EVOKED POTENTIALS

Evoked potentials may be helpful in establishing areas of demyelination that are clinically silent. Slowed conduction of visual, brain stem, and somatosensory potentials can be identified, although the sensitivity and specificity of these tests seem to be somewhat less than that seen with MRI or CSF evaluation.

BLOOD STUDIES

A recent report has documented that in CIS patients with abnormal brain MRIs and abnormal CSF consistent with MS, presence or absence of antimyelin antibodies in serum is very helpful in defining prognosis for further events consistent with clinically definite MS.⁶⁵

DIFFERENTIAL DIAGNOSIS

A number of disorders can mimic MS. Thus most patients are screened with blood tests for rheumatologic, collagen-vascular, infectious, and sometimes inherited metabolic diseases. MRI may rule out tumors and cervical spondylosis. There are many causes of nonspecific T₂ and FLAIR lesions seen in the subcortical white matter on a brain MRI, however, and use of established criteria for distinguishing MS lesions from other etiologies (e.g., migraine, hypertension, age greater than 50 years, and others) enhances diagnostic accuracy. Electromyography may help in diagnosing amyotrophic lateral sclerosis. Magnetic resonance angiography (MRA) and more traditional angiography may be useful in identifying CNS vasculitis and vascular malformations.

► TREATMENT: Multiple Sclerosis

Treatment of MS falls into three broad categories: symptomatic therapy, treatment of acute attacks, and disease-modifying therapies to alter the natural course of the disease. Symptomatic management of the disease is of utmost importance to maintain the patient's quality of life. Treatment of acute attacks will shorten the duration and possibly decrease the severity of the attack. Disease-modifying therapies that alter the course of the illness are most important to diminish progressive disability over time. In present usage, both attack therapies and disease-modifying therapies are based on principles of manipulation of the immune system and can be classified as immunotherapies. The basic goals of immunotherapy are to decrease the frequency and severity of exacerbations, diminish the progression of lesions seen on brain and spine MRIs, and slow progression of disability over time. Current therapies are variably successful at achieving these goals, and none is able to restore neurologic function in damaged nervous systems.^{66,67}

A number of different treatment modalities have been studied in the last 30 years, but many older trials had flawed designs.^{66,67} There are no universally accepted treatment algorithms, and treatments vary among clinicians and centers. Perhaps more important, treatment decisions frequently are based on the wishes and goals of individual patients. One potential algorithm for the immunotherapy of MS is shown in Fig. 53–3.

CLINICAL CONTROVERSY

When patients initially show signs of MS, many practitioners begin treatment with interferon- β or glatiramer acetate (ABC-R medications). However, it is controversial as to which medication to start. Most practitioners assist patients in making the decision of which medication best fits their lifestyle and offers the maximum efficacy. In patients with severe depression, interferon therapy is contraindicated, and patients are encouraged to use glatiramer acetate. None of the therapies should be used during pregnancy, while attempting to get pregnant, or while breastfeeding.

■ TREATMENT OF ACUTE EXACERBATIONS

4 Mild acute exacerbations that do not produce functional decline may not require treatment.⁶⁸ When functional ability is affected, although treatment suggestions may vary among clinicians, the standard intervention is intravenous injection of high-dose corticosteroids for 3 to 5 days. Results from a large trial of optic neuritis suggest and the American Academy of Neurology recommends that if treatment with steroids is warranted, it is best to use intravenous methylprednisolone. The mechanism of action for corticosteroids in MS is unknown, but it is speculated that steroids improve recovery by decreasing edema in the area of demyelination.⁶⁸

High-dose methylprednisolone has been shown to shorten the duration of acute exacerbations,⁶⁸ and it may delay repeat attacks after optic neuritis, although it has not been shown definitively to affect the progression of disease.^{67,69}

Comparative trials of the steroid precursor adrenocorticoid hormone (ACTH) and high-dose intravenous steroids suggest that steroids produce a quicker and more predictable improvement in acute exacerbations. Although the reasons for this are not entirely clear, differences between agents may be due to the variable adrenal secretion

of endogenous glucocorticoids following ACTH stimulation.^{65,68,70} The use of ACTH, therefore, largely has been supplanted by methylprednisolone.

5 Methylprednisolone doses may range from 500 to 1000 mg/day, given intravenously. The duration of therapy is variable and may range from 3 to (rarely) 10 days depending on clinical response. A standard time is 3 to 5 days. Some clinicians offer prednisone or other oral tapers to patients after the intravenous injections, but others do not, in an effort to limit lifetime exposure to steroids and resulting side effects. If improvement occurs, it is usually seen in the first 3 to 5 days.

A very small number of patients have very severe attacks, manifested by hemiplegia, paraplegia, or quadriplegia. If these patients fail to improve with aggressive steroid therapy, a recent study suggests that treatment with plasma exchange every other day for seven treatments may be beneficial for about 40% of patients.^{71,72}

CLINICAL CONTROVERSY

If a patient taking interferon decompensates and has neutralizing antibodies in the blood, most practitioners will stop the medication. In this situation it is controversial whether to rechallenge the patient at a later date with interferon therapy. Many clinicians will only rechallenge with interferon therapy if the patient does not do well on other therapies.

■ DISEASE-MODIFYING THERAPY: REDUCTION OF RELAPSES AND PROGRESSION (ABC-R THERAPY WITH AVONEX, BETASERON, COPAXONE, AND REBIF)

■ INTERFERON- β -1b AND INTERFERON- β -1a

6 Interferon- β -1b (Betaseron) was the first agent proven to alter the natural history of the illness.⁶⁵ Interferon- β -1b is a nonglycosylated synthetic analog of recombinant interferon- β and is produced synthetically in *Escherichia coli*. Although the exact mechanism of action is unknown, its effect in MS may be due to its immunomodulating properties, including the ability to augment suppressor cell function and reduce interferon- γ secretion by activated lymphocytes, its macrophage-activating effect, and its ability to downregulate the expression of interferon- γ -induced class II MHC gene products on antigen-presenting glial cells.⁶⁵ Interferon- β -1b also suppresses T-cell proliferation and may decrease BBB permeability.⁶⁵

Interferon- β -1b is administered every other day subcutaneously at a dose of 8 million IU. Clinical trials have demonstrated that at these doses, interferon- β -1b significantly reduces annual relapse rate and MRI burden of disease compared with placebo. With respect to clinical disability, however, no significant differences were noted between the interferon- and placebo-treated groups.⁶⁵ Betaseron is packaged in premixed syringes with a new formulation that does not require refrigeration. Betaseron costs approximately \$15,283 per year.

Interferon- β -1a (Avonex and Rebif) is a natural-sequence glycosolated interferon produced in recombinant Chinese hamster ovary cells. Avonex is given as 30 mcg (6 million IU) intramuscularly (IM) once weekly. The prefilled syringes should be refrigerated but may be kept at room temperature for 30 days. Avonex costs approximately \$12,915 per year. Rebif is given as 44 mcg subcutaneously three times weekly. It is supplied in a 0.5-mL prefilled syringe with an

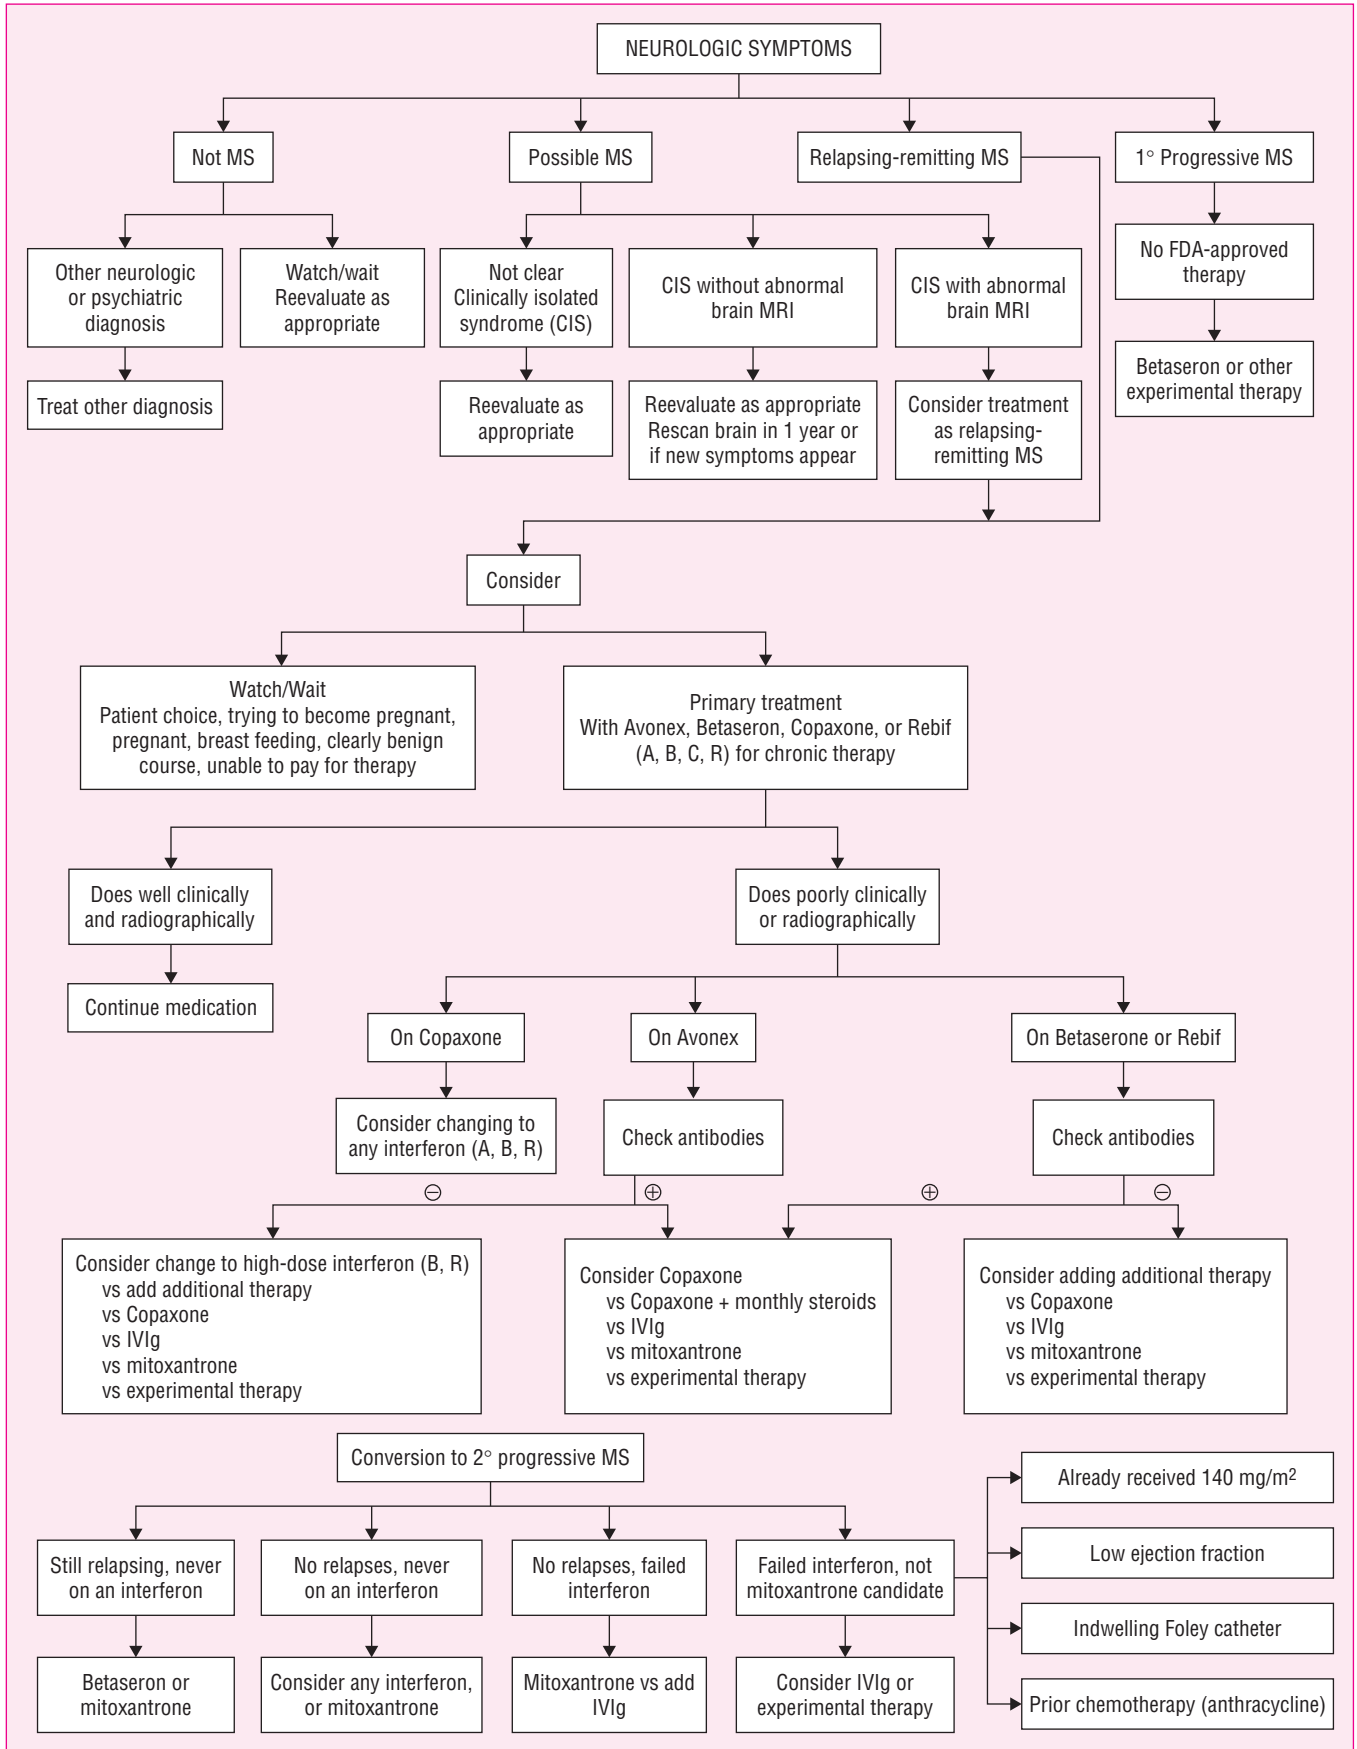

FIGURE 53-3. Algorithm for management of relapsing-remitting multiple sclerosis.

autoinjector and costs approximately \$16,730 per year. Rebif also should be kept refrigerated, but it is stable at room temperature for 30 days.

When given 30 mcg intramuscularly once weekly for 2 years,⁶⁵ patients receiving interferon- β -1a (Avonex) demonstrated, compared with patients receiving placebo, statistically significant reductions in annual relapse rate (by approximately one-third) as well as disease progression, which was defined as a confirmed increase of 1 point on the EDSS. Disease progression also was assessed by MRI studies, and patients receiving active drug had significantly fewer new enhancing lesions compared with placebo-treated patients. Similar results were seen with higher dose (44 mcg), more frequent administration (three times weekly), and subcutaneous injection of interferon- β -1a (Rebif).⁷³ Indeed, the effects on MRI burden of disease were more profound with Rebif than with Avonex in studies done separately.⁷³ More recent studies reveal significant effects on slowing brain atrophy⁷⁴ and the progression of cognitive decline⁷⁵ in patients treated with Avonex. Taken together, these observations show that interferon- β possesses significant disease-modifying activity.

Side effects are similar with all the interferons. Baseline complete blood counts, platelet determinations, and liver function tests should be documented before starting therapy, every 3 months for 1 year, and every 6 months thereafter. The most common adverse effects include injection-site redness, swelling, and possibly necrosis, as well as flulike symptoms (e.g., fever, chills, myalgias). These symptoms can be mild or severe and are seen in most patients. The flulike side effects typically occur for up to 24 hours after injection and are seen for 1 to 3 months after starting the injections. Injection-site reactions probably are worse with interferon- β -1b, may occur at any time, and can be lessened by using appropriate injection technique, including site rotation (thighs and buttocks) and hydrocortisone cream. Ice applied before and/or after the injection also may decrease the pain and the redness, as may the use of an autoinjector for the subcutaneous injections. Allowing the medications to be at body temperature (place under arm pits) will decrease injection-site pain. Nonsteroidal anti-inflammatory agents (NSAIDs) or acetaminophen taken before and at regular intervals for 24 hours after administration may alleviate the flulike symptoms. Initiation of one-quarter or one-half the standard dose and then increasing to full dosage over 1 to 2 months also may be beneficial in reducing flulike side effects.⁷⁶ Some authors suggest that because of the transient immune activation that may occur following the introduction of interferon- β , a short burst of oral prednisone may alleviate some adverse effects.⁷⁶

Less commonly reported side effects include shortness of breath, tachycardia, and depression. Clinicians must monitor patients carefully for signs of depression and treat accordingly. Although depression is a common finding in MS patients, all the interferons, especially interferon- β -1b, may produce depressive symptoms. Patients who develop depression should be monitored closely because there may be a risk for suicide. The other side effects usually are transient. Most patients will not feel better or have improvement in symptoms when taking this drug, and many will experience side effects; thus compliance may become a major issue. Finally, safety data on interferon- β in pregnancy and lactation are lacking. Abortifacient activity in primates has been noted, however. Until adequate safety data are available, women should be counseled as to appropriate contraception while using these products.

Although the adverse-effect profile of interferon- β -1a resembles that of interferon- β -1b, intramuscular interferon- β -1a (Avonex) may hold several advantages, including markedly fewer local injection-site reactions and once-weekly administration versus subcutaneous injection every other day (or three days per week with Rebif). Treatment-

emergent depression also may be less common with interferon- β -1a than with interferon- β -1b.⁷⁷

■ GLATIRAMER ACETATE (COPAXONE)

Glatiramer acetate (Copaxone, formerly known as *copolymer-1*) is a synthetic polypeptide consisting of L-alanine, L-glutamic acid, L-lysine, and L-tyrosine. Although the precise mechanism of action of this compound is unknown, glatiramer acetate appears to mimic the antigenic properties of MBP.⁷⁸ This agent also may act by directly binding to MHC class II receptors and inhibiting binding of MBP peptides to T-cell receptor complexes.⁷⁸ Recently, glatiramer acetate has demonstrated that it induces Th2 (anti-inflammatory) lymphocytes in experimental allergic encephalomyelitis (EAE).⁷⁸ This is thought to contribute to “bystander” suppression at the site of the MS lesion and thereby reduce inflammation, demyelination, and axonal damage.⁷⁹ Glatiramer acetate also may suppress T-cell activation.

It is given as a daily 20-mcg subcutaneous dose. Glatiramer acetate appears to have a relatively mild adverse-effect profile. Mild pain and pruritus at the injection site are the most frequent patient complaints. Approximately 10% of patients will experience a transient reaction consisting of chest tightness, flushing, and dyspnea beginning several minutes after injection and lasting usually no longer than 20 minutes. If patients have no history or evidence of coronary artery disease, they may be assured that these reactions are almost always self-limited and benign. Several adverse effects that have been associated with the interferons, including flulike symptoms and depression, do not appear to be provoked by glatiramer acetate. Multicenter trials with glatiramer acetate have demonstrated statistically significant reductions in mean annual relapse rate (~25%) that are comparable with the interferons. An extension trial, completed after the original, pivotal 2-year study, suggests that glatiramer acetate may slow the progression of disability in patients with RRMS.⁷⁹ Glatiramer acetate also slows development of T₁ holes on brain MRIs,⁸⁰ and long-term uncontrolled data show that it remains safe and effective for individuals who continue to take it over 8 years.⁸¹

■ REMAINING QUESTIONS FOR ABC-R THERAPY

Despite encouraging results from well-conducted clinical trials, several relevant issues remain. The most important question in the use of the ABC-R drugs is when to begin therapy. The Medical Advisory Board of the National Multiple Sclerosis Society has adopted recommendations regarding the use of the current MS disease-modifying agents, and these are summarized in Table 53–3.⁸²

Decisions about the use of any medication rest on determination of the severity of the illness, the efficacy of the medication, and the side effects and costs related to the therapy. Clearly, these drugs slow the course of the illness but do not suppress it completely, and in some individuals, there is no apparent benefit. These drugs also require injections and have side effects and costs that limit their use. There is now, however, overwhelming evidence that the vast majority of untreated patients will have progressive disease over time. Pathologic data clearly show that even in acute lesions there is significant axonal damage that is essentially irreversible. MRI data show that 80% to 90% of all new enhancing lesions are asymptomatic, suggesting that a “quiet” clinical course does not necessarily mean that there is not ongoing disease activity that ultimately will be reflected in cognitive problems and mood disorders.

TABLE 53–3. Disease Management Consensus Statement (Abridged)

- Initiation of therapy is advised as soon as possible following a definite diagnosis of MS and determination of a relapsing course.
- Patients' access to medication should not be limited by the frequency of relapses, age, or level of disability.
- Treatment is not to be stopped during evaluation for continuing treatment.
- Therapy is to be continued indefinitely, unless there is clear lack of benefit, intolerable side effects, new data that reveal other reasons for cessation, or better therapy becomes available.
- All three agents should be included in formularies and covered by third-party payers so that physicians and patients may determine the most appropriate agent on an individual basis.
- Movement from one immunomodulating drug to another should be permitted.
- Most concurrent medical conditions do not contraindicate use of any of these therapies.

Modified from Ref. 82.

Furthermore, it is now known that very early therapy is effective. In patients with CIS and two or more T₂ lesions on brain MRI (i.e., at high risk for developing clinically definite MS), treatment with Avonex produced, compared with patients receiving placebo, a 44% reduction in the likelihood of patients going on to have a second clinical attack over a 2-year period of study. Several MRI measures also were significantly better in treated patients.^{61,83} Similar results were seen with low-dose weekly Rebif.⁸⁴ Thus not only is very early therapy warranted, but it is also effective and is now approved by the FDA. Indeed, the National MS Society recommends that patients with relapsing disease should be placed on ABC-R therapy immediately after the diagnosis.⁸²

A second major issue is which drug to use in which patient. There has not been a single, randomized study comparing all four drugs with one another in a similar patient population at the same time.⁸⁵ The pivotal placebo-controlled trials produced results that were more similar than different when comparing across trials, including a nearly identical one-third reduction in relapse rate for all four drugs over 2 years. There has been speculation for some time, however, that higher dose and/or more frequent administration of interferon (Rebif or Betaseron) may be more beneficial than the lower dose once-weekly use of interferon (Avonex). To address this issue, two comparative trials of Avonex versus Betaseron⁸⁶ and Avonex versus Rebif⁸⁷ have now been completed. In both cases, Avonex was used in the standard 30 mcg per week intramuscular injection, and the other interferons were used at the usual higher dose, more frequent subcutaneous administration, as in a typical clinical practice. In both studies, there were small but statistically significant differences favoring Betaseron or Rebif in a variety of clinical and MRI measures of efficacy, and it was this short-term (6-month) comparative trial⁸⁷ that resulted in FDA approval of Rebif in the United States in 2002.

There were many scientific objections to these trials, most important of which was lack of control of dosing versus frequency of administration, absence of blinding of clinical outcomes, and the use of novel primary outcome measures with unclear biologic or clinical significance. In addition, published around the same time was a trial comparing 60 mcg with the standard 30 mcg Avonex in a weekly injection showing no difference over a 2-year study.⁸⁸ Thus the significance of these Phase IV marketing-driven studies remains to be determined.

A concern with all three interferon products that further muddies our understanding of the clinical differences between the interferon products is the development of neutralizing antibodies. In clinical trials, 38% of patients receiving interferon- β -1b developed antibodies directed against the drug.⁸⁹ In these patients, the exacerbation rate was similar to that in placebo-treated patients. With interferon- β -1a, neutralizing antibodies were found in 22% of early trials of Avonex, but later studies reported that only about 2% to 5% of treated patients developed antibodies.⁸⁸ Percentages for Rebif are intermediate, at about 22%.⁸⁷ The long-term clinical significance of these findings, however, is still unclear,⁶⁵ although most data are similar to the Betaseron data described earlier, i.e., suggesting reduction in clinical efficacy with production of antibodies. Whether these antibodies are truly cross-reactive between products is unknown, as is the duration during which antibodies may be detected. The clinical relevance of neutralizing antibodies must be evaluated prospectively. Significant neutralizing antibodies have not been seen with glatiramer acetate.

Intriguingly, *in vitro* data suggest a potential synergism between glatiramer acetate and interferon- β . Given the cost of these therapies, as well as the potential for additive adverse effects, this therapeutic combination cannot be recommended until clinical evidence demonstrating benefit is available. A study that will compare glatiramer acetate alone with interferon- β -1a (Avonex) alone versus a combination of the two has just been funded by NIH and is underway, with results expected in several years.

All four of the ABC-R drugs are approved by the FDA for relapsing forms of the disease. Clinical trials of Betaseron, Avonex, and Rebif in SPMS have had mixed results.^{90–92} Based primarily on a large European trial of Betaseron,⁹⁰ there is a suggestion that patients with SPMS and ongoing attacks or enhancing MRI lesions may benefit from using interferon, whereas those without such findings will not. Indeed, the FDA has now approved interferon- β -1b for use in SPMS when the patient continues to experience superimposed relapses, but neither interferon- β -1a product is approved by the FDA for SPMS. A planned 3-year trial of glatiramer acetate in PPMS was halted after 2 years when it was determined there was little likelihood continuation of the trial would result in a significant difference between the treated and placebo groups. Alternative delivery routes, including nasal and oral, are being studied but have not yet been shown to be effective. Finally, determination of “treatment failure” or inadequacy and treatment options in the event of progression of disease while on ABC-R therapy remains a difficult question.

OTHER THERAPIES

Short-term, intensive pulse doses of corticosteroids, similar to those used in acute exacerbations, initially may decrease disability, but prolonged steroid therapy has no established effects on the progression of disease.^{65,69} If progression continues while a patient is on a disease-modifying agent, an immunosuppressive agent may be tried.

Mitoxantrone (Novantrone), a member of the anthracenediene family, has now been approved by the FDA for reducing neurologic disability and/or the frequency of clinical relapses in patients with SPMS (chronic), PRMS, or worsening RRMS.⁶⁵ Mitoxantrone is administered as a brief (5- to 15-minute) intravenous infusion dosed at 12 mg/m² every 3 months. An evaluation of left ventricular ejection fraction is required prior to administration of the initial dose, before each dose, after an accumulated dosage of 100 mg/m² has been reached, and if signs or symptoms of congestive heart failure develop. The maximum allowable lifetime cumulative dose of mitoxantrone is

TABLE 53–4. Treatment of Selected Primary MS Symptoms

| Spasticity | Bladder Symptoms | Sensory Symptoms | Fatigue |
|------------|-----------------------------|-----------------------------|-------------------|
| Baclofen | Proprantheline | Carbamazepine | Amantadine |
| Dantrolene | Oxybutinin | Phenytoin | Pemoline |
| Diazepam | Dicyclomine | Amitriptyline or other TCAs | Antidepressants |
| Tizanidine | DDAVP | Gabapentin | Modafanil |
| Tiagabine | Self-catheterization | Lamotrigine | Methylphenidate |
| Gabapentin | Imipramine or amitriptyline | | Dextroamphetamine |
| | Prazosin | | |
| | Botulinum toxin type A | | |

140 mg/m².⁹³ Other potential side effects noted with this agent are nausea, alopecia, menstrual disorder, amenorrhea, upper respiratory tract infection, urinary tract infection, and leukopenia.⁹³ The role mitoxantrone will play in the treatment of MS remains unclear because potential cardiac toxicity appears to limit its long-term use. Currently, there are no proven therapies for the treatment of PPMS,⁹⁴ and a recent trial of Copaxone in PPMS was halted after 2 years of a planned 3-year trial owing to a lack of efficacy.

A number of other agents have been studied over the last 30 years but have either failed to provide definitive benefit, or the data are still evolving. Cyclophosphamide has been studied alone and in combination with other treatment modalities in attempts to slow progression of MS.⁹⁵ Maintenance therapy with intermittent (monthly) pulse doses of cyclophosphamide may slow the progression of disease in younger patients with rapidly progressive disease, but further study is required to confirm benefit in these patients. Prolonged therapy with cyclophosphamide usually is intolerable, but it appears that some form of maintenance is necessary.⁹⁵ Cyclosporine appears to produce only a modest delay in the progression of disability in chronic progressive MS. A significant number of patients may develop severe side effects, in particular nephrotoxicity and hypertension,⁹⁶ which may limit the usefulness of cyclosporine.

Conflicting results have been seen when azathioprine is used alone or in combination with other therapies. Reductions in the exacerbation rate and slowing of disease progression are only modest. It is usually given in doses of 2 to 3 mg/kg until the white blood cell count drops to less than 4000/mm³. It is then followed with corticosteroid therapy.⁶⁷ Although not without serious side effects, azathioprine may be less toxic than cyclophosphamide and may be tolerated for a longer period of time. Methotrexate given as 7.5 mg orally each week also has shown modest benefit in slowing disease progression.⁶⁷

Other experimental modalities include total lymphoid irradiation (TLI), interferon- α , monoclonal antibodies, cladribine, and intravenous immune globulin (IVIG).⁹⁷ IVIG may stimulate remyelination of neurons in established MS lesions. Further studies are required to confirm the observation of reduced exacerbations and improved neurologic function. Two monoclonal antibodies, one⁹⁸ directed against a cellular adhesion molecule (natalizumab, Antegren) and the other⁹⁹ against the lymphocyte cell marker CD52 (alemtuzumab, Campath), have shown significant activity in preliminary studies, especially with effects on gadolinium-enhancing lesions in relapsing patients, and both are in Phase III studies now. High-dose immunoablation therapy followed by stem cell rescue has been used in a small number of patients around the world with promising preliminary results,^{100,101} but this approach has significant potential toxicities that likely will limit its use to those with severe disease. Rituximab directed against CD20 cells may prove to be beneficial in the treatment of MS.

SYMPTOMATIC MANAGEMENT

Many of the symptoms of MS do not require pharmacologic management or do not respond to it. This section covers the primary symptoms in which pharmacologic management may be of benefit (Table 53–4). See the preceding section on the treatment of acute exacerbations for a discussion on optic neuritis.

GAIT DIFFICULTIES AND SPASTICITY

Problems with gait may be due to spasticity, weakness, ataxia, defective proprioception, or a combination of these factors. Spasticity is amenable to pharmacologic intervention, whereas physical therapy may be required in treating gait disturbances owing to any of the other factors. Spasticity is encountered commonly and tends to affect the legs more markedly than the arms. Spasticity may result in falls; however, in the later stages of the disease, the increased muscle tone of a spastic limb often lends strength to patients with underlying weakness. Therefore, when using muscle relaxants, one must be careful not to decrease the tone to an extent where ambulation is actually hindered.^{102,103} Baclofen (Lioresal), a γ -aminobutyric acid (GABA) analog, is the preferred agent and usually is started in dosages of 10 mg three times daily and titrated upward to achieve the desired response. Most patients will achieve a satisfactory response with dosages between 40 and 80 mg/day; however, dosages higher than the recommended daily maximum of 80 mg are required by some patients.^{102,103} Continuous intrathecal administration of baclofen may be an option for patients unable to tolerate or unresponsive to oral therapy. Baclofen should not be discontinued abruptly to avoid the possibility of seizures.¹⁰³ Small doses of diazepam (e.g., 0.5–1 mg) often are added to baclofen in patients in whom optimal response has not been achieved.

A newer agent, tizanidine (Zanaflex), is a short-acting, centrally acting α -adrenergic agonist that can reduce spasticity by increasing presynaptic inhibition of motor neurons. It appears to have efficacy comparable with that of baclofen.¹⁰³ Dosage must be titrated slowly over 2 to 4 weeks, starting with 4 mg at bedtime with adjustments based on clinical response. Effective tolerated dosages have ranged from 2–36 mg/day. Sedation, dizziness, and dry mouth are the most commonly reported adverse effects, but hypotension also can occur, as well as a rare but severe hepatotoxicity. Increased aminotransferase activity was noted in 5% of patients during clinical trials. In patients who are unable to tolerate baclofen or tizanidine, diazepam (Valium), clonazepam (Klonopin), or dantrium sodium (Dantrolene) may be considered as alternatives, but they generally are less effective than either baclofen or tizanidine. Mild spasticity also may respond to

moderately high doses of gabapentin (Neurontin). Tiagabine (Gabitril) may be useful in some patients with spasticity, but side effects may prohibit its use.

■ TREMOR

Cerebellar symptoms such as tremor can be troubling and difficult to control. Medications that may be helpful include propranolol, primidone, and isoniazid.

■ BOWEL AND BLADDER SYMPTOMS

Patients commonly complain of incontinence, urgency, frequency, and nocturia, which are indications of a hyperreflexic bladder (i.e., inability to store urine). A number of anticholinergic agents, including oxybutynin chloride (Ditropan, 10–20 mg/day), tolterodine (Detrol, 2–4 mg/day), propantheline bromide (Probanthine, 45–90 mg/day), and dicyclomine hydrochloride (Bentyl, 30–80 mg/day) are used to treat this problem if symptoms are mild. Ditropan is now also available in an extended-release formulation (5 and 10 mg). In addition, tricyclic antidepressants, such as imipramine (Tofranil) and amitriptyline (Elavil), also have been used for their anticholinergic properties. With all anticholinergic agents, great care must be used to avoid the problem of constipation, which is worsened by the patient's natural instinct to limit fluid intake (owing to the increasing the urge to urinate). As an alternative, the synthetic antidiuretic hormone preparation desmopressin (DDAVP) has been reported to be effective in the treatment of urgency and incontinence.¹⁰⁴ Use of DDAVP probably is best limited to bedtime so as to improve sleep because there may be significant problems with hyponatremia and possible seizures if overused. Patients with significant sphincter activity may benefit from the oral use of α -adrenergic blockers such as prazosin (Mini-press) or intramuscular use of botulinum toxin type A (Botox).

Intermittent self-catheterization with or without a concomitant anticholinergic agent is recommended in patients with large postvoid urine residual volumes (>100 mL) or when the urinary problem is hyporeflexic in nature (failure to empty). Patients with large postvoid residual volumes are at risk for developing urinary tract infections and often are prescribed urinary acidifiers such as vitamin C or antiseptics such as methenamine mandelate to prevent infections.

Constipation is the most common bowel complaint. Increases in dietary fiber and hydration may alleviate this problem, but in some instances laxatives or enemas may be necessary.¹⁰²

CLINICAL CONTROVERSY

In a depressed patient with a new diagnosis of MS, it is controversial whether to start interferon therapy because depression is a side effect of the interferon therapies, and the incidence of suicide is higher in this population. Practitioners generally will start patients on an antidepressant along with the interferon and watch them closely. Never should interferon be started in a severely depressed patient.

■ MAJOR DEPRESSION

⚠ Major depression is common in patients with MS, and the risk of suicide may be increased markedly as compared with healthy subjects.¹⁰⁵ Patients should be monitored closely for the development

of major depressive symptomatology and treated accordingly (see Chap. 67). Interferon products should be used cautiously in patients with significant depression.

■ SENSORY SYMPTOMS

Numbness and paresthesias are frequent sensory complaints but usually do not require treatment. Some MS patients may develop acute or chronic pain syndromes,¹⁰³ such as trigeminal neuralgia and painful dysesthesias, for which treatment is necessary. Carbamazepine (Tegretol) is the preferred agent for the treatment of trigeminal neuralgia and is used in the same doses that are used for the treatment of seizure disorders. Painful dysesthesias (i.e., burning sensations that occur commonly in the extremities) often respond to treatment with tricyclic antidepressants, carbamazepine, gabapentin, or other anticonvulsant medications such as lamotrigine (Lamictal).

■ SEXUAL DYSFUNCTION

Sexual dysfunction in both men and women is also common in MS, and counseling should be offered to both partners. Sildenafil citrate (Viagra), tadalafil (Cialis), and vardenafil (Levitra) are very effective for men with MS who have erectile dysfunction. Viagra is currently being studied in the female population with MS and sexual dysfunction.

■ FATIGUE

Fatigue, one of the most common complaints in MS patients, can be severely disabling. Typically present in the late to middle afternoon, it may increase with heat exposure, exertion, intercurrent infection, spasticity, weakness, and depression. Amantadine hydrochloride (100 mg twice daily) is used often and may offer significant relief.¹⁰³ Pemoline (Cylert) also has been used in doses starting at 18.75 to 37.5 mg/day,¹⁰³ but its use is limited by an FDA advisory suggesting very frequent monitoring of liver function tests owing to potential toxicity. Methylphenidate (Ritalin) and dextroamphetamine (Dexedrine) also are used commonly for fatigue in MS. Modafanil (Provigil), at 100 mg twice daily, is also helpful for MS-related fatigue. Antidepressants may be helpful, but only if the patient exhibits symptoms of depression. Otherwise, the sedating effects may worsen fatigue.

The aminopyridines, 4-aminopyridine and 3,4-diaminopyridine,¹⁰⁶ are potassium channel blockers that are currently under investigation in the symptomatic treatment of MS. These agents may improve conduction in demyelinated axons and may improve strength and decrease heat sensitivity.

Each symptom should be assessed individually, and therapy with available agents should be tried and modified when needed. In addition to counseling patients regarding the adverse effects associated with medications, pharmacists also should actively encourage patients to comply with their prescribed regimens.

■ COMPLEMENTARY AND ALTERNATIVE THERAPIES FOR MS

A large percentage of patients with MS use complementary or alternative medicine (CAM) instead of or in addition to disease-modifying

and symptomatic therapies. Common CAM therapies include diet and dietary supplements, such as vitamins, minerals, and herbs. To date, no one diet or dietary supplement has proven to modify the course of MS. Mildly beneficial results have been seen in clinical trials with diets that increase the intake of polyunsaturated fatty acids (PUFAs). Omega-3 fatty acid is an example of polyunsaturated fatty acids and may be obtained through fatty fish, such as salmon or tuna. Suggestive results have been obtained from *in vitro* and animal studies with vitamin D, ginkgo biloba, cannabinoids, and an herbal medicine known as Padma 28. Antioxidant supplements vitamin A, C, E, α -lipoic acid (ALA), CoQ10, grape seed, and pine bark extracts also have suggestive evidence in benefiting MS patients. However, for patients with MS, there is a theoretical risk involved with taking antioxidant supplements owing to their ability to stimulate the immune system (T cells and macrophages). Stimulating the immune system in a patient with MS could be counterproductive, possibly worsening or exacerbating their disease, and may counteract the effects of immunomodulators. Other immune-stimulating supplements that should be used with caution are garlic, ginseng (Asian and Siberian), echinacea, cat's claw, astragalus, alfalfa, and stinging nettle. A few agents that may pose a problem in MS but also may have benefit are zinc, melatonin (for insomnia), and dehydroepiandrosterone (DHEA).¹⁰⁷

Even though there is suggestive evidence for some of these CAM therapies, there are insufficient clinical trials supporting their use and safety as disease-modifying therapies for MS. However, for patients with MS who are willing to try new approaches with limited evidence, CAM may be a consideration. Health care providers can be a source of objective information regarding the use of CAM for MS and can assist their patients in making the best decision for them.¹⁰⁷

PHARMACOECONOMIC CONSIDERATIONS

As with many therapeutic decisions, economic cost both to the individual and to society must be considered. Currently, the annual cost of the new potentially disease-modifying therapies is considerable. The cost to the pharmacist of glatiramer and both currently available interferons is between \$10,000 and \$17,000 per patient per year. Given this expense, it must be remembered that these therapies are not curative and that individual patients may experience variable results. Future investigations evaluating these therapeutic modalities clearly will need to address not only clinical but also economic and humanistic outcomes.

EVALUATION OF THERAPEUTIC OUTCOMES

Response to treatment of acute exacerbations of MS is seen commonly within days. With respect to disease-modifying treatments, it is important for the clinician to recognize that over the short term (days to weeks), little or no apparent benefit may be noted by either patient or clinician. Evaluation of therapeutic outcomes, such as decreased MS exacerbations and hospitalizations or perhaps slowed disease progression and disability (as measured using scales such as EDSS), must be conducted over a period of months to years. Patients should be provided with realistic goals and expectations of these treatment options and encouraged to participate in the evaluation of therapeutic response. Initially, it may be important to reevaluate patients at relatively short time intervals to monitor for adverse effects.

Safety monitoring of patients on interferon includes regular laboratory monitoring, patient observation and questioning for adverse effects or changing disability, and regular neurologic examinations.

Specific laboratory monitoring should include a complete blood count, platelet count, and liver function tests. These should be completed at baseline, every 3 months for 1 year, and every 6 months yearly thereafter. Copaxone requires no laboratory monitoring.

CONCLUSION

MS is an inflammatory disease of the CNS that appears to strike young, genetically susceptible individuals living in high-risk geographic areas. Although the exact etiology of MS is unknown, it is likely that MS is an autoimmune disease triggered by a viral infection. There is no cure, but quality of life can be improved through symptomatic management. Because of the relapsing-remitting nature of MS, it is often difficult to assess whether improvement is due to treatment or to the natural course of the disease. The paucity of conclusive evidence for many of the described treatments and the lack of specific guidelines make treatment choices difficult.

ACKNOWLEDGMENT

We would like to acknowledge both Jennifer Stone, Pharm.D., and Ruth C. Taggart, MSN, ANP-C, for their contributions to this chapter.

ABBREVIATIONS

ABC-R: Avonex, Betaseron, Copaxone, and Rebif
 ACTH: adrenocorticotrophic hormone
 ALA: α -lipoic acid
 BBB: blood-brain barrier
 CAM: complementary or alternative medicine
 CD4+: T-helper cells
 CIS: clinically isolated syndrome
 CNS: central nervous system
 CSF: cerebrospinal fluid
 CT scan: computed tomographic scan
 DHEA: dehydroepiandrosterone
 EAE: experimental allergic encephalomyelitis
 EDSS: expanded disability status scale
 GABA: γ -aminobutyric acid
 HHV-6: human herpes virus type 6
 HLA: human leukocyte antigen
 HTLV: human T-cell leukemia virus
 IgG: immunoglobulin G
 IL-2: interleukin-2
 IL-10: interleukin-10
 INF- γ : interferon- γ
 IVIG: intravenous immunoglobulin
 MBP: myelin basic protein
 MHC: major histocompatibility complex
 MRA: magnetic resonance angiography
 MRI: magnetic resonance imaging
 MS: multiple sclerosis
 MSFC: Multiple Sclerosis Functional Composite
 NSAID: nonsteroidal anti-inflammatory drug
 OCBs: oligoclonal bands
 PPMS: primary-progressive multiple sclerosis
 PRMS: primary-relapsing multiple sclerosis
 PUFAs: polyunsaturated fatty acids
 RRMS: relapsing-emitting multiple sclerosis

SPMS: secondary-progressive multiple sclerosis
 SSPE: subacute sclerosing panencephalitis
 TGF- β : transforming growth factor β
 TLI: total lymphoid irradiation
 TNF- α : tumor necrosis factor alpha
 WHO: World Health Organization

EPILEPSY

Barry E. Gidal and William R. Garnett

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Accurate diagnosis and classification of seizure/syndrome type is critical to selection of appropriate pharmacotherapy.
- 2 Patient-specific treatment goal(s) should be identified. Treatment goals may change over time. In general, the goal of treatment should be seizure freedom and no adverse effects.
- 3 Patient characteristics such as age, medical condition, ability to comply with prescribed regimen, and insurance coverage also may influence choice of antiepileptic drugs.
- 4 Pharmacotherapy of epilepsy is highly individualized and requires titration of dose to optimize antiepileptic drug therapy (maximal seizure control with minimal or no side effects). About 70% of patients can be maintained on one antiepileptic drug.
- 5 If the therapeutic goal (seizure freedom and no intolerable adverse effects) is not achieved with maximal monotherapy, a second drug may be added or a switch to an alternative single antiepileptic drug can be made. The second antiepileptic drug should have a different mechanism of action from the first.
- 6 Some patients eventually can discontinue antiepileptic drug therapy. Several factors predict successful withdrawal of antiepileptic drugs.
- 7 The appropriate use of antiepileptic drugs requires a thorough understanding of their clinical pharmacology, e.g., mechanism of action, pharmacokinetics, adverse reaction, dosage forms, and drug interactions.

Epilepsy is a disorder that is best viewed as a symptom of disturbed electrical activity in the brain caused by a wide variety of etiologies. It is a collection of many different types of seizures that vary widely in severity, appearance, cause, consequence, and management. Epilepsy implies a periodic recurrence of seizures with or without convulsions.¹ Seizures that are prolonged or repetitive can be life-threatening. The effect epilepsy has on patients' lives can be extremely frustrating. Indeed, studies have shown that patients with epilepsy who do not experience complete seizure control have lower self-reported quality-of-life scores than patients who are seizure-free. It is also important to recognize that seizures may be just one (albeit the most obvious) symptom of an epileptic disorder. Not uncommonly, patients have other comorbid disorders, including depression, anxiety, and potentially neuroendocrine disturbances. Patients with epilepsy also may display neurodevelopmental delay, memory problems, and/or cognitive impairment. While, by convention, the focus of drug treatment is on the abolition of seizures, clinicians also need be attentive to addressing these common comorbidities.

EPIDEMIOLOGY

Each year, 120 per 100,000 people in the United States come to medical attention because of a newly recognized seizure.^{2,3} At least 8% of the general population will have at least one seizure in a lifetime. However, it is possible to have a seizure and not have epilepsy. The rate of recurrence of a first unprovoked seizure within 5 years ranges between 23% and 80%. Children with an idiopathic first seizure and a normal electroencephalogram (EEG) have a particularly favorable prognosis. Some seizures may occur as single events resulting from withdrawal

of central nervous system (CNS) depressants (e.g., alcohol, barbiturates, and other drugs) or during acute illnesses (such as meningitis or encephalitis) or toxic conditions (e.g., uremia or eclampsia). Some patients will have seizures only associated with fever. These febrile seizures do not constitute epilepsy.²

Epilepsy is a chronic disorder characterized by recurrent seizures.¹ The age-adjusted incidence of epilepsy is 44 per 100,000 person-years. Each year, about 125,000 new epilepsy cases occur; of these, 30% are in people younger than age 18 at the time of diagnosis. There is a bimodal distribution in the occurrence of the first seizure, with one peak occurring in newborn and young children and the second peak occurring in patients older than age 65. The relatively high frequency of epilepsy in the elderly is now being recognized. At least 10% of patients in long-term care facilities are taking at least one antiepileptic drug (AED).

ETIOLOGY

Seizures occur because small numbers of neurons discharge abnormally. Anything that disrupts the normal homeostasis of the neuron and disturbs its stability may trigger abnormal activity and seizures. A genetic predisposition to seizures has been suggested. Patients with mental retardation and cerebral palsy are at increased risk for seizures. The more profound the degree of mental retardation as measured by intelligence quotient (IQ), the greater is the incidence of epilepsy. However, mental retardation is not synonymous with epilepsy. In the elderly, seizures are primarily partial in onset. The causes of seizures in the elderly may be multifactorial and include cerebrovascular disease (both ischemic and hemorrhagic stroke), neurodegenerative

disorders, tumor, head trauma, metabolic disorders, and CNS infections. In some cases, if an etiology can be found and corrected, the patient will not require chronic AED treatment. In many cases, patients will present with seizures that do not have an identifiable cause and thus have idiopathic epilepsy. The incidence of idiopathic epilepsy is higher in children.³

Many factors have been shown to precipitate seizures in susceptible individuals. Hyperventilation may precipitate absence seizures. Sleep, sleep deprivation, sensory stimuli, and emotional stress may initiate seizures. Hormonal changes occurring around the time of menses, puberty, or pregnancy have been associated with the onset of or an increased frequency of seizures. A careful history should be obtained from patients presenting with seizures because theophylline, alcohol, high-dose phenothiazines, antidepressants (especially maprotiline or bupropion), and street drug use have been associated with provoking seizures. Also, AEDs in toxic concentrations may cause seizures in certain patients. Perinatal factors and subsequent events have been identified as risk factors for the subsequent development of epilepsy. Children who are small for gestational age or with neonatal seizures are also at increased risk for developing epilepsy. The most clearly established risk factors for epilepsy in all age groups are head trauma (especially in patients in whom the dura mater has been breached and in whom there is evidence of loss of consciousness), CNS infections, and stroke. Immunizations have not been associated with an increased risk of epilepsy.

PATHOPHYSIOLOGY

Seizure activity is characterized by paroxysmal discharges occurring synchronously in a large population of cortical neurons.⁴ This is characterized on EEG as a sharp wave or *spike*. The basic physiology of a seizure episode is traceable to an unstable cell membrane or its surrounding supportive cells. The seizure originates from the gray matter of any cortical or perhaps subcortical area. Initially, a small number of neurons fire abnormally. Normal membrane conductances and inhibitory synaptic currents break down, and excess excitability spreads, either locally to produce a focal seizure or more widely to produce a generalized seizure. This onset propagates by physiologic pathways to involve adjacent or remote areas. The clinical manifestations depend on the site of the focus, the degree of irritability of the surrounding area of the brain, and the intensity of the impulse.⁴

An abnormality of potassium conductance, a defect in the voltage-sensitive ion channels, or a deficiency in the membrane ATPases linked to ion transport may result in neuronal membrane instability and a seizure. Selected neurotransmitters (e.g., glutamate, aspartate, acetylcholine, norepinephrine, histamine, corticotropin-releasing factor, purines, peptides, cytokines, and steroid hormones) enhance the excitability and propagation of neuronal activity, whereas γ -aminobutyric acid (GABA) and dopamine inhibit neuronal activity and propagation. A relative deficiency of inhibitory neurotransmitters such as GABA or an increase in excitatory neurotransmitters such as glutamate would promote abnormal neuronal activity. Normal neuronal activity also depends on an adequate supply of glucose, oxygen, sodium, potassium, chloride, calcium, and amino acids. Systemic pH is also a factor in precipitating seizures. The different kinds of epilepsies probably arise from different neurophysiologic abnormalities.⁴

Control of abnormal neuronal activity with AEDs is accomplished by elevating the threshold of neurons to electrical or chemical stimuli or by limiting the propagation of the seizure discharge from its origin. Raising the threshold most likely involves stabilization of neuronal membranes, whereas limiting the propagation involves depression of synaptic transmission and reduction of nerve conduction.⁴

During a seizure, there is a large increase in the demand for blood flow to the brain to carry off CO₂ and to bring substrates for neuronal metabolic activity. The more prolonged the seizure, the more likely the brain is to suffer ischemia that may result in neuronal destruction and brain damage. Also, the continued exposure to glutamate, an excitatory neurotransmitter, may contribute to neuronal damage. Although individual seizures as such do not cause a significant decrease in intelligence, it has been suggested that patients suffering a large number (>100) of generalized tonic-clonic (GTC) seizures who have multiple episodes of status epilepticus may be at risk for eventual cognitive declines.

In addition, there appears to be a positive correlation between the early initiation of appropriate AED therapy and the ability to control seizure activity. The failure to control seizures seems to lead to an increase in seizure activity and also to the occurrence of other seizure types. Therefore, appropriate therapy should be initiated early after the diagnosis of epilepsy.

CLINICAL PRESENTATION

The International League Against Epilepsy (ILAE) has proposed two major schemes for the classification of seizures and epilepsies: the International Classification of Epileptic Seizures and the International Classification of the Epilepsies and Epilepsy Syndromes.^{5,6}

The International Classification of Epileptic Seizures (Table 54–1) combines the clinical description with certain electrophysiologic findings in order to classify epileptic seizures. Seizures are divided into two main pathophysiologic groups—partial seizures and generalized seizures—by EEG recordings and clinical symptomatology.

Partial (focal) seizures begin in one hemisphere of the brain and—unless they become secondarily generalized—result in an asymmetric motor manifestation. Partial seizures manifest as alterations in motor functions, sensory or somatosensory symptoms, or automatisms. Partial seizures with no loss of consciousness are classified as *simple partial*. In some cases, patients will describe somatosensory symptoms as a “warning” prior to the development of a GTC seizure.

TABLE 54–1. International Classification of Epileptic Seizures

| |
|---|
| I. Partial seizures (seizures begin locally) |
| A. Simple (without impairment of consciousness) |
| 1. With motor symptoms |
| 2. With special sensory or somatosensory symptoms |
| 3. With psychic symptoms |
| B. Complex (with impairment of consciousness) |
| 1. Simple partial onset followed by impairment of consciousness—with or without automatisms |
| 2. Impaired consciousness at onset—with or without automatisms |
| C. Secondarily generalized (partial onset evolving to generalized tonic-clonic seizures) |
| II. Generalized seizures (bilaterally symmetrical and without local onset) |
| A. Absence |
| B. Myoclonic |
| C. Clonic |
| D. Tonic |
| E. Tonic-clonic |
| F. Atonic |
| G. Infantile spasms |
| III. Unclassified seizures |
| IV. Status epilepticus |

Ref. 5, 6.

These warnings are in fact simple partial seizures and frequently are termed *auras*.

Partial seizures with an alteration of consciousness are described as *complex partial*. With complex partial seizures, the patient may have automatisms, periods of memory loss, or aberrations of behavior.¹ Some patients with complex partial epilepsy have been mistakenly diagnosed as having psychotic episodes. Complex partial seizures also may progress to GTC seizures. Patients with complex partial seizures typically are amnesic to these events.

Generalized seizures have clinical manifestations that indicate involvement of both hemispheres. Motor manifestations are bilateral, and there is a loss of consciousness. Generalized seizures may be further subdivided by EEG and clinical manifestations. A partial seizure that becomes generalized is referred to as a *secondarily generalized seizure*.

Generalized absence seizures are manifested by a sudden onset, interruption of ongoing activities, a blank stare, and possibly a brief upward rotation of the eyes. They generally occur in young children through adolescence. It is important to differentiate absence seizures from complex partial seizures.

GTC seizures are what many people think of as epilepsy. The seizure results in a sudden sharp tonic contraction of muscles followed by a period of rigidity and clonic movements. During the seizure, the patient may cry or moan, lose sphincter control, bite the tongue, or develop cyanosis. After the seizure, the patient may have altered consciousness, drowsiness, or confusion for a variable period of time (postictal period) and frequently goes into a deep sleep. Tonic and clonic seizures may occur separately.

Brief shocklike muscular contractions of the face, trunk, and extremities are known as *myoclonic jerks*. They may be isolated events or rapidly repetitive. A sudden loss of muscle tone is known as an *atonic seizure*. This may be described as a head drop, the dropping of a limb, or a slumping to the ground. These patients often wear protective headware to prevent trauma.

The International Classification of Epilepsies and Epilepsy Syndromes adds components such as age of onset, intellectual development, findings on neurologic examination, and results of neuroimaging studies to define epilepsy syndromes more fully. Syndromes can include one or many different seizure types (e.g., Lennox Gastaut syndrome). The syndromic approach includes seizure type(s) and possible etiologic classifications (e.g., idiopathic, symptomatic, or unknown). *Idiopathic* describes syndromes that are presumably genetic but also those in which no underlying etiology is documented or suspected. A family history of seizures is commonly present, and neurologic function is essentially normal except for the occurrence of seizures. *Symptomatic* cases involve evidence of brain damage or a known underlying cause. A *cryptogenic* syndrome is assumed to be symptomatic of an underlying condition that cannot be documented. *Unknown or undetermined* is used when no cause can be identified. This syndromic classification is more important for prognostic determinations than for a classification based simply on seizure type. The syndrome classification scheme requires more information and,

in return, provides a more powerful tool for comprehensive clinical management. A patient's epilepsy is classified based on seizure type (i.e., generalized versus partial) and syndromic type (i.e., idiopathic, symptomatic, or cryptogenic).

CLINICAL PRESENTATION OF EPILEPSY

GENERAL

In most cases, the health care provider will not be in a position to witness a seizure. Many patients (particularly those with complex partial or generalized tonic-clonic seizures) are amnesic to the actual seizure event. Obtaining an adequate history and description of the ictal event (including time course) from a third party (e.g., significant other, family member, or witness) is critically important.

SYMPTOMS

Symptoms of a specific seizure will depend on seizure type. While seizures can vary between patients, they tend to be stereotyped within an individual.

- Complex partial seizures may include somatosensory or focal motor features.
- Complex partial seizures are associated with altered consciousness.
- Absence seizures may appear relatively bland, with only very brief (seconds) periods of altered consciousness.
- Generalized tonic-clonic seizures are major convulsive episodes and are always associated with a loss of consciousness.

SIGNS

Interictally (between seizure episodes), there are typically no objective, pathognomonic signs of epilepsy.

LABORATORY TESTS

There are currently no diagnostic laboratory tests for epilepsy. In some cases, particularly following generalized tonic-clonic (or perhaps complex partial) seizures, serum prolactin levels may be transiently elevated. Laboratory tests may be done to rule out treatable causes of seizures (e.g., hypoglycemia, altered electrolyte concentrations, infections, etc.) that do not represent epilepsy.

OTHER DIAGNOSTIC TESTS

- EEG is very useful in the diagnosis of various seizure disorders.
- The EEG may be normal in some patients who still have the clinical diagnosis of epilepsy.
- While MRI is very useful (especially imaging of the temporal lobes), CT scan typically is not helpful except in the initial evaluation for a brain tumor or cerebral bleeding.

► TREATMENT: Epilepsy

■ DESIRED OUTCOME

The ultimate goal of treatment for epilepsy is no seizures and no side effects with an optimal quality of life. The best quality of life is associated with a seizure-free state.⁷ Often, however, a balance between efficacy and side effects must be reached because with the

older AEDs used as monotherapy, fewer than 50% of patients become seizure-free.

Because therapy is continued for many years (often a lifetime), chronic side effects must be considered. If the patient is overly sedated or develops other significant side effects, some seizure control may have to be sacrificed to improve functioning. The patient should be

involved in deciding what balance between frequency of seizures and the occurrence of side effects is most appropriate. The newer AEDs offer alternatives for balancing seizure frequency and drug side effects.

Providing optimal quality of life goes beyond balancing seizures and side effects. It involves assessing all the concerns of a patient with epilepsy. For example, patients with epilepsy are concerned about driving, their future, forming relationships, safety, social isolation, social stigma, and so on. It is also important to recognize that patients with epilepsy may have other neuropsychiatric comorbidities such as depression, anxiety, and sleep disturbances.^{8–10} Clinicians should be aware of these potential problems and consider therapy where appropriate.

■ GENERAL APPROACH TO TREATMENT

1 The general approach to treatment involves identification of goals, assessment of seizure type and frequency, development of a care plan, and a follow-up evaluation. During the assessment phase, it is critical to establish an accurate diagnosis of the seizure type and classification. This diagnostic step will help to determine the appropriate initial AEDs. Patient-specific treatment goals must be identified, and these may change over time. In all patients, the goal should be “no seizures, no side effects, and an optimal quality of life.” It must be recognized that this may not be possible in a significant minority of patients. Despite appropriate AED treatment, approximately 30% to 35% of patients will be refractory to treatment. In this setting, seizure freedom may not be obtained, and more obtainable outcomes should be established (e.g., decrease in the number of seizures and minimized drug adverse effects). Identification of specific goals will help in the development of the short- and long-term treatment plans. Patient characteristics such as age, medical condition, ability to comply with a prescribed regimen, and insurance coverage also should be explored because these may influence AED choices or help to explain a lack of response or unexpected adverse effects.

Once the assessment is complete, the advantages and disadvantages of appropriate AEDs are compared. For patients with new-onset seizures, the choice is whether to use drug therapy and, if so, which one. For a patient with long-standing epilepsy, adequacy of the current medication regimen must be evaluated. An AED should not be considered ineffective unless the patient has experienced unacceptable adverse effects with continued seizures.

4 If a decision is made to start AED therapy, monotherapy is preferred, and about 50% to 70% of all patients with epilepsy can be maintained on one drug.^{11,12} However, many of these patients are not seizure-free. The percentage of patients who are seizure-free on one drug varies by seizure type. The prognosis for 12-month seizure freedom is best for those who have only GTC seizures (48% to 55%), worst for those who have only complex partial seizures (23% to 26%), and intermediate for those with mixed seizure types (25% to 32%).¹² Drugs may be combined in an attempt to help the patient become seizure-free. Combining AEDs with different mechanisms of action may be advantageous, although this approach is as yet unproven.¹³ Approximately 65% of patients can be expected to be maintained on one AED and be considered well controlled, although not necessarily seizure-free.

5 Of the 35% of patients with unsatisfactory control, 10% will be well controlled with a two-drug treatment. Of the remaining 25%, 20% will continue to have unsatisfactory control despite multiple drug treatment. It has been suggested recently that there may be a genetic predisposition to epilepsy that is refractory to drug therapy. Some of these patients will become surgical can-

didates. For some patients, an implantable device such as the vagal nerve stimulator may be an additional nonpharmacologic option.

Once the care plan is established, a prescription is generated for a specific AED. Usually this includes a dose-titration schedule. At this point, patient education and assurance of patient understanding of the plan are essential. Detailed directions regarding titration, what to do in the event of a treatment-emergent side effect, and what to do if a seizure occurs must be provided to patients. Documentation of the assessment, care plan, and educational process is essential. Providing the patient with a seizure and side-effect diary will assist in the follow-up and evaluation phase. At the follow-up stage of treatment (which can be done in the hospital, clinic, or pharmacy or by phone), the treatment goals must be reviewed. If the goal has been achieved, new goals should be identified. For example, if the GTC seizures are now controlled, the goal may be to control partial seizures. If a patient fails to respond to the first AEDs, trials with other AEDs should be attempted. Completion of the evaluation often requires a reassessment of the patient and development of a new care plan. The assessment at this point should evaluate compliance, efficacy, and safety of the initial treatment.

Medication noncompliance may be the single most common reason for treatment failure. It is estimated that up to 60% of patients with epilepsy are noncompliant.¹⁴ The rate of noncompliance is increased by the complexity of the drug regimen and by doses taken three and four times a day. Noncompliance is not influenced by age, sex, psychomotor development, seizure type, or seizure frequency.¹⁴

CLINICAL CONTROVERSY

Epilepsy is a clinical diagnosis defined by recurrent seizures. Controversy surrounds the most appropriate time to initiate AED therapy. Many clinicians do not initiate treatment until a second unprovoked seizure has occurred. Some clinicians start AED treatment after the first seizure, whereas others may initiate prophylactic treatment following a CNS insult thought likely to cause epilepsy eventually (e.g. stroke or head trauma). Appropriate treatment decisions may vary depending on individual patient clinical characteristics and circumstances.

Drug treatment may not be indicated in patients whose seizures have minimal impact on their lives or those who have had only a single seizure. If a patient presents after a single isolated seizure, one of three treatment decisions can be made: treat, possibly treat, or do not treat. These decisions are based on the probability of the patient having a second seizure (Table 54–2). For patients with no risk factors, the probability of a second seizure is less than 10% in the first year and approximately 24% by the end of 2 years. If risk factors are present, this recurrence rate can increase dramatically and can be as high as 80% after 5 years.¹ Are these rates high enough to warrant AED therapy? This decision often depends on patient-specific factors such as epilepsy syndrome, seizure etiology, presence of a neuroanatomic defect, and the EEG. Clearly, the patient’s lifestyle and preferences are of paramount importance. Patients who have had two or more seizures generally should be started on AEDs.

■ WHEN TO STOP ANTIEPILEPTIC DRUGS

6 The AEDs used initially to control seizures may not need to be given for a lifetime. Polypharmacy may be reduced, and some patients can discontinue AEDs altogether. In reducing polypharmacy,

TABLE 54–2. Recurrence Risk for Patients Experiencing One Unprovoked Seizure

| Type of Patient | 1st-Yr Risk (%) | 5th-Yr Risk (%) |
|--|-----------------|-----------------|
| Adults with single unprovoked seizure | | 34 |
| No CNS insult | 10 | 29 |
| Influence of family history | | |
| Sibling with seizure | 29 | 46 |
| No sibling with seizures | 7 | 27 |
| EEG patterns | | |
| GSW on EEG | 15 | 58 |
| Normal EEG | 9 | 26 |
| Occurrence of previous seizure | 10 | 39 |
| Due to an illness or childhood | | |
| febrile seizure | | |
| Remote symptomatic with Todd's paresis | 26 | 48 |
| Status epilepticus at onset | 41 | 75 |
| Prior acute seizure | 37 | 56 |
| Idiopathic | 60 | 80 |
| | 10 | 29 |

CNS = central nervous system; EEG = electroencephalogram; GSW = generalized spikes and waves.

the drug considered less appropriate for the seizure type (or the agent deemed most responsible for adverse effects) should be discontinued first. In some cases, decreasing the number of AEDs a patient is receiving can decrease side effects and increase cognitive abilities.¹⁵ This improvement in cognition may be small, especially if the patient is on a drug that primarily affects psychomotor speed with less effect on higher-order cognitive functioning.

6 Factors favoring successful withdrawal of AEDs include a seizure-free period of 2 to 4 years, complete seizure control within 1 year of onset, an onset of seizures after age 2 but before age 35, and a normal neurologic examination and EEG. Factors associated with a poor prognosis in discontinuing AEDs, despite a seizure-free interval, include a history of a high frequency of seizures, repeated episodes of status epilepticus, a combination of seizure types, and development of abnormal mental functioning. Children who have irregular generalized spike and wave activity in EEG recordings prior to discontinuation of treatment may have a higher relapse rate (67%) compared with children without epileptiform activity (33%) or children with other types of epileptiform activity (33%) in their last EEG recordings before discontinuation. A 2-year seizure-free period is suggested for absence and rolandic epilepsy, whereas a 4-year seizure-free period is suggested for simple partial, complex partial, and absence associated with tonic-clonic convulsions. AED withdrawal generally is not suggested for patients with juvenile myoclonic epilepsy, absence with clonic-tonic-clonic seizures, or clonic-tonic-clonic seizures. The American Academy of Neurology has issued guidelines for discontinuing AEDs in seizure-free patients (Table 54–3). When the factors likely to be associated with successful withdrawal are present, the relapse rate is expected to be less than 32% for children and 39% for adults.

If the decision is made to attempt AED withdrawal, this should be done gradually. This may be particularly true for patients with profound developmental disabilities. Some patients will have a recurrence of seizures as the AEDs are withdrawn. Sudden withdrawal is associated with the precipitation of status epilepticus. Withdrawal seizures are of particular concern for agents such as benzodiazepines and barbiturates. Seizure relapse has been reported to be more common if the AEDs are withdrawn over 1 to 3 months than over 6 months.

TABLE 54–3. American Academy of Neurology Guideline for Discontinuing AEDs in Seizure-Free Patients

After assessing the risks and benefits to both patient and society from a recurrent seizure, the discontinuance of antiepileptic drugs may be considered by the physician and informed patient or parent/guardian if the patient meets the following profile:

- Seizure-free 2 to 5 years on AEDs (mean, 3.5 years)
- Single type of partial seizure (simple partial, complex partial, or secondary generalized tonic-clonic seizure) or single type of primary generalized tonic-clonic seizures
- Normal neurologic examination/normal IQ
- EEG normalized with treatment

The risk of seizure relapse has been estimated at 10% to 70%. A meta-analysis determined that the relapse rate was 25% after 1 year and 29% after 2 years. Withdrawal doubles the risk of seizure recurrence for the first 1 to 2 years but does not modify the long-term prognosis of a person's epilepsy. If seizures recur after AED withdrawal, AEDs should be restarted. Ninety percent of patients will regain at least another 2-year remission. In addition to seizure relapse, the withdrawal of AEDs has been associated with the emergence of anxiety and depression.¹⁵

CLINICAL CONTROVERSY

It is not entirely clear which patients with epilepsy will require lifelong treatment. While many clinicians feel that AED therapy is lifelong, others would argue that certain patients with idiopathic epilepsy and a normal neurologic examination and EEG may be candidates for AED withdrawal following a prolonged period of seizure freedom (e.g., >2 to 3 years). Most of the data supporting discontinuing AEDs have been obtained from children. Some adults will be reticent to discontinue AED therapy even if the clinician is in favor of it because of the fear of having a seizure and the consequences (e.g., loss of driver's license) that it would entail. The patient must be a willing participant in a therapeutic plan to discontinue an AED. The patient should agree to the plan to reduce or withdraw AED therapy.

There may be a significant psychosocial benefit to the patient from AED withdrawal. Withdrawal may need to be scheduled at the convenience of the patient. A follow-up of 5 years is suggested for any patient withdrawn from AED therapy.

NONPHARMACOLOGIC THERAPY

Nonpharmacologic therapy for epilepsy includes diet, surgery, and vagal nerve stimulation (VNS), which is implantation of a vagal nerve stimulator. A vagal nerve stimulator is an implanted medical device approved for use in epilepsy. The NCP system (NeuroCybernetic prosthesis) is indicated for use as an adjunctive therapy in reducing the frequency of seizures in adults and adolescents older than 12 years of age with partial-onset seizures that are refractory to AEDs. The device consists of an implantable, programmable pulse generator connected to a helical lead. The generator is implanted in a subcutaneous infraclavicular pocket and is powered by a lithium battery. The lead is attached to the left vagus nerve and delivers a biphasic current to the

TABLE 54-4. Drugs of Choice for Specific-Seizure Disorders

| Seizure Type | First-Line Drugs | Alternative Drugs |
|----------------------|---|---|
| Partial seizures | Carbamazepine Phenytoin Lamotrigine Valproic acid Oxcarbazepine | Gabapentin Topiramate Levetiracetam Zonisamide Tiagabine Primidone, phenobarbital Felbamate |
| Generalized seizures | | |
| Absence | Valproic acid, ethosuximide | Lamotrigine, levetiracetam |
| Myoclonic | Valproic acid, clonazepam | Lamotrigine, topiramate, felbamate, zonisamide, levetiracetam |
| Tonic-clonic | Phenytoin, carbamazepine, valproic acid | Lamotrigine, topiramate, phenobarbital, primidone, oxcarbazepine, levetiracetam |

nerve that can be programmed to different parameters by the physician through the skin. In addition, the patient can use a magnet placed over the generator to activate the generator during a seizure or aura.

The mechanisms of antiseizure actions of VNS are unknown, but recent studies have indicated that VNS acutely causes widespread bilateral cortical and subcortical alterations in blood flow, suggesting that it affects synaptic activity in humans.¹⁶

The VNS device is relatively safe. The most common side effect associated with stimulation is hoarseness, voice alteration, increased cough, pharyngitis, dyspnea, dyspepsia, and nausea. Serious adverse effects reported include infection, nerve paralysis, hyesthesia, facial paresis, left vocal chord paralysis, left facial paralysis, left recurrent laryngeal nerve injury, urinary retention, and low-grade fever. Over all the VNS studies, the percentage of patients who achieved a 50% or greater reduction in their seizure frequency (responders) ranged from 23% to 50%.

Surgery is the most widespread and most useful nonpharmacologic therapy.¹⁷ The use of surgery for intractable epilepsy that significantly interferes with patients' lives and functioning is increasing in both adult and pediatric patients. The success rate is reported to be between 80% and 90% in properly selected patients. A National Institutes of Health Consensus Conference identified three absolute requirements for surgery. They are an absolute diagnosis of epilepsy, failure on an adequate trial of drug therapy, and definition of the electroclinical syndrome. A focus in the temporal lobe has the best chance for a positive outcome; however, extratemporal foci may be excised successfully in more than 75% of patients. The procedure is not without risk. Learning and memory are most susceptible to impairment postoperatively, and general intellectual abilities are also affected in a small number of patients. Surgery may be particularly useful in children with intractable epilepsy. Patients may still need to receive AED therapy for a period of time following successful epilepsy surgery in order to prevent seizure recurrence.¹⁸

The ketogenic diet was devised in the 1920s.¹⁹ It is high in fat and low in carbohydrates and protein and thus leads to acidosis and ketosis. Protein and calorie intake are set at levels that will meet requirements for growth. Most of the calories are provided in the form of heavy cream and butter. No sugar is allowed. Vitamins and minerals are supplemented. Medium-chain triglycerides may be substituted for the dietary fats. Fluids are also controlled. It requires strict control and parent compliance. Although some centers find this useful for refractory patients, others have found that it is poorly tolerated by patients. Long-term effects are unknown.

PHARMACOLOGIC THERAPY

Optimal management of epilepsy therefore requires that AED treatment be individualized. Specifically, different patient groups (e.g., children, women of child-bearing potential, and the elderly) may be better suited to one AED versus another by virtue not only of seizure type but also of susceptibility or relative risk for certain adverse effects. These issues will be highlighted further below.

7 Selection and optimization of AED therapy require not only an understanding of drug mechanism(s) of action and spectrum of clinical activity but also an appreciation of pharmacokinetic variability as well as patterns of drug-related adverse effects. An AED must demonstrate efficacy for the specific seizure type being treated. The drug treatments of first choice depend on the type of epilepsy, as well as on the interface between drug-specific adverse effects and patient preferences (Table 54-4). Ultimately, AED effectiveness is the result of the interaction of each of these factors. A suggested algorithm for a general approach to the treatment of epilepsy is shown in Fig. 54-1.

The mechanism of action of most AEDs can be categorized as either affecting ion channels, augmenting inhibitory neurotransmission, or modulating excitatory neurotransmission. The ion channels affected include the sodium and calcium channels. Augmentation in inhibitory neurotransmission includes increasing CNS concentrations of GABA, whereas efforts to decrease excitatory neurotransmission are primarily focused on decreasing (or antagonizing) glutamate and aspartate neurotransmission. AEDs that are effective against GTC and partial seizures probably reduce sustained repetitive firing of action potentials by delaying recovery of sodium channels from activation. Drugs that reduce corticothalamic T-type calcium currents are effective against generalized absence seizures. Myoclonic seizures respond to drugs that enhance GABA_A receptor inhibition.²⁰ In addition to mechanism of action, awareness of pharmacokinetic properties (Table 54-5), adverse effects (Table 54-6), and drug-drug interactions (Tables 54-7 and 54-8) can aid in the optimization of AED therapy. Pharmacokinetic interactions are a common complicating factor in AED selection. Interactions can occur in any of the pharmacokinetic processes: absorption, distribution, or elimination. Caution should be used when AEDs are added to or withdrawn from a drug regimen.

