus hydralazine were more likely to experience headaches or dizziness compared to those receiving placebo. The mechanism(s) for these beneficial effects remains uncertain but are likely linked to nitric oxide donation from isosorbide and a hydralazine-mediated reduction in oxidative stress leading to an overall increase in nitric oxide availability. These results suggest, but do not confirm, that nitric oxide may play a protective role in attenuating myocardial hypertrophy and remodeling. Whether the benefits of isosorbide and hydralazine are specific for African-Americans or if other racial or ethnic groups may also benefit remains to be determined. Although not incorporated into current heart failure treatment guidelines, these results suggest that the addition of isosorbide dinitrate and hydralazine to standard therapy should be strongly considered in African-Americans with heart failure.

ABBREVIATIONS

ACC: American College of Cardiology
 ACE: angiotensin-converting enzyme
 AHA: American Heart Association
 ANP: atrial natriuretic peptide
 ARB: angiotensin receptor blocker
 AVP: arginine vasopressin
 BNP: B-type natriuretic peptide
 cAMP: cyclic adenosine monophosphate
 CNP: C-type natriuretic peptide
 CO: cardiac output
 COPD: chronic obstructive pulmonary disease
 COX-2: cyclooxygenase-2
 EF: ejection fraction
 ET: endothelin
 HTN: hypertension
 IABP: intraaortic balloon pump
 ICD: implantable cardioverter-defibrillator
 ICU: intensive care unit
 JVD: jugular venous distension
 LVEDV: left ventricular end-diastolic volume
 LVEDP: left ventricular end-diastolic pressure
 LVEF: left ventricular ejection fraction
 LVF: left ventricular failure
 MI: myocardial infarction
 NE: norepinephrine
 NSAID: nonsteroidal anti-inflammatory drug
 NYHA: New York Heart Association
 PA: pulmonary artery
 PAOP: pulmonary artery occlusion pressure
 P-gp: P-glycoprotein
 RAA: renin-angiotensin-aldosterone
 RVF: right ventricular failure
 SDC: serum digoxin concentration
 SVR: systemic vascular resistance
 TNF- α : tumor necrosis factor- α
 TZD: thiazolidinedione
 VAD: ventricular assist device

ISCHEMIC HEART DISEASE

Robert L. Talbert

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Ischemic heart disease (IHD) is caused primarily by coronary atherosclerosis, a very common disease in the U.S. population, and results in an imbalance between oxygen supply and demand with resulting ischemia.
- 2 Chest pain is the cardinal symptom of ischemia due to coronary artery disease (CAD).
- 3 Risk-factor identification and modification are important for individual patients with known or suspected IHD and as a population-based policy to reduce the impact of this disease.
- 4 Major risk factors that can be altered include dyslipidemia (high total and low-density lipoprotein [LDL] cholesterol, low high-density lipoprotein [HDL] cholesterol, and high triglycerides), smoking, glycemic control in diabetes mellitus, hypertension, and adoption of therapeutic lifestyle changes (exercise, weight reduction, and reduced cholesterol and saturated fat in the diet).
- 5 Chronic stable angina should be managed initially with β -blockers because they provide better symptomatic control at least as well as nitrates or calcium channel blockers and decrease the risk of recurrent myocardial infarction (MI) and CAD mortality.
- 6 Nitroglycerin and other nitrate products are useful for prophylaxis of angina when patients are undertaking activities known to provoke angina; however, when angina is occurring on a regular, routine basis, chronic prophylactic therapy should be instituted.
- 7 Although calcium channel blockers are effective as monotherapy, they generally are used in combination with β -blockers or as monotherapy if patients are intolerant of β -blockers; most patients with moderate to severe angina will require two drugs to control their symptoms.
- 8 Pharmacologic management is as effective as revascularization (PTCA, CABG, etc.) if one or two vessels are involved, and there are no differences in survival, recurrent MI, or other measures of effectiveness.
- 9 Multivessel involvement, especially if the patient has left main coronary artery disease or left main equivalent disease, or two- to three-vessel involvement with significant left ventricular dysfunction is best managed with revascularization.
- 10 Percutaneous transluminal angioplasty (PTCA) and coronary artery bypass grafting (CABG) produce similar results overall, but certain patient subsets (e.g., diabetics) should have CABG done.

The pathogenesis of ischemic heart disease (IHD), which is also known as *coronary artery disease* (CAD), is now known to be atherosclerosis of the epicardial vessels. This process begins early in life, often not being clinically manifest until the middle-aged years and beyond. IHD may present as an acute coronary syndrome (ACS), which includes unstable angina, non-ST-segment-elevation myocardial infarction (NSTEMI), and ST-segment-elevation myocardial infarction (STEMI), and MI diagnosed by biomarkers only, chronic stable exertional angina pectoris, and ischemia without clinical symptoms or owing to coronary artery vasospasm (variant or Prinzmetal's angina). Other manifestations of atherosclerosis include heart failure, arrhythmias, cerebrovascular disease (stroke), and peripheral vascular disease. The American Heart Association (AHA) recently published management guidelines for stable and unstable angina.^{1–3}

EPIDEMIOLOGY

The syndrome of angina pectoris is reported to occur with an average annual incidence rate (number of new cases per time period per total

number of persons in the population for the same time period) of about 1.5% (range 0.1 to 5 per 1000) depending on the patient's age, gender, and risk-factor profile.⁴ The presenting manifestation in women is more commonly angina, whereas men more frequently have MI as the initial event. Estimates of the incidence and prevalence of angina are not entirely accurate owing to waxing and waning of symptoms; angina may disappear in up to 30% of patients with angina that is less severe and of recent onset.

Cardiovascular diseases (CVD) claimed 949,619 lives, or 1 of every 2.5 deaths, in the United States in 1998.⁵ More than 2600 Americans die of CVD each day, or on average of 1 death every 33 seconds. In 1998, the death rates from CVD were 532.0 (per 100,000) for black males, 419.3 for white males, 400.7 for black females, and 294.9 for white females.⁵ CAD was responsible for 459,841 deaths (or 48%) from CVD. Men die earlier from IHD and acute myocardial infarction (AMI) than women, and aging of both sexes is associated with a higher incidence of these afflictions. The disparity in mortality from IHD between men and women decreases with aging, being about four to five times more common in men in their mid-30s to a preponderance of female deaths in the very elderly.

TABLE 15–1. Criteria for Determination of the Specific Activity Scale Functional Class^a

| | Any Yes | No |
|---|-----------|-----------|
| 1. Can you walk down a flight of steps without stopping (4.5–5.2 MET)? | Go to 2 | Go to 4 |
| 2. Can you carry anything up a flight of 8 steps without stopping (5–5.5 MET)? | Go to 3 | Class III |
| Or can you: | | |
| a. Have sexual intercourse without stopping (5–5.2 MET) | | |
| b. Garden, rake, weed (5.6 MET) | | |
| c. Roller skate, dance fox trot (5–6 MET) | | |
| d. Walk at a 4 mi/h rate on level ground (5–6 MET) | | |
| 3. Can you carry at least 24 lb up 8 steps (10 MET)? Or can you: | Class I | Class II |
| a. Carry objects that weigh at least 80 lb (18 MET) | | |
| b. Do outdoor work, shovel snow, spade soil (7 MET) | | |
| c. Do recreational activities such as skiing, basketball, touch football, squash, handball (7–10 MET) | | |
| d. Jog/walk 5 mi/h (9 MET) | | |
| 4. Can you shower without stopping (3.6–4.2 MET)? Or can you: | Class III | Go to 5 |
| a. Strip and make bed (3.9–5 MET) | | |
| b. Mop floors (4.2 MET) | | |
| c. Hang washed clothes (4.4 MET) | | |
| d. Clean windows (3.7 MET) | | |
| e. Walk 2.5 mi/h (3–3.5 MET) | | |
| f. Bowl (3–4.4 MET) | | |
| g. Play golf, walk and carry clubs (4.5 MET) | | |
| h. Push power lawn mower (4 MET) | | |
| 5. Can you dress without stopping because of symptoms (2–2.3 MET)? | Class III | Class IV |

^aMET, metabolic equivalents of activity.

From Goldman L, Hashimoto B, Cook F, et al. Comparative reproducibility and validity of systems for assessing cardiovascular functional class: Advantages of a new specific activity scale. *Circulation* 1981;64:1228, with permission.

Data from the Framingham Study showed that the prevalence was 5.9% for the 16-year period studied from earlier reports.⁶ More recent data from the Framingham Study showed that the prevalence in a 1970 cohort followed for 10 years was about 1.5% for women and 4.3% for men aged 50 to 59 years at inception.⁴ The AHA estimates that the prevalence of angina was 6.4 million in 1998.⁵ Other interesting trends noted include a 21% decline in the incidence of cardiovascular disease in women but only a 6% decline in men over two cohorts from 1950 and 1970. Cardiovascular mortality was reduced by 59% in women and 53% in men from the same cohorts. The risk of developing IHD is not the same worldwide. Countries such as Japan and France are on the low end of the spectrum, whereas Finland, Northern Ireland, Scotland, and South Africa have very high rates.^{7,8}

Angina may be classified according to symptom severity, disability induced, or a specific activity scale (Tables 15–1 and 15–2). The specific activity scale developed by Goldman and coworkers⁹ may be preferable because it has been shown to be equal to or better than the New York Heart Association (NYHA) or Canadian Cardiovascular Society (CCS) functional classifications for reproducibility and provides better agreement with treadmill testing.

An important determinate of outcome for the angina patient is the number of vessels obstructed. Twelve-year survivals from the Coronary Artery Surgery Study (CASS) for patients with zero-, one-, two-, and three-vessel disease were 88%, 74%, 59%, and 40%, respectively.¹⁰ Other factors that increase the risk of death in medically managed patients include the presence of heart failure (or markers such as poor ventricular wall motion and low ejection fraction), smoking, left main or left main equivalent CAD, diabetes, and prior MI. Twelve-year survivals for patients with at least one diseased vessel and ejection fractions in the ranges of 50% to 100%, 35% to 49%, and 0% to 34% are 73%, 54%, and 21%, respectively. Of particular note, patients with left main CAD (or left main equivalent) are

at extremely high risk and constitute a unique group for therapeutic consideration.¹¹ In the CASS, at 15 years of follow-up, 37% of the surgery group and 27% of the medical group are surviving; median survival is 13.3 years and 6.7 years, respectively ($p < .0001$). If systolic function was normal, then median survival and percent surviving were not different between the surgery and medical groups (median survival of about 15 years). Patients screened but not randomized to CASS had similar survival rates, suggesting that results from randomized patients may be applicable to more generalized populations as

TABLE 15–2. Grading of Angina Pectoris by the Canadian Cardiovascular Society Classification System

| Class | Description of Stage |
|-----------|--|
| Class I | Ordinary physical activity does not cause angina, such as walking, climbing stairs. Angina occurs with strenuous, rapid, or prolonged exertion at work or recreation. |
| Class II | Slight limitation or ordinary activity. Angina occurs on walking or climbing stairs rapidly, walking uphill, walking or stair climbing after meals, or in cold, or in wind, or under emotional stress, or only during the few hours after waking. Walking more than two blocks on the level and climbing more than one flight of ordinary stairs at a normal pace and in normal condition. |
| Class III | Marked limitations of ordinary physical activity. Angina occurs on walking one to two blocks on the level and climbing one flight of stairs in normal conditions and at a normal pace. |
| Class IV | Inability to carry on any physical activity without discomfort—anginal symptoms may be present at rest. |

From Campeau L. Grading of angina (letter). *Circulation* 1976;54:522–523, with permission.

a measure of external reliability. Other factors that predict outcome in ACS include age, heart rate, systolic blood pressure, ST-segment depression, signs of heart failure, and cardiac enzymes (also called biomarkers).¹²

ETIOLOGY AND PATHOPHYSIOLOGY

The pathophysiology that underlies this disease process is dynamic, evolutionary, and complex. An understanding of the determinants of myocardial oxygen demand (MVO₂), regulation of coronary blood flow, the effects of ischemia on the mechanical and metabolic function of the myocardium, and how ischemia is recognized is important in understanding the rationale for the selection and use of pharmacotherapy for IHD.

Ischemia may be defined as lack of oxygen and decreased or no blood flow in the myocardium. In contrast, anoxia, defined as the absence of oxygen to the myocardium, results in continued perfusion with washout of acid by-products of glycolysis, thereby preserving the mechanical and metabolic status of the heart to a greater extent than does ischemia for short periods of time.

DETERMINANTS OF OXYGEN DEMAND

The major determinants of MVO₂ are (1) heart rate, (2) contractility, and (3) intramyocardial wall tension during systole. Overall, intramyocardial wall tension is thought to be the most important among these three factors. Since the consequences of IHD are a result of increased demand in the face of a fixed supply of oxygen in most situations, alterations in MVO₂ are critically important in producing ischemia and for interventions intended to alleviate ischemia. MVO₂ cannot be measured directly in patients; however, an indirect assessment that correlates reasonably well with MVO₂ as determined in experimental animal models is the *tension-time index* (TTI). This is a measure of the area under the curve of the left ventricular (LV) pressure curve. Tension in the ventricle wall is a function of the radius of the left ventricle and intraventricular pressure. These factors are related through Laplace's law, which states that wall stress is related directly to the product of intraventricular pressure and internal radius and inversely to wall thickness multiplied by a factor of 2. Increasing systemic blood pressure or ventricular dilatation would increase wall tension and oxygen demand, whereas ventricular hypertrophy would tend to minimize increasing MVO₂. Clinical application of these principles has led to the use of the double product (DP), which is heart rate (HR) multiplied by systolic blood pressure (SBP) (DP = HR × SBP). Although this is a clinically useful indirect estimate of MVO₂, it does not consider changes in contractility (an independent variable), and because only changes in pressure are considered with the DP, volume loading of the left ventricle and increased MVO₂ related to ventricular dilation are underestimated.

REGULATION OF CORONARY BLOOD FLOW

Coronary blood flow is influenced by multiple factors; however, the caliber of the resistance vessels delivering blood to the myocardium and MVO₂ are the prime determinants in the occurrence of ischemia. The anatomy of the vascular bed will affect oxygen supply and, subsequently, myocardial metabolism and mechanical function.

ANATOMIC FACTORS

The normal coronary system (see Fig. 15-1 for normal anatomy) consists of large epicardial or surface vessels (R₁) that normally

FIGURE 15-1. Coronary artery anatomy with sternocostal and diaphragmatic views.

offer little intrinsic resistance to myocardial flow and intramyocardial arteries and arterioles (R₂), which branch into a dense capillary network (about 4000 capillaries/mm²) to supply basal blood flow of 60 to 90 mL/min per 100 g of myocardium. R₁ and R₂ are in series, and total resistance is the algebraic sum; however, under normal circumstances, the resistance in R₂ is much greater. Myocardial blood flow is inversely related to arteriolar resistance and directly related to the coronary driving pressure. The arterioles dynamically alter their intrinsic tone in response to demands for oxygen and other factors, and as a result, myocardial oxygen delivery and myocardial oxygen demand are tightly coupled in a rapidly responsive system.

Atherosclerotic lesions encroaching on the luminal cross-sectional area of the larger epicardial vessels (R₁) transform the relationships among R₁, R₂, and blood flow. As resistance increases in R₁ owing to occlusion, R₂ can vasodilate to maintain coronary blood flow. This response is inadequate with greater degrees of obstruction, and

the coronary flow reserve afforded by R_2 vasodilation is insufficient to meet oxygen demand (also referred to as *autoregulation*). The extent of functional obstruction is important in the limitation of coronary blood flow, and the presence of relatively severe stenosis (>70%) may provoke ischemia and symptoms at rest, whereas less severe stenosis may allow a reserve of coronary blood flow for exertion.¹³

The diameter of the lesion impeding blood flow through a vessel is important, but other factors such as length of the lesion and the influence of pressure drop across an area of stenosis also affect coronary blood flow and function of the collateral circulation. Resistance to flow in a vessel is directly related to length of the obstructing lesion, but resistance is inversely related to the diameter of the vessel to the fourth power. Diameter therefore is much more important. As blood flows across a stenotic lesion, the pressure drops (energy losses) owing to friction between blood and the lesion and owing to the abrupt turbulent expansion as blood emerges from the stenosis. This pressure drop is dynamic and directly related to flow, giving rise to a resistance that is not fixed but rather fluctuates as flow is changed. This relationship can affect collateral blood flow and its response to exercise dramatically, resulting in what has been called *coronary steal*. A similar situation also may occur when the epicardial or subepicardial vessels “steal” blood flow from the endocardium in the presence of a stenotic lesion.

Large and small coronary arteries may undergo dynamic changes in coronary vascular resistance and coronary blood flow. Dynamic coronary obstruction can occur in normal vessels and vessels with stenosis, in which vasomotion or spasm may be superimposed on a fixed stenosis. Although it is possible that these changes may be “active” in small coronary arteries, it is also possible that the observed changes may reflect collapse owing to poststenotic intraluminal pressure drop or increased intramyocardial compressive forces associated with inadequate ventricular relaxation.

Collateral blood flow exists to a certain extent from birth as native collaterals, but persisting ischemia may promote collateral growth as developed collaterals. These two types of collaterals differ in anatomy and in their ability to regulate coronary blood flow. Collateral development depends on the severity of obstruction, the presence of various growth factors (basic fibroblast growth factor [b-FGF] and vascular endothelial growth factor [VEGF]), endogenous vasodilators (e.g., nitrous oxide and prostacyclin), hormones such as estrogen, and potentially, exercise. Collateral development is highly species-dependent, and this should be considered when reading experimental literature.

METABOLIC REGULATION

Coronary blood flow is closely tied to oxygen needs of the heart. Changes in oxygen balance lead to very rapid changes in coronary blood flow. Although a number of mediators may contribute to these changes, the most important ones are likely to be adenosine, other nucleotides, nitric oxide, prostaglandins, CO_2 , and H^+ . Adenosine, which is formed from adenosine triphosphate (ATP) and adenosine monophosphate (AMP) under conditions of ischemia and stress, is a potent vasodilator that links decreased perfusion to metabolically induced vasodilation, or *reactive hyperemia*. The synthesis and release of adenosine into coronary sinus venous effluent occur within seconds of coronary artery occlusion, and about 30% of the hyperemic response can be blocked by metabolic blockers of adenosine.¹⁴

ENDOTHELIAL CONTROL OF CORONARY VASCULAR TONE

The vascular endothelium, a single-cell tissue with an enormous surface area separating the blood from vascular smooth muscle of the

artery wall, is capable of a broad range of metabolic functions. The endothelium functions as a protective surface for the artery wall, and as long as it remains intact and functional, it promotes vascular smooth muscle relaxation and inhibits thrombogenesis and atherosclerotic plaque formation; damaged endothelium reacts to numerous stimuli with vasoconstriction, thrombosis, and plaque formation. The vascular endothelium of the coronary arteries synthesizes large molecules such as fibronectin, interleukin-1, tissue plasminogen activator, and various growth factors. Small molecules that are also produced include prostacyclin, platelet-activating factor, endothelin-1, and endothelium-derived relaxing factor (EDRF) that is now characterized as nitric oxide. EDRF is synthesized from L-arginine via nitric oxide synthase and released by shear force on the endothelium, as well as through interaction with many biochemical stimuli such as acetylcholine, histamine, arginine, catecholamines, arachidonic acid, adenosine diphosphate (ADP), endothelin-1, bradykinin, serotonin, and thrombin.¹⁴ EDRF or nitric oxide then causes relaxation of the underlying smooth muscle and may be thought of as a paracrine homeopathic defense mechanism against noxious stimuli. Denudation or loss of the vascular endothelium results in loss of EDRF and this protective mechanism. Loss of the endothelial cell layer and function may occur secondary to physical disruption (e.g., percutaneous transluminal angioplasty [PTCA]), factors impinging from the vascular side (cyanide from smoke), or disruption of the intimal-medial layers (oxidized low-density lipoprotein). Impaired endothelial function may be related to the development of premature atherosclerosis based on recent family studies. Endothelial function may be improved with angiotensin-converting enzyme (ACE) inhibitors, statins, and exercise.

FACTORS EXTRINSIC TO THE VASCULAR BED

Blood flow to the coronary arteries arises from orifices located immediately distal to the aorta valve. Perfusion pressure is equal to the difference between the aortic pressure at an instantaneous point in time minus the intramyocardial pressure. Coronary vascular resistance is influenced by phasic systolic compression of the vascular bed. The driving force for perfusion therefore is not constant throughout the cardiac cycle. Opening of the aortic valve also may lead to a Venturi effect, which can slightly decrease perfusion pressure. If perfusion pressure is elevated for a period of time, coronary vascular resistance declines, and blood flow increases; however, continued perfusion pressure increases lead, within limits, to a return of coronary blood flow back toward baseline levels through autoregulation.

Alterations in intramyocardial wall tension throughout the cardiac cycle also will impose significant changes in coronary blood flow. Diastole is the period during which coronary artery filling can occur owing to these pressure differences, and little or no coronary blood flow occurs to the left ventricle during systole. The extent of pressure development in the ventricle and heart rate have a major effect on the development of wall tension, time for diastolic coronary artery filling, and myocardial oxygen demand.

Under normal conditions, the average global distribution of blood flow between the epicardial and endocardial layer is about 1:1 at rest and remains approximately even during exercise secondary to autoregulatory changes. Regional disparity of blood flow distribution does exist normally, and these disparities are magnified in the presence of diseased coronary arteries and with increased cardiac work as the vasodilator reserve in the resistance vessels of the subendocardium layers is exhausted. Factors that favor a reduction in subendocardial blood flow include decreased perfusion pressure owing to decreased diastolic blood pressure or coronary artery obstruction by atherosclerotic plaques with or without vasomotion, abbreviation of

diastole (increased heart rate), and increased intraventricular diastolic pressure (e.g., valvular obstruction to flow).

Extravascular resistance may decrease coronary blood flow, primarily during systole. This effect is much more pronounced in the left ventricle compared with the right ventricle. When the effect of increased contractility is separated from the effect of ventricular pressure, about 75% of extravascular resistance is accounted for by passive stretch in equilibrium with ventricular pressure, whereas only 25% results from active myocardial contraction.

FACTORS INTRINSIC TO THE VASCULAR BED

Metabolic factors, myogenic responses, neural reflexes, and humoral substances within the vascular bed of the coronary circulation function in an orchestrated fashion to maintain relative consistency in blood flow to the myocardium in the face of imposed changes in perfusion pressures. Autoregulation, mediated primarily through the effects of myogenic responses and metabolic factors, is thought to be responsible for maintaining regional blood flow in a narrow range while systemic pressure varies over a range of approximately 50 to 150 mm Hg.

Myogenic control (also known as the *Bayliss effect*) of coronary artery tone occurs when the vessel is stretched secondary to an increase in pressure and contracts to return blood flow to normal. It is thought that the myogenic response to stretching in coronary arteries is a modest one and that metabolic factors such as nitric oxide play a much larger role in autoregulation.

There are three well-studied metabolic factors that have the ability to modify coronary artery resistance and blood flow at the local level. Basal coronary blood flow meets oxygen demands of 8 to 10 mL/min per 100 g of myocardium with essentially complete extraction of oxygen from the blood. As cardiac output or mean arterial blood pressure increases, the increased demand for oxygen is met by increasing blood flow because little additional oxygen is available from hemoglobin. Decreased oxygen availability causes vasodilation of vascular smooth muscle and relaxation of precapillary sphincters, which increase tissue oxygen and help to maintain blood flow on a regional basis.

At perfusion pressures below 60 mm Hg, since the coronary arteries are maximally dilated and the buffering effect of autoregulation has reached its capacity, further reduction in coronary blood flow will decrease perfusion pressure and tissue oxygenation. It is thought that autoregulation works more efficiently in the epicardial layers than in the subendocardial layers, and this may contribute to coronary steal.

Neural components that participate in the regulation of coronary blood flow include the sympathetic nervous system, the parasympathetic nervous system, coronary reflexes, and possibly, central control of coronary blood flow. Within the sympathetic system, stimulation of the stellate ganglion elicits coronary vasodilation, which is associated with tachycardia and enhanced contractility. This indirect coronary vasodilation is secondary to increased MVO_2 related to increased heart rate, contractility, and aortic pressure and occurs following stellate stimulation. The direct effect of the sympathetic system is α_1 -mediated vasoconstriction at rest and during exercise. Other receptor types, α_2 and β_1 , have little influence on tone, whereas β_2 -stimulation produces a modest vasodilatory effect. Although coronary atherosclerosis may decrease blood flow secondary to obstruction, severe coronary atherosclerosis and obstruction also may increase the sensitivity of coronary arteries to the effects of α_1 -stimulation and vasoconstriction.

Vagal stimulation within the parasympathetic system produces a small to moderate increase in coronary blood flow, which in-

volves the coronary efferent and afferent parasympathetic components (Bezold-Jarish reflex). Indirectly, vasoconstriction may result, with vagal stimulation as the result of bradycardia and decreased contractility reducing myocardial oxygen demand.

Coronary reflexes have an undetermined role in the regulation of coronary blood flow. Based on experimental data, coronary reflexes that may be important include the baroreceptor, the chemoreceptor, the Bezold-Jarish reflex, and the pulmonary inhalation reflex.

FACTORS LIMITING CORONARY PERFUSION

During exercise and pacing, as MVO_2 increases, coronary vascular resistance can be reduced to about 25% of basal values, which results in a four- to fivefold increase in coronary blood flow. The cross-sectional area can be reduced by about 80% prior to any mechanical or biochemical changes in the myocardium, reflecting a margin of safety for coronary blood flow. The extent of cross-sectional obstruction, the length of the lesion, lesion composition, and the geometry of the obstructing lesion each can affect flow across coronary arteries with atherosclerosis. Bernoulli's theorem states that the pressure drop across a lesion is directly related to the length of the lesion and inversely related to the radius of the lesion to the fourth power; critical stenosis occurs when the obstructing lesion encroaches on the luminal diameter and exceeds 70%. Lesions creating obstructions of 50% to 70% may reduce blood flow; however, these obstructions are not consistent, and vasospasm and thrombosis superimposed on a "noncritical" lesion may lead to clinical events such as MI.¹⁵ If the lesion enlarges from 80% to 90%, resistance in that vessel is tripled. Coronary reserve is diminished at about 85% obstruction owing to vasoconstriction. Exaggerated responsiveness can be seen when the coronary stenosis reaches this critical level, and vasoactive substances such as prostaglandins, thromboxanes, and serotonin may play more of a role in the regulation of coronary vascular tone and thrombosis.

Little reserve exists for coronary blood flow, and a relatively small reduction of 10% to 20% results in decreased myocardial fiber shortening as the first evidence for abnormal function. The subendocardial layers are affected to a greater extent than the epicardium by ischemia, considering changes in fiber shortening, arteriovenous (AV) difference in oxygen saturation, and lactate production. A reduction of 80% gives rise to akinesis, and a 95% reduction of coronary blood flow produces dyskinesis during contraction of the ventricles. Although these abnormalities of contraction are associated with transient impaired function, depletion of high-energy phosphate compounds and ultrastructural changes may last for days even after transient ischemia; this has been referred to as *stunned myocardium*. Chronic hypoperfusion may lead to *hibernation*, in which ventricular function is impaired over longer time intervals. Hibernating myocardium can be differentiated from necrosis with various techniques (see Chap. 10), and revascularization of hibernating myocardium is useful in improving ventricular function. Regional loss of contractility may impose a burden on the remaining myocardial tissue, resulting in heart failure, increased MVO_2 , and rapid depletion of blood flow reserve. Consequently, zones of tissue with marginal blood flow may develop in a lateral or transmural fashion; such development puts this tissue at risk for more severe damage if the ischemic episode persists or becomes more severe. Nonischemic areas of myocardium may compensate for the severely ischemic and border zones of ischemia by developing more tension than usual in an attempt to maintain cardiac output. At the cellular level, ischemia and the attendant acidosis are thought to alter calcium release from storage sites such as the sarcolemma and the sarcoplasmic reticulum, as well as inhibiting the binding of calcium to

CLINICAL PRESENTATION OF ANGINA

GENERAL

- Many episodes of ischemia do not cause symptoms of angina (silent ischemia).
- Patients often have a reproducible pattern of pain or other symptoms that appear after a specific amount of exertion.
- Increased frequency, severity, duration, and symptoms at rest suggest an unstable angina pattern, and the patient should seek help immediately.

SYMPTOMS

- Sensation of pressure or burning over the sternum or near it, often but not always radiating to the left jaw, shoulder, and arm; also, chest tightness and shortness of breath.
- Pain usually lasting from 0.5 to 30 minutes, often with a visceral quality (deep location).
- Precipitating factors include exercise, cold environment, walking after a meal, emotional upset, fright, anger, and coitus.
- Relief occurs with rest and nitroglycerin.

SIGNS

- Abnormal precordial (over the heart) systolic bulge
- Abnormal heart sounds

LABORATORY TESTS

- Typically, no laboratory tests are abnormal; however, if the patient has intermediate- to high-risk features for unstable angina, electrocardiographic changes are seen, and serum troponin or creatine kinase concentrations may become abnormal (Table 15–3).
- Patients are likely to have laboratory test abnormalities for the risk factors for IHD, such as elevated total and low-density lipoprotein (LDL) cholesterol, low high-density lipoprotein (HDL) cholesterol, impaired fasting glucose or elevated glucose concentration, high blood pressure, and elevated C-reactive protein. Hemoglobin should be checked to make sure that the patient is not anemic.

OTHER DIAGNOSTIC TESTS

- A resting electrocardiogram (ECG) followed by an exercise tolerance test usually are the first tests done in stable patients.
- A chest x-ray should be done if the patient has heart failure symptoms.
- Cardiac imaging using radioisotopes to detect ischemic myocardium and measure ventricular function are done commonly when revascularization is being considered.
- Echocardiography also may be used to assess ventricular wall motion at rest or during stress.
- Cardiac catheterization and coronary arteriography are used to determine coronary artery anatomy and if the patient would benefit from angioplasty, coronary artery bypass grafting (CABG), or other revascularization procedures.

troponin, thereby impairing the association of actin and myosin. The clinical correlates of these cellular biochemical events leading to the development of LV or right ventricular (RV) dysfunction include an S₃ gallop, dyspnea, orthopnea, tachycardia, fluctuating blood pressure, transient murmurs, and mitral or tricuspid regurgitation.

Calcium accumulation and overload secondary to ischemia impair ventricular relaxation as well as contraction. This is apparently a result of impaired calcium uptake after systole from the myofilaments, leading to a less negative decline in the pressure in the ventricle over time. Impaired relaxation is associated with enhanced diastolic stiffness, decreased rate of wall thinning, and slowed pressure decay, producing an upward shift in the ventricular pressure-volume relationship; put more simply, MVO₂ is likely to be increased secondary to increased wall tension. Impairment of both diastolic and systolic function leads to elevation of the filling pressure of the left ventricle.

CLINICAL PRESENTATION AND DIAGNOSIS

Important aspects of the clinical history for chest pain for patients with angina include the nature or quality of the pain, precipitating factors, duration, pain radiation, and the response to nitroglycerin or rest. Because there can be considerable variation in the manifestations of angina, it is more accurate to refer to these symptoms as an *anginal syndrome*. For some patients with significant CAD, the presenting symptoms may differ from the classic symptoms, yet the symptoms are due to ischemic pain, and these are often referred to as *anginal equivalents*. Obtaining an accurate and detailed family history is useful in placing symptoms in perspective. Significant positive information includes premature coronary heart disease (<55 years in men and <65 years in women), as manifested as fatal and nonfatal MI, stroke, and peripheral vascular disease, and other risk factors such as hypertension, smoking, familial lipid disorders, and diabetes mellitus. Typical pain radiation patterns include anterior chest pain (96%), left upper arm pain (83.7%), left lower arm pain (29.3%), and neck pain at some time (22%). Pain from other areas is less common. Ischemia detected by ECG monitoring is more likely to be detected in the morning hours (6 AM to 12 noon) than other periods throughout the day. Patients suffering from variant or Prinzmetal's angina secondary to coronary spasm are more likely to experience pain at rest and in the early morning hours. Prinzmetal's anginal pain usually is not brought on by exertion or emotional stress nor relieved by rest; and the ECG pattern is that of current injury with ST-segment elevation rather than depression.

It is also important to differentiate the pattern of pain for stable angina from that of unstable angina. Unstable angina may be stratified into categories of risk ranging from high to low¹⁶ (see Table 15–3). Ischemia also may be painless or “silent” in 60% to 100% of patients depending on the series cited and the patient population.¹⁷ In patients with myocardial ischemia, approximately 70% of the episodes of documented ischemia are painless, as determined by ambulatory ECG monitoring, and the ST-segment changes associated with these episodes can be ST elevation or depression. The mechanism of silent ischemia is unclear, but studies have shown that patients not experiencing pain have altered pain perception, with the threshold and tolerance for pain being higher than those of patients who have pain more frequently. Although diabetics tend to have more extensive CAD than nondiabetics do and may suffer from autonomic neuropathy, asymptomatic ischemia is not more prevalent based on the Asymptomatic Cardiac Ischemia Pilot (ACIP) study.¹⁸ Altered endorphin release is a plausible explanation, but investigations with naloxone to block endorphins do not consistently show altered pain thresholds to various stimuli compared with patients with symptomatic ischemia, and

TABLE 15–3. Short-Term Risk of Death or Nonfatal MI in Patients with Unstable Angina

| Feature | High Risk (At least 1 of the following features must be present) | Intermediate Risk (No high-risk feature but must have 1 of the following) | Low Risk (No high- or intermediate-risk feature but may have any of the following) |
|-------------------|---|---|--|
| History | Accelerating tempo of ischemic symptoms in preceding 48 h | Prior MI, peripheral or cerebrovascular disease, or CABG, prior aspirin use | |
| Character of pain | Prolonged ongoing (>20 min), rest pain | Prolonged (>20 min), rest angina, now resolved, with moderate or high likelihood of CAD | New-onset CCS class III or IV angina in the past 2 weeks without prolonged (>20 min) rest pain but with moderate or high likelihood of CAD |
| Clinical findings | Pulmonary edema, most likely due to ischemia New or worsening MR murmur S ₃ or new/worsening rales Hypotension, bradycardia, tachycardia Age >75 yrs | | |
| ECG | Angina at rest with transient ST-segment changes > 0.05 mV Bundle-branch block, new or presumed new | T-wave inversions > 0.2 mV Pathologic Q waves | Normal or unchanged ECG during an episode of chest discomfort |
| Cardiac markers | Markedly elevated (e.g., TnT or Tnl > 0.1 ng/mL) | Slightly elevated (e.g., TnT > 0.01 but <0.1 ng/mL) | Normal |

Abbreviations: MI = myocardial infarction; CABG = coronary artery bypass grafting; CAD = coronary artery disease; CCS = Canadian Cardiovascular Society; MR = mitral regurgitation; ECG = electrocardiogram; TnT = troponin T; Tnl = troponin I

patients with asymptomatic ischemia do not necessarily have impaired somatic pain sensitivity.¹⁹ Alternatively, adenosine and substance P release during ischemia and mechanical stretch on coronary arteries may play a role in the perception of pain.