Adverse effects of AEDs can be divided into acute and chronic (see Table 54-6). Acute effects can be dose/serum concentration-related or idiosyncratic. Concentration-dependent effects are common and troublesome but not usually life-threatening. Neurotoxic

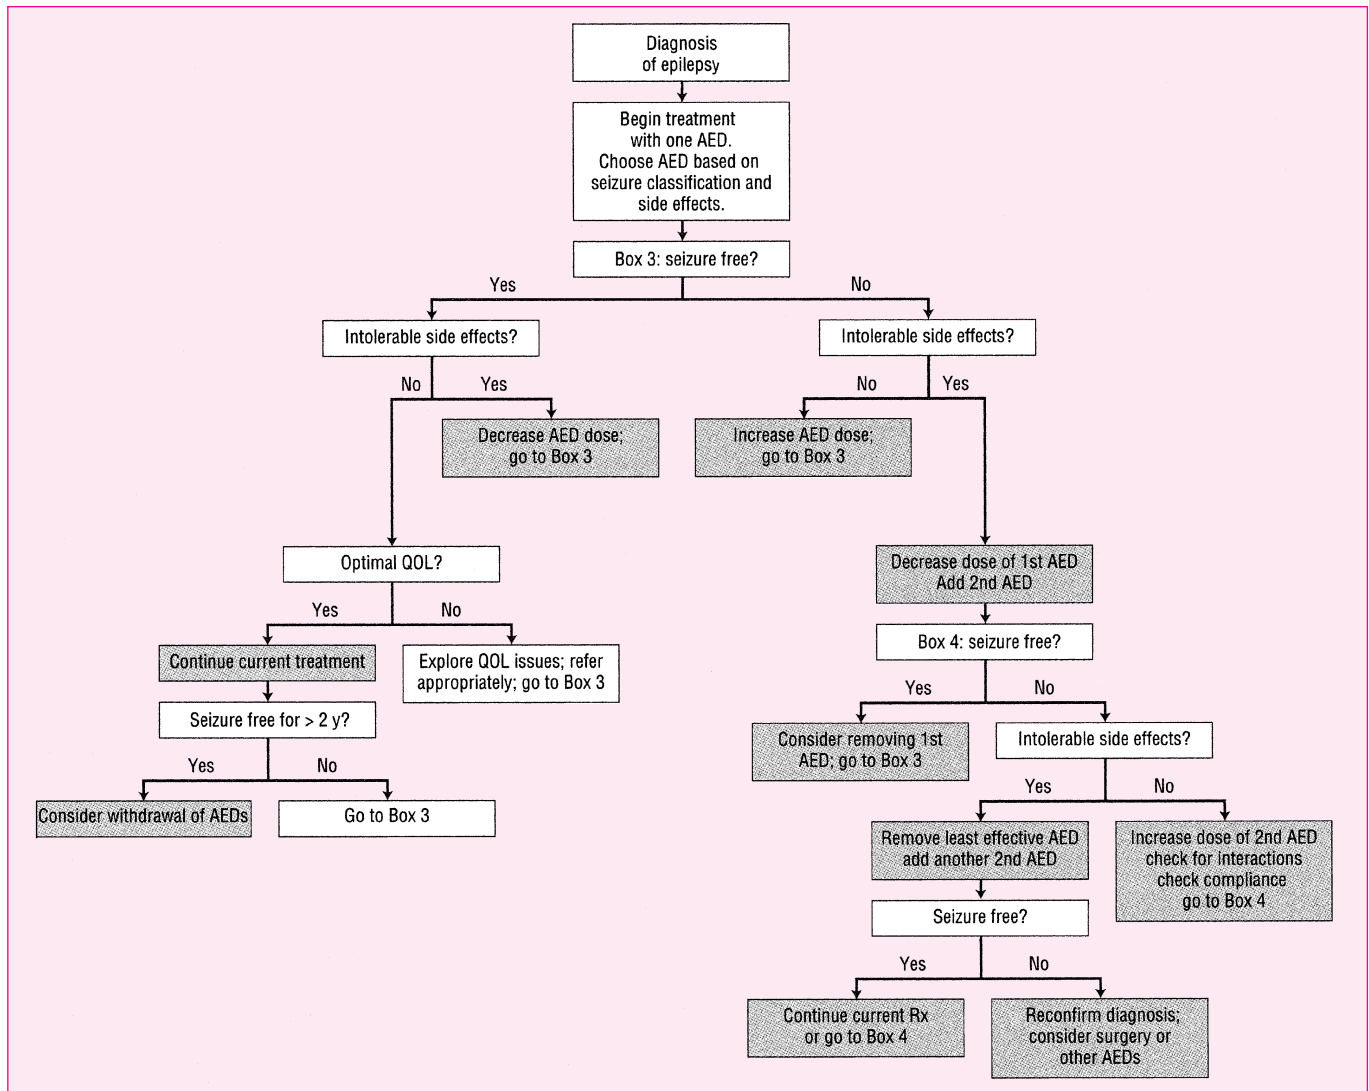

FIGURE 54-1. Algorithm for the treatment of epilepsy.

adverse effects are encountered commonly and can include sedation, dizziness, blurred or double vision, difficulty with concentration, and ataxia. In many cases these effects can be alleviated by decreasing drug dose. Most idiosyncratic reactions owing to an allergic reaction are mild, but they can be more serious if the hypersensitivity involves one or more organ systems. Other idiosyncratic side effects including hepatitis or blood dyscrasias are serious but rare.

Acute organ failure, if it is going to occur, generally occurs within the first 6 months of AED therapy. Unfortunately, screening laboratory evaluations of blood and urine typically are not helpful in predicting or detecting the early stage of severe reactions and generally are not recommended in asymptomatic patients. Laboratory assessment including white blood cell counts and liver function tests may be reasonable if the patient reports an unexplained illness (e.g., lethargy, vomiting, fever, or rash).²¹ It is important to recognize that adverse effects can occur despite serum concentrations being within the proposed therapeutic range.²²

Another potential long-term adverse effect of AED treatment is osteomalacia and osteoporosis.²³ The bone disorders associated with AED use consist of a heterogeneous group of disorders. These include findings ranging from asymptomatic high-turnover disease,

with findings of normal bone mineral density, to markedly decreased bone mineral density sufficient to warrant the diagnosis of osteoporosis. While the etiology of these osteopathies is still uncertain, it has been hypothesized that certain drugs, including phenytoin, phenobarbital, and perhaps carbamazepine and valproic acid, may interfere with vitamin D metabolism. Whether the newer AEDs are associated with these effects is as yet unknown. Common laboratory findings in these patients include elevated bone-specific alkaline phosphatase concentration and decreased serum calcium and 25-OH vitamin D concentrations. Patients receiving these drugs at the least should receive supplemental vitamin D and calcium.

The comparative effects of AEDs on cognition have been difficult to evaluate because of differences or inconsistencies in study design, included seizure types, control for serum drug concentrations, and the neuropsychological tests used. In general, there are not large differences between the older drugs,^{24,25} although the barbiturates phenobarbital and primidone appear to cause more cognitive impairment than other commonly used AEDs. Phenytoin, particularly when serum concentrations are above the commonly accepted therapeutic range, may have a greater effect on motor function and speed. Among the older AEDs, valproic acid may cause less impairment of cognition.

TABLE 54–5. Antiepileptic Drug Pharmacokinetic Data

| AED | $t_{1/2}$ (h) ^a | Time to Steady State (days) | Unchanged (%) | V_D (l/kg) | Clinically Important Metabolite | Protein Binding (%) |
|-------------------------|----------------------------|--|---------------|--------------------------------------|--------------------------------------|-------------------------|

Improvement in cognition has been reported in patients switched from phenytoin or phenobarbital to these agents. However, these effects are subtle and may not be pronounced if patients are in the same relative area of the therapeutic range. Patients reduced from polytherapy to monotherapy also may demonstrate improvement in cognition. Some of the newer agents are believed to cause fewer neurobehavioral or cognitive effects. Among the newer AEDs, gabapentin and lamotrigine have been shown in several studies to cause fewer cognitive impairments as compared with older agents such as carbamazepine.^{26–28} Conversely, topiramate may cause substantial cognitive impairment, particularly when used at high doses or during rapid dose escalation.²⁸ Finally, in some cases, AED treatment itself has been suggested to cause worsening of seizures. This may result from either improper selection of an AED for a specific seizure type or syndrome or may represent a paradoxical toxic effect of the drug.²⁹

CLINICAL CONTROVERSY

The role and necessity of AED serum concentration monitoring are controversial. Some clinicians feel that therapeutic blood level monitoring is essential for appropriate use of AEDs, whereas other feel that blood level monitoring is overused and, in many cases, unwarranted. AED blood level monitoring should be viewed as a tool to be used as part of overall AED treatment optimization. Achievement of a specific “therapeutic” level should not be an absolute goal in and of itself.

Because most adult patients have localization-related (partial onset) seizures, the most widely used AEDs traditionally have been carbamazepine, phenobarbital, phenytoin, and valproic acid. For com-

plex partial seizures, these AEDs have similar efficacy.^{30,31} Of these, carbamazepine and phenytoin are the most commonly prescribed AEDs for use in partial seizures in the United States. In large part, this preference is based on data derived from two landmark trials conducted through the Veterans Administration (VA) Epilepsy Cooperative Study Group. In the first of these trials, patients with new-onset partial or generalized epilepsy were randomized to receive either carbamazepine, phenobarbital, phenytoin, or primidone.³⁰ At the end of 3 years, patients who received either carbamazepine or phenytoin were equally likely and patients on phenobarbital or primidone were least likely to have remained on their originally assigned treatment. Thus carbamazepine and phenytoin were considered the drugs of first choice in patients with new-onset partial or generalized seizures. Carbamazepine was associated with fewer side effects. A follow-up study using almost identical methods compared carbamazepine and valproic acid.³¹ Carbamazepine- and valproic acid-treated groups had equal retention rates for tonic-clonic seizures. Carbamazepine was superior to valproic acid for partial seizures. Valproic acid caused slightly more adverse effects.

Based in large part on the earlier VA cooperative trials, carbamazepine traditionally has been recognized as the AED of first choice for partial seizures. Several of the newer-generation AEDs may prove to be reasonable alternatives. The newer antiepileptic drugs were first approved as adjunctive therapy for patients with refractory partial seizures. Monotherapy trials with several of these newer agents including lamotrigine, gabapentin, topiramate, and oxcarbazepine have been completed.^{32–34} Comparisons between lamotrigine and older agents including carbamazepine and phenytoin as initial monotherapy in partial seizures have been conducted in Europe, and the results would suggest comparable effectiveness and perhaps better tolerability, particularly in elderly patients. Preliminary observations

from a recently completed VA cooperative trial designed to compare gabapentin, lamotrigine, and carbamazepine in newly diagnosed elderly patients suggest that gabapentin efficacy is comparable with that of both lamotrigine and carbamazepine and in fact may be better tolerated than carbamazepine in this population (E. R. Ramsay et al., unpublished data, 2003). Clinical data would suggest that in newly diagnosed patients, oxcarbazepine is as effective as phenytoin, valproic acid, and immediate-release carbamazepine, with perhaps fewer adverse effects. Interestingly, close examination of the conversion to monotherapy trials would suggest that oxcarbazepine may demonstrate efficacy even in patients who previously had had an inadequate response to carbamazepine despite their structural similarity.

In addition, several monotherapy trials using an active control or pseudoplacebo design also have been performed. While these particular study designs do provide evidence of efficacy of the newer drugs, because the comparison is between active drug and placebo in patients who continue to have seizures despite current treatment with standard AEDs, it is difficult to compare the efficacy of the newer directly with the older AEDs. A meta-analysis designed to compare some of the newer AEDs³⁵ indirectly found that because of wide and overlapping confidence intervals for both efficacy and tolerability outcome measures, no statistically significant differences between agents could be found. Generally speaking, the newer AEDs appear to have comparable efficacy to the older agents and are perhaps better tolerated.

To date, among the newer-generation agents, only lamotrigine and oxcarbazepine have received Food and Drug Administration (FDA) approval for use as monotherapy in patients with partial seizures. Phenobarbital and primidone are also useful in partial

seizures, but sedation and cognitive adverse effects limit their utility. Felbamate, which has monotherapy approval, is effective but has been associated with some significant side effects. Interpretation of monotherapy trials with the newer AEDs can be daunting owing to the unique study designs and specific patient populations employed. While a complete discussion of this topic is beyond the scope of this chapter, several reviews and analyses have been published recently.³²

Primarily generalized seizures such as absence seizures may respond differently pharmacologically than other seizure types. Phenytoin, phenobarbital, and carbamazepine, although effective in GTC and partial seizures, are ineffective in treating absence seizures and in some cases may precipitate an increase in seizure activity. Absence seizures are best treated with ethosuximide, valproic acid, and perhaps lamotrigine. Either levetiracetam, topiramate, or zonisamide also may be effective, although further clinical data are needed to confirm this. Gabapentin and tiagabine do not appear to be effective in treating absence seizures. If the patient has a combination of absence and other generalized or partial seizures, valproic acid is the preferred first choice because it is the only AED effective against absence and other seizure types. If valproic acid is ineffective in treating a mixed seizure disorder that includes absence, ethosuximide should be used in combination with another AED.

The traditional treatment of tonic-clonic seizures is phenytoin or phenobarbital; however, the use of carbamazepine and valproic acid is increasing because these AEDs have a lower incidence of side effects and equal efficacy. Valproic acid generally is considered the drug of first choice for atonic seizures and for juvenile myoclonic epilepsy. Lamotrigine and perhaps topiramate and zonisamide may be alternative agents for these seizure types.

What has become obvious is that individuals may respond differently to each AED and that an understanding of each of these newer agents is needed to optimize therapy for individual patients. In most cases, selection of specific AED will depend on multiple factors, including seizure type, unique patient characteristics, and the expected adverse-effect/pharmacokinetic profile of each AED. An important clinical question remains as to the precise role of the newer-generation drugs. While several studies would suggest that at least some of the newer agents may have comparable efficacy, as well as improved tolerability, to the older drugs, definitive comparative studies with all agents are lacking. In the absence of randomized, double-blind clinical trials with all the AEDs, a recent consensus panel published a set of preferred AED treatment options for a variety of patient scenarios.³⁶

Another question that frequently confronts clinicians surrounds the role of therapeutic drug monitoring. Although most of the older AEDs have published therapeutic ranges, the serum concentration should be viewed as a tool with which to optimize therapy for an individual patient, not as a therapeutic end point in and of itself. The serum concentration is a target that should be correlated with clinical outcome. The desired response is the cessation of seizures without side effects. Seizure control may occur before the “minimum” of the published range is achieved, and side effects may appear before the “maximum” of the range is achieved. Some patients may need and tolerate concentrations beyond the maximum. The therapeutic range for AEDs may be different for different seizure types. Serum concentrations may need to be higher to control complex partial seizures than to control tonic-clonic seizures. Clinicians should define a therapeutic range for an individual patient above which there are side effects and below which the patient experiences seizures. The pharmacodynamic response to AEDs may change as the patient ages because elderly patients may be more sensitive to various neurocognitive adverse effects of these drugs. Along with this, elderly patients may demonstrate efficacy (e.g., control of seizures) at relatively lower serum concentrations as well. To date, therapeutic concentration ranges have not been established conclusively for the newer-generation drugs.

■ THERAPEUTIC CONSIDERATIONS IN WOMEN

Many hormones influence brain electrical excitability, and the steroid hormones estrogen and progesterone may interact in complex ways to alter neuronal excitability and protein synthesis.³⁷ Estrogen has a seizure-activating effect, whereas progesterone exerts a seizure-protective effect. Estrogen has an inhibitory effect on GABA receptors, potentiates excitatory glutaminergic activity, and may promote the development of kindling. Progesterone has the opposite effect and appears to potentiate GABA receptor activity and reduce neuronal discharge rates. AEDs, especially hepatic metabolizing enzyme inducers, also affect hormones by increasing the metabolism of steroid hormones and inducing the production of sex hormone-binding globulin. This may lead to decreases in the unbound fraction of the hormone. Enzyme-inducing AEDs, including topiramate and oxcarbazepine at higher doses, may cause treatment failures in women taking oral contraceptives owing to induction of both ethinyl estradiol and progestin metabolism. A supplemental form of birth control in addition to oral contraceptives is advised if breakthrough bleeding occurs. Valproic acid, benzodiazepines, and most of the newer AEDs such as lamotrigine, gabapentin, levetiracetam, tiagabine, and zonisamide are

not enzyme inducers and have not been associated with this effect.

In some women, vulnerability to seizures is highest just before and during the menstrual flow (catamenial seizures) and at the time of ovulation. The risk of catamenial epilepsy is estimated at 12.5%, but it may occur in as many as 50% of women with epilepsy. This pattern of seizure exacerbation may be related to progesterone withdrawal and changes in the estrogen-to-progesterone ratio. Conventional AEDs should be tried first in these women. Intermittent acetazolamide also has been used, but with variable and limited success. Hormonal therapy with progestational agents, particularly cyclic natural progesterone therapy, also may be effective. Reproductive endocrine disorders are common in women with epilepsy and include menstrual irregularity, infertility, sexual dysfunction, and possibly an increased risk of polycystic ovary syndrome.³⁸ Potential mechanisms for these disturbances include disruption of the hypothalamic-pituitary-adrenal (HPA) axis via seizure discharges in limbic structures and/or AEDs.³⁸ AEDs, particularly the enzyme-inducing agents (e.g., carbamazepine, phenytoin, and phenobarbital), also may affect HPA function by altering the metabolism of the neuroactive sex hormones, including testosterone. Although a definitive causal relationship has not yet been established, an apparent increased incidence of polycystic ovary syndrome has been suggested for women with epilepsy who are receiving valproic acid.³⁸

Pregnancy raises several concerns, including the possibility of increased maternal seizures, pregnancy complications, and adverse fetal outcome.³⁹ About 25% to 30% of women have increased seizures during pregnancy, whereas seizures decrease in a similar number. Increased seizure activity may result from either a direct effect on seizure threshold or a reduction in AED concentration. An increase in clearance has been reported for phenytoin, carbamazepine, phenobarbital, ethosuximide, lamotrigine, and clonazepam. Protein binding also may be altered. The altered disposition of AEDs may begin as early as the first 10 weeks of pregnancy and may take up to 4 weeks postpartum to return to normal. The return to the nonpregnant metabolism and binding requires longer for carbamazepine and phenobarbital than it does for phenytoin. There is a higher incidence of adverse pregnancy outcomes in women with epilepsy. Although the risk of congenital malformations is 4% to 6% (twice as high as in nonepileptic women), more than 90% of pregnancies in epileptic mothers have satisfactory outcomes. Barbiturates and phenytoin are associated with congenital heart malformations, orofacial clefts, and other malformations. Valproic acid and carbamazepine are associated predominantly with spina bifida (neural tube defect) and hypospadias. The risk of neural tube defect with valproic acid and carbamazepine has been estimated to be 0.5% to 1%, respectively, and appears to be related to drug exposure during gestational days 0 to 28. Other adverse pregnancy outcomes associated with maternal seizures but not necessarily caused by AEDs are growth, psychomotor, and mental retardation. Women with epilepsy are also more likely to have miscarriages, and 10% to 20% of infants are born with low birth weight. Guidelines have been developed for counseling and managing pregnant women with epilepsy.

Many of these teratogenic effects can be prevented by adequate folate intake; therefore, prenatal vitamins with folic acid (~ 0.4–5 mg/day) should be given to any woman of child-bearing potential who is taking AEDs.³⁹ Higher folate doses should be used in women with a history of a previous pregnancy with a neural tube defect. Higher AED doses and serum concentrations, polytherapy, and a family history of birth defects appear to increase the teratogenic risk. Therefore, deciding on the most effective single-drug treatment prior

to conception is vitally important. New AEDs are reported to be less teratogenic, and animal reproductive toxicology studies appear to be favorable. At present, clinical data are quite limited, and more experience is needed before the true risk (or lack thereof) can be determined. AEDs also can lead to neonatal hemorrhagic disorder. Vitamin K 10 mg orally given to the mother daily during the last month of pregnancy should prevent this coagulopathy.

Although AEDs pass into the breast milk, the concentrations are very low, and the infant receives a subtherapeutic dose. In general, knowledge of the degree of protein binding of a given AED can allow for prediction of breast milk accumulation, with drugs with less protein binding partitioning more. Treatment with AEDs is not necessarily a reason to discourage breast-feeding. It is advisable that women taking any AED (particularly barbiturates or benzodiazepines) closely observe infants for signs of excess sedation, irritability, or poor feeding.³⁹

Little is known regarding the effect of menopause on epilepsy. The perimenopausal period may be associated with worsening of seizures, possibly owing to fluctuations in sex hormones. At menopause, seizures actually may improve, particularly in women who previously presented with a catamenial pattern. The effect of hormone-replacement therapy on seizure control is still unclear, but clinicians should monitor for seizure exacerbation in women receiving supplemental estrogen.

CLINICAL CONSIDERATIONS WITH SPECIFIC DRUGS

Tables 54–5 to 54–9 list specific pharmacokinetic and typical dosing data for each of the commonly used AEDs. Below we summarize the relative properties, advantages and disadvantages, and perspectives as to the place in therapy of each of these agents.

CARBAMAZEPINE

Pharmacology and Mechanism of Action. The exact mechanism by which carbamazepine suppresses seizure spread is obscure, although it is believed to act primarily through inhibition of voltage-gated sodium channels.⁴⁰

Pharmacokinetics. The absorption of carbamazepine from immediate-release tablets is slow and erratic because of its low water solubility. There is also a large variability in the peak-to-trough concentrations of up to 40%. There is no first-pass metabolism. Food may enhance the bioavailability of carbamazepine. The suspension dosage form is absorbed faster than the tablets.⁴¹ Controlled-release (Tegretol-XR) and sustained-release (Carbatrol) preparations are also available. These dosage forms are bioequivalent in twice-daily (every 12 hours) dosing to dosing four times daily (every 6 hours) with immediate-release carbamazepine. Compared with immediate-release carbamazepine, both these formulations have lower peaks and higher troughs, which may decrease side effects and improve seizure control. Patients should be told to take Tegretol-XR with food and that the casing will be excreted in the feces. Tegretol-XR cannot be broken or crushed. Tegretol-XR and Carbatrol appear to be bioequivalent; however, there was less variability in the absorption of Carbatrol.⁴¹

Carbamazepine is a neutral and highly lipophilic drug that results in high body tissue binding. It binds to α_1 -acid glycoprotein and

to albumin. Most (98% to 99%) of an administered dose of carbamazepine is metabolized by the liver, primarily by CYP3A4.⁴¹ The major metabolite is carbamazepine-10,11-epoxide,⁴¹ which has anticonvulsant activity in animals and humans. The formation of the 10,11-epoxide is influenced by concurrent use of other enzyme-inducing or enzyme-inhibiting drugs; thus the 10,11-epoxide concentration may change with the administration of other drugs (e.g., valproate and felbamate) with no change in parent carbamazepine concentration.⁴¹

Carbamazepine has the unique ability to induce its own metabolism (autoinduction).⁴¹ The half-life after a single dose is much longer than the half-life after chronic therapy. The presence of enzyme-inducing drugs reduces the half-life even more. The enzyme-induction effect begins within 3 to 5 days of the initiation of therapy and takes 21 to 28 days to complete. Therefore, it is possible to achieve initial concentrations that are within the therapeutic range but have concentrations fall despite continued therapy with good compliance. Some patients who respond well to initial therapy may be labeled refractory or noncompliant if the autoinduction phenomenon is not considered. The autoinduction reverses rapidly if therapy with carbamazepine is discontinued temporarily. This would be very important in epilepsy monitoring units where all drugs are stopped in an attempt to precipitate seizures in patients being evaluated for seizure surgery.⁴¹

Adverse Effects. Side effects (see Table 54–6) of carbamazepine may fluctuate daily, paralleling the rise and decline of serum concentrations. The side-effect profile also may follow a circadian rhythm. Neurosensory side effects (e.g., diplopia, blurred vision, nystagmus, ataxia, unsteadiness, dizziness, and headache) are the most common, occurring in 35% to 50% of patients. These side effects are more common during initiation of therapy and may dissipate with continued treatment. Patients have variable threshold concentrations for the occurrence of CNS side effects. If the carbamazepine serum concentration is kept below the individual threshold, the CNS side effects can be minimized. Dosage manipulation, including the use of the controlled- or sustained-release preparations, should be tried before the patient is considered to be intolerant of carbamazepine. Carbamazepine may induce a hyponatremic hyposmolar condition that is similar to the syndrome of inappropriate antidiuretic hormone secretion. The incidence may increase with age. Periodic determinations of serum sodium concentration are recommended, especially in the elderly.⁴¹

Thrombocytopenia and anemia are relatively rare events that usually respond to discontinuation of the offending drug. Leukopenia is the most common hematologic side effect. An incidence as high as 10% has been reported. Leukopenia usually is transient, even when the drug is continued, and may be due to a redistribution of white blood cells (WBCs) rather than a decrease in their production. In about 2% of patients, the leukopenia is persistent, but even patients with WBC counts of 3000/mm³ or less do not seem to have an increased incidence of infection. A clinical guide is to continue carbamazepine therapy unless the WBC count drops to less than 2500/mm³ and the absolute neutrophil count drops to less than 1000/mm³.⁴¹

Rashes are the most frequent hypersensitivity response. An incidence of approximately 10% has been reported. These usually are mildly eczematous but may progress to Stevens-Johnson syndrome. Other rare side effects reported with carbamazepine include hepatitis, osteomalacia, cardiac conduction defects, and lupus-like reactions.

TABLE 54–9. AED Dosing and Target Serum Concentration Ranges

| | Trade Name | Manufacturer | Year Introduced | Usual Initial Dose | Usual Maximum Daily Dose | Target Serum Concentration Range |

^aBased on data from clinical trials—no established therapeutic ranges.

■ **Drug Interactions.** Because of concentration-dependent efficacy and side effects, drug interactions with carbamazepine often are very significant clinically. Valproic acid increases 10,11-epoxide metabolite concentrations without affecting the concentration of carbamazepine via inhibition of epoxide hydrolase. Drugs that inhibit CYP3A4 potentially may increase carbamazepine serum concentrations. Carbamazepine may interact with other drugs by inducing their metabolism.

■ **Dosing and Administration.** The variable contributions of the 10,11-epoxide metabolite and free carbamazepine concentrations have restricted a precise definition of the therapeutic range. Loading doses of carbamazepine are indicated only for critically ill patients. During dosage titration, it should be remembered that carbamazepine clearance increases with time. Doses may be started at one-fourth to

one-third the anticipated maintenance dose and increased every 2 to 3 weeks. Because of the auto- and heteroinduction of carbamazepine metabolism, it is necessary to administer the drug two to four times per day. The controlled- and sustained release formulations provide fewer peak-to-trough fluctuations, which may improve adherence, reduce side effects, and improve seizure control. Carbamazepine tablets should not be stored in places where they would be exposed to high heat and high humidity.⁴¹

■ **Advantages.** Carbamazepine was approved as an AED in 1974 and has been well studied. Oral immediate- and extended-release solid and liquid dosage forms are available. The oral solid dosage form is available as an immediate-release tablet and as a sustained-release capsule and a controlled-release tablet. The sustained- and controlled-release dosage forms allow for twice-daily dosing to reduce the

peak-to-trough fluctuations. Compared with other first-generation AEDs, carbamazepine causes minimal cognitive impairment.

■ **Disadvantages.** Carbamazepine has an active metabolite that can contribute to efficacy and toxicity. Other drugs can alter the concentration of this metabolite without changing the concentration of the parent carbamazepine. It induces its own metabolism, which requires careful dosage titration. It also induces the metabolism of other medications, and other drugs may interact with it and/or the active metabolite. There is no parenteral formulation. There are clinically meaningful CNS side effects including sedation. There may be fewer side effects with the sustained- or controlled-release formulations, but this has not been evaluated prospectively. Carbamazepine has been associated with a 1% risk of spina bifida. Chronic carbamazepine use also has been associated with alterations in bone mineral density in some studies. The generic formulations of immediate-release tablets have been associated with breakthrough seizures when brands have been switched.

■ **Place in Therapy.** Carbamazepine should be considered a first-line therapy for patients with newly diagnosed partial seizures and for patients with primary generalized convulsive seizures who are not in an emergent situation.

■ ETHOSUXIMIDE

■ **Pharmacology and Mechanism of Action.** The exact mechanism of action of ethosuximide remains elusive. Proposed mechanisms include inhibition of NADPH-linked aldehyde reductase, inhibition of the sodium-potassium ATPase system, a decrease in non-inactivating Na⁺ currents, blocking of Ca²⁺-dependent K⁺ channels, and inhibition of T-type Ca²⁺ channel currents.⁴²

■ **Pharmacokinetics.** Metabolism occurs in the liver by hydroxylation, and the metabolites are believed to be inactive. There is some evidence of a nonlinear metabolic process at higher concentrations.

■ **Adverse Effects.** The most frequently reported side effects are nausea and vomiting (up to 40%), and these symptoms may be minimized by administration of smaller doses and more frequent dosing. Other common side effects include drowsiness, fatigue, lethargy, dizziness, hiccups, and headaches. Rarely, idiosyncratic reactions such as rashes, lupus, and blood dyscrasias have been reported.⁴²

■ **Drug Interactions.** Because ethosuximide is not protein bound, displacement interactions cannot occur. The metabolism of ethosuximide may be induced by carbamazepine. A complex interaction between valproic acid and ethosuximide has been reported. Valproic acid may inhibit the metabolism of ethosuximide, but only if the metabolism of ethosuximide is near saturation.⁴⁰

■ **Dosing and Administration.** A loading dose of ethosuximide is not required. Titration over 1 to 2 weeks to maintenance doses of 20 mg/kg per day usually results in concentrations of approximately 50 mcg/mL. Data suggest that patients can be managed successfully on once-a-day therapy; however, gastrointestinal distress appears to be dose-related, and the total daily dose is usually divided into two equal doses.⁴¹

■ **Advantages.** This drug is very effective in the treatment of absence seizures. It is generally well tolerated and has few pharmacokinetic interactions.

■ **Disadvantages.** Ethosuximide has a very narrow spectrum of activity.

■ **Place in Therapy.** Ethosuximide is still a first-line treatment for absence seizures.

■ FELBAMATE

■ **Pharmacology and Mechanism of Action.** Felbamate appears to act as an antagonist of the glycine receptor site on the *N*-methyl-D-aspartate (NMDA) receptor. This action inhibits the initiation and propagation of seizures.²⁰ It also may inhibit NMDA/glycine-stimulated increases in intracellular Ca²⁺.⁴³

■ **Pharmacokinetics.** Felbamate is rapidly and well absorbed. The absorption is unaffected by food or antacids. About 40% to 50% of a dose of felbamate is metabolized by hydroxylation and conjugation pathways in the liver, with the remainder being excreted unchanged in the urine. Felbamate displays linear pharmacokinetics.⁴³

■ **Adverse Effects.** The most frequently reported side effects with felbamate prior to marketing were anorexia, weight loss, insomnia, nausea, and headache. Anorexia and weight loss may be especially problematic in children and in patients with diminished caloric intake. In addition, headache occasionally can be severe. After about 1 year of general use and 100,000 patient care exposures, the use of felbamate was found to be associated with aplastic anemia and acute liver failure. The onset was between 68 and 354 days of therapy. The approximate rate of occurrence of aplastic anemia is 1 in 3000 and of hepatitis is 1 in 10,000. Initially, no relationship with dose and no predictors of who is more likely to develop these life-threatening reactions were apparent. Data are now emerging suggesting an increased risk for aplastic anemia in patients, especially women, with a history of cytopenia, AED allergy or significant toxicity, viral infection, and/or immunologic problems.^{44–46}

■ **Drug Interactions.** Felbamate inhibits the clearance and increases the serum concentration of phenytoin, valproic acid, and phenobarbital. The concentration of carbamazepine decreases in patients on concurrent therapy with felbamate secondary to enzyme induction; however, the concentration of the 10,11-epoxide metabolite increases. It is recommended that the dose of phenytoin, carbamazepine, and valproic acid be decreased by about 30% when felbamate is added. Felbamate does not appear to interact with either gabapentin or lamotrigine. Phenytoin and carbamazepine are enzyme inducers and have been shown to increase the clearance of felbamate. Interactions with warfarin also have been reported.⁴³

■ **Dosing and Administration.** A therapeutic range for felbamate has not been established. The drug is dosed to clinical response. If felbamate is used as monotherapy, the dose is initiated at 1200 mg/day (15 mg/kg in children) and then is increased by 600 mg every 2 weeks up to a maximum dose of 3600 mg (45 mg/kg in children).

■ **Advantages.** Felbamate has a unique mechanism of action. It is approved for treating atonic seizures in patients with the Lennox

Gastaut syndrome and is effective in treating patients with partial seizures.

■ **Disadvantages.** The use of felbamate is limited by the association with aplastic anemia and hepatotoxicity, as well as multiple drug interactions.

■ **Place in Therapy.** This agent should be reserved for patients not responding to other AEDs.

■ GABAPENTIN

■ **Pharmacology and Mechanism of Action.** Gabapentin was designed to be a GABA agonist but does not react at the GABA receptor, alter GABA uptake, or interfere with GABA transaminase. Gabapentin appears to bind to an amino acid carrier protein and appears to act at a unique receptor. Gabapentin also may modulate specific voltage-sensitive Ca^{2+} channels.²⁰ It elevates human brain GABA levels, possibly via alterations in GABA synthesis or reversal of the neuronal GABA transporter, resulting in nonvesicular release of GABA.⁴⁷

■ **Pharmacokinetics.** Gabapentin is a substrate of the L-amino acid carrier protein in the gut (system L), as well as in the CNS.⁴⁸ This amino acid carrier protein transports the drug across the gut membrane by an active process. The binding of gabapentin to this system is saturable, and gabapentin therefore displays dose-dependent bioavailability that appears to vary considerably between individuals.⁴⁹ Food, including protein-rich meals, does not appear to interfere with gabapentin oral absorption.⁵⁰ Concentrations in human CSF are 5% to 35% of plasma levels, and tissue concentrations are approximately 80% of plasma levels.

Because gabapentin is eliminated exclusively by the kidneys, dosage adjustments will be necessary in patients with significantly impaired renal function. In anuric patients, 35% of gabapentin is removed by dialysis.⁵¹

■ **Adverse Effects.** Fatigue, somnolence, dizziness, and ataxia are the most frequently reported side effects. Rash is uncommon with this agent. Other side effects reported include nystagmus, tremor, and diplopia. Aggressive behavior has been reported in children.⁵² The CNS effects of gabapentin are generally less than those of traditional AEDs. Some clinicians have noted that patients may gain weight while on gabapentin.^{44–46}

■ **Drug Interactions.** Gabapentin does not induce or inhibit liver enzymes; therefore, drug interactions are not likely to occur with gabapentin. There is a 10% reduction in the clearance of gabapentin in patients taking cimetidine and a 20% reduction in the bioavailability if aluminum antacids are taken simultaneously with gabapentin. These interactions are unlikely to be clinically significant.

■ **Dosing and Administration.** Typical starting doses of gabapentin are 300 mg at bedtime on the first day, increasing to 900 mg/day over 3 days. Faster titration rates (e.g., starting at 300 to 900 mg three times daily) have been well tolerated.⁵³ The manufacturer recommends maintenance doses of 1800 to 2400 mg/day, but higher doses (5000 to 10,000 mg/day) have been used safely. It is important that clinicians titrate this drug to effect rather than a set preconceived absolute drug dosage. However, it is unclear if higher doses of gabapentin should be given more frequently than three times per day because of

saturable absorption.⁵⁴ Gabapentin does not appear to be absorbed rectally. Patients with end-stage renal disease maintained on hemodialysis should receive an initial 300- to 400-mg dose with 200 to 300 mg gabapentin given after every 4 hours of hemodialysis.⁵¹

■ **Advantages.** Gabapentin has multiple mechanisms of action and is mechanistically different from first-generation AEDs. It is not metabolized and is excreted unchanged by the kidney. Gabapentin has the additional advantages of a broad therapeutic index with minimal CNS adverse effects and no drug interactions. Doses can be escalated rapidly.

■ **Disadvantages.** Gabapentin is absorbed by an active process that saturates at higher doses. This may require more frequent daily dosing for patients who need doses greater than 3600 mg/day. Doses exceeding the 3600 mg/day maximum listed in the package insert may be required in some patients to achieve seizure remission. There is no parenteral formulation.

■ **Place in Therapy.** Gabapentin is a second-line agent for patients with partial seizures who have failed initial treatment. In addition, although monotherapy trials have no proven efficacy in previously diagnosed refractory patients, there may be a role for this drug in patients with less severe seizure disorders, such as new-onset partial epilepsy, particularly in the elderly patient. Gabapentin also has been shown to be useful in the treatment of chronic pain and other nonepilepsy conditions.

■ LAMOTRIGINE

■ **Pharmacology and Mechanism of Action.** A primary mechanism of action for lamotrigine appears to be blockade of neuronal sodium channels that is both voltage- and use-dependent. Lamotrigine produces dose-dependent inhibition of high-voltage activation Ca^{2+} currents, possibly through inhibition of presynaptic N-type Ca^{2+} channels, and blocks the release of excitatory amino acid neurotransmitters such as glutamate and aspartate.^{20,55}

■ **Pharmacokinetics.** Lamotrigine is completely and rapidly absorbed, with a bioavailability of 98%. Food does not significantly affect drug absorption. Lamotrigine is also absorbed following rectal administration, although the mean area under the curve (AUC) is approximately 50% of that achieved by oral administration. Lamotrigine is approximately 55% bound to plasma proteins. Lamotrigine is extensively hepatically metabolized by UDP-glucuronosyl transferase (UGT 1A4), which is inactive. Renal elimination of unchanged drug accounts for a minor fraction of the administered dose (<10%). When given as monotherapy in adults, lamotrigine elimination half-life is approximately 24 to 29 hours. Lamotrigine clearance is higher in children and lower in the elderly compared with young adults. There are only modest differences in the pharmacokinetics of lamotrigine in the elderly versus younger subjects. Hepatic disease, depending on severity, can influence lamotrigine pharmacokinetics. Approximately 17% of a lamotrigine dose may be removed by hemodialysis, with half-life being reduced to about 13 hours. For patients on dialysis, the half-life is much more prolonged between dialyses (57.4 hours) but shorter during dialysis (13 hours).⁵⁶

A well-defined serum concentration–effect range has not been established. The half-life is prolonged in patients with renal failure.

■ **Adverse Effects.** The most frequently reported side effects of lamotrigine include diplopia, drowsiness, ataxia, and headache.⁵⁵ Adverse effects are more common when lamotrigine is given in combination with other AEDs (e.g., diplopia when given concomitantly with carbamazepine or tremor with valproic acid) as compared with monotherapy and thus may be pharmacodynamic in nature. Lamotrigine may cause rash, which usually appears in the first 3 to 4 weeks of therapy. The rash typically is generalized, erythematous, and morbilliform and generally is mild to moderate in severity. However, Stevens-Johnson reaction also has been reported. Some rashes, especially those which develop early, may necessitate the withdrawal of lamotrigine.⁵⁷ Risk factors for the emergence of more serious rashes appear to be concomitant use of valproic acid and situations where high initial doses or rapid dosage escalation is used. Data from several European monotherapy trials suggest that when dosed appropriately, the incidence of rash from lamotrigine is similar to that of older agents such as carbamazepine and phenytoin. The incidence also may be higher in children than in adults. Lamotrigine does not appear to cause significant changes in body weight.^{44–46}

■ **Drug Interactions.** Lamotrigine does not inhibit or induce liver enzymes and has a low potential for pharmacokinetic interactions with other drugs. Lamotrigine does not interfere with oral contraceptives.

The metabolism of lamotrigine, however, does display substantial interpatient variability, and plasma clearance may be altered by concurrent therapy with other drugs. Lamotrigine elimination half-life is reduced by approximately 50% in the presence of inducing drugs, such as carbamazepine, phenobarbital, primidone, and phenytoin.⁵⁵ Concomitant treatment with oral contraceptives may lead to a reduction in the serum concentrations of lamotrigine. While this interaction has not been clearly defined, it may be speculated to result from induction of lamotrigine glucuronidation by the ethinyl estradiol component of the pill.⁵⁸ However, lamotrigine does not appear to influence the pharmacokinetics of either the estrogen or progestin component of these preparations.

Valproic acid inhibits the clearance of lamotrigine.⁵⁵ Inhibition of lamotrigine metabolism by valproic acid is substantial and appears to occur even at very low serum concentrations. Maximal inhibition of lamotrigine by valproic acid appears to occur at valproic acid doses/serum concentrations of 500 mg/day and 40–50 mcg/mL, respectively. Clinically, this implies that in order to achieve any given plasma concentration, larger maintenance doses of lamotrigine may be required in the presence of an inducer as compared with monotherapy, whereas lower doses may be necessary when given with valproic acid. A pharmacodynamic interaction may occur with concurrent carbamazepine therapy, leading to an increase in CNS side effects.

■ **Dosing and Administration.** In patients who are taking enzyme-inducing drugs, lamotrigine can be started more rapidly than in patients receiving valproic acid. The maintenance doses are also different (see Table 54–9). These different doses are critical owing to the relationship between rash, concomitant valproic acid, and the dose escalation rate. Removal of inducers from a lamotrigine regimen may necessitate decreases in lamotrigine doses, whereas removal of valproic acid may necessitate an increase in the lamotrigine dose. A dispersible tablet is available for patients who cannot swallow an oral solid.^{44–46}

■ **Advantages.** Lamotrigine is potentially a broad-spectrum AED, having efficacy in partial seizures as well as several types of

generalized seizures. A pediatric dosage form is available. It does not induce or inhibit the metabolism of other AEDs. Lamotrigine has linear pharmacokinetics and is not highly protein bound. Lamotrigine appears to be generally well tolerated in both children and elderly adult patients and does not cause weight gain.

■ **Disadvantages.** Lamotrigine is associated with rash, especially in patients who start at a high dose, have rapid dose escalation, and/or are taking concurrent valproic acid. Therefore, the initial doses must be low (lower if the patient is on valproic acid) and escalated slowly in order to maximize patient safety. There is no parenteral dosage form.

■ **Place in Therapy.** Lamotrigine is useful as both adjunctive treatment in patients with partial seizures and as monotherapy. Lamotrigine appears to have comparable effectiveness with more traditional AEDs such as carbamazepine and phenytoin in these patients when used as monotherapy. In addition, lamotrigine may be useful alternative therapy in patients with primary generalized seizure types such as absence.

■ LEVETIRACETAM

■ **Pharmacology and Mechanism of Action.** Levetiracetam, an *S*-enantiomer pyrrolidone derivative, is chemically unrelated to other available AEDs. While the precise mechanism of action of levetiracetam has yet to be delineated, it is known that this drug is not active in the classic models used to test antiepileptic drugs. This agent may have a unique mechanism of action, including reduction in high-voltage activated Ca^{2+} currents and delayed-rectifier K^{+} currents, as well as a unique action on GABA currents. Levetiracetam also appears to bind to a specific presynaptic binding site that may modulate neurotransmitter release. There is some limited evidence that levetiracetam may have *antiepileptogenic effects*, meaning that this compound may be able to prevent the development of epilepsy under certain circumstances.⁵⁹ Clinical confirmation of this animal research is still needed, however.

■ **Pharmacokinetics.** Levetiracetam is rapidly and completely absorbed following oral administration and displays negligible protein binding (<10%). Renal elimination of unchanged parent drug accounts for the majority of drug clearance (66%), with the remainder being metabolized in blood via nonhepatic enzymatic hydrolysis of an acetamide group to inactive metabolites.⁶⁰ This metabolic pathway does not involve either the CYP450 or UGT isozyme systems. The plasma half-life of this drug is approximately 7 hours. Because this drug is eliminated renally, clinicians should anticipate age-related reductions in clearance in elderly patients. Conversely, levetiracetam clearance appears to be approximately 40% higher in children than in adults. Currently, data are sparse regarding serum concentration–effect relationships, so the role of therapeutic drug level monitoring remains unclear.

■ **Adverse Effects.** Adverse effects appear to be modest, with sedation, fatigue, and coordination difficulties being the most common CNS effects. Behavioral disturbances, such as agitation, irritability, and occasionally depression, have been reported. The mechanism underlying these effects is unknown. Using a slower rate of dose escalation may be helpful in minimizing these adverse effects. Formal studies evaluating the cognitive effects of this medication have not yet been conducted.^{44–46}

■ **Drug Interactions.** Levetiracetam neither inhibits nor induces the CYP450, UGT, or epoxide hydrolase enzyme systems, and in vitro data predict a low potential for pharmacokinetic interactions. Levetiracetam does not appear to interact with other AEDs, warfarin, digoxin, or oral contraceptive drugs.^{60,61}

■ **Dosing and Administration.** Typical initial dosing of this agent is 500 mg orally twice daily, titrating at 1000-mg/day increments every 2 weeks to a maximum recommended dose of 3000 mg/day (1500 mg twice daily). In order to minimize CNS side effects, clinicians may consider initiating the drug at one-half this rate.

■ **Advantages.** Levetiracetam has a novel, although unknown, mechanism of action. It has linear pharmacokinetics and is not metabolized by the cytochrome P450 system. No significant drug interactions, including oral contraceptives, have been reported. Initial doses may be effective. The drug appears to be well tolerated, with transient sedation being the most troublesome adverse effect in most individuals.

■ **Disadvantages.** Dose adjustments are needed for patients with decreased renal functioning, and slower dose escalation may be needed to avoid CNS adverse effects. Behavioral problems may limit therapy in some patients. Currently, there is no parenteral formulation, but one is in development.

■ **Place in Therapy.** Currently, levetiracetam is indicated for patients with partial seizures who have failed initial therapy. Its role as monotherapy for partial seizures and as adjunctive treatment for generalized seizures remains to be clarified.

■ OXCARBAZEPINE

■ **Pharmacology and Mechanism of Action.** Oxcarbazepine, which is structurally related to carbamazepine, is a prodrug that is rapidly converted to a 10-monohydrate derivative (MHD), which is the active component. The mechanism of action of oxcarbazepine is similar to that of carbamazepine and perhaps lamotrigine. Oxcarbazepine and MHD block voltage-sensitive sodium channels, modulate the voltage-activated calcium currents, and increase potassium conductance. Interestingly, however, oxcarbazepine may display differing affinities for both sodium channels and Ca²⁺ channels compared with older drugs such as carbamazepine.⁶² Whereas carbamazepine may modulate L-type Ca²⁺ channels, oxcarbazepine appears to modulate N- and P-type Ca²⁺ channels.⁶³ Whether these receptor differences lead to differing patterns of clinical effectiveness is still uncertain. It has no significant interactions with brain neurotransmitters or modulation of receptor sites.

■ **Pharmacokinetics.** Oxcarbazepine is absorbed completely and is metabolized extensively by noninducible cytosolic ketoreductases to MHD.⁶⁴ The concentration of MHD peaks 4 to 6 hours after a dose of oxcarbazepine. The MHD is inactivated by glucuronide conjugation and eliminated by the kidneys. The plasma half-life of MHD is 9.3 ± 1.8 hours, and it does not change with repeated dosing because there is no autoinduction. The half-life of MHD is shorter in patients taking enzyme-inducing drugs. The relationship between dose and serum concentration is linear. Oxcarbazepine is 67% protein bound, and MHD is 35% to 40% protein bound. The pharmacokinetics of MHD in children and adolescents are similar to those in adults. Children 2 to 6 years of age need larger doses to achieve the same serum

concentration, suggesting a more rapid clearance. The C_{max} and bioavailability of MHD in elderly volunteers were higher than in younger volunteers, and the elimination rate was slower, possibly reflecting decreased renal elimination. Patients with significant renal impairment may require a dosage reduction. The suggested target serum concentration range for MHD is 20–200 mcmol/L.

■ **Adverse Effects.** Oxcarbazepine has been in clinical use worldwide since 1990 and was marketed in over 50 countries prior to approval in the United States. In U.S. clinical trials the most frequently reported adverse events were dizziness, nausea, headache, diarrhea, vomiting, upper respiratory tract infections, constipation, dyspepsia, ataxia, and nervousness. In comparative trials, oxcarbazepine generally caused fewer side effects than phenytoin, valproic acid, or carbamazepine. Dizziness may be more common in elderly patients. Overall, CNS adverse effects appear to be far more common at doses greater than 1200 mg/day. Hyponatremia, defined as a plasma sodium concentration of less than 125 mmol/L, has been reported in up to 25% of patients taking oxcarbazepine. As with carbamazepine, hyponatremia appears to occur more often in elderly patients. While the incidence of hyponatremia with oxcarbazepine is higher than that with carbamazepine, data suggest that many patients were asymptomatic, and about 80% were taking sodium-depleting medications. Clinicians should be particularly watchful in patients receiving concomitant sodium-depleting drugs such as diuretics. Hyponatremia appears to occur less frequently in children. Nevertheless, clinicians should consider monitoring serum sodium levels following the initiation of oxcarbazepine and instructing patients regarding the symptoms of hyponatremia. About 25% to 30% of patients who develop a rash with carbamazepine will experience a similar reaction with oxcarbazepine.^{44–46} The tolerability of oxcarbazepine has not been compared with that of extended-release formulations of carbamazepine that have lower peaks and potentially fewer side effects than immediate-release carbamazepine formulations.

■ **Drug Interactions.** Oxcarbazepine decreases the bioavailability of ethinyl estradiol and levonorgestrel.⁶⁵ Women concurrently taking oral contraceptives should be counseled about the potential for contraceptive failure. There are no interactions between cimetidine, erythromycin, or warfarin and oxcarbazepine. The administration of oxcarbazepine in doses greater than 1200 mg with phenytoin has resulted in a 40% increase in the concentration of phenytoin, consistent with inhibition of CYP450 2C19. Oxcarbazepine treatment also may cause modest declines in lamotrigine serum concentrations, suggesting induction of UGT isozymes.⁶⁶

Enzyme-inducing drugs increase the clearance of the active MHD. The replacement of carbamazepine with oxcarbazepine may result in a drug interaction because an enzyme-inducing drug is being removed.

■ **Dosing and Administration.** In adults, the starting dose of oxcarbazepine as monotherapy is 300 mg once or twice a day. The dose is titrated upward at a rate of 600 mg/day per week to a maximum dose of 2400 mg/day. Adverse effects frequently are dose-limiting at doses exceeding 1200 mg/day. Most patients require a slower titration rate. For children aged 4 to 16 years, the starting dose is 8 to 10 mg/kg given twice daily, not to exceed 600 mg/day. The dose is titrated to the target dose over 2 weeks. The recommended daily dose according to weight is 20–29 kg, 900 mg/day; 29.1–39 kg, 1200 mg/day; greater than 39 kg, 1800 mg/day. In patients being converted from carbamazepine, the typical maintenance doses of oxcarbazepine are 1.5 times the carbamazepine dose.

■ **Advantages.** The efficacy of oxcarbazepine is comparable with that of carbamazepine, phenytoin, and valproic acid. It has been approved in 50 countries, and thus broad international experience has been gained.

■ **Disadvantages.** About 30% of patients who have experienced a rash with carbamazepine have a cross-reaction with oxcarbazepine. There are more reports of hyponatremia with oxcarbazepine, especially in patients at risk, including the elderly and patients receiving sodium-depleting drugs such as diuretics. Replacing carbamazepine with oxcarbazepine may result in interactions with the removal of carbamazepine. Enzyme-inducing drugs may increase the clearance of MHD. This drug is not likely to be effective in seizure types where carbamazepine is ineffective, such as absence or myoclonic seizures.

■ **Place in Therapy.** Oxcarbazepine is indicated for use as monotherapy or adjunctive therapy in the treatment of partial seizures in adults and as monotherapy and adjunctive therapy in the treatment of partial seizures in patients as young as 4 years of age with epilepsy. It is also a potential first-line drug for patients with primary generalized convulsive seizures. Oxcarbazepine may be effective in patients not demonstrating a response to carbamazepine.

■ PHENOBARBITAL

■ **Pharmacology and Mechanism of Action.** Phenobarbital may elevate seizure threshold by decreasing postsynaptic excitation, possibly by stimulating postsynaptic GABAergic inhibitor responses.²⁰

■ **Pharmacokinetics.** Phenobarbital is absorbed rapidly and completely regardless of whether it is given orally, intramuscularly, or rectally.⁴⁰ Phenobarbital penetrates the brain at a rate comparable with that of phenytoin, and peak concentrations are achieved 3 to 20 minutes after an intravenous dose. Phenobarbital is about 50% bound to plasma proteins, and it has a very long half-life.

Drugs affecting liver enzymes may alter phenobarbital metabolism, but phenobarbital clearance is not affected by liver blood flow. The elimination of phenobarbital is linear. Because tubular reabsorption of phenobarbital is pH dependent, the amount excreted renally can be increased by giving diuretics and urinary alkalinizers.⁴⁰

■ **Adverse Effects.** CNS side effects are the primary factors limiting the use of phenobarbital. Tolerance usually develops to initial complaints of fatigue, drowsiness, sedation, and depression. In children, paradoxically, the primary side effect is hyperactivity. Phenobarbital impairs higher cortical function and depresses cognitive performance. Phenobarbital also may cause porphyria and rash, including serious rashes such as Stevens-Johnson⁶⁷ (see Table 54–6).

■ **Drug Interactions.** Phenobarbital is a potent enzyme inducer and may increase the elimination of any drug metabolized by CYP450- or UGT-mediated metabolism. Valproic acid, phenytoin, felbamate, cimetidine, and chloramphenicol inhibit phenobarbital metabolism, necessitating a decrease in dose. Ethanol increases the metabolism of phenobarbital.⁴⁰

■ **Dosing and Administration.** In nonacute situations, phenobarbital should be started in low doses and titrated upward. The dose-concentration relationship is linear. Because the half-life of phenobarbital is long, doses can be given once daily. Bedtime dosing may

minimize CNS depression. Because of its long half-life, phenobarbital takes 3 to 4 weeks to reach steady state. Therefore, rapid dosage adjustments should be avoided in a nonacute situation.

■ **Advantages.** Phenobarbital has linear and predictable pharmacokinetics. If the dose is doubled, the resulting serum concentrations double. Multiple dosage forms (e.g., oral solid, oral liquid, intramuscular, and intravenous) are available, so the route of administration can be tailored to patient needs, including emergent conditions. It is the most inexpensive AED.

■ **Disadvantages.** Phenobarbital is associated with significant side effects. These include delayed intellectual development and hyperactivity in children and significant cognitive impairment in adults. It is an enzyme inducer and interacts with many other drugs metabolized by the cytochrome P450 system. Phenobarbital has a very long half-life, and thus achievement of steady state is delayed. Dosage adjustments should not be made more often than every 2 to 3 weeks.

■ **Place in Therapy.** Phenobarbital is the drug of choice for neonatal seizures but in other situations is reserved for patients who have failed other AEDs. It may be useful given intravenously in refractory status epilepticus.

■ PHENYTOIN

■ **Pharmacology and Mechanism of Action.** Proposed mechanisms include alteration of ion fluxes associated with depolarization, repolarization, and membrane stability; alteration of calcium uptake in presynaptic terminals; influence on calcium-dependent synaptic protein phosphorylation and transmitter release; alteration of the sodium-potassium ATP-dependent ionic membrane pump; and prevention of cyclic nucleotide buildup and cerebellar stimulation.²⁰

■ **Pharmacokinetics.** The pharmacokinetics of phenytoin are complex and fascinating. Space does not permit an in-depth review of phenytoin pharmacokinetics in this chapter. For a more in-depth understanding, the reader is referred to a more extensive review.⁶⁸ The oral absorption of phenytoin is almost complete. Dissolution is the rate-limiting step, and absorption may be saturable at higher doses, such as those used for oral loading doses. Absorption following intramuscular administration of phenytoin is erratic and delayed, and intramuscular injections are painful. Intramuscular absorption following fosphenytoin is rapid and well tolerated.

Phenytoin enters the brain rapidly and is redistributed to other body tissues, including breast milk and the placenta. It is highly (>90%) protein bound. Phenytoin competes for albumin sites with other highly protein bound drugs. It is essential to know the patient's serum albumin level in interpreting the serum concentrations of phenytoin.⁶⁹ Patients with significant renal dysfunction will have altered phenytoin protein binding. Obesity increases the volume of distribution of phenytoin.

Phenytoin is metabolized in the liver by parahydroxylation. The major isoforms responsible for the metabolism of phenytoin are CYP2C9 and CYP2C19. Phenytoin displays Michaelis-Menton pharmacokinetics, which means that the metabolism of phenytoin saturates at doses used clinically. The clinical importance of this is that a small change in dose can result in a very disproportionately large increase in serum concentrations leading to potential toxicity. The metabolism of phenytoin may saturate even at low serum

concentrations within the therapeutic range. The metabolism of phenytoin has been shown to decrease with age.

■ **Adverse Effects.** When phenytoin is initiated, the CNS depressant effects may result in lethargy, fatigue, incoordination, blurred vision, higher cortical dysfunction, and drowsiness (see Table 54–6). These effects usually are transient and may be minimized by slow dosage titration. Nystagmus, ataxia, and altered mental status are associated with higher concentrations. At very high concentrations (>50 mcg/mL), phenytoin may exacerbate seizures.

It is difficult to determine whether the chronic side effects of phenytoin are concentration- or duration-dependent. One of the more common chronic side effects is gingival hyperplasia. Good oral hygiene may minimize gingival hyperplasia and should be encouraged. Other chronic effects include hirsutism, acne, coarsening of facial features, vitamin D deficiency, osteomalacia, folic acid deficiency, carbohydrate intolerance, immunologic disturbances, hypothyroidism, and peripheral neuropathy. Phenytoin is associated with rare hypersensitivity or idiosyncratic reactions resulting in rashes, Stevens-Johnson syndrome, pseudolymphoma, bone marrow suppression, lupus-like reactions, and hepatitis.⁷⁰

■ **Drug Interactions.** Phenytoin is associated with numerous drug interactions involving altered absorption, metabolism, and protein binding (see Tables 54–7 and 54–8) that can enhance or reduce its effects. Phenytoin is an inducer of both CYP450 and UGT isozymes. The absorption of phenytoin may be increased or decreased with the administration of food depending on the composition of the meal. The bioavailability of phenytoin suspension may be decreased in patients receiving continuous enteral nutrient tube feedings. A single-dose study of simultaneous administration of enteral feeding found no difference in phenytoin bioavailability, suggesting that the mechanism was something other than physical contact.⁶⁸

A complex interaction of phenytoin with folic acid also has been described, making vitamin ingestion an important part of the drug history. Phenytoin reportedly decreases folic acid absorption, but folic acid enhances the clearance of phenytoin. Replacement of folic acid can reduce phenytoin concentrations and result in loss of efficacy.⁶⁸

■ **Dosing and Administration.** Four dosage forms are used for oral administration of phenytoin (Table 54–10). The salt content should be considered when changing from one dosage form to another. Changes between dosage forms may lead to changes in phenytoin concentration. Phenytoin capsules are designated as immediate-release or extended-release. Only the extended-release capsules should be used in once-a-day dosing. Particle size rather than formulation may determine the rate of absorption. Recently, Phenytek has been marketed in the United States as an extended-release dosage form of phenytoin.

If oral administration is not feasible, intravenous administration of phenytoin is preferred over intramuscular administration. Fosphenytoin is a prodrug for phenytoin and is available as a parenteral dosage form. It is very water-soluble and is converted rapidly to phenytoin systemically. Fosphenytoin can be given rapidly intravenously and intramuscularly with reliable absorption and minimal pain. It is significantly better tolerated than phenytoin.

Oral dosing of phenytoin should start at about 5 mg/kg per day for adults. If using oral loading doses, 20 mg/kg is typical, and the total dose should be divided by four and given at 6-hour intervals. Subsequent dosage adjustments should be done cautiously owing to its nonlinear elimination. One author has suggested that if the serum concentration is less than 7 mcg/mL, the dose should be increased by 100 mg/day; if the serum concentration is between 7 and 12 mcg/mL, the dose can be increased by 50 mg/day; and if the serum concentration is greater than 12 mcg/mL, the dose can be increased by 30 mg/day or less. These increases are proposed to result in less than 10% of patients achieving a phenytoin serum concentration greater than 25 mcg/mL.⁷¹

■ **Advantages.** Phenytoin has been used for over 60 years, and its risk-to-benefit ratio is well developed. It is available in oral solid, oral liquid, extended-release oral solid, and parenteral (phenytoin and fosphenytoin) dosage forms, allowing flexibility in dosing and use in emergent conditions.

■ **Disadvantages.** Phenytoin displays Michaelis-Menton pharmacokinetics, meaning that the metabolism saturates at doses given clinically. This makes phenytoin a difficult drug to dose. Also, phenytoin is an inducer of cytochrome P450 isozymes, is metabolized by cytochrome P450 enzymes, and is highly protein bound. Therefore, many drug interactions are associated with this agent. Phenytoin also has multiple adverse effects, including gait disorders, cognitive slowing at higher concentrations, gingival hyperplasia, cosmetic alterations, osteomalacia, rash, and teratogenicity.

■ **Place in Therapy.** Phenytoin has long been a first-line AED for primary generalized convulsive and partial seizures. Its use in therapy may be reevaluated as more experience is gained with newer AEDs. Phenytoin or fosphenytoin is a first-line drug for the treatment of status epilepticus.

■ **TIAGABINE**

■ **Pharmacology and Mechanism of Action.** Tiagabine is a potent and specific inhibitor of GABA uptake into glial and other neuronal

TABLE 54–10. Phenytoin Dosage Forms

| Dosage Form | Salt or Acid | Extended or Prompt | Amount of Acid Available |
|--------------------------------------|------------------|--------------------|--------------------------|
| Dilantin capsules 100 mg 30 mg | Phenytoin sodium | Extended | 92 mg 27 mg |
| Dilantin suspension 125 mg/5 mL | Phenytoin acid | Prompt | 125 mg/5 mL |
| Dilantin Infatabs 50 mg | Phenytoin acid | Prompt | 50 mg |
| Phenytoin injectable 50 mg/mL | Phenytoin sodium | Prompt | 46 mg/mL |
| Fosphenytoin 50 mg PE/mL | | | 50 mg PHT equivalents/mL |
| Phenytoin capsules (generic) | Phenytoin sodium | Prompt | 92 mg |

PHT = phenytoin.

elements. Thus tiagabine enhances the action of GABA by decreasing its removal from the synaptic space.⁷²

■ **Pharmacokinetics.** Tiagabine is absorbed quickly and nearly completely after oral administration. There is a linear relationship between daily doses and serum concentrations. It is oxidized in the liver by CYP450 3A4 enzymes, and enzyme inducers increase its clearance. Children eliminate tiagabine slightly faster than adults. Subjects with hepatic impairment have higher and more prolonged plasma concentrations of total and unbound drug. Renal dysfunction does not change its pharmacokinetics.⁷²

■ **Adverse Effects.** The most frequently reported adverse effects of tiagabine are dizziness, asthenia, nervousness, tremor, diarrhea, and depression. Rash is uncommon with tiagabine. Adverse events usually are mild to moderate in severity and transient, and most were associated with dose titration.⁷³ CNS side effects may be diminished by taking tiagabine with food, thus slowing the absorption rate. Serious adverse events were uncommon, and no idiosyncratic events, including visual field defects, were reported.^{44–46}

■ **Drug Interactions.** Enzyme inducers, such as carbamazepine and phenytoin, increase tiagabine clearance and decrease the half-life. Food decreases the rate but not the extent of absorption. Tiagabine is displaced from protein by naproxen, salicylates, and valproate. However, tiagabine does not displace phenytoin, valproic acid, amitriptyline, tolbutamide, or warfarin.⁷²

■ **Dosing and Administration.** A clear dose-response has been demonstrated, and the minimal effective adult dose level is 30 mg/day. The initial dose, 4 mg/day, can be titrated up to 56 mg/day by adding 4 to 8 mg to the daily dose each week. The dosage range typically employed is 32 to 56 mg daily,⁷² and the variability can be explained in part by the presence of concomitant enzyme-inducing AEDs. Slow dosage titration is essential to decrease adverse CNS effects.^{44–46}

■ **Advantages.** Tiagabine has a specific, known mechanism of action. It is the first drug marketed in the United States that acts only on GABA reuptake. This drug has linear pharmacokinetics and is not reported to interact with other drugs.

■ **Disadvantages.** Initially high and rapid dosage escalation is associated with increased CNS side effects. Therefore, the drug must be started at a low dose and titrated gradually to patient response. Lower doses may be needed in patients with liver disease. Tiagabine is metabolized by CYP450 3A4 enzymes, and other drugs may alter its clearance. There is no parenteral formulation.

■ **Place in Therapy.** Tiagabine is considered a second-line therapy for patients with partial seizures who have failed initial therapy. It does not appear to have a role in primary generalized seizure types.

■ TOPIRAMATE

■ **Pharmacology and Mechanism of Action.** Topiramate is a sulfamate-substituted monosaccharide that has multiple modes of action involving voltage-dependent sodium channels, GABA receptors, and antagonism of α -amino-3-hydroxy-5-methyl-4-isoxazole-4-propionic acid (AMPA) subtype glutamate receptors.⁷⁴

■ **Pharmacokinetics.** While generally considered to have linear absorption and elimination pharmacokinetics, a greater than proportional increase in both maximal peak concentration and area under the concentration-time curve has been observed and probably is explained by saturable binding of the drug to erythrocytes.⁷⁵ Topiramate does not display significant protein binding. Approximately 50% of the dose is excreted unchanged renally; however, metabolism is increased by approximately 50% when topiramate is given with enzyme-inducing AEDs. Renal tubular reabsorption may be involved prominently in the renal handling of topiramate.⁷⁶

■ **Adverse Effects.** The main adverse events of topiramate are ataxia, impaired concentration, memory difficulties, attentional deficits, confusion, dizziness, fatigue, paresthesias, somnolence, and “thinking abnormally,” which rarely has included psychosis. Word-finding difficulties are a somewhat unique and specific problem with topiramate and may occur in a significant number of patients. Most of these occurred during rapid titration and at higher doses.⁷⁷ There may be an increased incidence of cognitive dysfunction in patients receiving concomitant therapy with topiramate and valproic acid. During long-term treatment, weight loss can occur, a phenomenon that may be dose-dependent. Nephrolithiasis has occurred in 1.5% of patients receiving topiramate, which is two to four times the incidence in the general population. Patients should be encouraged to maintain adequate fluid intake in order to minimize this problem. Recently, the use of topiramate was associated with acute narrow-angle glaucoma, oligohydrosis, and metabolic acidosis. Metabolic acidosis in part may explain the anorexia and weight loss seen with this drug.⁴⁴

■ **Drug Interactions.** Topiramate does not change plasma levels of carbamazepine, carbamazepine-epoxide, or lamotrigine. Oral clearance of digoxin is slightly increased when topiramate is added. Topiramate coadministration may result in increased phenytoin serum concentrations in some patients, an effect consistent with *in vitro* studies showing an inhibitory effect of topiramate on the CYP2C19 isoform. The variable response seen with the interaction of topiramate and phenytoin may be explained by the intersubject variability in the proportion of phenytoin clearance attributed to CYP2C19 metabolism and whether the patient is a homozygous or heterozygous carrier of the mutant allele responsible for the CYP2C9 and/or CYP2C19 “poor metabolizer” phenotype. Topiramate can increase the oral clearance of valproic acid modestly and increase formation of the 4-ene-VPA metabolite. The clinical significance of this interaction is unclear. Topiramate increases the clearance of ethinyl estradiol in a dose-dependant manner. Topiramate doses of less than 200 mg/day are unlikely to alter oral contraceptive pharmacokinetics. Carbamazepine and phenytoin increase topiramate clearance.⁷⁸

■ **Dosing and Administration.** Topiramate should be titrated slowly in order to avoid adverse events.⁷⁴ Starting doses are 12.5 to 50 mg/day, increasing by 12.5 to 50 mg/day every week or every other week. The minimally effective dose of topiramate is approximately 200 mg/day.⁷⁹ For patients on other AEDs, doses of greater than 600 mg/day do not appear to lead to improved efficacy and may cause increased adverse effects; however, higher doses may prove beneficial to individual patients who tolerate them.⁸⁰ Monotherapy doses as high as 1000 mg/day have been well tolerated and effective in some patients.

■ **Advantages.** Topiramate has multiple mechanisms of action and may be a broad-spectrum AED. The kidney mainly eliminates it,

although some liver metabolism occurs. It has linear pharmacokinetics and few drug interactions.

■ **Disadvantages.** With rapid dosage escalation, topiramate may compromise cognitive functioning, including impaired word finding and short-term memory. Therefore, low initial doses should be used, and the dose must be titrated slowly. Renal stones and weight loss also have been associated with topiramate use. The dose should be decreased in patients with renal failure. There is no parenteral formulation.

■ **Place in Therapy.** Topiramate is a second-line AED for patients with partial seizures who have failed initial therapy. Its role as a primary AED and in other seizure types is being evaluated.

■ VALPROIC ACID/DIVALPROEX SODIUM

■ **Pharmacology and Mechanism of Action.** Initially it was believed that valproic acid increased GABA by inhibiting its degradation or by activating its synthesis. Although this may explain in part valproic acid effects, the time course for the increase in GABA compared with the onset of anticonvulsant effects indicates that alterations of the synthesis and degradation of GABA do not fully explain the antiseizure activity of valproic acid. It has been proposed that valproic acid may potentiate postsynaptic GABA responses, may have a direct membrane-stabilizing effect, and may affect potassium channels.⁸¹

■ **Pharmacokinetics.** Valproic acid appears to be absorbed completely from available oral dosage forms when administered on an empty stomach.⁸¹ However, the rate of absorption differs among preparations. Peak concentrations occur in 0.5 to 1 hour with the syrup, 1 to 3 hours with the capsule, and 2 to 6 hours with the enteric-coated tablet.⁸¹ The extended-release formulation (Depakote-ER) is FDA approved for use in both patients with migraine headache and epilepsy. It should be noted, however, that the bioavailability of this formulation is approximately 15% less than that of enteric-coated divalproex sodium (Depakote).

Valproic acid is extensively bound to albumin, and this binding is saturable. Accordingly, the valproic acid free fraction will increase as the total serum concentration increases. Because of this saturable binding, measurement of unbound serum concentrations may be a better monitoring parameter than the total valproic acid serum concentration, especially at higher concentrations or in patients with hypoalbuminemia.⁴⁰

The primary route of valproic acid metabolism is β -oxidation, although up to 40% of a dose may be excreted as the glucuronide. At least 10 metabolites of valproic acid have been identified. Some of these may have weak anticonvulsant activity, and at least one metabolite may be responsible for the hepatotoxicity reported with valproic acid. One of the lesser oxidative metabolites, 4-en-valproic acid, causes significant hepatotoxicity in rats. The formation of this metabolite is increased when valproic acid is given with enzyme-inducing drugs.⁸¹

■ **Adverse Effects.** The most frequently reported side effects are gastrointestinal complaints (up to 20%), including nausea, vomiting, anorexia, and weight gain. Pancreatitis is very rare. The gastrointestinal complaints may be minimized but not totally alleviated with the enteric-coated formulation or by giving the drug with food. Other frequently reported side effects (e.g., drowsiness, ataxia, and postural tremor) may respond to a modification of dose (see Table 54–6).

Alopecia and hair changes are temporary, and hair growth returns even with continued dosing. Weight gain can be significant for many patients and may involve stimulation of appetite and/or inhibition of fatty acid β -oxidation leading to reduced metabolic rate.⁸² Valproic acid causes minimal cognitive impairment.⁸¹

The most serious side effect reported with valproic acid is hepatotoxicity. Hyperammonemia is common (50%) but does not necessarily imply liver damage; however, at least 67 fatalities have been attributed to valproic acid hepatotoxicity. Most deaths have occurred in patients who were younger than 2 years of age, mentally retarded, and receiving multiple AEDs. Hepatotoxicity occurred early in the course of therapy. Patients who complain of nausea, vomiting, lethargy, anorexia, and edema in the first 6 to 12 months of therapy should have liver function tests done. Multiple-AED therapy may alter the metabolism of valproic acid, leading to increased formation of the potentially liver-toxic 4-en-valproic acid. Valproic acid has been shown to alter carnitine metabolism, and it has been postulated that a deficiency of carnitine alters fatty acid oxidation that could lead to both liver toxicity and hyperammonemia.⁸³ However, valproic acid hepatotoxicity has occurred in a patient taking supplemental carnitine, and a prospective study demonstrated no effect on well-being when carnitine was added. While carnitine may ameliorate hyperammonemia in part, it is expensive, and there are only limited data to support routine supplemental use in patients taking valproic acid.⁸⁴

Thrombocytopenia and alterations in platelet aggregation occur in the patients receiving valproic acid, and these phenomena are related to serum concentration. Other hematologic toxicities have been reported, including leukopenia with transient neutropenia, transient erythroblastopenia, and bone marrow changes. Polycystic ovary syndrome and menstrual cycle irregularities also have been associated with valproic acid.⁸³

■ **Drug Interactions.** Drugs that affect liver enzymes may alter valproic acid kinetics by increasing or decreasing clearance; for example, phenytoin, phenobarbital, primidone, and carbamazepine all increase valproic acid clearance. Topiramate may reduce valproic acid serum concentrations modestly. Because it is highly protein bound, other highly protein-bound drugs may displace valproic acid. Free fatty acids and aspirin may alter valproic acid binding by displacement. Felbamate may impair valproic clearance via inhibition of β -oxidation.

Valproic acid is an enzyme inhibitor that can inhibit specific cytochrome P450 isozymes, epoxide hydrolase, and UGT isozymes. The addition of valproic acid to phenobarbital results in a 30% to 50% decrease in the clearance of phenobarbital and potential toxicity if the dose of phenobarbital is not reduced. Valproic acid may increase concentrations of 10,11-carbamazepine epoxide without affecting concentrations of the parent drug via inhibition of epoxide hydrolase. Valproic acid is also a potent inhibitor of lamotrigine, via inhibition of UGT enzymes, and can result in a doubling of the half-life of lamotrigine.⁸⁵

■ **Dosing and Administration.** Although some patients may have a half-life sufficiently long to permit once-daily dosing with enteric-coated divalproex, more frequent dosing is the norm. Based on half-life data, twice-daily dosing is feasible with any valproic acid dosage form; however, children and other patients taking enzyme inducers may require dosing three to four times daily.⁴⁰ The serum concentration–dose relationship is curvilinear (i.e., the concentration–dose ratio decreases with increasing dose) probably because of increasing free concentrations and a resulting increase in clearance.⁴⁰

Valproic acid is available as a soft gelatin capsule, an enteric-coated tablet, a syrup, a “sprinkle,” an extended-release formulation

designed for once-daily dosing, and a parenteral (intravenous) formulation for replacement of oral therapy or in situations where rapid loading of valproic acid is deemed necessary.⁸¹ This parenteral formulation must not be given intramuscularly because it may cause tissue necrosis. The sprinkle, designed to be opened and mixed with food, has a slower rate of absorption, which results in fewer fluctuations in the peak-to-trough ratio. The syrup is absorbed more rapidly than any solid dosage form. The enteric-coated tablet is not sustained-release; it consists of sodium divalproex, which must be metabolized in the gut to valproic acid. It is enteric coated to reduce the incidence of gastrointestinal distress. The enteric coating does cause delayed absorption, although once the enteric coating dissolves, sodium divalproex has absorption, metabolism, and elimination rates similar to those of the gelatin capsule. Clinicians may need to monitor serum drug concentrations if converting patients from divalproex (Depakote) to the extended-release formulation (Depakote-ER). If a patient is switched from Depakote to Depakote-ER, the dose should be increased by 14% to 20%. Depakote-ER may be given once daily.

Although 100–120 mcg/mL is widely quoted as the upper end of the therapeutic range, experience indicates that a significant number of patients have improved seizure control when the concentration is above this level. Although some reports have linked tremor, drowsiness, stupor, and decreases in fibrinogen to concentrations greater than 80 to 100 mcg/mL, there are very few clearly defined concentration-dependent side effects of valproic acid. In refractory or partially responding patients, the concentration of valproic acid may be titrated upward cautiously, provided the patient is closely monitored. As the concentration is increased, protein binding may become saturated, and serum concentration monitoring of free drug may be helpful.⁴⁰

■ **Advantages.** Valproic acid is available in multiple dosage formulations. It has a wide therapeutic index and can be considered a broad-spectrum AED. It also may be useful in other neurologic or psychiatric disorders, including migraine headache and bipolar-affective disorder.

■ **Disadvantages.** Some patients report significant weight gain with valproic acid, and this may limit compliance. Valproic acid is also associated with other side effects, such as alopecia, tremor, pancreatitis, polycystic ovary disease, and thrombocytopenia. This drug has been associated with hepatic necrosis in young children. Valproic acid is an enzyme inhibitor and is involved in multiple drug-drug interactions.

■ **Place in Therapy.** Valproic acid is first-line therapy for primary generalized seizures such as myoclonic, atonic, and absence seizures. It can be used as both monotherapy and adjunctive therapy for partial seizures, and it can be very useful in patients with mixed seizure disorders.

■ ZONISAMIDE

■ **Pharmacology and Mechanism of Action.** Zonisamide, a synthetic 1,2-benzisoxazole derivative classified as a sulfonamide, is chemically different from other AEDs. In animal testing it was demonstrated to be a broad-spectrum AED. It is believed to exert its antiepileptic effect by reducing repetitive neuronal firing via blockade of voltage-sensitive sodium channels, by reducing voltage-dependent T-type Ca^{2+} channels, by facilitating dopaminergic and serotonergic neurotransmission, by weakly inhibiting carbonic anhydrase, and by blocking K^{+} evoked glutamate release. It is also postulated that zonisamide may protect the neurons from free radical damage.⁸⁶

■ **Pharmacokinetics.** Zonisamide is absorbed completely, reaching a maximum peak concentration in 2 to 6 hours. It is only about 40% protein bound and has a very long half-life of approximately 63 to 69 hours in uninduced subjects. Zonisamide is metabolized by both CYP3A4 (50%) and *N*-acetylation (20%). Eight inactive metabolites have been identified. About 30% is excreted unchanged. Marked renal impairment ($\text{Cr}_{\text{Cl}} < 20 \text{ mL/min}$) was associated with an increase in the AUC of zonisamide by 35%. Zonisamide is distributed to most tissues, but the concentration in red blood cells, liver, kidney, and adrenal gland is twice as high. Zonisamide crosses the placenta. The concentration in breast milk is similar to that in the plasma. Although not firmly established, a target concentration range of 10–40 mcg/mL has been suggested.⁸⁷

■ **Adverse Effects.** The most common adverse effects of zonisamide include somnolence, dizziness, anorexia, headache, nausea, agitation, and irritability. Adverse effects may be more common during rapid dose escalation. Because zonisamide is structurally related to sulfonamides, hypersensitivity reactions may occur (0.02% of patients), and zonisamide should be used with caution (if at all) in patients with a confirmed history of allergy to sulfonamide compounds. A 2.6% incidence of symptomatic kidney stones has been reported in patients treated in the United States.⁸⁸ Because of reports of modest, reversible declines in renal function in some patients, monitoring of renal function may be advisable for certain patients. Oligohydrosis has been reported. In addition, modest weight loss has been reported with this agent.^{44–46}

■ **Drug Interactions.** Zonisamide does not inhibit or induce the cytochrome P450 system. Enzyme inducers and CYP3A4 inhibitors can affect the concentration of zonisamide.³² Treatment with enzyme inducers can reduce zonisamide half-life to 27 to 36 hours.⁸⁹

■ **Dosing and Administration.** In adults, the initial recommended dose of zonisamide is 100 mg/day. Doses should be titrated by 100 mg daily every 2 weeks to patient response. The dosage range in adults is 100 to 600 mg/day. In children, zonisamide can be initiated at a dose of 2–4 mg/kg per day and titrated to 4–8 mg/kg per day up to a maximum of 12 mg/kg per day. Zonisamide is stable for 48 hours when mixed with water, apple juice, or pudding for patients who have trouble swallowing oral solid dosage forms.

■ **Advantages.** Zonisamide has multiple mechanisms of action and may be a broad-spectrum AED. It has been used in other countries, and there is broad international experience with this drug. It has a very long half-life, which is suitable for once- or twice-daily dosing. Once-daily dosing is associated with more fluctuations around the mean concentration and perhaps more side effects. Patients may experience modest weight loss with this drug.

■ **Disadvantages.** The dose of zonisamide should be titrated slowly to patient response. Renal stones and oligohydrosis also have been associated with zonisamide. In addition, cognitive impairment may occur, especially if dosage is escalated rapidly.

■ **Place in Therapy.** Zonisamide is currently approved for the adjunctive treatment of partial seizures. Thus far, insufficient data exist to support its use as initial monotherapy. Zonisamide is potentially effective in a variety of partial and primary generalized seizure types.

PHARMACOECONOMIC CONSIDERATIONS

CLINICAL CONTROVERSY

Given the cost differential between the older-generation and newer-generation AEDs, the place in therapy of these newer drugs is controversial. The cost of the newer AEDs generally is much higher than that of the older drugs. Given that, in general, the efficacy of the newer drugs is comparable with that of the older agents, many clinicians (and patients) have been slow to adopt this newer generation of drugs. It is important to recognize that overall effectiveness encompasses both efficacy and tolerability assessments. Generally speaking, the newer generation of AEDs possesses fewer adverse effects and appears to be better tolerated than older, far less expensive agents such as the barbiturates. Whether these sometimes subjective differences justify the difference in cost needs to be determined on an individual basis.

The direct costs of epilepsy include the cost of the drug, treatment of adverse events, emergency room visits, drug levels, laboratory tests, physician visits, rehabilitation, and transportation. Indirect costs include the costs associated with time lost from work, the inability to get a job, decreased productivity, and mortality.

It is difficult to assess the entire cost of epilepsy to society. Pashko and coworkers,⁹⁰ using a cohort of Pennsylvania Medicaid patients, estimated that the total direct cost of epilepsy is in excess of \$10 billion annually, with the majority of the per-patient costs incurred for inpatient hospitalization (uncontrolled seizures or treatment-related toxicity). Another study suggested that the direct costs of epilepsy made up about 37% of the total costs, with indirect costs accounting for the remainder.⁹¹ This study also indicated that the costs were much less for a patient who is well controlled than for a patient who is poorly controlled. Drug costs in the Pashko study accounted for about 10% of the total costs of epilepsy. In another study, the cost-effectiveness of some of the newer drugs (lamotrigine, vigabatrin, and gabapentin) was estimated for the first year of drug therapy. There was little difference in initial costs, but gabapentin, with fewer adverse effects, resulted in cost savings.⁹² The methodology used in this study has been criticized. There have been no pharmacoeconomic studies comparing the older, less expensive AEDs with the newer, more expensive drugs.

Providing the best quality of life possible is a treatment goal for patients with epilepsy. This concept entails more than a balance between side effects and the number of seizures. Quality of life takes into account all the concerns of patients with epilepsy, including their social and economic concerns. This can best be assessed by the patient. Complete seizure freedom leads to the best quality of life.¹³ In one study, driving was listed as the most important concern by 28% of patients, followed by employment (21%), independence (9%), safety (6%), AED side effects (5%), seizure unpredictability (5%), and seizure avoidance (5%).⁹³ Assessment of quality of life as a therapeutic outcome ultimately may be more meaningful than measuring blood levels of the AEDs. Several quality-of-life instruments have been used, although primarily as research tools.⁹⁴ A single seizure can be devastating to a given patient.

It is clear that the cheapest drugs in epilepsy (e.g., phenobarbital) are not the best because of the number of side effects. Further drug therapy that would control seizures, decrease side effects, improve the quality of life, and reduce the use of other health care resources would be cost-effective. Because epilepsy treatment continues to be

very patient-specific, the drug or combination of drugs that controls seizures with the least number of side effects will be the drug of choice for that patient no matter how expensive the drug acquisition cost.

Because many patients with epilepsy require minimal variation in blood concentrations to prevent seizures and avoid side effects, generic prescribing for epilepsy remains controversial. One study suggested that the money saved by generic prescribing is outweighed by the negative health gain for the person with epilepsy, increased work in general practice, and increased social costs.⁹⁵

EVALUATION OF THERAPEUTIC OUTCOMES

A therapeutic range should be established for each patient. This range should define concentrations that result in minimal side effects and optimal seizure control. This therapeutic plasma concentration range should be used to identify the appropriate patient-specific dose. Patients should be monitored chronically for seizure control, comorbid conditions, social adjustment (including quality-of-life assessments), drug interactions, compliance, and adverse effects. Periodic screening for comorbid neuropsychiatric disorders such as depression and anxiety is also important. Clinical response is more important than the serum drug concentration.

Outcomes can be assessed by prospective clinical monitoring, drug utilization review, and quality-of-life assessments. Clinical monitoring involves identifying the number and type of seizures. Patients should be given a seizure diary, and the severity as well as the frequency of seizures should be monitored. There should be a decrease in the number and/or severity of seizures. Patients should be questioned regularly to determine whether they are seizure-free. It is important to recall that perhaps as many as 30% of patients will be intractable to current pharmacologic treatments. In these patients, if the clinician has determined that AED dosage has been maximized, one should consider either AED combination therapy or, potentially, evaluation for epilepsy surgery or the vagal nerve stimulator.

The treatment of epilepsy begins with a careful identification of the seizure type and selection of the most appropriate AED. Therapy should be initiated slowly, except in life-threatening situations, to avoid acute toxicity. Although most patients can be managed successfully on monotherapy, some patients' seizures remain uncontrolled despite the use of multiple AEDs. Some patients may be genetically refractory to AED therapy. The newer AEDs, as adjunctive therapy or monotherapy, offer additional opportunity for complete seizure control. There is a continuing need for new AEDs and additional research in this area.

STATUS EPILEPTICUS

Stephanie J. Phelps, Collin A. Hovinga, and Bradley A. Boucher

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Status epilepticus (SE) is a neurologic emergency that may be associated with significant morbidity (i.e., brain damage) and mortality.
- 2 Generalized convulsive status epilepticus (GCSE) is defined as any recurrent or continuous seizure activity lasting longer than 30 minutes in which the patient does not regain baseline mental status. Any tonic-clonic seizure that does not stop automatically within 10 minutes should be treated.
- 3 There are two types of status epilepticus, generalized convulsive status epilepticus (GCSE) and nonconvulsive status epilepticus (NCSE). GCSE is the most common type.
- 4 Most GCSE develops in patients with no history of epilepsy; however, a patient with preexisting epilepsy may experience GCSE as a result of acute anticonvulsant withdrawal, metabolic disorder or concurrent illness, or progression of neurologic disease.
- 5 Although the pathophysiology of GCSE is unknown, experimental models have shown that there is a dramatic decrease in γ -aminobutyric acid (GABA)-mediated inhibitory synaptic transmission and that glutamatergic excitatory synaptic transmission sustains the seizures.
- 6 General treatment includes patient stabilization, adequate oxygenation, preservation of cardiorespiratory function, management of systemic complications, and aggressive assessment of underlying causes.
- 7 The main purpose of treatment is to prevent or decrease cerebral damage by terminating all clinical and electrical seizure activity as soon as possible. The risk of damage is increased after 1 to 2 hours of continuous seizures.
- 8 Lorazepam is the preferred benzodiazepine in treatment of GCSE because of its long duration of action.
- 9 Currently, the hydantoins (phenytoin and fosphenytoin) are the long-acting anticonvulsants used most frequently. Either phenytoin or fosphenytoin should be given concurrently with benzodiazepines.
- 10 The maximum rate of infusion for phenytoin and fosphenytoin in adults is 50 mg/min and 150 mg PE/min, respectively.
- 11 If GCSE is not controlled by a benzodiazepine, hydantoin, or phenobarbital, the GCSE is considered to be refractory, and other therapies should be considered.

1 Status epilepticus (SE) is a common neurologic emergency that may be associated with brain damage and death. Although there is no consensus on its definition, the International Classification of Epileptic Seizures defines SE as (1) any seizure lasting longer than 30 minutes whether or not consciousness is impaired or (2) recurrent seizures without an intervening period of consciousness between 3 seizures.¹ SE can present in several forms (Table 55–1), including nonconvulsive status epilepticus (NCSE) and generalized convulsive status epilepticus (GCSE).¹

Absence, atypical absence, myoclonic, and complex partial NCSE occurs in about 25% of those with SE. It is characterized by a fluctuating or continuous “twilight” state that produces altered consciousness and/or behavior (e.g., lethargy, decreased mental function). An altered electroencephalogram (EEG) is the most important diagnostic and management tool.² In most instances, benzodiazepine and/or valproate remain the drugs of choice for absence and complex partial NCSE.² Although intravenous (IV) phenytoin/fosphenytoin or phenobarbital may be tried in patients who are refractory to the preceding therapies, general anesthesia or barbiturate coma is not appropriate.² The reader is referred to several reviews

for a more comprehensive discussion of NCSE and its pharmacologic management.^{2,3}

3 GCSE is the most common and severe form of status epilepticus and is characterized by repeated primary or secondary generalized seizures that involve both hemispheres of the brain and are associated with a persistent postictal state. This chapter will focus on the epidemiology, pathophysiology, presentation, and management of GCSE.

EPIDEMIOLOGY

It is difficult to determine the incidence of GCSE because most studies fail to consider the patient’s age, seizure etiology, and type or duration of the seizure. The global incidence of GCSE is thought to range between 1.2 and 5 million cases per year, with an annual incidence of about 100,000 to 152,000 cases each year in the United States.⁴ GCSE has no predilection for gender or socioeconomic status but does occur more frequently in nonwhites across all ages.⁵ Most episodes of GCSE occur in individuals without a previous history of epilepsy, and

TABLE 55–1. International Classification of Status Epilepticus

| Convulsive | | Nonconvulsive | |
|--|------------------------------------|---|---|
| International | Traditional Terminology | International | Traditional Terminology |
| Primary generalized SE • Tonic-clonic ^{a,b} • Tonic ^{a,c} • Clonic ^c • Myoclonic ^b • Erratic ^d | Grand mal, epilepticus convulsivus | Absence ^c | Petit mal, spike-and-wave stupor, spike-and-slow-wave or 3/s spike-and-wave, epileptic fugue, <i>epilepsia minora continua</i> , epileptic twilight, minor SE |
| Secondary generalized SE ^{a,b} • Tonic • Partial seizures with secondary generalization | | Partial SE ^{a,b} | Focal motor, focal sensory, <i>epilepsia partialis continua</i> s, <i>adversive SE</i> |
| | | Simple partial Somatomotor Dysphasic Other types | Elementary |
| | | Complex partial | Temporal lobe, psychomotor, epileptic fugue state, prolonged epileptic stupor, prolonged epileptic confusional state, continuous epileptic twilight state |

^aMost common in older children.
^bMost common in adolescents and adults.
^cMost common in infants and young children.
^dMost common in neonates.

about 5% of adults and 10% to 25% of children with known epilepsy will have an episode of GCSE.³

ETIOLOGY

4 Precipitating events for GCSE vary among studies and generally reflect different populations and referral patterns. Most episodes that occur in known epileptics occur because of acute anticonvulsant withdrawal, a metabolic disorder or concurrent illness, or progression of a preexisting neurologic disease. Common etiologies and mortality rates for pediatric and adult populations are shown in Table 55–2.^{5,6}

4 Precipitating events for GCSE are divided into type I and type II etiologies. Type I etiologies are not associated with new structural lesions but do include patients with a history of epilepsy. Elevated serum anticonvulsant concentrations or their acute withdrawal may precipitate GCSE. A number of prescription, over-the-counter (OTC), and recreational medications should be considered in any patient with new-onset GCSE. Type II etiologies are associated with structural lesions and have a poor prognosis.

There are major differences in etiologies for pediatric and adult patients (see Table 55–2). During their first few weeks of life, infants who are born to addicted mothers may develop drug withdrawal seizures. Another subset of the neonatal population may develop GCSE owing to a pyridoxine deficiency. The EEG should normalize within hours following treatment with intravenous pyridoxine (100 mg). Acute encephalopathy and metabolic disorders (inborn errors of metabolism) are the major causes of GCSE in patients younger than 1 year of age. In young children, the cause is frequently idiopathic but may be associated with such symptoms as fever and/or a viral illness. Unless accompanied by an underlying neurologic abnormality, fever-induced GCSE is less likely to be associated with sequelae.

The most frequent precipitating events in adults are cerebrovascular disease, withdrawal of anticonvulsants, and low anticonvulsant serum concentrations. Interestingly, infection is not a major cause of GCSE in adults; however, there have been increasing reports of association with human immunodeficiency virus infection. Cerebrovascular disease is the leading cause of GCSE in those who have their first seizures after age 60.

TABLE 55–2. Etiology and Mortality for Pediatric and Adult Cases of Status Epilepticus

| Etiology | Pediatric (n = 200) % SE cases (% mortality) | Adult (n = 512) % SE cases (% mortality) |
|--------------------------------------|--|--|
| Type I (no structural lesion) | | |
| Infection | 55 (5) | 6 (35) |
| CNS infection | 11 (0) | 2 (20) |
| Metabolic | 20 (5) | 12 (36) |
| Low AED levels | 16 (0) | 24 (7) |
| Alcohol | 0 (0) | 13 (8) |
| Idiopathic | 6 (0) | 13 (18) |
| Type II (structural lesion) | | |
| Anoxia/hypoxia | 27 (13) | 14 (65) |
| CNS tumor | 3 (50) | 5 (22) |
| CVA | 5 (0) | 26 (27) |
| Drug overdose | 5 (0) | 3 (23) |
| Hemorrhage | 5 (11) | 4 (35) |
| Trauma | 13 (0) | 3 (23) |
| Remote causes ^a | 33 (5) | 7 (13) |

Percentages do not add up to 100% because some patients had multiple etiologies. (AED = antiepileptic drug; CVA = cerebrovascular accident)
^aMore than half of remote causes were congenital malformations and CVA in pediatric and adult patients, respectively.
 Data modified from Refs. 5 and 6.

MORBIDITY

1 No one would dispute that GCSE is harmful to the brain and is associated with morbidity. However, whether the morbidity occurs from the underlying etiology or as a result of the GCSE itself remains to be determined. Most would contend that it is the GCSE that is responsible for the morbidity. GCSE neuronal damage in animal models is evident following 30 to 60 minutes regardless of the inducing stimulus, and most animals progress to the development of epilepsy following a prolonged seizure. Interestingly, inhibiting the neuronal damage associated with seizures does not prevent the development of epilepsy in these animals, suggesting that the seizures themselves may be harmful. It is difficult to establish a relationship between long-term outcomes in humans with GCSE. This is largely because it is difficult to weigh the effects of seizure type, etiology, duration, concurrent physiologic events, and therapy or lack thereof. However, it has been shown that humans with a history of prolonged febrile seizures who later developed epilepsy share similar histopathologic changes (i.e., hippocampal sclerosis) as those found in animal models of GCSE.^{7,8} In these cases the period between the initial prolonged seizure and the first epileptic seizure can take months to decades. This suggests that there may be a link between GCSE and the later development of epilepsy. Importantly, both animal and human studies of GCSE show that the currently available anticonvulsants do not prevent the development of epilepsy following prolonged seizures.^{8,9}

Patients who develop epilepsy following prolonged GCSE are less likely to experience remission of their seizures and may have decreased cognitive and memory function, mental retardation, or neurologic deficits.¹⁰ Most studies have found that younger children and those with preexisting epilepsy have a higher propensity for sequelae.

MORTALITY

The estimated mortality rate in the United States following GCSE ranges between 22,000 and 42,000 individuals per year.⁶ Recent estimates suggest a mortality rate of up to 10% in children,¹¹ 20% in adults,⁴ and 38% in the elderly.⁵ When compared with other populations, neonates with seizures have a higher mortality and more neurologic sequelae (e.g., mental retardation, cerebral palsy, and epilepsy).

Table 55-2 summarizes the etiology for GCSE and their corresponding mortality rates.^{5,6} Interestingly, the mortality associated with many etiologies is significantly greater in adults than in children. Unresponsive patients may die from GCSE, but more frequently they die as a result of the acute illness that precipitated the GCSE. For example, patients with serious central nervous system structural changes (e.g., hemorrhage, stroke) have a poor prognosis, whereas the majority (i.e., 80–90%) of patients with no structural lesion generally respond to intravenous phenytoin.

Two variables that affect outcome are the time between onset of GCSE and the initiation of treatment and the duration of the seizure. GCSE lasting longer than 60 minutes has a higher mortality (32%) than seizures lasting less than 60 minutes (2.5%).⁶ Although one might expect better outcomes for patients managed in major medical centers, there is no difference in mortality between community hospitals and medical centers.⁶ Fortunately, the likelihood of death has decreased over the past decade and probably reflects a change in the definition of GCSE (60 to 30 minutes), recognition of the need to initiate presequenced therapy immediately, and a greater understanding of the pathogenesis of GCSE.

PATHOGENESIS

Brain homeostasis is preserved by a local neuronal network's ability to terminate excessive excitatory impulses before they spread to other networks. Seizures occur when the excitatory neurotransmission overcomes inhibitory impulses in one or more brain regions (i.e., neural networks). Most seizures are brief (≤ 5 minutes) largely because of the brain's inhibitory mechanisms that restore the balance of normal neurotransmission.¹² Currently, there is little known about why the mechanisms that control normal brain homeostasis fail. However, when repeated seizures occur in close succession or the magnitude of the proconvulsant (i.e., seizure-inducing) stimulus is severe enough, compensatory mechanisms can be overwhelmed and lead to GCSE.

5 Although the exact cellular mechanisms responsible for the production of abnormal neural impulses are unknown, it appears that seizure *initiation* is caused by an imbalance between excitatory (e.g., glutamate, calcium, sodium, substance P, and neurokinin B) and inhibitory neurotransmission (e.g., γ -aminobutyric acid [GABA], adenosine, potassium, neuropeptide Y [NPY], opioid peptides, and galanin).¹² Seizure *maintenance* associated with GCSE is largely due to the excitatory neurotransmitter glutamate acting on postsynaptic *N*-methyl-d-aspartate (NMDA) and α -amino-3-hydroxy-5-methyl-4 isoxazolepropionate (AMPA)/kainate receptors. Most of what is known about GCSE has focused on ion channels (receptor-gated or voltage-dependent), with less known about receptor–second messenger systems (e.g., metabotropic glutamate receptors).¹²

5 During GCSE, glutamate activation of the NMDA and AMPA receptors causes opening of the gated calcium and sodium channels, respectively. Entry of the respective ions causes neuronal depolarization. Sustained depolarization not only may maintain GCSE but also may eventually cause neuronal death through calcium-, free radical-, and kinase-mediated events.⁸ Although drugs acting as NMDA and AMPA receptor antagonists seem to be attractive options for the treatment of GCSE, it is likely that glutamate is not the sole mechanism for GCSE and that other mechanisms become increasingly important as the duration of seizures increases.

5 GABA_A receptors are postsynaptic receptors that control chloride channels to produce hyperpolarization (inhibition) of the postsynaptic cell membrane. These receptors have binding sites for GABA, as well as for select anticonvulsants (e.g., the GABA agonists phenobarbital and benzodiazepines) and enhance GABA_A-mediated chloride inhibitory currents. It was once believed that there was a decrease in presynaptic GABA release that led to prolonged seizures during GCSE. Current data, however, suggest that GABA concentrations increase during the early phases of GCSE and continue to be elevated during late GCSE. Prolonged seizures lead to decreased inhibitory GABA_A receptor density because of postsynaptic receptor endocytosis, and GABA_A receptors may be modified during SE such that there is decreased response to both endogenous GABA and GABA agonists.¹³ Clinically, this can have a dramatic influence on response to both benzodiazepines and phenobarbital in that their relative potencies can be reduced up to tenfold if seizures persist for 30 minutes or longer.¹³ A similar phenomenon occurs with sodium channel antagonists (phenytoin); however, the magnitude of resistance is believed to be less.¹²

PATHOPHYSIOLOGY

As GCSE continues, there are systemic alterations, progression of motor phenomena, and development of specific EEG findings.¹⁴ Two

distinct and predictable phases have been identified. Phase I occurs during the first 30 minutes of seizure activity, and phase II begins 60 minutes later. Although the presence of systemic complications affects the prognosis of GCSE, one must remember that prolonged seizures may destroy neurons independent of these systemic events.⁸ In fact, the systemic effects of experimentally induced seizures in animals can be blocked, but the damage to the neocortex, cerebellum, and hippocampus persists.

During phase I, each seizure produces marked increases in plasma epinephrine, norepinephrine, and steroid concentrations that may cause hypertension, tachycardia, and cardiac arrhythmias.¹⁴ Within minutes, arterial systolic pressures may rise to values above 200 mm Hg, and heart rate may increase by 83 beats per minute. Although blood pressure returns to normal within 60 minutes, mean arterial pressure does not fall below 60 mm Hg; hence cerebral perfusion pressure is not compromised. In animals, cerebral blood flow is also increased by 200% to 600%, thereby protecting neurons from hypoxic injury.

Seizure-induced increases in sympathetic and parasympathetic stimulation of the heart, in the presence of a hypoxic myocardium, may result in ventricular arrhythmias. Autonomic neuron stimulation also can cause a release of insulin and glucagon. Concurrently, circulating catecholamines cause an elevation of hepatic cyclic adenosine monophosphate, producing glycogenolysis. Although the patient may be hyperglycemic initially, serum glucose concentration begins to fall.

Seizure-induced muscular contractions and hypoxia cause lactic acid release that can produce a severe acidosis that may be accompanied by hypotension and shock. Muscle contractions can be so severe that rhabdomyolysis with secondary hyperkalemia and acute tubular necrosis may occur. The airway may be obstructed, and the patient may become cyanotic or hypoxic at any time. Additionally, an increase in salivation and tracheal and pulmonary secretions may result in aspiration pneumonia. Although transient pleocytosis (i.e., white blood cell counts up to 20,000/mm³) may develop, it should not be attributed to GCSE until infectious causes have been eliminated.

Between seizures, the EEG slows, and blood pressure normalizes. Although metabolic demands are increased, the brain is able to compensate for these increased demands adequately. If seizure activity exceeds 60 minutes (phase II), the EEG ictal discharge and clonic motor activity become continuous, and the patient begins to decompensate. Despite elevated levels of catecholamines, blood pressure is no longer increased, and the patient may become hypotensive. During the late phase, autoregulation of cerebral blood flow becomes dependent on mean arterial pressure and begins to fail. There continues to be an excessive consumption of oxygen and glucose; however, compensatory mechanisms are no longer able to keep up with demands.

During phase II, the serum glucose concentration may be normal or decreased. Profound hypoglycemia, secondary to hyperinsulinemia, can occur in patients with hepatic dysfunction or in those with reduced glycogen stores (e.g., elderly, neonates). Hyperthermia and respiratory deterioration with hypoxia and ventilatory failure may develop. There also may be metabolic and biochemical complications, including respiratory and metabolic acidosis, hyperkalemia, hyponatremia, and azotemia. There is increased sweating and salivation. Marked elevations in plasma prolactin, glucagon, growth hormone, and adrenocorticotropic hormone concentrations also have been identified. Importantly, during prolonged seizures, motor activity may cease, but electrical seizures may persist. This fact has important clinical ramifications, in that a patient's seizures may appear to have

been terminated without treatment or when an ineffective therapy is given.

CLINICAL CONTROVERSY

Which long-acting anticonvulsant should be given following initial treatment of GCSE with a benzodiazepine is considered controversial. According to the 1993 recommendations of the Epilepsy Foundation of America's Working Group on Status Epilepticus, phenytoin should be used in seizures that recur after successful treatment with a benzodiazepine.¹¹ Although this has been the practice for decades, no studies have documented the superiority of a hydantoin over other medications.¹⁵⁻¹⁹

CLINICAL PRESENTATION AND DIAGNOSIS

Accurate diagnosis requires observation, physical examination, laboratory assessment, EEG, and neurologic imaging. A careful history of the nature and duration of the seizure should be obtained, and a diagnosis of GCSE should not be made until a clinician has observed at least one seizure in a patient with a history of repeated seizures and impaired consciousness. Most patients have an altered consciousness that ranges from obtunded to marked lethargy and somnolence with pronounced eyes-open unresponsiveness and waxy rigidity. Motor features may include muscle contractions, extensor or flexor posturing, and spasms. Over time, the clinical manifestations become less apparent, and the diagnosis requires careful assessment.

In addition to an assessment of language and cognitive abilities, the physical examination also should assess motor, sensory, and reflex abnormalities and pupillary response, asymmetry, and posturing on neurologic examination. Because generalized seizures may cause physical injury, the patient should be examined for secondary injuries (e.g., tongue lacerations, shoulder dislocations, head trauma, and facial trauma).

Laboratory tests are essential to the diagnosis of various etiologies. Hypoglycemia, hyponatremia, hypernatremia, hypomagnesemia, hypocalcemia, and renal failure all can cause seizures. A urine drug screen may help to rule out the possibility of illicit drug use or drug overdose. Serum drug concentration determination(s) in those on chronic anticonvulsants should be obtained because high concentrations of certain medications can induce seizures, and low or nondetectable concentrations may reflect noncompliance or rapid drug withdrawal. A baseline serum concentration is necessary to determine whether a loading dose of a specific anticonvulsant may or may not be required. Assessment of other laboratory parameters (e.g., albumin, renal function, and hepatic function) that affect anticonvulsant dosing also may be useful. An EEG is a valuable diagnostic tool, but treatment should not be delayed while awaiting testing or results.

A second phase in diagnosis occurs after the seizures have stopped and the patient is stabilized. It is important to determine if the patient is febrile or has a systemic or central nervous system (CNS) infection. Many physiologic consequences of GCSE (e.g., leukocytosis, pleocytosis, and hyperthermia) produce symptoms that may be confused with other conditions. If a CNS infection is suspected, empirical antibiotics should be started, and a spinal tap should be performed. In order to rule out vascular, neoplastic, or infectious etiologies, computed tomography (CT) or magnetic resonance imaging (MRI) should be obtained.

CLINICAL PRESENTATION OF GCSE**GENERAL**

Status epilepticus (SE) is a medical emergency that may be associated with significant morbidity and mortality.

SYMPTOMS

- Impaired consciousness (e.g., lethargy to coma)
- Disorientation once GCSE is controlled
- Pain associated with injuries (e.g., tongue lacerations, shoulder dislocations, head trauma, facial trauma)

EARLY SIGNS

- Acute injuries or CNS insults that cause extensor or flexor posturing
- Fever or intercurrent illnesses (signs of sepsis or meningitis)
- Evidence of head or other CNS injury (bradycardia, tachypnea, and hypertension; poor pupillary response; asymmetry on neurologic examination; abnormal posturing)
- Generalized convulsions
- Hypothermia or fever suggestive of intercurrent illnesses
- Incontinence
- Muscle contractions, spasms
- Normal blood pressure or hypotension
- Respiratory compromise

LATE SIGNS

- Pulmonary edema with respiratory failure
- Cardiac failure (dysrhythmias, arrest, cardiogenic shock)
- Hypotension/hypertension
- Disseminated intravascular coagulation, multi-organ failure

- Rhabdomyolysis
- Hyperpyremia

INITIAL LABORATORY TESTS

- Complete blood count (CBC) with differential
- Serum chemistry profile (e.g., electrolytes, calcium, magnesium, glucose, serum creatinine, ALT, AST)
- Urine drug/alcohol screen
- Blood cultures
- Arterial blood gas to assess for metabolic and respiratory acidosis
- Serum drug concentration if previous anticonvulsant suspected or known

OTHER DIAGNOSTIC TESTS

- Lumbar puncture if CNS infection suspected
- EEG—should be obtained on presentation and once clinical seizures are controlled
- CT with and without contrast (to assess for bleeding, infection, arteriovenous malformations, neoplasm)
- MRI later
- X-ray if indicated to diagnose fractures
- ECG, especially if ingestion confirmed

ALT, alanine aminotransferase; AST, aspartate aminotransferase; CBC, complete blood count; CNS, central nervous system; CT, computed tomography; ECG, electrocardiogram; EEG, electroencephalograph; GCSE, generalized convulsive status epilepticus; MRI, magnetic resonance imaging; SE, status epilepticus

▶ TREATMENT: Generalized Convulsive Status Epilepticus**■ NONPHARMACOLOGIC**

6 Concurrent with initiation of anticonvulsants, vital signs should be assessed, an adequate and protected airway should be established, ventilation should be maintained, and oxygen should be administered. Patients who seize for prolonged periods will require intubation and mechanical ventilation. Arterial blood gas determinations should be done frequently to assess for metabolic and/or respiratory acidosis. Metabolic acidosis resolves quickly following termination of GCSE; however, sodium bicarbonate should be given if the pH is less than 7.2. If the patient has respiratory acidosis, assisted ventilation should correct the imbalance.

6 Patients who continue to have altered consciousness after clinical control of their seizures should have an EEG performed. Some patients, including those who have been given neuromuscular blockers for airway management, may not have clinical motor manifestations but may continue to have electrical SE. An EEG is essential to detect and diagnose electrical GCSE. Although hypoglycemia is a rare cause of GCSE, all patients should receive glucose. Because Wernicke's encephalopathy can develop in alcoholics, adults should receive thiamine (100 mg) prior to glucose.¹¹ Initially, adults should be given 50 mL of a 50% dextrose solution, and children should be given 1 mL/kg of a 25% dextrose solution.¹¹ Serum glucose

concentration should be determined to assess the need for further glucose supplementation.

■ PHARMACOLOGIC

2 Although a diagnosis of GCSE technically cannot be made until seizures have persisted for longer than 30 minutes, therapy should not be withheld during this time. When a tonic-clonic seizure does not stop automatically, or when doubt exists regarding the diagnosis, patients should be treated as if they have GCSE. An algorithm of the choice of anticonvulsants, timing, and dosing for the treatment of GCSE in hospitalized patients is provided in the Fig. 55-1.

7 It is imperative that a clear, presequenced management plan be initiated rapidly. To ensure that this occurs, many institutions have developed and used a seizure protocol. There are four immediate goals in the management of GCSE: (1) patient stabilization, including adequate oxygenation, preservation of cardiorespiratory function, and management of systemic complications, (2) accurate diagnosis of the subtype of GCSE and identification of precipitating factors, (3) termination of clinical and electrical seizures as early as possible, and (4) prevention of seizure recurrence.

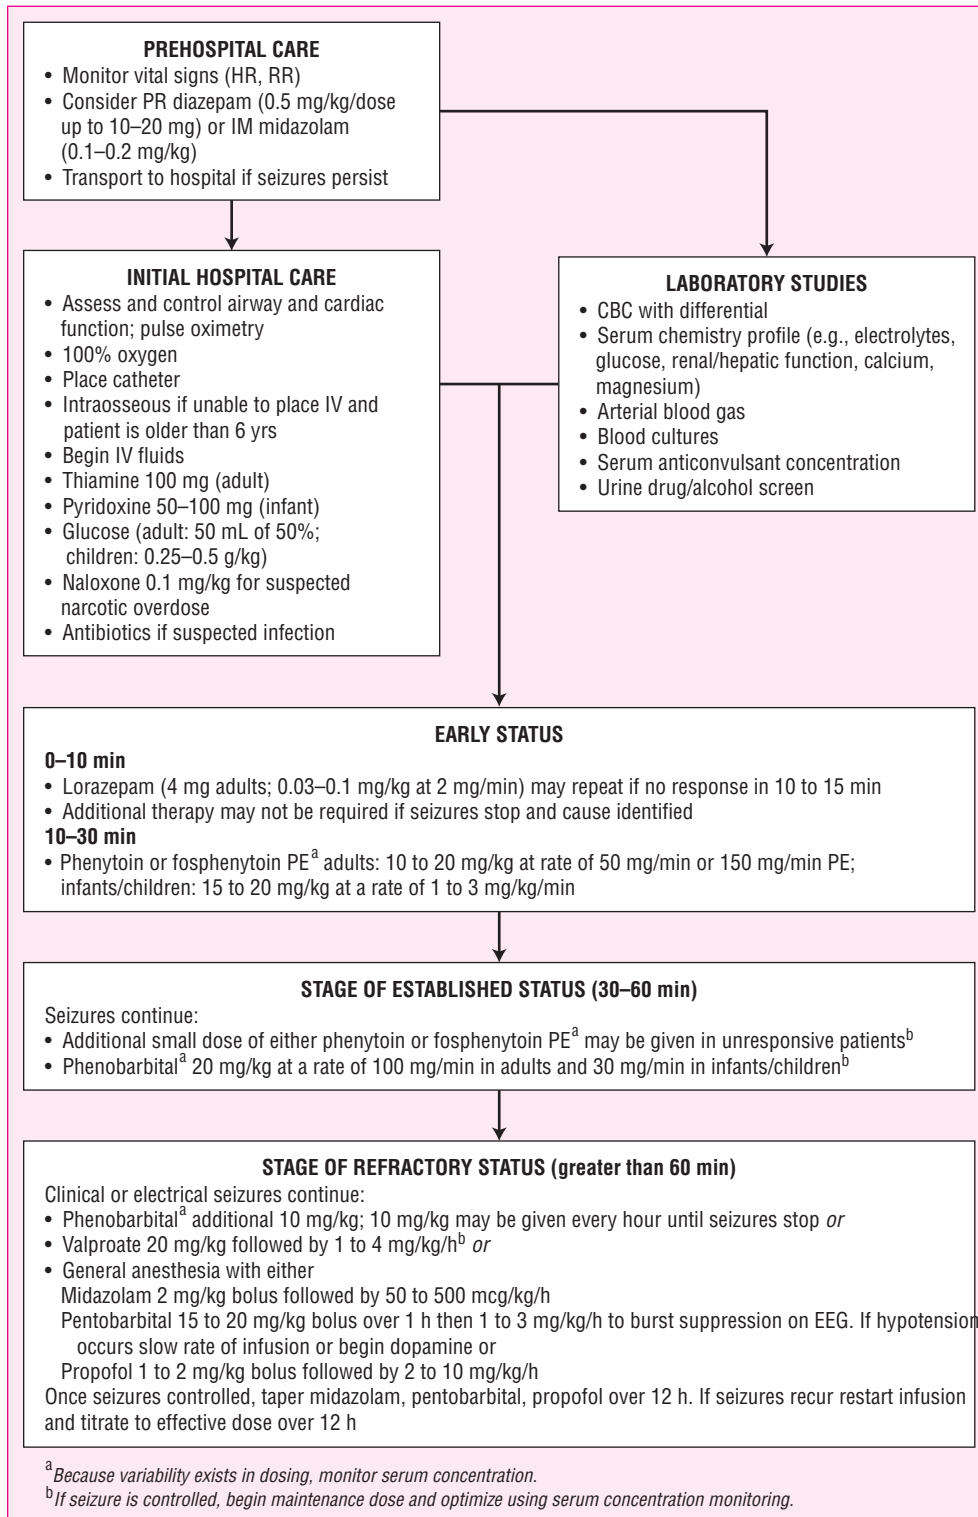

FIGURE 55–1. Algorithm for the treatment of GCSE in hospitalized patients.

The three most commonly used classes of anticonvulsants for the initial treatment of GCSE are the benzodiazepines, hydantoins, and barbiturates. Five prospective, randomized studies have compared these therapies for the treatment of GCSE.^{15–19} The first two studies were a blinded comparison of lorazepam versus diazepam in adults¹⁵ and children.¹⁷ The third study was a randomized comparison of

phenobarbital with phenytoin plus diazepam.¹⁸ The fourth study compared lorazepam with phenytoin.¹⁷ The fifth study was a multicenter, prospective, randomized, double-blind comparison of phenytoin and diazepam and phenytoin, lorazepam, or phenobarbital.¹⁹ There is no consensus regarding the anticonvulsant of choice, sequencing of therapy, or treatment of refractory GCSE.

BENZODIAZEPINES

The benzodiazepines are effective initial therapy in most patients with GCSE and should be administered as soon as possible. Generally, one or two intravenous doses will stop seizures within 2 to 3 minutes.⁴ Diazepam, lorazepam, and midazolam are the only benzodiazepines available in the United States in a parenteral formulation. Because these are equally effective in GCSE, the preferred benzodiazepine is determined by differences in the pharmacokinetic and pharmacoeconomic profiles of the available agents.

Diazepam is an extremely lipophilic moiety with a large volume of distribution (1 to 2 L/kg).¹¹ Although its initial distribution phase into the brain occurs within seconds, it rapidly redistributes into fat, causing its half-life in the brain to be less than 1 hour and its duration of effect to be less than 30 minutes.¹¹ If diazepam is the sole anticonvulsant, the rapid fall in brain concentration may cause seizure recurrence; hence a longer-acting anticonvulsant (e.g., phenytoin or phenobarbital) should be given immediately after diazepam. The initial dose of diazepam (Table 55–3) may be repeated if the patient does not respond within 5 minutes.¹¹ The maximum total dosage is 5 mg in children younger than 5 years of age, 10 mg in children 5 years of age or older, and 40 mg in adults. Although certain serum concentrations have been associated with seizure control, assays for the benzodiazepines are not readily available; hence therapeutic drug monitoring is impractical.

8 Although lorazepam is not approved by the Food and Drug Administration (FDA) for GCSE, it is currently considered the benzodiazepine of choice.¹¹ Lorazepam is less lipid soluble than diazepam and takes longer to achieve peak concentrations in the brain; however, it has minimal redistribution that results in a longer duration of action (>12 to 24 hours).¹¹ It also has a higher-affinity binding to the benzodiazepine receptor than diazepam.¹¹ For these reasons, significantly fewer patients treated with lorazepam require additional anticonvulsants for seizure termination.

The initial dose of lorazepam can be found in Table 55–3. Data suggest that a single dose produces adequate serum concentrations and provides seizure protection for 24 hours. A second dose may be given after 5 minutes, and if necessary, a third and final dose may be given after another 5 minutes.¹¹ It is important to remember that patients chronically on a benzodiazepine (e.g., clonazepam) may have developed tolerance and could require large doses before response.

Both diazepam and lorazepam cause vein irritation and should be diluted with an equal volume of compatible diluent before

administration. The intravenous forms of both diazepam and lorazepam contain propylene glycol, which may cause dysrhythmia and hypotension if administered too rapidly.¹¹ Because of slow and erratic absorption, these agents should not be given intramuscularly. If necessary, both medications may be given rectally.

Midazolam is a water-soluble benzodiazepine that diffuses rapidly into the brain. Unfortunately, it has an extremely short half-life that requires it to be given by continuous infusion. Various routes of administration (e.g., buccal, intranasal, and intramuscular) have been used successfully to terminate seizures rapidly when intravenous access cannot be established. Resulting peak serum concentrations occur within minutes and exceed those required for sedation in adults. Unfortunately, heavy breathing and increased nasal discharge may limit or delay intranasal absorption in a seizing patient. Buccal administration is performed easily by drawing up the desired volume of midazolam injection or syrup, parting the patient's lips, and squirting it into the mouth. The volume of fluid is small enough (e.g., 2 to 5 mL) to be placed in the cavity between the cheek and gum without significant concern for aspiration. Because of its increased solubility, intramuscular midazolam has a more reliable absorption than either diazepam or lorazepam. In fact, some practitioners have recommended that intramuscular midazolam be given by emergency medical technicians as first-line treatment in the out-of-hospital setting.²⁰ Midazolam has been well tolerated with all the aforementioned routes with minimal changes in blood pressure or respiration.

All benzodiazepines can impair consciousness and interfere with neurologic assessment.¹¹ Although rare, brief (<1 minute) cardiorespiratory depression may occur and can necessitate assisted ventilation or require intubation. This is especially true if a benzodiazepine is used concomitantly with a barbiturate. Hypotension secondary to a reduction in vasomotor tone may occur following large doses of a benzodiazepine.⁴

PHENYTOIN

9 Phenytoin is a second-line agent in GCSE that is unresponsive to the benzodiazepines or in seizures that recur after successful treatment with a benzodiazepine.²¹ While it is effective in terminating seizures in 40% to 91% of patients,¹¹ one study reported that phenytoin alone was inferior to lorazepam, phenobarbital, or diazepam plus phenytoin at stopping GCSE within 20 minutes of their infusion.¹⁹ Phenytoin has a relatively long half-life (20 to 36 hours) and causes

TABLE 55–3. Medications Used in the Initial Treatment of GCSE

| Anticonvulsant (Route) | Loading Dose (Maximum Dose) | | Rate of Infusion | | Maintenance Dose | |
|------------------------|--|---|------------------|----------------|------------------------------|------------------------------|
| | Adult | Pediatric | Adult | Pediatric | Adult | Pediatric |
| Diazepam (IV bolus) | 0.25 mg/kg ^{a,b,c} (40 mg) | 0.25–0.5 mg/kg ^{a,c} (0.75 mg/kg) | <5 mg/min | <5 mg/min | Not used | Not used |
| Fosphenytoin IV | 15–20 mg PE/kg | 15–20 mg PE/kg | 150 mg PE/min | 3 mg PE/kg/min | 4–5 mg PE/kg/day | 5–10 mg PE/kg/day |
| Lorazepam (IV bolus) | 4 mg ^{a,b,c} (8 mg) | 0.1 mg/kg ^{a,c} (4 mg) | 2 mg/min | Over 2–5 min | Not used | Not used |
| Midazolam IV | 200 mcg/kg ^{a,d} | 150 mcg/kg ^{a,d} | 0.5–1 mg/min | 2–3 min | 50–500 mcg/kg/h ^e | 60–120 mcg/kg/h ^e |
| Phenobarbital IV | 10–20 mg/kg ^e | 15–20 mg/kg ^e | 100 mg/min | 30 mg/min | 1–4 mg/kg/day ^e | 3–5 mg/kg/day ^e |
| Phenytoin IV | 15–20 mg/kg ^f | 15–20 mg/kg ^f | 50 mg/min | 1 mg/kg/min | 4–5 mg/kg/day ^e | 5–10 mg/kg/day ^e |

^aDoses may be repeated every 10 to 15 min until the maximum dosage is given.

^bInitial doses in the elderly are 2 to 5 mg.

^cLarger doses may be required if patients chronically on a benzodiazepine (e.g., clonazepam).

^dMay be given by the intramuscular, rectal, or buccal routes.

^eTitrate dose as needed.

^fAdminister additional loading dose based on serum concentration.

less respiratory depression and sedation than the benzodiazepines or phenobarbital¹¹; however, it cannot be delivered rapidly enough to be considered a first-line single agent.

Injectable phenytoin should be diluted to less than or equal to 5 mg/mL in normal saline. Microcrystals will precipitate if it is mixed in a glucose-containing solution. The vehicle (40% propylene glycol) may cause administration-related hypotension and cardiac arrhythmias. These effects are more likely to occur if large loading doses are given to elderly individuals with preexisting cardiac disease or in critically ill patients with marginal blood pressure.¹¹ Vital signs and an electrocardiogram (ECG) should be obtained during administration. The infusion rate should be slowed if the QT interval \blacktriangleleft 10 widens or if hypotension or arrhythmias develop.¹¹ The maximum rate of infusion is 50 mg/min in adults and 1 mg/kg per minute in children weighing less than 50 kg.¹¹ The rate should not exceed 25 mg/min in the elderly or in those with atherosclerotic cardiovascular disease. The rate should be reduced once seizures have stopped.¹¹

Suggested intravenous loading doses of phenytoin are provided in Table 55-3.¹¹ If the patient has been on phenytoin prior to admission and the phenytoin concentration is known, this should be considered in determining a loading dose. A reduction in the loading dose is recommended for elderly patients,¹¹ and a larger loading dose is required in obese patients.²² If seizures continue after the initial loading dose, some advocate an additional 5 mg/kg dose. There is no evidence that a total loading dose above 20 mg/kg will be beneficial in unresponsive GCSE. This practice may cause concentrations to exceed the reference range and produce toxicity. Serum concentrations within the reference range generally do not persist more than 24 hours in patients given a loading dose of less than 18 mg/kg. For this reason, maintenance doses (see Table 55-3) should be started within 12 to 24 hours of the loading dose.

Because phenytoin has poor lipid solubility and enters the brain slowly, it may take up to 60 minutes before the pharmacodynamic effect is apparent. This delay in response is important when considering administration of a second mini-loading dose. For a review of the distribution and elimination pharmacokinetics of phenytoin, see Chap. 54.

Phenytoin has an alkaline pH, which is associated with pain and burning during infusion; phlebitis may occur with chronic infusion, and tissue necrosis is likely on infiltration. Intramuscular administration is not recommended because absorption is delayed and erratic, and phenytoin may crystallize in tissue. Although an orally administered loading dose has been used in patients not actively seizing, it may take 4 to 12 hours before adequate serum concentrations are obtained; therefore, this practice is not recommended.

■ FOSPHENYTOIN

Fosphenytoin is a water-soluble phosphate ester that has no known pharmacologic activity.²¹ Because it does not contain propylene glycol, it is compatible with most common intravenous fluids. It should be diluted prior to intravenous administration in 5% dextrose or normal saline to a concentration of 1.5 to 25 mg PE/mL.²¹ It is converted rapidly (7 to 15 minutes) and completely (100%) to phenytoin by blood and tissue phosphatases after intravenous and intramuscular dosing.²¹ This inherent delay in conversion was a concern initially; however, the conversion delay is offset by high protein binding, saturable binding at high concentrations, and the rapid rate of infusion, which results in unbound concentrations exceeding those seen following phenytoin at an infusion rate of 50 mg/min or less.²¹

Nystagmus, dizziness, and ataxia are the most frequent adverse events with fosphenytoin and are attributed to phenytoin. The frequency of ECG or blood pressure changes is less than that reported for phenytoin. Paresthesia and pruritus are related to dose and infusion rate and occur more frequently with fosphenytoin than with phenytoin. These side effects typically have a distribution to the face and groin areas and subside within 5 to 10 minutes after the infusion.²¹ They are not allergic reactions and rarely necessitate discontinuation of fosphenytoin.

In order to minimize dosing errors, fosphenytoin should be dosed using phenytoin equivalents (PE), thereby obviating the need for interconversion between phenytoin and fosphenytoin. The loading dose of fosphenytoin can be found in Table 55-3. Because of delays in achieving adequate phenytoin serum concentrations, a loading dose of fosphenytoin should not be given intramuscularly unless intravenous \blacktriangleleft 10 access is impossible. The rate of administration is 100 to 150 mg PE/min and 1 to 3 mg PE/kg per minute in adult and pediatric patients, respectively.²² Continuous ECG, blood pressure, and respiratory status monitoring is recommended for all loading doses of fosphenytoin.

Tests for fosphenytoin serum concentration are not available commercially and are of no clinical value. Serum phenytoin concentrations are the end point for therapeutic drug monitoring, and the desired serum concentration range is the same as that when phenytoin is administered (10 to 20 mg/L). Because fosphenytoin cross-reacts with several immunoassays for phenytoin to cause a 1.2- to 6-fold overestimation of phenytoin concentration, blood should not be obtained for at least 2 hours after intravenous and 4 hours after intramuscular administration.²¹ In order to minimize in vitro conversion to phenytoin, blood should be collected in tubes containing EDTA, and samples should be refrigerated as soon as possible.²¹

CLINICAL CONTROVERSY

The debate continues as to which hydantoin (i.e., phenytoin or fosphenytoin) is the preferred agent in GCSE. Although phenytoin has been used for decades, it is associated with a variety of problems related to its formulation. Conversely, fosphenytoin is associated with less infusion pain and intravenous-site complications and fewer hemodynamic adverse effects than phenytoin. While most practitioners believe that fosphenytoin is clearly a "better" formulation, many practitioners and administrators struggle with the benefit of fosphenytoin when compared with phenytoin given its cost.

■ PHENOBARBITAL

There are three different opinions regarding the use of phenobarbital in GCSE. The most widely held contention is that because barbiturates cause CNS and respiratory depression, as well as hypotension, phenobarbital should be the third-line agent when a benzodiazepine plus phenytoin has failed.⁴ The second opinion suggests that the barbiturates are as safe and effective as other anticonvulsants and should be the drug of choice after the benzodiazepines have been administered. This belief is especially evident in pediatric institutions with large emergency departments. The third emerging opinion is that continuous-infusion midazolam should be the third-line anticonvulsant before the barbiturates.²³

Two studies have compared the efficacy of phenobarbital with other anticonvulsants in GCSE. The first study compared phenobarbital alone with diazepam plus phenytoin in adult patients with GCSE.¹⁸ Phenobarbital acted more rapidly and was as safe and effective as the

TABLE 55–4. Medications Used to Treat Refractory GCSE

| Anticonvulsant (Route) | Loading Dose | | Rate of Infusion | | Maintenance Dose | |
|------------------------|-------------------------|--|------------------|---------------|------------------------------|------------------------------|
| | Adult | Pediatric | Adult | Pediatric | Adult | Pediatric |
| Lidocaine | 50–100 mg | 1 mg/kg (maximum dose = 3–5 mg/kg in first hour) | | ≤2 min | 1.5–3.5 mg/kg/h | 1.2–3 mg/kg/h |
| Midazolam IV | 200 mcg/kg ^a | 150 mcg/kg ^a | 0.5–1 mg/min | 2–3 min | 50–500 mcg/kg/h ^b | 60–120 mcg/kg/h ^b |
| Pentobarbital (IV) | 10–20 mg/kg | 15–20 mg/kg | 1–2 h | 1–2 h | 1–5 mg/kg/h ^b | 1–5 mg/kg/h ^b |
| Propofol IV | 2 mg/kg | 3 mg/kg | 10 seconds | 20–30 seconds | 5–10 mg/kg/h | 2–18 mg/kg/h ^b |
| Valproate | 15–20 mg/kg | 20–25 mg/kg | 3 mg/kg/min | 3 mg/kg/min | 1–4 mg/kg/h ^b | 1–4 mg/kg/h ^b |

^aDoses may be repeated twice every 10 to 15 min until the maximum dosage is given.

^bTitrate dose as needed.

combination of diazepam plus phenytoin.¹⁸ A second multicenter trial reported that phenobarbital was as effective as lorazepam alone or diazepam plus phenytoin in GCSE and was not associated with serious adverse effects.¹⁹ Although there is technically no definitive answer, the Working Group on Status Epilepticus recommends that phenobarbital be given after a benzodiazepine plus phenytoin has failed.¹¹ Currently, most practitioners agree that phenobarbital is the long-acting anticonvulsant of choice in patients with a hypersensitivity to the hydantoin or in those with cardiac conduction abnormalities.

Following intravenous administration, phenobarbital has two phases of distribution into body organs.²⁴ During the first phase, the drug distributes into highly vascular organs, but it does not distribute into the brain. With the exception of fat, phenobarbital distributes throughout the body during the second phase²⁴; hence body fat should be considered when dosing. In order to avoid overdosing, estimated lean body mass should be used in obese patients.²⁴ Although phenobarbital penetrates into the brain slowly, the highest brain concentrations occur 12 to 60 minutes after an intravenous dose.²⁴ On average, seizures are controlled within minutes of the loading dose.¹⁹ Phenobarbital exhibits first-order linear pharmacokinetics, and there is no maximum dose beyond which further doses are likely to be ineffective.²⁵

The loading and maintenance dose for phenobarbital are given in Table 55–3. When necessary, larger loading doses (30 mg/kg) have been used in neonates without adverse effects. If the initial loading dose does not stop the seizures within 20 to 30 minutes, an additional 10 to 20 mg/kg dose may be given. If seizures continue, a third 10 mg/kg load may be given.²⁵ Once GCSE is controlled, the maintenance dose should be started within 12 to 24 hours.

Although injectable phenobarbital contains propylene glycol, it can be given more rapidly than phenytoin (see Table 55–3). Phenobarbital can be given intramuscularly, but its rate of absorption is too slow to be effective in GCSE. Phenobarbital may cause depression of consciousness and respiration. The risk of apnea and hypopnea may be more profound in patients treated initially with benzodiazepines.^{4,11} Medical personnel should be ready to provide respiratory support whenever the two agents are used concurrently. If significant hypotension develops, the infusion should be slowed or stopped.¹¹

■ TREATMENT OF REFRACTORY GCSE

When adequate doses of a benzodiazepine, hydantoin, or barbiturate have failed, the condition is termed *refractory*.²³ Approximately 10% to 15% of patients will develop refractory GCSE.²⁶

About 30% of patients whose seizures are “clinically” controlled will have persistent electrical manifestations (i.e., still in status) and will remain in GCSE after administration of these anticonvulsants.²³ When a patient develops refractory GCSE, a neurologist with expertise in epilepsy should be consulted, and an intense search should be performed for an acute or progressive cause.¹¹

It should be remembered that the longer GCSE lasts, the harder it is to treat and that failure to treat aggressively early in the course of GCSE increases the likelihood of nonresponse.¹¹ The optimal therapeutic approach for patients with refractory GCSE has not been determined. Approaches used include the continuous infusion of a benzodiazepines, medically induced coma, valproate, propofol, paraldehyde, or lidocaine. Doses for these agents can be found in Table 55–4. Regardless of the therapy selected, the goal is to stop electrical epileptiform activity.

■ BENZODIAZEPINES

Although refractory GCSE has been treated with a variety of agents, some practitioners have advocated not only that midazolam should be the first-line agent in refractory GCSE but also that it should be the third-line agent in patients unresponsive to lorazepam plus phenytoin.^{23,27,28} Table 55–4 contains the loading and maintenance doses for adult and pediatric patients. The continuous-infusion rate should be increased every 15 minutes until seizures are controlled.²⁹ Most patients respond within 65 minutes.

Because tachyphylaxis can develop, frequent increases in the infusion rate may be necessary, and dosing should be guided by EEG response.²³ Once GCSE is terminated, dosages can be decreased by 1 mcg/kg per minute every 2 hours. Successful discontinuation is enhanced by maintaining the patient’s phenytoin serum concentration near 20 mg/L and phenobarbital concentration above 40 mg/L.²³ Because of midazolam’s short half-life, patients may return to consciousness more rapidly than those receiving larger doses of more sedating anticonvulsants (e.g., phenytoin, phenobarbital). Generally, continuous-infusion midazolam has been well tolerated, with few cases of hypotension and respiratory depression seen. Hypotension and poikilothermia can occur and may require supportive therapies.

Large-dose continuous-infusion lorazepam and diazepam also have been used successfully in patients unresponsive to phenytoin or phenobarbital.^{30,31} Lorazepam contains propylene glycol, which can accumulate in patients receiving continuous infusions. It has been noted to cause a marked osmolar gap, metabolic acidosis, and renal toxicity, which was attributed to the infusion of propylene glycol.^{32–34}

CLINICAL CONTROVERSY

The positioning of midazolam among the medications used to treat GCSE is controversial. There are no guidelines or practice consensus to address this controversy. Some investigators have recommended that midazolam should be the anticonvulsant of choice and, therefore, should be used *in lieu* of lorazepam; others argue that it should be used after a hydantoin has failed to stop the seizures; still others recommend it only for refractory GCSE.

MEDICALLY INDUCED COMA

If there is an inadequate response to large doses of midazolam, anesthetizing the patient to suppress the cerebral ictal discharge is recommended.^{11,27,28} Although it is likely that the patient is already being mechanically ventilated, intubation and respiratory support are mandatory during barbiturate coma. Because hypotension is a concern, it is essential that vital signs be monitored continuously. A short-acting barbiturate (usually either pentobarbital or thiopental) generally is preferred because it allows a more rapid reversal of coma.

Several sources note that the initial loading dose of pentobarbital is 5 mg/kg.¹¹ However, this dose is inadequate to produce the serum concentrations (30 to 40 mg/L) necessary to induce an isoelectric EEG. Pentobarbital should be initiated with a loading dose of at least 10 to 20 mg/kg over 40 to 60 minutes²⁷ (see Table 55–4). If hypotension occurs during the loading dose, the rate of administration should be slowed, or dopamine should be administered. The loading dose should be followed immediately by a continuous infusion.¹¹ Rates are typically begun at 1 mg/kg/h and titrated as needed up to a dose of 5 mg/kg/h. The maintenance infusion should be increased gradually until there is evidence of burst suppression on EEG (i.e., flat EEG) or prohibitive adverse effects occur. Although the duration of barbiturate coma in most studies has been 2 to 3 days, pentobarbital coma has been used safely for 53 days in an 18-year-old patient.³⁵ In order to avoid complications (e.g., pneumonia, pulmonary edema), the pentobarbital should be discontinued as soon as possible. Twelve hours after a burst-suppression pattern is obtained, the rate of pentobarbital infusion should be titrated downward every 2 to 4 hours to enable the clinician to determine if the patient's GCSE is in remission.

VALPROATE

Limited human data exist regarding the use of valproate in refractory GCSE. Although an intravenous dosage form has been approved by the FDA, it is not approved for GCSE. A number of loading and continuous-infusion doses (see Table 55–4) have been used to treat GCSE in both adult^{36–38} and pediatric patients.^{38,39} One study suggested the need to consider the effects of enzyme-inducing anticonvulsants when dosing valproate.³⁹ This group recommended that the continuous-infusion rate be determined by the presence of concurrent anticonvulsants (no inducers present, 1 mg/kg per hour; one or more inducers [e.g., phenytoin, phenobarbital], 2 mg/kg per hour; and inducers and pentobarbital coma, 4 mg/kg per hour).

Although the manufacturer originally recommended intravenous valproate be given no faster than 20 mg/min, much faster rates have been studied (2 to 6 mg/kg per minute) and are used for administration of the loading dose.^{39,40} Currently, the manufacturer recommends that intravenous valproate be administered at a rate of 3 mg/kg per minute. In general, intravenous valproate has been well tolerated, with no cases of respiratory depression. Hemodynamic instability is extremely rare, but patients' vital signs should be monitored closely during the loading dose.

PROPOFOL

Propofol is extremely lipid soluble and has a large volume of distribution. It has a very rapid onset of action and an extremely short half-life (2 to 4 minutes), which promotes rapid awakening on drug discontinuation. Although extensive data are not available, it appears to be effective in GCSE.^{27,41} Doses can be found in Table 55–4. It may cause respiratory and cerebral depression and bradycardia. Although metabolic acidosis has been reported, the occurrence of propofol-associated metabolic acidosis is controversial.⁴² Finally, a normal adult dose may provide over 1000 calories per day as lipid at a cost to the patient that may exceed \$1000 per day.

OTHER AGENTS

Historically, rectal or intravenous paraldehyde has been used for refractory GCSE. Although effective, it is extremely difficult to administer, is associated with serious adverse effects (e.g., hypotension, tachycardia, pulmonary edema, and polyethylene emboli), and is no longer manufactured in the United States. The only available formulation currently licensed is an enteral product that is difficult to obtain in a timely manner. If a rectal dose is given, it should be diluted 1:1 in vegetable oil and given every 20 minutes as needed via a rubber catheter.¹¹

Lidocaine has been used in refractory GCSE, but its use is not recommended unless other agents have failed.⁴³ It is administered intravenously and has a rapid onset of action. Table 55–4 gives the recommended initial loading and continuous-infusion doses. Although the reference serum concentration range for the antiarrhythmic effects of lidocaine is 2 to 6 mg/L, the reference range for GCSE has not been established. Serum lidocaine concentrations should be monitored to avoid drug accumulation and toxicity. CNS toxicity (e.g., fasciculations, visual disturbances, and tinnitus) may occur at concentrations between 6 and 8 mg/L; seizures and obtundation may develop when concentrations exceed 8 mg/L.

Halothane, isoflurane, ketamine, and other inhaled anesthetics have been shown to produce EEG suppression; however, these gases are difficult to deliver outside the operating room and require the presence of an anesthesiologist. No proven advantages have been shown over traditional anticonvulsants (e.g., barbiturate coma or continuous-infusion benzodiazepine), and these gases can increase intracranial pressure. If used, dosing is titrated to obtain EEG burst suppression. It also may be prudent to validate that the patient does not have a low serum magnesium concentration because magnesium deficiency can lower the seizure threshold.

PHARMACOECONOMIC CONSIDERATIONS

Although no prospective pharmacoeconomic studies have been performed in patients with GCSE, a number of economic issues may

have an impact on formulary considerations. Clearly, there are intra- and interclass differences in medication costs and in ancillary tests or technologies associated with select therapies. For example, if one assumes five treatment options and hypothetically initiates

anticonvulsant therapy in a patient weighing 70 kg, the following differences in average wholesale prices are noted:

- Diazepam (20 mg) plus generic phenytoin (1 g): \$15.01
- Lorazepam alone (8 mg): \$15.62
- Midazolam alone (0.25 mg/kg load, 0.1 mg/kg/hr): \$31.10
- Generic phenytoin (1 g) alone: \$13.33
- Diazepam (20 mg) plus fosphenytoin PE (1 g): \$181.68
- Phenobarbital (20 mg/kg) alone: \$28.22
- Intravenous valproate (15 mg/kg load, 1 mg/kg per hour): \$88.20

Although many practitioners have heralded the arrival of fosphenytoin as an important therapeutic advancement, it has created a fiscal and ethical dilemma for many institutions. Fosphenytoin is associated with less infusion pain and fewer intravenous-site complications and hemodynamic adverse effects than phenytoin; however, the cost of this agent (\$180/g PE versus \$13.33/g phenytoin) has caused many practitioners and administrators to struggle with the practical and ethical importance of the increased safety profile relative to the cost of the product to an institution. When evaluating the difference in cost of these two agents, it is important to remember that phenytoin requires the placement of two intravenous catheters because of its incompatibility with many solutions and medications that are given concurrently. Additionally, some practitioners are giving fosphenytoin intramuscularly in the emergency room for non-SE indications and thereby avoiding the placement of a catheter and use of an infusion device. Many institutions fail to consider the expense associated with a tissue infiltration of phenytoin. Should an infiltration of phenytoin cause tissue necrosis that necessitates plastic surgery or amputation, the expense of a single multimillion-dollar lawsuit likely will offset the difference between phenytoin and fosphenytoin cost to several institutions.

There is little difference in expense if one advocates phenobarbital over midazolam as third-line therapy, but it might be argued that a patient who experiences phenobarbital-induced respiration depression ultimately may be more expensive to the health system. Finally, a 24-hour infusion of propofol to the same patient will cost in excess of \$1000.

EVALUATION OF THERAPEUTIC OUTCOMES

Initial success is defined as termination of all clinical and electrical activity, but ultimate success is measured by the patient's quality of life. The morbidity and mortality associated with GCSE are affected by the underlying etiology; however, these can be minimized by the rapid implementation of a rational therapeutic plan. An EEG is an extremely important tool that not only allows practitioners to determine when abnormal electrical activity has been aborted but also may assist in determining which anticonvulsant was effective. Because many of the anticonvulsants affect the cardiorespiratory system, it is imperative that vital signs (e.g., heart rate, respiratory rate, and blood pressure) be monitored during drug infusion. It also may be necessary to monitor the ECG in some patients. Finally, it is imperative that the infusion site be assessed for any evidence of infiltration before and during administration of phenytoin. Information regarding the patient's past medical and drug history and imaging studies (e.g., MRI) also may help to determine if there is a defined etiology for the original episode of GCSE. This information then may be used to guide future medication therapy, as well as help in determining if the patient is at risk for a poor outcome.

CONCLUSION

Our understanding of the cellular basis, physiology, and neuropathology of GCSE continues to evolve. Over the past decade, research into an activated cascade of pathophysiologic changes in neurotransmission, GABAergic inhibition, and NMDA receptor channel-mediated events has enhanced our understanding of this disorder. Although anticonvulsants will continue to be the mainstay of therapy in terminating seizures, specific agents including antagonists of excitatory amino acid neurotransmitters (e.g., glutamate and calcium channel blockers) and agonists of inhibitory neurotransmitters (GABA) may help to block further neuronal damage beyond the epileptogenic focus. Likewise, additional trials investigating the role of newer anticonvulsants in GCSE are warranted.

ACUTE MANAGEMENT OF THE BRAIN INJURY PATIENT

Bradley A. Boucher, Stephanie J. Phelps, and Shelly D. Timmons

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Cerebral ischemia is the key pathophysiologic event triggering secondary neuronal injury following severe traumatic brain injury (TBI). Intracellular accumulation of calcium is postulated to be a central pathophysiologic process in amplifying and perpetuating secondary neuronal injury via inhibition of cellular respiration and enzyme activation.
- 2 *Guidelines for the Management of Severe Brain Injury*, published by the Brain Trauma Foundation/American Association of Neurological Surgeons, serves as the foundation on which clinical decisions in managing adult neurotrauma patients are based; comparable guidelines for infants, children, and adolescents also have been published recently.
- 3 Correcting and preventing early hypotension (systolic blood pressure < 90 mm Hg) and hypoxemia (PaO_2 < 60 mm Hg) are primary goals during the initial resuscitative and intensive care of severe TBI patients.
- 4 The principal monitoring parameter for severe TBI patients within the intensive care environment is intracranial pressure (ICP). Cerebral perfusion pressure (CPP) is also a critical monitoring parameter and should be maintained at greater than 60 mm Hg (>40 mm Hg in pediatric patients) through the use of fluids, vasopressors, and/or ICP normalization therapy.
- 5 Nonspecific pharmacologic treatment in the management of intracranial hypertension should include analgesics, sedatives, antipyretics, and paralytics under selected circumstances.
- 6 Specific pharmacologic treatment in the management of intracranial hypertension includes mannitol, furosemide, and high-dose pentobarbital. Neither routine use of corticosteroids nor aggressive hyperventilation (i.e., Paco_2 < 25 mm Hg) should be used in the management of intracranial hypertension.
- 7 Use of phenytoin for the prophylaxis of posttraumatic seizures usually should be discontinued after 7 days if no seizures are observed.
- 8 Numerous investigational strategies (e.g., calcium antagonists, glutamate antagonists, antioxidants, and free-radical scavengers) targeted at interrupting the pathophysiologic cascade of events occurring following severe TBI have been employed.

Traumatic brain injury (TBI) has been referred to as America's "invisible epidemic" and is currently the leading cause of death and disability among children and young adults in the industrialized world.¹ Based on an ever-growing understanding of TBI pathophysiology, clinicians and scientists share an optimism that patient outcomes can be improved through the use of evidence-based management guidelines presently and administration of neuroprotective agents in the future. This chapter summarizes TBI epidemiology and pathophysiology and highlights guidelines and systematic reviews of the literature pertaining to the management of severe TBI patients.

EPIDEMIOLOGY

It is estimated that approximately 1.5 million persons sustain a non-fatal brain injury each year in the United States, resulting in 230,000 hospital admissions and 50,000 deaths annually based on data from

1989 to 1998.² Importantly, over 5 million Americans currently live with disabilities as a result of their TBI, highlighting the enormous physical and emotional toll of this health care problem in the United States.¹ The economic effects of acute neurotrauma are also enormous, with estimates of spending on TBI patients requiring hospitalization exceeding \$56 billion per year in the United States.³ While the frequency of TBI remains high, the mortality rate following traumatic brain injury has decreased from nearly 25 per 100,000 to 19.4 per 100,000 population per year since 1979.² Motor vehicle accidents account for about 50% of all adult cases, whereas falls, assaults, gunshot wounds, sports and recreational accidents, and other miscellaneous causes account for the remaining cases.⁴ Motor vehicle-related TBIs were the leading cause of death in individuals aged 0 to 19 years of age.² In TBI patients 20 to 74 years of age, gunshot wounds are responsible for the highest number of TBI fatalities, whereas fall-related TBIs caused the greatest number of deaths in patients 75 years of age or older.² Furthermore, TBI-related mortality in males exceeds that in females threefold.²

TABLE 56–1. Clinical Presentation of Acute Brain Injury

| | |
|------------------------|---|
| General | Level of consciousness on admission ranges from awake and alert to completely unresponsive (i.e., GCS 15 to 3, respectively). |
| Symptoms | Posttraumatic amnesia (e.g., greater than 1 hour), increasing dizziness, a moderate to severe headache, limb weakness, or paresthesia may indicate more severe injury. |
| Signs | CSF otorrhea or rhinorrhea and seizures may indicate more severe injury. A rapid deterioration in mental status strongly suggests the presence of an expanding lesion within the skull. Severe TBI may be accompanied by significant alterations or instability in vital signs, including abnormal breathing patterns (e.g., apnea, Cheyne-Stokes respiration, tachypnea), hypotension, or bradycardia. |
| Laboratory tests | ABGs indicating hypoxia (i.e., decreased PaO ₂) or hypercapnia (i.e., increased PaCO ₂) may indicate compromised ventilation. A positive blood ethanol concentration and/or positive urine drug screen indicates that drug intoxication may be affecting the patient's mental status in addition to the TBI. |
| Other diagnostic tests | CT of the head is an important diagnostic tool for detecting the presence of mass lesions. |

GCS, Glasgow Coma Scale; CSF, cerebrospinal fluid; TBI, traumatic brain injury; ABG, arterial blood gas; PaO₂, partial pressure of arterial blood oxygen; PaCO₂, partial pressure of arterial blood carbon dioxide; CT, computed tomography.

accumulation initiate a number of events that amplify and perpetuate secondary neuronal injury. High intracellular concentrations of calcium result in mitochondrial dysfunction, which further inhibits cellular respiration, a process already affected by ischemic and/or hypoxic insults.¹² A second major deleterious effect of calcium is to stimulate activation of autodestructive enzymes, including phosphatases, kinases, lipases, and proteases, such as calpain, caspase-1, and caspase-3.^{7,13,14} The effect of phospholipase A₂ stimulation includes formation of several arachidonic acid metabolites derived from membrane lipids: thromboxane A₂, prostaglandins, and leukotrienes.¹² The subsequent effects of these metabolites are lipid peroxidation and the formation of oxygen free-radical species.¹⁵ Lipid peroxidation is an especially damaging event because the formation of oxygen free radicals can propagate, resulting in further cellular membrane damage, unless quenched by endogenous antioxidants (e.g., vitamin E, ascorbic acid, superoxide dismutase).¹⁵ Recent data suggest that this event occurs very early after injury (e.g., before hospitalization), which may limit the effectiveness of exogenously administered antioxidants.¹⁶ A common end point with the release of excitatory amines, increases in intracellular calcium, and oxygen free radical generation is apoptosis or programmed cell death and nonprogrammed cellular necrosis.¹⁷

Cells with a more elaborate dendritic structure (e.g., cortical neurons, hippocampal cells) may be more vulnerable to the effects of apoptosis.¹⁸ Cell-mediated injury involving inflammatory mediators (e.g., cytokines, platelet-activating factor, etc.), nitric oxide, and cell adhesion molecules is yet another possible mechanism involved in secondary neuronal injury.¹⁹ Among the cell lines implicated are polymorphonuclear neutrophils, platelets, endothelial cells, and macrophages. Stimulation of platelet aggregation, vasodilation, and vasoconstriction, intravascularly, also may occur. Vasogenic cerebral edema can develop as a consequence of cerebral capillary endothelial damage.⁵ With cytotoxic and vasogenic edema comes expansion of the intracellular and extracellular fluid spaces, respectively. Elevated intracranial pressure (ICP) is the most detrimental consequence of cerebral edema formation and occurs as the brain tissue volume increases within the nondistensible skull. A significant increase in ICP may further compromise cerebral blood flow (CBF) and extend cytotoxic edema. Hence an increase in ICP can be self-perpetuating unless this cycle is reversed.