Last, it should be recognized that the threshold for pain owing to exertion is fixed in some patients and variable in others and that the amount of exercise or stress necessary to provoke symptoms can change over time. A fixed threshold for the induction of pain or ECG evidence of ischemia means that these indicators of ischemia occur at the same or nearly so, doubling the rate-pressure product. This is apparently owing to at least two factors. Over long periods of time, atherosclerosis may progress, leading to more severe stenosis, reduced oxygen supply, and less of an increase in demand to precipitate ischemic symptoms. Once stenotic lesions reach a critical level of about 80% or greater, vasomotion, vasospasm, and thrombotic occlusion become significant factors impairing blood flow to the myocardium. Consequently, anatomic considerations and vasoactive substances may interact to provide an environment amenable to changing thresholds for the production of angina.

There appears to be little relationship between the historical features of angina and the severity or extent of coronary artery vessel involvement. Therefore, one may speculate that severe symptoms might be associated with multivessel disease, but no predictive markers exist on a routine basis.

Chest pain may resemble pain arising from a variety of noncardiac sources, and the differential diagnosis of anginal pain from other etiologies may be quite difficult based on history alone. Table 15–4 outlines other common problems that may present with episodic chest pain. Although much less common, nonatherosclerotic etiologies of CAD do exist and should be excluded with appropriate tests. The clinical classification of chest pain encompasses typical angina, including (1) substernal chest pain with a characteristic quality and duration that is (2) provoked by exertion or emotional stress and (3) relieved by rest or nitroglycerin; atypical angina meets two of the characteristics for typical angina, and noncardiac chest pain meets one or fewer of the typical angina characteristics.¹

There are few signs apparent on physical examination to indicate the presence of CAD, and usually only the cardiovascular system reveals any useful information. Elevated heart rate or blood pressure can yield an increased DP and may be associated with angina, and it would be important to correct extreme tachycardia or hypertension if present. Other noncardiac physical findings that suggest that significant cardiovascular disease may be associated with angina include abdominal aortic aneurysms or peripheral vascular disease. Cardiac examination findings in CAD are noted in Table 15–5. During an angina attack, these findings may appear or become more prominent, making them more valuable if present.

In addition to screening for CVD risk factors (see Table 21–7), other recommended tests include hemoglobin, fasting glucose, fasting lipoprotein panel, resting ECG, and chest x-ray in patients with signs or symptoms of heart failure, valvular heart disease, pericardial disease, or aortic dissection/aneurysm.¹ Hemoglobin is assessed to ensure adequate oxygen-carrying capacity. Fasting glucose determinations to exclude diabetes and glucose monitoring for concurrent diabetes should be performed routinely. Lipids are assessed as total, LDL, and HDL cholesterol and triglycerides²⁰ (see Chap. 21). Other risk factors that may be important for some patients include C-reactive protein, homocysteine level, evidence of *Chlamydia* infection, and elevations in lipoprotein (a), fibrinogen, and plasminogen activator inhibitor.^{21,22} Cardiac enzymes all should be normal in stable angina. Troponin T or I, myoglobin, or creatinine phosphokinase-MB isoform may be elevated in patients with unstable angina, and interventions such as anticoagulation and antiplatelet therapy have been shown to reduce cardiac end points when these markers for injury are elevated²³ (see Table 15–3).

Patients presenting with chest pain are stratified into chronic stable angina or having features of intermediate- or high-risk unstable angina (Fig. 15–2; see also Table 15–3). These features include rest pain lasting more than 20 minutes, age greater than 65 years, ST-segment and T-wave changes, and pulmonary edema. Patients with ACS (unstable angina, NSTEMI, and STEMI) are managed differently from those with chronic stable angina.

TABLE 15-4. Differential Diagnosis of Episodic Chest Pain Resembling Angina Pectoris

| | Duration | Quality | Provocation | Relief | Location | Commet |
|-------------------|-------------------------------|-------------------------------|---|---|------------------------|----------------------|
| Effort angina | 5–15 min | Visceral (pressure) | During effort or emotion | Rest, NTG | Substernal, radiates | First episode vivid |
| Rest angina | 5–15 min | Visceral (pressure) | Spontaneous (?with exercise) | NTG | Substernal, radiates | Often nocturnal |
| Mitral prolapse | Min–hours | Superficial (rarely visceral) | Spontaneous (no pattern) | Time | Left anterior | No pattern, variable |
| Esophageal reflux | 10 min–1 h | Visceral | Spontaneous, cold liquids, exercise, lying down | Foods, antacids, H ₂ blockers, proton pump inhibitors, NTG | Substernal, radiates | Mimics angina |
| Peptic ulcer | Hours | Visceral, burning | Lack of food, “acid” foods | Foods, antacids, H ₂ blockers, proton pump inhibitors | Epigastric, substernal | |
| Biliary disease | Hours | Visceral (wax and wane) | Spontaneous, food | Time, analgesia | Epigastric, radiates | Colic |
| Cervical disk | Variable (gradually subsides) | Superficial | Head and neck, movement and palpation | Time, analgesia | Arm, neck | Not relieved by rest |
| Hyperventilation | 2–3 min | Visceral | Emotion, tachypnea | Stimulus removed | Substernal | Facial paraesthe |
| Musculoskeletal | Variable | Superficial | Movement, palpation | Time, analgesia | Multiple | Tenderness |
| Pulmonary | 30 min | Visceral (pressure) | Often spontaneous | Rest, time bronchodilator | Substernal | Dyspneic |

NTG = nitroglycerin.

TABLE 15-5. Cardiac Findings in Patients with Coronary Artery Disease

| Sign | Clinical Significance | Frequency |
|--|---|---|
| Abnormal precordial systolic bulge | Left ventricular wall motion abnormality | Not usually present unless patient has sustained a prior MI (especially anterior wall) or is experiencing angina at time of examination |
| Decreased intensity of S ₁ | Decrease in left ventricular contractility | Difficult to evaluate in resting state, but can be commonly demonstrated during angina |
| Paradoxical splitting of S ₂ | Left ventricular wall motion abnormality | Very uncommon but occasionally noted during angina |
| S ₃ (ventricular gallop) | Increased left ventricular diastolic pressure, with or without clinical CHF | Not usually present unless patient sustained extensive MI; may occasionally be present during angina |
| S ₄ (atrial gallop) | Reduced ventricular compliance (“stiff heart”) | Common; very common in patients who have sustained a prior MI as well as during angina |
| Apical systolic murmur (in absence of rheumatic mitral regurgitation or Barlow’s syndrome) | Papillary muscle dysfunction | Not usually present unless patient has sustained prior MI |
| Diastolic murmur (in absence of aortic regurgitation) | Coronary artery stenosis | Rare |

Abbreviations: S₁ = first heart sound; S₂ = second heart sound; S₃ = third heart sound; S₄ = fourth heart sound; MI = myocardial infarction; CHF = congestive heart failure.

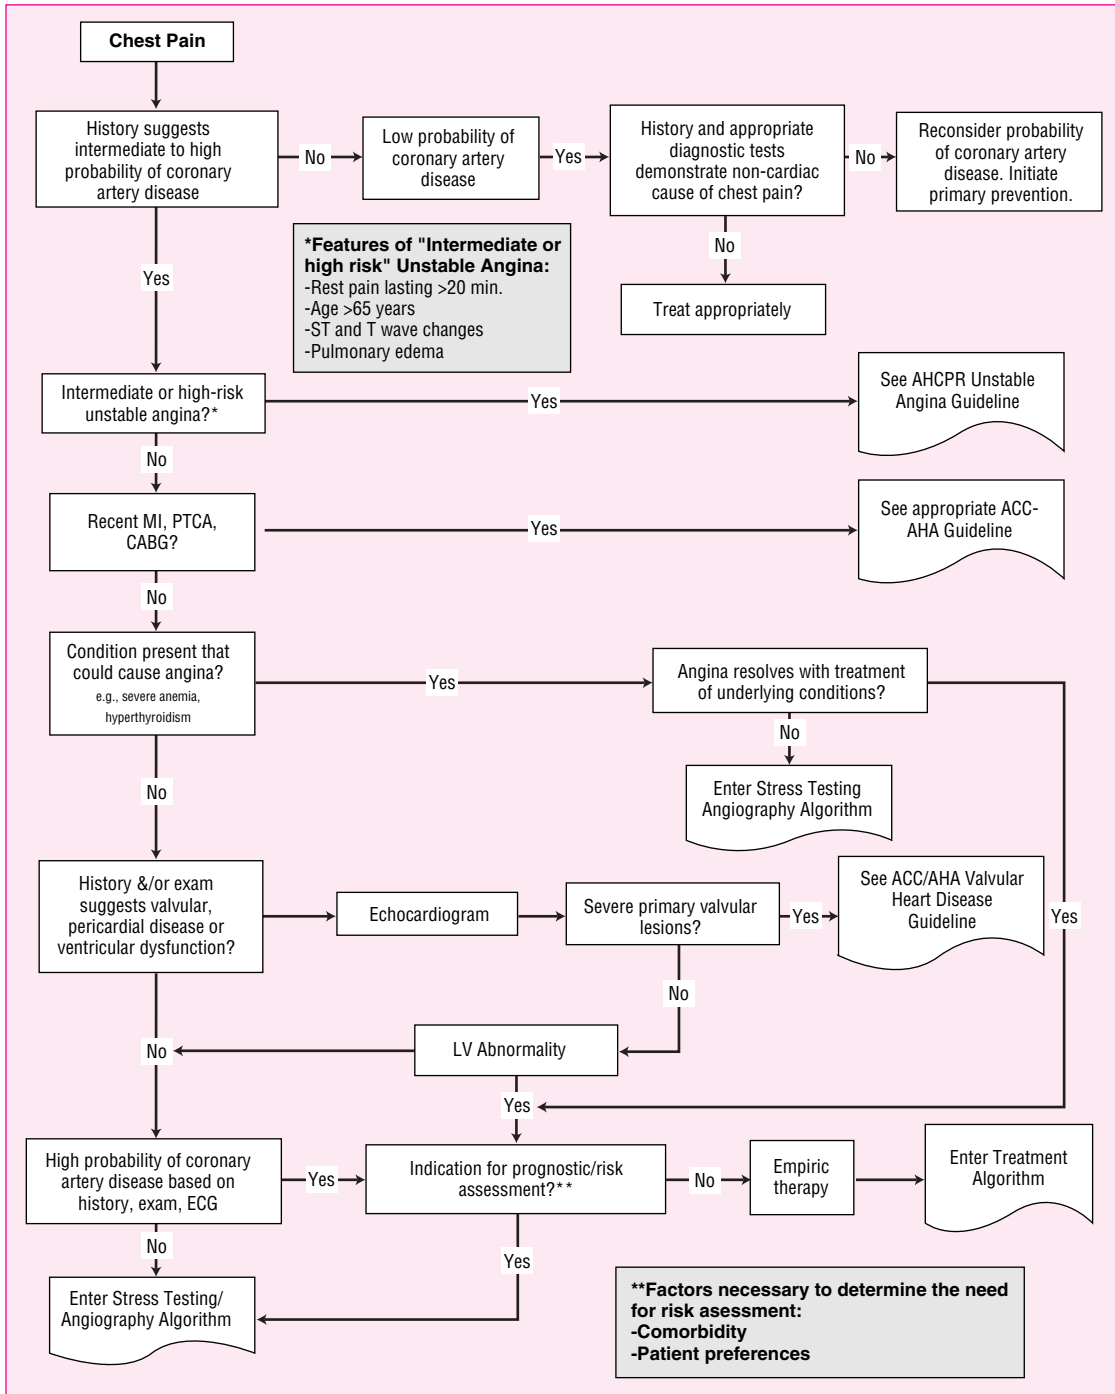

FIGURE 15-2. Clinical assessment (AHCPR = Agency for Health Care Policy and Research).

DIAGNOSTIC TESTS (See Chap. 11)

ELECTROCARDIOGRAM

The ECG is normal in about one-half of patients with angina who are not experiencing an acute attack. Typical ST-T-wave changes include depression, T-wave inversion, and ST-segment elevation. Forms of ischemia other than exertional angina may have ECG manifestations that are different; variant angina is associated with ST-segment elevation, whereas silent ischemia may produce elevation or depression. Significant ischemia is associated with ST-segment depression

of greater than 2 mm, exertional hypotension, and reduced exercise tolerance.

EXERCISE TOLERANCE TESTING²⁴

Exercise tolerance (stress) testing (ETT) is recommended for patients with intermediate pretest probability of CAD based on age, gender, and symptoms, including those with complete right bundle branch block or less than 1 mm of rest ST-segment depression (Fig. 15-3). Although ETT is insensitive for predicting coronary artery anatomy, it does correlate well with outcome, such as the likelihood of

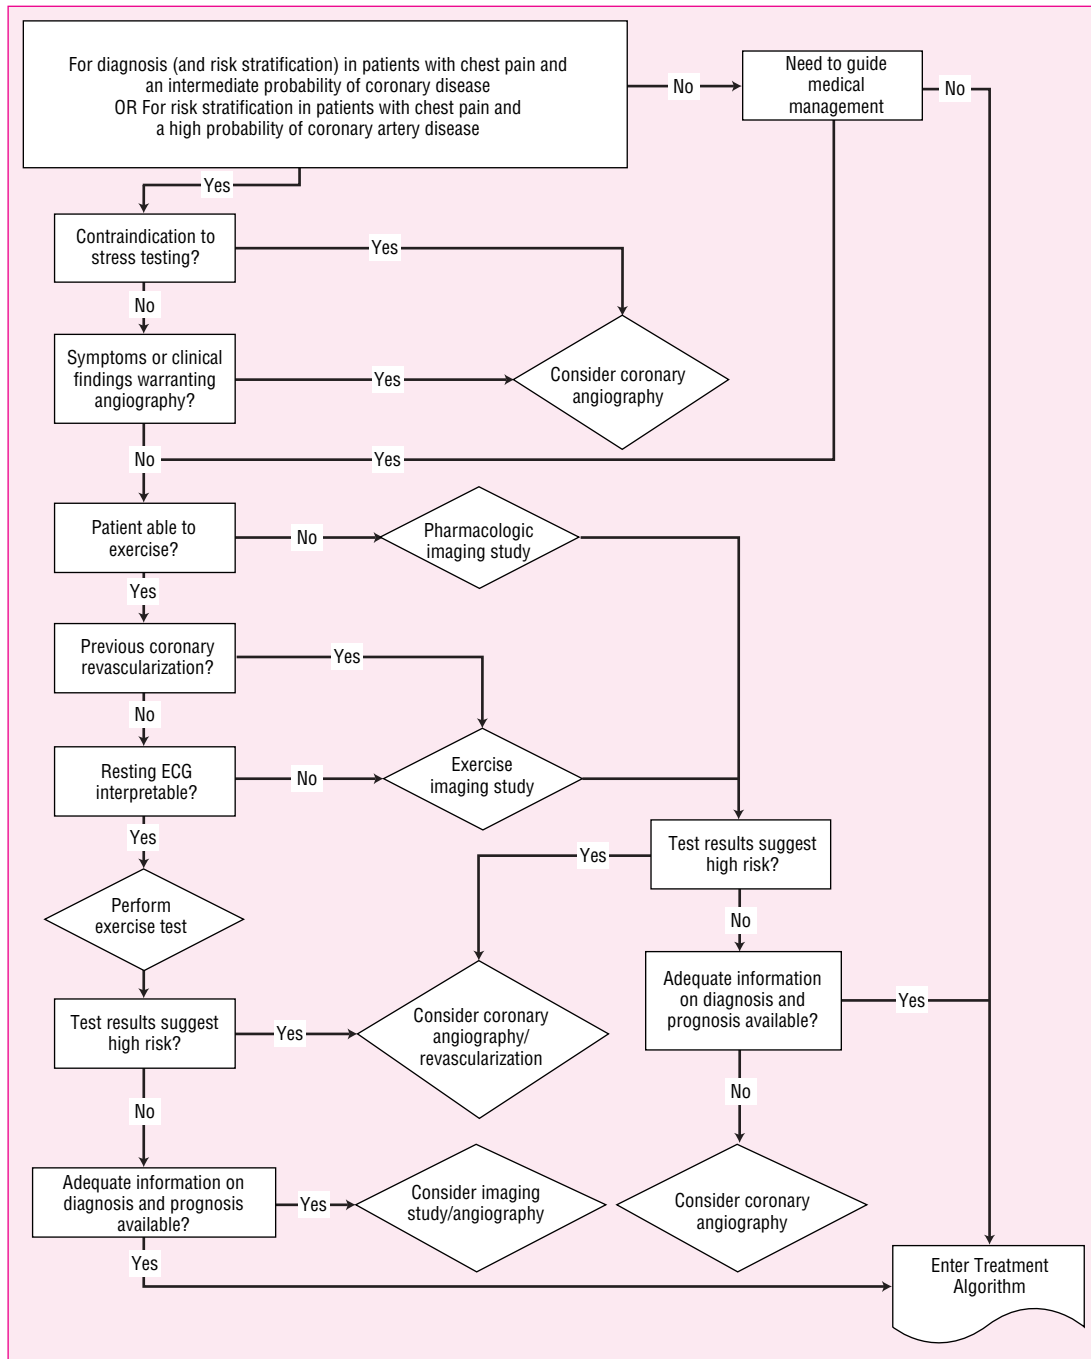

FIGURE 15-3. Stress testing/angiography.

progressing to angina, the occurrence of acute MI, and cardiovascular death. Ischemic ST-segment depression that occurs during ETT is an independent risk factor for cardiac events and cardiovascular mortality. Thallium (²⁰¹Tl) myocardial perfusion scintigraphy may be used in conjunction with ETT to detect reversible and irreversible defects in blood flow to the myocardium because it is more sensitive than ETT.

CARDIAC IMAGING

Radionuclide angiocardiology (performed with technetium-99m, a radioisotope) is used to measure ejection fraction, regional ventricular performance, cardiac output, ventricular volumes, valvular regurgitation, asynchrony or wall motion abnormalities, and intracar-

diac shunts.²⁵ Technetium pyrophosphate scans are used routinely for the detection and quantification of acute MI (see Chap. 11). Positron-emission tomography (PET) is useful for quantifying ischemia with metabolically important substrates such as oxygen, carbon, and nitrogen. Other metabolic probes use radiolabeled fatty acids and glucose to study metabolic processes that may be deranged during ischemia in animals and for investigative purposes in humans.

A new method using ultrarapid computed tomography (spiral CT, ultrafast CT, electron-beam CT) minimizes artifact owing to motion of the heart during contraction and relaxation and provides a semiquantitative assessment of calcium content in coronary arteries.²⁶ Calcium scores greater than 150 provide a sensitivity of 74% and specificity of 89%, and this method may be cost-effective compared with ETT.

ECHOCARDIOGRAPHY

Echocardiography is useful if patients have history or physical examination suggestive of valvular pericardial disease or ventricular dysfunction. For patients unable to exercise, pharmacologic stress echocardiography (dobutamine, dipyridamole, or adenosine) or pacing may be done to identify abnormalities during stress.

CARDIAC CATHETERIZATION AND CORONARY ARTERIOGRAPHY

Cardiac catheterization and angiography in patients with suspected CAD are used diagnostically to document the presence and severity of disease, as well as for prognostic purposes. High-risk features during ETT suggesting the need for coronary angiography include early and significant (≥ 2 mm) changes on the ECG during ETT, as well

as multiple lead involvement, prolonged recovery from ischemia, low workload performance, abnormal blood pressure response (reduction in blood pressure), or ventricular arrhythmias. Multiple defects with thallium scans, as well as lung uptake during exercise or postexercise ventricular cavity dilation, are also high-risk indications for catheterization. Interventional catheterization is used for thrombolytic therapy in patients with acute MI and for the management of patients with significant CAD to relieve obstruction through PTCA, atherectomy, laser treatment, or stent placement. Catheterization and angiography may be done after coronary artery bypass grafting (CABG) to determine if the graft has closed or if CAD has progressed. Coronary artery intravascular ultrasound (IVUS) is useful for directly imaging anatomy, calcified and fatty plaques, and thrombosis superimposed on plaque, as well as for determining patency following revascularization procedures. IVUS guidance of stent implantation may result in more effective stent expansion compared with angiographic guidance alone.²⁷

► TREATMENT: Ischemic Heart Disease

■ DESIRED OUTCOME

The short-term goals of therapy for IHD are to reduce or prevent the symptoms of angina that limit exercise capability and impair quality of life. Long-term goals of therapy are to prevent CHD events such as MI, arrhythmias, and heart failure and to extend the patient's life. Since there is little evidence that revascularization procedures such as angioplasty and CABG extend life, the primary focus should be on altering the underlying and ongoing process of atherosclerosis through risk-factor modification while providing symptomatic relief through the use of nitrates, β -blockers, and calcium channel blockers for anginal symptoms.

■ RISK-FACTOR MODIFICATION

3 Primary prevention of ischemic heart disease through the identification and modification of risk factors prior to the initial morbid event would be the optimal management approach and should result in a significant impact on the prevalence of IHD. However, early recognition of some risk factors may not be possible in all cases, and in others, the patient may not be willing to undertake intervention until overt evidence of CAD is apparent. Secondary intervention continues to be pursued more commonly by both health care professionals and patients, and it is important to recognize this type of intervention as effective in reducing subsequent morbidity and mortality. The presence of risk factors in individual patients plays a major role in determining the occurrence and severity of IHD.²⁰ Risk factors are additive in nature and can be classified as alterable or unalterable (see Table 21–7). Unalterable risk factors include gender; age; family history or genetic composition; environmental influences such as climate, air pollution, and trace metal composition of drinking water; and to some extent, diabetes mellitus. Improved glycemic control reduces the microvascular complications of diabetes mellitus (see Chap. 72) and reduces coronary end points; however, based on the Diabetes Control and Complications study, the reduction was impressive (40 versus 23 major events) but not significant because the trial was underpowered 4 to detect these changes.²⁸ Risk factors that can be altered include smoking, hypertension, hyperlipidemia, obesity, sedentary lifestyle, hyperuricemia, psychosocial factors such as stress and type A behavior patterns, and the use of certain drugs that may be detrimental, including progestins, corticosteroids, and cyclosporine.

Cigarette smoking is common; nearly 50 million people are regular smokers in this country, and the risk for IHD is increased by about 1.8 in active smokers and by about 1.3 in those exposed to passive or environmental smoke.²⁹ Approximately 430,700 Americans die each year from smoking-related illnesses, and one in five deaths owing to CVD are attributable to smoking.⁵ Risk owing to smoking is related to the number of cigarettes smoked per day and the duration of smoking. Passive smoking in angina pectoris patients has been shown to decrease exercise time.⁷ Pipe and cigar smokers are at increased risk compared with nonsmokers, but their risk is somewhat less than that of cigarette smokers.³⁰ The direct effects of cigarette smoke that are detrimental to patients with angina include (1) elevated heart rate and blood pressure from nicotine, which increases MVO_2 , and impaired myocardial oxygen delivery owing to carboxyhemoglobin generation from carbon monoxide inhalation in smoke, (2) the negative inotropic effect of carboxyhemoglobin, (3) increased platelet adhesiveness and promotion of aggregation, resulting in thrombotic tendencies owing to nicotine and carboxyhemoglobin, (4) lowered threshold for ventricular fibrillation during ischemia owing to carboxyhemoglobin, and (5) impaired endothelial function owing to smoking.³¹ Similar changes have been noted for marijuana smoking as well. Smoking also accelerates the risk for myocardial infarction, sudden death, cerebrovascular disease, peripheral vascular disease, and hypertension, and it reduces HDL concentrations. Clearly, primary prevention is needed for this risk factor, and much of the education effort to discourage initiation of smoking should be targeted to teenagers. Techniques for cessation of smoking that may be useful include aversive conditioning, group programs, self-help programs, hypnosis, “cold turkey,” and the use of nicotine substitutes (lobeline) or other sources of nicotine (Nicorette chewing gum and transdermal nicotine systems) for short-term substitution during withdrawal syndrome. Cessation of smoking reduces the incidence of coronary events to about 15% to 25% of that associated with continued smoking, and these benefits are noted within 2 years of cessation.³²

Hypertension, whether labile or fixed, borderline or definite, casual or basal, systolic or diastolic, at any age regardless of gender is the most common and a powerful contributor to atherosclerotic coronary vascular disease.³³ Morbidity and mortality increase progressively with the degree of elevation of either systolic or diastolic pressure and pulse pressure, and no discernible critical value exists (see Chap. 13). Numerous trials have documented the reduction in risk associated with blood pressure lowering; however, most of these studies show that mortality and morbidity reduction is a result of fewer strokes and

less renal failure and heart failure. The reduction in coronary heart disease end points is significant but not as dramatic. The reasons for this are unclear but perhaps relate to the multifactorial etiology of IHD.

Hypercholesterolemia is a significant cardiovascular risk factor, and risk is related directly to the degree of cholesterol elevation.²⁰ As with hypertension, there is no critical value that defines risk, but rather, risk is related incrementally to the degree of elevation and the presence of other risk factors (see Chap. 21 for a detailed discussion). A fasting lipoprotein panel should be obtained in all patients with known CAD. The goals for total, LDL, and HDL cholesterol and triglycerides are discussed in Chap. 21. All patients should undertake therapeutic lifestyle changes. Reductions in LDL cholesterol for primary prevention and secondary intervention have been shown to reduce total and CAD mortality and stroke, as well as the need for interventions such as PTCA and CABG. Supplemental vitamin E or other antioxidants reduce the susceptibility of LDL cholesterol to oxidation, but clinical trial data have failed to show any benefit with supplementation.³⁴

The prevalence of obesity, defined as greater than 20% over ideal body weight, ranges from 7.4% to 17% in men and from 9.6% to 34.7% in women in this country. Body mass index, weight (in kilograms) divided by height (in meters) squared, greater than about 32 is associated with an increased mortality ratio compared with individuals of normal body weight, and the objective for patients with IHD is to maintain or reduce to a normal body weight. This may be accomplished through dietary modification, exercise, pharmacologic therapy, or surgical therapy. Frequently associated with obesity is a sedentary lifestyle, and inactivity may contribute to higher blood pressure, elevated blood lipid levels, and insulin resistance associated with glucose intolerance in diabetics (insulin resistance syndrome). Exercise to the level of about 300 kcal three times a week is useful in improving maximal oxygen uptake, improving cardiorespiratory efficiency, promoting collateral artery formation, and promoting potential alterations in the risk of ventricular fibrillation, coronary thrombosis, and improved tolerance to stress. Epidemiologic studies have found that mortality is related directly to resting heart rate and a low heart rate difference between resting and maximal exercise heart rates and inversely related to exercise heart rate.³⁵ Although a regular exercise program may not reduce CVD mortality, participants feel better, and their overall cardiovascular risk may be reduced.³⁶

Competitiveness, intense striving for achievement, easily provoked hostility, a sense of urgency about doing things quickly and being punctual, impatience, abrupt and rapid speech and gestures, and concentration on self-selected goals to the point of not perceiving and attending to other aspects of the environment are traits that characterize the behavioral pattern known as the *type A* or *coronary-prone personality*. Although the issue is somewhat controversial, type A individuals may have increased cardiovascular risk, with risk ratios ranging from insignificant to three times that of a matched population. The mechanism by which personality affects the cardiovascular sys-

tem is not understood but may reflect the activity of the sympathetic system and enhanced responsiveness of other stress hormones when compared with non-type A personalities.

Alcohol ingestion in small to moderate amounts (<40 g/day of pure ethanol) reduces the risk of CAD; however, consumption of large amounts (>50 g/day) or binge drinking of alcohol is associated with increased mortality from stroke, cancer, vehicular accidents, and cirrhosis. The mechanisms for the presumed protective effects of alcohol are not known, but the effects may be related to increased HDL levels, impaired platelet function, or associations between the amount of alcohol ingested and personality type. Whatever the relationship, it is well to remember that alcohol drinking is implicated in over 40% of all fatal automobile accidents and that consumption of alcohol predisposes to hepatic cirrhosis, the sixth to seventh most common cause of death in middle age in the United States. With this in mind, it seems illogical to suggest alcohol ingestion as a prophylactic measure for CAD but rather advise moderation in alcohol consumption, if it is the preference of the individual.

Thiazide diuretics have been shown to elevate serum cholesterol and triglyceride levels, whereas β -blockers tend to lower HDL and raise LDL slightly; however, a direct association between these drugs and cardiovascular risk is tenuous and based on aggregating results rather than randomized clinical trials. Conjugated equine estrogen alone or in combination with progestin lowers LDL and raises HDL based on the Postmenopausal Estrogen/Progestin Interventions (PEPI) study.³⁷ Unfortunately, the HERS trial showed no benefit of hormone-replacement therapy (HRT) for secondary intervention and increased risk for thromboembolism.³⁸ In secondary intervention, HRT or estrogen alone in women after hysterectomy found that hormonal therapy health risks exceeded benefits as well.³⁹ Unopposed estrogen is the optimal regimen for elevation of HDL, but the high rate of endometrial hyperplasia restricts use to women without a uterus. In women with a uterus, estrogen with cyclic medroxyprogesterone has the most favorable effect on HDL and no excess risk of endometrial hyperplasia. Use of oral contraceptives in women who smoke and are over the age of 35 years increases the risk of MI, stroke, and venous thromboembolism by threefold or higher. Alternative forms of contraception and cessation of smoking should be promoted in these patients. The risk for nonsmoking oral contraceptive users under the age of 35 is very small. The relative risk of breast cancer is increased but in the absence of risk factors for breast cancer, the relative risk is approximately 1.3 (30% increase). Coffee consumption also has been linked to CAD, and caffeine does transiently elevate blood pressure; however, the overall risk, if any, appears to be low. Although thiazide diuretics and β -blockers (nonselective without intrinsic sympathomimetic activity) may elevate both cholesterol and triglycerides by some 10% to 20%, and these effects may be detrimental, no objective evidence exists from prospective, well-controlled studies to support avoiding these drugs at this time. This controversy is most pertinent in the treatment of mild hypertension, and it is discussed in greater detail in Chap. 13.

► TREATMENT: Stable Exertional Angina Pectoris

The current national guidelines recommend that all patients be given the following unless contraindications exist: (1) aspirin, (2) β -blockers with prior MI, (3) angiotensin-converting enzyme (ACE) inhibitor to patients with CAD and diabetes or LV systolic dysfunction, (4) LDL-lowering therapy with CAD and an LDL concentration

greater than 130 mg/dL (*Note:* this is likely to be lowered to less than 100 mg/dL after recent statin trials have shown benefit; see Chap. 21), (5) sublingual nitroglycerin for immediate relief of angina, (6) calcium antagonists or long-acting nitrates for reduction of symptoms when β -blockers are contraindicated, (7) calcium

antagonists or long-acting nitrates in combination with β -blockers when initial treatment with β -blockers is not successful, and (8) calcium antagonists or long-acting nitrates as a substitute for β -blockers if initial treatment with β -blockers leads to unacceptable side effects.¹

After assessing and manipulating the alterable risk factors, as discussed previously, the next intervention that could be undertaken is the institution of a regular exercise program. Training is possible in many patients with angina, and the observed benefits include decreased heart rate and systolic blood pressure and increased ejection fraction and duration of exercise. Although the mechanism of these effects has been debated, improved overall cardiovascular and muscular conditions are probably most important. Improved production of nitric oxide and coronary vasomotion may account partially for the beneficial effects of exercise. The intensity of exercise influences training, and more vigorous programs provide better overall results.^{14,40} Obviously, an exercise program should be undertaken with caution and in a graded fashion with adequate supervision.

5 Chronic prophylactic therapy for patients with more than one angina episode per day also may be instituted with β -adrenergic blocking agents, and in many instances, β -blockers may be preferable because of less frequent dosing and other properties inherent in β -blockade (e.g., potential cardioprotective effects, antiarrhythmic effects, lack of tolerance, and antihypertensive effects), as well as their antianginal effects and documented protective effects in post-MI patients.¹ Patients who continue to smoke have reduced antianginal efficacy of β -blockers. This may be due to enhanced hepatic metabolism of drugs that are eliminated through this route or related to the effects of smoking on MVO₂ and oxygenation.

The one characteristic that is relevant is the duration of effect on the DP. β -Blockers with longer half-lives (e.g., nadolol) are more likely to affect the DP for a longer period of time and require fewer doses per day. The choice of β -blocker for angina rests on selecting the appropriate dose to achieve the goals outlined for heart rate and DP and choosing an agent that is well tolerated by individual patients and of acceptable cost. Selective use may incorporate ancillary properties, but these are secondary considerations in overall drug product selection. Patients most likely to respond well to β -blockade are those who have a high resting heart rate and those having a relatively fixed anginal threshold. In other words, their symptoms appear at the same level of exercise or workload on a consistent basis. Symptoms appearing with variable workloads suggest fluctuations in myocardial oxygen supply, perhaps due to coronary artery vasomotion, and these patients are more likely to respond to calcium channel antagonists.

6 Nitrate therapy should be the first step in managing acute attacks for patients with chronic stable angina if the attacks are infrequent (i.e., a few times per month) or for prophylaxis of symptoms when undertaking activities known to precipitate attacks. In general, if angina occurs no more often than once every few days, then sublingual nitroglycerin tablets or spray or buccal products may be sufficient to allow the patient to maintain an adequate lifestyle. For episodes of “first effort” angina occurring in a predictable fashion, nitroglycerin may be used in a prophylactic manner with the patient taking 0.3 to 0.4 mg sublingually about 5 minutes prior to the anticipated time of activity. Nitroglycerin spray may be useful when inadequate saliva is produced to rapidly dissolve sublingual nitroglycerin or if a patient has difficulty opening the container. Most patients have a response that lasts about 30 minutes or so, but this is subject to interindividual variability.

When angina occurs more frequently than once a day, a chronic prophylactic regimen using β -blockers as the first line of therapy

should be considered (see Fig. 15–4 for a stable angina algorithm). Chronic prophylactic therapy with long-acting forms of nitroglycerin (oral or transdermal), isosorbide dinitrate, 5-mononitrate, and pentaerythritol trinitrate may be effective; however, the development of tolerance is a major limiting step in their continued effectiveness. Since long-acting nitrates are not as effective as β -blockers and do not have beneficial effects, monotherapy with nitrates should not be first-line therapy unless β -blockers and calcium channel blockers are contraindicated or not tolerated.

As described previously, providing a nitrate-free interval of 8 hours per day or longer appears to be the most promising approach to maintaining the efficacy of chronic nitrate therapy. Oral administration of nitrates is susceptible to a saturable first-pass effect; therefore, larger doses can produce a measurable hemodynamic effect, and dose titration should be based on these changes in the DP. There are few well-controlled studies comparing oral or sublingual nitrate efficacy, and the choice among these products should be based on familiarity with the preparation, cost, and patient acceptance.

7 Calcium channel antagonists have the potential advantage of improving coronary blood flow through coronary artery vasodilation, as well as decreasing MVO₂, and they may be used instead of β -blockers for chronic prophylactic therapy. However, in chronic stable angina, comparative trials of long-acting calcium channel blockers with β -blockers do not show significant differences in response.^{41,42} They are as effective as β -blockers and are most useful in patients who have a variable threshold for exertional angina. Calcium antagonists may provide better skeletal muscle oxygenation, resulting in decreased fatigue and better exercise tolerance. Additionally, if contraindications exist to β -blocker therapy, calcium antagonists can be used safely in many patients. The available calcium channel blockers appear to have similar efficacy in the management of chronic stable angina.