Lastly, preliminary data suggest that there may be a genetic vulnerability to the effects of TBI.⁷ Specifically, a link between

the gene that encodes for apolipoprotein E₄ and outcome has been postulated.^{20,21} Noteworthy is that this is the same protein that has been associated with the deleterious effects of various types of Alzheimer's disease.⁷

CLINICAL PRESENTATION

The clinical presentation of acute brain injury is summarized in Table 56–1. The Glasgow Coma Scale (GCS) is the most widely used system to grade the arousal and functional capacity of the cerebral cortex.⁶ The GCS defines the level of consciousness according to eye opening, motor response, and verbal response (Table 56–2). A GCS score of 15 corresponds to a normal neurologic examination. A GCS score of 3–8, 9–12, and 13–15 is consistent with severe, moderate,

TABLE 56–2. Glasgow Coma Scale

| Response | Score |
|---|-------|
| Eyes | |
| Open spontaneously | 4 |
| To verbal command | 3 |
| To pain | 2 |
| No response | 1 |
| Best Motor Response | |
| To verbal command | |
| Obeyes | 6 |
| To painful stimulus (pressure to nailbeds) | |
| Localizes pain | 5 |
| Flexion, withdrawal | 4 |
| Flexion, abnormal (decorticate rigidity) | 3 |
| Extension (decerebrate rigidity) | 2 |
| No response | 1 |
| Best Verbal Response (Arouse patient with painful stimulus if necessary) | |
| Oriented and converses | 5 |
| Disoriented and converses | 4 |
| Inappropriate words | 3 |
| Incomprehensible sounds | 2 |
| No response | 1 |
| Total | 3–15 |

and mild brain injury, respectively.⁶ The possibility of ethanol or drug intoxication, hypotension, hypoxia, postictal state, or hypothermia altering the neurologic examination always should be considered. Because narcotics and muscle relaxants affect the neurologic examination, they should not be administered until the initial examination

is complete if at all possible. Simple, rapidly attainable clinical variables that are predictive of survival include patient age, GCS score (especially the motor score), pupillary reactivity, and presence or absence of a hematoma and ventricular cisterns found on a computed tomographic (CT) scan of the head.²²

▶ TREATMENT: Traumatic Brain Injury

2 In July 1995, the Brain Trauma Foundation (BTF) published an extensive document entitled *Guidelines for the Management of Severe Brain Injury* as a joint initiative with the Guidelines Committee of the American Association of Neurological Surgeons (AANS) and the Joint Section on Neurotrauma and Critical Care of the AANS and the Congress of Neurological Surgeons, with subsequent revision in 2000.^{23,24} This landmark publication established for the first time a comprehensive series of evidence-based standards, guidelines, and options for the care of severe TBI patients. A recent survey suggested that significant changes consistent with the BTF/AANS guidelines in the acute management of TBI patients have occurred since 1991, providing indirect evidence as to their overall impact on patient care.²⁵ Since then, the European Brain Injury Consortium has issued guidelines for the management of severe TBI in adults,²⁶ prehospital TBI management,²⁷ surgical management, and management of penetrating brain injury. Furthermore, TBI management guidelines for infants, children, and adolescents have been developed.²⁸ In addition, a series of systematic reviews addressing TBI management emanating from The Cochrane Library has been published.^{29–36} These reviews have rigorously evaluated the literature for essentially all the major conventional TBI treatment strategies. The recommendations emanating from the published guidelines on TBI management and published systematic reviews will be highlighted throughout the remaining portion of this chapter. Until further clinical studies become available, recommendations from the published guidelines should serve as the foundation on which all clinical decisions in managing severe TBI are based.⁷ Recommendations provided in this chapter pertain to adults and children unless specifically noted to the contrary.

■ DESIRED OUTCOMES

The overall goal in TBI management is not only reduction in morbidity and mortality but also optimization of long-term functional outcome for these patients. This requires careful attention to the following short-term therapeutic goals: (1) establishment of an adequate airway and maintenance of ventilation and circulation during the initial period of resuscitation and evaluation, (2) maintenance of balance between CDO_2 and CMRO_2 , (3) prevention or attenuation of secondary neuronal injury, and (4) prevention and/or treatment of associated medical complications.

■ INITIAL RESUSCITATION

The first priority in the unconscious patient is the establishment of an airway, which ensures adequate oxygenation and prevents aspiration.⁶ Thereafter, restoration of circulating blood volume and maintenance of systolic arterial pressure (SBP) greater than 90 mm Hg are of utmost importance.⁸ In pediatric patients, the SBP goal should be in

3 excess of $70 \text{ mm Hg} + (2 \times \text{age in years})$.²⁸ Correcting and preventing early hypotension (SBP < 90 mm Hg) and hypoxia ($\text{PaO}_2 < 60 \text{ mm Hg}$) are essential because these two factors are among the most powerful predictors of outcome.^{8,37} Isotonic saline (0.9% normal saline) and lactated Ringer's solution are the most commonly used resuscitation fluids. However, some clinicians believe that hypertonic saline (e.g., 3% or 7.5% saline) should be the fluid of choice in the resuscitation of TBI patients.⁸ In children, the recommended infusion rate for 3% saline is 0.1–1 mL/kg per hour.²⁸ Clinical studies have yielded equivocal results relative to superiority over isotonic solutions.^{38–40} Vasopressors and inotropic agents may be needed to maintain an adequate mean arterial pressure (MAP) if hypotension persists after adequate restoration of intravascular volume. Figure 56–2 is an algorithm summarizing treatment priorities in the initial management of acute TBI.

■ POSTRESUSCITATIVE CARE

Following successful resuscitation, priorities shift toward diagnostic evaluation of intracranial and extracranial injuries and emergent surgical intervention as needed. Evacuation of intracranial hematomas (i.e., epidural, subdural, and intracerebral hematomas) is essential to control ICP and improve outcome. Elevation of depressed skull fractures and débridement of penetrating wound tracts are other important emergent surgical procedures in TBI patients. Continuous ICP monitoring (e.g., intraventricular catheter, intraparenchymal fiberoptic catheter) is indicated in patients with a GCS score of less than or equal to 8 with an abnormal admission CT scan or in high-risk severe TBI patients with a normal CT scan (i.e., age > 40 years, motor posturing, SBP < 90 mm Hg).^{23,24} Intraventricular catheters have a therapeutic advantage over the other alternatives but are associated with a higher complication rate and can be difficult to place in the setting of the swollen brain. Specifically, cerebrospinal fluid (CSF) can be drained using this device as a means to lower ICP.⁶ Continuous ICP monitoring is the only means to objectively evaluate the success of therapies used to decrease ICP. Once the ICP exceeds 20 to 25 mm Hg, therapy should be initiated to decrease ICP below 20 mm Hg.^{23,24,28} Aggressive use of ICP monitors in academic trauma centers across the United States was associated with a reduction in mortality risk as well as a shorter length of stay among survivors.⁴¹ Jugular venous oxygen saturation (Sjvo_2) monitoring is strongly advocated by some practitioners for detection of global cerebral hypoxia (i.e., adequacy of CBF relative to CMRO_2), although it is not currently addressed within the BTF/AANS guidelines.⁴² Hence its role remains unclear at present.^{6,43} Cerebral microdialysis techniques have been used successfully as research tools to measure the cerebral extracellular chemistry of TBI patients.⁴⁴ While the spread of this methodology to general clinical practice has been deemed unlikely, the use of brain tissue oxygen monitoring in TBI patients is promising.⁷ Recently, the roles of several biochemical markers of TBI (e.g., S-100 protein,

neuron-specific enolase) also were reviewed.⁴⁵ The utility of these or other proteins for the detection of secondary injury in TBI and/or as a treatment-monitoring parameter is uncertain at this time.

4 Another important monitoring parameter for severe TBI patients within the intensive care environment in recent years has been the cerebral perfusion pressure (CPP), which is the difference

between MAP and ICP (i.e., $CPP = MAP - ICP$). The maintenance of an acceptable CPP has been postulated to be critical in reducing cerebral ischemia and secondary injury. The goal CPP can be achieved by increasing MAP through the use of fluids and/or vasopressors or by lowering elevated ICP. The BTF/AANS guidelines originally recommended that CPP be maintained greater than 70 mm Hg based

on a number of studies that demonstrated decreased morbidity and mortality in patients whose CPP was actively sustained above 70 to 80 mm Hg.²³ However, in 2003, the BTF/AANS issued an updated recommendation that CPP be maintained at 60 mm Hg or more.⁴⁶ In children, the recommended CPP goal is greater than 40 mm Hg.²⁸ Furthermore, the updated recommendation is that aggressive attempts to maintain CPP greater than 70 mm Hg in adults should be avoided in the absence of cerebral ischemia because of the risk of the acute respiratory distress syndrome.^{24,47} One recent study challenges the relative importance of CPP in TBI patients, suggesting that the primary focus should be on lowering the ICP to less than 20 mm Hg.⁴⁸ In essence, the results of this clinical investigation were that an ICP of 20 mm Hg or more was the most powerful predictor of neurologic deterioration as long as the CPP was maintained above 60 mm Hg.⁴⁸

CLINICAL CONTROVERSIES

The principal goal in severe TBI patients should be normalization of ICP. However, for over a decade, much attention has been paid to maintenance of CPP (MAP – ICP) without conclusive evidence as to what an ideal goal for CPP should be. In either case, the goal should be to lower the ICP below 20 mm Hg.

Despite no significant improvement in outcome in the most extensive investigation to date, a recent meta-analysis of 12 hypothermia trials in the treatment of severe TBI patients did discern potential benefits of this cerebral-protective maneuver. At present, most clinicians would consider hypothermia to be an investigational treatment until additional data become available.

The MAP can be increased through normalization of the intravascular volume combined with pharmacologically inducing systemic hypertension as needed. The goal of volume expansion should be euvolemia as well as avoidance of a hyposmolar state and negative fluid balance.^{28,49} If the hematocrit is below 30%, transfusion of packed red blood cells (PRBCs) is indicated. Volume status should be targeted to a pulmonary artery wedge pressure of between 10 and 14 mm Hg if invasive monitoring is employed.⁵⁰ After achievement of euvolemia, the patient's head should be elevated at 30 degrees to promote venous drainage and decrease ICP. If restoration of the intravascular volume is inadequate in elevating MAP to an acceptable level, hypertension should be induced using vasopressors or inotropic support. The drugs employed most commonly to induce hypertension are the sympathomimetic amines, dopamine, norepinephrine, and phenylephrine. While none of these agents has shown superiority, norepinephrine is a reasonable selection at a starting dose of 0.02 mcg/kg per minute based on its predominant vasoconstrictive properties.⁵⁰ Patients should be monitored for renal dysfunction, lactic acidosis, and signs of peripheral ischemia when these agents are used, especially at large doses.

TREATMENT OF INTRACRANIAL HYPERTENSION

GENERAL PHARMACOLOGIC STRATEGIES

5 The use of analgesics, sedatives, and paralytics has an important primary role in the management of intracranial hypertension (Fig. 56–3). This is related directly to the association of pain,

agitation, excessive muscle movement, and resisting mechanical ventilation with transient increases in ICP.⁵¹ Nonetheless, there have been no studies of the effect of sedation on outcome in patients with severe TBI.²³ Morphine sulfate is the most commonly used analgesic and sedative in this setting.^{6,51,52} Propofol has become the sedative of choice in TBI patients among many clinicians because of its ease of titration, rapidly reversible effects on discontinuation, and possible neuroprotective effects.^{6,53,54} Although it is used for sedation in infants and children who are mechanically ventilated in the ICU setting, the Food and Drug Administration (FDA) required that the manufacturer labeling contain specific information that propofol is not approved for sedation of pediatric patients admitted to an ICU. This is due in part to the publication of 10 case reports of fatal metabolic acidosis in critically ill children who received propofol.⁵⁵ While a direct association between propofol and metabolic acidosis remains unclear, symptoms tend to occur with large doses (>4.8–30 mg/kg per hour) and prolonged infusions (>48–72 hours). Likewise, long-term infusions in excess of 5 mg/kg per hour should be used cautiously in TBI patients based on a recently published case report series suggesting an association between propofol and cardiac failure.⁵⁶ Triglyceride concentrations also should be monitored in patients receiving prolonged propofol infusions and/or high dosages of propofol considering its lipid emulsion formulation and the potential for inducing hypertriglyceridemia under these conditions. Alternative sedatives include etomidate (particularly useful in rapid-induction anesthesia),⁶ intermittent low-dose pentobarbital, and short-acting benzodiazepines (e.g., midazolam), especially if there is a reasonable suspicion of alcohol withdrawal as the underlying etiology of the agitation.^{51,52} The potential for these agents to decrease MAP and CPP must be monitored closely. The use of any sedative agent also must be weighed against its potential to obscure the neurologic examination of the patient. Cautious reversal of the effect of benzodiazepines with flumazenil can be used to allow examination of the patient.⁵² Interference with the neurologic examination is also associated with paralytic agents. Prophylactic neuromuscular blockade (i.e., unrelated to ICP control) is not recommended based on evidence indicating increased complications (e.g., pneumonia, prolonged paralysis) and length of stay following paralytic use.⁶

HYPERVENTILATION

6 The practice of prolonged aggressive hyperventilation (PaCO₂ < 25 mm Hg) to decrease ICP is no longer recommended.^{23,24} Hyperventilation acutely decreases systemic and cerebral PaCO₂. The resulting hypocapnia, in turn, induces cerebral vasoconstriction, thereby decreasing CBF and cerebral blood volume (CBV).^{57,58} For decades, it was a widely held belief that a reduction in CBV and any accompanying decrease in ICP were beneficial. Nonetheless, a systematic review of the literature concluded that data are inadequate to ascertain potential benefit or harm from hyperventilation.³² Other studies have determined that severe TBI patients with normocapnia versus those receiving aggressive hyperventilation have an improved outcome at 3 and 6 months.^{23,24} Furthermore, recent evidence using microdialysis and local CBF techniques suggests that aggressive hyperventilation may increase extracellular glutamate, a mediator of secondary injury, and lactate concentrations.⁵⁹ Despite the decrease in CBF during hyperventilation, no detrimental decrease in CMRO₂ was observed in a recent study.⁵⁸ Nonetheless, the potential for decreased CBF to increase the possibility for cerebral ischemia must be weighed. In consideration of the equivocal data relative to the merits of therapeutic

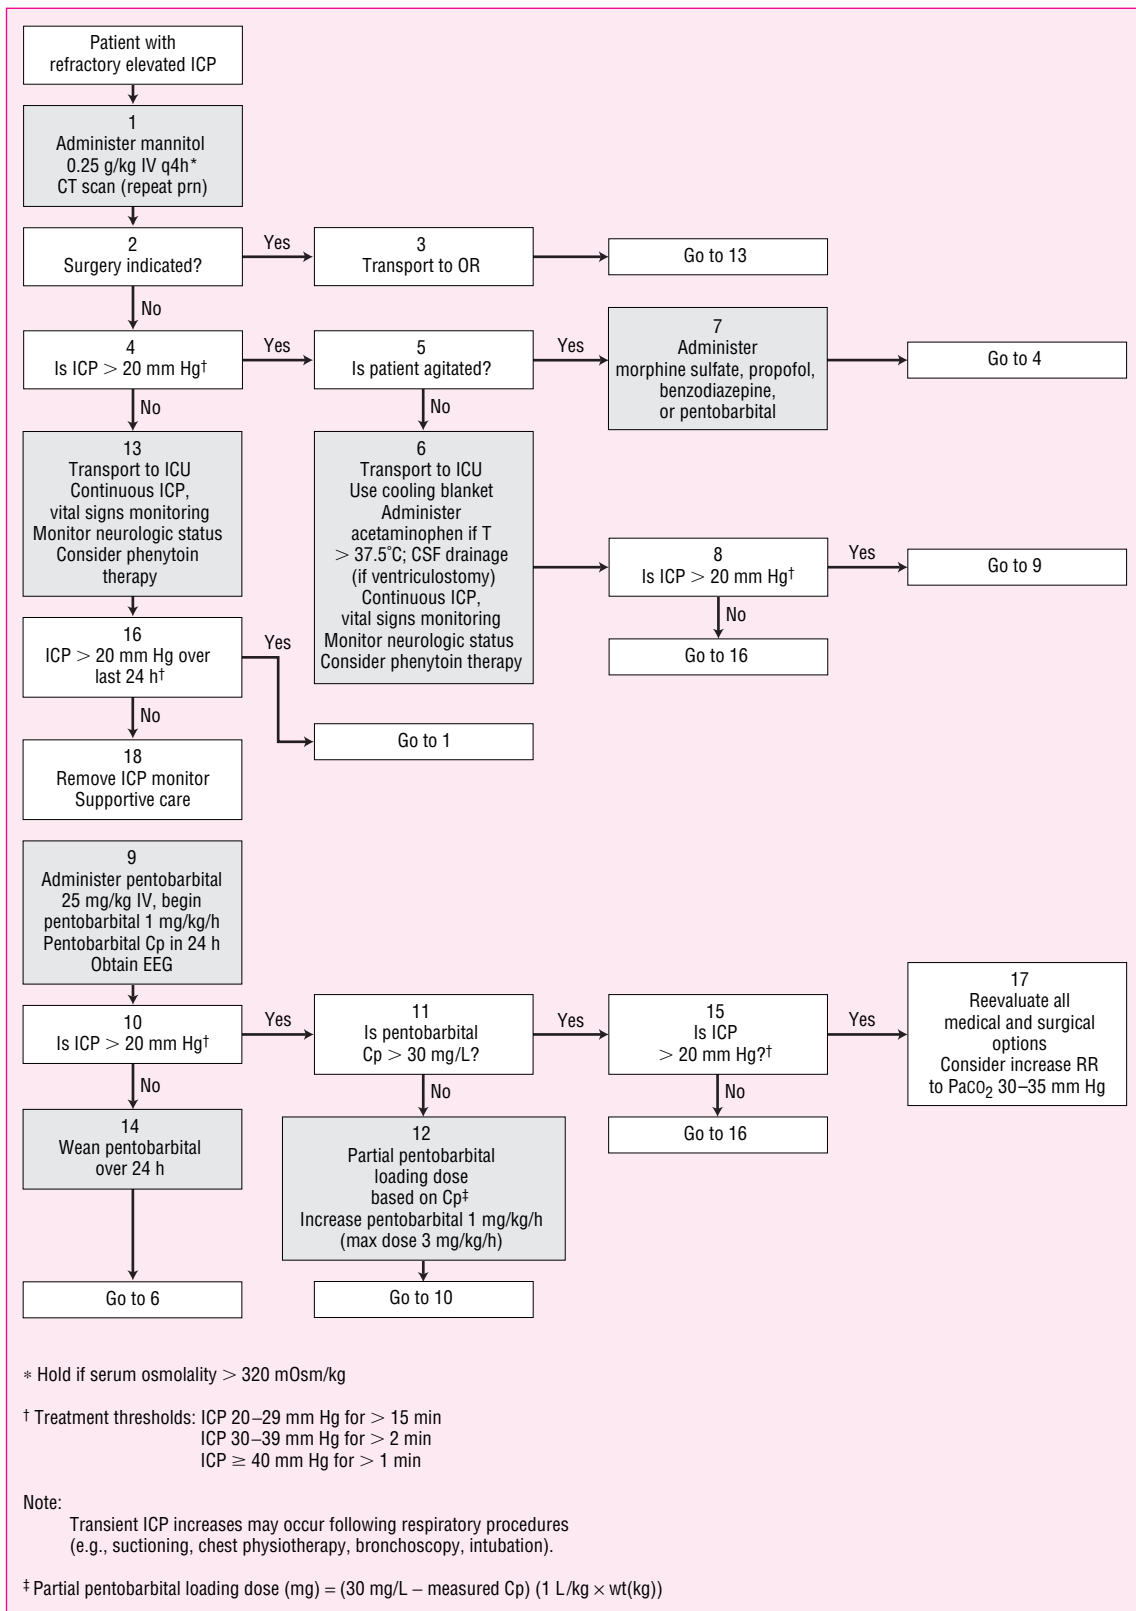

FIGURE 56-3. Algorithm for the management of increased ICP. Cp, plasma concentration; CT, computed tomography; OR, operating room; ICP, intracranial pressure; ICU, intensive care unit; T, temperature; CSF, cerebrospinal fluid; EEG, electroencephalogram; RR, respiratory rate; PaCO₂, partial pressure of arterial blood carbon dioxide. hyperventilation in TBI patients, BTF/AANS guidelines recommend that PaCO₂ be maintained near 35 mm Hg, especially during the first 24 hours.^{23,24} Thereafter, a PaCO₂ in the range of 30 to 35 mm Hg may be used if ICP control is inadequate.^{28,50} Aggressive hyperventilation (25–30 mm Hg) for brief periods may be considered as second-tier therapy in the setting of refractory intracranial hypertension.^{23,24,28}

HYPOTHERMIA

Hyperthermia also should be avoided in TBI patients because patients with elevated temperatures have poorer outcomes than normothermic patients.^{28,60} Hence aggressive maintenance of a core temperature of less than 37.5°C using acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), and cooling blankets is indicated for patients following severe TBI.⁵⁰ Several experimental cooling techniques, including intravascular cooling for use in TBI patients refractory to conventional management strategies, were discussed in a recent review of this topic.⁶⁰

While hypothermia has been discussed for nearly 50 years as a cerebral protective maneuver in TBI patients, a recent resurgence of interest has been fueled by the results of several preliminary studies in the early 1990s demonstrating trends in improvement in mortality and morbidity rates in severe TBI patients randomized to receive mild to moderate hypothermia. However, in the most extensive investigation to date, TBI patients randomized to receive hypothermia ($n = 199$) within 6 hours of injury (target body temperature 33°C) and maintained for 48 hours did not have significantly improved outcomes compared with a normothermia group of TBI patients ($n = 196$) at 6 months.⁶¹ Two meta-analyses confirm these results, concluding that hypothermia is not beneficial in the management of TBI patients.^{31,62} Regardless, a systematic review of the literature did discern potential benefits in reducing mortality and poor neurologic outcomes based on data combined from 12 trials.⁶³ Depth and duration of hypothermia, as well as the rate of rewarming after discontinuation of hypothermia, are additional factors that may affect outcomes with this therapeutic maneuver in TBI patients.^{63,64} The mechanism underlying a protective effect of hypothermia is likely multifactorial, although a reduction in CMRO₂ is offered most frequently as the basis of any therapeutic benefits. Potential side effects of hypothermia include coagulation disturbances, infectious complications, and cardiac arrhythmias.^{62,63} An increase in ICP also may occur secondary to hypothermia-associated shivering that can be prevented with neuromuscular blocking agents. Unfortunately, these agents are also associated with potential adverse events, as discussed previously. Considering these latter risks and equivocal data from clinical trials to date, hypothermia should continue to be considered an investigational treatment.

DIURETICS

Although a number of osmotic diuretics (e.g., urea, glycerol) can be used to decrease ICP, mannitol is unquestionably the most widely employed.⁵¹ Despite the common practice of administering mannitol to patients with suspected or actual increases in ICP following brain injury, no clinical trial comparing its effects against placebo have been performed.²⁹ The mechanisms responsible for mannitol's beneficial effects likely relate to (1) an immediate plasma-expanding effect that reduces blood viscosity and increases CBF and (2) establishment of an osmotic concentration gradient across an intact

blood-brain barrier that decreases ICP as water diffuses from the brain into the intravascular compartment.^{23,51} If the blood-brain barrier is disrupted as a result of injury, rebound elevations of ICP may occur with prolonged use of the osmotic agent because mannitol accumulates in the brain tissue, resulting in an increase in intracellular brain volume.⁵¹ Recommended doses of mannitol typically range from 0.25 to 1 g/kg intravenously every 4 hours.^{23,24,52} However, two recent studies using larger bolus doses of mannitol (i.e., approximately 1.4 g/kg) revealed improved clinical outcomes compared with TBI patients with temporal lobe hemorrhages and subdural hematomas treated with conventional dosages.^{65,66} These two studies not only address the importance of the mannitol dose for this indication, but they also represent the few data substantiating the benefits of mannitol despite its use in managing TBI for over 50 years.⁶⁷

Increased ICP is reduced within minutes following mannitol administration, and the duration of action ranges from 90 minutes to 6 hours depending on the dose and the clinical conditions that are present.^{23,24} In order to maximize benefit and minimize adverse events, it is generally recommended that mannitol be administered as a bolus and not as a continuous infusion in this setting.^{23,24} However, no clinical trials have directly compared these two different administration techniques.²⁹ Intravenous furosemide (0.5–1 mg/kg) may be used in conjunction with mannitol in refractory cases. During the first 24 to 48 hours after injury, children tend to develop a generalized cerebral hyperemia. Because mannitol may increase CBF and worsen ICP, some practitioners advocate the use of furosemide over mannitol in children.

Several adverse effects are associated with mannitol. In addition to hypotension resulting from its diuretic effect, a reversible acute renal dysfunction may occur in patients with previously normal renal function after long-term, large-dose administration, especially if the serum osmolality exceeds 320 mOsm/kg.^{23,24,52} Hence monitoring and maintaining the serum osmolality at less than 310 to 320 mOsm/kg are important to minimize adverse events. Mannitol should be avoided in patients with renal failure.^{6,28} Acute exacerbation of underlying congestive heart failure and pulmonary edema also may occur following rapid intravascular volume expansion. Furosemide is recommended as an alternative diuretic for lowering ICP in these latter patient groups.

BARBITURATES

High-dose barbiturate therapy (i.e., *barbiturate coma*) has been used for decades in the management of increased ICP despite a lack of evidence documenting beneficial effects on patient morbidity and mortality.³³ Nonetheless, based largely on beneficial outcomes observed in a randomized clinical trial published in 1988, BTF/AANS and pediatric guidelines recommend that high-dose barbiturate therapy be considered in hemodynamically stable severe TBI patients refractory to maximal medical ICP-lowering therapy and decompressive surgery.^{23,24,28} Prophylactic use of barbiturates is not advocated in light of insufficient evidence supporting this practice and the potential for adverse events (e.g., hypotension).^{24,33} Several mechanisms responsible for the cerebral protective effects of barbiturates have been proposed. These include (1) lowering the regional CMRO₂ with a coupled reduction in CBF to these areas, (2) inhibition of lipid peroxidation, and (3) alteration of cerebral vascular tone.⁵²

Prior to inducing a barbiturate coma, the severe TBI patient must be mechanically ventilated with continuous monitoring of arterial

blood pressure, electrocardiogram (ECG), and ICP. Pentobarbital is the most commonly used barbiturate for this indication, although thiopental also has been used. Pentobarbital should be administered as an intravenous loading infusion totaling 25 mg/kg (i.e., 10 mg/kg over 30 minutes and then 5 mg/kg per hour for 3 hours), followed by an initial maintenance infusion of 1 mg/kg per hour.⁴¹ The maintenance infusion can be titrated upward if needed to a maximum of 2–3 mg/kg per hour.⁵² If the systolic blood pressure falls during the loading or maintenance infusions, the rate should be slowed temporarily and blood pressure support initiated. The goal of a barbiturate coma is to maintain ICP and CPP at the previously discussed target thresholds in addition to achieving a pentobarbital steady-state concentration of between 30 and 40 mg/L and EEG burst suppression. Initiation of barbiturate therapy withdrawal can occur when ICP has been controlled satisfactorily for 24 to 48 hours.²⁴ Barbiturates should be tapered over 24 to 72 hours to prevent ICP spikes.

Side effects associated with high-dose barbiturate therapy involve primarily the cardiovascular system. Hypotension caused by peripheral vasodilation may occur, necessitating decreasing the barbiturate dose or the administration of fluids and vasopressors to maintain blood pressure. A recent systematic review of the literature suggested that one of every four patients receiving barbiturate therapy will develop hypotension.³³ Gastrointestinal (GI) effects of barbiturates include decreased GI muscular tone and decreased amplitude of contraction. On emergence from coma, there may be a period of GI hypermotility. Care should be taken to avoid extravasation of pentobarbital and thiopental solutions because severe tissue damage may occur. Barbiturates should be administered by continuous infusion through a central line dedicated for this purpose. The potential for barbiturates to induce the hepatic drug metabolism of concurrent medications should be also considered. Lastly, the potential for prolonged interference with the proclamation of brain death in TBI patients meeting the locally accepted brain death neurologic criteria must be considered prior to the initiation of high-dose barbiturate therapy.

CORTICOSTEROIDS

6 Although corticosteroids are effective in preventing or reducing cerebral edema in patients with nontraumatic conditions producing vasogenic edema, most studies in TBI patients have not demonstrated that they lower ICP or improve outcome.²⁴ In addition, use of corticosteroids following TBI has been associated with increased complications, including GI bleeding, glucose intolerance, electrolyte abnormalities, and infection.⁵⁰ Based on several major randomized trials, the BTF/AANS adult and pediatric guidelines recommend that corticosteroids not be used.^{24,28} Recent systematic reviews nonetheless have concluded that neither moderate benefits nor moderate harmful effects of corticosteroids in TBI patients can be excluded after review of all clinical trial data collected to date.³⁴ Noteworthy is that an international investigation known as the CRASH (Corticosteroid Randomization After Significant Head Injury) study was initiated in an attempt to define the merits of corticosteroid therapy in patients with TBI.⁶⁸ In this study 10,008 patients with a GCS score ≤ 14 were randomized to receive a 48-hour continuous infusion of methylprednisolone or placebo. Preliminary results of this study indicate a higher risk of death within 2 weeks of enrollment (relative risk 1.18) in those patients receiving corticosteroids compared with patients receiving placebo ($p < 0.001$).⁶⁸ Thus, corticosteroids should not be used to treat TBI patients regardless of severity.⁶⁸

TREATMENT AND PROPHYLAXIS OF POSTTRAUMATIC SEIZURES

It is generally agreed that patients who have experienced one or more seizures following a moderate to severe TBI should receive anticonvulsant therapy to avoid increases in CMRO₂ that occur with the onset of subsequent seizures. Initial therapy in these persons should consist of incremental intravenous doses of diazepam (5–40 mg adults, 0.1–0.5 mg/kg infants and children) or lorazepam (2–8 mg adults, 0.03–0.1 mg/kg infants and children) to terminate any active seizure activity followed by intravenous phenytoin to prevent seizure recurrence. Phenytoin dosing regimens for adults and pediatric patients include an intravenous loading dose of 15–20 and 10–15 mg/kg, respectively, followed by a maintenance dose of 5 mg/kg per day. Alternatively, fosphenytoin, a water-soluble phosphate ester of phenytoin, can be administered intravenously or intramuscularly using the same doses, specified as phenytoin equivalents (PE). The merits of preventive anticonvulsant therapy in patients who have not had a seizure postinjury historically has been more controversial. Risk factors for early posttraumatic seizures (<7 days after injury) include a GCS score of less than 10, a cortical contusion, a depressed skull fracture, a subdural hematoma, an epidural hematoma, an intracerebral hematoma, a penetrating head wound, or a seizure within the first 24 hours of injury.²⁴ In a landmark randomized, placebo-controlled study, the incidence of early posttraumatic seizures in patients receiving placebo was 14.2% compared with 3.6% in patients receiving phenytoin ($p < 0.05$) without a significant increase in drug-related side effects.^{69,70} A recent systematic review of the literature corroborated these findings, estimating an improved pooled relative risk for early seizure prevention of 0.34 (95% confidence interval: 0.21–0.54) in patients receiving anticonvulsants.³⁶ Thus it is recommended that phenytoin (or alternatively carbamazepine) should be used to prevent seizures in TBI patients at high risk during the first 7 days after injury.^{24,28,71} Valproate therapy is not recommended based on a trend for higher mortality in a study comparing valproate-treated patients with those receiving phenytoin short-term therapy.⁷² The benefits of prophylactic anticonvulsants beyond 7 days have not been demonstrated, and thus their use for this indication is not recommended.^{24,36,72} Unfortunately, despite reducing the incidence of early seizures following brain injury, no beneficial effects have been documented for anticonvulsants on patient mortality or long-term disability.³⁶

SUPPORTIVE CARE

While normalizing ICP and maintaining an adequate CPP are the highest priorities in preventing secondary injury following severe TBI, attention also must be given to preventing and/or treating systemic and extracranial complications. This includes careful ongoing fluid and electrolyte management.⁷³ Common electrolyte disturbances in TBI patients that should be monitored and treated aggressively include hyponatremia, hypomagnesemia, hypokalemia, and hypophosphatemia. Aggressive nutritional support of the TBI patient is another important therapeutic consideration.^{24,28} Evidence suggests that early feeding of TBI patients may be associated with a trend toward better outcomes in terms of survival and disability.³⁰ Infectious complications commonly encountered in severe TBI patients include nosocomial pneumonia, sepsis, urinary tract infections, and meningitis.^{74,75} Treatment of these potentially devastating infections should be aggressive, with careful attention being paid to antibiotic blood-brain barrier penetration

for intracranial infections. Adjunctive administration of granulocyte colony-stimulating factor also has received limited attention relative to preventing nosocomial infections in these patients.^{76,77} Other important therapeutic interventions include correction of any documented coagulopathy,⁷⁸ acute gastritis prophylaxis,⁶ prevention of thromboembolic events,^{78,79} fever control,⁸⁰ and prevention of decubi and contractures.

■ CLINICAL PATHWAYS/GUIDELINE IMPLEMENTATION

Use of clinical pathways and formal TBI management guidelines has been demonstrated to improve TBI patient outcomes and reduce institutional resource utilization. For example, implementation of a severe TBI clinical pathway resulted in a significant reduction in length of stay, ICU stay, and ventilator days among survivors at one institution.⁸¹ Implementation of published TBI guidelines also has been demonstrated to have significant impact on patient outcomes compared with historical controls in two other institutions.^{82,83} Nonetheless, the challenges of using historical controls in evaluating the effects of changes in practice standards was raised as a concern in one of these two investigations.⁸⁴ Regardless, few practitioners would dispute the overall importance of integrating current evidence-based management guidelines into clinical practice as a means to optimize care and improve the functional outcome of TBI patients.⁸⁴

■ INVESTIGATIONAL THERAPY

8 The steady decrease in morbidity and mortality following severe neurotrauma over the last 30 years can be attributed largely to expeditious and aggressive management of events resulting in secondary injury (i.e., ischemia, hypoxia, increased ICP) using conventional treatment strategies.⁷ Numerous neuroprotective agents targeting specific pathophysiologic processes that are theorized to occur following severe TBI have been investigated over the last decade in an attempt to further enhance the prospects for a meaningful recovery. A review of these investigations is presented below. Unfortunately, none of these agents to date has demonstrated a significant reduction in morbidity or mortality following severe TBI in phase III clinical trials with the exception of nimodipine in a subset of patients.

Numerous explanations have been offered as to the variance between benefits observed in animal models of brain injury using a variety of neuroprotective drugs and their lack of effectiveness in patients. These include mechanistic differences in secondary brain injury between animal models and patients,^{85–87} patient heterogeneity relative to intracranial and extracranial pathology,^{85,86} inadequate sample size,⁸⁸ poor drug penetration into the brain,^{89,90} insensitive outcome measures,^{89,90} patient enrollment imbalances,^{89,90} and unrealistic improvement expectations.^{86,89} Other issues that require careful attention in future clinical trials to maximize the utility of these agents are the dose, timing, and sequencing of drug administration; duration of therapy relative to the traumatic event; and possibly combination therapy.^{85–87} The process of obtaining informed consent in an expeditious manner is also a formidable challenge in this patient subset, as is true of other critically ill patient subsets.⁹¹ Inherent delays in obtaining informed consent prior to investigational drug administration may compromise potential benefits derived from the agent and eliminate the possibility of prehospital treatment of the TBI patient except in the rare instance where waiver of informed consent has

been granted. Despite the investigational study failures to date, the search is likely to continue for neuroprotective agents that eventually may improve the long-term outcome in severe TBI patients by avoiding some of the pitfalls in study design present in previous negative investigations.

■ MODULATION OF CALCIUM INFLUX

■ Calcium Antagonists

The calcium antagonists are obvious candidates for potentially attenuating the deleterious effects of calcium influx in acute neurotrauma patients. Nimodipine, a dihydropyridine, has been studied most extensively among the calcium antagonists that block the post-synaptic L-type calcium channel. Unfortunately, two major trials of nimodipine in adult TBI patients did not demonstrate a statistically significant improvement in outcome compared with placebo.⁹² A significant benefit was observed in the subgroup of patients with posttraumatic subarachnoid hemorrhage (tSAH) receiving nimodipine that was corroborated in a follow-up investigation.⁹³ The nimodipine dosage used in the latter investigation was 2 mg/h intravenously for 7 to 10 days, followed by 360 mg daily administered orally until day 21 of treatment.⁹³ A recent systematic review of the literature concluded that nimodipine may be beneficial in tSAH patients, although there is insufficient evidence to support the use of calcium antagonists in unselected TBI patients.³⁵ Systemic hypotension is a relative limitation with the use of other L-type calcium channel antagonists for this indication.

Another target for calcium modulation is the presynaptic N-type voltage-sensitive calcium channels. Omega conotoxin (SNX-111, ziconotide) is one such antagonist that has been evaluated in TBI patients. Unfortunately, a major phase III trial of omega conotoxin was halted prematurely after an interim analysis deemed the likelihood for a favorable outcome to be very small compared with placebo.⁸⁵ Profound systemic hypotension requiring vasopressor support was a major concern with use of this agent.

■ Glutamate Antagonists

A significant amount of experimental evidence has been accumulated confirming the efficacy of NMDA receptor antagonists in attenuating secondary injury events following model brain injury. Based on these results, both competitive and noncompetitive NMDA receptor antagonists have been developed as neuroprotective agents. D-CPP-ene and CGS 19755 (Selfotel) are investigational NMDA antagonists competing with glutamate at the receptor site (i.e., competitive antagonists). Results of two phase III Selfotel clinical trials involving 693 patients did not demonstrate increased efficacy compared with placebo and possible increased mortality and serious brain-related adverse events in the treatment groups during interim analysis of the data.⁹⁴ As such, the trials were stopped prematurely.⁹⁴ Noncompetitive NMDA antagonists or receptor channel blockers bind to the open NMDA receptor, thereby blocking the ionic current. Compounds within this group include ketamine, phencyclidine, dextromethorphan, dextrorphan, and the investigational agents dizocilpine (MK-801), dexanabinol (which also possesses free-radical scavenging properties),⁹⁵ and aptiganel (Cerestat). A phase III trial of aptiganel also was discontinued prematurely based on limited benefit (1.1%) in favor of the treatment over placebo in the first 340 patients studied.⁷ Another NMDA receptor antagonist that selectively blocks the NR2B regulatory site

on the postsynaptic receptor and has undergone clinical investigation is CP-101,606.⁹⁶ A phase III study involving 600 severe TBI patients randomized to receive either CP-101,606 or placebo was completed recently. Results of this investigation are expected in the future. A phase II trial of dexamethasone in 67 severe TBI patients was completed recently and demonstrates it to be safe and well tolerated; a trend toward faster and superior neurologic outcomes also was observed.⁹⁵

ANTIOXIDANTS/FREE RADICAL SCAVENGERS

The potential role of oxygen free radicals in the pathophysiology of TBI has stimulated interest in the use of antioxidants to interrupt the self-perpetuating cycle of membrane destruction in these patients. Tirilazad (Freedox), a 21-aminosteroid, is one such antioxidant that has undergone phase III testing in TBI, stroke, and subarachnoid hemorrhage (SAH) patients. An attractive feature of this steroid analog is that although it is a potent inhibitor of lipid peroxidation, it is essentially devoid of glucocorticoid activity. Unfortunately, two major trials of tirilazad in TBI patients were unable to demonstrate efficacy compared with placebo.^{89,97} An enzymatic free-radical scavenger that has undergone clinical trials in severe TBI patients is superoxide dismutase conjugated to a polyethylene glycol polymer (PEG-SOD; pegorgotein, Dismutec). While results of the preliminary phase II trial were promising, no statistically significant improvement in outcome

or mortality was observed in the larger phase III trial in severe TBI patients receiving two doses of pegorgotein compared with placebo.⁹⁸

OTHER TREATMENT STRATEGIES

Formation of inflammatory mediators including the metabolites of arachidonic acid has been implicated in the latter stages of tertiary injury following neurotrauma. As such, both cyclooxygenase inhibitors (e.g., NSAIDs)^{99,100} and mixed cyclooxygenase-lipoxygenase inhibitors (e.g., BW7544C) have been studied in experimental neurotrauma models with limited success. Furthermore, the immunosuppressant cyclosporin A has received some attention relative to attenuation of cortical damage in animal models of TBI.^{87,101} Inhibitors of inflammatory mediators also are under consideration as neuroprotective agents. These include antagonists to bradykinin,¹⁰² platelet-activating factor, cytokines, leukotriene LT₄, and capase-1.¹⁰³ Lastly, various growth factors, including brain-derived neurotrophic factor, nerve growth factor, neurotrophin-3, and erythropoietin,¹⁰⁴ and cofactors such as insulin-like growth factor I¹⁰⁵ and GM₁ ganglioside may have a future role in the management of TBI by promoting nerve cell regeneration and differentiation.³⁷ Such neurorestorative strategies may be classified as structural or functional.⁷ Importantly, such strategies may be the most fertile targets for genetic manipulation in the future and may have significant implications for post-TBI rehabilitation.⁷

EVALUATION OF THERAPEUTIC OUTCOMES

The process for evaluation of therapeutic outcomes is summarized in Table 56–3. Patients with severe TBI require ICU monitoring initially with the goals of maintaining or reestablishing neurologic and systemic homeostasis as well as readily detecting any neurologic deterioration.⁵⁰ This requires frequent evaluation of the patient’s neu-

rologic status (e.g., GCS) and measurement of vital signs, urine output, and arterial oxygen saturation (as well as ICP in patients with an ICP monitor in place). Furthermore, careful attention must be paid to the potential for a variety of electrolyte, mineral, and acid-base disturbances, coagulopathies, and infections by obtaining various laboratory tests on a daily basis initially. The intensity of monitoring will be a function of the relative degree of neurologic and hemodynamic

TABLE 56–3. Evaluation of Therapeutic Outcomes

| | |
|-----------------------|---|
| General | GCS: Record hourly initially, decrease frequency as neurologic status stabilizes Vital signs (BP, HR, RR, temperature): Record hourly initially, decrease frequency as neurologic status stabilizes Urine output: Record hourly initially, decrease frequency as neurologic status stabilizes |
| Risk of increased ICP | Arterial oxygen saturation: Continuously while in intensive care unit ICP: Record hourly, decrease frequency as ICP stabilizes less than 20 mm Hg CPP: Record hourly, decrease frequency as CPP stabilizes in excess of 60 mm Hg ^a |
| Laboratory tests | Ethanol concentration and urine drug screen: On admission ABGs: Daily at a minimum while intubated, repeated as needed based on pulmonary instability requiring ventilator setting changes CBC: Daily while in intensive care unit Serum electrolytes (Na, K, Cl): Daily while in intensive care unit Minerals (Mg, Ca, P): Daily initially until concentrations stable |
| Radiologic procedures | CT scan: Postresuscitation initially with repeat scan(s) as needed based on degree of neurologic instability (e.g., decrease in GCS) |

GCS, Glasgow Coma Scale; BP, blood pressure; HR, heart rate; RR, respiratory rate; CSF, cerebrospinal fluid; TBI, traumatic brain injury; ICP, intracranial pressure; CPP, cerebral perfusion pressure; ABG, arterial blood gas; CBC, complete blood count; Na, sodium; K, potassium; Cl, chloride; Mg, magnesium; Ca, calcium; P, phosphorus; CT, computed tomography.

^aContinuous monitoring mandated initially if technologically feasible.

stability of the patient in the hours and days following the neurologic insult. Lastly, radiologic tests (e.g., CT scans) are essential not only for the initial diagnostic evaluation of TBI patients but also as means to evaluate the etiology for any subsequent neurologic deterioration as well.

ABBREVIATIONS

AANS: American Association of Neurological Surgeons
 ABG: arterial blood gas
 ATP: adenosine triphosphate
 BTF: Brain Trauma Foundation
 CBF: cerebral blood flow
 CBV: cerebral blood volume
 CDO₂: cerebral oxygen delivery
 CMRO₂: cerebral oxygen consumption
 CNS: central nervous system
 CPP: cerebral perfusion pressure
 CSF: cerebrospinal fluid
 CT: computed tomography
 ECG: electrocardiogram
 GCS: Glasgow Coma Scale
 GI: gastrointestinal
 ICP: intracranial pressure
 MAP: mean arterial pressure
 NMDA: *N*-methyl-D-aspartate
 NSAID: nonsteroidal anti-inflammatory drug
 PBRCs: packed red blood cells
 SBP: systolic blood pressure
 Sjvo₂: jugular venous oxygen saturation
 TBI: traumatic brain injury
 tSAH: traumatic subarachnoid hemorrhage

PARKINSON'S DISEASE

Merlin V. Nelson, Richard C. Berchou, and Peter A. LeWitt

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Amantadine and anticholinergic medications are useful for relieving mild features of idiopathic Parkinson's disease (IPD).
- 2 The optimal time to start carbidopa/L-dopa is controversial, but in general, treatment should be started when the disease interferes with the patient's occupation, activities of daily living, or quality of life.
- 3 Anticholinergic medication should be used with caution in the elderly or those with preexisting cognitive difficulties.
- 4 Carbidopa/L-dopa is the most effective medication for symptomatic treatment of IPD.
- 5 L-Dopa response fluctuations may be explained primarily by its pharmacokinetic and pharmacodynamic properties.
- 6 Most carbidopa/L-dopa-treated patients eventually will develop response fluctuations.
- 7 Selegiline, catechol-O-methyl-transferase (COMT) inhibitors, and controlled-release carbidopa/L-dopa decrease response fluctuations through pharmacokinetic mechanisms.
- 8 Dopamine agonists are L-dopa-sparing and decrease response fluctuations but are more likely to cause psychiatric symptoms such as hallucinations.
- 9 Close management of medication dosing and administration times is necessary to optimize therapeutic outcomes and avoid adverse effects.

While its clinical manifestations previously had escaped attention, *paralysis agitans* acquired an unmistakable presence following the 1817 publication by an obscure British physician, James Parkinson.¹ Parkinson provided vivid descriptions of such characteristic features as an "involuntary tremulous motion," "the hand failing to answer with exactness to the dictates of the will," and the tendency to "pass from a walking to a running pace." Later observers added a variety of signs and symptoms, among them rigidity and instability of balance, to define idiopathic Parkinson's disease (IPD) as we know it today.

EPIDEMIOLOGY

The annual incidence of IPD increases with age from about 20 per 100,000 persons in the fifth decade of life to about 90 per 100,000 persons in the seventh decade of life, with the usual age of onset at about age 60.² Extensive epidemiologic research of IPD suggests that environmental factors such as rural living, drinking well water, and heavy metal and hydrocarbon exposure have small but demonstrable contributions to the risk for IPD. Interestingly, cigarette smoking, caffeine consumption, and nonsteroidal anti-inflammatory drug use are associated with protection against the illness.^{3–5}

The onset of IPD in later life implies that cumulative exposures to putative toxins, factors associated with central nervous system (CNS) aging, or other as yet uncharacterized cell death mechanisms may be responsible for the onset and progression of the disease. While IPD is sporadic in most instances, genetic factors may have a role in its etiology, particularly if the disease begins before age 50. Nine genetic linkages and four genes have been identified in parkinsonism.⁶

These include mutations of α -synuclein (which transcribes a presynaptic protein) and *parkin* genes. These genes have been associated with autosomal dominant and autosomal recessive early-onset Parkinson's kindreds, respectively. Pathologic findings and some aspects of the phenotype are different from those in IPD; however, *parkin* gene mutations may predispose to both early- and late-onset forms of IPD.⁷

ETIOLOGY

The pathogenesis of IPD is not known. Neurotoxins highly selective for substantia nigra pars compacta (SNc) dopaminergic neurons are instructive because animal models of parkinsonism can be created with 6-hydroxydopamine and with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). The latter compound is converted by monoamine oxidase (MAO) type B to the toxic 1-methyl-4-phenylpyridinium ion (MPP⁺). MAO-B inhibition by selegiline eliminates the toxicity of MPTP. MPP⁺ is toxic to neurons by interfering with mitochondrial metabolism. Another mechanism of toxicity that has received consideration for the pathogenesis of IPD is cellular damage from oxyradicals.⁸ Dopamine generates free radicals from autooxidation and from MAO metabolism (Fig. 57–1). Several antioxidative mechanisms are present within and outside neurons to limit any damage that might be produced by free-radical attack, but one possibility is that such protection might be overwhelmed or impaired in IPD. Excitotoxicity, programmed cell death activation, and chronic infection are also under consideration for IPD etiology.⁹

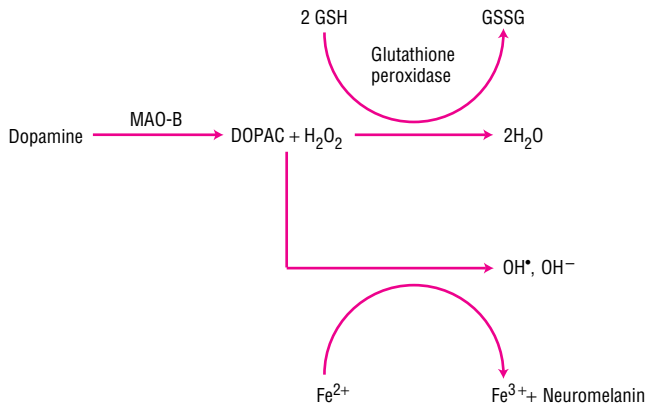

FIGURE 57-1. Dopamine metabolism results in hydrogen peroxide (H₂O₂) formation. If the glutathione system is deficient or excess hydrogen peroxide is present, hydrogen peroxide accepts an electron from ferrous iron (Fe²⁺), forming ferric iron (Fe³⁺) and the hydroxyl free radical (OH^{*}). The hydroxyl free radical can cause lipid peroxidation, thereby damaging neuronal cell membranes. MAO-B, monoamine oxidase B; DOPAC, 3,4-dihydroxyphenylacetic acid; H₂O, water; GSH, glutathione; GSSG, glutathione disulfide; OH⁻, the hydroxide ion.

PATHOPHYSIOLOGY

Dopaminergic projections from the SNc to the striatum (putamen and caudate) synapse on two populations of efferent neurons (Fig. 57-2). The direct pathway involves activation of striatal D₁ dopamine receptors that stimulate inhibitory γ -aminobutyric acid (GABA)/substance P efferents to the globus pallidus interna (GPI) and substantia nigra pars reticulata (SNr). The indirect pathway involves activation of striatal D₂ dopamine receptors that inhibit inhibitory GABA/enkephalin efferents to the globus pallidus externa (GPe). The GPe projects inhibitory GABA neurons to the subthalamic nucleus (STN). Here, excitatory glutaminergic neurons project to the GPI. GPI output is inhibitory on the ventroanterior and ventrolateral thalamic projections to the frontal cortex. Thus loss of nigrostriatal dopamine neurons in IPD results in reduction of cortical activation (see Fig. 57-2). Virtually all the motor deficits of IPD are attributable to the marked loss in dopaminergic neurons projecting to the putamen.

In actuality, the pathways and interactions involved have a greater complexity than those described in this model.¹⁰ The synaptic organization of the basal ganglia involves a variety of neurotransmitters and neuromodulators, including acetylcholine, dopamine, GABA, glutamate, enkephalins, substance P, adenosine, and serotonin. Each is a target for intervention in IPD. Drugs enhancing dopaminergic or inhibiting acetylcholine or glutamate neurotransmission have been successful in IPD therapeutics. The role for drug modulation of other neurotransmitters active in the basal ganglia has not been explored fully, but recent results with adenosine A_{2A} receptor antagonists are promising.^{11,12}

The model of dopaminergic depletion or blockade in producing parkinsonian features provided much of the impetus for development of therapies to augment stimulation of striatal dopamine receptors. Stimulation of D₁ dopamine receptors activates adenylate cyclase. D₂ dopamine receptors are coupled to a guanosine triphosphate (GTP)-binding protein that opens potassium channels to hyperpolarize neurons, thereby reducing the excitability of striatal cells.¹³ In IPD, activation of the D₂ receptor appears to be of primary importance for mediating both clinical improvements and some adverse effects (such as hallucinations). Dyskinesias are more likely to occur with L-dopa therapy (D₁ and D₂ agonism) than with dopamine agonist therapy

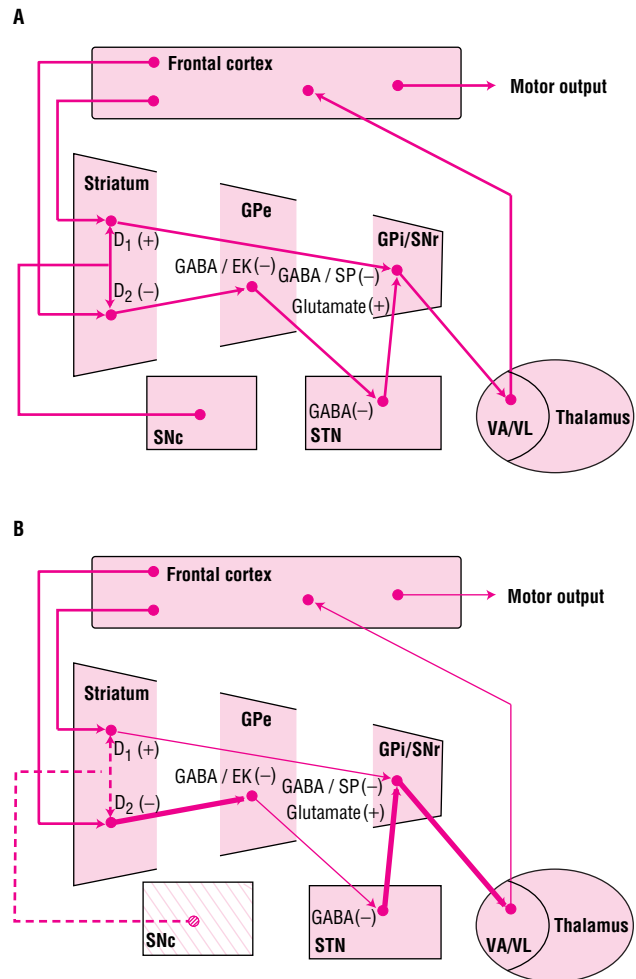

FIGURE 57-2. A. The normal balance of the basal ganglia–thalamocortical circuit. GPe, globus pallidus externa; GPI, globus pallidus interna; SNr, substantia nigra pars reticulata; SNc, substantia nigra pars compacta; VA, ventroanterior nuclei of the thalamus; VL, ventrolateral nuclei of the thalamus; STN, subthalamic nucleus. B. With nigrostriatal degeneration (dashed line), there is loss of inhibition of the GPI by the direct pathway and activation of the GPI via the indirect pathway, resulting in decreased activation of the cortex. See text for details.

(primarily D₂ agonism), suggesting D₁ receptor involvement in producing dyskinesia.

Pathologic findings reveal a markedly decreased number of nigrostriatal neurons and a correlation between the extent of nigrostriatal dopamine loss and the severity of clinical features. The threshold for onset of parkinsonism appears to be the loss of 70% to 80% of these neurons.¹⁴ [¹⁸F]Fluorodopa positron-emission tomography (PET) measures aromatic amino acid decarboxylase activity, whereas other PET ligands and [¹²³I]2 β -carbomethoxy-3 β -(4-iodophenyl)tropane (β -CIT) single-photon-emission computed tomography measure dopamine transporter (DAT) activity. In IPD, these functional imaging studies suggest compensatory responses such as upregulation of dopamine synthesis and downregulation of synaptic dopamine reuptake. These responses may help to explain how such a significant loss of neurons can be relatively asymptomatic.^{15,16} Progressive supranuclear palsy (PSP) and other “Parkinson plus” disorders are not responsive to dopamine replacement or dopamine agonist therapies, presumably on the basis of decreased dopamine receptors owing to postsynaptic damage beyond the neuropathologic changes in IPD.

FIGURE 57-3. Dopamine metabolism in presynaptic dopamine neuron (see text for full details). 3OMD, 3-*O*-methyldopa; AC, adenylate cyclase; AD, aldehyde dehydrogenase; COMT, catechol-*O*-methyl transferase; D₁-D₃, dopamine receptors; DA, dopamine; DAT, dopamine transporter; DOPAC, 3,4-dihydroxyphenylacetic acid; HVA, homovanillic acid; L-AAD, L-aromatic amine decarboxylase; MAO-B, monoamine oxidase B; TH, tyrosine hydroxylase.

Dopamine metabolism is shown in Fig. 57-3, and the range of therapeutic interventions for IPD is summarized in Table 57-1. L-Tyrosine, the metabolic precursor of dopamine, is converted by tyrosine hydroxylase (TH) to L-dihydroxyphenylalanine (L-dopa) in a highly regulated synthetic process. L-Dopa is decarboxylated to dopamine by the enzyme L-amino acid decarboxylase (L-AAD). L-AAD is present outside the CNS and in some nonaminergic neurons, whereas TH is found exclusively in aminergic neurons. Peripheral decarboxylation can be blocked by antagonists of L-AAD (carbidopa or benserazide) that do not pass the blood-brain barrier. Use of these drugs with L-dopa increases the CNS penetration of exogenously administered L-dopa and decreases adverse effects from the peripheral metabolism to dopamine. Dopamine is stored in synaptic vesicles until stimulated to be released into the synapse by calcium-dependent mechanisms. Dopamine activity is terminated primarily by reuptake into the presynaptic neuron by means of a specific dopamine transporter. Sequestration into the storage granules of the presynaptic neurons or the actions of catabolic pathways involving MAO or catechol-*O*-methyl-transferase (COMT) leads to inactivation of dopamine.

Since dopamine tonically inhibits acetylcholine neurons in the striatum, the degeneration of nigrostriatal dopamine neurons results in a relative increase of striatal cholinergic interneuron activity. This increased cholinergic activity contributes especially to the tremor of IPD, as evidenced by symptomatic improvement with the use of anticholinergics and worsening with cholinergic agents.

IPD has a characteristic neuropathologic picture that permits differentiation from similar clinical syndromes. In the SNc, loss of neurons and Lewy bodies (a neuronal inclusion body composed of amyloid neurofilaments) is always found. Lewy bodies appear in degenerating neurons in association with adjacent gliosis. The loss of pars compacta neurons is the basis for loss of dopamine projections to the striatum. Small numbers of Lewy bodies can be found in other neurologic disorders and in normal aging. The occurrence of SNc Lewy bodies in patients without parkinsonism indicates that the disease can exist as a pathologic entity with less involvement than necessary for

causing clinical signs and symptoms (incidental Parkinson's disease). Even patients whose clinical features strongly suggest IPD may lack its characteristic pathology.

CLINICAL PRESENTATION

While the disorder is unmistakable in its advanced form, distinguishing mild IPD from changes seen with normal aging can be challenging. Diagnostic criteria specify that at least two of the following must be present: limb muscle rigidity, resting tremor (at 3-6 Hz and abolished by movement), bradykinesia, or postural instability.¹⁷ For the diagnosis of IPD, other conditions must be excluded (Table 57-2). Medication-induced parkinsonism can mimic the idiopathic disorder, so it is important to establish if such medications have been used (e.g., antipsychotics, antiemetics, or metoclopramide). Several neurodegenerative conditions resemble the clinical picture of IPD, including PSP, striatonigral degeneration, olivopontocerebellar degeneration, and rarely, Huntington's or Wilson's disease. In order to distinguish IPD from secondary parkinsonism, other diagnostic criteria include lack of other neurologic impairments and responsiveness to L-dopa.

| Olivopontocerebellar atrophy |

IPD develops insidiously and progresses slowly in most patients, although progression sometimes arrests. Initial complaints may include sensory symptoms, but as the disease progresses, the patient exhibits one or more classic clinical features: resting tremor, rigidity, bradykinesia, or change in posture. Characteristic problems, even in mildly affected patients, include small handwriting (micrographia), decreased facial animation (hypomimia) and blink rate, diminished arm swing while walking, shuffling gait, soft or indistinct speech (hypophonia), and decreased dexterity in everyday activities. Symptoms can progress to severe functional impairment, at which time patients may require nursing home placement and may be confined to bed or wheelchair. Other clinical characteristics of IPD are listed in Table 57–3.

Bradykinesia refers to slowness of movement. Movement in IPD is often slow throughout an intended action, but initiation of movement may display a hesitation out of proportion to slowness affecting completion of the movement. A progressive slowing and decline in dexterity with repetition may impair tasks such as finger tapping. Intermittent immobility (*freezing*) is another common characteristic. Freezing is especially likely to occur in situations such as when walking in a crowd or when walking through a narrow doorway. Patients also may experience a slow shuffling gait with difficulty halting their steps while in motion.

Tremor occurring at rest is highly typical of IPD and often is the sole presenting complaint; however, only two-thirds of parkinsonian patients have tremor on diagnosis, and some will never develop this sign. Tremor in IPD is present most commonly in the hands, sometimes with a characteristic pill-rolling. It also can involve the jaw or legs. Sometimes the sensory equivalent is perceived as an “internal” sensation of vibration without outward manifestations. Like other symptoms of IPD, resting tremor often begins unilaterally and may persist in this distribution. Stressful situations or use of limbs in other activities may increase tremor amplitude in a limb at rest. Usually,

| Weight loss |

volitional movement abolishes resting tremor, and it is absent during sleep.

Rigidity is the increased muscular resistance to passive range of motion and often has a cog-wheeling quality. Because it can lead to falls, postural instability is one of the most disabling problems of parkinsonism. A disturbance of appropriate responses to the perturbation of balance is common in advanced IPD. Testing for impaired postural responses by means of the pull test (in which a patient is unable to recover balance after sudden backward displacement at the shoulders) can help to identify the risk for falling. Many patients with impaired postural responses also have tendencies for propulsive gait (festination) and a forward flexed posture of their axial structures along with partial flexion of the extremities.

IPD is predominantly a disorder of motor capabilities; however, neuropsychological abnormalities can be detected even in patients with early or mild forms of the disorder and without obvious cognitive impairments. Although intellectual deterioration is not inevitable in IPD, some patients deteriorate in a manner indistinguishable from Alzheimer’s disease and other dementing conditions.¹⁸ It is difficult to estimate the number of patients at risk because medications and concomitant illnesses can confound analysis for the extent of cognitive decline owing specifically to IPD. IPD patients are also at increased risk for depression. While the disabilities of IPD may provoke depression in some instances, the biochemical changes in the brain due to IPD also may predispose for endogenous depression.

► TREATMENT: Parkinson's Disease

■ SURGICAL THERAPY

The most effective surgical technique is deep brain stimulation (DBS) of the STN, which decreases outflow from this region (as shown in Fig. 57–2B) and thus reduces input to the thalamus.¹⁹ STN DBS is especially useful for tremor, dyskinesias, gait disorder, and start hesitation. Thalamic DBS and thalamotomy (a focal destructive lesion of the thalamus) can reduce disabling tremor. Pallidotomy (a focal destructive lesion of the GPi) and GPi DBS can help with severe dyskinesias and on/off fluctuations but is not as helpful for bradykinesia. Destructive lesions are immediate and permanent, whereas DBS requires lifelong maintenance. Transplantation of autologous adrenal medulla tissue was unsuccessful, as has been more recent experience in most cases of fetal tissue transplantation.

■ PHARMACOLOGIC THERAPY

Treatment algorithms for early and advanced IPD are shown in Figs. 57–4 and 57–5. More detailed treatment information has been published, as have evidence-based assessments of treatment interventions.^{20,21} The only established pharmacologic therapy for IPD is medication that can transiently reverse signs and symptoms.

Patients with mild features of IPD and no disability do not need symptomatic medication. With advancing disability, however, symptomatic therapy is vital for maintaining independence.

The most efficacious treatment for IPD is replacement of the natural neurotransmitter dopamine by the use of its immediate precursor L-dopa. As indicated in the treatment algorithm shown in Fig. 57–4, anticholinergic drugs or amantadine can be used for treating resting tremor as an alternative to L-dopa. While not highly effective against bradykinesia, gait disturbance, or other features of advanced parkinsonism, these medications can be useful for relieving mild disabilities experienced by patients in the first few years after the onset of parkinsonism. The decision to incorporate L-dopa or dopamine agonist therapy comes from advancing disability and ineffectiveness of alternative medications to provide adequate symptomatic control. Depending on profession and lifestyle, the same basic parkinsonian features may result in different degrees of disability, and drug therapy goals may need to be adjusted accordingly. A summary of available antiparkinsonian medications is listed in Table 57-4.

Selegiline and other MAO-B inhibitors (lazabemide and rasagiline) have been studied not only for symptomatic effects but also for possible neuroprotection. Recently, the National Institute of Neurological Disorders and Stroke formed a committee for identifying and implementing studies of potential therapies against the progression of IPD.²² Twenty-one promising agents were identified from an initial 59

| Ropinirole | Antioxidant |
| Rasagiline | Antioxidant/antiapoptotic |
| Selegiline | Antioxidant/antiapoptotic |

proposed agents. The agents identified as candidates for phase II or III neuroprotection studies are listed in Table 57-5. A recent coenzyme Q10 study in IPD found that 16 months of therapy with 1200 mg/day gave small but statistically beneficial effects at slowing decline in activities of daily living. The investigators concluded that it would be premature to recommend the use of coenzyme Q10 as a neuroprotective treatment of IPD until confirmatory studies are completed.²³ Vitamin E (2000 IU/day) has not proven useful in preventing disease progression. Pramipexole and ropinirole are associated with slower decline in imaging markers of dopaminergic function compared with L-dopa monotherapy, suggesting neuroprotection.^{24,25} These results are tempered by alternative explanations for these findings.²⁶

L-Dopa and dopaminergic agonists not only act on the nigrostriatal system but also facilitate mesolimbic dopaminergic projections. This may result in psychiatric symptoms, including compulsive behaviors, delirium, agitation, paranoia, delusions, and hallucinations. These effects tend to occur more frequently in older patients and in those with underlying confusion or dementia and are associated with poor outcome.²⁷ These problems can be managed using the guidelines and antipsychotic medications summarized in Table 57-6.^{28,29} Most other antipsychotic medications, including olanzapine and

TABLE 57-6. Stepwise Approach to Drug-Induced Psychosis in Parkinson's Disease

1. General measures such as evaluating for hypoxemia, infection (especially encephalitis, systemic sepsis, or urinary tract infection), or electrolyte disturbance (especially hypercalcemia or hyponatremia).
2. Simplify the antiparkinsonian regimen as much as possible by discontinuing the medications with the highest risk-benefit ratio first.
 - a. Discontinue anticholinergics, including other nonparkinsonian medications with anticholinergic activity such as antidepressants, e.g., amitriptyline.
 - b. Discontinue selegiline.
 - c. Taper and discontinue dopamine agonists.
 - d. Taper and discontinue amantadine, being aware that amantadine withdrawal delirium has been reported.
 - e. Consider reduction of levodopa (especially at the end of day) and discontinuation of COMT inhibitors.
3. Consider atypical antipsychotic medication if psychosis persists.
 - a. Quetiapine 12.5–50 mg at bedtime and gradually increased upward by 12.5–25 mg per week until psychosis controlled, *or*
 - b. Clozapine 12.5–50 mg at bedtime and gradually increased upward by 12.5 mg per week until psychosis controlled (requires weekly monitoring for leukopenia).

risperidone, can improve psychotic symptoms but tend frequently to worsen parkinsonian features.

The decision to start L-dopa early (as soon as the diagnosis of IPD is made) or late (only when symptoms compromise social, occupational, or psychological well-being) has generated controversy.^{30,31} Proponents for delaying treatment point to evidence suggesting that long-term L-dopa therapy is associated with an increased risk of response fluctuations, an increased risk of dementia, and loss of L-dopa efficacy.³² L-Dopa therapy hypothetically could increase oxidative stress in dopaminergic neurons and thus increase dopaminergic neuronal loss; however, there is no firm evidence that this mechanism actually affects the course of IPD. The counterargument is that response fluctuations are secondary to disease progression, not L-dopa.³³ A multicenter study found that withholding L-dopa therapy for more than 3 years after diagnosis resulted in a doubling of the excess mortality rate compared with early treatment.³⁴ A 40-week randomized, double-blind, placebo-controlled clinical trial comparing earlier versus later L-dopa treatment (ELLDOPA) now underway may address this issue.³⁵ Fortunately, medications other than carbidopa/L-dopa can be initiated in newly diagnosed young and cognitively intact patients (see Fig. 57-4) if symptoms are functionally disabling.

■ Anticholinergic Medications

The anticholinergic drugs can be effective against tremor but rarely show much benefit for bradykinesia or other disabilities of IPD. Not all patients with tremor respond to these medications. Sometimes dystonic features associated with IPD also will improve. Adverse effects of these drugs include dry mouth, blurred vision, constipation, and urinary retention. More serious reactions include forgetfulness, sedation, **3** depression, and anxiety. An encephalopathic state can evolve gradually in some patients. Increased Alzheimer's disease pathology (amyloid plaques and neurofibrillary tangles) is related to the use of these agents in IPD.³⁶ Patients with preexisting cognitive deficits and advanced age are at greater risk for central anticholinergic effects. The anticholinergic drugs differ little in their adverse effects and have essentially the same therapeutic potential. Anticholinergic drugs can be used alone or in conjunction with L-dopa and other antiparkinsonian agents.

■ Amantadine

Amantadine (Symmetrel, Endo; various generic brands) is often effective for relief of most signs and symptoms in patients with mild IPD.³⁷ More recently, it has been reported to suppress L-dopa-induced dyskinesia (at doses up to 400 mg/day).³⁸ Therapy with amantadine is also considered an independent predictor of improved survival in IPD.³⁹ Like anticholinergics, it can be especially effective against tremor. The drug typically is used at 200–300 mg/day. The elderly are particularly prone to confusion at higher doses. Adverse effects that may occur at onset of the drug (e.g., sedation and vivid dreams) may disappear with time. Dry mouth is a common adverse effect reminiscent of anticholinergic drugs, although amantadine does not block cholinergic receptors. Other adverse central effects seen uncommonly include depression, hallucinations, anxiety, dizziness, psychosis, and confusion. A common (and reversible) adverse effect of amantadine is livedo reticularis, a diffuse mottling of the skin.

Amantadine is eliminated renally, and a decreased dose should be administered when renal dysfunction is present (100 mg/day with

creatinine clearances of 30–50 mL/min, 100 mg every other day for creatinine clearances of 15–29 mL/min, and 200 mg every 7 days for creatinine clearances of less than 15 mL/min and patients on hemodialysis). Unlike other drugs for IPD, the precise mechanism of action of amantadine is unknown, but it may involve either dopaminergic or nondopaminergic mechanisms such as inhibition of NMDA receptors.

■ L-Dopa and Carbidopa/L-Dopa

4 L-Dopa (Larodopa, Roche) was first studied for parkinsonism in the 1960s, and recognition of its unequivocal benefit was reported in 1967.⁴⁰ It is still the most effective drug in the management of IPD. L-Dopa is the immediate precursor of dopamine. It crosses the blood-brain barrier, whereas dopamine does not. In the striatum and elsewhere, L-dopa is converted by L-amino acid decarboxylase (L-AAD) to dopamine. Peripherally formed dopamine is responsible for adverse effects such as nausea, vomiting, cardiac arrhythmias, and postural hypotension. By combining L-dopa with the peripherally acting L-AAD inhibitors carbidopa (Sinemet, Bristol-Myers Squibb; various generic brands) or benserazide (Madopar; not available in the United States), peripheral conversion of L-dopa to dopamine is blocked. As a result, increased amounts of L-dopa are transported into the brain, and peripheral adverse effects of dopamine are reduced.⁴¹

Today, L-dopa is used almost exclusively as a combination product with decarboxylase inhibitors. Starting L-dopa doses of 200–300 mg/day often are adequate for relief of disability. Some patients require larger amounts on a daily basis; however, the usual maximal dose of L-dopa needed by patients even with severe parkinsonism is 800 mg/day. Slow buildup of dose (e.g., increments of 100 mg L-dopa per week) can help to assess the lowest effective dose and minimizes the risk for adverse effects, such as postural hypotension, nausea, vomiting, sedation, and vivid dreams.

Generally, about 75 mg carbidopa is required to prevent peripheral adverse effects, but some patients may benefit from as much as 150 mg/day. Carbidopa/L-dopa is used most widely in a 25-mg/100-mg tablet form, although 25-mg/250-mg and 10-mg/100-mg forms are also available. Controlled-release preparations of carbidopa/L-dopa are available in 50-mg/200-mg and 25-mg/100-mg forms. If peripheral adverse effects are prominent, 25-mg carbidopa (Lodosyn, Bristol-Myers Squibb) tablets are available.