Differences in their electrophysiology, peripheral and central hemodynamic effects, and adverse-effect profiles are useful in selecting the appropriate agent. Patients with conduction abnormalities and moderate to severe LV dysfunction (ejection fraction <35%) should not be treated with verapamil, whereas amlodipine may be used safely in many of these patients. Diltiazem has significant effects on the atrioventricular node and can produce heart block in patients with pre-existing conduction disease or when other drugs, such as digoxin or β -blockers, with effects on conduction are used concurrently. Nifedipine may cause excessive heart rate elevation, especially if the patient is not receiving a β -blocker, and this may offset the beneficial effect it has on MVO₂. Gingival hyperplasia also has been reported with nifedipine, and some dental authorities say that this may be seen in as many as 20% of patients on nifedipine. Bepridil prolongs the QT interval in patients with certain conditions (e.g., hypokalemia, advanced age, and preexisting QT-interval prolongation), and because of this potential proarrhythmic effect, it is indicated only in patients who have been inadequately controlled with other antianginal therapy.

Case-control studies with calcium blockers suggest an increased risk for MI and cancer.^{43,44} The relationship to cancer appears to be weak to nonexistent, whereas the risk for MI is probably real and related to the type of drug used and the relationship to recent MI. Shorter-acting calcium blockers can activate the sympathetic nervous system and in patients with recent MI or significant CAD may induce ischemia. This effect has not been shown for longer-acting products. The hemodynamic effect of calcium antagonists is complementary to β -blockade, and consequently, combination therapy is rational, but clinical trial data do not support the notion that combination therapy is always more effective.^{41,45}

■ **NONPHARMACOLOGIC THERAPY**

■ **REVASCULARIZATION**

The decision to choose percutaneous coronary intervention (PCI) or CABG for revascularization is based on the extent of CAD (number of vessels and location/amount of stenosis) and ventricular function. The recommended mode of coronary revascularization is outlined in Table 15-6.¹⁶

The largest randomized trial of PCI versus CABG is the Bypass Angioplasty Revascularization (BARI) trial conducted in 1829 patients with two- or three-vessel disease; 64% of these patients had an admitting diagnosis of unstable angina (UA), and 19% were diabetic.⁴⁶ Seven-year survival for the total population was 84.4% for CABG and 80.9% for PTCA ($p = .043$). Patients with diabetes mellitus undergoing CABG had improved survival compared with nondiabetics (76.4% CABG and 55.7% PTCA; $p = .0011$). Among the remaining 1,476 patients without treated diabetes, survival was

TABLE 15–6. Recommended Mode of Coronary Revascularization

| Extent of Disease | Treatment | Class/Level of Evidence |
|---|-------------|-------------------------|
| Left main disease, ^a candidate for CABG | CABG PCI | I/A III/C |
| Left main disease, not a candidate for CABG | PCI | IIb/C |
| Three-vessel disease with EF < 0.50 | CABG | I/A |
| Multivessel disease including proximal LAD with EF < 0.50 or treated diabetes | CABG PCI | I/A IIb/B |
| Multivessel disease with EF > 0.50 and without diabetes | PCI | I/A |
| One- or two-vessel disease without proximal LAD but with large areas of myocardial ischemia or high-risk criteria on noninvasive testing (see text) | CABG or PCI | I/B |
| One-vessel disease with proximal LAD | CABG or PCI | IIa/B |
| One- or two-vessel disease without proximal LAD with small area of ischemia or no ischemia on noninvasive testing | CABG or PCI | III/C |
| Insignificant coronary stenosis | CABG or PCI | III/C |

Abbreviations: CABG = coronary artery bypass grafting; PCI = percutaneous coronary intervention; EF = ejection fraction; LAD = left anterior descending coronary artery. Class I evidence means conditions for which there is evidence and/or general agreement that a given procedure or treatment is useful and effective. Class IIa evidence means conditions for which there is conflicting evidence and/or divergence of opinion about usefulness/efficacy of a procedure or treatment. Class IIa indicates that the weight of evidence/opinion is in favor of usefulness/efficacy. Class IIb indicates that the usefulness/efficacy is less well established. Class III indicates that the evidence and/or general agreement that the procedure/treatment is not useful or effective and may be harmful. Level A evidence is derived from multiple randomized clinical trials with large numbers of patients. Level B evidence is derived from limited number of trials with small numbers of patients or from nonrandomized trials or observational studies. Level C evidence is based on expert opinion. From Braunwald E, Antman EM, Beasley JW, et al. ACC/AHA guidelines for the management of patients with unstable angina and non-ST-segment elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on the Management of Patients with Unstable Angina). *J Am Coll Cardiol* 2000;36:970–1062, with permission.

virtually identical by assigned treatment (86.4% CABG, 86.8% PTCA; $p = .72$). The PTCA group had substantially higher subsequent revascularization rates than the CABG group (59.7% versus 13.1%; $p < .001$); however, the changes between the 5- and 7-year rates were similar for the two groups. Insulin-requiring diabetics seem to be at the highest risk, and CABG is the revascularization procedure of choice for this population.⁴⁷ In a large observational study by Hannan and colleagues, patients with proximal left anterior descending coronary artery (LAD) lesions and multivessel disease had higher survival rates with CABG than with PTCA.⁴⁸ High-risk patients who should be considered for CABG over PCI are those with LV systolic dysfunction, patients with diabetes, and those with two-vessel disease with severe proximal LAD involvement or severe three-vessel or left main artery disease¹⁶ (Table 15–7). AWESOME (Angina With Extremely Serious Operative Mortality) is a large, randomized trial comparing PTCA with CABG, and the results should further define which method of revascularization is best for patients with refractory ischemia and high risk of adverse outcomes.⁴⁹

PCI has been used successfully in the management of UA.^{50–52} PTCA involves the insertion of a guidewire and inflatable balloon into the affected coronary artery and enlarging the lumen of the artery by stretching the vessel wall. This frequently causes atheroma plaque fracture by stretching inelastic components and denuding the endothelium, resulting in loss of nitric oxide and other vasodilators and exposure of plaque contents to the vascular compartment. Consequently, immediate vascular recoil, platelet adhesion and aggregation, mural thrombus formation, and smooth muscle proliferation and synthesis of extracellular matrix may give rise to acute occlusion and early or late restenosis.^{53,54} The presence of coronary artery spasm and intraluminal thrombus, common occurrences in UA, increases the hazard

of these complications. The advent of combination therapy with aspirin, unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH), and glycoprotein (GP) IIb/IIIa receptor antagonists and coronary artery stents has reduced the occurrence of early reocclusion and late restenosis dramatically.^{16,50} Patients best suited for PTCA are those with recent onset of worsening of angina without a long history of symptoms. Angiographic characteristics associated with these clinical findings that allow the greatest probability of success for PTCA are severe, discrete, proximal lesions found in a large epicardial vessel subtending a moderate or large area of viable myocardium and have high risk. Patients with focal saphenous vein graft lesions who are poor candidates for reoperation have a class IIa recommendation for PCI. Class IIb indications include patients with one or more lesions to be dilated in vessels subtending a less than moderate area of viable myocardium and patients with multivessel disease and proximal LAD lesions, diabetes, or abnormal LV function.⁵⁰

Candidates for PTCA also must be suited for CABG because a small percentage of procedures results in emergency CABG. Success of PCI may be defined as angiographic success (TIMI 3 flow and less than 20% residual stenosis), procedural success (lack of in-hospital clinical complications), and clinical success (anatomic and procedural success with relief of ischemic pain for at least 6 months). In trials of invasive versus conservative strategies (medical management) using PCI, death, or MI is less frequent in some trials but not all.^{51,55–57} Numerous studies support the use of IIb/IIIa receptor antagonists in addition to aspirin and UFH or LMWH, and as described previously, abciximab was superior to tirofiban in the only comparative study available.^{16,50} The initial success rate for PTCA in UA is approximately 80% to 90%, but these patients are at risk for

Note: See Table 15–6 for definitions for class I to III recommendations.

Abbreviations: PCI = primary coronary intervention; ECG = electrocardiogram; LAD = left anterior descending coronary artery; CAD = coronary artery disease; LV = left ventricular; CABG = coronary artery bypass grafting.

From ACC/AHA guidelines of percutaneous coronary interventions (revision of the 1993 PTCA guidelines): Executive summary. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 2001;37:22391–lxvi, with permission.

more complications than are those with stable angina because of the underlying pathophysiology.

In the event of prolonged chest pain and ischemic ECG changes unrelieved by nitrate therapy or calcium channel antagonists, one may assume total occlusion of a coronary vessel, and steps should be taken to restore blood flow with either PCI or CABG.

■ CORONARY ARTERY BYPASS GRAFTING

Following the introduction of saphenous vein graft replacement for the severely occluded coronary arteries by Favorolo and Garrett in 1967, coronary artery bypass grafting (CABG) became an accepted and commonly used approach for the management of IHD. The

objectives in performing CABG are twofold: (1) to reduce the number of symptomatic anginal attacks not controlled with medical management or PCI and improve the lifestyle of the patient and (2) to reduce the mortality associated with CAD. Surgery is effective in providing pain relief in large numbers of patients, with about 70% to 95% being pain-free at 1 year and 46% to 55% being pain-free at 5 years. This compares favorably with medical management, with which only about 30% are free of symptoms at 5 years. Mortality at 10 years from the largest published studies is 26.4% with CABG and 30.5% with medical management ($p = .03$), but there are significant differences based on subgroup analysis (e.g., left main coronary artery disease versus one-vessel without a proximal LAD lesion).⁵⁸ The second objective is met in certain patients, and this has been addressed in three large, well-controlled trials of bypass surgery. These three studies, the Veterans Administration (VA) study, the European Cooperative Surgery Study (ECSS), and the Coronary Artery Surgery Study (CASS), are not directly comparable because the inclusion and exclusion criteria for entry into each study were different and patients were followed for different periods of time. They also have been criticized for not being representative of the population that may be candidates for surgery, lacking women or late-middle-aged and elderly patients, and for crossover of medically managed patients to the surgical group. A major change in medical practice that influences the interpretation of these older studies is the common procedure of stent placement at the time of angioplasty.⁵⁹ There are about 20 different types of stents available, and their use is associated with greater luminal diameter after angioplasty, fewer acute reocclusions, and less restenosis after stent placement. Consequently, the validity of generalizing the results from these studies to routine practice has been questioned, but these studies are useful for providing a basis for decisions concerning surgery.

Current class I recommendations for CABG in asymptomatic or mild angina patient include significant (>50%) left main coronary artery stenosis, left main equivalent ($\geq 70\%$ stenosis of the proximal LAD and proximal left circumflex artery), and three-vessel disease, especially in patients with an LV ejection fraction of less than 0.50.⁵⁸ Class IIa recommendations for CABG are proximal LAD stenosis with one- or two-vessel disease and class IIb one- or two-vessel disease not involving the proximal LAD. In stable angina, class I recommendations are the same as for mild angina with the following additions: one- or two-vessel disease without significant proximal LAD stenosis but with a large area of viable myocardium and high-risk criteria in noninvasive testing and disabling angina despite maximal medical therapy when surgery can be performed with acceptable risk. Class IIb recommendations in stable angina include proximal LAD stenosis with one-vessel disease and one- or two-vessel disease without significant proximal LAD stenosis but with a moderate area of viable myocardium and ischemia on noninvasive testing. The indications for CABG in UA/NSTEMI were described previously. In STEMI, CABG is indicated for ongoing ischemia/infarction not responsive to maximal medical therapy (class IIb).

In patients with poor LV function, CABG is employed for the same indications as in mild angina for class I. Class IIa recommendations include poor LV function with significant viable, noncontracting, revascularizable myocardium without any of the aforementioned anatomic patterns (e.g., left main coronary artery disease). CABG is useful in patients with life-threatening ventricular arrhythmia in the presence of left main coronary artery disease and three-vessel disease (class I), in bypassable one- or two-vessel disease causing life-threatening ventricular arrhythmias, and in proximal LAD disease with one- or two-vessel disease (class IIa).

CABG also may be used for patients who have failed PTCA if there is ongoing ischemia or threatened occlusion with significant

myocardium at risk and in patients with hemodynamic compromise (class I). Class IIa recommendations for failed PTCA include a foreign body in a crucial anatomic position and hemodynamic compromise in patients with impairment of the coagulation system and without a previous sternotomy. CABG may be repeated in patients with a previous CABG if disabling angina exists despite maximal noninvasive therapy (class I) and if a large area of myocardium is threatened and is subtended by bypassable distal vessels (class IIa).

The need for nitrates and β -blockers clearly is reduced by surgery, with only 30% of CABG patients requiring chronic medication, in contrast to 70% of their medical counterparts who receive anginal drugs. Employment status after surgery has been shown in CASS to be more dependent on the pretreatment status than on an effect induced by the treatment arm, and about 70% of patients are employed before and after surgery. Recent follow-up analyses of these studies suggest that patients who have diabetes or peripheral vascular disease, who are African-Americans, or who continued to smoke are at high risk for CAD events, and diabetics in particular are more likely to have a better outcome with CABG than with PTCA.^{46,60,61} The overall benefit noted after CABG is similar in men and women, and elderly patients appear to have outcomes similar to younger patients.

Operative mortality is reported to range from 1% to 3% and is related to the number of vessels involved and preoperative ventricular function. Patients in CASS with one-, two-, or three-vessel disease had operative mortalities of 1.4%, 2.1%, and 2.8%, respectively. The relationship to LV ejection fraction follows a similar trend, with patients with ejection fractions of greater than 50%, 20% to 40%, and less than 20% having operative mortality rates of 1.9%, 4.4%, and 6.7%, respectively. Perioperative infarction averages 5% depending on the sensitivity of the method for assessment, and the occurrence of an infarct reduces long-term survival. Neurologic dysfunction is relatively common postoperatively in CABG patients (~6%), but many of the deficits are insignificant clinically and resolve with time. Fatal brain damage occurs in 0.3% to 0.7%, stroke in about 5%, and ophthalmologic defects in 25%, but only 3% have clinically apparent field defects. Peripheral nerve lesions (12%) and brachial plexopathy (7%) are also reported to occur. Other complications include constrictive pericarditis (0.2%), cellulitis at the site of the vein graft, and mediastinal infections (1% to 4%).

Graft patency influences the success for symptom control and survival, and the mechanism for early graft occlusion is probably different from that associated with late closure. Early occlusion is related to platelet adhesion and aggregation, whereas late occlusion may be related to endothelial proliferation and progression of atherosclerosis. Patency of grafts early on after the CABG is reported to range from 88% to 97% in at least one graft and 58% to 81% in all grafts at 1 year. Long-term patency based on the CASS Montreal Heart Institute experience suggests that 60% to 67% of all grafts remain patent at 5 to 11 years. Antiplatelet therapy has been demonstrated to improve early and late patency rates and probably should be used in all patients who do not have any contraindications. Aspirin with or without other antiplatelet agents (dipyridamole) reduces the late development of vein graft occlusions. Late graft closure is related to elevated lipid levels and the progression of atherosclerosis in the grafted vessels as well as the native circulation. Elevation of very low-density lipoprotein (VLDL), LDL, and LDL apolipoprotein B is correlated with disease progression and graft closure. Aggressive lipid lowering can stabilize the progression of CAD and may induce regression in selected coronary artery segments within a patient following CABG. Cessation of smoking is an important preoperative and postoperative objective, as well as in the management of other coronary risk factors (e.g., hypertension), and institution of a supervised daily exercise

program is recommended. Internal mammary artery grafts should be used for revascularizing the LAD system when possible owing to better graft survival and clinical outcomes.

Valvular heart disease can coexist with CAD, although this is relatively uncommon with rheumatic valve disease, usually the mitral valve, and more common with aortic stenosis and regurgitation. Angina may occur in 35% to 65% of patients with aortic stenosis or regurgitation and, if severe, may be the cause of angina in the absence of CAD. Patients being evaluated for possible CABG also should be evaluated for valvular disease to determine if valve replacement needs to be performed along with bypass grafting.

■ PERCUTANEOUS TRANSLUMINAL CORONARY ANGIOPLASTY⁶²

Since the introduction into clinical cardiology of PTCA^{63,64} by Gruentzig in 1977, this procedure has gained rapid acceptance as a safe and effective means of managing CAD. It is estimated that more than 750,000 PCI procedures are done each year in this country, and 525,000 of them are PTCAs. The proposed mechanisms of reduced stenosis with PTCA include (1) compression and redistribution of the atherosclerotic plaque, (2) embolization of plaque contents, (3) aneurysm formation, and (4) disruption of the plaque and arterial wall with distortion and tearing of the intima and media, which leads to denudation of the endothelium, platelet adhesion and aggregation, thrombus formation, and smooth muscle proliferation. Of these mechanisms, the last one is felt to be the most important, but the others may contribute to opening of the lesions in some situations.

9 The indications for PTCA have been provided by the ACC/AHA and now span single- or multivessel disease as well as asymptomatic and symptomatic patients⁵⁰ (see Table 15–7). PTCA generally is not useful if only a small area of viable myocardium is at risk, when ischemia cannot be demonstrated, with borderline (<50%) stenosis or with lesions that are difficult to dilate, or in patients who are at high risk for morbidity or mortality or both (e.g., left main or equivalent disease or three-vessel disease). PTCA alone or in conjunction or sequentially with thrombolysis for acute MI is discussed in Chap. 16. Stent placement accompanies balloon angioplasty in about 80% of cases in the United States. The current recommendations for PCI are provided in Table 15–7 based on class of angina.

Assessment of outcome with PCI can be based on several angiographic, procedural, and clinical outcomes, as discussed previously. The success of PCI depends on the experience of the operator (i.e., high volume, better outcome), on complicating factors for the patient (including the number of vessels to be dilated), and on technical advances in the equipment used (e.g., steerable and low-profile catheters). The acute success rate for opening of uncomplicated stenotic lesions ranges from 96% to 99% with the combined balloon-device–pharmacologic approach in experienced hands, and angina is decreased or eliminated in about 80% of cases. The success rate in totally occluded lesions is somewhat less (~65%). Mortality at 1 year is 1% and 2.5% for single-vessel disease and multiple-vessel involvement, respectively, reflecting the good prognosis associated with this degree of CAD. At 10 years, survival is 95% and 81% for single- and multiple-vessel disease, respectively.⁵⁰ Most patients remain event-free (no death, MI, or CABG) for an extended period.

Symptomatic status, as measured by the NYHA classification, is improved in many patients. Restenosis is noted in 32% to 40% of patients after balloon angioplasty at 6 months, and half these patients will have symptoms associated with restenosis.⁵⁰ A few late restenotic events occur, but most restenosis occurs within the first

6 months. Anatomic factors that predict restenosis include lesions greater than 20 mm in length, excessive tortuosity of the proximal segment, extremely angulated segments (>90 degrees), total occlusions more than 3 months old and/or bridging collaterals, inability to protect the major side branches, and degenerated vein grafts with friable lesions. Clinical factors that predict worse outcome include diabetes, advanced age, female gender, UA, heart failure, and multivessel disease. A four-variable scoring system that predicts cardiovascular collapse for failed PTCA includes percentage of myocardium at risk (e.g., >50% viable myocardium at risk and LV ejection fraction <25%), preangioplasty percent diameter stenosis, multivessel CAD, and diffuse disease in the dilated segment or a high myocardial jeopardy score.⁵⁰ Strut thickness of the stent influences restenosis as well, and thicker struts are associated with angiographic and clinical restenosis.⁶⁵

The overall complication rate ranges from 2% to 21% depending on the lesion type.⁵² Coronary occlusion, dissection, or spasm occurs in 4% to 8% of patients, whereas Q-wave MI occurs in 1.6% to 4.8%.⁵⁰ Prolonged angina and ventricular tachycardia or fibrillation occurs in 6.9% and 2.3%, respectively. In-hospital mortality ranges from 0.7% to 2.5% overall, and high-risk events for mortality include ventricular arrhythmias and myocardial infarction. The frequency of urgent CABG because of complications ranges from 0.4% to 5.8%.⁵⁰

Antiplatelet therapy with aspirin 81 to 325 mg/day given at least 2 hours prior to angioplasty is currently recommended. If patients are sensitive to aspirin, clopidogrel and ticlopidine are acceptable alternatives. Most centers now use clopidogrel owing to adverse effects. In elective settings, clopidogrel should be started at least 72 hours in advance of the procedure to allow for maximal antiplatelet effects. Alternatively, a loading dose of clopidogrel (300 to 600 mg) may be given to achieve a more rapid antiplatelet effect.⁶⁶ The combination of aspirin and clopidogrel currently is recommended for patients undergoing angioplasty and stenting, and this combination is safer and superior to antiplatelet therapy plus anticoagulation with warfarin-like drugs.⁶⁷ Follow-up for up to 4 years from the Intracoronary Stenting and Antithrombotic Regimen (ISAR) trial shows that the benefit of combined antiplatelet therapy evident after 30 days is maintained after 4 years.⁶⁸ Aspirin is an incomplete inhibitor of platelet aggregation, and combination therapy with aspirin and a GP IIb/IIIa receptor antagonist for PCI has shown a relative risk reduction of 37.5% for death and nonfatal MI at 30 days, favoring GP IIb/IIIa receptor antagonists over placebo (absolute rates of 5.5% versus 8.9% based on PCI trials of EPIC, IMPACT-II, EPILOG, CAPTURE, RESTORE, and EPISTENT).⁵⁰ High-risk patients and those having a stent placed are most likely to benefit from GP IIb/IIIa receptor antagonist use. Patients presenting with elevated cardiac biomarkers are also more likely to receive benefit from GP IIb/IIIa receptor antagonists than patients with normal levels of biomarkers.⁶⁹ In the only comparative trial (TARGET), abciximab was superior to tirofiban.⁷⁰

During PTCA, patients usually are heparinized to prevent immediate thrombus formation at the site of arterial injury and on coronary guidewires and catheters; anticoagulation is continued for up to 24 hours. The intensity of anticoagulation is monitored using the activated clotting time (ACT), and the targeted range for ACT is 250 to 300 seconds (HemoTec device) in the absence of GP IIb/IIIa receptor antagonist use.⁵⁰ When GP IIb/IIIa receptor antagonists are not used, UFH is given as an intravenous bolus of 70 to 100 IU/kg to achieve a target ACT of 200 seconds. The loading dose is lowered to 50 to 70 IU/kg when GP IIb/IIIa receptor antagonists are given. Target ACT for eptifibatid and tirofiban is less than 300 seconds during angioplasty; postprocedural UFH infusions are not recommended during GP IIb/IIIa receptor antagonist therapy. Some authors have advocated

heparin alternatives such as hirudin or hirulog, but there is no apparent long-term advantage with these agents.^{71–73}

Mechanisms that result in restenosis include acute lumen loss owing to “recoil,” mural thrombosis formation and smooth muscle cell proliferation with synthesis of extracellular matrix.⁶⁴ Approaches to preventing restenosis may be aimed at altering the underlying mechanisms. Recoil and loss of luminal diameter may be reduced by the use of stent placement; however, this beneficial effect is offset by an increased number of vascular complications. Cracking of the plaque leads to severe damage to the arterial wall, exposure of collagen, and endothelial dysfunction. These factors promote mural thrombi, and the propensity for thrombus formation is related in part to the composition of the plaque, as well as to the depth of injury. Combination therapy with aspirin, heparin, and GP IIb/IIIa receptor antagonists is recommended to minimize acute occlusion, and numerous clinical trials document the efficacy of this combined approach.⁵⁰ Unfortunately, antithrombotic therapy (i.e., warfarin, aspirin, dipyridamole, prostacyclin, UFH, hirudin, or antiplatelet combinations) has little effect on long-term restenosis rates.⁷⁴ Other pharmacologic interventions that have failed to alter restenosis include β -blockers, ACE inhibitors, calcium channel blockers, and omega-3 fatty acids. Pharmacologic therapy for which some evidence exists that restenosis may be prevented include investigational antiproliferative agents (e.g., rapradil, angiopeptin, and tranilast),^{75–77} cilostazol,⁷⁸ valsartan (angiotensin-receptor blocker)⁷⁹ enoxaparin,⁸⁰ and possibly ticlopidine.⁸¹ One of the most promising approaches is the use of brachytherapy (local gamma or beta irradiation of the stent and surrounding tissue).^{53,82} Intracoronary irradiation with iridium-192 resulted in lower rates of clinical and angiographic restenosis and the need for revascularization (43.8% versus 28.2% assigned to iridium-192; $p = .02$), although it also was associated with a higher rate of late thrombosis, resulting in an increased risk of MI. If the problem of late thrombosis within the stent can be overcome, intracoronary irradiation with iridium-192 may become a useful approach to the treatment of in-stent restenosis.⁸³

Alternatives to PTCA include directional coronary atherectomy (DCA), excimer laser, rotational atherectomy (Rotablator), and intracoronary stents or some combination of these interventions.⁸⁴ Based on randomized trials, DCA produces greater initial luminal diameter but results in a higher rate of postprocedural complications such as non-Q-wave MI and death and is more expensive. Consequently, PTCA is considered to be superior to DCA for most patients. Tissue debulking with DCA is useful for in-stent restenosis,

particularly for diabetic patients.⁸⁵ The use of abciximab may improve these results.⁸⁶ Excimer laser angioplasty followed by balloon angioplasty or rotational atherectomy provides no benefit over balloon angioplasty alone.⁸⁷

When medical therapy, PTCA, and CABG have been compared, low-risk patients with single-vessel CAD and normal LV function had greater alleviation of symptoms with PTCA than with medical treatment; mortality rates and rates of MI were unchanged. In high-risk patients (risk was defined by severity of ischemia, number of diseased vessels, and presence of LV dysfunction), improvement in survival was greater with CABG than with medical therapy. In moderate-risk patients with multivessel CAD (most had two-vessel disease and normal LV function), PTCA and CABG produced equivalent mortality rates and rates of MI.

PHARMACOLOGIC THERAPY (TABLE 15–8)

Historically, about 30% of anginal syndrome symptoms have responded regardless of which therapy was instituted. These observations stem from two problems inherent in clinical trials undertaken to assess the efficacy of any therapy for angina: (1) adequate trial design incorporating appropriate controls and washout periods and (2) assessment of treatment effects using objective measures of efficacy, including improvement in exercise performance, resting and ambulatory ECG improvement in ischemic changes, and other objective tests to address other aspects of myocardial function or metabolism. The use of pain episode frequency and nitroglycerin consumption is subjective, and their use as sole measures of efficacy should be avoided. Objective assessment using ETT has shown that placebo does not provide improvement in patients with exertional angina, substantiating this as a valid means to assess efficacy.

β -ADRENERGIC BLOCKING AGENTS⁸⁸

Decreased heart rate, decreased contractility, and a slight to moderate decrease in blood pressure with β -adrenergic receptor antagonism reduce MVO₂. The predominant receptor type in the heart is the β_1 -receptor, and competitive blockade minimizes the influence of endogenous catecholamines on the chronotropic and inotropic state of

TABLE 15–8. Recommendations for Pharmacologic Management of Patients Undergoing PCI

| Drugs | Class I Angina | Class II–IV Angina, UA/NSTEMI | Transmural MI Acute-Phase MI | Hospital After Thrombolysis | Management Phase |
|--------------------------|----------------|-------------------------------|------------------------------|-----------------------------|------------------|
| Aspirin | I ^a | I | I | I | I |
| Clopidogrel ^b | I ^e | I | I | I | I ^d |
| Warfarin ^c | III | III | III | II | I ^f |
| GP blockers ^g | II | I | II | I | III |
| UFH/LMWH | I | I | I | II | III |

^aRoman numerals refer to ACC/AHA class recommendations for use. See Table 15–6 for definitions.

^bIn conjunction with stenting.

^cTo be given 24–48 hours before planned stenting, if possible.

^dTo be given 2–4 weeks after stent placement.

^eIn patients without atrial fibrillation or other preexisting clinical indications.

^fPatients with anterior myocardial wall motion abnormalities or LV thrombus.

^gEvery indication may not apply to all available agents.

Abbreviations: PCI = primary coronary intervention; UA = unstable angina; NSTEMI = non-ST-segment myocardial infarction; MI = myocardial infarction; GP = glycoprotein receptor; UFH = unfractionated heparin; LMWH = low-molecular-weight heparin.

From ACC/AHA guidelines of percutaneous coronary interventions (revision of the 1993 PTCA guidelines): Executive summary. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 2001;37:2239i–lxvi, with permission.

TABLE 15–9. Effect of Drug Therapy on Myocardial Oxygen Demand^a

| | Heart Rate | Myocardial Contractility | LV Wall Tension | |
|------------|------------|--------------------------|-------------------|-----------|
| | | | Systolic Pressure | LV Volume |
| Nitrates | ↑ | 0 | ↓ | ↓↓ |
| β-Blockers | ↓↓ | ↓ | ↓ | ↑ |
| Nifedipine | ↑ | 0 or ↓ | ↓↓ | 0 or ↓ |
| Verapamil | ↓ | ↓ | ↓ | 0 or ↓ |
| Diltiazem | ↓↓ | 0 or ↓ | ↓ | 0 or ↓ |

^aCalcium channel antagonists and nitrates also may increase myocardial oxygen supply through coronary vasodilation. Diastolic function also may be improved with verapamil, nifedipine, and perhaps, diltiazem. These effects may vary from those indicated in the table depending on individual patient baseline hemodynamics.

Abbreviation: LV = left ventricular.

the myocardium. These beneficial effects may be countered to some degree by the increased ventricular volume and ejection time seen with β-blockade; however, the overall effect of β-blockers in patients with effort-induced angina is a reduction in oxygen demand (Table 15–9). The β-blockers do not improve oxygen supply, and in certain instances, unopposed α-adrenergic stimulation following the use of β-blockers may lead to coronary vasoconstriction. For patients with chronic exertional stable angina, β-blockers improve symptoms about 80% of the time, and objective measures of efficacy demonstrate improved exercise duration and delay in the time at which ST-segment changes and initial or limiting symptoms occur. β-Blockers do not alter the rate-pressure product (DP) for maximal exercise, therefore substantiating reduced demand rather than improved supply as the major consequence of their actions. Reflex tachycardia from nitrate therapy can be blunted with β-blocker therapy, making this a common and useful combination. Although β-blockade may decrease exercise capacity in healthy individuals or in patients with hypertension, it may allow angina patients previously limited by symptoms to perform more exercise and ultimately to improve overall cardiovascular performance through a training effect. Ideal candidates for β-blockers include patients in whom physical activity figures prominently in their anginal attacks, those who have coexisting hypertension, those with a history of supraventricular arrhythmias or post-MI angina, and those who have a component of anxiety associated with angina.⁸⁹ β-Blockers also may be used safely in angina and heart failure, as described in Chap. 14.

Pertinent pharmacokinetics for the β-blockers includes half-life and route elimination, which are reviewed in Chap. 13. Drugs with longer half-lives need to be dosed less frequently than drugs with shorter half-lives; however, disparity exists between half-life and duration of action for several β-blockers (e.g., metoprolol), and this may reflect attenuation of the central nervous system–mediated effects on the sympathetic nervous system, as well as the direct effects of this category on heart rate and contractility. Renal and hepatic dysfunction can affect the disposition of β-blockers, but these agents are dosed to effect, either hemodynamic or symptomatic, and route of elimination is not a major consideration in drug selection. Guidelines for the use of β-blockers in treating angina include the objective of lowering resting heart rate to 50 to 60 beats per minute and limiting maximal exercise heart rate to about 100 beats per minute or less. It also has been suggested that exercise heart rate should be no more than about 20 beats per minute or a 10% increment over resting heart rate with modest exercise. Because β-blockade is competitive, circulating catecholamine

concentrations vary depending on the intensity of exercise and other factors, and cholinergic tone may be important in controlling resting heart rate in some patients, these guidelines are general in nature. These effects generally are dose- and plasma concentration–related, and for propranolol, plasma concentrations of 30 ng/mL are needed for a 25% reduction in anginal frequency. Initial doses of β-blockers should be at the lower end of the usual dosing range and titrated to response, as indicated earlier.

There is little evidence to suggest superiority of any β-blocker; however, the duration of β-blockade depends in part on the half-life of the agent used, and those with longer half-lives may be dosed less frequently. Of note, propranolol may be dosed twice a day in most patients with angina, and the efficacy is similar to that seen with more frequent dosing. The ancillary property of membrane-stabilizing activity is irrelevant in the treatment of angina, and intrinsic sympathomimetic activity appears to be detrimental in rest or severe angina because the reduction in heart rate would be minimized, therefore limiting a reduction in MVO₂. Cardioselective β-blockers may be used in some patients to minimize adverse effects such as bronchospasm in asthmatic or chronic obstructive pulmonary disease patients, intermittent claudication, and sexual dysfunction. It should be remembered that cardioselectivity is a relative property, and the use of larger doses (e.g., metoprolol 200 mg/day) is associated with loss of selectivity and with adverse effects. Patients with angina after acute MI are particularly good candidates for β-blockade both because anginal symptoms may be treated as well as reducing the risk of post-MI reinfarction and because mortality has been demonstrated with timolol, propranolol, and metoprolol (see Chap. 16). Combined β-nonselective and α-selective blockade with labetalol may be useful in some patients with marginal LV reserve, and fewer deleterious effects on coronary blood flow are seen when compared with other β-blockers. Extension of pharmacologic effect is the underlying reason for many of the adverse effects seen with β-blockade. Hypotension, heart failure, bradycardia and heart block, bronchospasm, peripheral vasoconstriction and intermittent claudication, and altered glucose metabolism are directly related to β-adrenoreceptor antagonism. Patients with preexisting LV dysfunction who use other negative inotropic agents are most prone to developing overt heart failure, and in the absence of these agents, heart failure is uncommon (<5%). Other drugs that depress conduction are additive to β-blockade, and intrinsic conduction system disease predisposes the patient to conduction abnormalities. Altered glucose metabolism is most likely to be seen in insulin-dependent diabetics, and β-blockade obscures the symptoms of hypoglycemia, except for sweating. β-Blockers also may aggravate the lipid abnormalities seen in patients with diabetes; however, these changes are dose-related, are more common with normal baseline lipids than with dyslipidemia, and may be of short-term significance only.

One of the more common reasons for discontinuation of β-blocker therapy is related to central nervous system adverse effects of fatigue, malaise, and depression. Cognition changes seen with β-blockers are usually minimal and comparable with those of other categories of drugs based on studies done in hypertension.^{90,91} Abrupt withdrawal of β-blocker therapy in patients with angina has been associated with increased severity and number of pain episodes and MI. The mechanism of this effect is unknown but may be related to increased receptor sensitivity or disease progression during therapy that becomes apparent following discontinuation of β-blockade. In any event, tapering of β-blocker therapy over about 2 days should minimize the risk of withdrawal reactions for patients in whom therapy is being discontinued. β-Adrenoreceptor blockade is effective in chronic exertional angina as monotherapy and in combination with nitrates and/or calcium channel antagonists. β-Blockers should be

the first-line drug in chronic angina requiring daily maintenance therapy because β -blockers are more effective in reducing episodes of silent ischemia, reducing early-morning peak of ischemic activity, and improving mortality after Q-wave MI than nitrates or calcium channel blockers⁴¹ (see Fig. 15–4). If β -blockers are ineffective or not tolerated, then monotherapy with a calcium channel blocker or combination therapy if monotherapy is ineffective for either alone may be instituted. Patients with severe angina, rest angina, or variant angina (i.e., a component of coronary artery spasm) may be better treated with calcium channel blockers or long-acting nitrates.

■ NITRATES^{92,93}

Nitroglycerin has a well-documented role in the alleviation of anginal attacks when used as rapidly absorbed and readily available preparations by the oral and intravenous routes (Table 15–10; see also Fig. 15–4). Sublingual, buccal, or spray products are the products of choice for this indication. Prevention of symptoms may be accomplished by the prophylactic use of oral or transdermal products; however, concern has been expressed over the long-term efficacy of many of these preparations and the development of tolerance. Nitrates have multiple potential mechanisms of action, and for a given patient, it is not always clear which of these is most important. In general, the major action appears to be mediated indirectly through a reduction in myocardial oxygen demand secondary to venodilation and arterial-arteriolar dilation, leading to a reduction in wall stress from reduced ventricular volume and pressure (see Table 15–8).

Systemic venodilation also promotes increased flow to deep myocardial muscle by reducing the gradient between intraventricular pressure and coronary arteriolar (R_2) pressure. Direct actions on the coronary circulation include dilation of large and small intramural coronary arteries, collateral dilation, coronary artery stenosis dilation, abolition of normal tone in narrowed vessels, and relief of spasm; these actions occur even if the endothelium is denuded or dysfunctional. It is likely that depending on the underlying pathophysiology, different mechanisms become operative. For example, in the presence of a 60% to 70% stenosis, venodilation with MVO_2 reduction is most important; however, with higher-grade lesions, direct effects on the coronary circulation and vessel tone are the predominant effects. Although the cellular mechanism of vasodilation by nitrates is not entirely understood, organic nitrates are converted intracellularly to nitric oxide (EDRF) and 5-nitrosothiol via interaction with sulfhydryl groups.

Nitric oxide, and perhaps 5-nitrosothiol, activates soluble guanylate cyclase to increase intracellular concentrations of cyclic GMP. Increased cyclic GMP induces a sequence of protein phosphorylation associated with reduced intracellular calcium release from the sarcoplasmic reticulum or reduced permeability to extracellular calcium and, consequently, smooth muscle relaxation.

Pharmacokinetic characteristics common to the organic nitrates used for angina include a large first-pass effect of hepatic metabolism, short to very short half-lives (except for isosorbide mononitrate), large volumes of distribution, high clearance rates, and large interindividual variations in plasma or blood concentrations. Pharmacodynamic-pharmacokinetic relationships for the entire class remain poorly defined, presumably owing to methodologic difficulty in characterizing the parent drug and metabolite concentrations at or within vascular smooth muscle and secondary to counterregulatory or adaptive mechanisms from the drug's effects, as well as the occurrence of tolerance. Nitroglycerin is extracted by a variety of tissues and metabolized locally; differential extraction and metabolite generation occur depending on the tissue site. There are also numerous technical problems limiting the generation of reliable pharmacokinetic parameter estimates, including the following: assay sensitivity; arterial-venous extraction gradients and therefore extrahepatic metabolism; *in vitro* degradation, drug adsorption to polyvinyl chloride tubing and syringes; potentially saturable metabolism; accumulation of metabolites (some of which are active) with multiple doses; postural and exercise-induced changes in pharmacokinetics; and a number of variables associated with transdermal delivery, including the delivery system (matrix, membrane-limited, ointment), vehicle used, surface area and thickness of application, site application, and other skin variables (e.g., temperature and moisture content). Nitroglycerin concentrations are affected by the route of administration, with the highest concentrations usually obtained with intravenous administration and the lowest seen with lower oral doses. Peak concentrations with sublingual nitroglycerin appear within 2 to 4 minutes, with the oral route producing peaks at about 15 to 30 minutes and the transdermal route producing peaks at 1 to 2 hours. The half-life of nitroglycerin is 1 to 5 minutes regardless of route, hence the potential advantage of sustained-release and transdermal products. Transdermal nitroglycerin does produce sufficient concentrations for acute hemodynamic effects to occur, and these concentrations are maintained for long intervals; however, the hemodynamic and antianginal effects are minimal after 1 week or less with chronic, continuous (24 h/day) therapy. Isosorbide dinitrate (ISDN) is metabolized to isosorbide 2-mono- and 5-mononitrate (isosorbide mononitrate [ISMN]). ISMN is well absorbed, has a half-life of about 5 hours, and may be given once or twice daily depending on the product chosen. Multiple, larger doses of ISDN lead to disproportionate increases in the area under the plasma time profile curve, suggesting that metabolic pathways are being saturated or that metabolite accumulation may influence the disposition of ISDN. Little pharmacokinetic information is available for other nitrate compounds.

Nitrate therapy may be used to terminate an acute anginal attack, to prevent effort- or stress-induced attacks, or for long-term prophylaxis, usually in combination with β -blockers or calcium channel blockers. Sublingual nitroglycerin 0.3 to 0.4 mg will relieve pain in about 75% of patients within 3 minutes, with another 15% becoming pain-free in 5 to 15 minutes. Pain persisting beyond about 20 to 30 minutes following the use of two or three nitroglycerin tablets is suggestive of ACS, and the patient should be instructed to seek emergency aid. Patients should be instructed to keep nitroglycerin in the original, tightly closed glass container and to avoid mixing it with other medications because mixing may reduce nitroglycerin adsorption and vaporization. Additional counseling should include the

TABLE 15–10. Nitrate Products

| Product | Onset (min) | Duration | Initial Dose |
|-----------------------------|-------------|-----------|----------------------------|
| Nitroglycerin | | | |
| IV | 1–2 | 3–5 min | 5 μ g/min |
| Sublingual/lingual | 1–3 | 30–60 min | 0.3 mg |
| PO | 40 | 3–6 h | 2.5–9 mg tid |
| Ointment | 20–60 | 2–8 h | 1/2–1 in |
| Patch | 40–60 | >8 h | 1 patch |
| Erythritol tetranitrate | 5–30 | 4–6 h | 5–10 mg tid |
| Penterythritol tetranitrate | 30 | 4–8 h | 10–20 mg tid |
| Isosorbide dinitrate | | | |
| Sublingual/chewable | 2–5 | 1–2 h | 2.5–5 mg tid |
| PO | 20–40 | 4–6 h | 5–20 mg tid |
| Isosorbide mononitrate | 30–60 | 6–8 h | 20 mg qd, bid ^a |

^aProduct-dependent.

facts that nitroglycerin is not an analgesic but rather that it partially corrects the underlying problem and that repeated use is not harmful or addicting. Patients also should be aware that enhanced venous pooling in the sitting or standing position may improve the effect as well as the symptoms of postural hypotension and that inadequate saliva may slow or prevent tablet disintegration and dissolution. An acceptable, albeit expensive, alternative is lingual spray, which may be more convenient and has a shelf life of 3 years compared with the 6 months or so for some forms of nitroglycerin tablets. Chewable, oral, and transdermal products are acceptable for the long-term prophylaxis of angina; however, considerable controversy surrounds their use, and it appears that the development of tolerance or adaptive mechanisms limits the efficacy of all chronic nitrate therapies regardless of route. Dosing of the longer-acting preparations should be adjusted to provide a hemodynamic response, and as an example, this may require doses of oral ISDN ranging from 10 to 60 mg as often as every 3 to 4 hours owing to tolerance or first-pass metabolism, and similar large doses are required for other products. Nitroglycerin ointment has a duration of up to 6 hours, but it is difficult to apply in a cosmetically acceptable fashion over a consistent surface area, and response varies depending on the epidermal thickness, vascularity, and amount of hair. Percutaneous adsorption of nitroglycerin ointment may occur unintentionally if someone other than the patient applies the ointment, and limiting exposure through the use of gloves or some other means is advisable. Peripheral edema also may impair the response to nitroglycerin because venodilation cannot increase capacitance to a maximum, and pooling may be reduced. Transdermal patch delivery systems were approved on the basis of sustained and equivalent plasma concentrations to other forms of therapy. Trials required by the Food and Drug Administration using transdermal patches as a continuous 24-hour delivery system revealed a lack of efficacy for improved exercise tolerance. Subsequently, large, randomized, double-blind, placebo-controlled trials of intermittent (10 to 12 hours on, 12 to 14 hours off) transdermal nitroglycerin therapy in chronic stable angina demonstrated modest but significant improvement in exercise time after 4 weeks for the highest doses at 8 to 12 hours after patch placement.⁹⁴ Subjective assessment methods for nitrate effects include reduction in the number of painful episodes and the amount of nitroglycerin consumed. Objective assessment includes the resolution of ECG changes at rest, during exercise, or with ambulatory ECG monitoring. Because nitrates work primarily through a reduction in MVO_2 , the DP can be used to optimize the dose of sublingual and oral nitrate products. It is important to realize that reflex tachycardia may offset the beneficial reduction in systolic blood pressure, and calculation of the observed changes is necessary. The DP is best assessed in the sitting position and at intervals of 5 to 10 minutes and 30 to 60 minutes following sublingual and oral therapy, respectively. Owing to the placebo effect, the unpredictable and variable course of angina, the numerous pharmacologic effects of nitroglycerin, diurnal variation in pain patterns, stringent investigative protocols, and interindividual sensitivity to nitroglycerin, assessment with transdermal and sustained-release products is difficult. ETT provides valuable information concerning efficacy and mechanism of action for nitrates, but its use usually is reserved for clinical investigation rather than for routine patient care. Most ETT studies have shown nitrates to delay the onset of ischemia (ST-segment changes or initial chest discomfort) at submaximal exercise, but the threshold for maximal exercise is unaltered, suggesting a reduction in oxygen demand rather than an improved oxygen supply. More sophisticated studies of myocardial function such as wall motion abnormalities and myocardial metabolism could be used to document efficacy, but these studies are generally only for investigative purposes.

Adverse effects of nitrates are related most commonly to an extension of their pharmacologic effects and include postural hypotension with associated central nervous system symptoms, headaches, and flushing secondary to vasodilation and occasional nausea from smooth muscle relaxation. If hypotension is excessive, coronary and cerebral filling may be compromised, leading to MI and stroke. While reflex tachycardia is most common, bradycardia with nitroglycerin has been reported. Other noncardiovascular adverse effects include rash with all products but particularly with transdermal nitroglycerin, the production of methemoglobinemia with high doses given for extended periods, and measurable concentrations of ethanol (intoxication has been reported) and propylene glycol (found in the diluent) with intravenous nitroglycerin.

Tolerance with nitrate therapy was first described in 1867 with the initial experience using amyl nitrate for angina and later was widely recognized in munitions workers who underwent withdrawal reactions during periods of absence from exposure. Tolerance to nitrates is associated with a reduction in tissue cyclic GMP, which results from decreased production (guanylate cyclase) and increased breakdown via cyclic GMP-phosphodiesterase and increased superoxide levels. One proposed mechanism for the lack of cyclic GMP is lack of conversion of organic nitrates to nitric oxide owing to depletion of intracellular sulfhydryl cofactors (cysteine) in cells following chronic exposure to nitrates. This effect is more pronounced on the venous system than on the arterial system. Activation of neurohormonal systems following vasodilation with nitrates may result in vasoconstriction and sodium retention. The major systems thought to be involved in this second mechanism are the sympathoadrenal axis and the renin-angiotensin system. Concomitant use of captopril (25 mg three times daily) may attenuate the increased sensitivity to phenylephrine and angiotensin II noted in patients with stable CAD.^{95,96} Nitroglycerin administration is accompanied by a fall in hematocrit (caused by hemodilution rather than renal water conservation) and intravascular volume expansion, minimizing the ability of nitrates to decrease ventricular filling pressures as a third mechanism of tolerance. Logically, a diuretic would minimize this mechanism; however, Parker and colleagues⁹⁷ found no effect on the development of tolerance to continuous transdermal nitroglycerin. Diuretic therapy itself has important antianginal effects and improves exercise capacity in patients with stable angina.⁹⁷ Supplemental vitamin E also has been studied to restore cyclic GMP production and the vasodilatory response to nitroglycerin.⁹⁸ Most of the published information from controlled trials examining nitrate tolerance have been done with either ISDN or transdermal nitroglycerin, and these studies demonstrate the development of tolerance within as few as 24 hours of therapy.

While the onset of tolerance is rapid, the offset may be just as rapid, and one alternative dosing strategy to circumvent or minimize tolerance is to provide a daily nitrate-free interval of 6 to 8 hours. Studies with a variety of nitrate preparations and dosing schedules demonstrate that this approach is useful and that the nitrate-free interval should be a minimum of 8 hours and perhaps 12 hours for even better effects.⁹⁴ Another concern for intermittent transdermal nitrate therapy is the occurrence of rebound ischemia during the nitrate-free interval. Freedman and colleagues⁹⁹ found more silent ischemia during the patch-free interval during a randomized, double-blind, placebo-controlled trial than during the placebo patch phase, although others have not noted this effect. ISDN, for example, should not be used more often than three times per day if tolerance is to be avoided. Interestingly, hemodynamic tolerance does not always coincide with antianginal efficacy, but this is not well studied.

Nitrates may be combined with other drugs for anginal therapy, including β -adrenergic blocking agents and calcium channel

antagonists. These combinations usually are instituted for chronic prophylactic therapy based on complementary or offsetting mechanisms of action (see Table 15–9). Combination therapy generally is used in patients with more frequent symptoms or symptoms not responding to β -blockers alone (nitrates plus β -blockers or calcium channel blockers), in patients intolerant of β -blockers or calcium channel blockers, and in patients having an element of vasospasm leading to decreased supply (nitrates plus calcium blockers).¹⁰⁰

■ CALCIUM CHANNEL ANTAGONISTS¹⁰¹

Modulation of calcium entry into vascular smooth muscle and myocardium, as well as a variety of other tissues, is the principal action of the calcium antagonists. The cellular mechanism of these drugs is not completely understood, and it differs among the available classes of the phenylalkylamines (verapamil-like), dihydropyridines (nifedipine-like), benzothiazepines (diltiazem-like), bepridil, and a recent class referred to as *T-channel blockers*. Receptor-operated channels stimulated by norepinephrine and other neurotransmitters and potential-dependent channels activated by membrane depolarization control the entry of calcium and, consequently, the cytosolic concentration of calcium responsible for activation of the actin-myosin complex, leading to contraction of vascular smooth muscle and myocardium. In the myocardium, calcium entry triggers the release of intracellular stores of calcium to increase cytosolic calcium, whereas in smooth muscle, calcium derived from the extracellular fluid may do this directly. Binding proteins within the cell, calmodulin and troponin, after binding with calcium, participate in phosphorylation reactions, leading to contraction. Decreased calcium availability, through the actions of calcium antagonists, inhibits these reactions.

Direct actions of the calcium antagonists include vasodilation of systemic arterioles and coronary arteries, leading to a reduction in arterial pressure and coronary vascular resistance, as well as depression of the myocardial contractility and conduction velocity of the sinoatrial (SA) and atrioventricular (AV) nodes (see Chap. 17). Reflex β -adrenergic stimulation overcomes much of the negative inotropic effect, and depression of contractility becomes apparent clinically only in the presence of LV dysfunction and when other negative inotropic drugs are used concurrently. Verapamil and diltiazem cause less peripheral vasodilation than nifedipine, and consequently, the risk of myocardial depression is greater with these two agents. Conduction through the AV node is predictably depressed with verapamil and diltiazem, and they must be used with caution in patients with preexisting conduction abnormalities or in the presence of other drugs with negative chronotropic properties. Bepridil, in addition to having calcium channel-blocking properties, also has class I and III antiarrhythmic activity. MVO_2 is reduced with all the calcium channel antagonists because of reduced wall tension secondary to reduced arterial pressure and, to a minor extent, depressed contractility (see Table 15–9). Heart rate changes depend on the drug used and the state of the conduction system. Nifedipine generally increases heart rate or causes no change, whereas either no change or decreased heart rate is seen with verapamil and diltiazem because of the interaction of these direct and indirect effects. In contrast to the β -blockers, calcium channel antagonists have the potential to improve coronary blood flow through areas of fixed coronary obstruction by inhibiting coronary artery vasomotion and vasospasm. Beneficial redistribution of blood flow from well-perfused myocardium to ischemic areas and from epicardium to endocardium also may contribute to improvement in ischemic symptoms. Overall, the benefit provided by calcium channel antagonists is related to reduced MVO_2 rather than improved oxygen supply based

on lack of alteration in the rate-pressure product at maximal exercise in most studies performed to date. However, as CAD progresses and vasospasm becomes superimposed on critical stenotic lesions, improved oxygen supply through coronary vasodilation may become more important.

Absorption of the calcium channel antagonists is excellent, and large, variable first-pass metabolism results in oral bioavailability ranging from about 20% to 50% or greater for diltiazem, nifedipine, verapamil, felodipine, and isradipine. Amlodipine and bepridil have a range of bioavailability of approximately 60% to 80%. Saturation of this effect may occur with verapamil and diltiazem, resulting in greater amounts of drug being absorbed with chronic dosing. Nifedipine may have slow or fast absorption patterns, and the ingestion of food delays and impairs its absorption, as well as potential enhanced absorption in elderly patients. This variability in absorption produces fluctuations in the hemodynamic response with nifedipine. Sublingual nifedipine is used frequently to provide a more rapid response; however, the rationale for this application is suspect because little nifedipine is absorbed from the buccal mucosa, and the swallowed drug is responsible for the observed plasma concentrations. Absorption of verapamil in sustained-release products may be influenced by food, and when it is used in the fasted state, dose dumping may occur, resulting in high peak concentrations with some products. The sustained-release products for nifedipine, verapamil, and diltiazem are approved primarily for the treatment of hypertension (see Chap. 13). The presence of severe liver disease (e.g., alcoholic liver disease with cirrhosis) has been shown to reduce the first-pass metabolism of verapamil, and this shunting of drug around the liver gives rise to higher plasma concentrations and lower dose requirements in these patients. Interestingly, this effect appears to be stereoselective for the more active isomer of verapamil. Verapamil also may reduce liver blood flow; however, evidence for this reduction is based primarily on animal experiments. Few data are available regarding the influence of liver disease on the kinetics of calcium blockers; however, these drugs undergo extensive hepatic metabolism, with little unchanged drug being excreted renally, and liver disease can be expected to alter the pharmacokinetics. Nifedipine has no active metabolites, whereas norverapamil possesses 20% or less activity of the parent compound. Desacetyldiltiazem has not been studied in humans, but canine studies suggest that its potency ranges from 100% to 40% of the parent compound for various cardiovascular effects; the clinical importance of these observations remains to be determined. With chronic dosing of verapamil and diltiazem, apparent saturation of metabolism occurs, producing higher plasma concentrations of each drug than those seen with single-dose administration. Consequently, the elimination half-life for verapamil is prolonged, and less frequent dosing intervals may be used in some patients. The elimination half-life for diltiazem is also somewhat prolonged, and the half-life of desacetyldiltiazem is longer than that of the parent drug. However, it is not clear if less frequent dosing may be used. Bepridil also undergoes hepatic elimination, and an active metabolite, 4-hydroxyphenyl bepridil, is produced; the parent compound has a long half-life of 30 to 40 hours. Nifedipine does not accumulate with chronic dosing; however, it is eliminated via oxidative pathways that may be polymorphic, and slow and fast metabolizers have been described for nifedipine. Most of the calcium channel blockers are eliminated via cytochrome P (CYP) 3A4 and other CYP isoenzymes, and many inhibit CYP 3A4 activity as well.¹⁰² Renal insufficiency has little or no effect on the pharmacokinetics of these three drugs. Although disease alterations in kinetics have been described, the most important quantitative alteration is the influence of liver disease on bioavailability, and elimination has been shown to reduce the clearance of verapamil and diltiazem. Thus dosing in

this population should be done with caution. Altered protein binding owing to renal disease, decreased protein concentration, or increased α_1 -acid glycoprotein has been noted, but the clinical import of these changes is unknown.

Good candidates for calcium channel blockers in angina include patients with contraindications to or intolerance of β -blockers, those with coexisting conduction system disease (except for verapamil and diltiazem), those with Prinzmetal's angina (vasospastic or variable-threshold angina), those with peripheral vascular disease, those with severe ventricular dysfunction (amlodipine is probably the calcium channel blocker of choice, and others need to be used with caution if the ejection fraction is less than 40%), and those with concurrent hypertension.

In the diabetic substudy of the Heart Outcomes Prevention Evaluation (HOPE), 9297 high-risk men and women 55 years of age and older with previous cardiovascular disease or diabetes plus one risk factor were randomly assigned to ramipril (up to 10 mg/day), vitamin E (400 IU/day), their combination, or matching placebos.¹⁰³ During the mean follow-up of 4.5 years, there were 482 (10.4%) patients with MI and unexpected cardiovascular death in the ramipril group compared with 604 (12.9%) in the placebo group.¹⁰³ Ramipril was associated with a trend toward fewer fatal MIs and unexpected deaths¹⁰³ and with a significant reduction in nonfatal MIs [5.6% versus 7.2%; relative risk ratio (RRR) 23% (CI 9%–34%)]. This study and others suggest that ACE inhibitors provide significant protection against the long-term consequences of IHD.

■ INVESTIGATIONAL AGENTS

Ranolazine is a novel antianginal agent currently under investigation as monotherapy and adjunct therapy for the treatment of chronic stable angina. Although the mechanism of action of ranolazine is not understood completely, it is believed to involve a reduction in fatty acid oxidation, ultimately leading to a shift in myocardial energy production from fatty acid oxidation to glucose oxidation. Because the oxidation of glucose requires less oxygen than the oxidation of fatty acids, ranolazine can help to maintain myocardial function in times of ischemia. In addition, ranolazine does not affect blood pressure, heart rate, or cardiac conduction significantly. Ranolazine has been shown to improve exercise time as monotherapy or in combination with traditional antianginal agents.^{104,105}

Therapeutic angiogenesis aims to deliver an angiogenic growth factor or cytokine to the myocardium to stimulate collateral blood vessel growth throughout the ischemic tissue. The angiogenic factor may be administered as a recombinant protein or as a transgene within a plasmid or gene-transfer vector. An example of this approach is the intracoronary administration of the adenoviral gene for fibroblast growth factor (Ad5FGF-4) to determine if therapeutic angiogenesis could improve myocardial perfusion compared with placebo.¹⁰⁶ In a study of 52 patients with stable angina and reversible ischemia, Ad5FGF-4 decreased the ischemic defect by 21% ($p < .001$), as determined by single-photon-emission computed tomography (SPECT) imaging.¹⁰⁶ More trials are needed before angiogenesis becomes a standard therapy.

Selective 5-HT subtype 3 receptor (5-HT₃) antagonists may have potential in the treatment of the pain associated with MI. MCI-9042 (sarpogrelate) or other 5-HT_{2A} antagonists may have clinical potential for the treatment of vasospastic angina, IHD, reperfusion injury, and hindlimb ischemia. Several modulators of 5-HT (5-HT transporter inhibitors and 5-HT_{1B} and 5-HT_{2B} antagonists) may have potential alone or in combination in the treatment of pulmonary hypertension.¹⁰⁷

Tedisamil is a bradycardic agent because of its ability to inhibit transient outward current (I_{to}) in atria. Tedisamil inhibits I_{to} , potassium current (I_K), $I_{K(ATP)}$, and the protein kinase A-activated chloride channel in ventricles, as well as vascular I_K and Ca²⁺-activated I_K ($I_{K(Ca)}$). As compared with atenolol, tedisamil produced a prolongation of the QTc interval (+31 versus 8 ms) at initial values of 0.408 ± 0.018 seconds with the PQ and QRS intervals remaining unaltered. In patients with stable angina, tedisamil (100 mg twice daily) as compared with atenolol (50 mg twice daily) generated similar hemodynamic, neurohumoral, and anti-ischemic effects.¹⁰⁸

Markers of systemic inflammation (e.g., C-reactive protein [CRP] and interleukin-6 [IL-6]) have been proposed to be “nontraditional” risk factors for cardiovascular disease in patients with type 2 diabetes mellitus. Matrix metalloproteinase-9 (MMP-9) has been implicated in the pathogenesis of atherosclerotic plaque rupture, which raises the possibility of the use of MMP-9 levels as a marker for future MI or UA. In vitro and animal studies suggest that thiazolidinediones can reduce the expression of these markers. Rosiglitazone reduces serum levels of MMP-9 and the proinflammatory marker CRP in patients with type 2 diabetes, which indicates potentially beneficial effects on overall cardiovascular risk.¹⁰⁹ The management of UA and NSTEMI is covered in detail in Chap. 16.

► TREATMENT: Coronary Artery Spasm and Variant Angina Pectoris (Prinzmetal's Angina)

Prinzmetal, in his original description of variant angina pectoris, noted the waxing and waning course of this syndrome associated with ST-segment elevation and that it resolves most commonly without progression to MI. Patients who develop variant angina are usually younger and have fewer coronary risk factors but more commonly smoke than patients with chronic stable angina. Hyperventilation, exercise, and exposure to cold may precipitate variant angina attacks, or there may be no apparent precipitating cause. The onset of chest discomfort is usually in the early morning hours. The exact cause of variant angina is not well understood but may be an imbalance between endothelium-produced vasodilator factors (e.g., prostacyclin and nitric oxide) and vasoconstrictor factors (e.g., endothelin and angiotensin II), as well as an imbalance of autonomic control characterized by parasympathetic dominance.¹¹⁰

The diagnosis of variant angina is based on ST-segment elevation during transient chest discomfort (usually at rest) that resolves when

the chest discomfort diminishes in patients who have normal or nonobstructed coronary lesions. In the absence of ST-segment elevation, a provocative test using ergonovine, acetylcholine, or methacholine may be used to precipitate coronary artery spasm, ST-segment elevation, and typical symptoms. Nitrates and calcium antagonists should be withdrawn prior to provocative testing. Provocative testing should not be used in patients with high-grade lesions. Hyperventilation also may be used to provoke spasm, and patients with positive a hyperventilation test are more likely to have a higher frequency of attacks, multivessel disease, and a high degree of AV block or ventricular tachycardia.

Optimization of therapy includes dose titration using sufficiently high doses to obtain clinical efficacy without unacceptable adverse effects in individual patients. All patients should be treated for acute attacks and maintained on prophylactic treatment for 6 to 12 months following the initial episode. The occurrence of serious arrhythmias

during attacks is associated with a greater risk of sudden death, and these patients should be treated more aggressively and for prolonged periods. For patients without arrhythmias who become asymptomatic and remain so for several months after treatment has been instituted, withdrawal of therapy may be safe after first ascertaining that disease activity is quiescent. Aggravating factors such as alcohol or cocaine use and cigarette smoking should be eliminated when instituting treatment.

Nitrates have been the mainstay of therapy for the acute attacks of variant angina and coronary artery spasm for many years. Most patients respond rapidly to sublingual nitroglycerin or isosorbide dinitrate; however, intravenous and intracoronary nitroglycerin may be very useful for patients not responding to sublingual preparations. In particular, vasospasm provoked by ergonovine may require intracoronary nitroglycerin. Although studies with nitrates generally show them to be efficacious, high doses often are required, and it is unclear if they reduce mortality. Because calcium antagonists may be more effective, have few serious adverse effects in effective doses, and can be given less frequently than nitrates, some clinicians consider them the agents of choice for variant angina.

Nifedipine, verapamil, and diltiazem are all equally effective as single agents for the initial management of variant angina and

coronary artery spasm. Dose titration is important to maximize the response with calcium antagonists. Comparative trials are few in number and do not reveal significant differences among these three drugs for variant angina. Patients unresponsive to calcium antagonists alone may have nitrates added. Combination therapy with nifedipine-diltiazem or nifedipine-verapamil has been reported to be useful in patients unresponsive to single-drug regimens. This is probably rational because, at the cellular level, the drugs have different receptors, but the combination of verapamil-diltiazem should be used cautiously owing to their potential additive effects on contractility and conduction.

β -Adrenergic blockade has little or no role in the management of variant angina according to most authorities.¹¹¹ Although not all studies report increased painful episodes of variant angina with the addition of β -blockers, they may induce coronary vasoconstriction and prolong ischemia, as documented by continuous ECG monitoring. Other approaches to therapy attempting to modify sympathetic/parasympathetic tone include α -antagonists, anticholinergics, plexectomy, surgical interruption of the sympathetic innervation of the heart, thromboxane receptor antagonism, prostacyclin, lipoxigenase inhibition, and ticlopidine, but these drugs or procedures do not occupy a major place in therapy at the present time.

► TREATMENT: Silent Ischemia¹⁷

The objective in the treatment of silent myocardial ischemia is to reduce the total number of ischemic episodes, both symptomatic and asymptomatic, regardless of the direction of ST-segment shift. The incidence of silent ischemia in the general, asymptomatic population is not known. Significant day-to-day variability in the number of episodes, the duration of ischemia, and the amount of ST-segment deviation complicates both the understanding of this process and the utility of various therapeutic interventions. Silent ischemia in patients with known CAD is common (~80% of all ischemic episodes) and associated with the extent of disease, as well as a high risk for MI and sudden death when compared with symptomatic episodes of ischemia. Although the underlying mechanisms for silent ischemia continue to be defined, increased physical activity, activation of the sympathetic nervous system, increased cortisol secretion, increased coronary artery tone, and enhanced platelet aggregation owing to endothelial dysfunction leading to intermittent coronary obstruction may be additive in lowering the threshold for ischemia. Platelet aggregability is increased in the morning hours (7 to 11 AM), corresponding to circadian rhythms noted for the peak frequency of ischemia, acute MI, and sudden death. Silent ischemia is associated with ST-segment elevation or depression and frequently occurs without antecedent changes in heart rate or blood pressure, suggesting that this form of ischemia is a result of primary reduction in oxygen supply. Silent ischemia is classified into class I, patients who do not experience angina at any time, and class II, patients who have both asymptomatic and symptomatic ischemia. Patients with silent ischemia have a defective warning system for angina pain that may encourage excessive myocardial demand. Regardless of the exact mechanism, there is increasing concern that painless ischemia carries considerable risk for myocardial perfusion defects, detrimental hemodynamic changes, arrhythmogenesis, and sudden death. Silent ischemia is associated with reduced survival and increased need for PTCA and CABG, as well as increased risk of acute MI.¹¹² Because it is apparently very common in some settings, major emphasis should be placed on its management. A consensus has not been reached for the most appropriate method of detecting and quantifying the magnitude of silent ischemia; however,

ambulatory ECG monitoring is felt by many to be the most useful tool at the present time.

The initial step in management is to modify the major risk factors for IHD—hypertension, hypercholesterolemia, and smoking—and data from the Multiple Risk Factor Intervention Trial (MRFIT) show these interventions to be useful in patients with silent ischemia. In a subset of the study population that had abnormal baseline exercise ECG responses, the special intervention group had a 57% reduction in coronary heart disease death (22.2 of 1000 versus 51.8 of 1000) and a reduction in sudden death resulting from cessation of smoking and lowering of blood pressure and cholesterol when compared with the usual-care group.

The Asymptomatic Cardiac Ischemia Pilot study (ACIP), a randomized trial of medical therapy versus revascularization (PTCA or CABG), at the 2-year follow-up demonstrated that total mortality was 6.6% in the angina-guided strategy (i.e., therapy based on symptoms), 4.4% in the ischemia-guided strategy (based on ECG changes), and 1.1% in the revascularization strategy ($p < .02$). The rate of death or MI was 12.1% in the angina-guided strategy, 8.8% in the ischemia-guided strategy, and 4.7% in the revascularization strategy ($p < .04$).¹¹³ The rate of death, MI, or recurrent cardiac hospitalization was 41.8% in the angina-guided strategy, 38.5% in the ischemia-guided strategy, and 23.1% in the revascularization strategy ($p < .001$). Post-MI patients and those with a high level of sympathetic nervous system activity are perhaps the best candidates for β -blocker therapy.

Calcium channel antagonists alone and in combination have been shown to be effective in reducing symptomatic and asymptomatic ischemia; however, they do not interrupt the diurnal surge in ischemia observed on ambulatory monitoring, and in general, they are somewhat less effective than β -blockers for silent ischemia.^{114,115} Nifedipine in particular seems to provide less protection and provides wide fluctuations in response, with approximate reductions in the number of episodes ranging from 0% to 93% and in duration from 23% to 65% unless combined with β -blockers. Fewer studies are available with other calcium blockers, and comparative trials are uncommon.

Earlier studies have shown that combination therapy with calcium channel blockers and β -blockers provides a better response than calcium channel blockers and nitrates or monotherapy.^{116,117}

Surgical intervention using CABG does not appear warranted in asymptomatic patients without significant CAD. Based on the CASS 12-year follow-up results, survival following CABG was enhanced in men with three-vessel disease compared with medical therapy (61% versus 46%) but not for women (45% versus 50%) with silent

ischemia.¹¹⁸ The role for PTCA is promising in silent ischemia, and improvement in exercise tolerance and freedom from MI, CABG, and PTCA for new lesions or death may be seen in patients becoming asymptomatic after PTCA. However, exercise-induced silent myocardial ischemia is seen frequently early after successful PTCA and is more prevalent in patients undergoing multivessel angioplasty and incomplete revascularization. Both silent and symptomatic ischemia early after PTCA are predictors of an unfavorable prognosis.

► TREATMENT: Syndrome X¹¹⁹

Syndrome X refers to the occurrence of effort angina and exercise-induced ECG changes with a normal coronary arteriogram and no evidence of structural (stenosis) or functional (spasm) abnormalities. Although the basis for this syndrome is not yet established, it is thought that syndrome X may be a result of inducible myocardial ischemia caused by impaired functional coronary reserve at the microvascular level of intramural prearteriolar vessels.¹²⁰ It has been proposed that this defect is caused by defective prearteriolar regulation of blood flow into the arteriolar bed with subsequent focal, sustained, compensatory release of adenosine; excessive local concentrations of adenosine are then responsible for the pain seen in this syndrome. Cardiomyopathy and left bundle block may result from ischemia in some patients. Follow-up studies have shown that the occurrence of left bundle branch block in response to stress is associated

with a greater likelihood of deterioration of LV performance, whereas stress-induced ST-segment depression does not predict a detrimental outcome in ventricular function. Esophageal abnormalities may be seen in these patients, and acid refluxing into the esophagus may reduce coronary blood flow.

α -Adrenergic blockers are much less effective in many studies in syndrome X than in exertional angina, and one characteristic, if present, that may predict a good response to β -blockers is increased sympathetic nervous system activity.¹²¹ ACE inhibitors have been shown to improve coronary reserve, exercise capacity, and exercise time in patients with microvascular angina.^{122,123} Estrogen-replacement therapy in postmenopausal women has been shown to restore endothelial responsiveness to acetylcholine, and this has potential in the management of syndrome X patients.¹²⁴

PHARMACOECONOMIC CONSIDERATIONS

Pharmacoeconomic studies have been performed primarily in patients with acute coronary syndromes and only with LMWHs, GP IIb/IIIa receptor antagonists, and statins.¹²⁵ Most of the studies on LMWHs have been cost-minimization analyses and have focused on enoxaparin sodium because this is the only LMWH proven to be superior to UFH. Several analyses show that, compared with UFH plus aspirin, enoxaparin sodium provides cost savings both during hospitalization (30 days) and at 1-year follow-up. These cost savings are mainly attributable to fewer cardiac interventions, shorter hospital stays, and lower administrative costs. Indeed, the clinical and economic advantages of enoxaparin sodium have led to its recommendation in recent guidelines as the antithrombotic agent of choice for CAD. Most of the economic analyses of GP IIb/IIIa inhibitors have been cost-effectiveness analyses.¹²⁶ Such analyses indicate that the high acquisition costs of these drugs may be at least partially offset by reductions in other costs if a noninvasive approach to risk stratification is used. Furthermore, use of GP IIb/IIIa inhibitors appears to give favorable cost-effectiveness ratios compared with other accepted therapies, such as fibrin-specific thrombolytic therapy, in the cardiovascular field, particularly in high-risk patients and those undergoing PCI. However, more comprehensive economic data on the GP IIb/IIIa inhibitors are needed.