5 ■ *Pharmacokinetics and Pharmacodynamics.* The pharmacokinetic and pharmacodynamic properties of L-dopa explain many of its clinical effects, including response fluctuations. There is marked intra- and intersubject variability in the time to peak plasma concentrations after oral L-dopa. Often there may be more than one peak plasma concentration after a single dose, which is attributed to erratic gastric emptying. Meals delay gastric emptying, whereas antacids (which decrease gastric acidity) promote gastric emptying. L-Dopa is absorbed primarily in the proximal duodenum by a saturable large neutral amino acid (LNAA) transport system. Competition for this site by dietary or supplemental LNAAs can reduce L-dopa plasma concentrations. The gut wall also contains a saturable decarboxylase that limits the bioavailability of L-dopa unless it is combined with a peripheral decarboxylase inhibitor such as carbidopa.

L-Dopa is not bound to plasma proteins. It crosses the blood-brain barrier by stereospecific saturable facilitated diffusion and competes with LNAA for transport into the brain. High-dose infusions of phenylalanine and leucine decrease the clinical response to L-dopa without altering L-dopa plasma concentrations. This has led to

recommendations of protein restriction and special diets for improving L-dopa responsiveness, although generally reduction in protein intake is not needed to maintain good L-dopa effect. A metabolite of L-dopa, 3-*O*-methyldopa (3OMD), also competes for transport, but it is not clear how this affects L-dopa clinical response.

L-Dopa elimination is primarily by decarboxylation to dopamine. Additional pathways are by 3-*O*-methylation and transamination. With adequate decarboxylase inhibition, increased amounts of L-dopa are metabolized by the other pathways. The elimination half-life of L-dopa is about 1 hour, and this is extended to about 1½ hours with the addition of carbidopa. 3OMD has a half-life of about 15 hours and accumulates with chronic dosing.

6 ■ *Motor Complications of L-Dopa.* Between 5% and 10% of IPD patients will develop involuntary movements or motor fluctuations with each year of L-dopa treatment.⁴² Movement complications associated with long-term treatment with carbidopa/L-dopa and their suggested treatments are listed in Table 57–7 and have been reviewed recently.^{43,44} Initiating therapy with the controlled-release form of carbidopa/L-dopa did not reduce motor complications compared with standard-release carbidopa/L-dopa in a 5-year trial.⁴⁵

CLINICAL CONTROVERSY

Some clinicians are concerned with possible long-term risks (motor fluctuations) of L-dopa and will delay or avoid its use even though it is more effective than other medications currently available. Others believe that motor fluctuations are a consequence of disease severity and progression rather than due to L-dopa itself. Individualized considerations of a patient's disability should guide all interventions for IPD.

■ *Wearing Off.* End-of-dose deterioration (the wearing-off effect) has been related to increasing loss of neuronal storage capability for dopamine. Initially, exogenous L-dopa is taken up by the remaining presynaptic neurons, converted to dopamine, and stored in synaptic vesicles. With progressive loss of presynaptic neurons, storage capacity declines, and patients become more dependent on the rate of L-dopa delivery to the brain for the generation of dopamine. Hence the peripheral pharmacokinetic properties of L-dopa increasingly become the determinant of central dopamine synthesis.

With advancement of IPD, a single carbidopa/L-dopa dose may produce benefits for as little as 1.5 to 2 hours. As a result, carbidopa/L-dopa needs to be given more frequently in order to prevent the **7** wearing off of its benefits. Alternatively, a controlled-release product is available (Sinemet CR, Bristol-Myers Squibb; various generic brands) that can extend the duration of L-dopa effect; thus there is a more gradual wearing off of L-dopa effect and a need for fewer daily doses.⁴⁶ Some patients will require an increase in L-dopa intake when switched to the sustained-release form because of its decreased bioavailability. Patients maintained on the sustained-release product also may require a conventional carbidopa/L-dopa dose in the morning for its more rapid absorption and response.

Dopamine agonists also can be added to a carbidopa/L-dopa regimen in an attempt to treat wearing off. In addition, either intravenous or duodenal L-dopa infusions will produce constant serum L-dopa concentrations (and presumably striatal dopamine concentrations) and thus reduce response fluctuations.^{47,48} Although some patients have been maintained on duodenal and intravenous infusions for long periods of time, these invasive methods of administration require careful planning and generally are not used outside the research setting. Sipping small amounts of carbidopa/L-dopa solution is an easier way to

TABLE 57-7. Motor Fluctuations and Possible Interventions in IPD

| Effect | Possible Treatments |
|---|---|
| End of dose deterioration ("wearing off") | Increase frequency of doses; controlled-release carbidopa/L-dopa; consider dopamine agonists, selegiline, COMT inhibitors, or amantadine; duodenal or intravenous L-dopa infusions; carbidopa/L-dopa oral solution; subcutaneous apomorphine infusions; transdermal dopamine agonists |
| Delayed onset of response | Give on empty stomach before meals; crush or chew and take with a full glass of water; reduce dietary protein intake; antacids; morning standard-release carbidopa/L-dopa if on sustained-release carbidopa/L-dopa; infusions of L-dopa; dopamine agonists |
| Drug-resistant "off" periods | Increase carbidopa/L-dopa dose and/or frequency; give on empty stomach before meals; crush or chew and take with a full glass of water; infusions of L-dopa or dopamine agonists; apomorphine subcutaneous injection; consider deep brain stimulation |
| Random oscillations ("on/off") | Dopamine agonists; controlled-release carbidopa/L-dopa, selegiline; COMT inhibitors; infusions of L-dopa or dopamine agonists; consider drug holiday and deep brain stimulation |
| Start hesitation ("freezing") | Increase carbidopa/L-dopa dose; dopamine agonists; gait modifications (tapping, rhythmic commands, stepping over objects, rocking) |
| Peak-dose dyskinesia (I-D-I response ^a) | Smaller more frequent doses of carbidopa/L-dopa; controlled-release carbidopa/L-dopa; dopamine agonist; consider amantadine, propranolol, fluoxetine, buspirone, clozapine, deep brain stimulation |
| Diphasic dyskinesias (D-I-D response ^b) | Reduce anticholinergic medication |
| Dystonia | Baclofen; nighttime carbidopa/L-dopa; morning standard-release carbidopa/L-dopa if on sustained-release carbidopa/L-dopa; dopamine agonists; anticholinergics; selective denervation with botulinum toxin |
| Myoclonus | Decrease nighttime L-dopa doses; clonazepam |
| Akathisia | Benzodiazepines; propranolol; dopamine agonists; gabapentin |

^aI-D-I is the improvement-dyskinesia/dystonia-improvement pattern of response.

^bD-I-D is the dyskinesia-improvement-dyskinesia pattern of response.

noninvasively titrate drug intake to optimal effect.⁴⁹ A solution that is stable for 24 hours can be prepared by adding 10 tablets of carbidopa/L-dopa and 2 g crystalline ascorbic acid to 1 L of tap water.

Finally, MAO-B inhibitors such as selegiline and the COMT inhibitors tolcapone (Tasmar, Roche) and entacapone (Comtan, Novartis) extend the action of L-dopa. Entacapone is now available in fixed-dose combinations with carbidopa/L-dopa as well (Stalevo, Novartis).

Drug-Resistant Off Periods. Drug-resistant off periods or delayed response to carbidopa/L-dopa can be due to delayed stomach emptying or decreased absorption in the upper gastrointestinal tract. Chewing a tablet or crushing it and then drinking a full glass of water may decrease disintegration time and facilitate gastric emptying.

Rapid Fluctuations. Rapid fluctuations from on to off motor states (*yo-yoing*) can develop in patients receiving L-dopa chronically. Rapid transitions from normal or dyskinetic on motor activity to bradykinetic or off states may just be an extension of wearing off. Nonmotor symptoms also may fluctuate. Concentration versus effect data reveal nonlinear (sigmoid E_{max} model) relationships such that small changes in serum L-dopa concentrations may lead to large effect responses, even if the sustained-release product is used.⁵⁰ Differences in the pharmacodynamic parameters EC_{50} (concentration at half-maximal effect), K_{e0} (elimination rate constant from the effect compartment), and N (the sigmoidicity constant) have been found between stable and fluctuating IPD patients with no change in pharmacokinetic parameters.⁵¹ These same pharmacodynamic parameters have been found to change significantly in individual patients followed longitudinally over 4 years.⁵² With progression of IPD, motor skill performance decreases so that there will be larger differences between baseline capabilities and maximum therapeutic effect; hence there will be an even steeper slope at the EC_{50} and more clinically noticeable dose-by-dose effects. These circumstances contribute to rapid fluctuations in motor responses. Simulations of the number of times a patient could alternately tap two levers 25 cm apart using

mean pharmacodynamic and kinetic values for stable and fluctuating patients are shown in Fig. 57-6 to illustrate further the dramatic differences between these groups. These pharmacodynamic mechanisms have been reviewed in detail by Nutt and Holford.⁵³

Infusions of L-dopa or long-acting dopaminergic agonists tend to alleviate these fluctuations. Dopaminergic agonists can be added

FIGURE 57-6. Effect of change in carbidopa/L-dopa dosage form on tapping effect in stable (red line) and fluctuating (black line) patients. A. Carbidopa/L-dopa 25 mg/100 mg (K_{e1} of 1.242 h^{-1} , K_a of 3.384 h^{-1} , and V/f of 35.4 L) administered at typical administration times of 7 AM, 12 noon, and 5 PM. B. Carbidopa/L-dopa 50 mg/200 mg (same pharmacokinetic parameters as in A) administered at the same times. C. Carbidopa/L-dopa 50 mg/200 mg with a longer half-life of absorption of 1.4 h ($K_a = 0.5$) simulating the controlled-release form.

to L-dopa to treat on/off fluctuations. Other strategies include MAO inhibitors and COMT inhibitors that decrease the clearance of L-dopa. A drug-free period (“drug holiday”) has been investigated in an attempt to modify postsynaptic dopamine receptors and thus decrease unpredictable off states. Because of the discomforts and risks, as well as the limited gains for most patients, drug holidays are rarely recommended.

■ **Dyskinesias.** Another complication of L-dopa therapy is dyskinesias (choreiform abnormal involuntary movements involving usually the neck, trunk, and upper extremities). These involuntary movements usually are associated with peak antiparkinsonian benefit (peak-effect dyskinesia or improvement-dyskinesia/dystonia-improvement), although they also can develop during the rise and fall of L-dopa effects (the dyskinesia-improvement-dyskinesia or diphasic pattern of response). In the case of peak-effect dyskinesias or dystonias, smaller, more frequent doses of L-dopa, use of the sustained-release preparations, or addition of dopamine agonists sometimes can be beneficial. The optimal treatment for the dyskinesia-improvement-dyskinesia pattern is unknown and actually can worsen with strategies useful for extending L-dopa effect.

Simplistically, dyskinesias can be thought of as too much movement secondary to extension of the pharmacologic effect or too much striatal dopamine receptor stimulation. However, the phenomenology is far more complex, as demonstrated by the occasional patient simultaneously demonstrating parkinsonian features and dyskinesias. An interaction between different classes of dopamine receptors may be involved. A partial dopamine agonist, terguride, has been found to suppress dyskinesias without worsening parkinsonian symptoms, suggesting that some pharmacologic approaches may differentiate the effects of dopaminergic stimulation on different aspects of motor system activation. Propranolol, dextromethorphan, idazoxan (an α_2 -antagonist) and sarizotan (a 5HT_{1A} agonist) are nondopaminergic agents that have been studied for L-dopa-induced dyskinesia.⁵⁴

■ **Dystonias, Myoclonus, Akathisia.** Dystonias (sustained muscle contractions or abnormal postures) are especially common in the distal lower extremities. Clenching of the toes or involuntary turning of the foot can precede the development of IPD. Dystonias often occur in the early morning hours or on awakening and improve with the first L-dopa dose of the day. Remedies for this problem include bedtime administration of sustained-release L-dopa, dopaminergic agonists, baclofen, or selective denervation with botulinum toxin.

Another problem that can occur during sleep is myoclonus, a sometimes repetitive jerking of limbs (also known as *sleep jerks*). Lowering nighttime L-dopa doses or use of clonazepam can be beneficial. At nighttime or with wearing off of dopaminergic medication effect, another associated problem can be restless feelings in the legs that may prompt the need to move them by foot tapping or pacing. In this sense, the movements are voluntary in response to an uncomfortable sensation to make such movements. Restless leg syndrome, or akathisia, can be controlled symptomatically by nighttime dopaminergic medications or by a variety of other drugs, among them clonazepam, propranolol, gabapentin, and codeine.

■ Monoamine Oxidase B Inhibitors

Selegiline (Eldepryl, Somerset; various generic brands), an irreversible MAO-B inhibitor, also known as deprenyl, is marketed for extending L-dopa effects. By its central action, it modestly extends the duration of action from each dose of L-dopa. This can provide up

to 1 hour of extended on time for patients with wearing off of L-dopa actions. Selegiline also increases the peak effects of L-dopa and can worsen preexisting dyskinesias or psychiatric symptoms such as delusions and hallucinations. Often use of selegiline permits reduction of L-dopa intake to as little as one-half its previous optimal dose.

Selegiline has been used widely at a dose of 10 mg/day, although its irreversible inhibition of MAO-B can be achieved at lower doses.⁵⁵ In addition, renewal of the enzyme proceeds at a slow rate, so the effect of the drug lingers for weeks. Selegiline is lipophilic and penetrates the blood-brain barrier rapidly. The metabolic pathway of selegiline leads to end products of L-methamphetamine and L-amphetamine. Adverse effects of selegiline are minimal but can include insomnia (especially if administered at bedtime) and jitteriness. The hypertensive “cheese effect,” which occurs from ingesting tyramine with the use of MAO-A inhibitors, does not occur with selegiline.⁵⁶ Rarely, concomitant selective serotonin reuptake inhibitors can cause the *serotonin syndrome*, characterized by hypertension, diaphoresis, and shivering. A similar reaction has been reported with concomitant selegiline and meperidine.

Selegiline and other MAO-B inhibitors have been investigated for neuroprotective properties. They inhibit the oxidative deamination of dopamine, which generates hydrogen peroxide and ultimately oxyradicals capable of damaging nigrostriatal neurons (see Fig. 57–1). Since MAO-B inhibition diverts dopamine catabolism to an alternate route not generating peroxide, selegiline therapy may spare these neurons from oxidative stress. One study evaluating its neuroprotective properties showed that it delayed the need for L-dopa in newly diagnosed IPD patients by about 9 months. However, the study was inconclusive because of the drug’s symptomatic effects and loss of the apparent protective action after approximately 12 months.⁵⁷ Rasagiline, an MAO-B inhibitor similar to selegiline but without amphetamine metabolites, has similar effects as selegiline on enhancing L-dopa effects, as well as modest beneficial effects in monotherapy.^{58,59}

■ COMT Inhibitors

Two COMT inhibitors, tolcapone (Tasmar, Roche) and entacapone (Comtan, Novartis), have been developed to extend the effects from each dose of L-dopa. By themselves, they have no effect on IPD symptoms. Both prevent the peripheral conversion of levodopa to 3OMD, thus prolonging the dopaminergic effects of L-dopa. For patients with wearing off, these agents can decrease off time significantly by increasing the L-dopa area under the curve by about 35% without increasing C_{max} or T_{max} .⁶⁰ In clinical practice, COMT inhibition is more effective than controlled-release carbidopa/L-dopa in providing consistent extension of effect and avoids the delay in time to maximal effect that affects patients with controlled-release L-dopa preparations. The recently introduced triple-combination product carbidopa/levodopa/entacapone (Stalevo; Novartis) offers variable carbidopa/levodopa content (12.5 mg/50 mg, 25 mg/100 mg, and 37.5 mg/150 mg) with a fixed 200-mg entacapone content. Concomitant use of nonselective MAO inhibitors should be avoided to prevent inhibition of most of the pathways for normal catecholamine metabolism. It remains to be seen whether the use of these adjunctive agents will be more beneficial and cost-effective than maximizing therapy with carbidopa/L-dopa alone.

Tolcapone has effects on both peripheral and central COMT, but it is unclear what role central COMT inhibition has. Its use is limited by reports of three cases of fatal hepatotoxicity such that strict monitoring of hepatic function is required, as outlined in the package

insert. Tolcapone should be discontinued if there is any elevation in liver function tests above the upper limit of normal or if any signs or symptoms develop suggesting hepatic failure (e.g., persistent nausea, fatigue, lethargy, anorexia, jaundice, dark urine, pruritus, or right upper quadrant abdominal tenderness). An informed consent for use is included in the package insert to ensure that patients are informed of the risk of adverse effects. The starting and recommended dose is 100 mg three times per day as an adjunct to carbidopa/L-dopa. Delayed onset of diarrhea (weeks to months later) can occur in up to 5% of patients. Since an alternative similar but safer medication is available, any role for tolcapone is unclear.

Entacapone has a shorter half-life than tolcapone, and 200 mg needs to be given with each dose of carbidopa/L-dopa up to 8 times per day. In clinical trials, both tolcapone and entacapone increased on time by about 1 hour and permitted reduction of L-dopa dose if dyskinesias emerged.^{61,62} Dopaminergic adverse effects may occur and generally are manageable by reduction of the carbidopa/L-dopa dosage. Brownish-orange urinary discoloration may occur with entacapone, as with tolcapone, but there are no reports of hepatotoxicity from entacapone.

■ Dopamine Agonists

The ergot dopamine agonists pergolide (Permax, Amarin; various generic brands) and bromocriptine (Parlodel, Novartis; various generic brands) and the nonergots pramipexole (Mirapex, Pfizer) and ropinirole (Requip, GlaxoSmithKline) are beneficial as adjuncts to L-dopa therapy in patients with deteriorating response to L-dopa, in patients who are experiencing fluctuations in response to L-dopa, and in patients with limited clinical response to L-dopa owing to an inability to tolerate higher doses. The dopamine agonists decrease the frequency of off periods and provide an L-dopa-sparing effect. Crossover studies suggest that pergolide with L-dopa is similar or possibly more efficacious with fewer adverse effects than bromocriptine with L-dopa.⁶³ Pergolide may improve functional status in patients with deteriorating response to bromocriptine,⁶⁴ whereas bromocriptine does not appear to improve function in patients with a deteriorating response to pergolide.⁶⁵

Bromocriptine monotherapy in previously untreated IPD patients is limited by a high incidence of adverse effects and treatment failures necessitating either lowering the dose or the addition of L-dopa.⁶⁶ Pergolide, pramipexole, and ropinirole seem to be more effective as monotherapy alternatives to L-dopa, but only pramipexole and ropinirole are approved for monotherapy. Investigations comparing initial therapy with L-dopa with initial therapy with dopamine agonists (to which L-dopa could be added) revealed a decreased risk of developing response fluctuations at a cost of less motor control in the agonist group.^{67–69} This has generated controversy as to whether initial treatment of IPD should be with dopamine agonist monotherapy.^{70–72} The American Academy of Neurology practice parameter states that either can be used depending on the impact of improving motor function.⁷³ Younger patients are more likely to develop motor fluctuations, and therefore, dopamine agonists may be preferred. Older patients are more likely to suffer psychosis from the dopamine agonists, and thus carbidopa/L-dopa may be the best starting medication, particularly if cognitive problems or dementia is present. There is no rationale at this time to choose one dopamine agonist over another based on receptor specificity.

A recommended initial dose of bromocriptine is 1.25 mg once or twice daily. The dose of bromocriptine should be escalated slowly by 1.25 to 2.5 mg/day every week and maintained at the minimum amount

necessary to accomplish the desired therapeutic effect. Average daily dosages of less than 30 mg may be effective for several years in many patients; however, some patients may require dosages of up to 120 mg/day.

A recommended initial dose of pergolide (which is about 13 times more potent than bromocriptine) is 0.05 mg/day for 2 days, gradually increasing the dose by approximately 0.1–0.15 mg/day every 3 days over a 12-day period. Should more drug be needed, the dose then may be increased by 0.25 mg every 3 days until symptoms are eliminated or adverse effects occur. The mean therapeutic dose in most clinical trials was approximately 3 mg/day.

Pramipexole is initiated at a dose of 0.125 mg three times a day and increased every 5 to 7 days as tolerated. In a fixed-dose study, daily doses of 3, 4.5, and 6 mg were not more effective than 1.5 mg/day, and the higher doses were associated with a higher frequency of adverse effects.⁷⁴ When switching from bromocriptine or pergolide to pramipexole, a 10:1 and 1:1 dosage substitution is recommended, respectively.⁷⁵ Ropinirole is initiated at 0.25 mg three times a day and increased by 0.25 mg three times a day on a weekly basis to a maximum of 24 mg/day. The dose of dopaminergic agonists is best determined by slow titration to enhance tolerance and to find the least dose that provides optimal benefit.

Adverse effects are often a limiting factor in dopamine agonist therapy. These occur frequently at the start and are more likely at higher doses or with rapid escalation of dose. Nausea is the most common, followed by sedation, light-headedness, and vivid dreams. Asymptomatic postural hypotension is common but does not always require adjustment of medication. Among psychic effects, confusion, hallucinations, and daytime sedation (including sleep attacks) often are dose limiting. Attempts to reduce excessive daytime drowsiness and sleep attacks in patients on agonist therapy should include patient education, eliminating other sedative medications, reducing or changing the drug, and addressing coexisting sleep disorders.⁷⁶ The addition of a dopamine agonist to L-dopa therapy can increase the frequency and severity of dyskinesias during periods of good functional status but also can improve motor functioning even with reduction in carbidopa/L-dopa dose. Among other idiosyncratic effects occurring with dopaminergic agonists is pedal edema. In a study of pramipexole, 6% of patients developed this problem, which is dose-related, nonresponsive to diuretics, and resolved with stopping the medication.⁷⁷ The ergot dopamine agonists are associated rarely with pleuropulmonary fibrosis, and recently, cases of cardiac valvulopathy have been reported with pergolide.^{78,79}

Bromocriptine is fairly rapidly absorbed, exhibits high first-pass metabolism, is highly protein bound, and has multiple metabolites excreted primarily through the bile.⁸⁰ The elimination half-life is about 3 hours. A slow-release bromocriptine product has been investigated but is not available. A significant increase in bromocriptine plasma concentrations has been documented with erythromycin. Pergolide has similar properties as bromocriptine except that it has a longer elimination half-life (about 24 hours). Pramipexole is excreted primarily renally with an 8- to 12-hour half-life. The initial dosage must be adjusted in renal insufficiency (0.125 mg twice daily for creatinine clearances of 35–59 mL/min, 0.125 mg once daily for creatinine clearances of 15–34 mL/min). Ropinirole has a 6-hour half-life and is metabolized by cytochrome P450 1A2. A sustained-release form is under development. Potent inhibitors (fluoroquinolones) and inducers (smoking) of this enzyme likely will lead to alterations in ropinirole clearance.

Apomorphine is a dopamine agonist soon to be released in the United States. It will be marketed for subcutaneous injection and already has shown promise for rescue of freezing episodes.⁸¹

Cabergoline is a selective D₂ ergot agonist with a long half-life (70 hours) that is as effective as bromocriptine but dosed up to 4 mg once a day. It is available in the United States only as a 0.5-mg tablet (Dostinex, Pharmacia) for the treatment of hyperprolactinemia. A transdermal delivery form of the potent dopaminergic agonist

rotigotine is being investigated. Specific D₁ receptor agonists do not appear to have much antiparkinsonian effect. Domperidone is a peripheral dopamine receptor blocker (not available in the United States) that can be used to block some of the adverse effects of the dopamine agonists.⁸²

PHARMACOECONOMIC CONSIDERATIONS

Few pharmacoeconomic assessments have been reported in IPD treatment. Treatment with anticholinergic medications, amantadine, and carbidopa/L-dopa is inexpensive. For cost-effectiveness, the lowest dose giving adequate results should be used, and optimization of the carbidopa/L-dopa regimen should be attempted before adding more costly medications. In early IPD, a long-duration response can be seen such that a carbidopa/L-dopa dose every 3 days may be all that is required.⁸³ Initial therapy with the more expensive sustained-release product (Sinemet CR) or combination product (Stalevo) in the absence of response fluctuations is not indicated. As symptoms progress, the addition or continued use of dopamine agonists, selegiline, or COMT inhibitors can add considerable expense, sometimes with minimal or no benefit. A large trial underway in the United Kingdom to determine which class of drugs provides the most effective control with the fewest side effects for both early and later IPD hopefully also will provide information on cost-effectiveness.⁸⁴

EVALUATION OF THERAPEUTIC OUTCOMES

A list of monitoring parameters is given in Table 57–8. It is important to educate patients and caregivers that IPD is a neurodegenerative disease that often progresses with time and that not all symptoms are amenable to treatment. They can participate in treatment by recording medication administration times as well as the duration of on and off times that can be reviewed at each office visit. If a bothersome symptom such as dystonia occurs only infrequently, it can be videotaped by the family to be reviewed with the physician.

TABLE 57–8. Monitoring Parkinson's Disease Therapy

1. Determine medications, medication administration times, relationship to meals, and the time of the last dose. Educate the patient that carbidopa/L-dopa is absorbed best on an empty stomach.
2. Assess patient's general impression of motor functioning, and address any specific concerns the patient may have.
3. Inquire specifically about dose-by-dose effects of medication, wearing off of medication, inadequate response to a single dose of medication, "freezing," abnormal involuntary movements, cramps or spasms, hallucinations (particularly visual hallucinations), and nausea, vomiting, or light-headedness. Offer suggestions to help alleviate these.
4. Inquire about the preceding symptoms from the caregivers, and address any concerns they may have with specific attention to sleep disorders, depression, psychotic features, and dyskinesias that may not be apparent to the patient.
5. Observe the patient and determine if dyskinetic movements are present and if the patient is aware of them. If present, educate the patient about dyskinesias and recommend appropriate interventions.
6. Ensure that the patient and/or caregivers understand the recommended medication regimen.

9 The history always should include a detailed medication history because patients often may improvise and adjust their own medication schedules. It is important to determine the times of the day that may be most difficult for them to function. Assessment of general level of functioning including activities of daily living will help to determine when L-dopa or dopamine agonists should be added. A history of falls should be investigated further as to the circumstances surrounding them to determine whether falls are secondary to imbalance (such as retropulsion), freezing or stumbling, orthostatic hypotension, or some other etiology. The patient should be questioned about common adverse effects of the antiparkinsonian medications, including nausea, hypotension, pedal edema, sleep disorders, and psychiatric difficulties. The patient also should be observed for dyskinesias and, if present, educated about them. Recommendations always should be made in view of the patient's perception of the severity of symptoms.

CONCLUSIONS

Although the cause of IPD remains unknown, symptomatic therapy has been developed to involve a number of options for early and later stages of the disease. Several directions of neuroprotective therapy are under investigation. Pharmacologic therapy through manipulation of the dopaminergic system can improve a patient's comfort and functional status significantly. Despite problems that can be associated with L-dopa, it remains the standard of therapy for most patients with IPD. The goal of management remains maintaining acceptable functional control with the minimum amount of antiparkinsonian drug necessary.

ABBREVIATIONS

3OMD: 3-*O*-methyl-dopa
 COMT: catechol-*O*-methyl-transferase

PAIN MANAGEMENT

Terry J. Baumann

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 It is important, whenever possible, to ask patients if they have pain, to identify the source of pain, and to assess the characteristics of the pain.
- 2 Patients taking analgesics should be monitored for response and side effects, particularly sedation and constipation associated with the opioids.
- 3 Oral analgesics are preferred whenever feasible, but it is important to adjust the route of administration to the needs of the patient.
- 4 Equianalgesic doses are useful as a guide when converting from one agent to another, but further dose titration usually is required to achieve treatment goals.
- 5 Doses must be individualized for each patient and administered for an adequate duration of time. Around-the-clock regimens should be considered for acute and chronic pain. As-needed regimens should be used for breakthrough pain or when acute pain displays wide variability and/or has subsided greatly.
- 6 Whenever possible, a multidisciplinary approach and non-pharmacologic strategies should be used.
- 7 For neuropathic pain, capsaicins, tricyclic antidepressants, anticonvulsants, and methadone should be considered.
- 8 Placebo therapy should not be used as an attempt to diagnose psychogenic pain.

Although the world is full of suffering, it is also full of the overcoming of it.

Helen Keller¹

Humans have always known and sought relief from pain.² The act of relieving pain is probably as old as the medical profession itself. Today, pain's impact on society is still great, and indeed, pain complaints remain a primary reason patients seek medical advice.³

Regrettably, many health care providers do not receive adequate training in this area, and new information is not widely disseminated and/or understood. Clearly, pain management is enhanced when a multidisciplinary approach is applied. Thus, understanding the pathophysiology of pain therapy and maintaining a working knowledge of individual pain regimens are important to clinicians and are key factors in addressing inadequate pain control.

DEFINITION

An acceptable definition of pain remains an enigma. Once thought to be a punishment from the gods, the word is derived from the Latin *peone* and the Greek *poine*, meaning "penalty" or "punishment."² Aristotle considered pain a feeling and classified it as a passion of the soul, where the heart was the source or processing center of pain.² This Aristotelian concept predominated for the next 2000 years, although Descartes, Galen, and Vesalius postulated that pain was a sensation in which the brain played an important role. In the nineteenth century, Mueller, Van Frey, and Goldscheider hypothesized the concepts of neuroreceptors, nociceptors, and sensory input.² These theories developed into the current definition of pain: "an unpleasant sensory and emotional experience associated with actual or potential tissue

damage or described in terms of such damage."⁴ Pain is often so subjective, however, that many clinicians define pain as whatever the patient says it is. The best care is achieved when (1) the patient comes first and (2) when in doubt remember number 1.⁵

EPIDEMIOLOGY

Fifty million Americans are partially or totally disabled because of pain.³ The annual cost of pain to American society can be estimated to be in the billions of dollars.⁶ These numbers are expected to rise as more and more Americans work beyond 60 years of age and survive into their 80s.⁶

Unfortunately, pain often remains undertreated and continues to be a problem in hospitals, long-term care facilities, and the community. Seriously ill hospitalized patients have reported a 50% incidence of pain; 15% had extremely or moderately severe pain occurring at least 50% of the time, and 15% were dissatisfied with overall pain control.⁷ In a follow-up report, the authors state that pain control persists as a major problem in hospitalized patients, and some of these patients were still in pain many months after hospitalization and experienced pain even on their deathbeds.⁸ In addition, problems with inadequate use of analgesics have been reported in cancer patients residing in nursing homes.⁹ In the Michigan pain study, 70% of chronic pain patients claimed to have pain despite treatment, with 22% believing that treatment worsened pain.⁶

PATHOPHYSIOLOGY

The pathophysiology of pain involves a complex array of neural networks in the brain that are acted on by afferent stimuli to produce

TABLE 58–1. Nociception: Basic Process of Pain Transmission

1. **Stimulation.** Noxious stimulus sensitizes and/or stimulates nociceptors and causes the release of neural chemicals that also sensitize and/or stimulate nociceptors. This activation leads to the production of an action potential.
2. **Transmission.** The action potential continues from the site of noxious stimulus to the dorsal horn of the spinal cord and then ascends to higher centers in the CNS. Transmission takes place in at least five pathways:
 - a. Spinothalamic tract
 - b. Spinoreticular tract
 - c. Spinomesencephalic tract
 - d. Dorsal column postsynaptic spinomedullary pathway
 - e. Propriospinal multisynaptic ascending systems
3. **Perception.** Conscious experience of pain.
4. **Modulation.** Inhibition of nociceptive impulses. Neurons from the brain stem descend to the spinal cord and release substances such as endogenous opioids, serotonin, and norepinephrine that inhibit transmission of nociceptive impulses.

Compiled from refs. 11, 12, and 13.

the experience we know as pain. These peripheral and central mechanisms are dynamic and are modulated by changes that occur secondary to tissue damage. In acute pain, this modulation is short-lived, but in some situations, the changes may persist, and chronic pain develops.¹⁰ Classification by inferred pathology in terms of nociceptive and neuropathic pathways gives one a better understanding of both acute and chronic pain.¹¹ Nociceptive pain best outlines the pathophysiology of acute pain, whereas neuropathic pathophysiology is why some chronic pain develops.

NOCICEPTIVE PAIN

Nociceptive pain typically is classified as either somatic (arising from skin, bone, joint, muscle, or connective tissue) or visceral (arising from internal organs such as the large intestine or pancreas). While somatic pain most often presents as throbbing and well localized, visceral pain can manifest as pain feeling as if it is coming from other structures (referred) or as a well-localized phenomenon.¹¹ We can think of nociception in terms of stimulation, transmission, perception, and modulation¹¹ (Table 58–1).

STIMULATION

The first step leading to the sensation of pain is stimulation of free nerve endings known as *nociceptors*. These receptors are found in both somatic and visceral structures, distinguish between noxious and innocuous stimuli, and are activated and sensitized by mechanical, thermal, and chemical impulses.¹¹ The underlying mechanism of these noxious stimuli (which in and of themselves may sensitize/stimulate the receptor) may be the release of bradykinins, K^+ , prostaglandins, histamine, leukotrienes, serotonin, and substance P (among others) that sensitize and/or activate the nociceptors.^{12,13} Receptor activation leads to action potentials that are transmitted along afferent nerve fibers to the spinal cord¹¹ (Fig. 58–1).

TRANSMISSION

Nociceptive transmission takes place in A δ and C-afferent nerve fibers.¹¹ Stimulation of large-diameter, sparsely myelinated A δ fibers evokes sharp, well-localized pain, whereas stimulation of unmyelinated, small-diameter C fibers produces dull, aching, and poorly localized pain.¹¹ These afferent, nociceptive pain fibers synapse in various layers (laminae) of the spinal cord's dorsal horn,¹³ releasing a

FIGURE 58–1. Schematic representation of dorsal horn nociceptive modulation. (Adapted from Ref. 13.)

variety of neurotransmitters, including glutamate, substance P, and calcitonin gene-related peptide.¹⁴ The complex array of events that influence pain can be explained in part by the interactions between neuroreceptors and neurotransmitters that take place in this synapse. For example, by stimulating large sensory myelinated fibers (e.g., A β) that mutually connect in the dorsal horn with pain fibers, both noxious and nonnoxious stimuli can have an inhibitory effect on pain transmission¹⁵ (see Fig. 58–1). Functionally, the importance of the interplay between these different fibers and various neurotransmitters and neuroreceptors is evident in the analgesic response produced by topical irritants or transcutaneous electrical nerve stimulation. These pain-initiated processes reach the brain through a complex array of at least five ascending spinal cord pathways, which include the spinothalamic tract¹⁶ (see Table 58–1). Information other than pain is also carried along these pathways. Thus pain is influenced by many factors supplemental to nociception and precludes simple schematic representation. It is postulated that the thalamus acts as a relay station as these pathways ascend and passes the impulses to central structures where pain can be processed further.¹¹

PAIN PERCEPTION

At this point in transmission, pain is thought to become a conscious experience that takes place in higher cortical structures. The brain may accommodate only a limited number of pain signals; thus cognitive and behavioral functions can modify pain. Relaxation, distraction, meditation, and guided mental imagery may decrease pain by limiting the number of processed pain signals.¹¹

MODULATION

The body modulates pain through a number of complex processes. One, known as the *endogenous opiate system*, consists of

neurotransmitters (e.g., enkephalins, dynorphins, and β -endorphins) and receptors (e.g., mu, delta, and kappa) that are found throughout the central nervous system (CNS).¹⁶ Like exogenous opioids, endogenous opioids bind to opioid receptor sites and modulate the transmission of pain impulses.¹¹ Other receptor types also can influence this system. Activation of *N*-methyl-*D*-aspartate (NMDA) receptors, found in the dorsal horn, can decrease the mu receptors' responsiveness to opiates.¹⁶

The CNS also contains a highly organized descending system for control of pain transmission. This system can inhibit synaptic pain transmission at the dorsal horn and originates in the brain.¹¹ Important neurotransmitters here include endogenous opioids, serotonin, norepinephrine, γ -aminobutyric acid (GABA), and neurotensin.¹¹

NEUROPATHIC PAIN

Neuropathic pain is distinctly different from nociceptive pain. It is pain sustained by abnormal processing of sensory input by the peripheral or CNS. A large number of neuropathic pain syndromes exist (Fig. 58–2), and they are often difficult to treat.¹¹ In addition, the pain reported often is not evident by examining physical findings.¹¹

The mechanism responsible may be the nervous system's endogenous dynamic nature. Nerve damage or persistent stimulation may cause pain circuits to rewire themselves both anatomically and biochemically.¹⁴ This produces spontaneous nerve stimulation, autonomic neuronal pain stimulation, and a progressive increase in the discharge of dorsal horn neurons.^{11,14}

Clinically, patients present with spontaneous pain transmission (often described as burning, tingling, shocklike, or shooting), exaggerated painful response to normally noxious stimuli (hyperalgesia), or painful response to normally nonnoxious stimuli (allodynia).^{11,17} This change over time may help to explain why this type pain often manifests long after the actual nerve-related injury.

CLINICAL PRESENTATION

Clinical presentation of pain is best addressed by proper pain assessment. A patient-oriented approach is essential, and evaluation methods should not differ from those used in other medical conditions.² Therefore, a comprehensive history and physical exam-

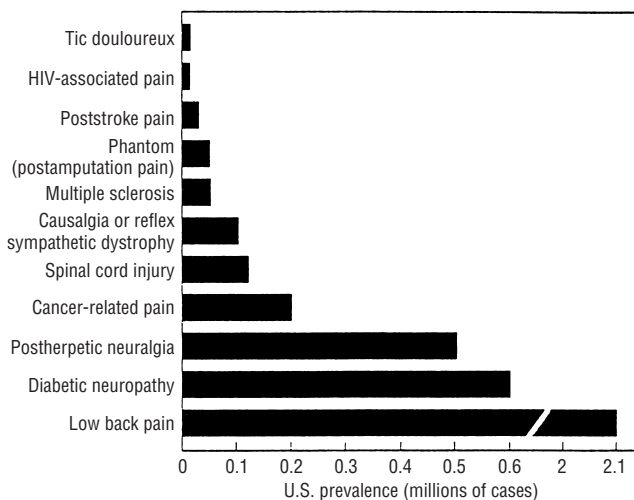

FIGURE 58–2. Estimated prevalence of neuropathic pain. (Adapted from Ref. 14.)

TABLE 58–2. PQRST Characteristics of Pain

| Characteristic | Factors | Questions |
|----------------|---|--|
| P | Palliative factors Provocative factors | What makes the pain better? What makes the pain worse? |
| Q | Quality | Describe the pain. |
| R | Radiation | Where is the pain? |
| S | Severity/intensity | How does this pain compare with other pain you have experienced? |
| T | Temporal factors | Does the intensity of the pain change with time? |

Modified from ref. 18.

ination are imperative to evaluate underlying diseases and possible contributing factors thoroughly.² This includes identifying the source of pain when possible.² A baseline characterization of pain can be obtained by assessing PQRST characteristics¹⁸ (Table 58–2). Attention also must be given to mental factors that alter the pain threshold. Anxiety, depression, fatigue, anger, and fear in particular are noted to lower this threshold, whereas rest, mood elevation, sympathy, diversion, and understanding raise the pain threshold.¹⁸

CLINICAL PRESENTATION OF PAIN

GENERAL

- Patients may be in obvious acute distress (trauma pain) or appear to have no noticeable suffering (chronic/persistent).

SYMPTOMS

- Pain can be described as sharp, dull, burning, shocklike, tingling, shooting, radiating, fluctuating in intensity, and varying in location.
- Over time, the same pain stimulus may cause symptoms that completely change (e.g., sharp to dull, obvious to vague).
- Nonspecific symptoms include anxiety, depression, fatigue, insomnia, anger, and fear.

SIGNS

- Acute pain can cause hypertension, tachycardia, diaphoresis, mydriasis, and pallor, but these signs are *not diagnostic*.
- In some acute cases and in most chronic/persistent pain, there may be no obvious signs.

LABORATORY TESTS

- Pain is always subjective
- There are *no* laboratory tests that can diagnose pain.
- Thus pain is best diagnosed based on patient description and history.

Source: Compiled from refs. 18 and 22.

Clinicians must evaluate all components of the pain experience, e.g., behavioral (part of our reaction to pain is learned),¹⁹ cognitive (thinking processes alter pain experiences),²⁰ social (pain expression differs in accordance with social environments),²¹ and cultural (cultural background may influence pain tolerance).²¹ In addition, separating pain with neuropathic pathophysiology (see Fig. 58–2) from that caused by a known nociceptive pathophysiology (e.g., post-trauma pain) allows for improved treatment regimens. Nociceptive

pain is often acute, localized, well described, and relieved with conventional analgesic therapy (e.g., opioids, acetaminophen, nonsteroidal anti-inflammatory drugs), whereas neuropathic pain is often chronic, not well recognized, and not easily treated with conventional analgesics. Proper patient assessment also must include an evaluation of pain management. Pain intensity, pain relief, and medication side effects (e.g., opioid-induced sedation or constipation) must be assessed and reassessed on a regular basis. The timing and regularity of this assessment will depend on the type of pain and the medications administered. Postoperative pain and

acute exacerbation of cancer pain may need to be assessed every hour, whereas chronic nonmalignant pain may need only daily assessment. Quality of life also must be assessed on a regular basis in all patients.

The clinician must remember, however, that “pain is always subjective. Objective observations of grimacing, limping, or tachycardia may be helpful in assessing patients, but these signs are often absent in patients with chronic pain caused by structural lesions. No neurophysiological or chemical test can measure pain. The clinician must accept the patient’s report of pain”²²

► TREATMENT: Acute and Chronic Pain

Acute pain may be a useful physiologic process warning individuals of disease states and potentially harmful situations. Unfortunately, severe, unremitting, undertreated, acute pain, when it outlives its biologic usefulness, can produce many deleterious effects (e.g., psychological problems). When acute pain is not treated effectively, the stress and concurrent reflex reactions often cause hypoxia, hypercapnia, hypertension, excessive cardiac activity, and emotional difficulties.

Under normal conditions, acute pain subsides quickly as the healing process decreases the pain-producing stimuli; however, in some instances, pain persists for months to years, leading to a chronic pain state with features quite different from those of acute pain (Table 58–3). Chronic pain can be divided into four subtypes: pain that persists beyond the normal healing time for an acute injury, pain related to a chronic disease, pain without identifiable organic cause, and pain that involves both the chronic and acute pain associated with cancer.²³ Patients in chronic pain can develop severe psychological problems caused by fear and memory of past pain. In addition, chronic pain patients may develop dependence on and tolerance to analgesics, have trouble sleeping, and react more readily to environmental changes that can intensify the pain response. Distinguishing between chronic and acute pain states is very important because of differing management techniques.

■ ACUTE PAIN MANAGEMENT

The obvious way to relieve pain is to eliminate the underlying cause. This is often not possible, however, and symptomatic relief usually

is indicated. Therapeutic interventions include pharmacologic treatment, stimulation therapies, and psychological therapies.

■ NONPHARMACOLOGIC THERAPY

■ Stimulation Therapy

Transcutaneous electrical nerve stimulation (TENS) has shown moderate success in managing surgical, traumatic, and oral-facial pain.¹⁵ Although opioid-like side effects certainly are prevented, this technique has not gained wide acceptance in acute pain.

■ Psychologic Intervention

Even though the cognitive, behavioral, and social aspects of pain are well established, psychologic techniques for the treatment of acute pain are not employed widely. Simple interventions (e.g., introductory information about sensations to expect after certain procedures) reduce patient distress and greatly reduce postprocedure suffering.²⁴ Other successful psychologic techniques include relaxation training, imagery, and hypnosis.²⁴

■ PHARMACOLOGIC TREATMENT

■ Nonopioid Agents

Analgesia should be initiated with the most effective analgesic agent having the fewest side effects. Acetaminophen, acetylsalicylic acid (aspirin), and nonsteroidal anti-inflammatory drugs (NSAIDs) often are preferred over opiates in the treatment of acute mild to moderate pain (Tables 58–4 and 58–5). These drugs (with the exception of acetaminophen) prevent formation of prostaglandins produced in response to noxious stimuli, thereby decreasing the number of pain impulses received by the CNS.²² Therapeutic outcomes are also less than desired in those who do not expect “mild” analgesics to relieve pain. Studies comparing the efficacy of these agents have been inconsistent. Therefore, the choice of a particular agent often depends on availability, cost, pharmacokinetics, pharmacologic characteristics (see Tables 58–4 and 58–5), and the side-effect profile (Table 58–6). It should be noted that all NSAIDs have some analgesic effects, but only those which are approved by the Food and Drug Administration (FDA) for the treatment of pain or primary dysmenorrhea are compared in the tables. There appears to be a great deal of interpatient variability in the therapeutic response to the NSAIDs. After an

TABLE 58–3. Characteristics of Acute and Chronic Pain

| Characteristic | Acute Pain | Chronic Pain |
|--|---------------------|-----------------------|
| Relief of pain | Highly desirable | Highly desirable |
| Dependence and tolerance to medication | Unusual | Common |
| Psychological component | Usually not present | Often a major problem |
| Organic cause | Common | Often not present |
| Environmental contributions and family involvement | Small | Significant |
| Insomnia | Unusual | Common component |
| Treatment goal | Cure | Functionality |
| Depression | Uncommon | Common |

adequate drug trial of any of these agents, it is considered rational therapy to switch to another member of this drug group for an additional trial period.

■ Opioid Agents

Most clinicians consider the use of opioids to be the next logical step in the management of acute pain. The classification of these agents, their equianalgesic doses, and dosing guidelines are outlined in Tables 58–7 and 58–8.

The pharmacologic activity of opioids depends on their affinity for opiate receptors.²⁵ Therapeutic activities and side effects range from those exhibited by the opiate agonists (e.g., morphine) to those seen with the opiate antagonists (e.g., naloxone). Partial agonists and antagonists (e.g., pentazocine) compete with agonists for opiate receptor sites and, depending on the inherent agonist and antagonist properties, exhibit mixed agonist-antagonist activity. Mixed agonist-antagonist agents with analgesic activity appear to exhibit selectivity for analgesic receptor sites.²⁵ This may result in analgesia with fewer undesirable side effects.

The effects of the opioid analgesics are relatively selective, and at normal therapeutic concentrations, these agents do not affect other sensory modalities,²⁶ such as sensitivity to touch, sight, or hearing; however, as the dosage increases, so do the undesirable side effects (see Table 58–9). Patients in severe pain may receive very high doses of opioids with no unwanted side effects, but as the pain subsides, they may not tolerate even very low doses.²⁷ Frequently, when opioids are administered, pain is not eliminated, but its unpleasantness is decreased.²⁷ Patients report that although their pain is still present, it no longer bothers them.

Opioids share related pharmacologic attributes and exert a profound effect on the CNS and gastrointestinal tract.²⁷ Mood changes, sedation, respiratory depression, nausea, vomiting, decreased gastrointestinal motility, dependence, and tolerance are evident in varying

degrees with all agents. Consideration of efficacy and side-effect profile assists in selection of the most appropriate agent.

❸ The route of administration depends on individual patient needs. With oral analgesics, the onset usually takes about 45 minutes, whereas the peak effect usually occurs 1 to 2 hours after administration.²² This delay must be a consideration when immediate relief is needed. The opioids differ greatly in equianalgesic dose, as seen in Table 58–7, which should be used only as a guide because the nature of pain makes it necessary to individualize pain regimens. True opioid allergies are rare, but Table 58–7 also can be used when treating a patient who is allergic to opiates. Although caution is always advised, a decrease in potential cross-sensitivity exists when moving from one opioid class to another. The classes are morphine-like agonists, meperidine-like agonists, and methadone-like agonists. When considering cross-sensitivity, the mixed agonist-antagonist class acts much like the morphine-like agonists.²⁸

❷ ❶ In the initial stages of acute pain, analgesics should be given around the clock. This should commence after administering a typical starting dose and titrating up or down depending on the patient's degree of pain and demonstrated side effects (e.g., sedation).²² As-needed schedules often produce wide swings in analgesic plasma concentrations that create wide swings in pain and sedation. This may initiate a vicious cycle where increasing amounts of pain medications are needed for relief. As the painful state subsides and the need for medication decreases, however, as-needed schedules can be used. Continuous intravenous and subcutaneous methods of opioid infusion are effective in some postoperative pain, but the probability of unwanted side effects is high.²² An alternative method that has gained prominence is patient-controlled analgesia (PCA). With this technique, patients can self-administer preset amounts of intravenous opioids via a syringe pump electronically interfaced with a timing device. Using this procedure, patients balance pain control with sedation.

Administration of opiates directly into the CNS (i.e., epidural and intrathecal/subarachnoid routes) has shown considerable promise in

TABLE 58–5. FDA-Approved Nonopioid Analgesics in Adults (does not include agents approved only for osteoarthritis or rheumatoid arthritis)

| Class and Generic Name | Usual Dosage Range (mg) | Maximal Dose (mg/day) |
|--|---|---------------------------|
| Salicylates | | |
| Acetylsalicylic acid ^a (aspirin) | 325–650 every 4 h | 4000 |
| Choline ^a | 870 every 3–4 h | 5220 |
| Magnesium ^a | 650 every 4 h or 1090 three times daily | 4800 in 3–4 divided doses |
| Sodium ^a | 325–650 every 4 h | 5400 |
| Diflunisal | 500–1000 initial 250–500 every 8–12 h | 1500 |
| para-Aminophenol | | |
| Acetaminophen ^a | 325–1000 every 4–6 h | 4000 |
| Fenamates | | |
| Meclofenamate | 50–100 every 4–6 h | 400 |
| Mefenamic acid | Initial 500 250 every 6 h (maximum of 7 days) | 1000 ^b |
| Pyranocarboxylic Acid | | |
| Etodolac | 200–400 every 6–8 h (immediate release only) | 1000 |
| Acetic Acid | | |
| Diclofenac potassium | In some patients, initial 100, 50 three times a day | 150 ^c |
| Propionic Acids | | |
| Ibuprofen ^a | 200–400 every 4–6 h | 3200 1200 ^d |
| Fenoprofen | 200 every 4–6 h | 3200 |
| Ketoprofen ^a | 25–50 every 6–8 h 12.5–25 every 4–6 h ^d | 300 75 ^d |
| Naproxen | 500 initial 500 every 12 h or 250 every 6–8 h | 1000 ^b |
| Naproxen sodium ^a | In some patients, 440 initial ^d 220 every 8–12 h ^d | 660 ^d |
| Naproxen delayed-release ^e | 500 every 12 h | 1000 |
| Naproxen controlled-release ^e | 500–1000 every 24 h | 1500 |
| Pyrrolizine Carboxylic Acid | | |
| Ketorolac (parenteral) | 30–60 (single IM dose only) 15–30 every 6 h (maximum of 5 days) | 30–60 120 |
| Ketorolac (oral) (indicated for continuation with parenteral only) | In some patients, initial oral dose 20 10 every 4–6 h (maximum of 5 days, which includes parenteral doses) | 40 |
| Cyclooxygenase 2 Inhibitors | | |
| Celecoxib | Initial 400 followed by another 200 on first day then 200 twice daily ^f | 400 ^f |
| Valdecoxib | 20 twice daily ^g | 40 ^g |

the control of acute pain²⁹ (see Table 58–10) and is common in both large and small institutions throughout the United States. Because of reports of marked sedation, respiratory depression, pruritus, nausea, vomiting, urinary retention, and hypotension,³⁰ these methods of analgesia require careful monitoring and are best employed by experienced practitioners. Respiratory depression is of concern and can occur within the first half hour or manifest as late as 12 hours after a single dose of epidural morphine.³⁰ Naloxone is used to antagonize this effect, but continual infusion may be required.³⁰ Analgesia and side effects are evident at lower doses when the opioids are administered intrathecally instead of epidurally. Intrathecally, single morphine doses of 0.1 to 0.3 mg are common, whereas epidurally, doses of 1 to 6 mg are the norm.²⁹ These intrathecal and epidural opioids often

are administered on a continuous-infusion and/or patient-controlled basis, and when given simultaneously with intrathecal or epidural local anesthetics such as bupivacaine, they have been proven safe and effective.³¹ All agents administered directly into the CNS should be preservative-free.

■ **Morphine and Congeners.** Despite the availability of several newer agents, morphine remains the prototype opiate analgesic. As new opioid and nonopioid compounds are developed, their efficacy and side-effect profiles are compared against morphine as the standard. Many clinicians consider morphine the first-line agent when treating moderate to severe pain. Morphine can be given parenterally, orally, or rectally.

Morphine's CNS effects are numerous. Through direct stimulation of the chemoreceptor trigger zone, morphine causes nausea and vomiting.²⁷ Opioid-induced nausea is observed most frequently after the initial dose and often subsides with subsequent doses.³² Although euphoria and dysphoria have been reported, morphine's unpleasant effects are more prominent when administered to those not experiencing pain.²⁷ As doses of morphine are increased, the respiratory center becomes less responsive to carbon dioxide, resulting in progressive respiratory depression. This effect is less pronounced in those being treated for severe pain. Respiratory depression often manifests as a decrease in respiratory rate (although minute volume and tidal volume are also affected) and is further compounded because the cough reflex is also depressed. Morphine-induced respiratory depression can be reversed by pure opioid antagonists.²⁷ In patients with underlying pulmonary dysfunction, caution must be employed when using morphine or any related opioid. Although these patients may be functioning normally, they are already using compensatory breathing mechanisms and are at risk for further respiratory compromise.²⁷ Precaution is also urged when using opiate analgesics with alcohol or other CNS depressants. This combination amplifies CNS depression and is potentially harmful and possibly lethal.

Therapeutic doses of morphine have minimal effects on blood pressure, cardiac rate, or cardiac rhythm when patients are supine; however, morphine does produce venous and arteriolar vessel dilatation, and orthostatic hypotension may result. Hypovolemic patients are more susceptible to morphine-induced cardiovascular changes (e.g., decreases in blood pressure).²⁷ Because morphine prompts a decrease in myocardial oxygen demand in ischemic cardiac patients, it is often considered the drug of choice when using opioids to treat pain associated with myocardial infarction.

Morphine decreases the propulsive contractions of the gastrointestinal tract, and biliary and pancreatic secretions are reduced.²⁷ The end result, especially when morphine is administered over extended time periods, is constipation. Morphine-induced spasms of the sphincter of Oddi have been observed.²⁷ However, the clinical significance of such an occurrence should be assessed on an individual basis. Although morphine's effect on the urinary bladder varies, urinary

retention can become a problem; tolerance develops to this effect over time.²⁷ Morphine-induced histamine release often manifests as pruritus, and although not seen often, it may exacerbate bronchospasm in patients with a history of asthma.²⁷ Therapeutic doses of morphine do not directly affect cerebral circulation, but drug-induced respiratory depression can increase intracranial pressure. Thus caution is advised in head trauma patients who are not ventilated because morphine may exaggerate this pressure²⁷ while clouding the neurologic examination results.

Hydromorphone is more potent, has better oral absorption characteristics, and is more soluble than morphine, but its overall pharmacologic profile parallels that of morphine. A sustained-release hydromorphone product has recently become available. Oxycodone can be administered rectally and by injection. Although it is more potent than morphine, it offers no real pharmacologic advantages. Levorphanol has an extended half-life, but its overall therapeutic effects are similar to those of morphine.

Codeine is an analgesic that is effective in the treatment of mild to moderate pain. It is often combined with other analgesic products and enjoys a popularity that makes it the standard for other oral opioids. Unfortunately, codeine has the same propensity to produce tolerance, dependence, and constipation as morphine. Hydrocodone, a derivative of codeine, also is seen most often in combination products and has pharmacologic properties similar to those of morphine. Oxycodone has a similar potency to morphine and is an excellent oral analgesic for moderate to severe pain. This is especially true when the product is used in combination with nonopioids; however, its predilection for causing tolerance and dependence, along with its basic opioid characteristics, likens it to morphine. It should be noted that sustained-release oxycodone is also available.

■ **Meperidine and Congeners (Phenylpiperidines).** The prototype phenylpiperidine, meperidine, has a pharmacologic profile comparable with that of morphine; however, it is not as potent and has a shorter analgesic duration. This necessitates larger doses that often must be administered more frequently for satisfactory pain relief. Although meperidine is effective orally, larger doses must be

TABLE 58–7. Opioid Analgesics

| Class and Generic Name | Route | Equianalgesic Dose (mg) (Adults) |

^aReference 22 considers 5 mg rectal morphine = 5 mg rectal oxymorphone.

^bStarting dose only (equianalgesia not shown).

^cStarting doses lower (oxycodone, 5–10 mg).

^dEquivalent IM morphine dose = 8–22 mg day.

^eThe equianalgesic dose of methadone when compared with other opioids will decrease progressively the higher the previous opioid dose has been.

^fStarting doses to be used in cases of opioid overdose.

Compiled from refs. 22, 26, 34, and 35.

administered to achieve the same effect as obtained with the parenteral form (Table 58–7). With high doses or in patients with renal failure, the metabolite normeperidine accumulates, causing CNS excitability, manifested as tremor, muscle twitching, and possibly seizures.³³ The combination of monoamine oxidase inhibitors and meperidine should not be used because this mixture can produce severe respiratory depression or excitation, delirium, hyperpyrexia, and convulsions.²⁷ In most clinical settings, meperidine offers no real advantage over morphine and is largely being replaced by other opioids.

Fentanyl is a synthetic opioid structurally related to meperidine and is used often in anesthesiology as an adjunct to general anesthesia.³³ This agent is more potent and shorter acting than

meperidine (see Tables 58–7 and 58–11). Transdermal fentanyl is also available for the treatment of chronic pain in patients requiring opioid analgesics. One patch can provide analgesic support for 72 hours, but it takes 12 to 24 hours to obtain optimal analgesic effect after a patch is applied. In addition, it may take 6 days after increasing a dose before new steady-state levels are achieved. Thus the patch should not be used in patients with acute pain.³⁴ A fentanyl lozenge on a stick is available for the treatment of breakthrough cancer pain.³⁴

■ **Methadone and Congeners.** Methadone has gained considerable popularity because of its oral efficacy, extended duration of action, and ability to suppress withdrawal symptoms in heroin addicts. With

TABLE 58–8. Dosing Guidelines

| Agent(s) | Doses (Titrate Up or Down Based on Patient Response) | Notes |
|------------------------------|--|--|
| NSAIDs/acetaminophen/aspirin | Dose to maximum before switching to another agent (see Table 58–5) | Used in mild to moderate pain May use in conjunction with opioid agents to decrease doses of each Regular alcohol use and high doses of acetaminophen may result in liver toxicity Care must be exercised to avoid overdose when combination products containing these agents are used Drug of choice in severe pain |
| Morphine | PO 5–30 mg q 3–4 h ^a IM 5–10 mg q 3–4 h ^a IV 1–2.5 mg q 5 min prn ^a SR 15–30 mg q 12 h (may need to be q 8 h in some patients) Rectal 10–20 mg q 4 h ^a | Use immediate-release product with SR product to control “breakthrough” pain in cancer patients Every 24 hour product available |
| Hydromorphone | PO 2–4 mg q 3–6 h ^a IM 1–4 mg q 3–6 h ^a IV 0.1–0.5 mg q 5 min prn ^a Rectal 3 mg q 6–8 h ^a | Use in severe pain More potent than morphine; otherwise, no advantages Use immediate-release product with sustained-release product to control “breakthrough” pain in cancer patients Use sustained-release product only in those patients who have demonstrated opioid tolerance 12-mg, 16-mg, 24-mg, and 32-mg sustained-release capsules are available and should be dosed every 24 hours |
| Oxymorphone | IM 1–1.5 mg q 4–6 h ^a IV 0.5 mg initially Rectal 5 mg q 4–6 h ^a | Use in severe pain No advantages over morphine |
| Levorphanol | PO 2–3 mg q 6–8 h ^a IM 1–2 mg q 6–8 h | Use in severe pain Extended half-life useful in cancer patients In chronic pain, wait 3 days between dosage adjustments |
| Codeine | PO 15–60 mg q 3–6 h ^a IM 15–60 mg q 3–6 h ^a IV 15–60 mg q 3–6 h ^a (max. 360 mg q day) | Use in moderate pain Weak analgesic; use with NSAIDs or aspirin or acetaminophen |
| Hydrocodone | PO 5–10 mg q 3–6 h ^a | Use in moderate/severe pain Most effective when used with NSAIDs or aspirin or acetaminophen |
| Oxycodone | PO 5–10 mg q 3–6 h ^a Controlled release, 10–20 mg q 12 h | Use in moderate/severe pain Most effective when used with NSAIDs or aspirin or acetaminophen Use immediate-release product with controlled-release product to control “breakthrough” pain in cancer patients |
| Meperidine | IM 50–150 mg q 3–4 h ^a IV 5–10 mg q 5 min prn ^a | Use in severe pain Oral not recommended Do not use in renal failure May precipitate tremors, myoclonus, and seizures Monoamine oxidase inhibitors can induce hyperpyrexia and/or seizures or opioid overdose symptoms |
| Fentanyl | IV 25–50 mcg/h IM 0.05–0.1 mg q 1–2 h ^a Transdermal 25 mcg/h q 72 h Transmucosal 200 mcg may repeat × 1, 30 minutes after first dose is given then titrate | Used in severe pain Do not use transdermal in acute pain Transmucosal for “breakthrough” cancer pain |
| Methadone | PO 2.5–10 mg q 3–4 h (acute) ^a IM 2.5–10 mg q 3–4 h (acute) ^a PO 5–20 mg q 6–8 h (chronic) ^a | Effective in severe chronic pain Sedation can be major problem Some chronic pain patients can be dosed every 12 hours The equianalgesic dose of methadone when compared with other opioids will decrease progressively the higher the previous opioid dose has been |
| Propoxyphene | PO 100 mg q 4 h ^a (napsylate) PO 65 mg q 4 h ^a (HCl) (max. q day 600 mg of napsylate, 390 mg HCl) | Use in moderate pain Weak analgesic; most effective when used with NSAIDs or aspirin or acetaminophen Will cause carbamazepine levels to increase 100 mg of napsylate salt = to 65 mg of HCl salt |
| Pentazocine | PO 50–100 mg q 3–4 h ^b (max. 600 mg q day) | Third-line agent for moderate to severe pain May precipitate withdrawal in opiate-dependent patients Parenteral doses not recommended |

TABLE 58–8. (continued)

| Agent(s) | Doses (Titrate Up or Down Based on Patient Response) | Notes |
|---------------|---|---|
| Butorphanol | IM 1–4 mg q 3–4 h ^b IV 0.5–2 mg q 3–4 h ^b Intranasal 1 mg (1 spray) q 3–4 h ^b If inadequate relief after initial spray, may repeat in other nostril × 1 in 30–60 minutes Max 2 sprays (one per nostril) q 3–4 h ^b | Second-line agent for moderate to severe pain May precipitate withdrawal in opiate-dependent patients |
| Nalbuphine | IM/IV 10 mg q 3–6 h ^b (max 20 mg dose, 160 mg q day) | Second-line agent for moderate to severe pain May precipitate withdrawal in opiate-dependent patients |
| Buprenorphine | IM 0.3 mg q 6 h ^b Slow IV 0.3 mg q 6 h ^b May repeat × 1, 30–60 min after initial dose | Second-line agent for moderate to severe pain May precipitate withdrawal in opiate-dependent patients Naloxone may not be effective in reversing respiratory depression |
| Dezocine | IM 5–20 mg q 3–6 h ^b IV 2.5–10 mg q 2–4 h ^b | Second-line agent for moderate to severe pain May precipitate withdrawal in opiate-dependent patients |
| Naloxone | IV 0.4–1.2 mg | When reversing opiate side effects in patients needing analgesia, dilute and titrate (0.1–0.2 mg q 2–3 min) so as not to reverse analgesia |
| Tramadol | PO 50–100 mg q 4–6 h ^a If rapid onset not required, start 25 mg/day and titrate over several days | Maximum dose is 400 mg/24 h Decrease dose in renal impairment and in the elderly |

SR, sustained release; h, hour; q, every; mg, milligram; mcg, microgram; prn, as needed.
^aMay start with an around-the-clock regimen and switch to prn if/when the painful signal subsides or is episodic.
^bMay reach a ceiling analgesic effect.

TABLE 58–9. Major Adverse Effects of the Opioid Analgesics

| Effect | Manifestation |
|---|--|
| Mood changes | Dysphoria, euphoria |
| Somnolence | Lethargy, drowsiness, apathy, inability to concentrate |
| Stimulation of chemoreceptor trigger zone | Nausea, vomiting |
| Respiratory depression | Decreased respiratory rate |
| Decreased gastrointestinal motility | Constipation |
| Increase in sphincter tone | Biliary spasm, urinary retention (varies among agents) |
| Histamine release | Urticaria, pruritus, rarely exacerbation of asthma (varies among agents) |
| Tolerance | Larger doses for same effect |
| Dependence | Withdrawal symptoms upon abrupt discontinuation |

Compiled from 2, 25, and 27.

repeated doses, the analgesic duration of action is prolonged,³⁴ and excessive sedation also may result. Although methadone is effective in acute pain,³⁴ it is usually used to treat chronic pain. The pharmacologic profile resembles that of morphine. However, properties unique to methadone when compared with other opioids include the d-isomer’s ability to antagonize NMDA receptors and block the reuptake of serotonin and norepinephrine.^{35–37} These properties may prove useful in the treatment of neuropathic pain. Contrary to previous thought, the equianalgesic dose of methadone when compared with other opioids will decrease progressively the higher the previous opioid use has been.³⁵

CLINICAL CONTROVERSY

Some clinicians believe that methadone should be tried before other opioids in many chronic pain conditions where an opioid is warranted because they believe that neuropathic pain is often present, whereas others believe that sustained-released morphine and oxycodone are better first choices.

TABLE 58–10. Intraspinal Opioids

Compiled from refs. 27, 32, 33, and 34.

Propoxyphene is usually used in combination with acetaminophen in the treatment of moderate pain. The toxicity profile of propoxyphene is similar to that of codeine.

■ Opioid Agonist-Antagonists Derivatives

Analgesic agents that stimulate the analgesic portion of opioid receptors while blocking or having no effect on the toxicity portion would be considered ideal. The agonist-antagonist derivatives were developed with this in mind. The analgesic class produces analgesia and has a ceiling effect on respiratory depression.²⁵ These agents also have a lower abuse potential than morphine, but psychotomimetic responses (e.g., hallucinations and dysphoria, as seen with pentazocine), a ceiling analgesic effect, and a propensity to initiate withdrawal in opioid-dependent populations²⁵ have diminished their widespread clinical use.

■ Opioid Antagonists

The pure opioid antagonist naloxone binds competitively to opioid receptors but does not produce an analgesic or opioid side-effect response. Therefore, it is used most often to reverse the toxic effects of agonist- and agonist-antagonist-derived opioids.

■ Central Analgesic

Tramadol has two basic modes of action: mu opiate receptor binding and inhibition of norepinephrine and serotonin reuptake. It is indicated for the relief of moderate to moderately severe pain.³⁸

Although associated with less respiratory depression than morphine at recommended doses, tramadol has a side-effect profile that in some ways is similar to that of the previously mentioned opioid analgesics (e.g., dizziness, euphoria, hallucinations, cognitive dysfunction, and constipation).³³ Tramadol alone may enhance the risk of seizures. In addition, concomitant use with serotonin reuptake

inhibitors, opioids, tricyclic antidepressants, monoamine oxidase inhibitors, neuroleptics, or other drugs that can reduce the seizure threshold and use in patients with seizure disorders may increase the risk of seizures.³⁸

Tramadol may have a place in treating patients with chronic pain, especially that of neuropathic origin.³⁹ However, this agent has little advantage over the previously mentioned opioid analgesics when treating patients for acute pain.

■ Combination Therapy

The combination of opioid and nonopioid oral analgesics often results in analgesia superior to that produced by either agent alone.²⁴ Attacking pain on two fronts, prostaglandins and opiate receptors, enhances pain relief and facilitates the use of lower doses of each agent. This frequently produces a more favorable side-effect profile and is the reason there are so many aspirin- and/or acetaminophen-opioid analgesic combination products on the market. Patients must be cautioned, however, when combination products are used to be aware of the many over-the-counter preparations that contain acetaminophen or aspirin so as not to exceed a safe dose of these agents. The addition of an injectable NSAID (ketorolac) makes this combination possible also in patients who cannot take oral medications. The clinician should not be limited by the availability of commercially established fixed-ratio combinations. For example, the administration of NSAIDs in combination with scheduled opioid regimens is often very effective in the treatment of pain resulting from bone metastases in advanced cancer.⁴⁰

Agents shown to potentiate the analgesic efficacy of parenteral opioids include hydroxyzine and dextroamphetamine.⁴⁰ Promethazine and chlorpromazine, once thought to possess this potentiating property, apparently offer no inherent analgesic or potentiating characteristics when combined with narcotics, although unwanted sedation may be increased.²⁴ Methotrimeprazine, a phenothiazine derivative, does induce analgesia but also produces sedation, orthostatic hypotension, and dizziness.³⁴

TABLE 58–12. Local Anesthetics^a

| Agent | Onset (min) | Duration (h) |
|--------------------------|-------------|--------------|
| Esters | | |
| Procaine | 2–5 | 0.25–1 |
| Chloroprocaine | 6–12 | 0.5 |

REGIONAL ANALGESIA

Regional analgesia with properly administered local anesthetics can provide relief of both acute and chronic pain³¹ (Table 58–12). These agents can be positioned by injection (i.e., in joints, in the epidural or intrathecal space, along nerve roots, or in a nerve plexus) or topically. Regional anesthetics relieve pain by blocking nociceptive transmission and interrupting sympathetic reflexes.³¹ Their lipid solubility, pK_a , percentage of un-ionized drug, drug concentration, vasodilator behavior, and amount of vasoconstrictor (commonly epinephrine) used concomitantly determine the mechanism of action.³¹ High plasma concentrations can cause signs of CNS excitation and depression, including dizziness, tinnitus, drowsiness, disorientation, muscle twitching, seizures, and respiratory arrest.³³ Cardiovascular effects include myocardial depression, hypotension, decreased cardiac output, heart block, bradycardia, ventricular arrhythmia, and cardiac arrest.³⁴ Disadvantages of such methods include the need for skillful technical application, the need for frequent administration, and highly specialized follow-up procedures.

CHRONIC PAIN MANAGEMENT

CANCER PAIN

Managing the pain of malignant diseases encompasses both acute and chronic management techniques. Thus pharmacologic treatment and psychological therapies are best combined with surgical methods, anesthetic procedures, and supportive care measures in a multidisciplinary approach to pain relief.⁴¹ The goal is to provide patients with enough pain amelioration to tolerate diagnostic and therapeutic manipulation and permit them to function at a level that will allow freedom of movement and choice.⁴⁰ Unfortunately, a number of patients with cancer suffer significant pain needlessly.^{9,42} Barriers to effective pain management in this population are outlined in Table 58–13. A barrier that consistently causes clinicians to misjudge and mistreat pain is the misunderstanding of opioid tolerance, physical dependence, addiction, and pseudoaddiction. “Tolerance is the diminution of drug effect over time as a consequence of exposure to the drug.”⁴³ It develops at different rates and with tremendous patient variation. However, with stable disease, opioid use often stabilizes, and tolerance does not lead to addiction.⁴³ “Physical dependence is a pharmacological effect of a drug defined by the occurrence of an abstinence syndrome following administration of an antagonist drug

TABLE 58–13. Barriers to Effective Pain Management in Cancer Pain

Problems Related to Health Care Professionals

Inadequate knowledge about pain management
 Poor assessment skills
 Fear of addiction
 Overconcern about opioid side effects
 Overconcern about regulation of opioids

Problems Related to Patients

Reluctance to report pain (pain may mean cancer is getting worse)
 Fear of addiction
 Poor adherence to prescribed regimens

Problems Related to the Health Care System

Inadequate reimbursement
 Restrictive regulations on opioids
 Opioids unavailable in the pharmacies

Modified from ref. 42.

or abrupt dose reduction or discontinuation.”⁴³ Clinicians must understand that physical dependence and tolerance are not equivalent to addiction, and although with chronic opioid use, they are likely to develop, the risk of developing addiction is very small and should not be a concern when treating cancer pain.²² “Addiction is best defined as a behavioral pattern characterized as loss of control over drug use, compulsive drug use, and continued use of a drug despite harm.”⁴³ When opioids are being used, these behaviors must be evaluated continually, but extreme caution is advised when using the term *addiction* because of its many negative connotations, which can lead to harmful clinician-patient relationship and ineffective pain control.^{22,43} In addition, clinicians must be aware that an individual’s behaviors may suggest addiction, when in reality the behaviors noted are a reflection of unrelieved pain or pseudoaddiction.²² Assessment of the factors described in Table 58–2 also apply to cancer patients. Special attention must be given to continual reassessment of the painful state, and individualization of therapy is always required.⁴⁰

Nonpharmacologic Treatment

Psychologic and Supportive Care. Previously mentioned psychologic techniques (e.g., relaxation training, controlled mental imagery) are very helpful in relieving pain experienced in malignant disease⁴⁰ and prove especially useful in conjunction with pharmacologic therapy.

Supportive care, in and outside the hospital, using programs such as hospice is one of the cancer patient’s greatest allies not only in coping with pain but also in accepting the disease. The positive effect this has on the patient cannot be overstated.