Atorvastatin when used in ACS has been shown to reduce events, and this offsets the upfront acquisition costs.¹²⁶ The total expected cost was (British) £784.05 per patient in the placebo cohort and £851.59 per patient in the atorvastatin cohort, resulting in an incremental cost of £67.54 per patient in the atorvastatin group. The cost per event avoided was £1762.04. A third of the cost of atorvastatin treatment was offset within 16 weeks by the cost savings resulting from the reduction in the number of events in the atorvastatin cohort compared with the placebo cohort.

Aspirin and clopidogrel have been evaluated for secondary prevention of CHD, and clopidogrel is only cost-effective for patients who cannot take aspirin.

CLINICAL CONTROVERSIES

Once patients with angina develop symptoms sufficient for pharmacologic therapy on a daily basis, the initial prophylactic therapy recommended is a β -blocker. There is a paucity of comparative, long-term clinical trials of β -blockade versus calcium channel blockers to determine which is superior for survival benefit. β -Blockers are recommended first-line therapy because of their efficacy in post-MI patients and favorable adverse-effect profile.

There is continuing controversy whether the vasculoprotective effects of the ACE inhibitors are seen with only tissue-selective ACE inhibitors or if this effect extends across the entire class. Quantitative differences in lipophilicity and enzyme-binding capabilities do exist among the ACE inhibitors, and optimal doses for therapeutic benefit must be established in large-scale clinical trials.

The use of high-sensitivity CRP in diagnosis and risk stratification in IHD has gained support in recent years, but not all studies consistently demonstrate improved sensitivity and specificity in the diagnosis of CAD.

EVALUATION OF THERAPEUTIC OUTCOMES

Improved symptoms of angina, improved cardiac performance, and improvement in risk factors all may be used to assess the outcome of treatment of IHD and angina. Symptomatic improvement in exercise capacity (longer duration) or fewer symptoms at the same level of

exercise is subjective evidence that therapy is working. Once patients have been optimized on medical therapy, symptoms should improve over 2 to 4 weeks and remain stable until the disease progresses. There are several instruments [e.g., the Seattle Angina Questionnaire, the Specific Activity Scale (see Table 15–1), and the Canadian Classification System (see Table 15–2)] that could be used to improve the reproducibility of symptom assessment.¹ If the patient is doing well, then no other assessment may be necessary. Objective assessment is obtained through increased exercise duration on ETT and the absence of ischemic changes on ECG or deleterious hemodynamic changes. Echocardiography and cardiac imaging also may be used; however, owing to their expense, they are used only if a patient is not doing well to determine if revascularization or other measures should be undertaken. Coronary angiography may be used to assess the extent of stenosis or restenosis after angioplasty or CABG.

ACUTE CORONARY SYNDROMES

Sarah A. Spinler and Simon de Denus

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The cause of an acute coronary syndrome (ACS) is the rupture of an atherosclerotic plaque with subsequent platelet adherence, activation, aggregation, and activation of the clotting cascade. Ultimately, a clot forms and is composed of fibrin and platelets.
- 2 The American Heart Association (AHA) and the American College of Cardiology (ACC) recommend strategies or guidelines for ACS patient care for ST-segment- and non-ST-segment-elevation ACS.
- 3 Patients with ischemic chest discomfort and suspected ACS are risk-stratified based on a 12-lead electrocardiogram (ECG), past medical history, and results of creatine kinase (CK) MB and troponin biochemical marker tests.
- 4 The diagnosis of myocardial infarction (MI) is confirmed based on the results of the CK MB and troponin tests.
- 5 Three key features identifying high-risk patients with non-ST-segment-elevation ACS are a Thrombolysis in Myocardial Infarction (TIMI) risk score of 5 to 7, the presence of ST-segment depression on ECG, and positive CK MB or troponin.
- 6 Early reperfusion therapy with either primary percutaneous coronary intervention (PCI) or administration of a fibrinolytic agent is the recommended therapy for patients presenting with ST-segment-elevation ACS.
- 7 In addition to reperfusion therapy, additional pharmacotherapy that all patients with ST-segment-elevation ACS and without contraindications should receive within the first day of hospitalization and preferably in the emergency department are intranasal oxygen (if oxygen saturation is low), aspirin, sublingual nitroglycerin, intravenous nitroglycerin, intravenous followed by oral β -blockers, and unfractionated heparin (UFH).
- 8 High-risk patients with non-ST-segment-elevation ACS should undergo early coronary angiography and revascularization with either PCI or coronary artery bypass graft (CABG) surgery.
- 9 In the absence of contraindications, all patients with non-ST-segment-elevation ACS should be treated in the emergency department with intranasal oxygen (if oxygen saturation is low), aspirin, sublingual nitroglycerin, intravenous nitroglycerin, intravenous followed by oral β -blockers, and either unfractionated heparin (UFH) or a low-molecular-weight heparin (enoxaparin preferred). Most patients should receive additional therapy with clopidogrel. High-risk patients also should receive a glycoprotein IIb/IIIa receptor blocker.
- 10 Following MI, all patients, in the absence of contraindications, should receive indefinite therapy with aspirin, a β -blocker and an angiotensin-converting enzyme (ACE) inhibitor for secondary prevention of death, stroke, and recurrent infarction. Most patients will receive a statin to reduce low-density lipoprotein cholesterol to less than 70 to 100 mg/dL. Anticoagulation with warfarin should be considered for patients at high risk of death, reinfarction, or stroke.
- 11 Secondary prevention of death, reinfarction, and stroke is more cost-effective than primary prevention of coronary heart disease (CHD) events.

Since the early 1900s cardiovascular disease (CVD) has been the leading cause of death. Acute coronary syndromes (ACSs), including unstable angina (UA) and myocardial infarction (MI), are forms of coronary heart disease (CHD) that constitute the most common cause of CVD death.¹ The cause of an ACS is the rupture of an atherosclerotic plaque with subsequent platelet adherence, activation, aggregation, and activation of the clotting cascade. Ultimately, a clot forms and is composed of fibrin and platelets. Correspondingly, pharmacotherapy of ACS has advanced to include combinations of fibrinolytics, antiplatelets, and anticoagulants with more traditional therapies such as nitrates and β -adrenergic blockers. Pharmacother-

apy is integrated with reperfusion therapy and revascularization of the culprit coronary artery through interventional means such as percutaneous coronary intervention (PCI) and coronary artery bypass graft (CABG) surgery. The American Heart Association (AHA) and the American College of Cardiology (ACC) recommend strategies or guidelines for ACS patient care for ST-segment- and non-ST-segment-elevation ACS. These joint practice guidelines are based on a review of available clinical evidence, have graded recommendations based on the weight and quality of evidence, and are updated periodically. The guidelines form the cornerstone for quality patient care of the ACS patient.^{2,3}

EPIDEMIOLOGY

Each year more than 1 million Americans will experience an ACS, and 239,000 will die of an MI.¹ In the United States, more than 7.6 million living persons have survived an MI.¹ Chest discomfort is the most frequent reason for patient presentation to emergency departments, with up to 7 million emergency department visits, or approximately 3% of all emergency department visits, linked to chest discomfort and possible ACS. CHD is the leading cause of premature, chronic disability in the United States. The cost of CHD is high, with more than \$10 billion being paid to Medicare beneficiaries in 1999, or more than \$10,000 per MI hospital stay. The average length of hospital stay for MI in 1999 was 5.6 days.¹

Much of the epidemiologic data regarding ACS treatment and survival come from the National Registry of Myocardial Infarction (NRFMI), the Global Registry of Acute Coronary Events (GRACE), and statistical summaries of U.S. hospital discharges prepared by the AHA. In patients with ST-segment-elevation ACS, in-hospital death rates are approximately 7% for patients who are treated with fibrinolytics and 16% for patients who do not receive reperfusion therapy. In patients with non-ST-segment-elevation MI, in-hospital mortality is less than 5%. In-hospital mortality and 1-year mortality are higher for women and elderly patients. In the first year following MI, 38% of women and 25% of men will die, most from recurrent infarction.¹ At 1 year, rates of mortality and reinfarction are similar between ST-segment-elevation and non-ST-segment-elevation MI.

Approximately 30% of patients develop heart failure at some time during their hospitalization for MI. In-hospital death rates for patients who present with or develop heart failure are more than three-fold higher than for those who do not.⁴

Because reinfarction and death are major outcomes following ACS, therapeutic strategies to reduce morbidity and mortality, particularly use of coronary angiography, revascularization, and pharmacotherapy, will have a significant impact on the social and economic burden of CHD in the United States.

ETIOLOGY

In this section we will discuss the formation of atherosclerotic plaques, the underlying cause of coronary artery disease (CAD) and ACS in most patients. The process of atherosclerosis starts early in life. Its earliest stage, endothelial dysfunction, progresses over the ensuing decades into plaque formation and atherosclerosis.⁵ A number of factors are directly responsible for the development and progression of endothelial dysfunction and atherosclerosis, including hypertension, age, male gender, tobacco use, diabetes, obesity, elevated plasma homocysteine concentrations, and dyslipidemias.^{5,6}

Endothelial dysfunction is characterized by an imbalance between vasodilating (including nitric oxide and prostacyclin) and vasoconstricting (including endothelin-1, angiotensin II, and norepinephrine) substances resulting in an increase in vascular reactivity. This also leads to an imbalance between procoagulant (plasminogen activator inhibitor-1 and tissue factor) and anticoagulant (tissue plasminogen activator and protein C) substances, thereby promoting platelet aggregation and thrombus formation. Furthermore, endothelial dysfunction is characterized by an increase in the expression of leukocyte adhesion molecules, which promotes the migration of inflammatory cells in the subintimal vessel wall.⁶ Finally, endothelial dysfunction increases the permeability of the endothelium to low-density lipoprotein (LDL) cholesterol and inflammatory cells that promote their migration and infiltration in the subintimal vessel wall.^{6,7}

Taken together, all these factors contribute to the evolution of endothelial dysfunction to the formation of fatty streaks in the coronary arteries and eventually to atherosclerotic plaques.

PATHOPHYSIOLOGY

SPECTRUM OF ACS

Acute coronary syndromes (ACSs) is a term that includes all clinical syndromes compatible with acute myocardial ischemia resulting from an imbalance between myocardial oxygen demand and supply.³ In contrast to stable angina, an ACS results primarily from diminished myocardial blood flow secondary to an occlusive or partially occlusive coronary artery thrombus. ACSs are classified according to electrocardiographic changes into ST-segment-elevation ACS (ST-elevation MI [STEMI]) or non-ST-segment-elevation ACS (non-ST-elevation MI [NSTEMI] and unstable angina [UA]) (Fig. 16–1). NSTEMI differs from UA in that ischemia is severe enough to produce myocardial necrosis, resulting in the release of a detectable amount of biochemical markers, mainly troponins T or I and creatine kinase (CK) myocardial band (MB) from the necrotic myocytes, in the bloodstream.³ The clinical significance of serum markers will be discussed in more details in later sections of this chapter. Following an STEMI, pathologic Q waves are seen frequently on the electrocardiogram (ECG), whereas such an ECG manifestation is seen less commonly in patients with NSTEMI.⁷ The presence of Q waves usually indicates transmural MI.

PLAQUE RUPTURE AND CLOT FORMATION

▶ The predominant cause of ACS, in more than 90% of patients, is atheromatous plaque rupture, fissuring, or erosion of an unstable atherosclerotic plaque that encompasses less than 50% of the coronary lumen prior to the event rather than a more stable 70% to 90% stenosis of the coronary artery.³ Stable stenoses are characteristic of stable angina. Plaques that are more susceptible to rupture are characterized by an eccentric shape, a thin fibrous cap (particularly in the shoulder region of the plaque), large fatty core, a high content in inflammatory cells such as macrophages and lymphocytes, and limited amounts of smooth muscle. Inflammatory cells promote the thinning of the fibrous cap through the release of proteolytic enzymes, particularly matrix metalloproteinases.⁷

Following plaque rupture, a partially occlusive or completely occlusive thrombus, a clot, forms on top of the ruptured plaque. The thrombogenic contents of the plaque are exposed to blood elements. Exposure of collagen and tissue factor induce platelet adhesion and activation, which promote the release of platelet-derived vasoactive substances, including adenosine diphosphate (ADP) and thromboxane A₂ (TXA₂).⁸ These produce vasoconstriction and potentiate platelet activation. Furthermore, during platelet activation, a change in the conformation in the glycoprotein (GP) IIb/IIIa surface receptors of platelets occurs that cross-links platelets to each other through fibrinogen bridges. This is considered the final common pathway of platelet aggregation. Other substances known to promote platelet aggregation include serotonin, thrombin, and epinephrine.⁸ Inclusion of platelets gives the clot a white appearance. Simultaneously, the extrinsic coagulation cascade pathway is activated as a result of exposure of blood components to the thrombogenic lipid core and endothelium, which are rich in tissue factor. This leads to the production of thrombin (factor IIa), which converts fibrinogen to fibrin through enzymatic activity.⁸ Fibrin stabilizes the clot and traps red blood cells, which give the clot a red appearance. Therefore, the clot is composed of cross-linked platelets and fibrin strands.⁸

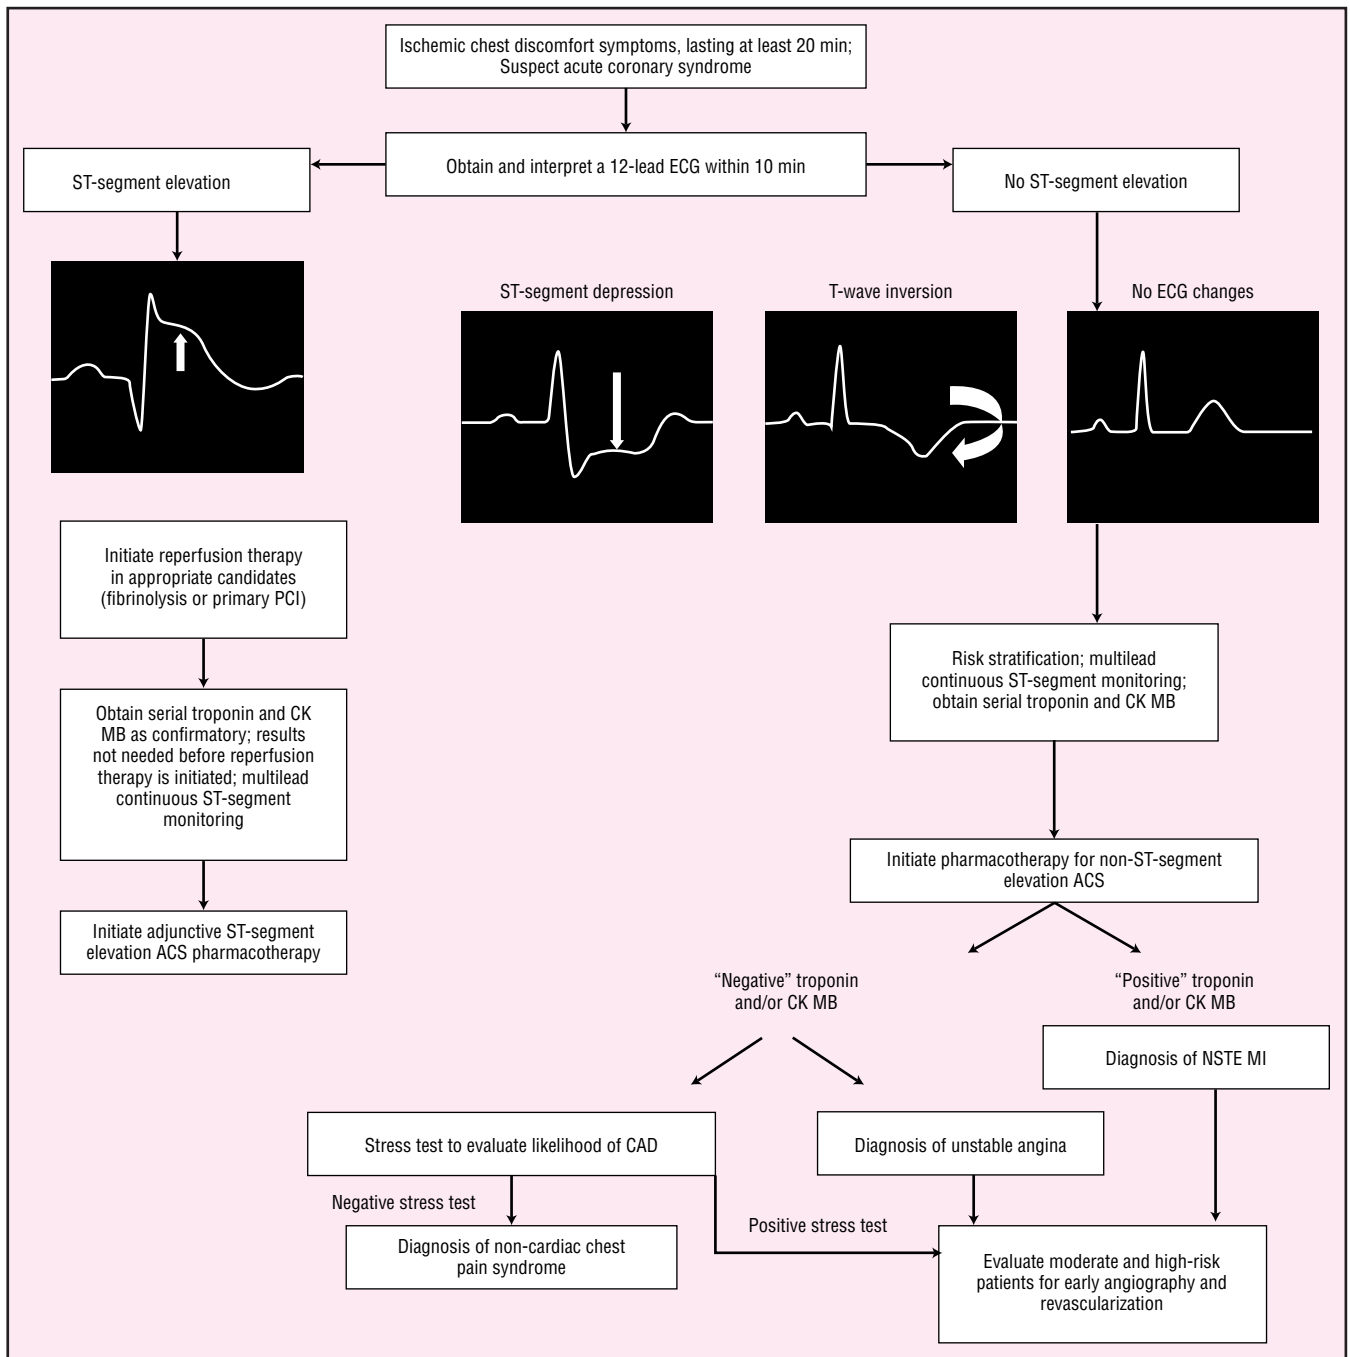

FIGURE 16-1. Evaluation of the acute coronary syndrome patient. ACS = acute coronary syndrome; CAD = coronary artery disease; CK = creatine kinase; ECG = electrocardiogram; PCI = percutaneous coronary intervention; Positive = above the MI decision limit; Negative = below the MI decision limit.

A thrombus containing more platelets than fibrin, or a “white” clot, generally produces an incomplete occlusion of the coronary lumen and is more common in non-ST-segment-elevation ACS. In patients presenting with an ST-segment-elevation ACS, the vessel generally is completely occluded by a “red” clot that contains larger amounts of fibrin and red blood cells but a smaller amount of platelets compared with a “white” clot.² As will be discussed later on in this chapter, the composition of the clot influences the selection of the combinations of antithrombotic agents used in ST-segment- and non-ST-segment-elevation ACS. Finally, myocardial ischemia can re-

sult from the downstream embolization of microthrombi and produce ischemia with eventual necrosis.²

VENTRICULAR REMODELING FOLLOWING AN ACUTE MI

Ventricular remodeling is a process that occurs in several cardiovascular conditions, including heart failure and following an MI. It is characterized by changes in the size, shape, and function of the left

ventricle and leads to cardiac failure.⁹ Because heart failure represents one of the principal causes of mortality and morbidity following an MI, preventing ventricular remodeling is an important therapeutic goal.⁹

Many factors contribute to ventricular remodeling, including neurohormonal factors (e.g., activation of the renin-angiotensin-aldosterone and sympathetic nervous systems), hemodynamic factors, mechanical factors, and changes in gene expression.¹⁰ This process affects both cardiomyocytes (cardiomyocyte hypertrophy, loss of cardiomyocytes) and the extracellular matrix (increased interstitial fibrosis), thereby promoting both systolic and diastolic dysfunction.¹⁰

Angiotensin-converting enzyme (ACE) inhibitors, β -blockers, and aldosterone antagonists are all agents that slow down or reverse ventricular remodeling through neurohormonal blockage and/or through improvement in hemodynamics (decreasing preload or afterload).⁹ These agents also improve survival and will be discussed in more detail in subsequent sections of this chapter. This underlines the importance of the remodeling process and the urgency of preventing, halting, or reversing it in patients who have experienced an MI.

COMPLICATIONS

This chapter will focus on management of the uncomplicated ACS patient. However, it is important for clinicians to recognize complications of MI because such patients have increased mortality. The most serious complication is cardiogenic shock, occurring in approximately 10% of hospitalized MI patients. Mortality in cardiogenic shock patients with MI is high, approaching 60%.¹¹ Other complications that may result from MI are heart failure, valvular dysfunction, ventricular and atrial tachyarrhythmias, bradycardia, heart block, pericarditis, stroke secondary to left ventricular (LV) thrombus embolization, venous thromboembolism, and LV free wall rupture.¹² In fact, more than one-quarter of MI patients die, presumably from ventricular fibrillation, prior to reaching the hospital.¹

CLINICAL PRESENTATION

The key points in clinical presentation of the patient with ACS are described in Table 16–1.

SYMPTOMS AND PHYSICAL EXAMINATION FINDINGS

The classic symptom of an ACS is midline anterior anginal chest discomfort, most often either at rest, severe new-onset, or increasing angina that is at least 20 minutes in duration. The chest discomfort may radiate to the shoulder, down the left arm, to the back, or to the jaw. Associated symptoms that may accompany the chest discomfort include nausea, vomiting, diaphoresis, or shortness of breath. All health care professionals should review these warning symptoms with patients at high risk for CHD. On physical examination, no specific features are indicative of ACS.

TWELVE-LEAD ELECTROCARDIOGRAM (ECG)

3 There are key features of a 12-lead ECG that identify and risk-stratify a patient with an ACS. Within 10 minutes of presentation to an emergency department with symptoms of ischemic chest discomfort (or preferably pre-hospital) a 12-lead ECG should be

TABLE 16–1. Presentation of Acute Coronary Syndromes (ACS)

General

The patient is typically in acute distress and may develop or present with cardiogenic shock.

Symptoms

The classic symptom of ACS is midline anterior chest discomfort.

Accompanying symptoms may include arm, back, or jaw pain; nausea; vomiting; and shortness of breath.

Patients less likely to present with classic symptoms include elderly patients, diabetic patients, and women.

Signs

No signs are classic for ACS.

However, patients with ACS may present with signs of acute heart failure, including jugular venous distension and an S_3 sound on auscultation.

Patients also may present with arrhythmias and therefore may have tachycardia, bradycardia, or heart block.

Laboratory Tests

Troponin I or T and creatine kinase (CK) MB are measured.

Blood chemistry tests are performed, with particular attention given to potassium and magnesium, which may affect heart rhythm.

The serum creatinine is measured to identify patients who may need dosing adjustments for some pharmacotherapy, as well as to identify patients who are at high risk of morbidity and mortality.

Baseline complete blood count (CBC) and coagulation tests (activated partial thromboplastin time and international normalized ratio) should be obtained because most patients will receive antithrombotic therapy, which increases the risk for bleeding.

Other Diagnostic Tests

The 12-lead electrocardiogram (ECG) is the first step in management.

Patients are risk-stratified into two groups, ST-segment-elevation ACS and suspected non-ST-segment-elevation ACS.

During hospitalization, a measurement of left ventricular function, such as an echocardiogram, is performed to identify patients with low ejection fractions (<40%), who are at high risk of death following hospital discharge.

Selected low-risk patients may undergo early stress testing.

obtained and interpreted. If available, a prior 12-lead ECG should be reviewed to identify whether or not the findings on the current ECG are new or old, with new findings being more indicative of an ACS. Key findings on review of a 12-lead ECG that indicate myocardial ischemia or MI are ST-segment elevation, ST-segment depression, and T-wave inversion (see Fig. 16–1). ST-segment and/or T-wave changes in certain groupings of leads help to identify the location of the coronary artery that is the cause of the ischemia or infarction. In addition, the appearance of a new left bundle branch block accompanied by chest discomfort is highly specific for acute MI. About one-half of patients diagnosed with MI present with ST-segment elevation on their ECG, with the remainder having ST-segment depression, T-wave inversion, or in some instances, no ECG changes. Some parts of the heart are more “electrically silent” than others, and myocardial ischemia may not be detected on a surface ECG. Therefore, it is important to review findings from the ECG in conjunction with biochemical markers of myocardial necrosis, such as troponin I or T, and other risk factors for CHD to determine the patient’s risk for experiencing a new MI or having other complications.

BIOCHEMICAL MARKERS

4 Biochemical markers of myocardial cell death are important for confirming the diagnosis of MI. *Evolving MI* is defined by the

FIGURE 16-2. Biochemical markers in suspected acute coronary syndrome.

ACC as “typical rise and gradual fall (troponin) or more rapid rise and fall (CK MB) of biochemical markers of myocardial necrosis.”¹³ Troponin and CK MB rise in the blood following the onset of complete coronary artery occlusion subsequent myocardial cell death. Their time course is depicted in Fig. 16-2. Typically, blood is obtained from the patient at least three times, once in the emergency department and two additional times over the next 12 to 24 hours, in order to measure troponin and CK MB. A single measurement of a biochemical marker is not adequate to exclude a diagnosis of MI because up to 15% of values that were below the level of detection initially (a negative test) are above the level of detection (a positive test) in the subsequent hours. An MI is identified if at least one troponin value is greater than the MI decision limit (set by the hospital laboratory) or two CK MB results are greater than the MI decision limit (set by the hospital laboratory). While troponins and CK MB appear in the blood within 6 hours of infarction, troponins stay elevated in the blood for up to 10 days, whereas CK MB returns to normal values within 48 hours. Therefore, if a patient is admitted with elevated troponin and CK MB concentrations and several days later experiences recurrent chest discomfort, the troponin will be less sensitive to detect new myocardial damage because it would still be elevated. If early reinfarction is suspected, CK MB concentration determination is the preferred diagnostic test.¹³

RISK STRATIFICATION

5 Patient symptoms, past medical history, ECG, and troponin or CK MB determinations are used to stratify patients into low, medium, or high risk of death or MI or likelihood of failing pharmacotherapy and needing urgent coronary angiography and percutaneous coronary intervention (PCI). Initial treatment according to risk stratification is depicted in Fig. 16-1. Patients with ST-segment elevation are at the highest risk of death. Initial treatment of ST-segment-elevation ACS should proceed without evaluation of the troponin or CK MB

levels because these patients have a greater than 97% chance of having an MI subsequently diagnosed with biochemical markers. The ACC/AHA defines a target time to initiate reperfusion treatment of within 30 minutes of hospital presentation for fibrinolytics and within 90 minutes or less from presentation for primary PCI.³ The sooner the infarct-related coronary artery is opened for these patients, the lower is their mortality, and the greater is the amount of myocardium that is preserved.^{14,15} While all patients should be evaluated for reperfusion therapy, not all patients may be eligible. Indications and contraindications for fibrinolytic therapy are described in the treatment section of this chapter. Fewer than 15% of hospitals in the United States are equipped to perform primary PCI. If patients are not eligible for reperfusion therapy, additional pharmacotherapy for ST-segment-elevation patients should be initiated in the emergency department, and the patient should be transferred to a coronary intensive care unit. The typical length of stay for a patient with uncomplicated STEMI is 3 to 5 days.

Risk stratification of the patient with non-ST-segment-elevation ACS is more complex because in-hospital outcomes for this group of patients vary, with reported rates of death of 0% to 12%, reinfarction of 0% to 3%, and recurrent severe ischemia of 5% to 20%.¹⁶ Not all patients presenting with suspected non-ST-segment-elevation ACS will even have CAD. Some will be diagnosed eventually with nonischemic chest discomfort.

Newer markers that identify patients at high risk of mortality or reinfarction that are under development but have not been incorporated currently into routine patient care include C-reactive protein,⁵ a maker of vascular inflammation; elevated serum creatinine or reduced creatinine clearance, identifying patients with chronic kidney disease¹⁷; and brain (B-type) natriuretic peptide (BNP),¹⁸ which is released predominately from ventricular myocytes in response to cell stretch as the infarct remodels. Dialysis patients have a 1-year mortality rate of more than 40% following a first MI.¹⁷

► **TREATMENT: Acute Coronary Syndromes**

■ **GENERAL APPROACH TO TREATMENT**

The short-term goals of treatment for the ACS patient are

1. Early restoration of blood flow to the infarct-related artery to prevent infarct expansion (in the case of MI) or prevent complete occlusion and MI (in UA)
2. Prevention of death and other complications
3. Prevention of coronary artery reocclusion
4. Relief of ischemic chest discomfort

General treatment measures for all ST-segment-elevation ACSs and high- and intermediate-risk non-ST-segment-elevation patients include admission to hospital, oxygen administration (if oxygen saturation is low, <90%), continuous multilead ST-segment monitoring for arrhythmias and ischemia, frequent measurement of vital signs, bed rest for 12 hours in hemodynamically stable patients, avoidance of Valsalva maneuver (prescribe stool softeners routinely), and pain relief.

Because risk varies and resources are limited, it is important to triage and treat patients according to their risk category. Initial

approaches to treatment of the ST-segment-elevation and non-ST-segment-elevation ACS patient are outlined in Fig. 16–1. Patients with ST-segment elevation are at high risk of death, and efforts to reestablish coronary perfusion should be initiated immediately. Reperfusion therapy should be considered immediately and adjunctive pharmacotherapy initiated.³

Features identifying low-, moderate-, and high-risk non-ST-segment-elevation ACS patients are described in Table 16–2.¹⁹ Patients at low risk for death or MI or for needing urgent coronary artery revascularization typically are evaluated in the emergency department, where serial biochemical marker tests are obtained, and if they are negative, the patient may be admitted to a general medical floor with ECG telemetry monitoring for ischemic changes and arrhythmias, undergo a noninvasive stress test, or may be discharged from the emergency department. Moderate- and high-risk patients are admitted to a coronary intensive care unit, an intensive care step-down unit, or a general medical floor in the hospital depending on the patient’s symptoms and perceived level of risk. High-risk patients should undergo early coronary angiography and revascularization if a significant coronary artery stenosis is found. Moderate-risk patients with positive biochemical markers for infarction typically also will

TABLE 16–2. TIMI Risk Score for Non-ST-Segment-Elevation Acute Coronary Syndromes

| Past Medical History | Clinical Presentation | |
|--|--|----------------------------|
| Age ≥65 years ≥3 Risk factors for CAD Hypercholesterolemia HTN DM Smoking Family history of premature CHD ^a Known CAD (≥50% stenosis of coronary artery) Use of aspirin within the past 7 days | ST-segment depression (≥0.5 mm) ≥2 Episodes of chest discomfort within the past 24 hours Positive biochemical marker for infarction ^b | |
| Using the TIMI Risk Score | | |
| One point is assigned for each of the seven medical history and clinical presentation findings. The score (point) total is calculated, and the patient is assigned a risk for experiencing the composite end point of death, myocardial infarction, or urgent need for revascularization as follows: | | |
| High Risk | Medium Risk | Low Risk |
| TIMI risk score 5–7 points Other Ways to Identify High-Risk Patients Other findings that alone or in combination may identify a high-risk patient: <ul style="list-style-type: none"> • ST-segment depression • Positive biochemical marker for infarction • Deep symmetric T-wave inversions (≥2 mm) • Acute heart failure • DM • Chronic kidney disease • Refractory chest discomfort despite maximal pharmacotherapy for ACS • Recent MI within the past 2 weeks | TIMI risk score 3–4 points | TIMI risk score 0–2 points |

ACS = acute coronary syndrome; CAD = coronary artery disease; CHD = coronary heart disease; DM = diabetes mellitus; HTN = hypertension; MI = myocardial infarction; TIMI = Thrombolysis in Myocardial Infarction.

^aAs defined in Chapter 21.

^bA positive biochemical marker for infarction is a value of troponin I, troponin T, or creatine kinase MB of greater than the MI detection limit.

undergo angiography and revascularization during hospital admission. Moderate-risk patients with negative biochemical markers for infarction also may undergo angiography and revascularization or first undergo a noninvasive stress test, with only patients with a positive stress test proceeding to angiography.

Following risk stratification, pharmacotherapy for non-ST-segment-elevation ACS is initiated. Urgent (within 24 hours) coronary angiography and revascularization of the infarct-related coronary artery with PCI or CABG surgery is considered for moderate- and high-risk patients² (see Fig. 16–1 and Table 16–2).

■ NONPHARMACOLOGIC THERAPY

■ PRIMARY PERCUTANEOUS CORONARY INTERVENTION (PCI) FOR ST-SEGMENT-ELEVATION ACS

6 Either fibrinolysis or immediate primary PCI is the treatment of choice for reestablishing coronary artery blood flow for patients with ST-segment-elevation ACS when the patient presents within 3 hours of symptom onset and both options are available at the institution. For primary PCI, the patient is taken from the emergency department to the cardiac catheterization laboratory and undergoes coronary angiography with either balloon angioplasty or placement of a bare metal or drug-eluting intracoronary stent. Additional details regarding angioplasty and intracoronary stenting are provided in Chap. 15. Results from a recent meta-analysis of trials comparing fibrinolysis with primary PCI indicate a lower mortality rate with primary PCI.²⁰ One reason for the superiority of primary PCI compared with fibrinolysis is that more than 90% of occluded infarct-related coronary arteries are opened with primary PCI compared with less than 60% of coronary arteries with currently available fibrinolytics.²¹ In addition, the intracranial hemorrhage and major bleeding risks from primary PCI are lower than following fibrinolysis. An invasive strategy of primary PCI is generally preferred in patients presenting to institutions with skilled interventional cardiologists and a catheterization laboratory immediately available, in patients with cardiogenic shock, in patients with contraindications to fibrinolytics and in patients presenting with symptom onset greater than 3 hours.³ A quality indicator in the care of MI patients with ST-segment elevation is the time from hospital presentation to the time that the occluded artery is opened with PCI. This “door-to-primary PCI time” should be ≤ 90 minutes^{3,22} (Table 16–3). Unfortunately, most hospitals do not have interventional cardiology services capable of performing primary PCI 24 hours a day. Therefore, only 7% of MI patients are currently treated with primary PCI.

PCI during hospitalization for STEMI also may be appropriate in other patients following STEMI, such as those in whom fibrinolysis is not successful, those presenting later in cardiogenic shock patients with life-threatening ventricular arrhythmias, and those with persistent rest ischemia or signs of ischemia on stress testing following MI.^{3,21} The strategy of routine angiography and revascularization in all ST-segment-elevation patients later (after hospital day 1) during hospitalization is controversial.