Pharmacologic Treatment

Pharmacologic management is the mainstay of therapy, and a typical progression of analgesic use is outlined in Fig. 58–3. The objective is to prevent the patient from experiencing constant fluctuations between severe pain and pain relief. This is best accomplished by around-the-clock administration schedules that inhibit serum analgesic concentrations from falling below the point at which a patient experiences the suffering of pain. As-needed (prn) schedules are to be employed in conjunction with around-the-clock regimens and are used when patients experience breakthrough pain. Again, nonopioid agents

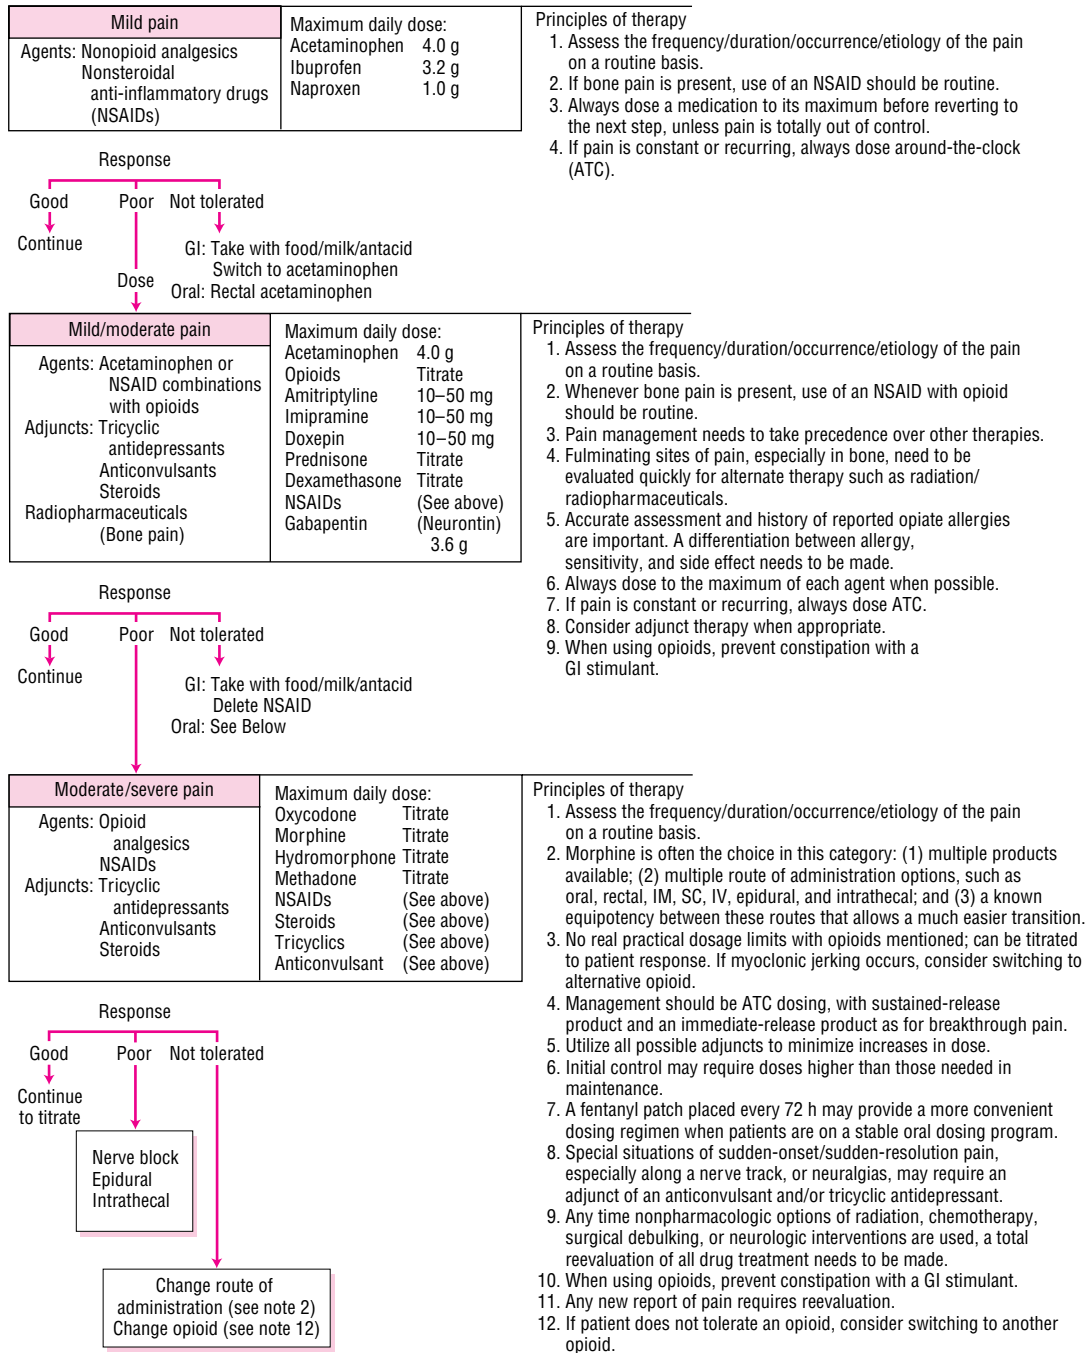

FIGURE 58-3. Algorithm for pain management in oncology patients. (Adapted from the Kaiser Permanente Algorithm for Pain Management in Patients with Advanced Malignant Disease and Ref. 40.)

are used as first-line agents, with NSAIDs being especially effective in treating bone pain.⁴⁰ Bone pain also can be treated with radiopharmaceuticals. Both strontium-89 and samarium SM 153 lexidronam have been shown to provide pain relief.³⁴ The choice of opiate should be based on patient acceptance; analgesic effectiveness; and pharmacokinetic, pharmacodynamic, and side-effect profiles. Many clinicians have found morphine both safe and effective when administered by the oral route (sustained-release, liquid, and fast-release), subcutaneous route, rectal route, continual intravenous infusion, patient-controlled intravenous route, and epidural or intrathecal route.⁴⁰

Recently, methadone has regained prominence in treating cancer pain.⁴² It has a prolonged mechanism of action, excellent oral

absorption, NMDA receptor antagonist activity (d-isomer),³⁷ and is inexpensive. However, its unpredictable half-life have make it hard to titrate. In addition, when switching to methadone from another opioid, the dose of the initial opioid used will greatly affect the equianalgesic dose needed. In general, the higher the previous dose of opioid, the lower is the needed dose of methadone.⁴² Methadone can be used initially, as an alternative, or in addition to other opioids when managing cancer pain. Epidural clonidine is also effective with epidurally administered opioid analgesics for the treatment of refractory pain.³⁴ The fentanyl patch may provide a more convenient dosing alternative in patients on stable regimens. Meperidine is not recommended for long-term use because of its relatively short duration of action and

the CNS hyperirritability of normeperidine, one of its metabolites.⁴⁰ Anticonvulsant drugs and tricyclic antidepressants have been shown to be effective in pain of neuropathic origin.⁴³ Antihistamines, amphetamines, and steroids are used as adjuvant pain medications⁴⁰; however, they have enjoyed only limited success as pain relievers.

Anesthetic procedures have proven successful in alleviating pain but require special expertise and usually are reserved for patients who are refractory to conventional analgesic routes.⁴⁰

■ NONMALIGNANT CHRONIC PAIN

6 The numerous etiologies that produce nonmalignant chronic pain make treatment complex, and its management assumes multidisciplinary aspects. As pain becomes gradually more chronic, it loses many of the autonomic characteristics evident in the acute stage, and additional symptoms such as depression, sleep disturbances, anxiety, irritability, work problems, and family instability tend to dominate. Patients should not be told that the pain they are feeling is “psychosomatic” or in their head. In most cases, etiology is not as important as symptomatic relief. Evaluation objectives include establishing an accurate diagnosis, identifying iatrogenic factors, obtaining a comprehensive psychiatric and psychosocial assessment, paying special attention to family and social problems, and obtaining a 8 description of factors that alleviate or exacerbate pain.² Given these objectives, placebo’s should never be used to diagnose pain.²

Pharmacologic approaches to patient care do not differ from those described previously; however, neuropathic pain may require 7 medications not normally thought of as analgesics. Topically applied capsaicin (which depletes nerves of substance P), tricyclic antidepressants (which block the reuptake of serotonin and norepinephrine, thus enhancing pain inhibition), anticonvulsants (e.g., gabapentin, which may decrease neuronal excitability), and NMDA receptor antagonists (e.g., dextromethorphan, which may enhance opioid effectiveness and decrease neuronal excitability) all have been effective in managing neuropathic pain.^{44–46} In addition, it is important to remember that chronic pain patients often have received many pharmacologic regimens. Adding another traditional analgesic (e.g., opioids) to their therapy may promote dependence and not improve pain control. Other nonpharmacologic therapies (e.g., spinal

cord stimulation) or psychological techniques may prove more successful. Nevertheless, many times a trial of opioids is warranted, but such a trial should not be done without a complete assessment of the 7 pain complaint.⁴⁷ Since methadone (d-isomer)³⁷ antagonizes NMDA receptors and blocks the reuptake of serotonin and norepinephrine,^{35–37} it may prove useful in patients with a neuropathic component to their pain. In all cases, an integrated, systematic approach often provided by pain clinics, with a strong emphasis on patient-clinician relationships, is essential. The goal is to improve or maintain the patient’s level of functioning, decrease the rate of physical deterioration, decrease pain perception, improve the patient’s sense of well-being, improve family and social relationships, and decrease dependency on drug therapy.² Patients and clinicians must realize that maximum effective treatment may take months or even years.

CLINICAL CONTROVERSY

Many clinicians believe that some chronic painful conditions (e.g., osteoarthritis) never should be treated with opioids, whereas others feel that when other modalities are not effective or seem to pose more of a risk to that particular patient than conventional therapy (e.g., NSAIDs), then opioids are necessary.

Some practitioners feel that the term *chronic pain* should never be used because it is associated with negative images (e.g., drug-seeking behavior, malingering, psychiatric problems). They feel that this is especially true in the elderly and that this type of pain should be referred to as *persistent pain*.⁴⁸

■ SPECIAL POPULATIONS

The elderly and the young are at a higher risk for undertreatment because of misunderstandings regarding the pathophysiology of their pain. Although care must be taken in these populations to ensure that proper individualized treatment plans follow accepted guidelines,^{48,49} the key concepts in pain management as outlined in this chapter are the guiding tenets in maximizing pain control.

PHARMACOECONOMIC CONSIDERATIONS

One cannot overemphasize the *suffering* component of pain. Most of us know how devastating pain can be to our daily lives. Swift relief from acute and cancer pain and well-planned treatment regimens in chronic nonmalignant pain will allow patients to concentrate on recovery and regaining control of their lives. Although few well-designed pharmacoeconomic studies have been performed,^{50,51} most pain clinicians believe that this approach leads to decreased time in the hospital, decreased time away from work, and an overall increase in the quality of life.

EVALUATION OF THERAPEUTIC OUTCOMES

2 5 The key to treating pain effectively is to consistently monitor effectiveness (pain relief) versus side effects (e.g., sedation) and titrate treatment accordingly (see Table 58–8). In acute pain this often needs to be done several times a day (in the early stages,

hourly), whereas in chronic pain this may take place daily or even weekly. The frequency of evaluation also depends on the drug, the administration route, and other therapies being used. When patients cannot be asked about their pain (e.g., coma), monitoring agitation and heart rate is appropriate. Given the subjective nature of pain, the most successful therapies will involve not only frequent patient assessment but also a large degree of patient control (as with PCA).

2 All opioids can cause constipation. The best management of constipation is prevention. Patients should be counseled on the proper intake of fluids and fiber. A laxative may be added, if needed. As noted earlier, CNS depressants (e.g., alcohol, benzodiazepines) amplify CNS depression when used with opioid analgesics and should be monitored closely and discouraged when possible.

CONCLUSIONS

Poor training of health care practitioners in pain assessment and management, improper patient education, and inadequate communication

among health care professionals are some of the reasons for inadequate pain relief.^{52,53} The use of an integrated approach, employing the expertise of many disciplines, may well be the most overlooked principle of pain pharmacotherapy. Indeed, it is the responsibility of all health care professionals who deal with pain to work together to ensure proper management in an effort to relieve treatable suffering and pain.

HEADACHE DISORDERS

Deborah S. King and Katherine C. Herndon

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Acute migraine therapies should provide consistent, rapid relief and enable the patient to resume his or her normal activities at home, school, or work.
- 2 A stratified care approach, in which the selection of initial treatment is based on headache-related disability and symptom severity, is the preferred treatment strategy for the migraineur.
- 3 Strict adherence to maximum daily and weekly doses of antimigraine medications is essential.
- 4 Preventive therapy should be considered in the setting of recurring migraines that produce significant disability; frequent attacks requiring symptomatic medication more than twice per week; symptomatic therapies that are ineffective, contraindicated, or produce serious side effects; and uncommon migraine variants that cause profound disruption and/or risk of neurologic injury.
- 5 The selection of an agent for migraine prophylaxis should be based on individual patient response, tolerability, convenience of the drug formulation, and comorbid conditions of the patient.
- 6 Each prophylactic medication should be given an adequate therapeutic trial to judge its efficacy, usually 2 to 3 months.
- 7 A general wellness program and avoidance of migraine triggers should be included in the management plan.
- 8 After an effective abortive agent and dose have been identified, subsequent treatments should begin with that same regimen.

Headache is one of the most common complaints encountered by health care practitioners, accounting for over 1% of visits to physicians' offices or emergency departments.¹ As one of the top 10 presenting complaints in ambulatory medical care, headache may be symptomatic of a distinct pathologic process or may occur without an underlying cause.^{1,2} In 2004, the International Headache Society (IHS) updated its classification system and diagnostic criteria for headache disorders, cranial neuralgias, and facial pain³ (Table 59–1). Designed to facilitate headache diagnosis in clinical practice and research, the IHS classification provides more precise definitions and standardized nomenclature for both the primary (tension-type, migraine, and cluster headache) and secondary (symptomatic of organic disease) headache disorders. This chapter focuses on the management of the primary headache disorders.

Most recurrent headaches are the result of a benign chronic primary headache disorder.¹ Less often, headaches are symptomatic of a serious underlying medical condition, such as infection, cerebral hemorrhage, or brain mass lesion. The peak prevalence of tension-type and migraine headache, the most common of the primary headache disorders, occurs during the most productive years of life (20 to 55 years of age).⁴ Despite the prevalence of these disorders and their associated disability, studies indicate that most migraine and tension-type headache sufferers do not seek medical care for their headaches.^{4,5} An improved understanding of the diagnosis and pathophysiologic mechanisms of the primary headache disorders, particularly migraine, has led to the development of specific medications capable of providing rapid relief from moderate to severe attacks. However, a thorough evaluation of the headache history is essential to establish an accurate

headache diagnosis and identify patients who may benefit from these newer therapeutic options.

MIGRAINE HEADACHE

EPIDEMIOLOGY

Results of the American Migraine Study II indicate that 18.2% of women and 6.5% of men in the United States experience one or more migraine headaches per year.⁶ The prevalence of migraine varies considerably by age and gender. Before the age of 12 years, migraine is more common in boys than in girls, but prevalence increases more rapidly in girls after puberty.⁴ After age 12, females are two to three times more likely than males to suffer from migraine. Gender differences in migraine prevalence have been linked to menstruation, but these differences persist beyond menopause. Prevalence is highest in both men and women between the ages of 35 and 45 years.⁶ The usual age of onset is 10 to 29 years of age, but onset of migraine in early childhood is not uncommon.⁷ In the American Migraine Study II, 92% of women and 89% of men with migraine reported some headache-related disability, and 53% were severely disabled or needed bed rest during an attack.⁶ A number of neurologic and psychiatric disorders, including stroke, epilepsy, major depression, and anxiety disorder, show increased comorbidity with migraine.⁴ Whether this relationship is causal or representative of a common pathophysiologic mechanism is unknown. The economic burden of migraine is substantial; however, the direct medical costs associated with migraine treatment

are far exceeded by the indirect costs that result from work-related disability.⁸

ETIOLOGY AND PATHOPHYSIOLOGY

The etiologic and pathophysiologic mechanisms of migraine are not completely understood. According to the vascular hypothesis proposed by Harold Wolff in 1938, the migraine aura is caused by intracerebral arterial vasoconstriction that is followed by reactive extracranial vasodilation and associated headache.⁴ Although studies of regional blood flow in the brain do not support the vascular hypothesis, the aura phase of migraine is associated with a reduction in cerebral blood flow that begins in the occipital region and moves across the cerebral cortex at a rate of 2 to 3 mm/min.⁹ However, most clinicians now believe that the positive and negative symptoms of the migraine aura are caused by neuronal dysfunction, not ischemia.

The neurologic changes of the aura parallel those which occur during spreading depression, a neuronal event characterized by a wave of depressed electrical activity that advances across the brain cortex at a rate that is consistent with the spread of aura symptoms.⁹ Migraine without aura is a neurobiologic disorder.³ Migraine pain is believed to result from activity within the trigeminovascular system, a network of visceral afferent fibers that arises from the trigeminal ganglia and projects peripherally to innervate the pain-sensitive intracranial extracerebral blood vessels, dura mater, and large venous sinuses¹⁰ (see Fig. 59–1). These fibers also project centrally, terminating in the trigeminal nucleus caudalis in the brain stem and upper cervical spinal cord, and thus provide a pathway for nociceptive transmission from meningeal blood vessels into higher centers of the central nervous system (CNS). Activation of trigeminal sensory nerves triggers the release of vasoactive neuropeptides, including calcitonin gene-related peptide (CGRP), neurokinin A, and substance P, from perivascular axons. The released neuropeptides interact with dural blood vessels to promote vasodilation and dural plasma extravasation, resulting in perivascular inflammation.¹⁰ Orthodromic conduction along trigeminovascular fibers transmits pain impulses to the trigeminal nucleus caudalis, where the information is relayed further to higher cortical pain centers. Continued afferent input may result in sensitization of these central sensory neurons, producing a hyperalgesic state that prolongs and intensifies headache pain as the attack progresses.¹¹

Despite recent advances in understanding of the pathophysiology of headache pain, there is still a considerable lack of knowledge regarding the mechanisms involved in the initiation of a migraine attack. Although the exact pathophysiology of migraine needs further elucidation, new imaging techniques have provided insight into mechanisms. Previous vascular and neural theories of migraine development have merged into a combined theory of neurovascular mechanisms through evidence provided by neuroimaging. Activity within the trigeminovascular system may be regulated in part by noradrenergic and, most important, serotonergic neurons within the brain stem. Thus the pathogenesis of migraine may be related to an imbalance in the activity of serotonin-containing neurons and/or noradrenergic pathways in brain stem nuclei that modulate cerebral vascular tone and nociception.¹⁰ This imbalance may result in vasodilation of intracranial extracerebral blood vessels and consequent activation of the trigeminovascular system. Future research may further delineate the role of the brain stem as the “migraine generator.”

Genetic factors appear to play an important role in an individual's susceptibility to migraine attacks. Studies in monozygotic twins suggest that up to 50% of the contribution to the common migraine variants is genetically based, with a substantial influence from environmental factors.¹² While it may be possible for any individual to experience a migraine attack, it is the recurrence of attacks in the migraineur that is abnormal. Attack occurrence and frequency are governed by the sensitivity of the CNS to migraine-specific triggers. Migraineurs appear to have a lowered threshold of response to specific triggers as a result of genetic factors that govern the balance of excitation and inhibition at various levels in the CNS.⁹ Thus trigger factors can be viewed as modulators of the genetic set point that predisposes to migraine headache. The hyperresponsiveness of the migrainous brain may be the result of an inherited abnormality in P/Q-type calcium channels that regulate cortical excitability through the release of serotonin and other neurotransmitters.⁴ Low levels of magnesium or dopamine, increased levels of excitatory amino acids, and alterations in levels of endogenous opioids also may affect the migraine threshold.⁹

Serotonin (5-hydroxytryptamine, or 5-HT) has long been implicated as an important mediator of migraine headache. Specific

FIGURE 59-1. The pathophysiology of migraine headache. Vasodilation of intracranial extracerebral blood vessels (possibly the result of an imbalance in the brain stem) results in the activation of the perivascular trigeminal nerves that release vasoactive neuropeptides to promote neurogenic inflammation. Central pain transmission may activate other brain stem nuclei, resulting in associated symptoms (nausea, vomiting, photophobia, phonophobia). The antimigraine effects of the 5-HT_{1B/1D} receptor agonists are highlighted at areas 1, 2, and 3. (Adapted with permission from Ferrari MD. *Migraine*. *Lancet* 1998;351:1043–1051. © by The Lancet Ltd.)

populations of the seven subfamilies of 5-HT receptors (5-HT₁ to 5-HT₇) appear to be involved in the pathophysiology and treatment of migraine headache.¹³ Specific acute antimigraine drugs such as the ergot alkaloids and triptan derivatives are agonists of vascular and neuronal 5-HT₁ receptor subtypes, resulting in vasoconstriction of meningeal blood vessels and inhibition of vasoactive neuropeptide release and pain signal transmission.¹⁰ Drugs used for migraine prophylaxis appear to stabilize serotonergic neurotransmission and raise the migraine threshold by antagonizing or downregulating 5-HT₂ receptors or by modulating serotonergic neuronal discharge.¹³

CLINICAL PRESENTATION

The migraine attack has been divided into several phases that merit description. *Premonitory symptoms* are experienced by approximately 20% to 60% of migraineurs in the hours or days before the onset of headache.^{3,14} The previously popular terms *prodrome* and *warning symptoms* should be avoided because these are often used mistakenly to include aura.³ Premonitory symptoms vary widely among migraineurs but usually are consistent within an individual. Neurologic symptoms (e.g., phonophobia, photophobia, hyperosmia, and difficulty concentrating) are most common, but psychological (e.g., anxiety, depression, euphoria, irritability, drowsiness, hyperactivity, and restlessness), autonomic (e.g., polyuria, diarrhea, and constipation), and constitutional symptoms (e.g., stiff neck, yawning, thirst, food cravings, and anorexia) also are reported.^{4,15}

CLINICAL PRESENTATION OF MIGRAINE HEADACHE

GENERAL

Migraine is a common, recurrent, severe headache that interferes with normal functioning. It is a primary headache

disorder divided into two major subtypes, migraine without aura and migraine with aura.

SYMPTOMS

Migraine is characterized by recurring episodes of throbbing head pain, frequently unilateral, that when untreated can last from 4 to 72 hours. Migraine headaches can be severe and associated with nausea, vomiting, and sensitivity to light, sound, and/or movement. Not all symptoms are present at every attack.

In the headache evaluation, diagnostic alarms should be identified. These include: acute onset of the “first” or “worst” headache ever, accelerating pattern of headache following subacute onset, onset of headache after age 50, headache associated with systemic illness (e.g., fever, nausea, vomiting, stiff neck, and rash), headache with focal neurologic symptoms or papilledema, and new-onset headache in a patient with cancer or human immunodeficiency virus (HIV) infection.

SIGNS

A stable pattern, absence of daily headache, positive family history for migraine, normal neurologic examination, presence of food triggers, menstrual association, long-standing history, improvement with sleep, and subacute evolution are all signs of migraine headache. Aura may signal the migraine headache but is not required for diagnosis.

LABORATORY TESTS

In selected circumstances and secondary headache presentation, serum chemistries, urine toxicology profiles, thyroid function tests, Lyme studies, and other blood tests such as a complete blood count, antinuclear antibody titer, erythrocyte

sedimentation rate, and antiphospholipid antibody titer may be considered.

DIAGNOSTIC TESTS

Perform a general medical and neurologic physical examination. Check for abnormalities: vital signs (fever, hypertension), funduscopy (papilledema, hemorrhage, and exudates), palpation and auscultation of the head and neck (sinus tenderness, hardened or tender temporal arteries, trigger points, temporomandibular joint tenderness, bruits, nuchal rigidity, and cervical spine tenderness), and neurologic examination (identify abnormalities or deficits in mental status, cranial nerves, deep tendon reflexes, motor strength, coordination, gait, and cerebellar function).

Consider neuroimaging studies in patients with abnormal neurologic examination findings of unknown etiology and in those with additional risk factors warranting imaging.

The migraine *aura*, a complex of positive and negative focal neurologic symptoms that precedes or accompanies an attack, is experienced by approximately 31% of migraineurs on some occasions.¹⁶ The aura typically evolves over 5 to 20 minutes and lasts less than 60 minutes. Headache usually occurs within 60 minutes of the end of the aura. Occasionally, aura symptoms begin at the onset of headache or during the attack. The aura is most often visual and frequently affects half the visual field.^{3,4} Visual auras vary in their complexity and can include both positive (scintillations, photopsia, teichopsia, or fortification spectrum) and negative (scotoma, hemianopsia) features. Sensory and motor aura symptoms, such as paresthesias or numbness involving the arms and face, dysphasia or aphasia, weakness, and hemiparesis, also are reported.

The average migraineur experiences between one and five attacks per month.¹⁷ Migraine *headache* may occur at any time of the day or night but occurs most often in the early morning hours on awakening. Pain is usually gradual in onset, peaking in intensity over a period of minutes to hours and lasting between 4 and 72 hours in adults. Pain may occur anywhere in the face or head but most often involves the frontotemporal region. The headache is typically unilateral and throbbing or pulsating in nature; however, pain may be bilateral at onset or become generalized during the course of an attack.⁹ Gastrointestinal symptoms almost invariably accompany a migraine headache. During an attack, as many as 90% of migraineurs experience nausea, and emesis occurs in approximately one-third of patients.¹⁷ Other systemic symptoms associated with the headache phase include anorexia, food cravings, constipation, diarrhea, abdominal cramps, nasal stuffiness, blurred vision, diaphoresis, facial pallor, and localized facial, scalp, or periorbital edema. Sensory hyperacuity, manifested as photophobia, phonophobia, or osmophobia, is reported frequently. Since headache pain usually is aggravated by physical activity, most migraineurs seek a dark, quiet room for rest and relief. Impaired concentration, depression, irritability, fatigue, or anxiety often accompany the headache. Once headache pain wanes, patients may experience a *resolution phase* characterized by feeling tired, exhausted, irritable, or listless. Impaired concentration may continue, as well as scalp tenderness or mood changes. Some patients may experience depression and malaise, whereas others may feel unusually refreshed or euphoric.¹⁴ The reader is referred to the IHS classification and recent reviews for descriptions of the classic migraine variants and other migraine subtypes^{3,4,9,14,18} (see also Table 59–1).

Although headaches have many potential causes, most are caused by the primary headache disorders. A comprehensive headache history is the most important element in establishing the clinical diagnosis of migraine.⁹ A thorough headache history always should be obtained from the patient. Information collected should include age at onset, attack frequency and timing, duration of attacks, precipitating or aggravating factors, ameliorating factors, description of neurologic symptoms, characteristics of the headache pain (quality, intensity, location, and radiation), associated signs and symptoms, treatment history, family and social history, and the impact of headaches on daily life.

Secondary headache can be identified or excluded based on the headache history, as well as the results of general medical and neurologic examinations. Diagnostic and laboratory testing also may be warranted in the setting of suspicious headache features or an abnormal examination. The routine use of neuroimaging (computed tomography or magnetic resonance imaging) generally is not indicated in patients with migraine and a normal neurologic examination, but it should be considered in patients with an unexplained abnormal neurologic examination or an atypical headache history.¹⁹ Because migraine headaches usually begin by the second or third decade of life, headaches beginning after age 50 suggest an organic etiology such as a mass lesion, cerebrovascular disease, or temporal arteritis. Table 59–2 lists the IHS diagnostic criteria for migraine with and without aura.³

TABLE 59–2. IHS Diagnostic Criteria for Migraine

Migraine without Aura

- At least five attacks
- Headache attack lasts 4 to 72 hours (untreated or unsuccessfully treated)
- Headache has at least two of the following characteristics:
 - Unilateral location
 - Pulsating quality
 - Moderate or severe intensity
 - Aggravation by or avoidance of routine physical activity (ie, walking or climbing stairs)
- During headache at least one of the following:
 - Nausea, vomiting, or both
 - Photophobia and phonophobia
 - Not attributed to another disorder

Migraine with Aura (Classic Migraine)

- At least two attacks
- Migraine aura fulfills criteria for typical aura, hemiplegic aura, or basilar-type aura
- Not attributed to another disorder

Typical Aura

- Fully reversible visual, sensory, or speech symptoms (or any combination) but no motor weakness
- Homonymous or bilateral visual symptoms including positive features (e.g., flickering lights, spot, lines) or negative features (e.g., loss of vision) or unilateral sensory symptoms including positive features (e.g., visual loss, pins and needles) or negative features (i.e., numbness), or any combination
- At least one of the following:
 - At least one symptom that develops gradually over a minimum of 5 minutes or different symptoms that occur in succession or both
 - Each symptom lasts for at least 5 minutes and for no longer than 60 minutes
 - Headache that meets criteria for migraine without aura begins during the aura or follows aura within 60 minutes

▶ TREATMENT: Migraines

■ DESIRED OUTCOME

Clinicians who care for migraineurs must appreciate the impact of this painful and debilitating disorder on the life of the patient, the patient's family, and the patient's employer. Treatment strategies must **1** address both immediate and long-term goals. Acute migraine therapies should provide consistent, rapid relief and enable the patient to resume normal activities at home, school, or work. Recurrence of symptoms and treatment-related adverse effects should be minimal. Ideally, patients should be able to manage their own headaches effectively without a visit to a physician's office or emergency room. In addition, migraineurs should take an active role in the creation of a long-term formal management plan. An individualized approach to treatment can result in a reduction in attack frequency and severity, thus minimizing headache-related disability and emotional distress and improving the patient's quality of life. Goals of long-term and acute treatment of migraine are listed in Table 59-3.

■ GENERAL APPROACH TO TREATMENT

Nonpharmacologic and pharmacologic interventions are available for the management of migraine headache; however, drug therapy remains the mainstay of treatment for most patients. Pharmacotherapeutic management of migraine may be acute (e.g., symptomatic or abortive) or preventive (e.g., prophylactic). When choosing acute or preventive therapies, the clinician should consider the patient's response to specific medications and their tolerability, as well as co-existing illnesses that may limit treatment choices. Abortive or acute therapies can be migraine-specific (e.g., ergots and triptans) or non-specific (e.g., analgesics, antiemetics, nonsteroidal anti-inflammatory drugs, and corticosteroids) and are most effective at relieving pain and associated symptoms when administered at the onset of migraine^{14,20} **2** (Table 59-4). A stratified care approach in which the selection of

initial treatment is based on headache-related disability and symptom severity is the preferred treatment strategy for the migraineur.^{19,21} Because attack severity varies in individuals, patients may be advised to use nonspecific agents for mild to moderate headache while reserving migraine-specific medications for more severe attacks. The absorption and efficacy of orally administered drugs may be compromised by the gastric stasis or nausea and vomiting that often accompany migraine.²² Pretreatment with antiemetic agents or the use of non-oral treatment (e.g., suppositories, nasal sprays, or injections) may be advisable when nausea and vomiting are severe. Administration of the prokinetic agent metoclopramide enhances the absorption of oral medications, in addition to its antiemetic effects.²²

The frequent or excessive use of acute migraine medications can result in a pattern of increasing headache frequency and drug consumption known as *medication-overuse headache* (or *rebound headache*).^{21,23,24} The syndrome appears to evolve as a self-sustaining headache-medication cycle in which the headache returns as the medication effect wears off, leading to the consumption of more drug for relief. The headache history often reflects the gradual onset of an atypical daily or near-daily headache with superimposed episodic migraine attacks. Medication overuse is one of the most common causes of chronic daily headache.⁴ Agents most commonly implicated in this syndrome include simple and combination analgesics, opiates, ergotamine tartrate, and triptans.^{19,23,24} Discontinuation of the offending agent leads to a gradual decrease in headache frequency and severity and a return of the original headache characteristics. While detoxification usually can be accomplished on an outpatient basis, hospitalization may be necessary for the control of refractory rebound headache and other withdrawal symptoms (e.g., nausea, vomiting, asthenia, restlessness, and agitation). Regulation of nociceptive systems and renewed responsiveness to therapy may not occur for 3 to **3** 12 weeks following medication withdrawal.^{4,24} Most experts recommend limiting use of acute migraine therapies to 2 days per week in order to avoid the development of medication misuse headache.^{19,23}

Preventive migraine therapies are administered on a daily basis to reduce the frequency, severity, and duration of attacks and improve responsiveness to symptomatic migraine therapies¹⁹ (Table 59-5). **4** Preventive therapy should be considered in the setting of recurring migraines that produce significant disability despite acute therapy; frequent attacks requiring symptomatic medication more than twice per week with the risk of developing rebound headache; symptomatic therapies that are ineffective, contraindicated, or produce serious side effects; uncommon migraine variants that cause profound disruption and/or risk of permanent neurologic injury (e.g., hemiplegic migraine, basilar migraine, and migraine with prolonged aura); and patient preference to limit the number of attacks.^{19,25} Preventive therapy also may be administered preemptively or intermittently when headaches recur in a predictable pattern (e.g., exercise-induced migraine or menstrual migraine). The efficacy of the various agents used for migraine prophylaxis appears to be similar, but the quality of published data is limited for many commonly used drugs (only propranolol, timolol, and valproic acid are currently approved by the Food and Drug Administration [FDA] for the indication).^{26,27} Thus the selection of an agent typically is based on its side-effect profile and the patient's comorbid conditions.²⁵ A therapeutic trial of 2 to 3 months is necessary to judge the efficacy of each medication, but some reduction in attack frequency may be evident by the first month of therapy.^{19,25} **6** Drug therapy should be initiated with low doses and advanced slowly until a therapeutic effect is achieved or side effects become

TABLE 59-3. Goals of Therapy in Migraine Management

Goals of Long-Term Migraine Treatment

- Reduce migraine frequency, severity, and disability
- Reduce reliance on poorly tolerated, ineffective, or unwanted acute pharmacotherapies
- Improve quality of life
- Prevent headache
- Avoid escalation of headache medication use
- Educate and enable patients to manage their disease
- Reduce headache-related distress and psychological symptoms

Goals for Acute Migraine Treatment

- Treat migraine attacks rapidly and consistently without recurrence
- Restore the patient's ability to function
- Minimize the use of backup and rescue medications^a
- Optimize self-care for overall management
- Be cost-effective in overall management
- Cause minimal or no adverse effects

^aRescue medications are defined as medications used at home when other treatments fail that permit the patient to get relief without a visit to the physician's office or emergency department.

Adapted from refs. 19 and 42.

TABLE 59-4. Acute Migraine Therapies^a

| Medication | Dosage | Comments |
|---|--|---|
| Analgesics | | |
| Acetaminophen | 1000 mg at onset; repeat every 4–6 hours as needed | Maximum daily dose is 4 g |
| Acetaminophen 250 mg/aspirin 250 mg/caffeine 65 mg | 2 tablets at onset and every 6 hours | Available over-the-counter as Excedrin Migraine |
| Aspirin or acetaminophen with butalbital, caffeine | 1–2 tablets every 4–6 hours | Limit dose to 4 tablets/day and usage to 2 days/week |
| Isometheptene 65 mg/dichloralphenazone 100 mg/acetaminophen 325 mg (Midrin) | 2 capsules at onset; repeat 1 capsule every hour as needed | Maximum of 6 capsules/day and 20 capsules/month |
| Nonsteroidal Anti-Inflammatory Drugs | | |
| Aspirin | 500–1000 mg every 4–6 hours | Maximum daily dose is 4 g |
| Ibuprofen | 200–800 mg every 6 hours | Avoid doses >2.4 g/day |
| Naproxen sodium | 550–825 mg at onset; may repeat 220 mg in 3–4 hours | Avoid doses >1.375 g/day |
| Diclofenac potassium | 50–100 mg at onset; may repeat 50 mg in 8 hours | Avoid doses >150 mg/day |
| Ergotamine Tartrate | | |
| Oral tablet (1 mg) with caffeine 100 mg | 2 mg at onset; then 1–2 mg every 30 minutes as needed | Maximum dose is 6 mg/day or 10 mg/week; consider pretreatment with an antiemetic |
| Sublingual tablet (2 mg) | | |
| Rectal suppository (2 mg) with caffeine 100 mg | Insert 1/2 to 1 suppository at onset; repeat after 1 hour as needed | Maximum dose is 4 mg/day or 10 mg/week; consider pretreatment with an antiemetic |
| Dihydroergotamine | | |
| Injection 1 mg/mL | 0.25–1 mg at onset IM or SQ; repeat every hour as needed | Maximum dose is 3 mg/day or 20 mg/week |
| Nasal spray | One spray (0.5 mg) in each nostril at onset; repeat sequence 15 minutes later (total dose is 2 mg or 4 sprays) | Maximum dose is 3 mg/day; prime sprayer 4 times before using; do not tilt head back or inhale through nose while spraying; discard open ampules after 8 hours |
| Serotonin Agonists (Triptans) | | |
| Sumatriptan | | |
| Injection | 6 mg SC at onset; may repeat after 1 hour if needed | Maximum daily dose is 12 mg |
| Oral tablets | 25, 50, or 100 mg at onset; may repeat after 2 hours if needed | Optimal dose is 50–100 mg; maximum daily dose is 200 mg |
| Nasal spray | 5, 10, or 20 mg at onset; may repeat after 2 hours if needed | Optimal dose is 20 mg; maximum daily dose is 40 mg; single-dose device delivering 5 or 20 mg; administer one spray in one nostril |
| Zolmitriptan | 2.5 or 5 mg at onset as regular or orally disintegrating tablet; may repeat after 2 hours if needed | Optimal dose is 2.5 mg; maximum dose is 10 mg/day |
| Naratriptan | 1 or 2.5 mg at onset; may repeat after 4 hours if needed | Do not divide ODT dosage form |
| Rizatriptan | 5 or 10 mg at onset as regular or orally disintegrating tablet; may repeat after 2 hours if needed | Optimal dose is 2.5 mg; maximum daily dose is 5 mg |
| Almotriptan | 5 or 10 mg at onset as regular or orally disintegrating tablet; may repeat after 2 hours if needed | Optimal dose is 10 mg; maximum daily dose is 30 mg; onset of effect is similar with standard and orally disintegrating tablets; use 5-mg dose (15 mg/day max) in patients receiving propranolol |
| Frovatriptan | 6.25 or 12.5 mg at onset; may repeat after 2 hours if needed | Optimal dose is 12.5 mg; maximum daily dose is 25 mg |
| Eletriptan | 2.5 or 5 mg at onset; may repeat in 2 hours if needed | Optimal dose 2.5–5 mg; maximum daily dose is 7.5 mg (3 tablets) |
| Eletriptan | 20 or 40 mg at onset; may repeat after 2 hours if needed | Maximum single dose is 40 mg; maximum daily dose is 80 mg |
| Miscellaneous | | |
| Butorphanol nasal spray | 1 spray in 1 nostril (1 mg) at onset; repeat in 1 hour if needed | Limit to 4 sprays/day; consider use only when nonopioid therapies are ineffective or not tolerated |
| Metoclopramide | 10 mg IV at onset | Useful for acute relief in the office or emergency department setting |
| Prochlorperazine | 10 mg IV or IM at onset | Useful for acute relief in the office or emergency department setting |

^aLimit use of symptomatic medications to 2 days/week when possible to avoid medication misuse headache. Compiled from refs. 20, 22, 24, 34, 42, and 47.

TABLE 59–5. Prophylactic Migraine Therapies

| Medication | Dose |
|---|---------------------------------------|
| β-Adrenergic Antagonists | |
| Atenolol | 25–100 mg/day |
| Metoprolol ^a | 50–300 mg/day in divided doses |
| Nadolol | 80–240 mg/day |
| Propranolol ^{ab} | 80–240 mg/day in divided doses |
| Timolol ^b | 20–60 mg/day in divided doses |
| Antidepressants | |
| Amitriptyline | 25–150 mg at bedtime |
| Doxepin | 10–200 mg at bedtime |
| Imipramine | 10–200 mg at bedtime |
| Nortriptyline | 10–150 mg at bedtime |
| Protriptyline | 5–30 mg at bedtime |
| Fluoxetine | 10–80 mg/day |
| Phenelzine ^c | 15–60 mg/day in divided doses |
| Valproic Acid/Divalproex Sodium ^b | 500–1500 mg/day in divided doses |
| Verapamil ^a | 240–360 mg/day in divided doses |
| Methysergide ^{b,c} | 2–8 mg/day in divided doses with food |
| Nonsteroidal Anti-inflammatory Drugs^c | |
| Aspirin | 1300 mg/day in divided doses |
| Ketoprofen ^a | 150 mg/day in divided doses |
| Naproxen sodium ^a | 550–1100 mg/day in divided doses |
| Vitamin B ₂ | 400 mg/day |

intolerable. Drug doses for migraine prophylaxis are often lower than those necessary for other indications.⁴ Overuse of acute headache medications will interfere with the therapeutic effects of preventive treatment.²⁵ Prophylactic treatment usually is continued for at least 3 to 6 months after the frequency and severity of headaches have diminished and then is tapered gradually and discontinued. Many migraineurs experience fewer and less severe attacks for lengthy periods following discontinuation of prophylactic medications or taper to a lower dose.²⁵ Figures 59–2 and 59–3 identify treatment and management algorithms for migraine headache.

NONPHARMACOLOGIC THERAPY

Nonpharmacologic therapy of acute migraine headache is limited but may include application of ice to the head and periods of rest or sleep, usually in a dark, quiet environment. Preventive management of migraine should begin with the identification and avoidance of factors that consistently provoke migraine attacks in susceptible individuals^{24,28} (Table 59–6). Changes in estrogen levels associated with menarche, menstruation, pregnancy, menopause, oral contraceptive use, and other hormone therapies can trigger, intensify, or alleviate migraine.^{29–32} Attacks are linked exclusively to menstruation in approximately 14% of women (i.e., true menstrual migraine).^{20,29} A headache diary that records the frequency, severity, and duration of attacks may facilitate identification of migraine triggers. Patients also may benefit from adherence to a wellness program that includes regular sleep, exercise, and eating habits, smoking cessation, and limited caffeine intake. Behavioral interventions, such

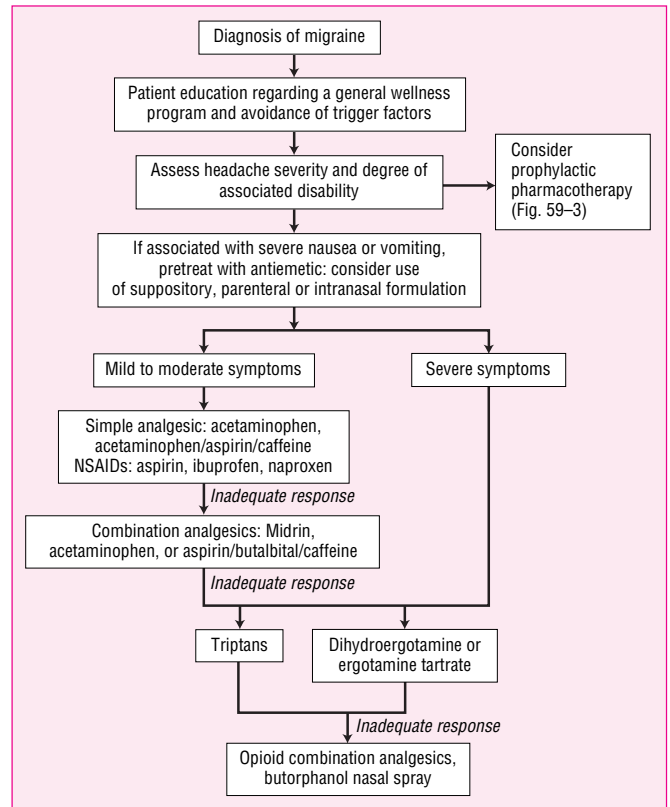

FIGURE 59–2. Treatment algorithm for migraine headaches.

as relaxation therapy, biofeedback (often used in combination with relaxation therapy), and cognitive therapy, are preventive treatment options for patients who prefer nondrug therapy or when symptomatic therapies are poorly tolerated, contraindicated, or ineffective.¹⁹

ACUTE MIGRAINE TREATMENT

CLINICAL CONTROVERSY

The availability of many over-the-counter drugs that were formerly prescription medications enables some migraine patients to self-medicate and delay entry into appropriate medical management. Some clinicians feel that over-the-counter products invite patients to take a less effective step-care approach rather than being treated according to evidence-based guidelines.³³

Although controversial, some clinicians argue that the efficacy and tolerability of over-the-counter medications for migraine relief are limited because of patient dissatisfaction with the route of administration, the onset of action, the completeness of pain relief, and the length of suffering and prolonged disability.³³

ANALGESICS AND NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS)

Simple analgesics and NSAIDs are effective medications for the management of many migraine attacks^{6,21,34} (see Table 59–4). They offer a reasonable first-line choice for treatment of mild to moderate

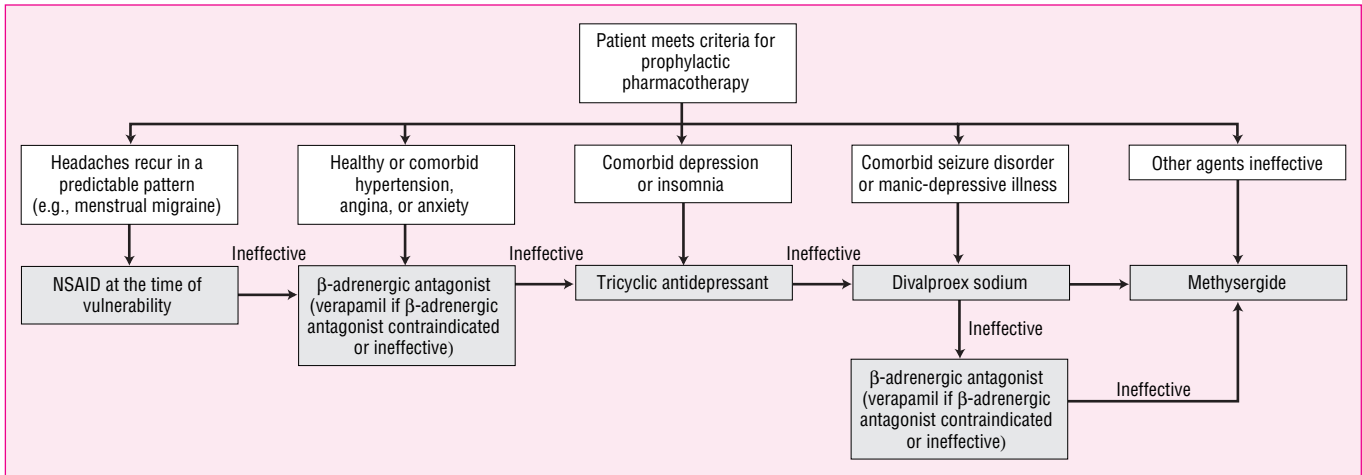

FIGURE 59-3. Treatment algorithm for prophylactic management of migraine headaches.

TABLE 59-6. Precipitating Factors Associated with Migraine

Food Triggers

- Alcohol
- Caffeine/caffeine withdrawal
- Chocolate
- Citrus fruits, bananas, figs, raisins
- Dairy products
- Fermented and pickled foods
- Monosodium glutamate (e.g., in Chinese food, seasoned salt, and instant foods)
- Nitrate-containing foods (e.g., processed meats)
- Saccharin/aspartame (e.g., diet foods or diet sodas)
- Sulfites in shrimp
- Tyramine-containing foods
- Yeast products

Environmental Triggers

- Glare or flickering lights
- High altitude
- Loud noises
- Strong smells and fumes
- Tobacco smoke
- Weather changes

Behavioral-Physiologic Triggers

- Excess or insufficient sleep
- Fatigue
- Menstruation, menopause
- Skipped meals
- Strenuous physical activity (e.g., prolonged overexertion)
- Stress or post-stress

Medications

- Analgesic overuse
- Benzodiazepine withdrawal
- Cimetidine
- Decongestant overuse
- Ergotamine overuse
- Estrogen therapy
- Indomethacin
- Nifedipine
- Nitrates
- Oral contraceptives
- Reserpine
- Theophylline

Compiled from refs. 24 and 28.

migraine attacks or severe attacks that have been responsive in the past to similar NSAIDs or nonopiate analgesics.¹⁹ Of the NSAIDs, aspirin, ibuprofen, naproxen sodium, tolfenamic acid, and the combination of acetaminophen plus aspirin and caffeine have demonstrated the most consistent evidence of efficacy.²⁸ Although conclusions regarding clinical efficacy are not available, intramuscular ketorolac is an option for physician-supervised settings.^{19,34} Evidence for other NSAIDs is either limited (only one study) or inconsistent (some positive and some negative studies).³⁴ Acetaminophen alone is not generally recommended for migraine because the scientific support is not optimal.^{14,19,34} Comparisons with other pharmacotherapeutic classes are limited.

NSAIDs appear to prevent neurogenically mediated inflammation in the trigeminovascular system through the inhibition of prostaglandin synthesis. In general, NSAIDs with a long half-life that preclude their frequent use are preferred.³⁵ Combination therapy with metoclopramide can speed the absorption of analgesics and NSAIDs and alleviate migraine-related nausea and vomiting.²⁴ Suppository analgesic preparations and intramuscular ketorolac are also options when nausea and vomiting are severe.²⁰ Effervescent formulations may offer the advantage of enhanced absorption.²⁴ Acute NSAID therapy is associated with gastrointestinal (e.g., dyspepsia, nausea, vomiting, and diarrhea) and CNS side effects (e.g., somnolence, dizziness). NSAIDs should be used cautiously in patients with previous ulcer disease, renal disease, or hypersensitivity to aspirin.³⁴

The over-the-counter combination of acetaminophen, aspirin, and caffeine was approved for the treatment of migraine in the United States because of its proven efficacy in relieving migraine pain and associated symptoms.^{34,36} Aspirin and acetaminophen are also available in prescription combination products containing a short-acting barbiturate (butalbital) or narcotic (codeine, propoxyphene). No randomized, placebo-controlled studies support the efficacy of butalbital-containing products in the treatment of migraine. The use of butalbital-containing analgesics or narcotics should be limited because of concerns about overuse, medication-overuse headache, and withdrawal.^{14,19,34} Midrin, a combination of acetaminophen, isometheptene mucate (a sympathomimetic amine), and dichloralphenazone (a chloral hydrate derivative), has demonstrated modest benefits in placebo-controlled studies and generally is viewed as an alternative for patients with mild to moderate migraine attacks.^{19,34} Although frequent consumption of aspirin or acetaminophen alone

can result in medication overuse headache, combination analgesics appear to pose a greater risk.²³

■ OPIATE ANALGESICS

Narcotic analgesic drugs (e.g., meperidine, butorphanol, oxycodone, and hydromorphone) are effective but generally should be reserved for patients with moderate to severe infrequent headaches in whom conventional therapies are contraindicated or as “rescue medication” after patients have failed to respond to conventional therapies.¹⁴ Frequent use of narcotic analgesics may lead to the development of dependency and rebound headache.³⁴ The intranasal formulation of butorphanol, a synthetically derived opioid agonist-antagonist, is a treatment option and alternative to frequent office or emergency department visits for injectable migraine therapies. Butorphanol is used widely despite the established risk of overuse and dependence. Opioid therapy should be supervised closely.^{19,34}

■ ANTIEMETICS

Adjunctive antiemetic therapy is useful for combating the nausea and vomiting that accompany migraine headaches and the medications used to treat acute attacks (e.g., ergotamine tartrate). A single dose of an antiemetic, such as metoclopramide, chlorpromazine, or prochlorperazine, administered 15 to 30 minutes before ingestion of oral abortive migraine medications is often sufficient. Suppository preparations are available when nausea and vomiting are particularly prominent. Metoclopramide is also useful to reverse gastroparesis and improve absorption from the gastrointestinal tract during severe attacks.^{19,34}

In addition to antiemetic effects, dopamine antagonist drugs also have been used successfully as monotherapy for the treatment of intractable headache. Prochlorperazine administered by the intravenous and intramuscular routes and intravenous metoclopramide provided more effective pain relief than placebo. Chlorpromazine also has provided relief of migraine headache comparable to that provided by intravenous metoclopramide and dihydroergotamine when administered parenterally. Domperidone has a possible role for preemptive treatment of migraine. The precise mechanism of action for these agents is unknown. The dopamine antagonists offer an alternative to the narcotic analgesics for the treatment of refractory migraine. Drowsiness and dizziness were reported occasionally with the use of dopamine antagonists in migraineurs. Extrapyramidal side effects were reported infrequently in migraine trials.³⁴

■ MISCELLANEOUS NONSPECIFIC MEDICATIONS

Corticosteroids may be an effective rescue therapy for status migrainosus (a severe, continuous migraine that may last up to 1 week).¹⁹ Open-label studies also suggest that short courses of orally or parenterally administered prednisone, dexamethasone, and hydrocortisone appear to be useful in the management of refractory headache that has persisted for several days.¹⁴

Limited studies suggest a role for intranasal lidocaine in the treatment of acute migraine headache.³⁴ Intranasal lidocaine provides rapid pain relief within 15 minutes of administration, but headache recurrence is common. Adverse effects generally are limited to local irritation of the nose or eye, an unpleasant taste, and numbness of the throat.

Preliminary investigations of intramuscular droperidol, nitrous oxide, and intravenous propofol have yielded favorable results in the treatment of acute migraine headache.^{37–39} Future studies may establish a more defined role for these agents in migraine management.

■ ERGOT ALKALOIDS AND DERIVATIVES

Ergotamine tartrate and dihydroergotamine are useful and may be considered for the treatment of moderate to severe migraine attacks.¹⁹ These drugs are nonselective 5-HT₁ receptor agonists that constrict intracranial blood vessels and inhibit the development of neurogenic inflammation in the trigeminovascular system.⁴⁰ Central inhibition of the trigeminovascular pathway is also reported.⁴¹ These agents also display activity at α -adrenergic, β -adrenergic, and dopaminergic receptors. Venous and arterial constriction occur with therapeutic doses, but ergotamine tartrate exerts more potent arterial effects than dihydroergotamine.⁴⁰

Ergotamine tartrate is available for oral, sublingual, and rectal administration (see Table 59–4). Oral and rectal preparations contain caffeine to enhance absorption and potentiate analgesia. Some patients respond preferentially to rectal dosing.¹⁴ Dosage requirements should be titrated strictly to establish an effective but subnauseating dose for future attacks. Ergotamine is most effective when administered early in the migraine attack.⁴² Despite its widespread clinical use since 1925, evidence supporting the efficacy of ergotamine tartrate in migraine is inconsistent.^{14,34}

Dihydroergotamine is available for intranasal and parenteral administration by the intramuscular, subcutaneous, and intravenous routes^{14,19} (see Table 59–4). Parenteral dihydroergotamine was viewed previously as inpatient or emergency department treatment for moderate to severe migraine, but patients can be trained to self-administer dihydroergotamine intramuscularly or subcutaneously. The bioavailability of dihydroergotamine is approximately 30% following intranasal administration, and maximum plasma concentration is achieved in 30 to 60 minutes.⁴³

Nausea and vomiting (resulting from stimulation of the chemoreceptor trigger zone) are among the most common adverse effects of the ergotamine derivatives; however, ergotamine is 12 times more emetic than dihydroergotamine.⁴⁰ Pretreatment with an antiemetic agent should be considered with ergotamine and intravenous dihydroergotamine therapy. Other common side effects include abdominal pain, weakness, fatigue, paresthesias, muscle pain, diarrhea, and chest tightness. Occasionally, symptoms of severe peripheral ischemia (ergotism), including cold, numb, painful extremities, continuous paresthesias, diminished peripheral pulses, and claudication, may result from the vasoconstrictor effects of the ergot alkaloids. Gangrenous extremities, myocardial infarction, hepatic necrosis, and bowel and brain ischemia have been reported rarely.^{4,40–42} Dihydroergotamine is rarely associated with such side effects.^{42,44} Triptans and ergot derivatives should not be used within 24 hours of each other.⁴² Recently, reports of severe vasospasm during concomitant therapy with ergotamine and protease inhibitors have appeared in the literature.^{45,46} These cases are attributed to protease inhibitor inhibitory effects on the CYP3A4 isoenzyme and a consequent rise in ergotamine blood levels. Ergotamine derivatives are contraindicated in patients with renal or hepatic failure; coronary, cerebral, or peripheral vascular disease; uncontrolled hypertension; and sepsis and in women who are pregnant or nursing.^{4,42} Dihydroergotamine does not appear to cause rebound headache, but dosage restrictions for ergotamine tartrate should be observed strictly to prevent this complication.⁴

SEROTONIN RECEPTOR AGONISTS (TRIPTANS)

Introduction of the serotonin receptor agonists, or triptans, represented a significant advance in migraine pharmacotherapy. The first member of this class, sumatriptan, and the second-generation agents zolmitriptan, naratriptan, rizatriptan, almotriptan, frovatriptan, and eletriptan are selective agonists of the 5-HT_{1B} and 5-HT_{1D} receptors. Relief of migraine headache is the result of three key actions: vasoconstriction of pain-producing intracranial blood vessels through stimulation of vascular 5-HT_{1B} receptors, inhibition of vasoactive neuropeptide release from trigeminal perivascular nerves through stimulation of presynaptic 5-HT_{1D} receptors, and interruption of pain signal transmission within the brain stem trigeminal nuclei through stimulation of 5-HT_{1D} receptors (centrally acting agents).^{10,22} Individual affinities for 5-HT_{1B} and 5-HT_{1D} receptors vary somewhat but are comparable.^{10,47} These agents also display varying affinity for 5-HT_{1A}, 5-HT_{1E}, and 5-HT_{1F} receptors. The triptans are appropriate first-line therapy for patients with moderate to severe migraine and are used for rescue therapy when nonspecific medications are ineffective.^{19,20}

Sumatriptan, the most extensively studied antimigraine therapy, is available for subcutaneous, oral, and intranasal administration.²² Subcutaneous sumatriptan is consistently superior to placebo in alleviating migraine headache and associated symptoms, with relief reported in 71% of patients at 1 hour (43% pain-free) and 79% at 2 hours (60% pain-free) in a meta-analysis of placebo-controlled studies.^{22,47} In addition to enhanced efficacy, subcutaneous sumatriptan has a more rapid onset of action (10 minutes) when compared with the oral formulation (30 minutes).^{20,47} The subcutaneous injection is packaged as an autoinjector device for self-administration by patients. Intranasal sumatriptan provides a faster onset of effect (15 minutes) than the oral formulation and produces similar rates of response (relief in 61% of patients at 2 hours) in placebo-controlled studies.⁴⁷ Approximately 30% to 40% of patients who respond to sumatriptan experience headache recurrence within 24 hours.⁴⁷ This has been attributed to the drug's short half-life, but recurrence is a problem with most acute migraine therapies.^{22,47} A second dose given at the time of recurrence usually is effective.

The second-generation triptans appear to offer an improved pharmacokinetic and pharmacodynamic profile compared with oral

sumatriptan.^{22,47,48} These agents have higher oral bioavailability and longer half-lives than oral sumatriptan, which theoretically could improve within-patient treatment consistency and reduce headache recurrence.^{16,22,49} (Table 59–7). Despite the fact that oral absorption may be delayed during migraine attacks, most patients prefer oral formulations, and these account for 80% of all triptan prescriptions.⁵⁰ Frovatriptan has the longest half-life of the triptans but the slowest onset of action. Penetration of the blood-brain barrier, as a result of increased lipophilicity, allows for a central site of action within the trigeminal nuclei and may hasten the onset of therapeutic effect of the second-generation agents.^{10,22} Sumatriptan does not cross the intact blood-brain barrier in experimental systems. However, evidence suggests that the blood-brain barrier may be disrupted during a migraine attack, allowing central access for sumatriptan as well.¹⁰

Results of placebo-controlled studies with each of the second-generation agents reveal somewhat comparable 2-hour response rates. Direct comparative clinical trials are necessary to determine their relative efficacy, but these are available for only a few of the triptans. A recent meta-analysis summarizes the efficacy and tolerability of the different oral triptans across both published and unpublished studies.⁵⁰ At all marketed doses, the oral triptans are effective and well tolerated. Across studies for sumatriptan 100 mg, mean results were a 2-hour headache response of 59%, with 29% pain-free at 2 hours, 20% sustained pain-free, and 67% consistency. Compared with sumatriptan 100 mg, rizatriptan 10 mg showed better efficacy and consistency and similar tolerability; eletriptan 80 mg showed better efficacy, similar consistency, but lower tolerability; almotriptan 12.5 mg showed similar efficacy at 2 hours but better other results; naratriptan 2.5 mg and eletriptan 20 mg showed lower efficacy and better tolerability; and zolmitriptan 2.5 and 5 mg, eletriptan 40 mg, and rizatriptan 5 mg all showed similar results. Available data suggest lower efficacy for frovatriptan.⁵⁰

Clinical response to the triptans can vary considerably among individual patients. Individual responses cannot be predicted, and if one triptan fails, a patient may be switched successfully to another triptan.^{14,50} After an effective agent and dose have been identified, subsequent treatments should begin with that same regimen.

Side effects to the triptans are common but usually mild to moderate in nature and of short duration. Adverse effects are consistent among the class and include paresthesias, fatigue, dizziness, flushing,

TABLE 59–7. Pharmacokinetic Characteristics of Triptans

| Drug | Half-Life (hours) | Time to Maximal Concentration (t _{max}) | Bioavailability | Elimination |
|-----------------------------|-------------------|---|-----------------|-----------------------------|
| Almotriptan | 3–4 | 1.4–3.8 h | 70% | MAO-A, CYP450 3A4 and 2D6 |
| Eletriptan | 5 | 1.4–2.8 h | 50% | CYP 3A4 |
| Frovatriptan | 25 | 2–4 h | 24–30% | CYP 1A2 |
| Naratriptan | 5–6 | 2–3 h | 63–74% | CYP450 (various isoenzymes) |
| Rizatriptan | 2–3 | 1–1.5 h | 40–45% | MAO-A |
| Oral tablets Disintegrating | | 1.6–2.5 h | | |
| Sumatriptan: | 2 | | | MAO-A |
| SC injection | | 12–15 min | 97% | |
| Oral tablets | | 2.5 h | 14% | |
| Nasal spray | | 1–2.5 h | 17% | |
| Zolmitriptan | 3 | | 40% | CYP 1A2, MAO-A |
| Oral | | 1.5 h | | |
| Disintegrating | | 3 h | | |
| Nasal | | 4 h | | |

Compiled from refs. 16, 35, and 47–49.

warm sensations, and somnolence. Local side effects are reported with the subcutaneous (minor injection-site reactions) and intranasal (taste perversion, nasal discomfort) routes. Doses that provide the best ratio of efficacy and safety are considered optimal. Up to 15% of patients receiving a triptan consistently report “chest symptoms,” including tightness, pressure, heaviness, or pain in the chest, neck, or throat.^{20,22} The mechanism of these symptoms is unknown, but a cardiac source of pain seems unlikely in most patients.²² However, all triptans are partial agonists of human 5-HT_{1A} coronary artery receptors *in vitro*, resulting in a small but significant vasoconstrictor response.^{22,48} Adverse cardiac events are rare because 5-HT_{2A} receptors mediate most of the effects of serotonin on coronary vessels.²⁰ Isolated cases of myocardial infarction and coronary vasospasm with ischemia have been reported, but myocardial ischemia is unlikely in patients with normal coronary vasculature.⁴⁸ The triptans are contraindicated in patients with a history of ischemic heart disease (e.g., angina pectoris, Prinzmetal’s angina, or previous myocardial infarction), uncontrolled hypertension, and cerebrovascular disease. Patients at risk for unrecognized coronary artery disease (e.g., postmenopausal women, men over 40 years of age, and patients with multiple risk factors) should receive a cardiovascular assessment prior to triptan use and have their initial dose administered under medical supervision. Triptans are also contraindicated in patients with hemiplegic and basilar migraine. The triptans should not be given within 24 hours of the ergotamine derivatives. Administration of sumatriptan, rizatriptan, and zolmitriptan within 2 weeks of therapy with monoamine oxidase inhibitors is not recommended. Concomitant therapy with the selective serotonin reuptake inhibitors (SSRIs) should be monitored carefully because of isolated reports of serotonin syndrome in sumatriptan-treated patients. Frequent use of the triptans has been associated with the development of medication misuse headache.^{16,19,34}

■ PREVENTIVE THERAPY

■ β -ADRENERGIC ANTAGONISTS

β -Adrenergic antagonists are the most widely used drugs for migraine prophylaxis.²⁵ Propranolol, nadolol, timolol, atenolol, and metoprolol have proven efficacy in controlled clinical trials, reducing the frequency of attacks by 50% in 60% to 80% of patients^{25,27} (see Table 59–5). Because the relative efficacy of the individual agents has not been established, selection of a β -blocker may be based on β selectivity, convenience of the formulation, and tolerability. β -Blockers with intrinsic sympathomimetic activity are ineffective for migraine prophylaxis.²⁵ Although their precise mechanism of antimigraine action is unknown, they may raise the migraine threshold by modulating adrenergic or serotonergic neurotransmission in cortical or subcortical pathways. β -Blockers are particularly useful in patients with comorbid anxiety, hypertension, or angina. Side effects can include drowsiness, fatigue, sleep disturbances, vivid dreams, memory disturbance, depression, impotence, bradycardia, and hypotension. β -Blockers should be used with caution in patients with congestive heart failure, peripheral vascular disease, atrioventricular conduction disturbances, asthma, depression, and diabetes. Bronchoconstrictive and hyperglycemic effects may be minimized with β_1 -selective agents.

■ ANTIDEPRESSANTS

The beneficial effects of antidepressants in migraine are independent of their antidepressant activity and may be related to downregulation of central 5-HT₂ and adrenergic receptors.²⁵ Amitriptyline, the most

widely studied antidepressant for migraine prophylaxis, has demonstrated efficacy in placebo-controlled and comparative studies.²⁷ Use of other antidepressants is based primarily on clinical and anecdotal experience (see Table 59–5). Other tricyclic antidepressants (TCAs) that have been used successfully for migraine prophylaxis include doxepin, nortriptyline, protriptyline, and imipramine.^{19,25} Anticholinergic side effects are common and limit use of these agents in patients with benign prostatic hyperplasia and glaucoma. Evening doses are preferred because of associated sedation. Increased appetite and weight gain may occur. Orthostatic hypotension and cardiac toxicity (slowed atrioventricular conduction) also are reported occasionally. The more favorable side-effect profile of nortriptyline and protriptyline could prove advantageous in patients who are particularly intolerant of the anticholinergic and sedative side effects of amitriptyline.

SSRIs have not been studied extensively for the preventive treatment of migraine headaches, but clinicians have used them nonetheless.²⁰ Fluoxetine is the most studied SSRI for migraine prevention, but definitive benefit has not been demonstrated in a rigorous clinical study.²⁵ Prospective data evaluating the other SSRIs (e.g., sertraline, paroxetine, fluvoxamine, and citalopram) are lacking.¹⁹ The SSRIs are considered to be less effective than TCAs for migraine prophylaxis but have gained favor with some clinicians as a result of their more favorable adverse-effect profile.⁴ These agents should not be considered as first- or second-line medications for the management of migraine, but they are useful in patients with comorbid depression.^{4,25} Preliminary evidence suggests a possible benefit with venlafaxine, an inhibitor of serotonin and norepinephrine reuptake.⁵¹

Monoamine oxidase inhibitors (MAOIs), such as phenelzine, have been used in the management of refractory headache, but their complex adverse-effect profile limits their use to experienced prescribers.⁵¹ Strict adherence to a tyramine-free diet is necessary to avoid potentially life-threatening hypertensive crisis.

■ ANTICONVULSANTS

Anticonvulsant medications have emerged as an important therapeutic option for the prevention of migraine headaches. The beneficial effects of these agents are likely due to multiple mechanisms of action, including enhancement of γ -aminobutyric acid (GABA)-mediated inhibition, modulation of the excitatory neurotransmitter glutamate, and inhibition of sodium and calcium ion channel activity.⁵² Anticonvulsants, such as divalproex sodium and topiramate, are particularly useful in migraineurs with comorbid seizures, anxiety disorder, or bipolar disorder.⁴ The efficacy of valproic acid and divalproex sodium (a 1:1 molar combination of valproate sodium and valproic acid) has been demonstrated in multiple placebo-controlled studies.²⁵ Nausea and vomiting, the most common early side effects, are self-limited and appear to be less common with divalproex sodium and gradual titration of doses. Alopecia, tremor, asthenia, somnolence, and weight gain are also common complaints.^{25,53} The extended-release formulation of divalproex sodium is administered once daily and is better tolerated than the enteric-coated formulation.⁵³ Hepatotoxicity is the most serious side effect of valproate therapy, but the risk appears to be low in migraineurs (e.g., patients older than 10 years of age who are receiving monotherapy and have no underlying metabolic or neurologic disorder).²⁵ Baseline liver function tests should be obtained, but routine follow-up studies are not necessary in asymptomatic adults on monotherapy. Patient evaluation is recommended every 1 to 2 months during the first 6 to 9 months of therapy. Valproate is contraindicated in pregnant women (owing to potential teratogenicity) and patients with a history of pancreatitis or chronic liver disease. Although valproate level determinations may be useful for assessing compliance

and toxicity, a recent study suggests that serum levels of less than 50 mcg/mL (usual therapeutic level is 50 to 100 mcg/mL) may provide similar benefit to higher levels.⁵⁴

Topiramate is currently undergoing FDA review for a migraine prophylaxis indication based on the results of a randomized, double-blind study that demonstrated significantly greater reductions in mean monthly migraine frequency with 100 and 200 mg topiramate daily compared with placebo.⁵⁵ Treatment-emergent adverse events associated with topiramate included paresthesia, fatigue, anorexia, diarrhea, weight loss, difficulty with memory, and nausea. Kidney stones, acute myopia and acute angle-closure glaucoma, and oligohidrosis have been reported infrequently with topiramate use.⁵⁶

A recent study suggests that gabapentin also may be an effective agent for migraine prevention in patients achieving a daily dose of 2400 mg.^{25,57} Somnolence, dizziness, and asthenia were the most commonly reported adverse events. Preliminary studies suggest a possible role for other anticonvulsants, including tiagabine, levetiracetam, and zonisamide; however, further clinical studies are needed to confirm their utility in migraine prophylaxis.^{56,58}

■ CALCIUM CHANNEL BLOCKERS

The calcium channel blockers generally are considered second- or third-line options for preventive treatment when other drugs with established clinical benefit are ineffective or contraindicated.²⁰ Verapamil is the most widely used calcium channel blocker for preventive treatment, but it provided only modest benefit in decreasing the frequency of attacks in two placebo-controlled studies.⁴ The therapeutic effect of verapamil may not be noted for up to 8 weeks after initiation of therapy.⁵¹ Side effects of verapamil may include constipation, hypotension, bradycardia, atrioventricular block, and exacerbation of congestive heart failure. Evaluations of nifedipine, nimodipine, diltiazem, and nicardipine have yielded equivocal results.²⁵

■ METHYSERGIDE

The semisynthetic ergot alkaloid methysergide is a potent 5-HT₂ receptor antagonist that appears to stabilize serotonergic neurotransmission in the trigeminovascular system to block the development of neurogenic inflammation.⁵⁹ Although methysergide is an effective preventive medication, its utility is limited by the rare (1 in 5000 patients) development of retroperitoneal, endocardial, and pulmonary fibrosis during long-term administration.⁴ Consequently, a medication-free interval of 4 weeks is recommended following each 6-month treatment period.⁵⁹ The dosage should be tapered over a 1-week period to prevent rebound headaches. Monitoring for fibrotic complications should include periodic auscultation of the heart, as well as yearly chest roentgenography, echocardiography, and abdominal magnetic resonance imaging.²⁵ Methysergide is best tolerated when

taken with meals. In addition to gastrointestinal intolerance, muscle aching, leg cramps, claudication, weight gain, and hallucinations are also reported with its use. It is contraindicated in pregnancy, peripheral vascular disorders, coronary artery disease, severe hypertension, thrombophlebitis or cellulitis of the legs, peptic ulcer disease, liver or renal dysfunctions, and valvular heart disease.⁵⁹ Peripheral vasospasm and severe claudication have been reported occasionally in patients without a prior history of vascular disease. Methysergide is reserved for patients with refractory headaches that do not respond to other preventive therapies.

■ NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS)

NSAIDs are modestly effective for reducing the frequency, severity, and duration of migraine attacks, but potential gastrointestinal and renal toxicity may limit the daily or prolonged use of these agents.^{25,27} Consequently, NSAIDs have been used intermittently to prevent headaches that recur in a predictable pattern, such as menstrual migraine. Administration of NSAIDs in the perimenstrual period may be beneficial in women with true menstrual migraine.⁶⁰ NSAIDs should be initiated 1 to 2 days prior to the expected onset of headache and continued during the period of vulnerability.⁴ Prostaglandin production may be enhanced in women with menstrual migraine, and the preventive mechanism of NSAIDs is thought to involve inhibition of prostaglandin synthesis.⁴ If long-term NSAID therapy is initiated, monitoring of renal function and occult blood loss is necessary.

■ MISCELLANEOUS PROPHYLACTIC AGENTS

A double-blind, placebo-controlled study demonstrated the efficacy of riboflavin (vitamin B₂) 400 mg daily in migraine prophylaxis. Riboflavin was associated with 50% or greater improvement in attack frequency in 59% of patients.⁵⁶ More recently, localized injections of botulinum toxin type A have reduced the frequency, severity, and disability associated with migraine headaches significantly in three small double-blind, placebo-controlled trials.⁶¹ The angiotensin-converting enzyme inhibitor lisinopril and the angiotensin II receptor blocker candesartan provided effective migraine prophylaxis in recent double-blind, placebo-controlled, crossover studies of these agents.^{62,63} Further research is needed to establish the safety and efficacy of the herbal medication feverfew (*Tanacetum parthenium*) because studies to date have yielded conflicting results.⁴ Authors of a recent double-blind, placebo-controlled study concluded that petasites, an extract from the plant *Petasites hybridus*, may be an effective preventive treatment for migraine.⁵⁸ Further study is needed to determine the clinical utility and comparative efficacy of these agents for the prophylactic management of migraine.

PHARMACOECONOMIC CONSIDERATIONS

Although migraine is widely recognized as a disease that exacts an enormous toll on the sufferer, the direct and indirect costs associated with migraine headache impose a substantial burden on society as well. The direct costs associated with migraine diagnosis and treatment are substantial. The volume of health care services used

by migraineurs is two or more times that of nonmigraineurs, with 2.5 times as many pharmacy claims, more emergency department visits, and more than 6 times the cost of diagnostic procedures.⁶⁴ A large portion of the cost of treatment is pharmacotherapy, but this actually represents a small percentage of the total cost of migraine.⁶⁴ The indirect costs of the illness related to work absenteeism, decreased productivity, and impairment greatly exceed the direct cost of medical

care.^{8,65} The estimated indirect cost of migraine-related disability, the most important determinant of the economic impact of migraine, is approximately \$13 billion each year.^{8,65}

According to the American Migraine Study II, only 48% of those surveyed with clear symptoms of migraine were diagnosed by a physician.^{5,6} Although 96% of severe migraine sufferers take some medication for their headaches, only 41% of those with moderate to severe headache-related disability take prescription medication.^{5,6} Because many migraineurs who receive inadequate care experience substantial levels of pain and disability, improvement in migraine diagnosis, care, and treatment potentially could result in lower direct and indirect costs of the disease.

Education of headache patients regarding required behavior changes and effective use of acute and prophylactic pharmacotherapy may be time-consuming, but it is also extremely cost-effective. Oversights may lead to decreased efficacy of medications resulting in repeat dosing and polypharmacy, decreased compliance, increased emergency department use, increased “doctor shopping,” and, perhaps, increased use of expensive diagnostic procedures and inpatient services. Recent studies demonstrate that effective migraine treatment can reduce productivity loss during a migraine attack.⁶⁶ Health care resource use and time lost from workplace productivity and nonworkplace activity also were reduced significantly 3 to 6 months after the initiation of sumatriptan therapy in a managed-care population.⁶⁷ Health-related quality of life also improved in these patients. These studies demonstrate that the clinical benefits of effective migraine therapy ultimately may translate into reduced indirect migraine-related costs. Further studies should be conducted to demonstrate the value of effective migraine pharmacotherapies in reducing the overall costs of managing the migraineur.