■ PERCUTANEOUS CORONARY INTERVENTION IN NON-ST-SEGMENT-ELEVATION ACS

8 The most recent non-ST-segment-elevation ACC/AHA clinical practice guidelines recommend early coronary angiography with either PCI or CABG revascularization as an early treatment for

TABLE 16–3. Quality Patient Care Indicators for Acute Myocardial Infarction

| |
|---|
| ST-Segment-Elevation Myocardial Infarction |
| Eligible patients receiving any type of reperfusion therapy |
| Primary percutaneous coronary intervention within 90 minutes of hospital presentation |
| Initiation of fibrinolysis within 30 minutes of hospital presentation |
| ST-Segment-Elevation or Non-ST-Segment-Elevation Myocardial Infarction |
| Within the first 24 hours |
| Administration of aspirin |
| Administration of β -blocker |
| At or before hospital discharge |
| Smoking-cessation counseling |
| Lipid panel measurement |
| Aspirin prescription |
| β -Blocker prescription |
| Angiotensin-converting enzyme inhibitor prescription (if ejection fraction $<40\%$) |

Note: Increasing compliance (approaching 100% of patients) with each factor indicates excellence in patient care. Achievement of indicators is reported to U.S. governmental agencies (e.g., Centers for Medicare and Medicaid Services, Veterans Affairs Health System), managed-care organizations (e.g., National Committee for Quality Assurance), and hospital accrediting bodies (e.g., Joint Commission on the Accreditations of Healthcare Organizations).

From refs. 2 and 37.

high- and moderate-risk non-ST-segment-elevation ACS patients.² Several recent clinical trials support an “early invasive strategy” with PCI or CABG versus a “medical stabilization management strategy” whereby coronary angiography with revascularization is reserved for patients with symptoms refractory to pharmacotherapy and patients with signs of ischemia on stress testing.²³ An early invasive approach results in fewer MIs, and less need for additional revascularization procedures over the next year following hospitalization, and is less costly than the conservative medical stabilization approach.²³

■ ADDITIONAL TESTING AND RISK STRATIFICATION

At some point during hospitalization but prior to discharge, patients with MI should have their LV function evaluated for risk stratification.^{2,3} The most common way LV function is measured is using an echocardiogram to calculate the patient’s LV ejection fraction (EF). LV function is the single best predictor of mortality following MI. Patients with LVEFs of less than 40% are at highest risk of death. Patients with ventricular fibrillation or sustained ventricular tachycardia more than 2 days following MI and those with LVEFs $<30\%$ measured at least 1 month following STEMI and 3 months after coronary artery revascularization with either PCI or CABG benefit from placement of an implantable cardioverter-defibrillator (ICD).³ The Multicenter Automatic Defibrillator Implantation II trial (MADIT) demonstrated a 29% reduction in mortality in patients with a history of MI, low LVEFs, and no history of symptomatic ventricular arrhythmias who received prophylactic implantation of an ICD.²⁴ Additional discussion of the role of ICDs in the management of high-risk patients and those with ventricular arrhythmias may be found in Chap. 17.

Predischarge stress testing (see Fig. 16–1) may be indicated in moderate- or low-risk patients in order to determine which patients would benefit from coronary angiography to establish the diagnosis of CAD and also in patients following MI to predict intermediate and long-term risk of recurrent MI and death.²⁵ In most cases, patients

with a positive stress test indicating coronary ischemia will then undergo coronary angiography and subsequent revascularization of significantly occluded coronary arteries. Exercise stress testing, most often with the addition of a radionuclide imaging agent, is preferred over nonpharmacologic stress testing because it evaluates the workload achieved with exercise, as well as the occurrence of ischemia. If a patient has a negative exercise stress test for ischemia, the patient is at low risk for subsequent CHD events. Therefore, exercise stress testing has high negative predictive value. Additional discussion of the types of stress testing may be found in Chap. 11.

Patients admitted for ACS should have a fasting lipid panel drawn within the first 24 hours of hospitalization because following that period, values for cholesterol, an acute-phase reactant may be falsely low. Initiation of pharmacotherapy with a statin is common for all ACS patients and does not depend on the results of this lipid panel, however.

EARLY PHARMACOLOGIC THERAPY FOR ST-SEGMENT-ELEVATION ACS

Pharmacotherapy for early treatment of ACS is outlined in Fig. 16–3. According to the ACC/AHA ST-segment-elevation ACS practice

guidelines, early pharmacotherapy of ST-segment elevation should include intranasal oxygen (if oxygen saturation is <90%), sublingual (SL) followed by intravenous (IV) nitroglycerin (NTG), aspirin, an IV β -blocker, unfractionated heparin (UFH), and fibrinolysis in eligible candidates. Morphine is administered to patients with refractory angina as an analgesic and a venodilator that lowers preload. These agents should be administered early, while the patient is still in the emergency department. Dosing and contraindications for SL and IV NTG, aspirin, IV β -blockers, UFH, and fibrinolytics are listed in Table 16–4.^{2,3,26}

FIBRINOLYTIC THERAPY

Administration of a fibrinolytic agent is indicated in patients with ST-segment-elevation ACS presenting to hospital within 24 hours of the onset of chest discomfort who have at least 1 mm of ST-segment elevation in two or more contiguous ECG leads.³ The mortality benefit of fibrinolysis is highest with early administration and diminishes after 12 hours. Fibrinolytic therapy is preferred over primary PCI in patients presenting within 3 hours of symptom onset where there is a delay to primary PCI because of a delay in access to a cardiac catheterization laboratory or a delay in obtaining patient vascular access which would result in a “door-to-primary PCI” delay that would be greater

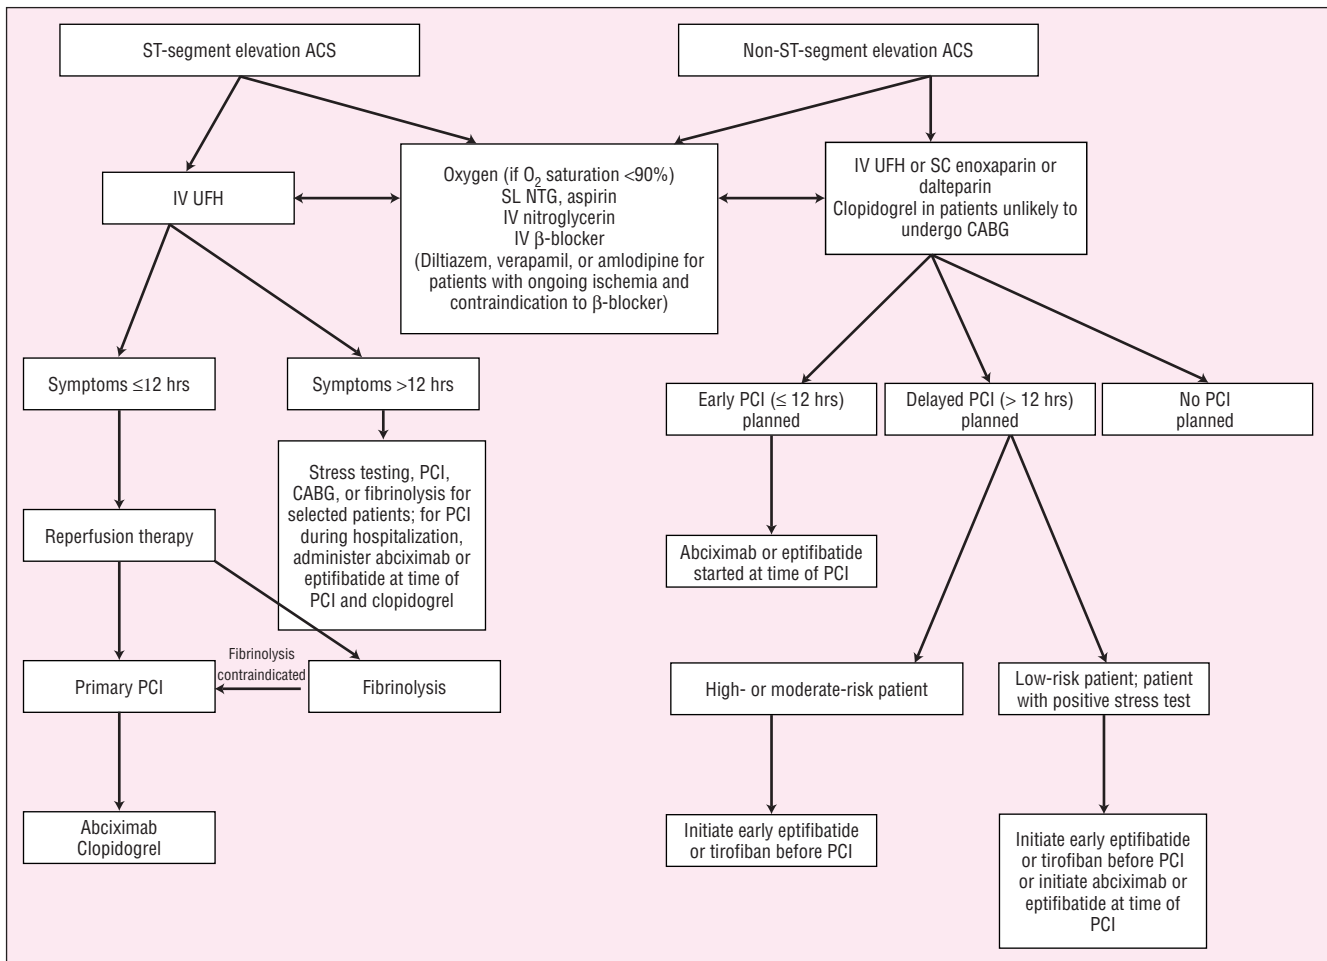

FIGURE 16–3. Initial pharmacotherapy for acute coronary syndromes (ACS). CABG = coronary artery bypass graft; IV = intravenous; PCI = percutaneous coronary intervention; SC = subcutaneous; SL = sublingual; UFH = unfractionated heparin.

TABLE 16–4. Pharmacotherapy for Acute Coronary Syndrome (ST-Segment-Elevation and Non-ST-Segment-Elevation)

| Drug | Clinical Condition and ACC/AHA Guideline Recommendation | Contraindications ^a | Dose |
|------------------------------|---|---|---|
| Aspirin | STE ACS, class I recommendation ^b for all patients NSTE ACS, class I recommendation for all patients | Hypersensitivity Active bleeding Severe bleeding risk | 160–162 mg on hospital day 1 75–162 mg daily starting hospital day 2 and continued indefinitely |
| Clopidogrel | STE ACS, class I recommendation in patients allergic to aspirin NSTE ACS, class I recommendation for all hospitalized patients in whom a noninterventional approach is planned In PCI in STE and NSTE ACS, class I recommendation | Hypersensitivity Active bleeding Severe bleeding risk | 300–600 mg loading dose on hospital day 1 followed by a maintenance dose of 75 mg PO qd starting on hospital day 2 Administer indefinitely in patients with an aspirin allergy (class I recommendation) Administer for at least 9 months in medically managed patients with NSTE ACS (class I recommendation) Administer for at least 30 days to 1 year in patients with STE or NSTE ACS (class I recommendation) undergoing PCI If possible, withhold for at least 5 days in patients whom CABG is planned to decrease bleeding risk (class I recommendation) |
| Unfractionated heparin (UFH) | STE ACS, class I recommendation in patients undergoing PCI and for patients treated with alteplase, reteplase, or tenecteplase, class IIa recommendation for patients not treated with fibrinolytic therapy NSTE ACS, class I recommendation in combination with aspirin PCI, class I recommendation | Active bleeding History of heparin-induced thrombocytopenia Severe bleeding risk Recent stroke | For STE ACS administer 60 units/kg IV bolus (maximum 4000 μ) followed by a constant IV infusion at 12 units/kg/h (maximum 1000 units/h) For NSTE ACS administer 60–70 units/kg IV (maximum 5000 μ) bolus followed by a constant IV infusion of 12–15 units/kg/h (maximum 1000 μ /hr) Titrated to maintain aPTT between 1.5 to 2.5 times control for NSTE ACS and 50 to 70 s in STE ACS The first aPTT should be measured at 4 to 6 h for NSTE ACS and STE ACS in patients not treated with thrombolytics The first aPTT should be measured at 3 h in patients with STE ACS who are treated with thrombolytics |
| Low-molecular-weight heparin | STE ACS, class IIb recommendation for patients <75 yrs old treated with fibrinolytics, class IIa for patients not undergoing reperfusion therapy NSTE ACS, class I recommendation in combination with aspirin, class IIa recommendation over UFH in patients without renal failure who are not anticipated to undergo coronary artery bypass graft surgery within 24 h | Active bleeding History of heparin-induced thrombocytopenia Severe bleeding risk Recent stroke Cr _{CL} <10 mL/min (enoxaparin) Cr _{CL} <30 mL/min (dalteparin) | Enoxaparin 1 mg/kg SC q12h (Cr _{CL} \geq 30 mL/min) Enoxaparin 1 mg/kg SC q24h (Cr _{CL} 10–29 mL/min) Dalteparin 120 IU/kg SC q12h (maximum single bolus dose of 10,000 units) |
| Fibrinolytics | STE ACS, class I recommendation in patients age <75 yrs presenting within 12 h following the onset of symptoms, class IIa recommendation in patients age 75 yrs and older, class IIa in patients presenting between 12 and 24 h following the onset of symptoms with continuing signs of ischemia. NSTE ACS: class III recommendation | Absolute and relative contraindications as per Table 16-5 | Streptokinase: 1.5 million units IV over 60 min Alteplase: 15 mg IV bolus followed by 0.75 mg/kg IV over 30 min (max 50 mg) followed by 0.5 mg/kg (max 35 mg) over 60 min (max dose = 100 mg) Reteplase: 10 units IV \times 2, 30 min apart Tenecteplase <60 kg = 30 mg IV bolus 60–69.9 kg = 35 mg IV bolus 70–79.9 kg = 40 mg IV bolus 80–89.9 kg = 45 mg IV bolus \geq 90 kg = 50 mg IV bolus |

| | | | Eplerenone | 25 | 50 once daily |
| | | | Spironolactone | 12.5 | 25–50 once daily |
| Morphine sulfate | STE and NSTE ACS, class I recommendation for patients whose symptoms are not relieved after three serial sublingual nitroglycerin tablets or whose symptoms recur with adequate anti-ischemic therapy | Hypotension Respiratory depression Confusion Obtundation | | 2–5 mg IV dose May be repeated every 5 to 30 min as needed to relieve symptoms and maintain patient comfort | |

^aAllergy or prior intolerance contraindication for all categories of drugs listed in this chart.

^bClass I recommendations are conditions for which there is evidence and/or general agreement that a given procedure or treatment is useful and effective.

Class II recommendations are those conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of a procedure or treatment. For Class IIa recommendations, the weight of the evidence/opinion is in favor of usefulness/efficacy. Class IIb recommendations are those for which usefulness/efficacy is less well established by evidence/opinion.

^cChoice of the specific agent is not as important as ensuring that appropriate candidates receive this therapy. If there are concerns about patient intolerance due to existing pulmonary disease, especially asthma, selection should favor a short-acting agent, such as propranolol or metoprolol or the ultra short-acting agent, esmolol. Mild wheezing or a history of chronic obstructive pulmonary disease should prompt a trial of a short-acting agent at a reduced dose (e.g., 2.5 mg intravenous metoprolol, 12.5 mg oral metoprolol, or 25 mcg/kg/min esmolol as initial doses) rather than complete avoidance of beta-blocker therapy.

ACC = American College of Cardiology; ACE = angiotensin-converting enzyme inhibitor; AHA = American Heart Association; AMI = acute myocardial infarction; CAD = coronary artery disease; EF = ejection fraction; IV = intravenous; Cr_{CL} = creatinine clearance; SC = subcutaneous.

TABLE 16–5. Indications and Contraindications to Fibrinolytic Therapy: ACC/AHA Guidelines for Management of Patients with ST-Segment-Elevation Myocardial Infarction

| |
|--|
| Indications |
| Ischemic chest discomfort at least 20 minutes in duration but 12 hours or less since symptom onset |
| ST-segment elevation of at least 1 mm in height in two or more contiguous leads |
| New or presumed new left bundle branch block |
| Absolute Contraindications |
| Active internal bleeding (not including menses) |
| Previous intracranial hemorrhage at any time; ischemic stroke within 3 months |
| Known intracranial neoplasm |
| Known structural vascular lesion (example arteriovenous malformation) |
| Suspected aortic dissection |
| Significant closed head or facial trauma within 3 months |
| Relative Contraindications |
| Severe, uncontrolled hypertension on presentation (blood pressure >180/110 mm Hg) |
| History of prior ischemic stroke >3 months, dementia, or known intracranial pathology not covered above under absolute contraindications |
| Current use of anticoagulants |
| Known bleeding diathesis |
| Traumatic or prolonged (>10 min) CPR or major surgery (<3 weeks) |
| Noncompressible vascular puncture (such as a recent liver biopsy or carotid artery puncture) |
| Recent (within 2–4 weeks) internal bleeding |
| For prior streptokinase administration, prior administration (5 days–2 years), or prior allergic reactions |
| Pregnancy |
| Active peptic ulcer |
| History of severe, chronic poorly controlled hypertension |

INR = international normalized ratio; CPR = cardiopulmonary resuscitation. From ref.³

than 90 minutes.³ Other indications and contraindications for fibrinolysis are listed in Table 16–5.³ It is not necessary to obtain the results of biochemical markers before initiating fibrinolytic therapy. Because administration of fibrinolytics results in clot lysis, patients at high risk for major bleeding, including intracranial hemorrhage, have either relative or absolute contraindications. Patients presenting with an absolute contraindication likely will not receive fibrinolytic therapy, and primary PCI is preferred. Patients with a relative contraindication may receive fibrinolytic therapy if the perceived risk of death from the MI is higher than the risk of major hemorrhage. For every 1000 patients with anterior wall MI, treatment with fibrinolysis saves 37 lives compared with placebo. For patients with inferior wall MI, who generally have smaller MIs and are at lower risk of death, treatment with fibrinolysis saves 8 lives per 1000 patients treated.¹⁴

Fibrinolytic therapy is controversial in patients older than 75 years of age. More than 60% of all MI deaths occur in this group. Benefit, in terms of absolute mortality reduction compared with placebo, varies from approximately 1% to 9%, with some observational studies suggesting higher mortality in the very elderly treated with fibrinolysis compared with no fibrinolysis. Stroke rates also grow in number with increasing patient age. While the intracranial hemorrhage rate is approximately 1% in younger patients, it is 2% in older patients. There is no excess risk of stroke in patients younger than 55 years of age, of whereas patients older than 75 years of age experience an excess of 8 strokes per 1000 patients treated.¹⁴ However, the ACC/AHA practice guidelines recommend the use of fibrinolytics for this age group, provided that the patient has no contraindications.³ A 1% absolute mortality benefit is felt to be clinically significant, and the benefit in terms of lives saved per 1000 patients treated has been reported to range from 10 to 80 in patients older than age of 75 years.¹⁴ Because older patients may have cognitive impairment, careful history taking and assessment weighing the bleeding risk versus the benefit must be performed prior to administration of fibrinolysis.

The comparative pharmacology of commonly prescribed fibrinolytics is described in Table 16–6.²⁶ According to the ACC/AHA

TABLE 16–6. Comparison of Fibrinolytic Agents

| Agent | Fibrin Specificity | TIMI-3 Blood Flow, Complete Perfusion at 90 min | Systemic Bleeding Risk/ICH Risk | Administration | Approximate Cost per Patient (MI Dosing) | Other Approved Uses |
|------------------------|--------------------|---|---------------------------------|--|--|---|
| Streptokinase | + | 35% | +++/+ | Infusion over 60 min | \$400 | Pulmonary embolism, deep vein thrombosis, arterial thromboembolism, clearance of an occluded arteriovenous catheter |
| Alteplase (rt-PA) | +++ | 50%–60% | ++/++ | Bolus followed by infusions over 90 min, weight-based dosing | \$2400 | Pulmonary embolism, stroke, clearance of an occluded arteriovenous catheter |
| Reteplase (rPA) | ++ | 50%–60% | ++/++ | 2 bolus doses, 30 min apart | \$2400 | |
| Tenecteplase (TNK-tPA) | ++++ | 50%–60% | + / ++ | Single bolus dose, weight-based dosing | \$2400 | |

ICH = intracranial hemorrhage; MI = myocardial infarction; TIMI = Thrombolysis in Myocardial Blood Flow (TIMI-3 blood flow indicates complete perfusion of the infarct artery)

Adapted from ref. 26 with permission.

ST-segment-elevation ACS practice guideline, a more fibrin-specific agent, such as alteplase, reteplase, or tenecteplase, is preferred over a non-fibrin-specific agent, such as streptokinase.³ Fibrin-specific fibrinolytics open a greater percentage of infarct arteries when measured in patients undergoing emergent angiography. Because an early open artery results in smaller infarcts, administration of fibrin-specific agents should result in lower mortality. This concept has been termed the *open-artery hypothesis*. In a large clinical trial, administration of alteplase reduced mortality by 1% (absolute reduction) and costs about \$30,000 per year of life saved compared with streptokinase.²⁷ Two other trials compared alteplase with reteplase and alteplase with tenecteplase and found similar mortality between agents.^{28,29} Therefore, either alteplase, reteplase, or tenecteplase is acceptable as a first-line agent. Most hospitals have at least two agents on their formulary. Most often, formulary decisions are based on frequency of use of fibrinolytics for other approved indications, with alteplase having the most indications of the fibrin-specific agents. Administration considerations also guide formulary decision making and choice for patient treatment with tenecteplase given as a single, weight-based dose and reteplase given as two fixed doses without weight adjustment. Therefore, both tenecteplase and reteplase are easier to administer than alteplase.

Intracranial hemorrhage and major bleeding are the most serious side effects of fibrinolytic agents (see Table 16–6). The risk of intracranial hemorrhage is higher with fibrin-specific agents than with streptokinase. Models are available for use in clinical practice to predict an individual patient's risk of intracranial hemorrhage following administration of a fibrinolytic.³ The risk of systemic bleeding other than intracranial hemorrhage is higher with streptokinase than with other, more fibrin-specific agents.²⁷

Only 20% to 40% of patients presenting with ST-segment-elevation ACS receive fibrinolysis compared with 7% receiving primary PCI.^{30,31} Therefore, many patients do not receive early reperfusion therapy. The primary reason for lack of reperfusion therapy is that most patients present more than 12 hours after the time of symptom onset.³¹ Of those presenting within the first 12 hours, the main reason that patients fail to receive fibrinolysis is the contraindication of prior stroke.³⁰ The percentage of eligible patients who receive reperfusion therapy is a quality indicator of care in patients with MI²⁷ (see Table 16–3). The “door-to-needle time,” the time from presentation to start of fibrinolytic therapy, is another quality indicator²⁷ (see Table 16–3). While the ACC/AHA guidelines recommend a door-to-needle time of less than 30 minutes, the average in the United States currently is approximately 37 minutes.³¹ Therefore, health care professionals can work to shorten administration times.

■ ASPIRIN

Based on several randomized trials, aspirin has become the preferred antiplatelet agent in the treatment of all ACSs.^{2,3} Early aspirin administration to all patients without contraindications within the first 24 hours of hospital admission is a quality care indicator²⁷ (see Table 16–3). The antiplatelet effects of aspirin are mediated by inhibiting the synthesis of thromboxane A₂ through an irreversible inhibition of platelet cyclooxygenase-1.³² Following the administration of a non-enteric-coated formulation, aspirin rapidly (<10 minutes) inhibits thromboxane A₂ production in the platelets. Aspirin also has anti-inflammatory actions, which decrease C-reactive protein and also may contribute to its effectiveness in ACS.³² In patients undergoing PCI, aspirin prevents acute thrombotic occlusion during the procedure.

The Second International Study of Infarct Survival (ISIS-2), which studied the impact of streptokinase and aspirin (162.5 mg/day) either alone or in combination, is a landmark clinical trial that convincingly demonstrated the value of aspirin in patients with ST-segment-elevation ACS.³³ In this trial ($n = 17,187$), patients receiving aspirin demonstrated a lower risk of 35-day vascular mortality compared with placebo (9.4% versus 11.8%; $p < .0001$). The use of aspirin was not associated with any increase in major bleeding, although the incidence of minor bleeding was increased. Furthermore, the combination of aspirin plus streptokinase reduced mortality compared with placebo, as well as compared with either agent alone, thereby highlighting the additive effects of combination antithrombotic therapy. Because of its important role in the treatment of the MI patient, aspirin administration within the first 24 hours of hospital admission in patients without contraindications is a quality indicator of care²⁷ (see Table 16–3).

In patients experiencing an ACS, an initial dose equal to greater than 160 mg nonenteric aspirin is necessary to achieve a rapid platelet inhibition^{32,33} (see Table 16–4). This first dose can be chewed in order to achieve high blood concentrations and platelet inhibition rapidly.^{2,3} The notion of chewing aspirin came from the use of an enteric-coated formulation of aspirin in the ISIS-2 trial in order to break the enteric coating to ensure more rapid effect.³³ Current data suggest that although an initial dose 160 to 325 mg is required, long-term therapy with doses of 75 to 150 mg daily are as effective as higher doses and that doses of less than 325 mg daily are associated with a lower rate of bleeding.^{34,35} The major bleeding rate associated with chronic aspirin administration in doses of less than 100 mg/day is 1.1%, whereas the frequency with doses of more than 100 mg/day is 1.7%.³⁵ Therefore, a daily maintenance dose of 75 to 160 mg is recommended in order to inhibit the 10% of the total platelet pool that is regenerated daily.²

Although the risk of major bleeding, particularly gastrointestinal bleeding, appears to be reduced by using low-dose aspirin,³² low-dose aspirin, taken chronically, is not free of adverse effects. Patients should be counseled on the potential risk of bleeding.^{34,36} In order to minimize the risk of bleeding, the use of aspirin with other agents that can induce bleeding, including clopidogrel and warfarin, should be avoided, unless the combination is clinically indicated and the increased risk of bleeding has been considered in evaluating the potential benefit of using such a combination. Other gastrointestinal disturbances, including dyspepsia and nausea, are infrequent when low-dose aspirin is used.³² The ACC/AHA STE ACS guidelines specifically recommend that ibuprofen not be administered on a regular basis for pain relief concurrently with aspirin due to a reported drug interaction with aspirin whereby ibuprofen blocks aspirin's antiplatelet effects.³ Finally, although some concern has been voiced regarding the possible increased risk of hemorrhagic stroke in patients taking aspirin,³⁷ this risk appears to be very small and is outweighed by the benefit in reducing the risk of ischemic stroke and other vascular events.³⁸ The risk of hemorrhagic stroke appears to be minimal in patients with adequate blood pressure control.¹⁴ Aspirin therapy should be continued indefinitely.

■ THIENOPYRIDINES

Clopidogrel is recommended to be administered to patients with ST-segment-elevation ACS if they have an aspirin allergy³ (see Table 16–4). Although aspirin is effective in the setting of ACS, it is a relatively weak platelet inhibitor that blocks platelet aggregation through only one pathway. The thienopyridines clopidogrel and ticlopidine are antiplatelet agents that mediate their antiplatelet effects

through a blockade of ADP receptors on platelets.³⁹ Because ticlopidine is associated with the occurrence of neutropenia that requires frequent monitoring of the complete blood count (CBC) during the first 3 months of use,⁴⁰ clopidogrel is the preferred thienopyridine for ACS and PCI patients.

Although clopidogrel and ticlopidine have not been studied as monotherapy for ST-segment-elevation ACS, their use as an alternative, second-line agent for patients who are allergic to aspirin seems reasonable. Their efficacy as single antiplatelet agents used without aspirin has been demonstrated in various settings, including UA,⁴¹ and in secondary prevention of vascular events in patients with a recent MI, stroke, or symptomatic peripheral vascular disease.⁴² Studies evaluating the combination of clopidogrel with aspirin in patients with ST-segment-elevation ACS are ongoing.

At this point, the combination of clopidogrel and aspirin should be reserved for non-ST-segment-elevation patients and those patients undergoing PCI.^{2,21} A more detailed discussion of clopidogrel administration in patients undergoing PCI may be found in Chap. 15. For PCI, clopidogrel is administered as a 300- to 600-mg loading dose followed by a 75 mg/day maintenance dose, in combination with aspirin, to prevent subacute stent thrombosis and long-term events such as the composite end point of death, MI, or need to undergo repeat PCI.^{2,21} The most frequent side effects of clopidogrel are nausea, vomiting, and diarrhea, which occur in approximately 5% of patients. Rarely, thrombotic thrombocytopenic purpura has been reported with clopidogrel.⁴⁰ The most serious side effect of clopidogrel is bleeding, which will be discussed in more detail in the section “Pharmacotherapy for Non-ST-Segment-Elevation ACS.”

■ GLYCOPROTEIN IIB/IIIA RECEPTOR INHIBITORS

Abciximab is a first-line GP IIB/IIIA receptor inhibitor for patients undergoing primary PCI^{3,21,43} who have not received fibrinolytics. It should not be administered for medical management of the ST-segment-elevation ACS patient who will not be undergoing PCI. Abciximab is preferred over eptifibatid and tirofiban in this setting because abciximab is the most common GP IIB/IIIA receptor inhibitor studied in primary PCI trials.^{3,21,43} Abciximab, in combination with aspirin, a thienopyridine, and UFH (administered as an infusion for the duration of the procedure), has been shown to reduce the risk of reinfarction^{44,45} and need for repeat PCI⁴³ in ST-segment-elevation ACS clinical trials.

Dosing and contraindications for abciximab are described in Table 16–4. GP IIB/IIIA receptor inhibitors block the final common pathway of platelet aggregation, namely, cross-linking of platelets by fibrinogen bridges between the GP IIB and IIIa receptors on the platelet surface. Abciximab typically is initiated at the time of PCI, and the infusion is continued for 12 hours. Administration of a GP IIB/IIIA receptor inhibitor increases the risk of bleeding, especially if it is given in the setting of recent (<4 hours) administration of fibrinolytic therapy.^{43–45} An immune-mediated thrombocytopenia occurs in approximately 5% of patients.⁴⁶

Some trials suggest that early administration of abciximab results in early opening of the coronary artery, making primary PCI easier for the interventional cardiologist. Clinical trials performed to date suggest that the combination of early administration of a reduced dose of a fibrinolytic agent in combination with abciximab does not reduce mortality and increases the risk of bleeding, including intracranial hemorrhage, in elderly patients with ST-segment-elevation ACS.^{44,45} Additional clinical trials of combined antithrombotic therapy for ST-segment-elevation PCI patients are ongoing.

■ ANTICOAGULANTS

UFH, administered as a continuous infusion, is a first-line anticoagulant for the treatment of patients with ST-segment-elevation ACS, both for medical therapy and for patients undergoing PCI.^{3,21} UFH binds to antithrombin and then to clotting factors Xa and IIa (thrombin). Anticoagulant therapy should be initiated in the emergency department and continued for 24 hours or longer in patients who will be bridged over to receive chronic warfarin anticoagulation following acute MI.³ In the United States, UFH typically is continued until the patient has undergone PCI during the hospitalization for ST-segment-elevation ACS. UFH dosing is described in Table 16–4. The dose of the UFH infusion is adjusted frequently to a target activated partial thromboplastin time (aPTT) (see Table 16–4). When coadministered with a fibrinolytic, aPTTs above the target range are associated with an increased rate of bleeding, whereas aPTTs below the target range are associated with increased mortality and reinfarction.⁴⁷ UFH is discontinued immediately after the PCI procedure.

A meta-analysis of small randomized studies from the 1970s and 1980s suggests that UFH reduces mortality by approximately 17%.³ Other beneficial effects of anticoagulation are prevention of cardioembolic stroke, as well as venous thromboembolism, in MI patients.³ If a fibrinolytic agent is administered, UFH is given concomitantly with alteplase, reteplase, and tenecteplase, but UFH is not administered to patients receiving the non-fibrin-selective agent streptokinase because no benefit of combined therapy can be demonstrated.⁴⁸ Rates of reinfarction are higher if UFH is not given in combination with the fibrin-selective agents.⁴⁸

Besides bleeding, the most frequent adverse effect of UFH is an immune-mediated clotting disorder, heparin-induced thrombocytopenia, which occurs in up to 5% of patients treated with UFH. Heparin-induced thrombocytopenia is less common in patients receiving low-molecular-weight heparins (LMWHs).⁴⁹

LMWHs have not been studied in the setting of primary PCI. LMWHs, like UFH, bind to antithrombin and inhibit both factor Xa and IIa. However, because their composition is mostly short saccharide chain lengths, they preferentially inhibit factor Xa over factor IIa, which requires larger chain lengths for binding and inhibition. Limited data, primarily with enoxaparin, suggest that LMWHs may be an alternative to UFH. Pooled data from smaller ST-segment-elevation ACS trials suggest that enoxaparin is associated with similar safety and reduced reinfarction when coadministered with fibrinolytics (and aspirin).⁵⁰ A larger trial evaluating enoxaparin versus UFH in combination with fibrinolytics for ST-segment-elevation ACS is ongoing.

■ NITRATES

One SL nitroglycerin (NTG) tablet should be administered every 5 minutes for up to three doses to relieve myocardial ischemia. If patients have previously been prescribed sublingual NTG and ischemic chest discomfort persists for more than 5 minutes after the first dose, the patient should be instructed to contact emergency medical services before self-administering subsequent doses in order to activate emergency care sooner. IV NTG then should be initiated in all patients with an ACS who do not have a contraindication and who have persistent ischemic symptoms, heart failure, or uncontrolled blood pressure, and should be continued for approximately 24 hours after ischemia is relieved³ (see Table 16–4). Importantly, other life-saving therapy, such as ACE inhibitors or β -blockers, should not be withheld because the mortality benefit of nitrates is unproven. Nitrates promote the release of nitric oxide from the endothelium, which results in venous

and arterial vasodilation. Venodilation lowers preload and myocardial oxygen demand. Arterial vasodilation may lower blood pressure, thus reducing myocardial oxygen demand. Arterial vasodilation also relieves coronary artery vasospasm, dilating coronary arteries to improve myocardial blood flow and oxygenation. Nitrates play a limited role in the treatment of ACS patients because two large, randomized clinical trials failed to show a mortality benefit for IV followed by oral nitrate therapy in acute MI.^{51,52} The most significant adverse effects of nitrates are tachycardia, flushing, headache, and hypotension. Nitrate administration is contraindicated in patients who have received oral phosphodiesterase-5 inhibitors, such as sildenafil and vardenafil within the past 24 hours and tadalafil within the past 48 hours.