SUMMARY

Acute and preventive pharmacotherapy for migraine should be individualized based on the individual patient response, tolerability of the available agents, and presence of comorbid conditions. Migraine management should be individualized on the basis of the patient’s clinical presentation and medical history. Analgesics and NSAIDs may be considered the drugs of choice for infrequent mild to moderate attacks. The triptans or dihydroergotamine can be used as secondary agents if initial therapies prove ineffective or as first-line therapy in moderate to severe migraine headache. Abortive therapy should be instituted early in the course of the attack to optimize efficacy and minimize migraine-related pain and disability. Preventive therapy should be considered in the setting of recurring migraines that produce significant disability, frequent attacks requiring symptomatic medication more than twice per week, symptomatic therapies that are ineffective, contraindicated, or produce serious side effects, and uncommon migraine variants that cause profound disruption and/or risk of neurologic injury. Efficacy of a prescribed prophylactic regimen should be reassessed periodically. A prolonged headache-free interval could allow for gradual dosage reduction and discontinuation of therapy.

► TREATMENT: Tension-Type Headaches

■ GENERAL APPROACH TO TREATMENT

The vast majority of episodic tension-type headache sufferers self-medicate with over-the-counter medications and do not

TENSION-TYPE HEADACHE

EPIDEMIOLOGY

Tension-type headache is the most common type of primary headache, with an estimated 1-year prevalence of 63% in men and 86% in women.² First onset of tension-type headache typically is early in life (before age 20 in 40% of patients), and prevalence peaks between the ages of 20 and 50 years.^{2,4} It is more common among women in adulthood, with a female-to-male ratio of 4:3.⁶⁸ The mean frequency of attacks is 2.9 days per month, with most sufferers experiencing fewer than one attack per month.⁴ The prevalence of chronic tension-type headache (defined as ≥ 180 headache days per year) is estimated at 2% to 3%.⁴ Although an estimated 60% of tension-type headache sufferers experience some degree of functional impairment during their attacks, only 16% of patients have consulted a general practitioner for their headaches.^{4,68}

PATHOPHYSIOLOGY

Although tension-type headache is the most common type of headache, it is the least studied of the primary headache disorders, and there is limited understanding of key pathophysiologic concepts.⁶⁸ Some practitioners theorize that migraine and tension-type headaches may represent a continuum of headache severity within the same entity.⁶⁹ However, more recently, tension-type headache has been recognized as a distinct disorder. The pain of episodic tension-type headache is thought to originate from the myofascial tissues, although central mechanisms also may be involved.⁶⁸ Following activation of supraspinal pain perception structures, a self-limiting headache results in most individuals owing to central modulation of the incoming peripheral stimuli.⁶⁸ Chronic tension-type headache may evolve from episodic tension-type headache in predisposed individuals owing to a disturbance of central nociceptive processing and subsequent sensitization of the CNS.⁶⁸ It is likely that other pathophysiologic mechanisms also contribute to the development of tension-type headache.

CLINICAL PRESENTATION

Premonitory symptoms and aura are absent with tension-type headache. The pain usually is mild to moderate in intensity and often is described as a dull, nonpulsatile tightness or pressure.^{3,4} Bilateral pain is most common, but the location can vary (frontal and temporal pain are most common; occipital and parietal regions also may be affected).³ The pain is classically described as having a “hatband” pattern. Associated symptoms generally are absent, but mild photophobia or phonophobia may be reported. The disability associated with tension-type headache typically is minor in comparison with migraine headache, and routine physical activity does not affect headache severity.^{3,4} Palpation of the pericranial or cervical muscles may reveal tender spots or localized nodules in some patients.³ Tension-type headache is classified as either episodic (infrequent or frequent) or chronic based on the frequency and duration of the attacks.⁴

consult a health care professional. While pharmacologic and non-pharmacologic treatments are available, simple analgesics and NSAIDs are the mainstay of acute therapy. Most agents used for tension-type headache have not been studied in controlled clinical trials.⁷⁰

■ NONPHARMACOLOGIC THERAPY

Psychophysiologic therapy and physical therapy have been used in the management of tension-type headache. Psychophysiologic therapy may consist of reassurance and counseling, stress management, relaxation training, and biofeedback. Relaxation training and biofeedback training (alone or in combination) can result in a 50% reduction in headache activity.⁴ Evidence supporting physical therapeutic options, such as heat or cold packs, ultrasound, electrical nerve stimulation, stretching, exercise, massage, acupuncture, manipulations, ergonomic instruction, and trigger point injections or occipital nerve blocks, is somewhat inconsistent.⁴ However, patients may benefit from selected modalities (e.g., massage) during an acute episode of tension-type headache.

■ PHARMACOLOGIC THERAPY

Simple analgesics (alone or in combination with caffeine) and NSAIDs are effective for the acute treatment of mild to moderate tension-type headache. Acetaminophen, aspirin, ibuprofen, naproxen,

ketoprofen, indomethacin, and ketorolac have demonstrated efficacy in placebo-controlled and comparative studies.⁴ Failure of over-the-counter agents may warrant therapy with prescription drugs. High-dose NSAIDs and the combination of aspirin or acetaminophen with butalbital or, rarely, codeine are effective options. Use of butalbital and codeine combinations should be avoided when possible owing to the high potential for overuse and dependency. As with migraine headache, acute medication should be taken for episodic tension-type headache no more than 2 days per week to prevent the development of chronic tension-type headache.^{4,71} There is no evidence to support the efficacy of muscle relaxants (e.g., cyclobenzaprine, baclofen, and methocarbamol) in the management of episodic tension-type headache.^{4,70} Preventive treatment should be considered if headache frequency (more than two per week), duration (greater than 3–4 hours), or severity results in medication overuse or substantial disability. The principles of preventive treatment for tension-type headache are similar to those for migraine headache. TCAs are prescribed most often for prophylaxis, but other drugs also can be selected after consideration of comorbid medical conditions and respective side-effect profiles.⁴ Injection of botulinum toxin into pericranial muscles has demonstrated efficacy in the prophylaxis of chronic tension-type headache in two recently published placebo-controlled studies.⁷⁰

CLUSTER HEADACHE

EPIDEMIOLOGY

Cluster headache, the most severe of the primary headache disorders, is characterized by attacks of severe, unilateral head pain that occur in series lasting for weeks or months (i.e., cluster periods) separated by remission periods usually lasting months or years.^{4,72} Cluster headaches may be episodic or chronic.³ Cluster headache is relatively uncommon among the primary headache disorders, with an estimated prevalence of approximately 0.4% for men and 0.08% for women.⁷² Unlike migraine, men are four to seven times more likely than women to suffer from cluster headache.⁴ Onset can occur at any age but is most common in the late twenties. Recent evidence suggests that a genetic predisposition for cluster headache may exist in certain families.⁴

PATHOPHYSIOLOGY

The etiologic and pathophysiologic mechanisms of cluster headache are not completely understood. Similar to migraine headache, the head pain of cluster attacks is thought to involve activation of trigeminovascular neurons with resulting release of vasoactive neuropeptides and the development of sterile, neurogenic inflammation.⁷² The characteristic location of head pain appears to implicate the cavernous sinus as the site of the inflammatory process.⁹ Triggers of cluster headache attacks may cause periodic discharges of the trigeminovascular system that result in headache pain; however, the mechanisms that activate the trigeminovascular system are not yet understood. The periodicity and regularity of attacks may implicate hypothalamic dysfunction and resulting alterations in circadian rhythms in the pathogenesis of cluster headache.^{4,72} Hypothalamus-induced changes in cortisol, prolactin, testosterone, growth hormone, β -endorphin, and melatonin have been demonstrated during periods of cluster headache attack.⁷² Neuroimaging studies performed during acute cluster headache

attacks have demonstrated activation of the ipsilateral hypothalamic gray area.⁹ This region may be the fundamental “driver” of the cluster attack. Because serotonergic systems modulate activity in both the hypothalamus and trigeminovascular neurons, 5-HT may play a significant role in cluster headache pathophysiology. The association of cluster headache with high-altitude hypoxia, rapid-eye-movement sleep, and vasodilator therapy, as well as the efficacy of oxygen inhalation therapy in aborting cluster attacks, suggests that hypoxemia also may play a role in the pathogenesis of cluster headache.⁷²

CLINICAL PRESENTATION

Attacks occur in cluster periods lasting 2 weeks to 3 months in most patients, followed by long pain-free intervals.^{4,72} Periods of remission average 2 years in length but have been reported to be from 2 months to 20 years in duration. Approximately 10% of patients have chronic symptoms with no remission periods. Cluster headache attacks occur at night in more than 50% of patients and appear to be more common in the spring and fall.⁷² Attacks occur suddenly, with pain peaking quickly after onset and generally lasting 15 to 180 minutes.³ Auras are not present with cluster headaches. The pain is excruciating and penetrating but usually nonthrobbing and is most often unilateral in orbital, supraorbital, and temporal locations.^{4,72} The headache is associated with autonomic features consistent with sympathetic system paresis and parasympathetic overdrive. These features are present on the pain side and include conjunctival injection, lacrimation, and nasal stuffiness or rhinorrhea. Ipsilateral scalp and facial tenderness, ptosis, miosis, and periorbital swelling also are described. During the cluster period, attacks occur from once every other day to eight times per day.⁴ Whereas migraine patients retreat to a quiet dark room, cluster headache patients generally move about during an attack and may rub or beat their heads against objects in an attempt to alleviate the pain.⁷² Male patients often have a history of heavy tobacco and/or alcohol use.⁷² Specific diagnostic criteria for cluster headaches are provided within the IHS classification system.³

▶ TREATMENT: Cluster Headaches

As in migraine, therapy for cluster headaches involves both abortive and prophylactic therapy. Abortive therapy is directed at managing the acute attack. Prophylactic therapy is intended to shorten the duration of episodic cluster attacks, in addition to reducing the frequency and severity of attacks in both episodic and chronic cluster headache. Prophylactic therapies are started early in the cluster period and administered daily until the patient is headache-free for at least 2 weeks. The medication is then tapered but may be restarted with the next cluster period. Patients with chronic cluster headache may require prophylactic medications indefinitely.

■ ABORTIVE THERAPY

■ OXYGEN

The standard acute treatment of cluster headache is inhalation of 100% oxygen by facial mask at a rate of 7–10 L/min for 10 to 15 minutes.^{4,72} Repeat administration may be necessary because of recurrence because oxygen appears merely to delay, rather than abort, the attack in some patients.⁷² No side effects have been reported with the use of oxygen.

■ ERGOTAMINE DERIVATIVES

Intravenous or intramuscular dihydroergotamine provides effective relief for acute attacks of cluster headache.^{4,72} Onset of effect usually occurs within 10 minutes following intravenous administration.⁷² Intramuscular administration is effective within 30 minutes, and patients may be trained to self-administer the intramuscular injection.⁷² Repeated intravenous administration of dihydroergotamine for 3 to 7 days can break the cycle of frequent cluster headache attacks with minimal side effects.⁷² Ergotamine tartrate also has provided effective relief of cluster headache attacks when administered sublingually or rectally, but the pharmacokinetics of these preparations frequently limit their clinical utility.^{4,72} Dosing guidelines are similar to those for migraine headache therapy.

■ TRIPTANS

Subcutaneous and intranasal sumatriptan is considered safe and effective treatment for acute cluster headaches.^{49,73} Adverse events reported in cluster headache patients are similar to those seen in migraineurs. Sumatriptan has been used in the management of cluster headaches for up to 1 year without evidence of tachyphylaxis or increased toxicity.⁷³ Orally administered sumatriptan has limited use in cluster attacks because of its relatively long onset of action; oral zolmitriptan, however, was efficacious in patients with episodic cluster headache, with 60% of patients experiencing relief (mild or no pain) at 30 minutes.^{49,73}

■ PROPHYLACTIC THERAPY

■ VERAPAMIL

Verapamil, the preferred calcium channel blocker for the prevention of cluster headaches, is effective in approximately 70% of patients.⁴ The

beneficial effects of verapamil often appear after 1 week of therapy. Effective doses usually range from 240 to 360 mg/day for episodic attacks, but higher doses may be necessary to control chronic cluster headache.

■ LITHIUM

Lithium carbonate is effective against episodic and chronic cluster headache attacks, with beneficial effects often appearing during the first week of therapy. A positive response is seen in up to 78% of patients with chronic cluster headache and in up to 63% of patients with episodic cluster headache.⁴ The usual dose of lithium for cluster headache is 600 to 900 mg/day administered in divided doses. Tachyphylaxis to lithium has been reported occasionally during prolonged therapy.^{4,72} Optimal plasma lithium levels for the prevention of cluster headache have not been established, but efficacy has been reported at relatively low serum concentrations (0.3–0.8 mEq/L).^{4,72}

Initial side effects are mild and include tremor, lethargy, nausea, diarrhea, and abdominal discomfort. Lithium treatment has been associated with headache symptoms described as episodes of moderately severe, throbbing occipital pain lasting 6 to 12 hours, but these headaches are easily distinguishable from the cluster headache and disappear when lithium is withdrawn. Lithium should be administered with caution to patients with significant renal or cardiovascular disease, dehydration, pregnancy, or concomitant diuretic use.

■ ERGOTAMINE

Ergotamine can be an efficacious agent for prophylactic as well as abortive therapy of cluster headaches.⁴ A 2-mg bedtime dose is often beneficial for the prevention of nocturnal headache attacks. Daily use of 1 to 2 mg ergotamine alone or in combination with verapamil or lithium may provide effective headache prophylaxis in patients refractory to other agents with little risk of ergotism or rebound headache.^{4,72}

■ METHYSERGIDE

In patients unresponsive to other therapies, methysergide 4 to 8 mg/day in divided doses is usually effective in shortening the course of cluster headaches.⁷² Response to treatment usually occurs within 1 week of initiation of the drug. Response rates in patients with episodic cluster headache approach 70%, but chronic cluster headache patients receive less benefit.⁷² Precautions regarding methysergide use were described earlier in this chapter.

■ CORTICOSTEROIDS

Corticosteroids are useful for chronic cluster headaches refractory to verapamil, lithium, ergotamine, and methysergide or combinations of these agents.^{4,72} Therapy is initiated with 40 to 60 mg/day prednisone and tapered over approximately 3 weeks. Relief appears within 1 to 2 days of initiating therapy. To avoid steroid-induced complications, long-term use is not recommended. Headaches may recur when therapy is tapered or discontinued.

MISCELLANEOUS AGENTS

Other therapies that have been used in the acute management of cluster headache include intranasal lidocaine, intranasal capsaicin, and intramuscular leuprolide.⁷² Preliminary evidence also may support the use

of divalproex sodium, gabapentin, baclofen, topiramate, and phototherapy treatments, but well-designed, controlled studies are needed.^{4,72,75,76} Neurosurgical intervention may be necessary for patients with chronic cluster headache that is resistant to all medical therapies.^{4,72}

EVALUATION OF THERAPEUTIC OUTCOMES

Because of the prevalence of headache disorders, clinicians need to be actively involved in patient care issues. Patients should be monitored for frequency, intensity, and duration of headaches, as well as any change in the headache pattern. To this end, migraineurs should be encouraged to keep a headache diary to document the frequency, severity, and duration of migraine attacks, as well as response to medication and potential trigger factors. Careful monitoring is essential to initiate the most appropriate pharmacotherapy, document therapeutic successes and failures, identify medication contraindications, and prevent or minimize adverse events. Patients using acute therapies should be monitored for frequency of use of prescription and over-the-counter medications in order to identify potential medication misuse headache. Patient counseling is necessary to allow for proper medication use (e.g., self-injection with sumatriptan), to encourage early use of medications in the headache cycle, and to enhance patient compliance. Strict adherence to dosing guidelines should be stressed to minimize potential toxicity. Patterns of abortive medication use can be documented to establish the need for prophylactic therapy. Prophylactic therapies also should be monitored closely for adverse reactions, abortive therapy needs, adequate dosing, and compliance. Consultation with other health care practitioners should be encouraged when changes in headache patterns or medication use occur.

CONCLUSIONS

Although headache disorders such as migraine and cluster headaches appear to occur as a result of neuronal dysfunction, the precise etiology and nature of the dysfunction are unknown. Serotonergic neurotransmission and the trigeminovascular system appear to play important roles. A careful patient workup, including patient history, physical examination, and appropriate laboratory tests, should identify most headache patients with major disease. A variety of strategies can be helpful for managing migraine, tension-type and cluster headaches. Management of primary headache disorders is directed at suppressing acute attacks and preventing recurrences. Continuing research will better define pathophysiologic mechanisms and aid the search for less toxic and more efficacious pharmacologic agents.

EVALUATION OF PSYCHIATRIC ILLNESS

Patricia A. Marken, Mark E. Schneiderhan, and Stuart Munro

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Patients with psychiatric conditions are treated in all areas of health care. All clinicians need to develop basic skills in psychiatric assessment in order to best care for their patients.
- 2 *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, Text Revision (DSM-IV-TR) is the most widely accepted diagnostic reference. It, along with the American Psychiatric Association (APA) *Practice Guidelines for the Psychiatric Evaluation of Adults*, provides the clinician a standardized approach for the initial assessment and follow-up of patients with mental illness.
- 3 At times, it can be challenging to gather needed information from patients suffering from mental illness, as their condition prevents them from fully cooperating with the assessment. A range of strategies can be used to gather the needed information while increasing the safety and comfort of both patient and clinician.
- 4 A thorough medication history that assesses what medications were taken to treat the condition, in what combination, and whether there was an adequate trial (dose and duration) is a cornerstone of effective patient management.
- 5 A baseline mental status examination (MSE), along with a specific target symptom list, is a critical tool in monitoring response to treatment.
- 6 There is no consensus about what specific physical and laboratory tests are needed in the evaluation of patients with psychiatric conditions. Testing is best individualized based on the patient's age, medical history, current physical health, and current medication use.

1 Patients with mental illnesses are treated by all disciplines and in all settings of health care and may in fact receive the bulk of their care from nonpsychiatrists. Hence the need for good psychiatric assessment skills is not limited to mental health specialists. Along with traditional assessments used across all medical specialties (laboratory tests, medical history, and physical examination), psychiatrists use additional strategies to manage their patients that are less objective and perhaps less familiar to the nonpsychiatrist. This chapter provides a basic overview of appropriate assessment techniques used by clinicians when working with psychiatric patients to develop an individualized treatment plan. Readers needing greater depth than the materials provided in this chapter are referred to other reference materials.¹⁻⁵

OVERVIEW OF DIAGNOSTIC AND STATISTICAL MANUAL OF MENTAL DISORDERS

2 *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, Text Revision (DSM-IV-TR) is the most widely accepted and most important diagnostic reference used in the care of the mentally ill. It provides a common language for mental health practitioners to describe and diagnose psychiatric disorders.⁶ Common language is essential because there is considerable overlap of symptoms across

many diagnoses. The DSM-I was introduced in 1952 and was the first manual on mental disorders to contain a description of diagnostic categories. The most recent edition, DSM-IV-TR, was released in 2000. The DSM-IV-TR uses essentially the same diagnostic criteria sets as DSM-IV.⁶ Its purpose is to correct factual errors in DSM-IV and update the text sections (e.g., associated features, prevalence, and differential diagnosis) with more contemporary data. A more significant rewriting of diagnostic criteria and introduction of new diagnoses will appear in DSM-V, which probably will not be available until 2006.⁶ The DSM-IV-TR contains many components that provide a comprehensive understanding of a specific mental illness and assist clinicians in making an accurate diagnosis. For example, the multiaxial patient evaluation ensures that most factors that could contribute to, or complicate, the condition are considered during a patient assessment and treatment planning. Axis I lists the principal psychiatric disorder, developmental disorders, or provisional diagnoses present in the patient. Mental retardation and personality disorders are listed on Axis II. Axis III lists existing physical disorders or conditions. Axis IV lists the severity of psychosocial stressors that may have contributed to a new or recurrent mental disorder or exacerbation of an existing condition. Stressors are rated on a scale of 1 (none) to 6 (catastrophic) and can be acute (lasting less than 6 months) or enduring (lasting longer than 6 months). Examples of stressors include difficulties with interpersonal relationships, parenting, occupation, living circumstances,

finances, the legal system, and health. Axis V describes the global assessment of functioning (GAF), rated on a scale from 1 (persistent danger to self or others) to 90 (minimal or absent symptoms). A GAF rating is based on the current level of functioning compared with the highest level of functioning seen in the previous months to a year prior to the current evaluation. By documenting the baseline level of functioning, the GAF helps evaluate progress toward a patient's therapeutic goals.

DSM-IV-TR provides general information on all mental disorders recognized by the American Psychiatric Association (APA) and includes age of onset, clinical course, complications, predisposing factors, prevalence, and differential diagnoses. The specific diagnostic criteria for each mental illness and the number of symptoms required to establish a diagnosis are also listed. The DSM-IV-TR also includes decision trees for differential diagnosis and a glossary of technical terms. *The Clinical Interview Using DSM-IV* is a 2-volume companion publication that provides extensive information on interviewing techniques assisting the clinician in establishing a specific diagnosis using DSM-IV criteria.⁷

Additional information besides the DSM-IV-TR diagnosis is required before a comprehensive treatment plan can be developed. The *American Psychiatric Association Practice Guidelines for Psychiatric Evaluation of Adults* offers a more comprehensive approach to patient assessment. It includes a full discussion of the domains needed for a thorough clinical evaluation, including chief complaint; history of present illness; past psychiatric history; general medical history; social, family, and occupational history; physical and mental status examinations; and diagnostic tests. It further describes issues of privacy, evaluations in the elderly, and techniques for working with multidisciplinary teams.⁵

In summary, by using the DSM-IV-TR and the American Psychiatric Association Practice Guidelines, clinicians can evaluate patients

in a systematic manner, thereby creating better treatment plans and a more consistent evaluation of response.

THE CLINICAL INTERVIEW

The interview should be conducted in a quiet, nonstimulating, and comfortable area where the patient and the interviewer feel at ease. The interviewer should introduce himself or herself and explain the procedure in order to facilitate establishment of a trusting relationship. Generally, open-ended questions should come first, followed by questions focused on more specific or personal data. Open-ended questions allow the patient to provide descriptions and other information in his or her own words. Even though more specific questions may then be necessary to fill in the gaps, beginning in this manner minimizes the risk of "leading" the patient. Patients may respond to specific questions and "yes" or "no" questions with answers they think the interviewer wants to hear. The interviewer must be nonjudgmental about the information offered by the patient in order to develop trust and rapport with the patient and to ensure completeness and accuracy of the information. Whether a clinician takes notes during the interview is an individual decision, with the primary considerations being to make an accurate record of the content of the examination and assuring that the patient is comfortable with the note taking. Table 60–1 provides examples of questions that can be used to gather information during the completion of the clinical interview.

THE CHALLENGING PATIENT

3 Patient assessment may be challenging when symptoms of the condition prevent effective engagement between the patient

TABLE 60–1. Examples of Interview Questions for Assessing Mental Illnesses

Mania

1. Do your thoughts go faster than you can say them?
2. Have you noticed a change in the amount of sleep that you require?
3. Have you spent a lot of money lately and what did you spend it on?
4. Do you have a lot of extra energy?
(To assess hallucinations and delusions, see schizophrenia section below.)

Depression

1. Do you cry without any reason?
2. Do you still enjoy the same hobbies/activities that you once did?
3. Has your weight changed recently?
4. Have you had changes in your energy level recently?
5. Do you have any guilty feelings?
6. Do you find it difficult to remember phone numbers, names of friends, appointments, etc?
(To assess sleep and suicidal potential, see sleep and suicide sections below.)

Schizophrenia

Delusions

1. Do you feel that people plot against you?
2. Do you ever feel that you are watched or spied on?
3. Do you have any special abilities?
4. Does anyone ever try to mess with you or bother you?
5. Do others read your thoughts?

Hallucinations

1. Does the TV/radio ever tell you things?
2. Do you hear voices that other people don't hear?
3. What do they say? How many voices?
4. How often do they bother you?

5. Do the voices ever tell you to hurt yourself or someone else?
6. Have you ever heard your name called when there is no one there?
7. Have you ever seen anything strange that you can't explain?
8. Do you ever see things that bother you and no one else?
9. Do you want to act on what the voices say?

Thought broadcasting/insertion

1. If I stood by you could I hear your thoughts?
2. Does your head ever act like a radio?
3. Do you feel that others can put thoughts in your head?

Insight

1. What reasons did your family give you for coming here?
2. What brought you here?
3. Do you consider yourself in need of help?
4. What does your medication do for you?

Sleep

1. Tell me about your sleep.
2. How many hours do you sleep each night at present?
3. How many hours do you usually sleep at night?
4. Do you sleep all through the night?
5. Is there a reason for your waking up?
6. Do you have trouble falling asleep?
7. How do you feel when you wake up?

Suicide potential

1. Do you feel your life is worth living?
2. Do you ever think of hurting yourself?
3. Do you see things improving in the future?
4. Do you think you will try to hurt yourself now?
5. How would you do it?
6. Do you have the means to hurt yourself?

and the clinician. Patients ramble if their speech patterns are circumstantial or tangential in nature, or they ruminate as part of a depression. Patients in the manic phases of bipolar disorder may not pause as they speak, making it difficult for the interviewer to interject. In all cases, the interviewer can regain control of the assessment by politely redirecting the patient back toward the question. Psychotic patients may be paranoid as part of their illness and appear guarded or frightened by the questions. The best approach is to remain calm and respectful with the patient and try using shorter or more close-ended questions to seek the desired information. Patients with mental illnesses can become agitated and occasionally violent. Often the violence is preceded by increasing psychomotor agitation as evidenced by pacing, speaking in a loud voice, or gripping the arms of the chair very firmly. If the interviewer is concerned about safety, he or she should avoid any behavior that could be misconstrued as threatening, such as touching the or staring unnecessarily and should complete the interview in the presence of another health care provider. Both the patient and the interviewer should have equal access to leave the room if either becomes too uncomfortable during the interview. If a patient describes suicidal thoughts, he or she should be further assessed using the questions outlined in Table 60–1, and depending upon the results of further assessment be directed to the appropriate type of care, including hospitalization for patients at immediate risk of harming themselves. A suicidal patient should never be left alone. Asking a patient about suicidal thoughts will not increase the risk, as patients are able to reach these conclusions independently of the interviewer’s questioning. Before any conclusions are made about the content of the interview, consideration of the impact of culture on the patient’s presentation should be made. Something that sounds delusional in Western culture may be the norm in other cultures. If a clinician is unclear whether culture of origin accounts for some of the patient’s symptoms, they should more fully explore these options before any conclusions are drawn.

PSYCHIATRIC HISTORY

Both the patient’s and their family’s history of mental illness provide important information when formulating a diagnosis and treatment plan. Information should be descriptive and include the current and previous psychiatric diagnoses, presentation of each illness, time frame between episodes, level of functioning between episodes, length of each episode, total duration of illness, and treatment given during each episode. Baseline functioning or the highest level of functioning achieved in the past few years is important information because it provides a target or goal for treatment. Information on the history of the current episode and reasons for coming to the clinician also should be gathered. A family history should include a medication history of the immediate relatives because a family member’s response to a given medication may predict an individual patient’s response to that same medication.

SOCIAL HISTORY

A social history should include educational and occupational background, religion, marital status, substance use patterns including smoking, and current living situation. By understanding a patient’s living environment and social situation, strategies to prevent noncompliance, reduce stress, and increase social support can be developed.

MEDICATION HISTORY

4 A thorough medication history is one of the most important contributions a clinician can make to treatment planning. The

history should include medications for both psychiatric and medical conditions. It should list all medications taken by the patient, and report on how each was tolerated and the nature of the response to that drug or combination of drugs. Because most psychiatric medications have a delay in the onset of effect, it is important to determine whether an adequate trial (adequate dose and duration) was provided before the patient was considered nonresponsive to that drug. If a patient has a history of noncompliance, specific causes such as cost, complicated dosing schedules, lack of insight, and adverse effects should be investigated.

MENTAL STATUS EXAMINATION

5 The mental status examination (MSE) is a key patient assessment in psychiatry and is analogous to the physical examination in medicine. The MSE is completed through a direct patient interview, and it results in a description of current patient behavior, thoughts, perceptions, and functioning. The results of an MSE provide an objective evaluation used in diagnosis, assessment of the course of the illness, and response to treatment. The MSE is combined with other components of the patient work-up (history of present illness, physical examination, appropriate labs, and medical and psychiatric history) in order to give a full picture of the presenting problem and factors contributing to the illness. An MSE has several components.^{5,7}

APPEARANCE AND ATTITUDE TOWARD EXAMINER

The appearance of the patient throughout the interview should be noted, including age, dress, grooming and hygiene, use of cosmetics, and facial expressions. A description of appearance also should include unusual physical characteristics and the general state of physical health. The interviewer should note whether the patient is cooperative, mute, hostile, paranoid, guarded, or withdrawn.

ACTIVITY

Changes in motor activity include overactivity, underactivity, and catatonia. Overactivity is an increase in purposeful movements or agitation and can include pacing; hand wringing; picking at clothing, skin, or hair; inability to sit still during the interview; and excessive hand gestures. Underactive patients move less than expected. Patients with rigid posture, an absence of movement, and failure to communicate may be catatonic, paranoid, or experiencing medication-induced adverse effects.

SPEECH AND LANGUAGE

The quantity, flow, and speed of speech and the amount of eye contact should be noted. Speech should be assessed as to whether it proceeds logically in a goal-directed manner or whether the content is vague and poorly organized. Abnormal speech characteristics include *blocking*, whereby the person suddenly stops speaking without any obvious reason. *Thought blocking* usually occurs when a hallucination or delusion intrudes into the person’s thinking or when upsetting issues are discussed. *Circumstantial speech* lacks a clear direction because of excess unnecessary information, but the circumstantial patient eventually will make his or her point. In *tangential speech*, however, the ultimate point is never made. *Perseveration* is repetition of an original answer to subsequent questions. *Flight of ideas* is overproductive, rapid speech during which the patient jumps rapidly from

one idea to the next. *Mutism* is identified when the patient does not respond even though he or she is aware of the discussion.

MOOD AND AFFECT

Affect describes the patient's current emotional tone, as expressed through facial expression and tone of voice, all of which may be objectively observed by the clinician. *Mood* describes more sustained feelings which are subjectively reported by the patient. To properly evaluate a patient's mood and affect, his or her appearance and the content of speech must be considered. Change in facial expression and the presence of tears, flushing, sweating, or tremors should be noted. Affect can be described further by its range, appropriateness, intensity, and stability. For example, in schizophrenia or depression, the affect may be flat, whereby no change in expression occurs throughout the interview. In contrast, during a manic episode, the affect is very intense and often labile. The range of emotional expression is reduced, but not absent, with blunted affect. An example of inappropriate affect is when a patient laughs when he or she is depressed or cries when stating that he or she is happy. A rapidly shifting affect from one extreme to the other is described as labile.

THOUGHT AND PERCEPTUAL DISTURBANCES

A variety of thought disturbances can occur in mental illness. These disturbances generally indicate the presence of psychosis, or impaired reality testing. *Delusions* are fixed, false beliefs that are not based in reality or consistent with the patient's religion or culture. Delusions can be paranoid, somatic, or grandiose in nature. Delusions are often unshakable, and one should not attempt to talk a patient out of a delusion. *Thought broadcasting* is the belief that one's thoughts are audible to others. *Hallucinations* are false sensory impressions or perceptions that occur in the absence of an external stimulus. Hallucinations may be auditory, visual, olfactory, or gustatory, and may be continuous or intermittent. In contrast, *illusions* are visual misperceptions involving a misinterpretation of a real sensory stimulus. For example, a person who initially misperceives a curtain blown by the wind to be an intruder has experienced an illusion. This phenomenon is not indicative of psychiatric illness, and can be seen in normal persons. Other thought disturbances are not considered to be psychotic. For example, the couplet of obsessions and compulsions may be indicative of the presence of obsessive-compulsive disorder, which is not considered to be a psychotic disorder. *Obsessions* are unwanted thoughts or ideas that intrude into a person's thinking. *Compulsions* are actions performed in response to the obsessions or to control anxiety associated with the obsession.

NEUROPSYCHIATRIC EVALUATION

A neuropsychiatric evaluation assesses sensorium, attention, concentration, memory, and higher cognitive functions such as orientation and abstraction. Prior to initiation of the neuropsychiatric evaluation, it should be documented whether the patient has received medications with sedative properties, because the outcome of the examination could be altered if central nervous system depressants have recently been taken.

Sensorium, or level of consciousness, refers to the alertness of the patient, and if he or she is not fully alert, the amount of stimulation needed to awaken the patient. Attention and concentration can be assessed using serial 7s or 3s, whereby the patient subtracts backward

from 100 in increments of 7 or 3, respectively. Another concentration test is to have a patient spell a five-letter word backward. Language skills are assessed initially by having a patient read something aloud and silently. General intelligence can be assessed loosely by asking factual information about current news items, recent presidents, or popular television shows or sporting events. Memory is the ability to recall past experiences and is classified as sensory stores, which lasts seconds, short-term memory (the ability to recall information immediately after acquisition), working memory (i.e., immediate application of visual or auditory instructions), and long-term or remote memory (historical facts). Orientation to time, place, person, and situation assesses sensory stores and short-term memory. Asking a patient to recall three objects 5 minutes after they are learned is the definitive test for short-term memory. Patients with depression or anxiety may have deficits in short-term memory. Asking the patient to do a certain task such as pick up a pen with his or her right hand and then fold a piece of paper and pass it to the examiner can assess the patient's working memory. Patients with cognitive deficits such as those seen in dementias and schizophrenia may exhibit deficits in working memory. Remote memory is assessed by asking the patient to recall old facts about their life, such as where they were born or where they went to school. Remote memory usually stays intact the longest in patients with intellectual decline, while the ability to create new memories is generally the first sign of a memory deficit. Abstraction is the ability to interpret information such as a proverb ("People in glass houses shouldn't throw stones") or identify similarities or differences between words (apple and orange). Abstraction is influenced by education and linguistic fluency; thus inability to abstract is not always a sign of a psychiatric disorder.

INSIGHT AND JUDGMENT

Insight refers to patient awareness that they have a mental illness and the consequences of that illness on their life. Patients typically have a lack of insight when they are psychotic. Patients with poor insight are often noncompliant with prescribed medications. *Judgment* is the ability to make decisions appropriate to the situation and may be impaired in a variety of mental illnesses. Often this can be assessed by asking the patient how they would handle either their current or a hypothetical situation. Both insight and judgment can be quite fluid. For example, an intoxicated patient may demonstrate poor insight and judgment which improves over several hours as blood alcohol levels diminish.

PHYSICAL AND LABORATORY ASSESSMENT IN PSYCHIATRY

Patients who present with psychiatric symptoms need a careful medical assessment for many reasons.¹⁻³

Both medical illnesses and medications can cause psychiatric symptoms. The rapidity of onset of psychiatric symptoms is an important clue that a medical cause may be present. Most chronic mental illnesses have a prodromal period, whereas medically based psychiatric symptoms often have a more rapid onset of symptoms. Patients over age 40 at first presentation are more likely to have a medical cause for their psychiatric symptoms because major psychiatric illnesses such as schizophrenia and bipolar disorder usually first present in adolescence or early adulthood. A family history of physical illnesses with a psychiatric component, such as Huntington's chorea or systemic lupus erythematosus, may provide an additional clue.

Patients with fluctuating levels of consciousness, disorientation, memory impairment, or visual, tactile, or olfactory hallucinations, substance abuse, and serious medical conditions are more likely to have a medical basis for their illness.

Patients with psychiatric illnesses, especially depression and anxiety disorders, will often present with only physical complaints, leading to inappropriate care for medical problems that are not present or as serious as they may appear, while the root cause is ignored. Psychotropic medications can cause or exacerbate medical conditions, such as diabetes mellitus or cardiac arrhythmias, necessitating an understanding of the patient's other risk factors for these conditions before medication is selected. Finally, patients with chronic psychiatric illnesses often receive inadequate health care and have poorly controlled medical conditions for many reasons, including their appearance or behavior prohibiting a thorough evaluation, inaccurate information from the patient secondary to impaired memory or perception, and incomplete data to make an appropriate diagnosis and treatment recommendation. In a recent retrospective review, it was found that patients with diabetes or hypertension and diagnoses of schizophrenia, bipolar disorder, or posttraumatic stress disorder were statistically less likely to utilize medical services than similar patients without these psychiatric conditions.⁸

6 There is no consensus about specific laboratory tests needed in the evaluation of a patient with mental illness.^{2,5} General laboratory screening is useful for ruling out medical causes of psychiatric illnesses, but extensive testing is usually unnecessary and not cost-effective. Laboratory tests should be individualized to the age, medical history, cooperativeness, and physical health of the patient. For example, a fasting glucose determination is preferred over a random measure when a patient takes medications known to cause significant weight gain and/or induce diabetes mellitus.⁹ If available, recent laboratory tests can be used to evaluate medical status, provided that no change in physical status has occurred since they were taken.

A complete physical examination, along with a detailed medical and medication history, vital signs, weight and body mass index, and routine blood chemistry are commonly part of the work-up of persons with mental illness. Clinicians will want diagnostic tests to help evaluate the relative safety of specific medications (e.g., renal status when using lithium or an electrocardiogram when using a tricyclic antidepressant such as amitriptyline or an antipsychotic such as ziprasidone or clozapine) or when baseline information is needed to identify future adverse effects from medications (e.g., lithium-induced hypothyroidism, clozapine-induced leukopenia, antipsychotic-induced diabetes mellitus). Serum concentration monitoring of selected medications is also helpful in increasing probability of response and minimizing the likelihood of adverse effects. Urine drug screens and blood alcohol tests play an important role in identifying the contribution of substances of abuse to the presenting symptoms.

In patients with underlying medical problems, more extensive testing is indicated to rule out possible contributing etiologies or confounding factors which may create similar presenting symptoms. Additional testing can include an electroencephalogram to evaluate for the presence of seizure activity or other neurologic conditions, computed tomography or magnetic resonance imaging to detect structural abnormalities, sedimentation rate and antinuclear antibodies for autoimmune disorders, a test for the human immunodeficiency virus, thyroid function tests, or B₁₂ and folate concentrations for anemias.²

The identification of biologic markers as diagnostic tools and predictors or indicators of drug response is of great interest but currently of little clinical utility. The most promising was the dexamethasone suppression test, proposed to be a marker for endogenous melancholic depression. However, its lack of sensitivity and specificity has

limited its utility as a routine screening tool during a work-up for depression.²

In summary, a range of assessments aids the clinician in making an accurate diagnosis and identifying underlying or potential drug-related problems. The MSE is the cornerstone of the psychiatric work-up, although selective medical tests, a good medical, psychiatric and medication history, and a thorough physical exam are also important.

PSYCHIATRIC RATING SCALES

Psychiatric rating scales can be useful tools to provide an objective way of measuring subjective data (i.e., feelings, thoughts, and perceptions), assess certain domains of psychiatric illnesses, and even to diagnose disorders. Unfortunately it may be puzzling to the rater since there are so many types of scales to choose from. The rater needs special training and experience to use and select the most appropriate scale that will assess the specific domain under question. These specific domains may include: cognition, behavior (i.e., aggression), severity of illness including response to treatment and medication side effects, level of functioning, and quality of life. These tools may be used in a variety of settings, including research and patient care and may serve an administrative purpose such as quality control.⁴

Some drawbacks include a substantial time commitment for staff to administer the tests and the inability of some patients to tolerate these interviews, especially patients who are severely paranoid or agitated. In addition, a single psychiatric rating scale score may only provide a limited picture or snapshot of a complex clinical situation. Therefore repeated ratings are usually necessary to objectively describe longitudinal changes over a defined treatment period.

Some rating scales are self-administered and do not require a staff member to interview a patient; thus they require minimal resources to administer. However, there are many cases in which the patient is unable to complete a questionnaire for a variety of reasons, including literacy and severity of symptoms.

In contrast to symptom-based rating scales (i.e., brief psychiatric rating scale [BPRS] or Hamilton Rating Scale for Depression [HAMD]), global rating scales such as the Clinical Global Impression (CGI) scale assess the overall severity of illness based on a rater's clinical experience.¹⁰ The rating scale will not determine the reason for the symptoms. For example, a patient may have a high global severity score; however, the scale will not specifically elucidate whether the severity of illness is due to paranoia or a primary anxiety disorder. Second, when evaluating the results of rating scales either clinically or in the literature, it is important to know the range of clinically significant scores; for example, a patient may have a statistically significant (e.g., *p* value <0.05) drop in a rating scale score from one week to the next, but remain severely ill.

Psychiatric medication treatment can potentially expose a patient to a myriad of adverse effects. To ensure safe medication use and to decrease clinician liability, rating scales are available to measure adverse side effects. Global and specific assessments of adverse effects are a federal requirement in clinical drug trials. In clinical practice medical professionals should also report significant adverse medication reactions to the U.S. Food and Drug Administration (FDA) using MEDWatch.¹¹ Often, important adverse effects are realized only after a medication product has been prescribed to a large population in the postmarketing period. Specific adverse side effect measures may be used for specific categories of medications. For example, patients treated with antipsychotic agents may be susceptible to extrapyramidal side effects (EPSs). Tardive dyskinesia is a potentially irreversible

TABLE 60–2. Adverse Effects Measures

| Rating Scale | Type | Scoring | Comments |
|---|---|--|--|
| Systematic Assessment for Treatment Emergent Events—General Inquiry (SAFTEE-GI) | Structured interview and global assessment | Summary scores of number of events, average severity, and impairment | 5–10 minutes to complete. Baseline and weekly evaluations. Easy to administer. The specific reported information may be more useful than an overall summary score |
| MED Watch | Global assessment | No scoring involved | Minutes to complete. The one-page form requires a narrative description of the problem or adverse reaction. Online submission: http://www.fda.gov/medwatch/ |
| Abnormal Involuntary Movement Scale (AIMS) | Tardive dyskinesia assessment | 12-item, 5-point severity scale. Items 1–4 orofacial movement; 5–7 extremity and truncal movement; 8–10 global severity; 11 and 12 problems with teeth or dentures (yes or no) | 5–10 minutes to complete. Commonly used in most clinical settings for dyskinesia assessment. Requires training and clinical experience to make diagnosis. Diagnostic criteria: at least 3 months of antipsychotic treatment. Mild severity score (2) in two discrete areas or moderate severity (3) in one area (i.e., orofacial) |
| Dyskinesia Identification System: Condensed User Scale (DISCUS) | Tardive dyskinesia assessment | 15-item, 5-point severity scale. Items 1, 2 face; 3 eyes; 4, 5 oral; 6–9 lingual; 10, 11 head/neck/trunk; 12, 13 upper limb; 14, 15 lower limb | 10–15 minutes to complete. More descriptive criteria for scoring severity than the AIMS. Scoring based on three dimensions: frequency, detectability, and intensity. A flow chart is provided in the user's manual to assign an item score |
| Rating Scale for Extrapyrarnidal Side Effects (Simpson-Angus EPS Scale) | Drug-induced Parkinson's and dystonia assessments | 10-item, 5-point anchored severity scale. Mean score is obtained by adding all scores and dividing by 10. A mean score of 0.3 is the upper limit for no EPS | 10 minutes to complete. Item domains include gait, arm dropping, shoulder shaking, elbow rigidity, wrist rigidity, leg pendulousness, head dropping, glabella tap, tremor, and salivation. Requires training and practice to administer |
| Barnes Akathisia Rating Scale (BARS) | Drug-induced akathisia | 4 items including three 4-point anchored severity scored items and a 5-point global rating score item. Total score of 12 possible | 10 minutes to complete. Items 1–3 (objective akathisia, subjective awareness of restlessness, and subjective distress related to restlessness). Diagnostic criteria: requires both objective and subjective ratings of at least 1 in either two subjective items. Pseudoakathisia is suggested with a positive objective rating but no subjective score is noted |

EPS, extrapyramidal symptoms.

Adapted from Schooler and Chengappa¹¹ and Sprague and Kalachnik.¹²

movement disorder (see Chap. 66 on schizophrenia) that requires close monitoring approximately every 3 to 6 months if present during treatment with antipsychotic agents.¹² Table 60–2 provides a summary of the most common rating scales used to assess and quantify the presence and severity of adverse effects.

Sensitivity, specificity, reliability, and validity are important considerations when selecting a rating scale. The sensitivity of a test refers to its ability to detect a symptom or illness, given that the symptom or illness is present. Specificity refers to a test's ability to determine that a symptom or illness is absent given that the person does not have the illness.

Reliability is the extent to which the score on the scale reflects the hypothetical "true" score and how much interference occurs from outside influences.¹³ Reliability is reported by the correlation coefficient, which represents a chance correlation (zero) or perfect correlation (one). Rating scales with reliability correlation coefficients of less than 0.7 are usually considered unreliable for clinical studies. Interrater reliability—agreement in rating scores among clinicians—is important to achieve when multiple clinicians rate the same patient or population. Interrater reliability is established by having all raters independently rate individual patients at the same time to determine the correlation of their scores. Other types of reliability include

TABLE 60–3. Schizophrenia Rating Scales

| Rating Scale | Type | Scoring | Comments |
|--|-----------------|--|--|
| Brief Psychiatric Rating Scale (BPRS) | Clinician-rated | 18 items, 7-point severity scale: score ≥ 38 indicates moderate severity | The anchored BPRS provides descriptions of each severity rating to increase the interrater reliability. The BPRS has four clusters of symptoms: thinking disturbance, anxious depression, withdrawal-retardation, and hostility-suspiciousness |
| Scale for Assessment of Negative Symptoms (SANS) | Clinician-rated | 30 items, 6-point severity scale: 0 = normal; 5 = severe | Measures degree of: affect, avolition, anhedonia, and attention |
| Schedule for Affective Disorders and Schizophrenia—Change (SADS-C) | Clinician-rated | 29-item, 6-point scale and global assessment scale. Subsets of items can be combined to score specific affective symptoms | Structured interview to measure change in symptoms and assess anxiety, depression, manic features, and delusions or disorganization |
| Positive and Negative Syndrome Scale (PANSS) | Clinician-rated | 30-item scale, 7-point severity scale | Based on the 18-item brief psychiatric rating scale |
| Nurses' Observation Scale for Inpatient Evaluation (NOSIE) | Observational | 30-item, 5-point severity scale 0 = never; 1 = sometimes; 2 = often; 3 = usually; 4 = always | Patient behavior is rated daily |
| Clinical Global Impression (CGI) Scale | Observational | Severity of illness 7-point rating scale. Global improvement 7-point rating scale. Efficacy index: 1–4 marked improvement; 5–8 moderate; 9–12 minimal; 13–16 unchanged/worse | Observational rating scale to compare severity of illness compared to other similar patients and measures improvement from baseline. The efficacy index measures therapeutic effect and side effects to determine the score |

test-retest reliability (assesses the stability of the scale in producing the same results with repeated use) and internal consistency (the degree to which items in the scale measure different aspects of the same condition without overlap).

Validity, in contrast, is the ability of a scale to measure what it was designed to measure. Content validity measures the extent to which the scale assesses appropriate aspects of the illness. Concurrent validity is a measure of the correlation of the rating scale with an external measure such as diagnosis or clinical change. Construct validity is the extent to which the test appears to measure

symptom traits in contrast to measuring a more limited, specific symptom.

Psychiatric rating scales should not be confused with psychological tests such as neuropsychological and intellectual assessments, and are best used as only one part of a comprehensive diagnostic plan. Tables 60–3, 60–4, and 60–5 describe commonly used patient-rated and clinician-rated scales for a variety of disease states.^{14–19} In clinical research, a combination of clinician- and self-rated rating scales and diagnostic tests provides the most accurate measurement of drug efficacy and treatment outcome.

TABLE 60–4. Depression Rating Scales

| Rating Scale | Type | Scoring | Comments |
|--|-----------------|---|--|
| Hamilton Psychiatric Rating Scale for Depression (HAM-D) | Clinician-rated | 17-item scale; <6 = normal mood; 17–25 = mild depression; >25 = severe depression | Used to screen patients for drug studies and to determine severity of symptoms, treatment outcome, and is the standard to compare other depression rating scales |
| Montgomery Asberg Depression Rating Scale (MADRS) | Clinician-rated | 10-item, 7-point scale. For each item: 0 = no symptoms; 6 = severe symptoms | Differentiates between all the intermediate grades of depression. Decreases bias in patients with other medical illness and increased somatization |
| Beck Depression Inventory (BDI) | Patient-rated | 21-item scale; 0–9 = normal; 10–15 = mild depression; 16–19 = mild-moderate; 20–29 = moderate-severe; 30–63 = severe depression | The standard for self-rating scales and an objective measure of change in symptoms as a result of treatment |
| Zung Self-Rating Depression Scale (SDS) | Patient-rated | 20-item scale, 4-point severity; <50 normal; 50–59 minimal-mild; 60–69 moderate-marked; ≥ 70 severe depression | Severity rated by frequency of occurrence of symptoms. May not be as sensitive in measuring changes in severity of symptoms |
| Raskin's Mood Scales and Modified Mood Scales for Depression (RMS) | Patient-rated | 53-item scale | Measures the presence or absence of symptoms. Sensitive in measuring changes resulting from treatment |

TABLE 60–5. Anxiety Rating Scales

| Rating Scale | Type | Scoring | Comments |
|--|------------------------------|--|---|
| Hamilton Anxiety Scale (HAM-A or HAM-AS or HAMRS) | Clinician-rated | 14 items, 5-point scales; scores of ≥ 18 –20 for moderate anxiety | Consists of subscales to measure somatic and psychic anxiety |
| Self-Rating Anxiety Scale (SAS) (Zung) | Patient-rated | 20-item scale; 4-point intensity ratings | Correlates to the clinician-rated Anxiety Status Inventory (ASI); however, there is little information on the validity of either test |
| State Trait Anxiety Inventory (STAI) | Patient-rated | 20-item state anxiety (A-state) and 20 items trait anxiety (A-trait); 4-point intensity ratings; total scores range from 20–80 | A-Trait scale reflects the patient's general or baseline anxiety. A-State scale reflects the patient's most current anxiety and measures changes in anxiety. The A-State score is sensitive to stress-induced testing |
| Sheehan Panic and Anticipatory Anxiety Scale (SPAAS) | Patient- and clinician-rated | Three-part scale | Measures panic attacks, anticipatory anxiety, and limited symptom attacks |
| Yale-Brown Obsessive Compulsive Scale (YBOCS) | Clinician-rated | Semistructured interview | Consists of several clusters of obsessions and compulsions. Used to assess change in treatment studies |

SYSTEMATIC MEASUREMENT OF COGNITIVE FUNCTION

Neuropsychiatric rating scales provide specific information such as the rate of change and severity of cognitive decline or improvement. They are useful in situations in which repeated measurements of a patient's mental status are needed because they allow the clinician to determine response to an intervention (e.g., medication) in a more systematic manner. In addition, some cognitive function measures are useful screens for Alzheimer's and other dementias, cerebral infarction, and encephalitis or encephalopathies. A number of cognitive

rating scales are available, the most common being the mini-mental status examination (MMSE). The MMSE globally assesses many cognitive domains including orientation, visuospatial organization, memory, and reasoning to determine an overall score of cognitive function. The MMSE takes 5 to 10 minutes to administer and is used routinely in the clinical setting.²⁰ Other examples of cognitive rating scales include the information-memory-concentration (IMC) test the dementia rating scale (DRS), and the clock drawing and Alzheimer's Disease assessment scale.^{20,21} Some scales are useful for identifying deficits in specific cognitive domains such as orientation, speech and language, visuospatial, visuoperceptual and visuomotor skills, memory, arithmetic calculations, and reasoning (Table 60–6).

TABLE 60–6. Selected Neuropsychiatric Measures

| Rating Scale | Type | Scoring | Comments |
|--|----------------------|--|--|
| Mini-Mental Status Examination (MMSE) | Structured interview | Maximum score is 30; 23 or less is indicative of cognitive impairment. Level of consciousness also listed | 5–10 minutes to administer. Global assessment of orientation, attention, recall and language, memory |
| Dementia Rating Scale (DRS) | Structured interview | Total scores range from 0–144 (perfect score) | 30–40 minutes to administer. Global measure of dementia using 5 subscales: attention, initiation and perseveration, construction, conceptualization, memory |
| Neurobehavioral Cognitive Status Examination (NCSE, COGNISTAT) | Structured interview | Eight separately scored cognitive domains (11 subsets). The 8 domains are scored and plotted on a graph provided | 5–10 minutes to nonimpaired and up to 30 minutes in impaired patients. Distinguishes confusional states from dementias by using separate domain scores such as language, memory, calculations, etc. Requires some practice; however, it is easy to administer. |
| Clock Drawing | Instructional | Qualitative assessment (template matching). Quantitative scoring. Points awarded for correctness of design | Assessment at bedside which involves either copying a clock, putting hands on a clock, and/or showing a specific time. Cognitive domains: comprehension, conceptualization, visuospatial skills |
| Alzheimer's Disease Assessment Scale (ADAS) | Structured interview | 21 items total; 11 items in the cognitive (COG) subset. 10 items in the noncognitive behavioral subset. Each subset may be scored separately from the total ADAS score | Takes 45 minutes to administer the ADAS and 35 minutes for the ADAS-COG. The ADAS-COG refers to the cognitive assessment subset commonly used to measure cognitive function in clinical drug trials. Requires training for administration and scoring |

TABLE 60–7. Common Psychological Tests**Wechsler Adult Intelligence Scale-Revised (WAIS-R) and Wechsler Intelligence Scale for Children-Revised (WISC-R)**

Measures abstract thinking, learning from experience, problem solving, adjustment to new situations. Score less than 70 denotes mental retardation

Bender Visual Motor Gestalt Test

Screening test for brain damage, learning problems, emotional difficulties, nonverbal intelligence. Person is asked to reproduce nine geometric designs

Interpretation of Projective Drawings

Patient draws a person, house-tree-person, family, or spontaneously to assess unconscious feeling, conflicts, and strengths

Rorschach

Patient interprets 10 inkblots and explains what they mean. Assesses personality structure

Minnesota Multiphasic Personality Inventory (MMPI-2)

Measures personality traits from 567 true/false questions. Can be affected by intelligence, education, socioeconomic status

Most of the rating scales involve a structured interview that requires clinician training to ensure accurate administration. Noise and distraction can affect the patient's performance ability; therefore the interview should be conducted in a quiet area with adequate lighting. The interviewer should speak slowly and clearly to the patient when providing instructions or asking questions.

PSYCHOLOGICAL TESTING

Although most clinicians do not administer psychological testing, they can use the results to evaluate the role of medication in relationship to the diagnosis. Psychological testing alone cannot establish a firm diagnosis but can be a useful diagnostic tool when coupled with clinical judgment. Types of psychological testing include personality tests, intelligence tests, and neuropsychological tests.³ Table 60–7 describes common psychological tests.

CONCLUSIONS

Patient assessment is the basis from which a pharmaceutical care plan evolves. Problem identification and therapeutic monitoring cannot occur until a thorough assessment is complete. The initial assessment is also the basis for evaluating response to therapy throughout the course of treatment. Psychiatric assessment requires sensitivity and good listening skills on the part of the clinician because it is based primarily on a subjective interview and not objective tests. With careful data collection, clinicians can make substantial contributions to care that improve patient outcomes.

CHILDHOOD DISORDERS

Julie A. Dopheide, Karen A. Theesen, and Michael Malkin

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Inattention and impulsivity due to attention-deficit/hyperactivity disorder (ADHD) begins before age 7 and can continue into adolescence and adulthood, often requiring ongoing drug treatment.
- 2 Coexisting disorders have an impact on drug selection. A mood stabilizer is appropriate if bipolar disorder coexists, while an antidepressant may be needed if a mood or anxiety disorder coexists.
- 3 Stimulants are first-line treatment for ADHD; atomoxetine, bupropion, and tricyclic antidepressants (TCAs) are second-line agents; clonidine, guanfacine, and other medications are adjunctive treatments.
- 4 Tourette's disorder presents with both motor and vocal tics, which are present during childhood, plateau during adolescence, and may continue during adulthood with a fluctuating course.
- 5 The decision to medicate for Tourette's disorder is based on the degree of concern perceived by the patient, symptom severity, and comorbid disorders.
- 6 Individuals with Tourette's disorder are particularly sensitive to medication side effects, so medication dosing must be individualized carefully, and close monitoring is essential.
- 7 Nondrug approaches to enuresis management, such as dry-bed training or using moisture-sensitive alarms, are preferred because of higher cure rates and avoidance of drug side effects.
- 8 Desmopressin is effective orally and intranasally for enuresis, but it is expensive and works better in older than in younger children.
- 9 Imipramine and other TCAs are effective for enuresis at wide dosage ranges. TCAs have rapid onset, but side effects may be problematic for some patients.

All neuropsychiatric disorders can first present during childhood.¹ Attention-deficit/hyperactivity disorder (ADHD), Tourette's disorder, and enuresis are the focus of this chapter because the onset of symptoms occurs explicitly during childhood.

Treating children with psychotropic drugs requires a very different approach than treating adults. A child's neurologic, physiologic, and psychosocial status is undergoing constant changes throughout the developmental period. Age-related pharmacodynamic and pharmacokinetic differences can alter drug disposition and response. Well-defined diagnostic criteria guide drug selection;¹ however, frequent comorbid disorders present treatment challenges.² In addition, children may not be able to verbalize symptom response or adverse effects of a medication. All factors considered, children generally are given psychotropic drugs to control a group of symptoms or behaviors in order to facilitate the child's learning and development.

The psychiatric assessment of a child requires obtaining information from the child, parents, caregivers, and teachers.

ATTENTION-DEFICIT/HYPERACTIVITY DISORDER

CLINICAL PRESENTATION AND EPIDEMIOLOGY

ADHD evaluation should be considered whenever a child presents with developmentally inappropriate inattention, impulsivity, and or

hyperactivity (Table 61-1). Symptom presence and severity vary with the situation. It is unusual for a child to display signs of the disorder in all settings or even in the same setting at all times.¹ The onset of ADHD is typically by the age of 3 years and must occur by age 7, although the disorder may not require professional attention until the child enters school. The National Institutes of Health (NIH) estimate the prevalence in school-age children to be 3% to 5%;³ however, community sample estimates average 2.9% for girls and 9.2% for boys.⁴ Girls display more inattention and less hyperactive and impulsive symptomatology.^{3,4} Symptoms may persist lifelong for both sexes, but hyperactivity is much less prominent in adolescence and adulthood.^{2,4,5}

It is critical to clarify the diagnosis of ADHD in individuals with these symptoms. Inattention and distractibility can be symptoms of an anxiety disorder, depression, or bipolar disorder.^{2,3,6} In other cases, these anxiety or mood disorders can coexist with ADHD, just as learning deficiencies and conduct or oppositional disorders are common comorbid conditions.^{2,6,7} The presence of multiple comorbid conditions, particularly conduct or oppositional disorder, may increase the likelihood of ADHD chronicity.²

ETIOLOGY AND PATHOPHYSIOLOGY

ADHD is a clinical diagnosis with multiple heterogeneous causes.^{3,7} Both genetic and nongenetic factors are involved. The child of a

TABLE 61–1. Clinical Presentation of ADHD

| | |
|-------------------------------|---|
| Inattention | <ul style="list-style-type: none"> • Often fails to give close attention to details or makes careless mistakes in schoolwork or other activities • Often has difficulty sustaining attention in activities • Often has difficulty organizing tasks and activities • Avoids tasks that require sustained mental effort • Often does not seem to listen when spoken to directly • Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace • Is easily distracted by extraneous stimuli • Is often forgetful in daily activities • Loses things necessary for activities |
| Hyperactivity and impulsivity | <ul style="list-style-type: none"> • Often fidgets with hands or feet or squirms in seat • Often leaves seat when remaining seated is expected • Often runs about or climbs excessively at inappropriate times • Often has difficulty playing quietly • Is often on the go or acts as if driven by a motor • Often talks excessively • Often blurts out answers before questions have been completed • Often has difficulty waiting to take turns • Often interrupts or intrudes on others |

Symptoms must be present before age 7; six or more of the symptoms must persist for 6 months; significant impairment must be seen in two or more settings (e.g., home and school); symptoms must be documented by parent, teacher, and clinician.

Adapted from American Psychiatric Association.¹

parent with ADHD has up to a 50% chance of developing ADHD; monozygotic twins have up to a 92% concordance rate for ADHD.^{3,4,7} In addition, children with fetal alcohol syndrome, lead poisoning, and meningitis have a higher incidence of ADHD symptomatology.^{3,4} An association of ADHD with a variety of environmental risks including obstetric adversity, maternal smoking, and adverse parent-child relationships has been noted.^{7,8} Dietary causes are unlikely.^{3,4}

Although brain studies show no definitive pathophysiologic markers of ADHD, the prefrontal cortex, basal ganglia, and caudate volumes are consistently reported as abnormal, typically smaller.^{9–12} In addition, individuals with ADHD are twice as likely to display a defective 7-repeat allele of the dopamine₄ receptor gene. This gene has been related to a deficiency in translating the dopaminergic signal to the second messenger system. Norepinephrine and epinephrine are agonists at this receptor as well. Implications of these findings are being studied.¹²

A prevailing pathophysiologic explanation for ADHD symptoms involves deficits in prefrontal cortex–mediated executive brain function also known as *response inhibition*. Children with ADHD are unable to control their behavior, resist distractions, and develop an awareness of space and time.^{9,12} In addition, a dysregulation of arousal in frontosubcortical pathways has been proposed. Children with ADHD display insufficient alertness during dull and repetitive tasks, alternating with overarousal.¹²

Effective treatments modulate dopamine (DA) and norepinephrine (NE) to improve executive functioning and regulate arousal for improved performance. The clinical response associated with stimulants is not paradoxical, and is not diagnostic for ADHD because stimulants can increase attention, decrease motor activity, and improve learning tasks in those with subclinical ADHD or in individuals with such problems from other sources (e.g., fatigue).^{3,4,13}

▶ TREATMENT: Attention-Deficit/Hyperactivity Disorder

■ STIMULANTS

3 Stimulants are considered first-line therapy in most cases of ADHD; however, comorbid conditions have an impact on the drug selection process, calling for a careful, systematic approach. Pharmacotherapy should be considered whenever a thorough diagnostic assessment indicates symptoms of ADHD that cause significant functional impairment. Several studies demonstrate the superiority of stimulants compared with behavioral interventions in alleviating core symptoms of ADHD.^{4,14} However, stimulants have not been shown to improve social and academic functioning reliably; therefore multimodal treatment, individualized to the specific needs of the child and family, is crucial for overall positive therapeutic outcome.^{3,15} Table 61–2 describes behavioral interventions for ADHD. Multimodal treatment includes parent training, family therapy, classroom interventions, and contingency management (e.g., rewards for good behavior).^{3,16} Figure 61–1 provides an algorithm for drug selection in the treatment of ADHD.

3 Stimulants (e.g., methylphenidate, mixed amphetamine salts, dextroamphetamine, and pemoline) are the most effective drug treatment options, with efficacy ranging from 70% to 96% when a trial of each drug is given using wide dosage ranges.^{3,15,16} Mixed amphetamine salts (Adderall), a combination of dextroamphetamine and D, L-amphetamine salts, is a longer-acting alternative to methylphenidate.¹⁷ Pemoline is considered to be a “last-resort” therapy because of the risk of hepatic toxicity.^{6,15}

Despite knowledge of the effects of stimulants on neurotransmitter activity, how these drugs affect the primary symptoms of ADHD is unclear. To varying degrees the central nervous system (CNS) stimulants inhibit the reuptake of DA and NE, enhance release of DA and NE from the presynaptic neuron, or inhibit the enzyme monoamine oxidase (MAO). Because stimulants work through slightly different mechanisms, lack of response to one stimulant does not preclude response to another.^{6,15}

Dosing of the stimulants should be titrated for maximum individual efficacy and minimum side effects. Table 61–3 provides initial dose and titration recommendations for stimulants based on manufacturer’s recommendations and published guidelines developed by experienced clinicians.^{6,15,16,18}

Drug response is maximal during the absorption phase, is evident in 15 to 30 minutes, and lasts 2 to 6 hours.¹⁵ With immediate-release stimulants, most patients require a two or three times daily dosing schedule due to the short half-lives of these drugs (2 to 4 hours for methylphenidate and dextromethylphenidate and approximately 6 hours for dextroamphetamine).^{15,16,18}

Drug delivery systems of once-daily products (Concerta, Metadate CD, Ritalin LA, Adderall XR) provide 8 to 12 hours of symptom control.^{15,19} Concerta uses an oral osmotic (OROS) controlled-release delivery system, while other preparations use combinations of immediate-release or extended-release beads containing drug.¹⁹ Concerta is a nondeformable tablet and it should not be given to children with gastrointestinal narrowing due to the risk of obstruction. Older wax-matrix sustained-release products (e.g., Ritalin SR)

TABLE 61–2. Behavioral Interventions for ADHD

| Technique | Description | Example |
|------------------------|--|---|
| Positive reinforcement | Providing rewards or privileges contingent on the child's performance | Child completes an assignment and is permitted to play on the computer |
| Time-out | Removing access to positive reinforcement contingent on performance of unwanted or problem behavior | Child hits sibling impulsively and is required to sit for 5 minutes in the corner of the room |
| Response cost | Withdrawing rewards or privileges contingent on the performance of unwanted or problem behavior | Child loses free time privileges for not completing homework |
| Token economy | Combining positive reinforcement and response cost. The child earns rewards and privileges contingent on performing desired behaviors and loses the rewards and privileges based on undesirable behavior | Child earns stars for completing assignments and loses stars for getting out of seat. The child cashes in the sum of stars at the end of the week for a prize |

From American Academy of Pediatrics.¹⁶

are less effective and infrequently used.¹⁵ When choosing between immediate-release or once-daily stimulants, the convenience of once-daily dosing must be weighed against the potential for difficulty falling asleep with once-daily or sustained-release products.^{15,16} Adolescents and adults with ADHD are also responsive to stimulants. Methylphenidate is demonstrated effective in adults using doses up to 1 mg/kg per day.^{6,15}

ADVERSE EFFECTS

The most common adverse effects of stimulants and their management strategies are listed in Table 61–4. Growth suppression or delay is a possibility. Proposed mechanisms of stimulant effects on growth include alterations in growth hormone secretion and suppression of appetite leading to reduced caloric intake. One study measured the

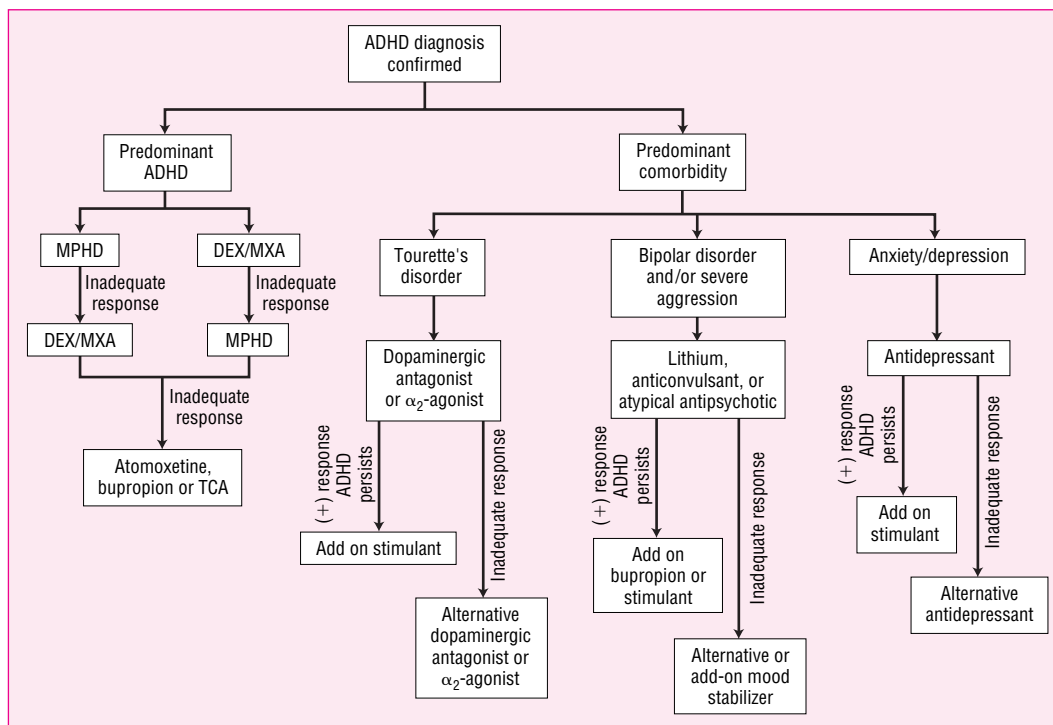

FIGURE 61–1. Algorithm for management of ADHD. Treat predominant disorder first, reassess, and consider alternative or adjunct medications for optimal symptom control. MPH, methylphenidate; DEX, dextroamphetamine; MXA, mixed amphetamine salts; TCA, tricyclic antidepressant; AD, antidepressant. TABLE 61–3. Stimulant Comparison

| Stimulant | Duration of Effect | Initial Dose and Available Strengths | Usual Dosing Range Maximum Dose |
|---|--------------------|---|--|
| Methylphenidate C-II FDA approved for children >6 y old <i>Short-acting</i> Immediate release (IR) Ritalin, Methylin, generics | 3–5 h | 5 mg two or three times a day; increase by 5–10 mg/day at weekly intervals; available as: 5, 10, 20 mg | 5–20 mg two or three times a day; max dose: 60 mg/day |
| <i>Intermediate-acting</i> Ritalin SR (sustained-release) Methylphenidate SR Metadate ER (extended-release) Methylin ER | 3–8 h | SR, ER doses; corresponds to the IR dose | 20–40 mg every AM or 40 mg every AM and 20 mg in the early afternoon; max dose: 60 mg/day |
| <i>Long-acting</i> Metadate CD 30% IR beads, 70% ER beads Ritalin LA 50% IR, 50% ER beads Concerta (oral osmotic [OROS] controlled-release delivery) ER inner compartments coated with IR methylphenidate | 8–12 h | 20 mg every AM; available as: 10, 20, and 30 mg 20 mg every AM; available as: 20, 30, and 40 mg 18 mg every AM; available as 18, 27, 36, and 54 mg; 90% bioavailability of IR | 20–40 mg every AM and 20 mg in early afternoon; max dose: 60 mg/day 20–60 mg/day, given every AM; max dose: 72 mg/day |
| Dexmethylphenidate (Focalin) C-II FDA approved for children ≥6 y old | 3–5 h | 2.5 mg every AM or twice a day; available as: 2.5, 5, and 10 mg tablets | 5–10 mg/day given twice a day; max initial dose: 7.5 mg/day max dose: 20 mg/day |
| Dextroamphetamine C-II FDA approved for children >3 y old <i>Short-acting</i> Dextroamphetamine generics Dexedrine, Dextrostat | 4–6 h 3–5 h | 2.5 mg every AM to two or three times daily dosing 5 mg every AM; available as: 5 and 10 mg | 5–15 mg twice a day 10–40 mg/day given twice a day |
| <i>Intermediate-acting</i> Dexedrine Spansule | 5–8 h | Available as: 5-, 10-, and 15-mg spansules | 5–30 mg every day or 5–15 mg twice a day; max: 40 mg/day |

C-II = schedule II, the Drug Enforcement Agency label that refers to significant abuse potential.

TABLE 61–4. Stimulant Adverse Effects and Management

| Common | Recommendation/Management Strategy |
|-------------------------------|--|
| Reduced appetite, weight loss | Give high-calorie meal when stimulant effects are low (at breakfast or at bedtime) |
| Stomach ache | Administer stimulant on a full stomach |
| Insomnia | Give dose earlier in the day; lower the last dose of the day or give it earlier; consider a sedating medication at bedtime (guanfacine or clonidine) |
| Headache | Divide dose; give with food; or give an analgesic (e.g., acetaminophen or ibuprofen) |
| Rebound symptoms | Consider longer-acting stimulant trial or antidepressant trial |
| Irritability/jitteriness | Assess for comorbid condition (e.g., bipolar disorder); reduce dosage; consider mood stabilizer or atypical antipsychotic |
| Uncommon to Rare | |
| Dysphoria | Reduce dosage; reassess diagnosis; consider alternative therapy |
| Zombie-like state | Reduce dosage or change stimulant medication |
| Tics or abnormal movements | Reduce dosage; consider alternative medication |
| Hypertension | Reduce dosage; change medication |
| Hallucinations | Discontinue stimulant; reassess diagnosis; mood stabilizer and/or antipsychotic may be needed |

height of 84 children with ADHD treated with methylphenidate and compared their growth to non-ADHD siblings over 2 years. Significant differences in growth were found over a broad range of doses (10 to 80 mg), suggesting that the prevalence of growth-suppressive effects of methylphenidate is greater than previously suggested.²⁰ Some evidence exists attributing maturational delays to ADHD itself, not stimulant treatment.²¹

A related aspect of stimulant use concerns drug holidays and duration of treatment. Drug holidays are important because they provide time to reassess treatment.¹⁶ All children should be given a drug-free trial every year. Consideration must be given to the risks of negative effects on learning, socialization, and self-image while off stimulant therapy when determining the frequency and duration of drug holidays. Drug dosage often varies from year to year, largely due to age-related pharmacokinetic changes. As a child develops, hepatic metabolism slows and volume of distribution increases.

CLINICAL CONTROVERSY

According to recent studies growth suppression or delay is a possibility with stimulant use in children; however, results are mixed. Some studies indicate that effects are temporary, with normalization in height and weight occurring through mid-adolescence.^{3,4,20}

A diagnosis of ADHD confers at least a twofold greater risk of adolescent and adult substance abuse.^{42,43} The risk is

greater if conduct disorder, antisocial personality, or bipolar disorder coexists.^{12,42} Stimulant therapy does not increase the risk of substance abuse, and effective treatment of ADHD may facilitate functioning and participation in substance abuse recovery.⁴²

NONSTIMULANTS

Atomoxetine, a selective norepinephrine reuptake inhibitor, is the first nonstimulant approved by the Food and Drug Administration (FDA) for the treatment of ADHD. In contrast to the stimulants, it has no apparent abuse potential and is not a controlled substance. Placebo-controlled, short-term trials (6 to 12 weeks) have shown that atomoxetine is effective in reducing ADHD symptoms in children, teens, and adults. It is not clear whether it is as effective as the stimulants, although one preliminary open study suggested comparable efficacy with methylphenidate.²²

Atomoxetine has a significantly slower onset of therapeutic effect than stimulants (2 to 4 weeks versus 1 hour with an effective stimulant dose). Atomoxetine may be taken once daily or in divided doses in the morning or late afternoon.²² Table 61-5 provides dosing and titration recommendations for all nonstimulant medications.