■ β -BLOCKERS

IV bolus doses or oral doses of a β -blocker should be administered early in the care of patients with ST-segment-elevation ACS and then an oral β -blocker continued indefinitely. Early administration of a β -blocker within the first 24 hours of hospitalization in patients lacking a contraindication is a quality care indicator²⁷ (see Table 16–3). In ACS, the benefit of β -blockers results mainly from the competitive blockade of β_1 -adrenergic receptors located on the myocardium. β_1 -Blockade produces a reduction in heart rate, myocardial contractility, and blood pressure, decreasing myocardial oxygen demand. In addition, the reduction in heart rate increases diastolic time, thus improving ventricular filling and coronary artery perfusion.⁵³ As a result of these effects, β -blockers reduce the risk for recurrent ischemic, infarct size, risk of reinfarction, and occurrence of ventricular arrhythmias in the hours and days following MI.⁵³

Landmark clinical trials have established the role of early β -blocker therapy in reducing MI mortality. Most of these trials were performed in the 1970s and 1980s before routine use of early reperfusion therapy. In the First International Study of Infarct Survival (ISIS-1), 16,027 patients with a suspected MI were randomized to IV atenolol 5 to 10 mg followed by atenolol 100 mg daily for 7 days or to no treatment.⁵⁴ After 7 days, vascular death was reduced by 15% ($p < .04$). The benefit was apparent after 1 day of treatment ($p < .003$), reflecting the ability of β -blockers to prevent early reinfarction and sudden death. In the Metoprolol In Acute Myocardial Infarction (MI-AMI) trial, 5778 patients with a suspected MI were randomized to IV metoprolol followed by oral metoprolol or placebo, and mortality was reduced from 4.9% to 4.3%⁵⁵ ($p = \text{NS}$), and the occurrence of early progression to Q-wave MI also was reduced ($p = .024$).⁵⁶

Data regarding the acute benefit of β -blockers in MI in the reperfusion era is derived mainly from the Thrombolysis in Myocardial Infarction (TIMI) II trial.⁵⁷ In this trial, patients with ST-segment-elevation ACS were randomized to either IV metoprolol to be given as soon as possible following fibrinolytic administration followed by oral metoprolol or oral metoprolol deferred until day 6. Early administration of metoprolol was associated with a significant decrease in recurrent ischemia and early reinfarction. Patients receiving fibrinolytic therapy within 2 hours of symptom onset demonstrated the greatest benefit from early metoprolol administration. Based on the results of these trials, early administration of β -blockers (to patients without contraindications) within the first 24 hours of hospital admission is a standard of quality patient care²⁷ (see Table 16–3).

The most serious side effects of β -blocker administration early in ACS are hypotension, bradycardia, and heart block. While initial acute administration of β -blockers is not appropriate for patients who present with decompensated heart failure, initiation of β -blockers may be attempted before hospital discharge in most patients following

treatment of acute heart failure. It cannot be underemphasized that diabetes mellitus does not constitute a contraindication to β -blockers. Although the use of β -blockers may mask symptoms of hypoglycemia, except sweating, diabetics greatly benefit from β -blocker administration because they are at high risk of recurrent events.⁵³ In patients in whom a major concern exists regarding a possible intolerance to β -blockers, such as patients with chronic obstructive pulmonary disease, a short acting β -blocker, such as metoprolol or esmolol, should be administered intravenously initially.⁵³ β -Blockers are continued indefinitely.

■ CALCIUM CHANNEL BLOCKERS

Administration of calcium channel blockers in the setting of ST-segment-elevation ACS is reserved for patients who have contraindications to β -blockers and is used for relief of ischemic symptoms.³ Patients prescribed calcium channel blockers for treatment of hypertension who are not receiving β -blockers and who do not have a contraindication to β -blockers should have the calcium channel blocker discontinued and a β -blocker initiated. Calcium channel blockers inhibit calcium influx into myocardial and vascular smooth muscle cells, causing vasodilatation. Although all calcium channel blockers produce coronary vasodilatation and decrease blood pressure, other effects are more heterogeneous between agents. Dihydropyridine calcium channel blockers (e.g., amlodipine, felodipine, and nifedipine) primarily produce their anti-ischemic effects through peripheral vasodilatation with no clinical effects on atrioventricular (AV) node conduction and heart rate. Diltiazem and verapamil, on the other hand, have additional anti-ischemic effects by reducing contractility and AV nodal conduction and slowing heart rate.⁵⁸

Current data suggest little benefit on clinical outcomes beyond symptom relief for dihydropyridine calcium channel blockers in the setting of ACS.⁵⁸ Moreover, the use of first-generation short-acting dihydropyridines, such as nifedipine, should be avoided because they appear to worsen outcomes through their negative inotropic effects, induction of reflex sympathetic activation, tachycardia, and increased myocardial ischemia.⁵⁸

Although earlier trials suggested that verapamil and diltiazem may provide improved benefit in selected patients, the large Incomplete Infarction Trial of European Research Collaborators Evaluating Prognosis post-Thrombolysis (INTERCEPT) has dampened the interest for the use of diltiazem in patients receiving fibrinolytics.⁵⁹ In this trial, the use of extended-release diltiazem had no effect on the 6-month risk of cardiac death, MI, or recurrent ischemia. Therefore, the role of verapamil or diltiazem appears to be limited to relief of ischemia-related symptoms or control of heart rate in patients with supraventricular arrhythmias for whom β -blockers are contraindicated or ineffective.^{2,3}

Adverse effects and contraindications of calcium channel blockers are described in Table 16–4. Verapamil, diltiazem, and first-generation dihydropyridines also should be avoided in patients with acute decompensated heart failure or LV dysfunction because they can worsen heart failure and potentially increase mortality secondary to their negative inotropic effects. In patients with heart failure requiring treatment with a calcium channel blocker, amlodipine is the preferred agent.^{60,61}

Two groups of patients may benefit from calcium channel blockers as opposed to β -blockers as initial therapy. Cocaine-induced ACS and variant (or Prinzmetal's) angina are two conditions in which coronary vasospasm plays an important role.^{2,3,58} Calcium channel blockers and/or NTG generally are considered the agents of choice in these

patients because they can reverse the coronary spasm by inducing smooth muscle relaxation in the coronary arteries. In contrast, β -blockers generally should be avoided in these patients unless there is uncontrolled sinus tachycardia (>100 beats per minute) or severe uncontrolled hypertension (systolic blood pressure greater than 150 mm Hg) following cocaine use because β -blockers actually may worsen vasospasm through an unopposed β_2 -blocking effect on the smooth muscle cells.²

EARLY PHARMACOTHERAPY FOR NON-ST-SEGMENT-ELEVATION ACS

In general, early pharmacotherapy for non-ST-segment-elevation ACS (see Fig. 16–3) is similar to that for ST-segment-elevation ACS with four exceptions:

1. Fibrinolytic therapy is not administered.
2. Clopidogrel should be administered, in addition to aspirin, to most patients.
3. GP IIb/IIIa receptor blockers are administered to high-risk patients for medical therapy as well as for PCI patients.
4. There are no standard quality indicators for patients with non-ST-segment-elevation ACS who are not diagnosed with MI.

9 According to the ACC/AHA non-ST-segment-elevation ACS practice guidelines, early pharmacotherapy for non-ST-segment elevation should include intranasal oxygen (if oxygen saturation is $<90\%$), SL followed by IV NTG, aspirin, an IV β -blocker, and UFH or, preferably, LMWH. Morphine is also administered to patients with refractory angina, as described previously. These agents should be administered early, while the patient is still in the emergency department. Dosing and contraindications for SL and IV NTG, aspirin, IV β -blockers, UFH, and LMWHs are listed in Table 16–4.^{2,26}

FIBRINOLYTIC THERAPY

Fibrinolytic therapy is not indicated in any patient with non-ST-segment-elevation ACS, even those who have positive biochemical markers (e.g., troponin) that indicate infarction. Because the risk of death from MI is lower in patients with non-ST-segment-elevation ACS, whereas the risk for life-threatening adverse effects, such as intracranial hemorrhage, with fibrinolytics is similar between patients with ST-segment-elevation and non-ST-segment-elevation ACS, the risks of fibrinolytic therapy outweigh the benefit for non-ST-segment-elevation ACS patients. In fact, increased mortality has been reported with fibrinolytics compared with controls in clinical trials where fibrinolytics have been administered to patients with non-ST-segment-elevation ACS (patients with normal or ST-segment-depression ECGs).¹⁴

ASPIRIN

Aspirin reduces the risk of death or developing MI by about 50% (compared with no antiplatelet therapy) in patients with non-ST-segment-elevation ACS.³⁴ Therefore, aspirin remains the cornerstone of early treatment for all ACSs. Dosing of aspirin for non-ST-segment-elevation ACS is the same as that for ST-segment-elevation ACS (see Table 16–4). Aspirin is continued indefinitely.

THIENOPYRIDINES

For patients with non-ST-segment-elevation ACS, the addition of clopidogrel started on the first day of hospitalization as a 300- to 600-mg loading dose followed the next day by 75 mg/day orally is recommended for most patients.² Although the use of aspirin in ACS is the mainstay of antiplatelet therapy, morbidity and mortality following an ACS remains high. Researchers explored whether or not combining two oral antiplatelet agents with different mechanisms of action, aspirin and clopidogrel, would result in additional clinical benefit over using aspirin alone. Efficacy and safety of this dual antiplatelet therapy were demonstrated in the Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial.⁶² In CURE, 12,562 patients with unstable angina or an NSTEMI randomized to a loading dose of 300 mg clopidogrel followed by a daily dose of 75 mg or placebo in addition to aspirin for a mean duration of 9 months. Clopidogrel reduced the combined risk of death from cardiovascular causes, nonfatal MI, or stroke from 11.4% to 9.4% compared with placebo, mainly through a reduction in the risk of MI. Cardiovascular mortality was similar between groups. Because this study was conducted primarily in Canada and in Europe, patients routinely did not undergo angiographic evaluation, and fewer than 50% of patients eventually underwent PCI. Although a subsequent analysis of non-ST-segment-elevation patients undergoing PCI⁶³ suggested benefit for the prolonged use of clopidogrel in these patients, the applicability of these results was limited by its observational nature and the low use of a GP IIb/IIIa receptor antagonist, considered a standard of PCI care in the United States. In addition, there was no statistical benefit demonstrated for event reductions between 30 days and 1 year. Administration of clopidogrel for at least 30 days in patients undergoing intracoronary stenting is a standard of care.²¹

Results from a second trial in PCI patients, the Clopidogrel for the Reduction of Events During Observation (CREDO) trial,⁶⁴ in which patients treated with long-term clopidogrel (1 year), demonstrated a lower risk of death, MI, or stroke compared with patients receiving only 28 days of clopidogrel (8.5% versus 11.5%; $p = .02$). However, the interpretation of this study is limited in that the control group did not receive a loading dose of clopidogrel on the first day. Whether or not treatment with clopidogrel should be extended to more than 1 year is currently being investigated in a large, randomized trial. Therefore, based on the results of these three clinical trials, clopidogrel is indicated for at least 9 months in non-ST-segment-elevation ACS patients who do not undergo PCI or CABG (medical management) and for at least 30 days in patients receiving bare metal intracoronary stents.

The major concern when combining two antiplatelet agents is the increased risk of bleeding. In CURE, the risk of major bleeding was increased in patients receiving clopidogrel plus aspirin compared with aspirin alone (3.7% versus 2.7%; $p = .001$).⁶² A post-hoc analysis of CURE revealed that the rate of major bleeding depends on the dose of aspirin and showed that doses equal to or less than 100 mg daily reduced the risk of bleeding with similar efficacy when compared with higher doses.⁶⁵ Therefore, using a low dose of aspirin (75–100 mg/day) for maintenance therapy is recommended when aspirin is used in combination with clopidogrel.

In patients undergoing CABG, major bleeding was increased in patients having the procedure within 5 days of clopidogrel discontinuation (9.6% versus 6.3%; $p = .06$) but not in patients for which clopidogrel was discontinued more than 5 days before the procedure.⁶² Aspirin was continued up to and after CABG. Therefore, in patients scheduled for CABG, clopidogrel should be withheld at least 5 days and preferably 7 days before the procedure.²

The timing of initiation of clopidogrel for a patient presenting with non-ST-segment-elevation ACS is controversial. Although it is clear that clopidogrel should be initiated as soon as possible in patients being treated with a noninterventional strategy or in patients who have a contraindication to aspirin, the need to delay CABG for 5 to 7 days following clopidogrel has led many to suggest that clopidogrel administration should be delayed until coronary angiography is performed and the need for CABG is excluded. This is particularly relevant in centers in which the waiting time for CABG is less than 5 days. However, existing data also suggest that early treatment with clopidogrel before angiography is performed reduces the number of cardiovascular events following the procedure.⁶⁴ Therefore, others have advocated the expanded use of early clopidogrel in all patients experiencing a non-ST-segment-elevation ACS.

A pragmatic yet non-evidence-based approach suggests that in centers in which patients can undergo coronary angiography within 24 hours of admission, it is reasonable to wait until after angiography is performed and it has been determined that a CABG will not be performed before clopidogrel is initiated.²

■ GLYCOPROTEIN IIB/IIIa RECEPTOR INHIBITORS

Administration of tirofiban or eptifibatide is recommended for high-risk non-ST-segment-elevation ACS patients as medical therapy without planned revascularization, and administration of either abciximab or eptifibatide is recommended for non-ST-segment-elevation ACS patients undergoing PCI. Administration of tirofiban or eptifibatide is also indicated in patients with continued or recurrent ischemia despite treatment with aspirin and an anticoagulant.² The pharmacologic similarities and differences between GP IIB/IIIa receptor inhibitors are reviewed in Chap. 15. As discussed in Chap. 15, the benefits of GP IIB/IIIa receptor inhibitors in PCI is well established, and they are considered first-line agents to reduce the risk of reinfarction and the need for repeat PCI.²¹

Two large clinical trials highlight their role in the setting of ACS and PCI. In the Platelet Glycoprotein IIB/IIIa in Unstable Angina: Receptor Suppression Using Integrilin Therapy (PURSUIT) trial ($n = 10,948$), eptifibatide added to aspirin and UFH and continued for up to 72 hours reduced the combined end point of death or MI at 30 days (14.2% versus 15.7%) compared with aspirin and UFH alone.⁶⁶ In the Platelet Receptor Inhibition in Ischemic Syndrome Management in Patients Limited by Unstable Signs and Symptoms (PRISM-PLUS) study ($n = 1915$), tirofiban added to aspirin and UFH and continued for up to 72 hours reduced the rate of death, MI, or refractory ischemia at 7 days compared with aspirin and UFH alone.⁶⁷ However, in these and other trials of GP IIB/IIIa inhibitors for non-ST-segment-elevation ACS, the benefit was limited to patients undergoing PCI and not those treated without interventional therapy.⁶⁸ This concept was proven in the Global Use of Strategies to Open Occluded Arteries (GUSTO) IV trial ($n = 7800$), in which medical therapy with abciximab continued for up to 48 hours failed to demonstrate benefit and trended toward worsened outcomes.⁶⁹ Therefore, medical therapy with GP IIB/IIIa receptor inhibitors is reserved for higher-risk patients, such as those with positive troponin or ST-segment depression, and patients who have continued or recurrent ischemia despite other antithrombotic therapy.² Patients undergoing PCI in these trials received several hours to days of pretreatment with the GP IIB/IIIa receptor blocker before proceeding to PCI.

The role of GP IIB/IIIa receptor antagonists in patients with non-ST-segment-elevation ACS undergoing PCI also was evaluated in two large clinical trials that used GP IIB/IIIa receptor blockers initiated at

the time of PCI. In the Enhanced Suppression of the Platelet IIB/IIIa Receptor with Integrilin Therapy Trial (ESPRIT) ($n = 1024$), eptifibatide in combination with aspirin and UFH reduced the rate of death or MI up to 1 year in patients undergoing PCI.⁷⁰ The benefits of treatment in ACS subgroup were more pronounced compared with the stable angina subgroup, thereby establishing a role for eptifibatide in the ACS PCI patient.

Only one trial has compared two GP IIB/IIIa receptor blockers with each other. In the Do Tirofiban and ReoPro Give Similar Efficacy Outcomes Trial (TARGET), tirofiban, at a different dose from that used in the PRISM-PLUS study, was compared with abciximab in patients undergoing PCI.^{71,72} In the subgroup of patients with ACS, there was a statistically significant reduction in the composite end point of death, nonfatal MI, or need for repeat PCI at 30 days in patients randomized to receive abciximab compared with tirofiban (6.3% versus 9.3%).⁷¹ While the numerical benefit of a 3% absolute risk reduction was maintained at 6 months, it approached but was no longer statistically significant (hazard ratio 1.19, abciximab better than tirofiban, 95% confidence interval 0.99–1.42).⁷² Therefore, while there is an early benefit to administering abciximab, perhaps it is not sustained. Following TARGET, the dose of tirofiban that was used in that trial has been shown to be ineffective at inhibiting platelet aggregation during the PCI procedure.⁷³ Therefore, tirofiban cannot be recommended for PCI unless the patient has been treated with tirofiban for several hours to days prior to PCI and adequate inhibition of platelet aggregation can be ensured. If a GP IIB/IIIa receptor blocker is initiated while the patient is undergoing the procedure, abciximab or eptifibatide should be used because the most appropriate tirofiban dose is not known at this time.

As emphasized in the ACC/AHA guidelines, the benefits of GP IIB/IIIa receptor blockers are greater in patients undergoing PCI. A recent meta-analysis estimates that 30 adverse outcomes (either death or MI) are prevented for every 1000 patients treated with a GP IIB/IIIa receptor blocker before PCI, whereas only 4 events are prevented for medical management of non-ST-segment-elevation ACS patients using GP IIB/IIIa receptor blockers without PCI.⁷⁴ This translates into a number needed to treat 32 patients to prevent 1 event if a GP IIB/IIIa receptor blocker is administered before PCI and 250 patients to prevent 1 event if it is administered as medical therapy without PCI.⁷⁴

Doses and contraindications to GP IIB/IIIa receptor blockers are described in Table 16–4, and common adverse effects are described in the preceding section. Administration of intravenous GP IIB/IIIa receptor blockers in combination with aspirin and an anticoagulant results in major bleeding rates of 3.6%³⁵ but no increased risk of intracranial hemorrhage in the absence of concomitant fibrinolytic treatment. The risk of thrombocytopenia with tirofiban and eptifibatide appears to be lower than that with abciximab. Bleeding risks appear similar among agents. However, major bleeding with the combination of aspirin, heparin, and a GP IIB/IIIa inhibitor is higher (approximately 3% to 4%) than using a heparin plus aspirin (<2%).

■ ANTICOAGULANTS

Either UFH or LMWHs should be administered to patients with non-ST-segment-elevation ACS. Therapy should be continued for up to 48 hours or until the end of the angiography or PCI procedure. In patients initiating warfarin therapy, UFH or LMWHs should be continued until the international normalization ratio (INR) with warfarin is in the therapeutic range. Data supporting the addition of UFH to aspirin stems from a meta-analysis of six randomized trials demonstrating a 33% reduction in the risk of death or MI at 6 weeks with UFH

plus aspirin compared with aspirin alone.⁷⁵ One trial compared the LMWH dalteparin plus aspirin with aspirin alone and found a 60% reduction in death or MI at 6 days.⁷⁶ Three clinical trials have compared UFH with LMWHs for medical management of NSTEMI ACS.^{77–79} Two trials in a total of approximately 7000 patients demonstrated a 15% reduction in the composite end point of death, MI, or recurrent ischemia with enoxaparin compared with UFH.^{77,78} One trial with dalteparin in approximately 1400 patients demonstrated similar outcomes between dalteparin and UFH.⁷⁹ The results from these trials also showed no increased risk of major bleeding with LMWHs compared with UFH.^{77–79} Minor bleeding, mostly injection-site hematomas, was increased because the LMWHs are given by subcutaneous injection, whereas UFH is administered by continuous infusion.^{77–79} Because of a reduction in event rates compared with UFH, enoxaparin was mentioned as “preferred” over UFH in the ACC/AHA clinical practice guidelines.²

Previously, lack of data with LMWHs in non-ST-segment-elevation ACS patients undergoing PCI has limited their use in this setting. Traditionally, interventional cardiologists monitor the degree of anticoagulation of UFH using the activated clotting time (ACT) in the cardiac catheterization laboratory. Because LMWHs have only a small effect on increasing the ACT owing to their preferential effect on activated factor X inhibition, the ACT cannot be used to monitor LMWH efficacy or toxicity. One large clinical trial of enoxaparin compared with UFH in this setting found similar efficacy with a slightly higher risk of major bleeding with enoxaparin. This trial was confounded by a large number of patients who received both UFH and enoxaparin. The authors concluded that the use of enoxaparin has similar reduction in death or MI compared to UFH. Enoxaparin is an option that may be initiated and then continued through PCI, but switching between UFH and enoxaparin should be avoided.⁸⁰

The risk of major bleeding with UFH or LMWHs is higher in patients undergoing angiography because there is an associated risk of hematoma at the femoral access site. Major bleeding rates in these patients are less than or equal to 2%. The risk of heparin-induced thrombocytopenia is lower in some, but not all, clinical trials with LMWHs compared with UFH.

Because LMWHs are eliminated renally and patients with renal insufficiency generally have been excluded from clinical trials, some practice protocols recommend UFH for patients with creatinine clearance rates of less than 30 mL/min. (Creatinine clearance is calculated based on total patient body weight.) However, recent recommendations for dosing adjustment of enoxaparin in patients with creatinine clearances between 10 and 30 mL/min are now listed in the product manufacturer’s label (see Table 16–4). Administration of LMWHs should be avoided in dialysis patients. UFH is monitored and the dose adjusted to a target aPTT, whereas LMWHs are administered by a fixed, weight-based dose. Other dosing information and contraindications are described in Table 16–4.

■ NITRATES

SL followed by IV NTG should be administered to all patients with non-ST-segment-elevation ACS in the absence of contraindications (see Table 16–4). The mechanism of action, dosing, contraindications, and adverse effects are the same as described in the section “Early Pharmacotherapy for ST-Segment-Elevation ACS” above. IV NTG typically is continued for approximately 24 hours following ischemia relief. The mechanism of action, dosing, contraindications, and adverse effects are the same as described in the section “Early Pharmacotherapy for ST-Segment-Elevation ACS” above.

■ β -BLOCKERS

IV followed by oral β -blockers should be administered to all patients with non-ST-segment-elevation ACS in the absence of contraindications. The mechanism of action, dosing, contraindications, and adverse effects are the same as described in the section “Early Pharmacotherapy for ST-Segment-Elevation ACS” above. β -Blockers are continued indefinitely.

■ CALCIUM CHANNEL BLOCKERS

As described above, calcium channel blockers should not be administered to most patients with ACS. Their role is a second-line treatment for patients with certain contraindications to β -blockers and those with continued ischemia despite β -blocker and nitrate therapy. They are a first-line therapy in patients with Prinzmetal’s vasospastic angina and those with cocaine-associated ACS. Administration of either amlodipine, diltiazem, or verapamil is preferred.² Agent selection based on heart rate and LV dysfunction (diltiazem and verapamil contraindicated in patients with bradycardia, heart block, or systolic heart failure) is described in more detail in the section “Early Pharmacotherapy for ST-Segment-Elevation ACS” above. Dosing and contraindications are described in Table 16–4.

■ SECONDARY PREVENTION FOLLOWING MI

The long-term goals following MI are to

1. Control modifiable CHD risk factors
2. Prevent the development of systolic heart failure
3. Prevent recurrent MI and stroke
4. Prevent death, including sudden cardiac death

◀ Pharmacotherapy that has been proven to decrease mortality, heart failure, reinfarction, or stroke should be initiated prior to hospital discharge for secondary prevention. Guidelines from the ACC/AHA suggest that following MI from either ST-segment-elevation ACS or non-ST-segment-elevation ACS, patients should receive indefinite treatment with aspirin, a β -blocker, and an ACE inhibitor.^{2,3} For patients with non-ST-segment-elevation ACS, most should receive clopidogrel, in addition to aspirin, for up to 9 months.² Selected patients also will be treated with long-term warfarin anticoagulation. Newer therapies include eplerenone, an aldosterone antagonist. For all ACS patients, treatment and control of modifiable risk factors such as hypertension, dyslipidemia, and diabetes mellitus are essential. Most patients with CHD will require drug therapy for hyperlipidemia, usually with a statin (hydroxymethylglutaryl coenzyme A reductase inhibitor). Benefits and adverse effects of long-term treatment with these medications are discussed in more detail below.

■ ASPIRIN

Aspirin decreases the risk of death, recurrent MI, and stroke following MI. An aspirin prescription at hospital discharge is a quality care indicator in MI patients²⁷ (see Table 16–3). The clinical value of aspirin in secondary prevention of ACS and other vascular diseases was demonstrated in a large number of clinical trials. Following an

MI, aspirin is expected to prevent 36 vascular events per 1000 patients treated for 2 years.³² Because the benefit of antiplatelet agents appears to be sustained for at least 2 years following an MI,³⁴ all patients should receive aspirin indefinitely, or clopidogrel in patients with a contraindication to aspirin.^{2,3}

The risk of major bleeding from chronic aspirin therapy is approximately 2% and is dose-related. Aspirin doses of 75 to 150 mg are not less effective than doses of 160 to 325 mg and may have lower rates of bleeding. Therefore, chronic doses of 75 to 162 mg are now recommended.³

■ CLOPIDOGREL

For patients with non-ST-segment-elevation ACS, clopidogrel decreases the risk of developing either death, MI, or stroke. The benefit is primarily in reducing the rate of MI.⁶² The ACC/AHA guidelines suggest a duration of therapy of 9 months² because this was the average duration of treatment in the CURE trial.⁶² Patients who have undergone a PCI with stent implantation may receive clopidogrel for up to 12 months.⁶⁴ The benefits of clopidogrel therapy in PCI are discussed in more detail in Chap. 15.

Because of the risk of bleeding with clopidogrel and aspirin doses higher than 100 mg, low-dose aspirin should be administered concomitantly.⁶⁵ Although not specifically studied, longer duration of therapy with clopidogrel plus aspirin may be considered for patients with many recurrent vascular events such as stroke, MI, or recurrent ACS. In addition, patients with concomitant peripheral arterial disease or CABG surgery may benefit from combined therapy with aspirin and clopidogrel to prevent CHD events.⁴²

■ ANTICOAGULATION

Warfarin should be considered in selected patients following an ACS, including patients with a left ventricular thrombus, patients demonstrating extensive ventricular wall motion abnormalities on cardiac echocardiogram, and patients with a history of thromboembolic disease or chronic atrial fibrillation.³ A more detailed discussion regarding the use of warfarin is available in Chap. 19.

Because of the importance of thrombus formation in the pathophysiology of ACS and the findings from several studies suggesting residual thrombus at the site of plaque rupture even months following an MI, anticoagulants, primarily warfarin, have been the subject of many clinical trials in patients following an ACS. These trials have produced varying and inconsistent results. Because the intensity of anticoagulation varied among these trials, it is important to take into consideration the intensity of the anticoagulation when interpreting these trials.

Data from two large, randomized trials demonstrate that the use of low, fixed-dose warfarin (mean INR 1.4) combined with aspirin⁸¹ or of low-intensity anticoagulation (mean INR 1.8) monotherapy⁸² provides no significant clinical benefit compared with aspirin monotherapy but significantly increases the risk of major bleeding. Therefore, warfarin therapy targeted to an INR of less than 2 cannot be recommended for secondary prevention of CHD events following MI.

Subsequently, in two large, randomized trials, a strategy of combining intermediate-intensity anticoagulation (target INR 2–2.5) with low-dose aspirin reduced the combined end point of death, MI, or stroke in patients following MI compared with aspirin alone. The

Antithrombotics in Secondary Prevention of Events in Coronary Thrombosis 2 (ASPECT-2)⁸³ and the Warfarin Re-Infarction Study 2 (WARIS-2)⁸⁴ reported that warfarin alone targeted to a high-intensity INR and medium-intensity warfarin plus low-dose aspirin were superior to aspirin alone in preventing the combined end point of death, MI, or stroke. The target INRs in the high-intensity warfarin monotherapy group were 3 to 4⁸³ and 2.8 to 4.2,⁸⁴ respectively. The target INR in the more effective medium-intensity warfarin and low-dose aspirin group was 2 to 2.5 in both trials. No significant differences in efficacy were observed between the combination of medium-intensity anticoagulation and low-dose aspirin and monotherapy with high-intensity anticoagulation.

The use of warfarin in combination with aspirin was associated with an increased risk of minor and major bleeding. Furthermore, patients in the warfarin groups were two to three times more likely to discontinue their treatment. Since the trials were analyzed as intention to treat, the treatment effect of warfarin probably is greater, but the long-term bleeding risks may be greater as well. A meta-analysis of seven clinical trials of secondary prevention with aspirin, warfarin, and the combination suggested that the risk of cardiovascular death, MI, or stroke was reduced by 3.3% (absolute risk reduction 15.9% versus 12.6%) and reported the risk of major bleeding to be increased by 1.3% (absolute risk 3% versus 1.7%) for a net benefit of 2%.⁸⁵ Many consider this net benefit for a composite end point to be small in comparison with the large management issues related to warfarin therapy, such as INR monitoring and drug interactions. WARIS-2 and ASPECT-2 were conducted in the Netherlands and in Norway, two countries renowned for the quality of their anticoagulation programs and clinics, thereby limiting generalization of the findings. Furthermore, because a large proportion of ACS patients in North America undergo coronary revascularization with subsequent stent implementation, patients require a combination of aspirin and clopidogrel to prevent stent thrombosis, a platelet-dependent phenomenon that warfarin does not effectively prevent.⁸⁶ Therefore, because of the complexity of managing current anticoagulants, the use of warfarin is unlikely to gain wide acceptance. Despite the superiority of warfarin plus aspirin over aspirin alone, it is not currently recommended as a preferred regimen by any professional association practice guidelines in the absence of the conditions for selected patients outlined previously.

■ β -BLOCKERS, NITRATES, AND CALCIUM CHANNEL BLOCKERS

Current treatment guidelines recommend that following an ACS, patients should receive a β -blocker indefinitely^{2,3} whether they have residual symptoms of angina or not.⁸⁷ β -Blocker prescription at hospital discharge in the absence of contraindications is a quality care indicator²⁷ (see Table 16–3). Overwhelming data support the use of β -blockers in patients with a previous MI. Data from a systematic review of long-term trials of patients with recent MI demonstrate that the number needed to treat for 1 year with a β -blocker to prevent one death is only 84 patients.⁸⁸ Because the benefit from β -blockers appears to be maintained for at least 6 years following an MI,⁸⁹ it is recommended that all patients receive β -blockers indefinitely in the absence of contraindications or intolerance.^{2,3} Currently, there are no data to support the superiority of one β -blocker over another, although the only β -blocker with intrinsic sympathomimetic activity that has been shown to be beneficial following MI is acebutolol.⁹⁰

Although β -blockers should be avoided in patients with decompensated heart failure from LV systolic dysfunction complicating an MI, clinical trial data suggest that it is safe to initiate β -blockers prior to hospital discharge in these patients once heart failure symptoms have resolved.⁹¹ These patients actually may benefit more than those without LV dysfunction.⁹²

Despite the overwhelming benefit demonstrated in clinical trials, β -blockers are still widely underused, perhaps because clinicians fear that patients will experience adverse reactions, including depression, fatigue, and sexual dysfunction. A recent systematic review of 15 trials that included more than 35,000 patients demonstrated that withholding β -blocker therapy in such a group was not founded because β -blockers do not significantly increase the risk of depression and only modestly increase the risk of fatigue and sexual dysfunction.⁹³

In patients who cannot tolerate or have a contraindication to a β -blocker, a calcium channel blocker can be used to prevent anginal symptoms but should not be used routinely in the absence of such symptoms.^{2,3,87} Finally, all patients should be prescribed short-acting SL NTG or lingual NTG spray to relieve any anginal symptoms when necessary and should be instructed on its use.^{2,3} Chronic long-acting nitrate therapy has not been shown to reduce CHD events following MI. Therefore, IV NTG is not followed routinely by chronic, long-acting oral nitrate therapy in ACS patients who have undergone revascularization unless the patient has chronic stable angina or significant coronary stenoses that were not revascularized.⁸⁷

■ ACE INHIBITORS AND ANGIOTENSIN RECEPTOR BLOCKERS

ACE inhibitors should be initiated in all patients following MI to reduce mortality, decrease reinfarction, and prevent the development of heart failure.^{2,3} Dosing and contraindications are described in Table 16–4. The benefit of ACE inhibitors in patients with MI most likely comes from their ability to prevent cardiac remodeling. Other proposed mechanisms include improvement in endothelial function, a reduction in atrial and ventricular arrhythmias, and promotion of angiogenesis, leading to a reduction in ischemic events. The largest reduction in mortality is observed for patients with LV dysfunction [low LV ejection fraction (EF)] or heart failure symptoms. The use of ACE inhibitors in relatively unselected patients without a contraindication to ACE inhibitors may be expected to save 5 lives per 1000 patients treated for 30 days.⁹⁴ Long-term studies in patients with LV systolic dysfunction with or without heart failure symptoms demonstrate greater benefit because mortality reductions are larger (23.4% versus 29.1%; $p < .0001$) such that only 17 patients need treatment to prevent 1 death, with 57 lives saved for every 1000 patients treated.⁹⁵ ACE inhibitor prescription at hospital discharge following MI, in the absence of contraindications, to patients with depressed LV function (ejection fraction $< 40\%$) is currently a quality care indicator, and there are plans to make administration of an ACE inhibitor in all patients without contraindications a quality care indicator.²⁷ (see Table 16–3).

Early initiation (within 24 hours) of an *oral* ACE inhibitor appears to be crucial during an acute MI because 40% of the 30-day survival benefit is observed during the first day, 45% from days 2 to 7, and approximately only 15% from days 8 to 30.⁹⁴ However, current data do not support the early administration of *intravenous* ACE inhibitors in patients experiencing an MI because mortality may be increased.⁹⁶ Hypotension should be avoided because coronary artery filling may be compromised. Because the benefits of ACE inhibitor

administration have been documented out to 3 years following MI,²⁷ administration should continue indefinitely.

More recent data suggest that all patients with CAD, not just ACS or heart failure patients, benefit from an ACE inhibitor. In the Heart Outcome Prevention Evaluation (HOPE) trial, ramipril significantly reduced the risk of death, MI, or stroke in high-risk patients aged 55 years or older with chronic CAD or with diabetes and one cardiovascular risk factor.⁹⁷ The more recent European trial On Reduction Of Cardiac Events With Perindopril In Stable Coronary Artery Disease (EUROPA) extended the benefit of chronic therapy with ACE inhibitors to patients with stable CAD at lower risk of cardiovascular events compared with patients from the HOPE trial.⁹⁸ In the EUROPA trial, patients randomized to perindopril experienced a lower risk of the combined end point of cardiovascular death, MI, or cardiac arrest compared with patients randomized to placebo. Therefore, based on the extensive benefit of ACE inhibitors in patients with CAD, their routine use should be considered in all patients following an ACS in the absence of a contraindication.

Besides hypotension, the most frequent adverse reaction to an ACE inhibitor is cough, which may occur in up to 30% of patients. Patients with ACE inhibitor cough and either clinical signs of heart failure or LVEF less than 40% may be prescribed an angiotensin-receptor blocker (ARB).³ Both candesartan and valsartan have improved outcomes in clinical trials in patients with heart failure.^{99,100} Other less common but more serious adverse effects of ACE inhibitors include acute renal failure, hyperkalemia, and angioedema. Although some data have suggested that aspirin use may decrease the benefits from ACE inhibitor treatment, a systematic review of more than 20,000 patients demonstrated that ACE inhibitors improve outcome irrespective of treatment with aspirin.¹⁰¹

■ LIPID-LOWERING AGENTS

There are now overwhelming data supporting the benefits of statins in patients with CAD in the prevention of total mortality, cardiovascular mortality, and stroke. According to the National Cholesterol Education Program (NCEP) Adult Treatment Panel recommendations, all patients with CAD should receive dietary counseling and pharmacologic therapy in order to reach a low-density lipoprotein (LDL) cholesterol concentration of less than 100 mg/dL, with statins being the preferred agents to lower LDL cholesterol.¹⁰² Results from landmark clinical trials have demonstrated unequivocally the value of statins in secondary prevention following MI in patients with moderate to high cholesterol levels. These trials, which included only patients with stable CAD, showed that the benefit of statins appears approximately after 1 year of treatment.¹⁰² Although the primary effect of statins is to decrease LDL cholesterol, statins are believed to produce many non-lipid-lowering or “pleiotropic” effects. These effects, which include improvement in endothelial dysfunction, anti-inflammatory and antithrombotic properties, and a decrease in matrix metalloproteinase activity, may be relevant in patients experiencing an ACS and result in short-term (< 1 year) benefit.⁶ Newer recommendations from the NCEP give an optional goal of an LDL cholesterol of less than 70 mg/dL.¹⁰³ This recommendation is based upon a large clinical trial evaluating recurrence of major cardiovascular events in patients with a history of an ACS occurring within the past 10 days. This trial documented the benefit of lowering LDL cholesterol to, on average, 62 mg/dL, with 80 mg of atorvastatin compared to 95 mg/dL in patients treated with pravastatin 40 mg daily.¹⁰⁴ Whether or not a statin

should be used routinely in all patients irrespective of their baseline LDL cholesterol level is currently being investigated, but preliminary data from the Heart Protection Study suggests that patients benefit from statin therapy irrespective of their baseline LDL cholesterol level.¹⁰⁵

In addition, early initiation in patients with ACS appears to increase long-term adherence with statin therapy, which should result in clinical benefit.¹⁰⁷ Recent data suggest that long-term adherence to statins in patients with an ACS and in patients with chronic CAD is poor, with less than 50% of patients being compliant with their statin regimen 2 years following drug initiation.¹⁰⁵ Therefore, in patients with an ACS, statin therapy initiation should not be delayed, and statins should be prescribed at or prior to discharge in most patients.

A fibrate derivative or niacin should be considered in selective patients with a low high-density lipoprotein (HDL) cholesterol concentration (<40 mg/dL) and/or a high triglyceride level (>200 mg/dL). In a large, randomized trial in men with established CAD and low levels of HDL cholesterol, the use of gemfibrozil (600 mg twice daily) significantly decreased the risk of nonfatal MI or death from coronary causes.¹⁰⁸

Additional discussion, dosing, monitoring, and adverse effects of using lipid-lowering drugs for secondary prevention may be found in Chap. 21.

■ FISH OILS (MARINE-DERIVED OMEGA-3 FATTY ACIDS)

Eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) are omega-3 polyunsaturated fatty acids that are most abundant in fatty fish such as sardines, salmon, and mackerel. Epidemiologic and randomized trials have demonstrated that a diet high in EPA plus DHA or supplementation with these fish oils reduces the risk of cardiovascular mortality, reinfarction, and stroke in patients who have experienced an MI.¹⁰⁹ Although the exact mechanism responsible for the beneficial effects of omega-3 fatty acids has not been clearly elucidated, potential mechanisms include triglyceride-lowering effects, antithrombotic effects, retardation in the progression of atherosclerosis, endothelial relaxation, mild antihypertensive effects, and reduction in ventricular arrhythmias.¹⁰⁹

The GISSI-Prevenzione trial, the largest randomized trial of fish oils published to date, evaluated the effects of open-label EPA plus DHA in 11,324 patients with recent MI who were randomized to receive 850 to 882 mg/day of n-3 polyunsaturated fatty acid (EPA plus DHA), 300 mg vitamin E, both, or neither.¹¹⁰ The use of EPA plus DHA reduced the risk of death, nonfatal acute MI, or nonfatal stroke, whereas the use of vitamin E had no significant impact on this combined clinical end point. Therefore, based on current data, the AHA recommends that CHD patients consume approximately 1 g EPA plus DHA per day, preferably from oily fish.¹⁰⁹ Because oil content in fish varies, the number of 6-oz servings of fish that would need to be consumed to provide 7 g EPA plus DHA per week varies from approximately 4 to more than 14 for secondary prevention. The average diet only contains one-tenth to one-fifth the recommended amount.¹⁰⁹ Supplements should be considered in selected patients who do not eat fish, have limited access to fish, or who cannot afford to purchase fish. Approximately three 1-g fish oil capsules per day should be consumed to provide 1 g omega-3 fatty acids depending on the brand of supplement.¹⁰⁹ Finally, current guidelines suggest that higher doses of EPA plus DHA (2 to 4 g/day) also can be considered for the management of hypertriglyceridemia.¹⁰⁹

Adverse effects from fish oils include fishy aftertaste, nausea, and diarrhea.¹⁰⁹

■ OTHER MODIFIABLE RISK FACTORS

Smoking cessation, control of hypertension, weight loss, and tight glucose control for patients with diabetes mellitus, in addition to treatment of dyslipidemia, are important treatments for secondary prevention of CHD events.³ Smokers should be instructed to stop smoking. A recent systematic review has highlighted that smoking cessation is accompanied by a significant reduction in all-cause mortality in patients with CAD.¹¹¹ Smoking cessation counseling at the time of discharge following MI is a quality care indicator²⁷ (see Table 16–3). The use of nicotine patches or gum or of bupropion alone or in combination with nicotine patches should be considered in appropriate patients.³ Hypertension should be strictly controlled according to published guidelines.¹¹² Patients who are overweight should be educated on the importance of regular exercise, healthy eating habits, and of reaching and maintaining an ideal weight.¹¹³ Finally, because diabetics have up to a fourfold increased risk of mortality compared with nondiabetics, the importance of tight glucose control, as well as other CHD risk factor modification, cannot be understated.¹¹⁴

■ NEW THERAPIES FOR SECONDARY PREVENTION: ALDOSTERONE ANTAGONISTS

Administration of an aldosterone antagonist, either eplerenone or spironolactone, should be considered within the first 2 weeks following MI in all patients already receiving an ACE inhibitor who have an EF of 40% or less and either heart failure symptoms or a diagnosis of diabetes mellitus to reduce mortality.³ Aldosterone plays an important role in heart failure and MI because it promotes vascular and myocardial fibrosis, endothelial dysfunction, hypertension, LV hypertrophy, sodium retention, potassium and magnesium loss, and arrhythmias. Aldosterone blockers have been shown in experimental and human studies to attenuate these adverse effects.¹¹⁵ As discussed in Chap. 14, the benefit of aldosterone blockade in patients with stable, severe heart failure was highlighted in the Randomized Aldactone Evaluation Study (RALES), where spironolactone decreased the risk of all-cause mortality.¹¹⁶

Eplerenone, like spironolactone, is an aldosterone blocker that blocks the mineralocorticoid receptor. In contrast to spironolactone, eplerenone has no effect on the progesterone or androgen receptor, thereby minimizing the risk of gynecomastia, sexual dysfunction, and menstrual irregularities.¹¹⁵ The Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS) evaluated the effect of aldosterone antagonism in patients with an MI complicated by heart failure or LV dysfunction. Patients ($n = 6642$) were randomized 3 to 14 days following the MI to eplerenone or placebo.¹¹⁷ Eplerenone significantly reduced the risk of mortality (14.4% versus 16.7%; $p = .008$). Data from EPHESUS suggest that eplerenone reduced mortality from sudden death, heart failure, and MI. Eplerenone also reduced the risk of hospitalizations for heart failure. Most patients in EPHESUS also were being treated with aspirin, a β -blocker, and an ACE inhibitor. Approximately half the patients also were receiving a statin. Therefore, the mortality reduction observed was in addition to that of standard therapy for secondary CHD prevention. These benefits were obtained at the expense of an increased

risk of severe hyperkalemia (5.5% versus 3.9%; $p = .002$), defined as a potassium concentration equal or greater than 6 mmol/L. Patients with a serum creatinine concentration of greater than 2.5 mg/dL or a serum potassium concentration of greater than 5 mmol/L at baseline were excluded. The risk of hyperkalemia was particularly alarming in patients with a creatinine clearance of less than 50 mL/min. This highlights the importance of close monitoring of potassium level and renal function in patients being treated with eplerenone. There was no increase in gynecomastia, breast pain, or impotence.

The results from EPHEsus have raised the question of which aldosterone blocker, spironolactone or eplerenone, should be used preferentially. Currently, there are no data to support that the more selective but more expensive eplerenone is superior to or should be preferred to the less expensive generic spironolactone unless a patient has experienced gynecomastia, breast pain, or impotence while receiving spironolactone. Finally, it should be noted that hyperkalemia is just as likely to appear with both these agents.

PHARMACOECONOMIC CONSIDERATIONS

11 The risks of CHD events, such as death, recurrent MI, and stroke, are higher for patients with established CHD and a history of MI than for patients with no known CHD. Because the costs for chronic preventative pharmacotherapy are the same for primary and secondary prevention, whereas the risk of events is higher with secondary prevention, secondary prevention is more cost-effective than primary prevention of CHD. Pharmacotherapy that has demonstrated cost-effectiveness to prevent death in ACS and post-MI patients includes fibrinolytics, aspirin, GP IIb/IIIa receptor blockers, β -blockers, ACE inhibitors, statins, and gemfibrozil.¹²³ Studies documenting cost-effectiveness of ACS and secondary prevention are based on the landmark clinical trials discussed throughout this chapter. The cost-effectiveness ratio of administering streptokinase compared with no reperfusion therapy is \$2000 to \$4000 per year of life saved, whereas administering alteplase compared with streptokinase has a cost-effectiveness ratio of about \$33,000 per year of life saved.^{123,124} While no formal cost-effectiveness analyses on aspirin therapy have been performed, the profound benefit in ACS, accompanied by its low cost, makes aspirin intuitively cost-effective.¹²⁵ The cost-effectiveness of β -blockers is less than \$5000 per year of life saved for patients at highest risk of death and less than \$15,000 for patients at lower risk of death, with β -blockers being cost-savings in some scenarios.^{126,127} ACE inhibitor cost-effectiveness ratios range from \$3000 to \$5000 per year of life gained following MI.¹²⁸ Other studies have suggested that even in relatively unselected low-risk MI patients, the highest cost-effectiveness ratio is approximately \$40,000 per year of life saved.¹²⁹ Lipid-lowering therapy with statins has a secondary prevention cost-effectiveness ratio of between \$4500 and \$9500 per year of life saved,¹³⁰ whereas gemfibrozil has a cost-effectiveness ratio of less than \$17,000 per year of life saved.¹³¹ In patients with non-ST-segment-elevation ACS, the cost per life year added for eptifibatid treatment in U.S. patients ranges from \$13,700 to \$16,500.¹³² Newer therapies such as fish oils also have demonstrated cost-effectiveness, with a cost-effectiveness ratio of approximately \$28,000 per year of life gained.¹³³ Because cost-effectiveness ratios of less than \$50,000 per added life-year are considered economically attractive from a societal perspective,¹²³ pharmacotherapy as outlined earlier for ACS and secondary prevention are standards of care because of their efficacy and cost attractiveness to payers.

■ THERAPIES NOT USEFUL AND POTENTIALLY HARMFUL FOLLOWING MI

Administration of hormone-replacement therapy (HRT) to all women following MI does not prevent recurrent CHD events and may be harmful.^{118,119} Postmenopausal women already taking estrogen plus progestin should not continue, especially while at bedrest in hospital, owing to an increased risk of venous thromboembolism.³ Administration of vitamin E for secondary prevention is ineffective following MI.^{120,121} Similarly, because of the uniformly disappointing results from trials evaluating the protective effects of vitamins, the U.S. Preventive Services Task Force has published a statement concluding that there was insufficient evidence to recommend the use of supplements of vitamins A, C, or E, multivitamins with folic acid, or a combination of antioxidants to prevent CVDs. Furthermore, they conclude against the use of β -carotene supplementation, particularly in heavy smokers, because of an apparent increased risk of lung cancer.¹²²

CLINICAL CONTROVERSIES

- Administration of fibrinolytic agents to patients older than 75 years of age:
 - Clinical trials have not been conducted specifically in this age group.
 - Number of relative contraindications is likely larger than in younger patients.
 - Risk of intracranial hemorrhage and bleeding is higher.
 - Benefit may be larger but not well documented.
- Spironolactone administration rather than eplerenone following MI in patients with an EF of 40% or less, either diabetes mellitus, or signs of heart failure:
 - Spironolactone is the standard of care for patients with LV dysfunction and New York Heart Association class III or IV heart failure symptoms regardless of cause (ischemic or nonischemic cardiomyopathy).
 - Spironolactone has not been studied specifically in acute MI.
 - Eplerenone is more expensive than spironolactone.
 - Eplerenone causes less gynecomastia, breast pain, and sexual dysfunction.
 - The frequency of hyperkalemia is similar between eplerenone and spironolactone.

EVALUATION OF THERAPEUTIC OUTCOMES

The monitoring parameters for *efficacy* of nonpharmacologic and pharmacotherapy for both ST-segment-elevation and non-ST-segment-elevation ACS are similar:

- Relief of ischemic discomfort
- Return of ECG changes to baseline
- Absence or resolution of heart failure signs

Monitoring parameters for recognition and prevention of *adverse effects* from ACS pharmacotherapy are described in Table 16–7. In general, the most common adverse reactions from ACS therapies are hypotension and bleeding. Treatment for bleeding and hypotension involves discontinuation of the offending agent(s) until symptoms

TABLE 16–7. Therapeutic Drug Monitoring for Adverse Effects of Pharmacotherapy for Acute Coronary Syndromes

| Drug | Adverse Effects | Monitoring |
|--|---|---|
| Aspirin | Dyspepsia, bleeding, gastritis | Clinical signs of bleeding ^a ; gastrointestinal upset; baseline CBC and platelet count; CBC platelet count every 6 months |
| Clopidogrel | Bleeding, thrombocytopenia (rare) | Clinical signs of bleeding ^a ; baseline CBC and platelet count; CBC and platelet count every 6 months following hospital discharge |
| Unfractionated heparin | Bleeding, heparin-induced thrombocytopenia | Clinical signs of bleeding ^a ; baseline CBC and platelet count; aPTT every 6 hour until target then every 24 hours; CBC and platelet count daily |
| Low-molecular-weight heparins | Bleeding, heparin-induced thrombocytopenia | Clinical signs of bleeding ^a ; baseline CBC and platelet count; daily CBC, platelet count every 3 days (minimum, preferably every day); S _{Cr} daily |
| Fibrinolytics | Bleeding, especially intracranial hemorrhage | Clinical signs of bleeding ^a ; baseline CBC and platelet count; mental status every 2 hours for signs of intracranial hemorrhage; daily CBC |
| Glycoprotein IIb/IIIa receptor blockers | Bleeding, acute, profound thrombocytopenia | Clinical signs of bleeding ^a ; baseline CBC and platelet count; daily CBC; platelet count at 4 hours after initiation then daily |
| Intravenous nitrates | Hypotension, flushing, headache, tachycardia | BP and HR every 2 hours |
| β-Blockers | Hypotension, bradycardia, heart block, bronchospasm, heart failure, fatigue, depression, sexual dysfunction, nightmares, and masking hypoglycemia symptoms in diabetics | BP, RR, HR, 12-lead ECG, and clinical signs of heart failure every 5 min during bolus intravenous dosing; BP, RR, HR, and clinical signs of heart failure every shift during oral administration during hospitalization; then BP and HR every 6 months following hospital discharge |
| Diltiazem/verapamil | Hypotension, bradycardia, heart block, heart failure, gingival hyperplasia | BP and HR every 8 hours during oral administration during hospitalization; then every 6 months following hospital discharge; dental exam and teeth cleaning every 6 months |
| Amlodipine | Hypotension, dependent peripheral edema, gingival hyperplasia | BP and HR every 8 hours during oral administration during hospitalization; then every 6 months following hospital discharge; dental exam and teeth cleaning every 6 months |
| Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers | Hypotension, cough (with ACEIs), hyperkalemia, prerenal azotemia, angioedema | BP every 2 hours × 3 for first dose; then every 8 hours during oral administration during hospitalization; then once every 6 months following hospital discharge; baseline S _{Cr} ; daily S _{Cr} while hospitalized then every 6 months; baseline serum potassium concentration; then daily if taking concomitant potassium supplements, spironolactone, or eplerenone or if renal insufficiency; potassium concentration every 6 months following discharge unless taking concomitant eplerenone (see below) or spironolactone; counsel patient on throat, tongue, and facial swelling |
| Eplerenone | Hypotension, hyperkalemia | BP and HR every 8 hours during oral administration during hospitalization; then once every 6 months; baseline S _{Cr} and serum potassium concentration; S _{Cr} and potassium at 48 h; then at one month then 6 months following hospital discharge |
| Warfarin | Bleeding, skin necrosis | Clinical signs of bleeding ^a ; baseline CBC and platelet count; CBC and platelet count every 6 months following hospital discharge; baseline aPTT and INR; daily INR until two consecutive INRs are within the target range; then once weekly × 2 weeks; then every month |
| Morphine | Hypotension, respiratory depression | BP and RR 5 min after each bolus dose |

ACEIs = angiotensin-converting enzyme inhibitors; aPTT = activated partial thromboplastin time; BP = blood pressure; CBC = complete blood count; HR = heart rate; INR = international normalized ratio; RR = respiratory rate; S_{Cr} = serum creatinine.

^aNote: Clinical signs of bleeding include bloody stools, melena, hematuria, hematemesis, bruising, and oozing from arterial or venous puncture sites.

resolve. Severe bleeding resulting in hypotension secondary to hypovolemia may require blood transfusion.

ARRHYTHMIAS

Jerry L. Bauman and Marieke Dekker Schoen

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The use of antiarrhythmic drugs in the United States is declining because of major trials that show increased mortality with their use in several clinical situations, the realization of proarrhythmia as a significant side effect, and the advancing technology of nondrug therapies such as ablation and the internal cardioverter-defibrillator.
- 2 Antiarrhythmic drugs frequently cause side effects and are complex in their pharmacokinetic characteristics. The therapeutic range of these agents provides only a rough guide to modifying treatment; it is preferable to attempt to define an individual's effective (or target) concentration and match that during long-term therapy.
- 3 The most commonly prescribed antiarrhythmic drug is now amiodarone. This agent is effective in terminating and preventing a wide variety of symptomatic tachycardias but is plagued by frequent side effects and therefore requires close monitoring. The most concerning toxicity is pulmonary fibrosis; side-effect profiles of the intravenous (acute, short-term) and oral (chronic, long-term) forms differ.
- 4 In patients with atrial fibrillation, therapy traditionally has been aimed at controlling ventricular response (e.g., digoxin, calcium antagonists, and β -blockers), preventing thromboembolic complications (e.g., warfarin and aspirin), and restoring and maintaining sinus rhythm (e.g., antiarrhythmic drugs and direct-current cardioversion). Recent studies show that there is no need to pursue strategies aggressively to maintain sinus rhythm (e.g., long-term antiarrhythmic drugs); rate control alone is often sufficient in patients who can tolerate it.
- 5 Paroxysmal supraventricular tachycardia is usually due to reentry in or proximal to the atrioventricular (AV) node or AV reentry incorporating an extra nodal pathway; common tachycardias can be terminated acutely with AV nodal blocking agents such as adenosine, and recurrences can be prevented by ablation with radiofrequency current.
- 6 Patients with Wolff-Parkinson-White (WPW) syndrome may have several different tachycardias that are treated acutely by different strategies: orthodromic reentry (adenosine), antidromic reentry (adenosine or procainamide), and atrial fibrillation (procainamide or amiodarone). AV nodal blocking drugs are contraindicated with WPW syndrome and atrial fibrillation.
- 7 Because of the results of the Cardiac Arrhythmia Suppression Trials and other trials, antiarrhythmic drugs (except β -blockers) should not be used routinely in patients with prior myocardial infarction (MI) or left ventricular (LV) dysfunction and minor ventricular rhythm disturbances (e.g., premature ventricular complexes).
- 8 Patients with hemodynamically significant ventricular tachycardia or ventricular fibrillation not associated with an acute MI who are resuscitated successfully (electrical cardioversion, pressors, amiodarone) are at high risk for death and should receive implantation of an internal cardioverter-defibrillator.
- 9 The clinical approach to patients with left ventricular dysfunction and nonsustained ventricular tachycardia is a major remaining controversy, with three divergent strategies: invasive electrophysiologic studies with possible internal cardioverter-defibrillator implantation, empirical amiodarone therapy, and conservative (no treatment beyond β -blockers) management. Invasive electrophysiologic studies can aid in deciding among these strategies, particularly in patients with coronary artery disease.
- 10 Life-threatening proarrhythmia generally takes two forms: sinusoidal or incessant monomorphic ventricular tachycardia (type Ic agents) and torsade de pointes (type Ia or III agents and others such as select antihistamines).

The heart has two basic properties, namely, an electrical property and a mechanical property. The synchronous interaction between these two properties is complex, precise, and relatively enduring. The study of the electrical properties of the heart has grown at a steady rate, interrupted by periodic salvos of scientific breakthroughs. Einthoven's pioneering work allowed graphic electrical tracings of cardiac rhythm and probably represents the first of these breakthroughs. This discov-

ery (of the surface electrocardiogram [ECG]) has remained the cornerstone of diagnostic tools for cardiac rhythm disturbances. Since then, intracardiac recordings and programmed cardiac stimulation have advanced our understanding of arrhythmias, whereas microelectrode, voltage clamp, and patch clamping techniques have allowed considerable insight into the electrophysiologic actions and mechanisms of antiarrhythmic drugs. Certainly, the new era of molecular biology and

mapping of the human genome promises even greater insights into mechanisms (and potential therapies) of arrhythmias. Noteworthy in this regard is the discovery of genetic abnormalities in the ion channels that control electrical repolarization (heritable long-QT syndromes) or depolarization (Brugada syndrome).

The clinical use of drug therapy started with the use of digitalis and then quinidine, followed somewhat later by a surge of new agents in the 1980s. A theme of drug discovery during this decade initially was to find orally absorbed lidocaine congeners (such as mexilitene and tocainide), and later the emphasis was on drugs with extremely potent effects on conduction, i.e., flecainide-like agents. The most recent focus of investigational antiarrhythmic drugs is the potassium channel blockers, with dofetilide being the most recently approved in the United States. Previously, there was some expectation that advances in antiarrhythmic drug discovery would lead to a highly effective and nontoxic agent that would be effective for a majority of patients (the so-called magic bullet). Instead, significant problems with drug toxicity and proarrhythmia have resulted in a decline in the overall volume of antiarrhythmic drug usage in the United States since 1989. The other phenomenon that has contributed significantly to the decline in drug usage is the development of extremely effective nondrug therapies. Technical advances have made it possible to permanently interrupt reentry circuits with radiofrequency ablation, which renders long-term antiarrhythmic drug use obsolete in certain arrhythmias. Further, refinement of the internal cardioverter-defibrillators continues to advance at an impressive rate, and this, combined with the now known hazards of drugs, has led most clinicians to choose this form of therapy as the first-line treatment of serious, recurrent ventricular arrhythmias. What does the future hold for the use of antiarrhythmic drugs? Certainly, new knowledge and technological advances have forced investigators and clinicians to rethink the concept of traditional membrane-active drugs. Although some degree of enthusiasm exists for some of the newer or investigational agents, the overall impact of these drugs has yet to be determined.

The purpose of this chapter is to review the principles involved in both normal and abnormal cardiac conduction and to address the pathophysiology and treatment of the more commonly encountered arrhythmias. Certainly, many volumes of complete text could be (and have been) devoted to basic and clinical electrophysiology. Therefore, this chapter briefly addresses those principles necessary for clinicians.

ARRHYTHMOGENESIS

NORMAL CONDUCTION

Electrical activity is initiated by the sinoatrial (SA) node and moves through cardiac tissue via a treelike conduction network. The SA node initiates cardiac rhythm under normal circumstances because this tissue possesses the highest degree of automaticity or rate of spontaneous impulse generation. The degree of automaticity of the SA node is largely influenced by the autonomic nervous system in that both cholinergic and sympathetic innervations control sinus rate. Most tissues within the conduction system also possess varying degrees of inherent automatic properties. However, the rates of spontaneous impulse generation of these tissues are less than that of the SA node. Thus these latent automatic pacemakers are continuously overdriven by impulses arising from the SA node (primary pacemaker) and therefore do not become clinically apparent.

From the SA node, electrical activity moves in a wavefront through an atrial specialized conducting system and eventually gains entrance to the ventricle via an atrioventricular (AV) node and a large

bundle of conducting tissue referred to as the *bundle of His*. Aside from this AV nodal–Hisian pathway, a fibrous AV ring that will not permit electrical stimulation separates the atria and ventricles. The conducting tissues bridging the atria and ventricles are referred to as the *junctional areas*. Again, this area of tissue (junction) is largely influenced by autonomic input and possesses a relatively high degree of inherent automaticity (about 40 beats per minute, less than that of the SA node). From the bundle of His, the cardiac conduction system bifurcates into several (usually three) bundle branches: one right bundle and two left bundles. These bundle branches further arborize into a conduction network referred to as the *Purkinje system*. The conduction system as a whole innervates the mechanical myocardium and serves to initiate excitation-contraction coupling and the contractile process. After a cell or group of cells within the heart is stimulated electrically, a brief period of time follows in which those cells cannot be excited again. This time period is referred to as the *refractory period*. As the electrical wavefront moves down the conduction system, the impulse eventually encounters tissue refractory to stimulation (recently excited) and subsequently dies out. Then the SA node recovers, fires spontaneously, and begins the process again.

Prior to cellular excitation, an electrical gradient exists between the inside and the outside of the cell membrane. At this time, the cell is polarized. In atrial and ventricular conducting tissue, the intracellular space is about 80 to 90 mV negative with respect to the extracellular environment. The electrical gradient just prior to excitation is referred to as *resting membrane potential (RMP)* and is the result of differences in ion concentrations between the inside and the outside of the cell. At RMP, the cell is polarized primarily by the action of active membrane ion pumps, the most notable of these being the sodium-potassium pump. For example, this specific pump (in addition to other systems) attempts to maintain the intracellular sodium concentration at 5–15 mEq/L and the extracellular sodium concentration at 135–142 mEq/L and the intracellular potassium concentration at 3–5 mEq/L and the extracellular potassium concentration at 3–5 mEq/L. RMP can be calculated by using the Nernst equation:

$$\text{RMP} = -61.5 \log \frac{[\text{ion outside}]}{[\text{ion inside}]}$$

Electrical stimulation (or depolarization) of the cell will result in changes in membrane potential over time or a characteristic action potential curve (Fig. 17–1). The action potential curve results from the transmembrane movement of specific ions and is divided into

FIGURE 17–1. Purkinje fiber action potential showing specific ion flux responsible for the change in membrane potential.

different phases. Phase 0, or initial, rapid depolarization of atrial and ventricular tissues, is due to an abrupt increase in the permeability of the membrane to sodium influx. This rapid depolarization more than equilibrates (overshoots) the electrical potential, resulting in a brief initial repolarization, or phase 1. Phase 1 (initial repolarization) is due to a transient and active potassium efflux. Calcium begins to move into the intracellular space at about -60 mV (during phase 0), causing a slower depolarization. Calcium influx continues throughout phase 2 of the action potential (plateau phase) and is balanced to some degree by potassium efflux. Calcium entrance (only through L-channels in myocardial tissue) distinguishes cardiac conducting cells from nerve tissue and provides the critical ionic link to excitation-contraction coupling and the mechanical properties of the heart as a pump (see Chap. 14). The membrane remains permeable to potassium efflux during phase 3, resulting in cellular repolarization. Phase 4 of the action potential is the gradual depolarization of the cell and is related to a constant sodium leak into the intracellular space balanced by a decreasing (over time) efflux of potassium. The slope of phase 4 depolarization determines, in large part, the automatic properties of the cell. As the cell is slowly depolarized during phase 4, an abrupt increase in sodium permeability occurs, allowing the rapid cellular depolarization of phase 0. The juncture of phase 4 and phase 0, where rapid sodium influx is initiated, is referred to the *threshold potential* of the cell. The level of threshold potential also regulates the degree of cellular automaticity.

Not all cells in the cardiac conduction system rely on sodium influx for initial depolarization. Some tissues depolarize in response to a slower inward ionic current caused by calcium influx. These calcium-dependent tissues are found primarily in the SA and AV nodes (both L- and T-channels) and possess distinct conduction properties in comparison with the sodium-dependent fibers. Calcium-dependent cells generally have a less negative RMP (-40 to -60 mV) and a slower conduction velocity. Furthermore, in calcium-dependent tissues, recovery of excitability outlasts full repolarization, whereas in sodium-dependent tissues, recovery is prompt after repolarization. These two types of electrical fibers also differ dramatically in how drugs modify their conduction properties (see below).

Ion conductance across the lipid bilayer of the cell membrane occurs via the formation of membrane pores or channels (Fig. 17–2).

FIGURE 17–2. Lipid bilayer, sodium channel, and possible sites of action of the type I agents (A). Type I antiarrhythmic drugs theoretically may inhibit sodium influx at an extracellular, intramembrane, or intracellular receptor sites. However, all approved agents appear to block sodium conductance at a single receptor site by gaining entrance to the interior of the channel from an intracellular route. Active ionized drugs block the channel predominantly during the activated or inactivated state and bind and unbind with specific time constants (described as fast on/off, slow on/off, and intermediate).

Selective ion channels probably form in response to specific electrical potential differences between the inside and the outside of the cell (voltage dependence). The membrane itself consists of both organized and disorganized lipids and phospholipids in a dynamic sol-gel matrix. During ion flux and electrical excitation, changes in this sol-gel equilibrium occur and permit the formation of activated ion channels. Besides channel formation and membrane composition, intrachannel proteins or phospholipids, referred to as *gates*, also regulate the transmembrane movement of ions. These gates are thought to be positioned strategically within the channel to modulate ion flow (see Fig. 17–2). Each ion channel conceptually has two types of gates: an activation gate and an inactivation gate. The activation gate opens during depolarization to allow the ion current to enter or exit from the cell, and the inactivation gate closes to stop ion movement. When the cell is in a rested state, the activation gates are closed, and the inactivation gates are open. The activation gates then open to allow ion movement through the channel, and the inactivation gates later close to stop ion conductance. Therefore, the cell cycles between three states: resting, activated or open, and inactivated or closed. Activation of SA and AV nodal tissue depends on a slow depolarizing current through calcium channels and gates, whereas activation of atrial and ventricular tissue depends on a rapid depolarizing current through sodium channels and gates.

ABNORMAL CONDUCTION

The mechanisms of tachyarrhythmias classically have been divided into two general categories: those resulting from an abnormality in impulse generation, or “automatic” tachycardias, and those resulting from an abnormality in impulse conduction, or “reentrant” tachycardias. Automatic tachycardias depend on spontaneous impulse generation in latent pacemakers and may be due to several different mechanisms. Experimentally, chemicals such as digitalis glycosides and catecholamines and conditions such as hypoxemia, electrolyte abnormalities (e.g., hypokalemia), and fiber stretch (e.g., cardiac dilatation) may lead to an increased slope of phase 4 depolarization in cardiac tissues other than the SA node. These factors, which lead experimentally to abnormal automaticity, are also known to be arrhythmogenic in clinical situations. The increased slope of phase 4 causes heightened automaticity of these tissues and competition with the SA node for dominance of cardiac rhythm. If the rate of spontaneous impulse generation of the abnormally automatic tissue exceeds that of the SA node, then an automatic tachycardia may result. Automatic tachycardias have the following characteristics: (1) The onset of the tachycardia is not related to an initiating event such as a premature beat, (2) the initiating beat is usually identical to subsequent beats of the tachycardia, (3) the tachycardia cannot be initiated by programmed cardiac stimulation, and (4) onset of the tachycardia usually is preceded by a gradual acceleration in rate and termination by a deceleration in rate. Clinical tachycardias owing to the classic forms of enhanced automaticity, as just described, are not as common as once thought. Examples are sinus tachycardia and junctional tachycardia.

Triggered automaticity is also a possible mechanism for abnormal impulse generation. Briefly, *triggered automaticity* refers to transient membrane depolarizations that occur during repolarization (early after-depolarizations [EADs]) or after repolarization (delayed afterdepolarizations [DADs]) but prior to phase 4 of the action potential. After-depolarizations may be related to abnormal calcium and sodium influx during or just after full cellular repolarization. Experimentally, early after-depolarizations may be precipitated by hypokalemia, type Ia antiarrhythmic drugs, or slow stimulation rates—any factor that blocks the ion channels (e.g., potassium) responsible

FIGURE 17-3. Conduction system of the heart. The magnified portion shows a bifurcation of a Purkinje fiber traditionally explained as the etiology of reentrant ventricular tachycardia. A premature impulse travels to the fiber, damaged by heart disease or ischemia. It encounters a zone of prolonged refractoriness (area of unidirectional block) (*cross-hatched area*) but fails to propagate because it remains refractory to stimulation from the previous impulse. However, the impulse may slowly travel (*squiggly line*) through the other portion of the Purkinje twig and will “reenter” the cross-hatched area if the refractory period is concluded and it is now excitable. Thus the premature impulse never meets refractory tissue; circus movement ensues. If this site stimulates the surrounding ventricle repetitively, clinical reentrant ventricular tachycardia results.

for cellular repolarization. EADs provoked by drugs that block potassium conductance and delay repolarization are the underlying cause of torsade de pointes. Late after-depolarizations may be precipitated by digitalis or catecholamines and suppressed by calcium channel inhibitors and have been suggested as the mechanism for multifocal atrial tachycardia, digitalis-induced tachycardias, and exercise-provoked ventricular tachycardia. Triggered automatic rhythms possess some of the characteristics of automatic tachycardias and some of the characteristics of reentrant tachycardias (described below).

As mentioned previously, the impulse originating from the SA node in an individual with sinus rhythm eventually meets previously excited and thus refractory tissue. Reentry is a concept that involves indefinite propagation of the impulse and continued activation of previously refractory tissue. There are three conduction requirements for the formation of a viable reentrant focus: two pathways for impulse conduction, an area of unidirectional block (prolonged refractoriness) in one of these pathways, and slow conduction in the other pathway (Fig. 17-3). Usually a critically timed premature beat initiates reentry. This premature impulse enters both conduction pathways but encounters refractory tissue in one of the pathways at the area of unidirectional block. The impulse dies out because it is still refractory from the previous (sinus) impulse. Although it fails to propagate in one pathway, the impulse may still proceed in a forward direction (antegrade) through the other pathway because of this pathway’s relatively shorter refractory period. The impulse may then proceed through a loop of tissue and “reenter” the area of unidirectional block in a backward direction (retrograde). Because the antegrade pathway has slow conduction characteristics, the area of unidirectional block has time to recover its excitability. The impulse can proceed retrograde through this (previously refractory) tissue and continue around the loop of tissue in a circular fashion. Thus the key to the formation of a reentrant focus is crucial conduction discrepancies in the electrophysiologic characteristics of the two pathways. The reentrant focus may excite surrounding tissue at a rate greater than that of the SA node, and a clinical tachycardia results. This model is anatomically determined in that there is only one pathway for impulse conduction with a fixed circuit length. Another model of reentry, referred to as a *functional reentrant loop* or *leading circle model* also may occur¹ (Fig. 17-4).