TABLE 61-5. Antidepressants and Other Agents for ADHD and Associated Symptoms

| Drug | Dosing Range and Titration Schedule | Adverse Effect Monitoring |
|--|---|---|
| Atomoxetine (Strattera) | ≤70 kg: start at 0.5 mg/kg every AM or twice a day; max: 1.4 mg/kg per day ≥70 kg: start at 40 mg every AM or twice a day; max: 100 mg/day | Nausea, anorexia, ↑ blood pressure, ↑ pulse, insomnia, fatigue, sedation, severe liver injury |
| Bupropion (Wellbutrin) | 50–300 mg/day; 3 mg/kg per day by end of week one; may increase to 6 mg/kg per day or maximum of 300 mg/day as tolerated | Nausea, insomnia, rash, tics; dose-related risk of seizures |
| Tricyclic antidepressants: desipramine or nortriptyline | 50–150 mg/day; start at 0.5–1 mg/kg per day; increase as tolerated to 2–3 mg/kg per day; max: 300 mg/day of desipramine (adults only) or 150 mg/day nortriptyline | Sedation, dizziness, constipation, heart block (check ECG), weight gain, overdose toxicity, rapid heartbeat |
| Clonidine (Catapres) | 0.05 mg two or four times daily; may increase as tolerated to 0.1–0.4 mg/day | Sedation, dizziness, heart block (check ECG), constipation |
| Guanfacine (Tenex) | 0.5 mg once to twice a day; may increase as tolerated to 1–4 mg/day | Same as above with potentially lower risk of sedation |
| Risperidone ^a (Risperdal) | 0.25–0.5 mg twice daily; may titrate every 3–4 days as tolerated to response, (1–4 mg/day) | Extrapyramidal symptoms, dizziness, ↑ prolactin, hepatotoxicity, weight gain |
| Olanzapine ^a (Zyprexa) | 2.5–5 mg every day; may titrate every 3–4 days as tolerated to response (usual range: 7.5–15 mg/day) | Sedation, weight gain, restlessness, diabetes, hyperlipidemia |
| Ziprasidone ^a (Geodon) | 10–20 mg twice daily; may titrate every 3–4 days as tolerated to response (usual range: 40–120 mg/day) | Nausea, restlessness, insomnia, QTc prolongation |
| Haloperidol ^a (Haldol) | 0.5–1 mg twice daily; may titrate every 3–4 days as tolerated to response (usual range: 0.5–5 mg/day) | Extrapyramidal symptoms, dizziness, ↑ prolactin, sedation |

^aShort-term use (1–4 months) only for severe aggression associated with ADHD.

Bupropion, a monocyclic antidepressant, is a DA and NE reuptake inhibitor with no significant direct effect on serotonin or MAO. Its active metabolites augment noradrenergic and dopaminergic function. Investigations with bupropion in children demonstrated efficacy greater than placebo in a controlled trial⁶ and efficacy comparable with methylphenidate ($n = 15$ children) in another controlled trial.⁶ Advantages of bupropion include less toxicity on overdose compared with TCAs and less appetite suppression compared with stimulants. Bupropion also may be effective in adults at antidepressant doses.⁵

Imipramine and desipramine are the most systematically studied TCAs in the treatment of ADHD, although nortriptyline is also effective.^{6,16} The onset of TCA clinical response occurs within the first 2 to 4 weeks.^{6,16} Variability in dosage requirements for TCAs and atomoxetine may be due to interpatient variability in drug plasma concentration achieved at a given dose. Both are metabolized via cytochrome P450 2D6, and bioavailability and half-life may be 4 to 8 times greater in those taking a P450 2D6 inhibitor (e.g., bupropion, fluoxetine, or paroxetine) or in poor metabolizers. For example, atomoxetine's half-life is 5 hours in extensive metabolizers and 19 hours in poor metabolizers.^{22,23} If tolerance seems to develop after months of therapy, a dosage adjustment may be necessary to compensate for age-related changes in distribution and metabolism.

Atomoxetine, bupropion, and TCAs are second-line alternatives to the stimulants for treatment of ADHD in children, teens, and adults. The potential benefits of these agents in comparison with stimulants include reduced risk of abuse and somewhat lower potential for sleep disturbance. TCAs are the most dangerous in overdose and pose the greatest risk for cardiovascular side effects.^{5,6,16,22} The monoamine oxidase inhibitor tranylcypromine is effective but used infrequently due to the potential for dangerous drug and dietary interactions.⁵ Selective serotonin reuptake inhibitors (SSRIs) are not effective for ADHD.^{6,16}

ADVERSE EFFECTS

Possible adverse effects and management for atomoxetine are listed in Table 61–5 and are strikingly similar to those of stimulants. Atomoxetine has a greater risk of fatigue and sedation compared to stimulants. The relative risk of all potential adverse events compared to stimulants (decreased appetite, growth delay, sleep disturbance, gastrointestinal side effects, and tics) and bupropion require further study.^{22,23} Atomoxetine labeling has recently been updated to include a bolded warning of potential for severe liver injury following reports in two patients.

Bupropion's adverse effects and their management are listed in Table 61–5 and include nausea, which may resolve over time or with slower dosage titration, and rash, which may require discontinuation of therapy if severe. Bupropion can cause or exacerbate tics and therefore should be used with caution in individuals with tics or a family history of tics.²⁴

TCAs are effective for control of impulsivity and hyperactivity, but they are not as effective as stimulants in increasing attention.^{5,6,16} TCAs should be taken throughout the week and not just during school days. TCA withdrawal effects are common in children and include nausea, vomiting, and diarrhea.²⁵

Possible CNS adverse effects of TCAs include dizziness, aggressiveness, excitement, nightmares, insomnia, forgetfulness, and irritability. Signs of CNS toxicity are confusion, impaired concentration, hallucinations, and delusions.

Clonidine and guanfacine are less effective alternatives to stimulant monotherapy. They are prescribed more frequently as adjuncts to reduce disruptive behavior, control aggression, or to improve sleep.^{6,16,26} Clonidine and guanfacine, central α_2 -adrenergic agonists, inhibit noradrenergic activity by decreasing the release of NE from the presynaptic neuron. Both reduce the firing rate within the locus ceruleus, decrease excessive arousal, and are thought to “prime” the posterior attention system to external stimuli.^{13,26} Guanfacine has a longer elimination half-life (12 to 18 hours) compared with clonidine (2.5 to 4 hours).²⁷

The most common side effect of clonidine is dose-dependent sedation that usually subsides after 2 to 3 weeks of therapy.^{6,26} Of concern are reports of bradycardia, rebound hypertension, heart block, and sudden death.^{6,26} Four children have died on the combination of methylphenidate and clonidine; however, complicating factors make it impossible to link the drug combination directly with the cause of death.⁶ Of 10,060 children exposed to clonidine and assessed by a poison control center over a 7-year period, moderate (19%) to major (2%) toxic effects (bradycardia, hypotension, and respiratory depression) including one death were reported. Overdoses, concurrent clonidine and stimulant administration, as well as missed doses of clonidine all add to the risk of adverse cardiovascular events.^{28,29} Similar adverse-effect concerns apply to treatment with guanfacine, although its α_{2a} selectivity may result in less sedation and hypotension than clonidine.²⁷

Lithium and anticonvulsants are used increasingly to control aggression and explosive behavior in patients with a diagnosis of ADHD. Some patients actually may have childhood-onset bipolar disorder or combined ADHD-intermittent explosive disorder.^{6,30} Lithium, valproate, and carbamazepine are effective for explosive behavior, aggression, and impulsivity, but they are not beneficial treatments for a child with the inattentive subtype of ADHD. Dosing starts in low divided doses with titration over 1 to 2 weeks to therapeutic response.^{2,6,31}

Conventional antipsychotics improve symptoms of hyperactivity and impulsivity, but may have negative effects on learning and cognitive functioning as well as extrapyramidal side effects (e.g., dystonia and tardive dyskinesia) that limit their usefulness.⁶ The atypical antipsychotics risperidone, olanzapine, quetiapine, and ziprasidone have been used to control severe aggression in refractory cases of ADHD, particularly if conduct disorder or bipolar disorder coexists. More studies are needed to clarify their place in therapy.^{6,32,33}

If multiple drugs are started simultaneously, it is impossible to determine the impact of each drug. The predominance and urgency of symptoms guide the drug-selection process (see Fig. 61–1). For example, if a child presents as severely anxious or depressed with associated attentional problems, then an antidepressant should be initiated first with monitoring to determine if attentional symptoms improve.³⁴ When a child presents with severe ADHD and associated anxiety or depression, a stimulant should be initiated to treat the more severe ADHD. If ADHD symptoms improve significantly but anxiety or depression persists, then an antidepressant can be added. Careful monitoring is needed to detect drug interactions that lead to higher drug plasma levels and increased adverse effects.⁶ Studies show that stimulants do not routinely make anxiety disorders worse, but they may not improve symptoms either.^{6,16} In children with epilepsy, methylphenidate is effective; however, the child must be stabilized and seizure-free on an anticonvulsant prior to initiation of the stimulant.³⁵ Patients with seizure disorders should not receive bupropion.

PHARMACOECONOMIC CONSIDERATIONS

A study comparing medical care use and costs between persons with and without ADHD over 9 years found that the median cost for a person with ADHD was more than double (\$4306 vs. \$1944; $p < 0.001$) that of someone without ADHD. Increased costs are attributed to accidental injuries, diagnostic assessments, hospital visits, and outpatient visits.³⁶ The cost-effectiveness of drug treatment has not been assessed. Immediate-release generic methylphenidate, dextroamphetamine, and mixed amphetamine salts appear to provide the most effective and economic therapy due to relatively low drug cost. The cost of once-daily Concerta, Ritalin LA, Metadate CD, Adderall XR, and Strattera is approximately 2 to 4 times that of an immediate-release generic stimulant. Generic bupropion is the least expensive nonstimulant treatment. Imipramine, desipramine, clonidine, and mood stabilizers are relatively inexpensive, but ongoing electrocardiographic and blood-level monitoring can increase costs significantly.^{6,29}

EVALUATION OF THERAPEUTIC OUTCOMES

Careful documentation of baseline symptoms and complaints over a 1-month predrug period is essential to the evaluation of therapeutic and adverse outcomes. Baseline symptoms can be measured using videotapes, clinician rating scales (e.g., Child Behavioral Checklist or ADHD Rating Scale-IV), or both. In addition, height, weight, and eating and sleeping patterns should be recorded at baseline and every 3 months.^{6,37}

After the initiation and titration of any drug treatment, it is necessary that parents, teachers, and clinicians assess the overall functioning of the child using standardized rating scales to determine if significant therapeutic benefit justifies continuing medication.^{6,15,37,38} Therapeutic effects of the stimulants include decreased motor activity and impulsivity and increased attention span. Improved cognitive performance may result from an overall improvement in attention and concentration and may not be a direct drug effect on cognition.^{9,15} This suggests that stimulants are indicated for ADHD symptoms and not for primary learning disorders. The benefits of drug therapy must outweigh the adverse effects.^{39–41}

Atomoxetine and bupropion require monitoring to detect changes in appetite, weight, and sleep patterns, or if pulse or blood pressure changes occur. A therapeutic trial of atomoxetine or bupropion consists of 1 month of maximum tolerated doses.^{5,22,24}

When clonidine or guanfacine are given, careful clinical monitoring for fatigue, dizziness, and autonomic changes (e.g., blood pressure and pulse) is recommended.⁶ The American Heart Association has stated that electrocardiographic monitoring is not required for clonidine treatment in children, although many clinicians continue to assess for electrocardiogram changes. When discontinuing treatment, clonidine and guanfacine should be withdrawn slowly (0.05 mg clonidine/0.5 mg guanfacine reductions every 3 days) to prevent rebound hypertension or behavioral dyscontrol.²⁸ A therapeutic trial takes 1 to 2 months, although increased sleep can be seen immediately.

The effects of TCAs on the electrocardiogram should be monitored carefully. Of more concern are reports of sudden death in children taking desipramine or imipramine.³⁸ Children and adolescents given TCAs should have pretreatment and follow-up electrocardiograms to assess the effects of TCA therapy on cardiac rate and rhythm.^{6,16,38}

CONCLUSION

At this time, the preferred first-line drug therapy for ADHD is either methylphenidate, dextromethylphenidate, mixed amphetamine salts, or dextroamphetamine. Atomoxetine, bupropion, or TCAs are good options for those unresponsive to or unable to tolerate stimulants. Clonidine and guanfacine are third-line options or adjuncts that require careful cardiovascular monitoring. Mood stabilizers (e.g., lithium, divalproex, and carbamazepine) and atypical antipsychotics are adjuncts for control of aggression or comorbid bipolar disorder. Other agents require further investigation before their status in the treatment of ADHD can be fully determined.

TOURETTE'S DISORDER

EPIDEMIOLOGY AND CLINICAL PRESENTATION

Once considered rare, Tourette's disorder is present in 0.7% to 1.1% of boys and 0.4% of girls.^{44,45} The essential features of this CNS disorder are multiple motor tics and one or more vocalizations. A tic is a sudden, rapid, recurrent, nonrhythmic, stereotyped motor movement or vocalization. See Table 61–6 and the accompanying references for examples of motor and vocal tics.^{45,46} The clinical presentation may vary from barely noticeable to debilitating, and the type of tic expressed may change over time.^{1,45,46}

4 Presence of both motor and vocal tics is necessary for more than 1 year before the diagnosis of Tourette's disorder is made. The median age of onset of motor tics is 6 years, with an average delay in diagnosis of 6.8 years.^{1,45,46}

Transient tic disorder is diagnosed if motor or vocal tics occur for less than 1 year, with chronic tic disorder diagnosed if motor or vocal tics are present for longer than 1 year.^{1,45} Tics are most prominent during childhood and may plateau or attenuate during adolescence. The early 20s frequently bring stabilization of symptoms, although exacerbations occur during adulthood with characteristic fluctuating symptom severity.^{1,45,46}

Over 90% of children with Tourette's disorder have coexisting conditions such as ADHD (75%), mood disorders (60%), obsessive-compulsive disorder (40%), other anxiety disorders, or a combination of comorbidities.^{45–47} Tourette's disorder itself does not cause diminished intellectual functioning; however, the severity of tics and associated illnesses can result in significant impairment in school functioning, sometimes necessitating special education classes.^{45–47}

TABLE 61–6. Clinical Presentation of Tourette's Disorder

- Onset before age 18 years
- Multiple motor or one or more vocal tics present
- Motor and vocal tics do not need to occur concurrently

| Motor Tics | Vocal Tics |
|---------------------------|----------------------------|
| Eye blinking, lip licking | Clicks, grunts |
| Facial twitching | Barking, yelping |
| Shoulder shrugging | Throat clearing, echolalia |
| Squatting, twirling | Coprolalia, palilalia |

The tics occur many times a day (usually in bouts) nearly every day or intermittently throughout a period of more than 1 year, and during this period there was never a tic-free period of more than 3 consecutive months.

Data from American Psychiatric Association.¹

ETIOLOGY AND PATHOPHYSIOLOGY

Tourette's disorder is transmitted in a complex polygenic pattern, whereas symptoms and severity of the disorder vary from one generation to another.^{45–47} The neurochemical pathophysiology involves an imbalance in the interaction of dopaminergic, serotonergic,

γ -aminobutyric acid (GABA)-ergic, glutamatergic, cholinergic, noradrenergic, and opioid systems in multiple brain regions, most notably the basal ganglia and caudate nucleus. The imbalance may cause a lack of regulation of the brain's inhibitory mechanisms, resulting in tics and associated behavior disorders. This multisystem etiology best explains the success of a variety of treatment options.^{46,47}

► TREATMENT: Tourette's Disorder

5 Whenever symptoms are severe enough to impair the child's ability to function, drug therapy should be initiated. Haloperidol and pimozide (dopamine [D_2] receptor antagonists) are approved by the FDA and are highly effective with a relatively rapid onset. Clonidine is significantly less effective but has no risk of extrapyramidal side effects. Psychotherapy and behavioral treatment are useful adjuncts.^{45–47}

Therapy with haloperidol or pimozide should be initiated at very low doses of 0.25 to 0.5 mg/day given at bedtime and then increased gradually. Gradual titration over 2 to 3 weeks helps minimize extrapyramidal and sedative effects while permitting careful assessment of response. Symptoms may regress within 48 to 72 hours after an effective dose is reached. Doses less than 5 mg/day are effective in controlling tics for most patients, but occasionally up to 10 mg/day or even 20 mg/day are required.^{46,47} Pimozide is considered comparable or possibly superior to haloperidol in efficacy when equivalent doses are used.^{45,46}

Risperidone, a serotonin (5-HT₂)/ D_2 receptor antagonist, was significantly more effective than placebo in decreasing motor and vocal tic severity according to two controlled trials.^{48,49} The mean daily dose was 2.5 mg/day (range 1 to 6 mg/day). In addition, in parallel comparison trials risperidone was found to be as effective as pimozide or clonidine. The mean risperidone dose in the pimozide trial was 3.8 mg/day, while the dose of risperidone ranged from 0.6 to 2.4 mg/day in the clonidine trial.^{50,51} Ziprasidone, another 5HT₂/ D_2 antagonist, showed significant efficacy versus placebo in a controlled study at an average dose of 30 mg/day titrated from a starting dose of 5 mg/day.^{52,53} An open trial with olanzapine at a mean dose of 10.9 mg/day showed a 50% reduction in global tic severity.⁵⁴ Clozapine, a 5-HT₂ antagonist with minimal D_1 -blocking and no significant D_2 -blocking effects, was found to be ineffective with worsening of symptoms in some Tourette's patients.^{46,47}

Clonidine is the most widely prescribed treatment for Tourette's disorder, according to an international database of 3500 cases, but its efficacy is not robust, and it is not more effective than DA antagonists.^{46,47} In some patients, the response is limited to improvement in attention and behavior with no changes in the frequency of tics. A clonidine trial should be initiated carefully, usually 0.025 to 0.05 mg given in the morning or divided two to three times daily with gradual titration every 4 to 7 days to the usual therapeutic trial dose of 0.15 to 0.25 mg/day (maximum 0.6 mg/day).^{45–47} Doses usually are divided during maintenance therapy for more continuous symptom control and to minimize adverse effects. Case reports describe a positive response from the clonidine patch as well. The onset of therapeutic effects for both tablet and patch is slow, ranging from 2 weeks to a few months.^{46,47}

CLINICAL CONTROVERSY

The decision to treat Tourette's disorder with a D_2 receptor antagonist vs. an α_2 -agonist can be controversial and challenging. The choice is usually based on whether high

efficacy (D_2 antagonist) or milder adverse effect burden (α_2 -agonist) is more desirable in an individual patient.^{45–47}

■ COMORBIDITY

Pharmacotherapy of Tourette's disorder is challenging due to multiple coexisting disorders typically requiring medication combinations. Often the behavioral problems precede and are more disturbing than the involuntary movements, making them a treatment priority.

■ TOURETTE'S AND ADHD

Pharmacotherapy with stimulants increases dopaminergic and noradrenergic activity, which has the potential to aggravate or precipitate tics. One study examined the comparative effects of methylphenidate and dextroamphetamine on tics in children and found the majority experienced improvement in ADHD symptoms with acceptable effects on tics.^{46,55} Methylphenidate was better tolerated than dextroamphetamine. Another double-blind placebo-controlled trial compared methylphenidate or clonidine monotherapy to combination methylphenidate and clonidine in patients with ADHD and Tourette's disorder. Combination therapy demonstrated the greatest benefit in reducing symptoms of ADHD and tics ($p < 0.0001$).⁵⁶ Clonidine appeared most helpful for impulsivity and hyperactivity, while methylphenidate was most helpful for inattention. All treatments were well tolerated.

Patients and caregivers should be aware of the risks of using stimulants in children with Tourette's disorder (see ADHD section); careful monitoring is essential.^{46,47,55}

Controlled trials of TCA therapy for comorbid ADHD and chronic tics or Tourette's disorder show significant improvement in inattentive and hyperactive/impulsive symptoms without worsening of tics.⁵⁷ In one study, both tics and symptoms of ADHD improved.⁵⁷ TCAs offer an alternative to clonidine or combined clonidine/methylphenidate therapy that may be more effective for some patients.

Clonidine or guanfacine monotherapy is a less effective alternative to stimulants in the treatment of children with Tourette's disorder and ADHD. Guanfacine, a central α_{2a} -selective noradrenergic receptor agonist, was administered to 34 children (mean age 10.4 years), with ADHD and tic disorder during an 8-week placebo-controlled trial at a dose of 1.5 to 3 mg/day. Tic severity decreased by 31% in the guanfacine group compared to 0% in the placebo group.^{27,46} There was a mean improvement of 37% on the teacher-rated ADHD scale compared to 8% improvement with placebo. Due to its similarity to clonidine, guanfacine's cardiovascular effects warrant careful clinical monitoring.^{6,28,46,47}

Nicotine administration by gum or patch may potentiate the effects of dopamine-blocking agents in relieving tics, according to small

controlled trials.^{45,46,58} ADHD symptoms may improve as well.^{46,58} The long-term adverse effects of nicotine on overall health may limit usefulness.

■ TOURETTE'S AND ANXIETY OR MOOD DISORDERS

Therapeutic trials (6 to 8 weeks) of an SSRI or clomipramine should be tried when obsessive-compulsive, anxiety, or depressive symptoms cause functional impairment in patients with Tourette's disorder.^{46,47} Careful monitoring for behavioral activation, disinhibition, and motor restlessness is essential during SSRI or clomipramine therapy, because these symptoms occur in 20% to 40% of children and may require drug discontinuation.^{45,46,59}

■ ADJUNCTIVE OR ALTERNATIVE TREATMENTS

For those who are unresponsive, partially responsive, or unable to tolerate DA antagonists or α_2 -agonists, there are several adjuncts or alternative treatments available. Clonazepam, selegiline, or baclofen appear to offer the most promise in relieving tics and associated symptoms. Opioid agonists or antagonists are not effective. Botulinum toxin requires further study.^{45–47} Nonpharmacologic interventions include support groups, "habit-reversal therapy," and even neurosurgery.^{45,46,60}

■ ADVERSE EFFECTS

Adverse effects have been reported with haloperidol doses of 2 mg/day or greater. In one review of 24 patients treated with haloperidol for Tourette's disorder, 66.7% discontinued treatment due to intolerable side effects (e.g., dysphoria, akathisia, nervousness, sedation,

dystonia, and cognitive dulling or feeling drugged).⁶¹ Lowering the dose may alleviate side effects. An antiparkinsonian agent such as benzotropine (at a starting dose of 0.5 mg orally twice daily) generally will reverse extrapyramidal side effects. Whether a patient with Tourette's disorder is developing a new symptom or is developing tardive dyskinesia can be difficult to determine. Dosage titration of the medication and careful monitoring will assist in this clinical decision-making process.^{46,47}

Pimozide is less likely to cause extrapyramidal side effects compared to haloperidol. Anticholinergic side effects may occur in addition to drowsiness, and occasionally, anxiety will occur. Electrocardiographic changes, including T- and U-wave abnormalities and prolongation of the QTc interval, are found rarely with recommended therapeutic doses for Tourette's disorder; however, drugs that inhibit cytochrome P450 isoenzyme 3A4 (e.g., clarithromycin or fluoxetine) should not be combined with pimozide due to the risk of excessively elevating pimozide blood levels and lethal QTc prolongation.^{6,46,47}

Adverse effects reported during clinical studies in children taking risperidone and olanzapine include light-headedness, sedation, akathisia or agitation, weakness, insomnia, depressed mood, aggressive behavior, tachycardia, weight gain, hepatotoxicity, and extrapyramidal side effects including tardive dyskinesia.^{32,46,47} Risperidone is more likely to be associated with hyperprolactinemia and extrapyramidal effects compared to olanzapine. However, olanzapine has been associated with greater weight gain and more cases of new-onset diabetes compared to risperidone. Ziprasidone carries a risk of QTc prolongation, hyperprolactinemia, extrapyramidal effects, restlessness, nausea, and mild sedation, but minimal to no weight gain.^{32,53}

For clonidine and guanfacine the most common adverse effect is sedation. Fortunately, tolerance usually develops to this effect over days to weeks. The most potentially serious side effects are cardiovascular (see the ADHD section).²⁸ Other α_2 -agonist side effects include dry mouth, constipation, headache, mood changes, and even a temporary worsening of tics in 10% of patients.

PHARMACOECONOMIC CONSIDERATIONS

No pharmacoeconomic studies have been published on Tourette's disorder. Haloperidol provides the most economic therapy due to high efficacy and low drug cost. Pimozide is more expensive than generic haloperidol. Although generic clonidine is inexpensive, delayed onset of effect and significantly lower efficacy substantially increase total costs of treatment. 5-HT₂/D₂ antagonists such as risperidone are expensive alternatives due to high medication costs.

EVALUATION OF THERAPEUTIC OUTCOMES

Evaluating therapeutic interventions is challenging, as most patients can suppress their tics voluntarily for minutes to hours.^{45,46} Also numerous factors such as stress, concentration, and relaxation can impact tic frequency and severity. The use of regular videotaped assessments in conjunction with standardized rating scales (Yale Global Tic Severity Scale) is helpful in objectively evaluating symptoms, side effects, and overall drug response.^{45–47}

6 Individuals with Tourette's disorder are particularly sensitive to medication side effects, so medication dosing must be

individualized with low starting doses and careful weekly titration to response, realizing that it may take 1 to 2 months for an adequate therapeutic trial. Children taking any dopamine-blocking medication should receive monitoring every 3 to 6 months for extrapyramidal effects with a standardized rating scale (e.g., abnormal involuntary movement scale [AIMS]).^{32,33} Patients given pimozide should receive baseline and follow-up electrocardiograms.^{6,46,47} Adult patients with Tourette's disorder still may be responsive to drug treatments that were effective during childhood, although the dose and schedule may require adjustment.^{45–47}

CONCLUSION

Haloperidol, pimozide and potentially risperidone have the advantage of greatest efficacy and rapid onset in the treatment of Tourette's disorder. Ziprasidone shows promise; however, comparison studies with haloperidol, pimozide, or risperidone are needed to determine its relative safety and efficacy. Clonidine and guanfacine have the advantage of no extrapyramidal side effects, but they are significantly less effective and require ongoing cardiovascular monitoring. Drug treatment must be highly individualized, considering comorbid disorders, side-effect sensitivity, and drug interactions.

ENURESIS

ETIOLOGY, PATHOPHYSIOLOGY, AND CLINICAL PRESENTATION

The essential feature of enuresis is repeated involuntary or intentional voiding of urine by day or night that is not caused by a general medical condition (Table 61–7).¹ Medical causes of inappropriate voiding (e.g., diabetes mellitus, diabetes insipidus, seizure disorders, or urinary tract infections) should be ruled out. Enuresis may be primary or secondary. Primary enuresis, the most common type, is diagnosed if the child has never established urinary continence. Secondary enuresis follows an established period (3 to 6 months) of urinary continence.

At age 5, prevalence is 15% to 20%; at age 10 it is 5%; for adolescents it is 1%, and 0.5% of adults wet the bed at least once a month. There is a 15% annual rate of spontaneous remission. The ratio of males to females with enuresis is 3:2.^{62–64} Factors that predispose a child to either type of enuresis include a positive family history,

► TREATMENT: Enuresis

The first step in treating the child with enuresis is to educate the family about the high frequency of the problem, dispel any misconceptions, provide emotional support, and strongly discourage punishment. For younger children who have not been toilet trained properly, the conditioning technique of dry-bed training should be tried first. This technique encourages extra fluids during the day and restricts fluids close to bedtime. Children are encouraged to use the toilet before bedtime. If this method is unsuccessful, then a bed-wetting alarm can be used. After 3 to 4 months of using a bed-wetting alarm, enuresis is cured in more than 70% of children.^{66,67}

7 Teaching continence skills and various behavioral and conditioning methods remain the primary treatments for enuresis, and drug treatment remains a secondary approach.^{63,64,68,69} Combined treatment with an enuresis alarm and desmopressin may be successful for severe enuresis.⁷⁰

■ DESMOPRESSIN

8 Desmopressin acetate, a synthetic analog of the natural human ADH arginine vasopressin, is currently available in a nasal spray and oral tablet for the treatment of nocturnal enuresis. Desmopressin raises overnight urinary osmotic concentration by increasing water reabsorption and reducing the volume of urine entering the bladder.^{71,72} Desmopressin is effective in reducing the number of wet nights in 70% of children.⁷³ In a short-term (2-week) controlled study, 24.5% of adolescents/adults became completely dry,⁶⁷ whereas in a naturalistic 6-week trial, 22% of children became completely dry.⁷⁴ Patients with colds or allergies that affect the nasal mucosa may have a less-than-optimal response to desmopressin nasal spray.

Predictors of best response to desmopressin include older age (>9 years), fewer initial wet nights, and larger bladder capacity.^{75,76} For children 6 years of age and older, the initial recommended nasal dose is 20 mcg at bedtime, increasing to 40 mcg at bedtime after 3 days if there is no response. Some patients may respond to as little as 10 mcg. One-half of each dose is administered in each nostril. About 10% of the dose of desmopressin is absorbed from the nasal mucosa,

TABLE 61–7. Clinical Presentation of Enuresis

- Age 5 years or older
- Child repeatedly voids urine into bed or clothes
- May be involuntary or intentional
- Clinically significant problem for child
- Either a frequency of twice a week for at least 3 consecutive months or presence of distress or impairment in social, academic, or occupational functioning.

Modified from American Psychiatric Association.¹

reduced functional bladder capacity, delayed or lax toilet training, constipation, psychological factors, and developmental delay. Some children with nocturnal enuresis lack the normal circadian variation in urine excretion rate, urine osmolality, and antidiuretic hormone (ADH) secretion. Nocturnal enuresis is not associated with a particular sleep stage, although children with enuresis are more difficult to arouse.^{63–65}

and plasma concentrations reach a maximum about 45 minutes after administration. Less than 1% of oral desmopressin is absorbed, with effective dosages ranging from 200 to 600 mcg/day.⁷¹ Biologic half-life is 4 to 6 hours, and the duration of action varies from 6 to 24 hours.⁷¹

■ TRICYCLIC ANTIDEPRESSANTS

9 Imipramine significantly increases the number of dry nights for 70% to 80% of children with enuresis.⁷⁷ Imipramine is the most studied TCA, although desipramine, amitriptyline, and nortriptyline are also effective. The exact mechanism of action of TCAs in treating enuresis is unknown; proposed mechanisms include an anticholinergic effect, an α -adrenergic agonist effect, and an increase in ADH.^{63,71} An initially effective dose often becomes ineffective in 2 to 6 weeks, but increasing the dose usually re-establishes control. For children 6 years of age and older, the initial dose of imipramine should be 25 mg at bedtime, with weekly increases of 25 mg if necessary. A nightly dose greater than 75 mg is rarely necessary, although doses up to 150 mg have been required in teenagers.^{25,78}

■ ADVERSE EFFECTS

Infrequent adverse effects of desmopressin spray include nasal irritation, epistaxis, rhinitis, and nasal congestion, whereas desmopressin tablets or spray may cause transient headache, chills, dizziness, nausea, and abdominal pain. Rarely, water intoxication, hyponatremia, and subsequent tonic-clonic seizures have been reported,⁷⁴ particularly in children with concurrent physical disorders, intentional overdoses, or excessive fluid intake. When desmopressin is administered, evening fluids should be limited to 8 ounces to prevent hyponatremia or water intoxication.^{79,80}

TCA adverse effects are dose related and include sedation, dizziness, dry mouth, constipation, weight gain, and the risk of electrocardiographic changes, heart block, and lowering of the seizure threshold.²⁵

PHARMACOECONOMIC CONSIDERATIONS

No pharmacoeconomic studies on enuresis are available. The use of a bed-wetting alarm provides the highest overall cure rate, and drugs are a secondary approach. However, insurance companies commonly reimburse drug therapy, whereas they do not reimburse for alarms. The most inexpensive drug therapy is low-dose TCA; however, electrocardiographic and TCA blood level monitoring increases overall costs. Therapy with desmopressin is substantially more expensive than with TCAs due to higher drug cost.

EVALUATION OF THERAPEUTIC OUTCOMES

Before treatment begins, an accurate baseline of bed-wetting frequency must be established. A 50% or greater increase in dry nights is considered a therapeutic response. For example, if baseline dry nights are 2 out of 7 days per week, and drug treatment results in 4 or more dry nights per week, the drug is considered effective. If only one more dry night per week occurs and the drug is at the low end of the dosing range, a dosage increase is needed.^{66,67,71,72}

At least 1 week is needed to evaluate the efficacy of TCAs, and 2 weeks may be needed for evaluation of desmopressin. If drug treatment is ongoing for several months, particularly if enuresis has resolved, attempts to discontinue the drug every 3 to 6 months are recommended to assess for spontaneous remission. Slow tapering of the medication may decrease the frequency of relapse. Unfortunately, therapeutic drug efficacy does not extend beyond drug discontinuation.^{73,77,81,82} Drug plasma level monitoring is not established for desmopressin; however, plasma concentrations of imipramine plus desipramine of greater than 116 ng/mL have been correlated with increased clinical response.⁷⁷

CONCLUSION

Overall, both desmopressin and TCAs are effective in the treatment of nocturnal enuresis as long as the drug is maintained. Drug selection is based on adverse-effect profiles, ease of administration, and cost. Imipramine has a higher adverse effect burden compared to desmopressin, and the risk of accidental overdose is of concern, especially in very disorganized families. In contrast, desmopressin is markedly more expensive than imipramine.

ABBREVIATIONS

ADH: antidiuretic hormone
 ADHD: attention-deficit/hyperactivity disorder
 AIMS: abnormal involuntary movement scale
 DA: dopamine
 D₂, D₄: dopamine receptors
 GABA- γ : aminobutyric acid
 5-HT₂: serotonin
 MAO: monoamine oxidase
 NE: norepinephrine
 SSRI: selective serotonin reuptake inhibitor
 TCA: tricyclic antidepressant

EATING DISORDERS

Patricia A. Marken and Roger W. Sommi

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The causes of eating disorders are complex, so ongoing multidisciplinary treatment is needed to ensure a positive outcome. Outpatient treatment is appropriate for the majority of patients.
- 2 Careful medical and psychiatric assessments are needed at baseline to determine severity of illness and comorbid conditions.
- 3 Nonpharmacologic measures such as cognitive behavioral therapy (CBT), nutritional counseling, family therapy, and interpersonal psychotherapy are the cornerstone of management of anorexia nervosa (AN).
- 4 In patients with AN, one goal is to achieve and maintain a body weight within 85% of the normal weight for age and height. If the patient is malnourished, oral refeeding with the daily caloric intake slowly titrated upward to 2,000 to 3,000 kcal/day is preferred. Parenteral refeeding is a treatment of last resort.
- 5 Antidepressants in AN are reserved for patients with mood, anxiety, and obsessional symptoms that persist after weight has improved.
- 6 Antidepressants can improve both mood and specific target symptoms in bulimia nervosa (BN), but they remain adjunctive to nonpharmacologic treatments.
- 7 Selective serotonin reuptake inhibitors (SSRIs) are first-line agents when medications are indicated for BN, because of improved tolerability and safety, but they do not have superior efficacy compared with other antidepressant classes. The dose of fluoxetine in BN is higher (60 mg/day) than the dose usually used in depression.
- 8 An adequate drug therapy trial is 4 to 8 weeks. If drug treatment fails, consider a lack of absorption as a cause, since the patient may be vomiting up the drug.
- 9 The optimal duration of antidepressant treatment is unknown, but most clinicians will continue them for 6 to 12 months in patients who respond and then re-evaluate the need for ongoing medication management. The long-term course is variable, but there is the potential for a fatal outcome from cardiac arrest or suicide.
- 10 Monitoring in BN should include frequency and severity of binge/purge episodes, exercise patterns, use of laxatives or ipecac, mood and anxiety symptoms, eating habits, daily caloric intake, weight, and changes in laboratory abnormalities.

The eating disorders encompass several complex diseases that share a central pathologic feature of overvaluation of shape and weight. Eating disorders arise from the interaction between environmental, societal, developmental, psychosocial, genetic, and biologic factors. It is estimated that 5 to 10 million women and 1 million men in the United States have an eating disorder. The urbanization of society and an increasing obsession with perfection have led to an increasing prevalence of eating disorders, most alarmingly in an increasingly younger population.¹⁻³ Anorexia nervosa (AN) was described over a century ago; bulimia nervosa (BN) emerged as a distinct disorder in 1979, and other eating disorders and subtypes continue to be defined.⁴⁻⁶ Extensive research has improved our understanding of these severely disabling and potentially fatal disorders. Management, however, remains difficult, and pharmacologic management is only a small part of a comprehensive plan that emphasizes cognitive behavioral therapy and psychotherapy.

EPIDEMIOLOGY

ANOREXIA NERVOSA

AN occurs predominantly in females (90%) and usually presents in late adolescence. The median age of onset is 17, with new cases rarely

occurring after age 40. Its reported prevalence in the United States ranges from 1 in 100 to 1 in 800 for females between the ages of 12 and 18 years.⁷ AN is reportedly on the rise, with the prevalence increasing sixfold in the 1970s versus the 1960s, and a rise in the number of prepubertal teens and males with the disease.³

BULIMIA NERVOSA

BN also occurs predominantly in females (90%) and usually presents in adolescence or early adult life.⁴ Between 1% and 4.6% of adolescent and young adult females meet diagnostic criteria for BN, with the prevalence being 10 times higher than in males.^{3,7,8}

EATING DISORDER NOT OTHERWISE SPECIFIED

Eating disorder not otherwise specified is also described in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, Text Revision (DSM-IV-TR).^{3,7} Its prevalence is 4.7% of the population and up to 50% of eating disorder patients admitted to tertiary care settings have this condition.⁹ Individuals present with symptoms characteristic of eating disorders, but they do not meet the diagnostic criteria for a specific eating disorder.

BINGE EATING DISORDER

Binge eating disorder (BED) is currently a research diagnosis, although there is significant interest in treatment. The diagnostic criteria for BED describe recurrent episodes of binge eating without compensatory behavior (purging, excessive exercise, or fasting). BED typically presents later in life (40s), and approximately one-fourth of BED patients are male.^{9,10}

ETIOLOGY AND PATHOPHYSIOLOGY

1 The potential etiologic or exacerbating factors for eating disorders represent an array of physiologic, biochemical, developmental, genetic, psychological, psychosocial, and psychiatric phenomena. The biologic basis for eating disorders is difficult to delineate because it is unclear whether the observed biologic changes are caused by or are a result of the aberrant eating behavior.

Abnormalities of the hypothalamic-pituitary-gonadal, hypothalamic-pituitary-adrenal, and hypothalamic-pituitary-thyroid axes are described as potential causes of AN. An extensive review of the psychoneuroendocrinology of AN is provided by the Work Group on Eating Disorders.⁹ Although many endocrine abnormalities occur in other forms of starvation, a primary difference with AN is that the dysfunction may not correct despite weight normalization, suggesting a primary biologic abnormality.¹⁰ Amenorrhea is found in the majority of females with AN, supporting the role of the hypothalamic-pituitary-gonadal axis, and in particular, the function of the gonadotropins luteinizing hormone, follicle-stimulating hormone, and gonadotropin-releasing hormone.⁸ Up to 25% of females have amenorrhea before the onset of AN, and the return of menses lags behind weight normalization.

The roles of serotonin, norepinephrine, and dopamine have been studied extensively, as these neurotransmitters have important functions in controlling eating behaviors. Dysfunctions in these systems have been found, although many are thought to be secondary to associated weight loss. Some aspects of serotonin function do remain abnormal after weight restoration, leading investigators to propose that other mechanisms are involved.^{11,12}

Reasonably strong genetic influences are present in AN, and genetics may play a role in the occurrence of BN as well. In twin studies, concordance of approximately 55% and 35% in monozygotic twins and 5% and 30% in dizygotic twins for AN and BN, respectively, has been reported. Genetic mutation studies have focused on polymorphisms of the serotonin 2A receptor, with mixed preliminary results.¹⁰

A great deal of emphasis is placed on psychological and developmental issues in the pathogenesis of eating disorders, especially regarding the role of the family. Family separations, losses, and dysfunction (sexual or physical abuse, neglect, and substance dependence) may trigger abnormal eating behavior.^{3,8,9,13} Whether family-related issues are truly etiologic for eating disorders remains controversial, although the prognosis is better when a relatively healthy family environment is present. Finally, athletes are at special risk for eating disorders, especially female gymnasts, figure skaters, distance runners, swimmers, and male wrestlers and body builders.¹⁴

Eating disorders are complex and cannot be explained by a simple physiologic, biochemical, developmental, psychological, or psychiatric model. Instead a multifaceted perspective will best serve the clinician in making decisions about treatment alternatives.

DIAGNOSTIC CRITERIA AND CLINICAL PRESENTATION

2 AN and BN occur together in about 30% to 64% of patients with eating disorders, and may not be distinct diagnostic entities, but rather occur along a continuum of symptoms.¹⁵⁻¹⁷ Many patients initially present with either AN or BN and alternate from one eating disorder to the other or with an atypical eating disorder. Figure 62-1 presents symptoms that are specific to AN or BN and those symptoms that are shared between the disorders.

The medical consequences of eating disorders are many and are related primarily to self-induced starvation and purging. Patients commonly present with vague complaints of lethargy and pain. Metabolic and electrolyte disturbances along with dehydration are common

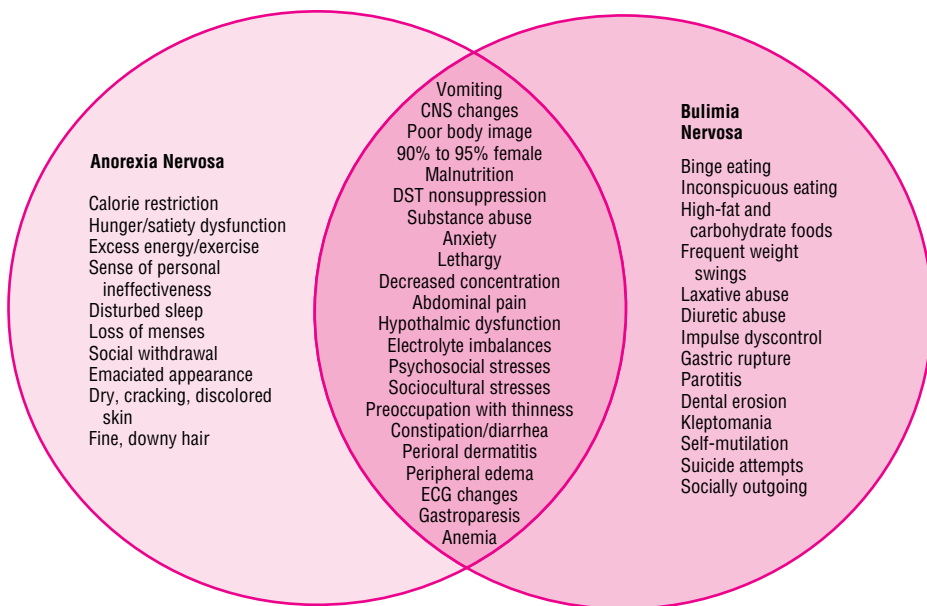

FIGURE 62-1. Signs and symptoms of anorexia nervosa and bulimia nervosa.

and occur because of poor dietary intake, self-induced vomiting, or chronic laxative and diuretic abuse. Severe electrolyte disturbances can cause cardiac disturbances and even sudden death. Abnormalities of the hypothalamic-pituitary-gonadal axis are likely the result of starvation. These abnormalities include effects on estradiol, the gonadotropins (e.g., luteinizing hormone, follicle-stimulating hormone, and gonadotropin-releasing hormone), thyroid function, adrenal function, and growth hormone.⁸ Osteoporosis and infertility are potential long-term complications of endocrine changes. Vomiting can cause dental problems, including decalcification, erosion of the enamel and dentin layers, and staining of the surfaces of the teeth.⁷ Chronic starvation can cause brain atrophy visible on computed tomographic scan as an increase in ventricular:brain ratio. Decreases in white matter and cerebrospinal fluid volumes return to normal after a healthy weight is achieved, but gray matter loss may continue to persist. Gray matter loss can be demonstrated during neuropsychological testing.^{9,18,19} A thorough physical and laboratory evaluation, as described in Table 62–1, is needed to determine the severity of medical complications.^{7,13,20} The presence of a particular medical complication depends on whether the patient engages in starvation or purging (vomiting or laxative abuse) and the frequency and severity of the behavior.

Depression, schizophrenia, obsessive-compulsive disorder, and conversion disorders should be included in the differential diagnosis of AN and BN because eating abnormalities can be a component of these illnesses. The salient difference between these psychiatric disorders and eating disorders is the overriding drive for thinness, a disturbed body image, increased energy directed toward losing weight, and binge eating episodes that are relatively specific for the eating disorders. Additionally, many patients will experience relief of the psychiatric symptoms on refeeding and not require psychotropics.⁹

TABLE 62–1. Physical and Laboratory Assessment of Eating Disorders

| Evaluation | Target Symptoms |
|----------------------|---|
| Pulse | Bradycardia |
| Blood pressure | Hypotension, orthostasis |
| Respiratory rate | Rapid if heart failure occurs during refeeding |
| Temperature | Hypothermia, cold intolerance |
| Electrocardiogram | ST depression, flat T waves, U waves, increased QT interval, atrioventricular block |
| Gastrointestinal | Hypoactive bowel sounds, gastritis, abdominal distention |
| Skin | Dry, scaling, lanugo, hair loss, calluses on fingers and hands |
| Menses | Amenorrhea |
| Complete blood count | Leukopenia, anemias, thrombocytopenia |
| Electrolytes | Hypokalemia, hypomagnesemia, hypo- or hyperphosphatemia |
| pH | Metabolic alkalosis (acidosis if laxative abuse) |
| Amylase | Elevated, pancreatitis rare |
| Liver | Hypoalbuminemia, γ -glutamyl transferase if alcohol abuse |
| Thyroid | Low to low normal, but not true disease |
| Cortisol | Elevated with lack of suppression on dexamethasone suppression test |
| Bone density | Osteoporosis |

Modified from American Psychiatric Association⁷ and Halmi.¹³

ANOREXIA NERVOSA

The core features of AN include refusal to maintain a minimal normal body weight (e.g., >85% normal body weight or body mass index >17.5 kg/m²) or failure to make expected weight gains, intense fear and obsession about weight gain or being “fat,” a distorted body image, and amenorrhea for at least three consecutive cycles. Patients typically lack an appreciation for the degree of weight loss experienced, or are preoccupied with the idea that a part of their body is too large, despite evidence to the contrary. DSM-IV-TR further classifies AN into restricting type (the person does not regularly engage in binge eating or purging behavior), or binge eating/purging type, in which they regularly participate in such behavior.⁷ The AN patient has difficulty sensing when he or she is full (satiety) and commonly complains of feeling bloated soon after they start eating. Patients also describe not feeling in control of various aspects of their life, and in particular, of caloric intake. When patients with AN are underweight, they often present with features of major depression, but these symptoms should initially be considered to be secondary to starvation and not indicative of a true mood disorder.

CLINICAL PRESENTATION OF ANOREXIA NERVOSA

GENERAL

Patients refuse to maintain body weight and have distorted perceptions about their body.

SYMPTOMS

- Patients have obsessions and fears about eating and gaining weight.
- They complain about feeling full even when they have eaten very little food.
- Denial of symptoms and low self-esteem is the norm. They often feel ineffective and have a lack of self-control.

SIGNS

Weakness, lethargy, cachexia, amenorrhea, vomiting, restricted food intake, inappropriate exercise, delayed sexual development, edema, delayed gastric emptying, constipation, bradycardia, hypotension, osteoporosis, dry cracking skin, lanugo, callus on dorsum of hand, perioral dermatitis, erosion of dental enamel

LABORATORY TESTS

Hypokalemia, hypokalemic alkalosis, hypomagnesemia, leukopenia, QT interval prolongation, ST-segment depression, U Waves, hypercholesterolemia, anemia

OTHER DIAGNOSTIC TESTS

Nonspecific EEG changes

Psychiatric comorbidity is common, as up to 75% of patients have a primary mood disorder.²¹ A link between AN and anxiety disorders, especially social phobia (fear of eating in public) and obsessive-compulsive disorder, has been noted. The lifetime prevalence of obsessive-compulsive disorder in patients with AN is reported to be as high as 25%, much higher than the lifetime prevalence in the general population (2.5%).^{21,22} Personality disorders are also more common among people with AN, especially the avoidant and obsessive-compulsive types, than in the general population.^{23,24}

CLINICAL PRESENTATION OF BULIMIA NERVOSA

GENERAL

- Patients binge eat and stop when they have abdominal pain or self-induced vomiting or are interrupted by another individual.
- They have a pattern of severe dieting followed by binge-eating episodes.
- They are concerned about their body image but do not have the drive to thinness as do patients with AN.

SYMPTOMS

- Patients do not eat regular meals and do not feel satiety at the end of a meal.
- May use laxatives for weight control.
- They have guilt, depression, and self-disparagement after binges.
- Social isolation can result from frequent bingeing.
- Chaotic and troubled personal relationships and substance abuse are common.

SIGNS

Bingeing, vomiting, salivary gland inflammation, erosion of dental enamel, callus on dorsum of hand, perioral dermatitis, caries, parotid gland enlargement, abdominal pain. Upper end of normal weight or slightly overweight. Frequent weight fluctuations. Diminished masticatory ability.

LABORATORY TESTS

Hypokalemia, hypochloremic metabolic acidosis, elevated serum amylase

OTHER DIAGNOSTIC TESTS

None

BULIMIA NERVOSA

The core feature of BN is recurrent episodes of binge eating (an excessive intake of calorie-laden food over a short period of time). Persons with BN are overly sensitive about their weight and have a

distorted body image. Most have normal weight, although they may fluctuate between being slightly underweight to slightly overweight for body size and age. Patients lack control over their eating and participate in recurrent compensatory behavior to prevent weight gain. This can include self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; strict dieting or fasting; or excessive exercise. To meet DSM-IV-TR criteria, the binges and compensatory behaviors must occur on average at least twice weekly for 3 months. DSM-IV-TR further differentiates an episode of BN into purging type (the person regularly engages in self-induced vomiting or the misuse of laxatives, diuretics, or enemas) or nonpurging type (the person uses other inappropriate compensatory behaviors, such as fasting or excessive exercise, but doesn't engage in purging activities).⁷

Patients typically binge one or more times daily and vomit at least once daily. Patients can consume between 5,000 and 20,000 calories during a single binge, although caloric intake can be smaller. Patients tend to consume foods that are easy to ingest, do not require much chewing or preparation, and are high in carbohydrates or fat (e.g., ice cream, bread, candy, or doughnuts). Binge eating typically is secretive, and episodes are often precipitated by a stressful event. Because patients lose control over their eating behavior, they are often remorseful after a binge. Binges typically last less than 2 hours, but can last for more than 8 hours. To compensate for the excessive caloric intake, many patients fast for prolonged periods, exercise compulsively, purge, or abuse laxatives.

Psychiatric comorbidity includes depression (up to 80%), impulse-control problems, and substance abuse. Approximately 30% to 37% of bulimic patients have a personal history of substance abuse.²⁵ Kleptomania is reported more commonly in patients with BN than in the general public. Patients commonly steal comfort items such as laxatives, candies, and clothes.⁸ Personality disorders, especially borderline and avoidant types, are more common in these patients than in the general population.^{23,24}

BINGE EATING DISORDER

Binge eating disorder presents with recurrent episodes of binge eating without the compensatory behaviors associated with bulimia or anorexia. It is estimated that 5% to 10% of patients seeking treatment for obesity have the disorder. BED patients are likely to have comorbid depressive disorder, although the self-deprecating focus on body image is less severe than in AN or BN.^{10,24}

► TREATMENT: Eating Disorders

■ PROGNOSIS

■ ANOREXIA NERVOSA

The long-term prognosis of AN patients is not clear, as studies focus on people who receive treatment and not all who experience the condition. The course of AN most commonly consists of a single episode with subsequent return to normal weight. These patients may still experience issues with disturbed body image, disordered eating, and other psychiatric problems.⁹ Some patients experience an unremitting course leading to death, while others suffer episodically. One study found that 50% of AN patients had a "good" outcome, 30% had a "medium" outcome, and 20% a "poor" outcome.²⁶ More recent data showed that only 10% of patients met full criteria for AN a decade after initial treatment, although chronic symptoms including lower body weight and perfectionism continued. Many later developed BN,

but in most cases it remitted. Finally, their rates of anxiety disorders, major depression, and alcohol dependence were higher than in the general population.²⁷ A poorer prognosis is associated with a longer duration of illness, presenting with a lower initial weight, having a premorbid history of poor family relationships, and the presence of BN or purging behavior.^{10,28,29} The actual mortality rates in AN are unclear, but they are among the highest of all psychiatric disorders. Long-term follow-up shows that over 10% of AN patients eventually die, primarily from cardiac arrest or suicide.⁷

■ BULIMIA NERVOSA

The prognosis of BN has not been well studied. Overall, BN patients appear to have a better prognosis than AN patients. Patients with

milder presenting symptoms who are treated as outpatients tend to do better, whereas patients with electrolyte imbalances, esophagitis, dental caries, and salivary gland enlargement have a more complicated course.⁸ A 6-year follow-up of patients who received intensive treatment found that 60% were “good,” 29% had “intermediate” response, 10% were doing “poorly,” and 1% had died.³⁰ It is important to note that even in cases in which patients respond, they continue to exhibit symptoms, the severity of which waxes and wanes over time in response to their external environment. Total absence of symptoms is a less common outcome. The actual definition of recovery varies, since once-a-month binge/purge episodes are considered by some to be recovery if their episodes were previously more frequent, whereas others consider a patient recovered only when complete absence of these behaviors occurs.²⁸ Of concern is that ongoing symptoms may predispose patients to relapse.³¹

GENERAL APPROACH TO TREATMENT

The overall goals for patients with AN, BN, and BED are to reduce distorted body image, restore and maintain healthy body weight, re-establish normal eating patterns, improve associated psychological and physical problems, resolve contributory family problems, and prevent relapse. An individualized treatment plan is based on the specific core features of the eating disorder and comorbid medical and psychiatric conditions present in the patient, along with the severity of those symptoms. Psychiatrists, nutrition specialists, psychologists, nurses, and pharmacists all play a role in the care of these complex patients. The patient and their close friends and relatives must all be engaged in treatment planning, as denial is a common problem, and without their active participation, treatment will not be a success. Even with a comprehensive treatment approach, complete recovery can be difficult to attain. A critical first step is to determine the illness severity, as that drives both the intensity and the setting for delivery of care. For example, a patient with severe medical complications from starving and purging will require hospitalization, as opposed to the patient who binges and purges daily, but is medically stable and can be managed as an outpatient. Hospitalization is based on the criteria outlined in Table 62–2 and is limited to only the most severely ill patients.^{10,13,14} Patients with BN are usually managed in the outpatient setting, as they are usually medically stable. Medications are rarely indicated as a sole treatment for eating disorders, but are part of a comprehensive treatment strategy.^{32–34}

TABLE 62–2. Criteria for Hospitalization of Patients with Eating Disorders

- Significant weight loss of 20% or more of normal weight, particularly if weight loss has been recent and rapid, severe starvation symptoms are present, or the patient has been ill for more than 2 years
- Medical complications (e.g., edema) and metabolic abnormalities (e.g., hypoproteinemia) from bingeing, purging, and starvation (e.g., heart rate <40 bpm, blood pressure <90/60 mm Hg, glucose <60 mg/dL, potassium <3 mEq/L, temperature <97°F)
- Suicidal ideation or psychotic depression
- Nonresponsive to outpatient treatment (after 3–4 months) and poor motivation to recover
- Demoralization or nonfunctional family
- Continuous supervision required to prevent purging (vomiting or laxative abuse)

Modified from Fairburn and Harrison,¹⁰ Halmi,¹³ and Powers.¹⁴

ANOREXIA NERVOSA

Nonpharmacologic Treatments

3 Evidence supports that nonpharmacologic treatments have the greatest likelihood of causing a response in AN patients.^{9,32} Behavioral management, cognitive behavioral therapy (CBT), interpersonal psychotherapy (IP), nutritional counseling, and family therapy, especially for adolescent patients, are all options available to the clinician.^{9,13} CBT helps the patient overcome distorted thinking, self-worth that is measured by body image, feelings of being fat despite evidence to the contrary, and denial of the seriousness of the condition. CBT also teaches patients how to use strategies besides food to cope. IP focuses on interpersonal relationships and functioning, whereas behavioral therapy provides positive reinforcement for weight gain.²¹ The benefit of treatment based on an addiction model (12-step program) is not supported by the literature.^{9,10} It is critical to note that many psychiatric symptoms in an acutely ill patient, such as depression and anxiety, will diminish or disappear entirely after normal weight is restored. Hence, initial treatment is directed toward restoring a healthy weight (>90% of normal weight for age-matched controls) and treating food phobias.³⁵ After the patient is medically stable and at their appropriate weight, therapy can be redirected toward addressing ongoing interpersonal problems, weight maintenance, cognitive restructuring, and finally, skill development for relapse prevention.³⁶ Oral refeeding, initially with liquid formulas if necessary, is the most common approach to weight restoration.

4 Total parenteral nutrition is reserved for the initial management of severely malnourished patients, or when oral refeeding fails. The decision to administer total parenteral nutrition must be made carefully because of the potentially devastating psychological effect on patients who do not wish to gain weight. A controlled weight gain of no more than two to three pounds each week is recommended. Patients usually start by consuming 1000 to 1600 calories per day and slowly titrate upwards until they demonstrate sustained weight gain. Some patients may need as many as 70 to 100 kcal/day during the weight gain phase. Patients may also need 200 to 400 extra calories a day to maintain their weight gain.^{10,37} Slow refeeding is important in order to minimize medical and psychological consequences that can occur with a more rapid weight gain.¹⁰ Complications can include circulatory overload and severe anxiety.

Pharmacologic Therapy

Antidepressants currently play no role in treating acute AN. Antidepressants, and in particular selective serotonin reuptake inhibitors (SSRIs), theoretically work because of their impact on serotonin, a neurotransmitter which is involved with many of the behaviors that are disturbed in AN.¹³ This recommendation is based on recent analyses of the literature and the most recent practice guidelines from the American Psychiatric Association.^{9,10,32}

5 Data suggest that medication is ineffective if a patient weighs less than 85% of their expected weight.^{35,38} Antidepressants should be initiated only if depression, anxiety, obsessions, or compulsions persist after the target weight is achieved.¹⁰ The duration of treatment when antidepressants are used in this manner is unclear, but the trial that found a benefit treated patients for 1 year.³ Antidepressants, along with psychotherapy, have been used to help maintain weight and prevent relapse, although the data are limited.³⁹ If antidepressants are indicated, most clinicians prefer the SSRIs because

they are better tolerated and have greater cardiovascular safety than tricyclic antidepressants (TCAs), especially in low-weight patients.⁴⁰ Patients are sensitive to anticholinergic and cardiovascular effects, and if TCAs are used at all, low starting doses and a slow titration toward an effective dose are needed. The risk of cardiotoxicity in a malnourished population must not be underestimated, especially in chronic purgers, who may have hypokalemia. A baseline electrocardiogram (ECG) must be obtained before beginning an antidepressant. Open trials used fluoxetine, 20 to 60 mg/day.^{37,41} The one long-term trial that found a benefit used 20 mg/day.³⁹ Since dosing information is limited, most clinicians will initiate patients at lower doses, for example 20 mg/day, and increase to a maximum of 60 mg/day if there is an inadequate response or relapse and the drug is tolerated.

■ **Antipsychotics.** Typical antipsychotics were the first medications used to treat AN because of their potential to reduce obsessive thoughts, paranoid ideation about weight gain and anxiety, and promote weight gain.⁴² Clinical experience found little specific improvement secondary to typical antipsychotic administration in AN patients and that the risks outweighed the benefits. However, interest in antipsychotics for acutely ill AN patients has re-emerged because of the introduction of atypical agents whose safety profile is improved over older agents. Most of the data are from case reports or small trials using risperidone 0.5 to 1.5 mg daily or olanzapine 5 to 10 mg daily.^{43–45} Improvement has been shown in some, but not all trials, hence these agents require further study before they become a routine part of care. Caution is important as revealed by a case report of increased QTc interval in an AN patient taking risperidone.⁴⁶ Any change in QTc interval must be taken seriously in a population at risk for hypokalemia. Optimal treatment duration is unknown, as most of the larger studies were ≤ 3 months in length. In some case studies symptoms remained in remission even after the medication was discontinued.⁴⁷

■ **Miscellaneous Agents.** Metoclopramide may be helpful in reducing the bloating, early satiety, and abdominal pain commonly found in AN, but it does not impact weight gain.⁹ Low-dose short-acting benzodiazepines (0.25 mg alprazolam or 0.5 mg lorazepam) given before meals are useful when severe anxiety limits eating.⁹ Estrogen replacement has been used, but restoring menses through refeeding is a better approach to minimizing bone density loss. Estrogen use to restore menses may reinforce the patient's denial of their illness.³⁵

Overall, the treatment goals in AN are for the patient to recognize their need for treatment, restore and maintain their weight at a healthy level, normalize eating habits, and improve psychosocial functioning (body image and peer interactions). The value of family therapy for treating adolescents has been demonstrated in the literature and should be provided to AN patients. Overall, CBT is the most commonly applied strategy in eating disorder programs. Currently antidepressants have no role in acutely ill patients, while the data in weight maintenance are limited but suggestive of some value.^{9,10} Atypical antipsychotics may be used in acutely ill patients, but further data are needed to determine their precise role.

CLINICAL CONTROVERSY

Clinicians continue to look for medications that are beneficial during the acute phase of AN. Atypical antipsychotics are being used by some clinicians in acutely ill patients with severe obsessions and paranoia about eating, although the data supporting this are limited.

■ BULIMIA NERVOSA

■ Nonpharmacologic Therapy

The nondrug strategies used in BN are similar to those used with AN and are equally critical to success. CBT has the strongest evidence supporting its benefit in managing BN.^{9,10} IP also plays a role and has a moderate degree of evidence to support its use.^{9,10} Behavioral approaches such as planned meals and self-monitoring can help interrupt the binge-purge cycle. Nutritional counseling and family therapy are also important components of treatment. Family therapy in BN patients is less critical than with AN, as these patients tend to be older. Programs using guided self-manuals based on CBT as a non-pharmacologic approach are also showing promise, although further study is indicated.^{13,48} Twelve-step programs for BN play an adjunctive role at best, as the data supporting their efficacy are lacking.^{9,10} Supportive counseling encouraging medication compliance may be needed early in treatment while the patient becomes tolerant to adverse effects.

■ Pharmacologic Therapy

6 ■ **Antidepressants.** Antidepressants are used in the acute and maintenance phase of BN management, although they are adjunctive to nonpharmacologic approaches. Theoretically, the benefit is derived from an increase in central serotonin concentrations.⁸ A wide array of antidepressants, including TCAs, monoamine oxidase inhibitors, trazodone, and SSRIs, have been studied in numerous clinical trials since the 1980s, and many of these studies were placebo controlled.^{49–58} Additionally, several recent reviews analyzing this body of literature have been published, although there is limited new literature since the mid-1990s.^{10,32} Antidepressants are reported to reduce depression, anxiety, obsessions, impulsive behaviors such as binge eating and purging, and improve eating habits, although their impact on body dissatisfaction remains unclear. The presence of comorbid mood disorders is not necessary for an antidepressant response, as patients with and without depression responded equally well to the medication.^{10,59,60}

The benefit appears to be more robust in the acute phase of the illness, as relapse despite continued antidepressant use is common in patients who are in or near remission.^{10,13,34} Short-term (6 to 8 weeks) antidepressant response varies across trials, and reduction in frequency of binge/purge behavior has been as high as 73% and as low as zero.³² Abstinence rates with short-term use range from none to 68%. More data are needed to determine the long-term benefits of antidepressants for preventing relapse of BN symptoms. One recent trial evaluating the impact of fluoxetine versus placebo in the maintenance of response was promising, as it found a better outcome in patients receiving fluoxetine 60 mg/day. It should be noted that dropout rates were high in both groups, somewhat blurring the overall benefit of active medication.⁶¹

7 ■ SSRIs are the preferred agents because of their tolerability and because they may have been studied in the largest number of patients. Fluoxetine is the only agent to have Food and Drug Administration approval for BN. Tolerability is the primary criterion for selecting an antidepressant in BN because of patients' heightened sensitivity to adverse effects and lack of a clear difference in efficacy between the classes. Even though there is a suggestion that monoamine oxidase inhibitors produce the most robust effect, the complications of using these medications in impulsive patients and the fact that the data are

more than 10 years old limits their use.³⁴ Bupropion is not used in patients with BN because of an unacceptably high risk of seizures.

A careful baseline physical examination, ECG, and laboratory work-up are essential. Underlying ECG changes (U waves, prolonged QT interval, or flattened T waves) secondary to hypokalemia or bradycardia and atrioventricular block from starvation may be present. All antidepressants can cause seizures; thus a careful risk-benefit assessment is warranted if the patient has predisposing factors such as a personal or family history of seizures, cerebrovascular disease, or alcohol or sedative-hypnotic withdrawal.

Doses in BN are in the same range as for patients with depression. Readers are referred to Chap. 67 on depressive disorders for a discussion of dosing ranges for antidepressants. For fluoxetine, the higher end of the dosing range, 60 mg/day, may be necessary for response.⁵⁶ With other agents, most clinicians will initially target the bottom to the middle of the dosing range and increase the dose if there is an inadequate response and the patient is known to be compliant. Slow titration is needed to allow time to develop tolerance to adverse effects. TCA serum concentration monitoring is recommended to ensure that absorption is not compromised by purging. The same TCA serum concentration ranges are used in depression and BN.

8 The time for antidepressant onset of effect in BN is unclear. In the absence of data, the definition of a therapeutic trial from the depression literature (4 to 8 weeks at a therapeutic dose) should be used. Since the majority of subjects will not experience a complete remission, and there are few data on predictors of response or whether switching to another class will improve response, a clear and specific target should be stated initially.⁹ For example, will the medication be continued if the patient has a 50% reduction in binge-purge episodes, or if abstinence from such behavior is the ultimate therapeutic goal.

9 Optimal duration of treatment after response is also poorly defined. Most clinicians will treat for 6 months to 1 year and then re-evaluate the need for ongoing treatment. The evidence is mixed as to whether any early benefit is sustained, hence the decision to continue treatment should be made based on both initial response and the maintenance of that benefit. If the symptoms return within a few months after the antidepressant is discontinued, then the treatment may need to be reinitiated.

Table 62-3 describes potential guidelines for medication use in BN, but it must be noted that no evidence-based consensus for treatment has been endorsed, even with the recent meta-analyses and reviews of the literature.^{3,10,32,34,40} The selection of an effective treatment approach is especially challenging when patients fail CBT.¹⁰

Mood Stabilizers (Lithium and Anticonvulsants). Due to the lack of evidence demonstrating their benefit, lithium and anticonvulsants are reserved for BN patients with a comorbid bipolar affective disorder.^{9,62-66} Target serum concentrations and doses are similar to those used for patients with seizure or mood disorders. Lithium must be used cautiously, because purging and laxative abuse increases the risk of toxicity. The adverse effect of weight gain often makes mood stabilizers and anticonvulsants unacceptable to patients in the long term.

Miscellaneous Agents. Low-dose benzodiazepines, such as 0.25 mg alprazolam three times a day administered before meals, may help reduce anxiety associated with refeeding, although long-term use is not warranted for many patients because of the risk of dependence. One double-blind trial with ondansetron has shown benefit, but the data remain too limited to recommend a specific role for the agent.⁶⁷

TABLE 62-3. Guidelines for Medication Use in Bulimia Nervosa

1. Determine baseline frequency of binge and vomiting episodes, laxative abuse, obsessive thoughts, and compulsive behavior. Document weight and patient's subjective feelings of self-image. Describe a baseline level of functioning.
2. Identify comorbid psychiatric conditions (e.g., depression, anxiety disorder, substance abuse, or bipolar disorder).
3. Determine baseline physical status (especially nutritional status, electrocardiogram, and fluid status [dehydration and electrolytes]).
4. Consider whether an antidepressant is part of a comprehensive treatment plan that includes nonpharmacologic measures, especially cognitive behavioral therapy.
5. If antidepressant is indicated, start at a low dose, and use a selective serotonin reuptake inhibitor unless there is a medical reason not to do so.
6. Monitor carefully for response, adverse effects, and compliance. Response usually is seen after 6-12 weeks. Response is determined by change from baseline frequency and severity of target symptoms.
7. If patient responds and response is sustained, continue treatment for 6-12 months, then reassess.
8. If response is poor, evaluate compliance and whether patient is receiving nonpharmacologic therapy.
9. There is no good evidence as to what treatment to try if medication is not effective.

Antipsychotics and appetite suppressants do not play a role in managing this condition.¹⁰

■ Nonpharmacologic versus Pharmacologic Approaches

Antidepressants have been compared directly to CBT and other forms of psychotherapy. The results were mixed, and some studies had very high dropout rates, making interpretation difficult. Overall, nonpharmacologic methods were superior to medication alone, and in many cases were better accepted by the patient.^{32,68} There are limited data to suggest that some patients who fail psychotherapy (CBT or IP) respond to antidepressants.^{69,70} Antidepressants without some form of psychotherapy have also been proposed as a first step in the primary care setting before referral to specialty care occurs. Primary care settings are generally ill-prepared to provide the type of specialty psychotherapy required in BN patients, but can manage antidepressant issues.¹⁰

The most common scenario, and one recommended by most clinicians, is a combination of drug and nondrug approaches.⁹ The literature is somewhat mixed as to whether the addition of antidepressants offers significant benefit, but there is enough positive literature to recommend this course of treatment.^{49,71-74} A serious challenge in the care of these and other eating disorder patients is that quality CBT and other nonpharmacologic approaches are often unavailable.

In summary, the combination of pharmacologic and nonpharmacologic measures appears to produce the best chance for a positive outcome for patients with BN.³² Antidepressants are the class of choice in patients with BN, while other medications such as mood stabilizers are reserved for patients with comorbid psychiatric conditions. Only in unusual circumstances should patients be treated with antidepressants alone, as the chances for success are not high. SSRIs are the antidepressant class of choice for managing BN patients. Evidence suggests the greatest benefit in the acute phase of treatment, whereas data are more mixed for their role in the prevention of relapse.

CLINICAL CONTROVERSY

The optimal time to continue antidepressant therapy in BN patients after a response is unclear. Some patients will maintain their response, while others will deteriorate and become symptomatic while continuing on medication. Most clinicians advise the patient to continue the antidepressant for 6 to 12 months if they respond, then re-evaluate whether further treatment is needed.

BINGE EATING DISORDER

The treatment goals for BED are different from those of the other eating disorders because patients are often obese and in need of significant weight loss along with control of their binge eating behavior. Many patients also experience depression. As with the other eating disorders, CBT and IP appear to be the most effective interventions.¹⁰ Antidepressants, anticonvulsants, and appetite suppressants are the pharmacologic agents with the greatest promise in BED, but data are limited, trials are short in duration (16 weeks or less), and

the issue of sustained benefit is unclear.⁷⁵ Antidepressants have demonstrated efficacy during the acute phases of the illness compared to placebo.^{10,76–78} The majority of the data are with SSRIs given at antidepressant doses.⁷⁵ Topiramate 50 to 600 mg daily (a median dose is approximately 200 mg daily) is receiving attention in treating BED because anticonvulsants have been used with some benefit in patients with impulse control disorder and because it promotes weight loss. Short-term data demonstrating superiority over placebo have been published, but long-term data are lacking.⁷⁹ Sibutramine 15 mg/day has also demonstrated benefit in reducing weight and binge frequency in obese patients with BED compared to placebo.⁸⁰

In summary, the question of where BED fits on the diagnostic spectrum continues to be explored. An increasing body of literature suggests that three different types of pharmacologic agents (SSRIs, topiramate, and sibutramine) hold promise in the short term, but long-term data are lacking. As with other eating disorders, nonpharmacologic treatments are key to a successful outcome. Control of both weight and binge eating is important, as these patients are at risk for developing cardiovascular and endocrine complications as well as the negative consequences from the psychiatric sequelae.

PHARMACOECONOMIC CONSIDERATIONS

There are no formal evaluations of the economic impact of eating disorders on individual patients, on global health care costs, or on indirect costs such as unemployment, premature death, or disability payments. Certainly the chronic course, the disability found in severe cases, and the lack of improvement in up to a third of patients suggest a significant cost impact. Clinicians should contribute to the appropriate use of resources by ensuring that medications are used in situations in which there is evidence demonstrating their benefit and that they are never used as the sole treatment modality. For example, antidepressants are started after normal weight is restored in AN patients and not to treat depressive symptoms in significantly malnourished patients. One study evaluating the relative costs of CBT alone, medication alone, or combination treatment of BN concluded that if overall effectiveness was the prime consideration, then CBT, with medication added if the response was inadequate, was the best approach. If cost-effectiveness was the basis for making treatment decisions, then antidepressants alone as a first step, followed by the addition of CBT when response was inadequate, was the preferred direction to take.⁸¹ These data were published in 1994, and clearly more study is needed to make evidence-based decisions about the best order and combination of treatment.

EVALUATION OF THERAPEUTIC OUTCOMES

ANOREXIA NERVOSA

A combination of subjective and objective measures is used to assess patient response. A reduction in the frequency and severity of abnormal eating habits, normalized exercise patterns and laboratory tests, and a sustained weight close to age-matched normals are key indicators of response. A diary recording exercise frequency, menses, food intake, patterns of eating, and associated feelings while eating is a useful tool to track progress, especially in the outpatient setting. Weekly weigh-ins on the same scale, preferably at a clinician's office, help monitor progress early in treatment and reduce the focus on weight and anxiety due to the variability found among different

scales.³⁶ Follow-up laboratory tests and ECGs are not part of routine monitoring unless the patient is restricting food intake, is purging, or continues to lose weight despite treatment. Inpatients require daily assessment of weight and caloric intake, vital signs, and urine output because of the more severe nature of their illness. They also may need monitoring of bathroom privileges early in their care. A healthy weight gain of no more than two to three pounds per week toward a goal of 90% to 95% of normal weight or a body mass index $> 18.5 \text{ kg/m}^2$ is a critical sign of treatment success. A patient's use of coping skills and contingencies for dealing with stress other than manipulating food consumption also should be assessed. Antidepressants may assist in alleviation of persistent depression, anxiety, and obsessions, after weight restoration. Improvement in mood is expected to occur within 8 weeks. Patients receiving TCAs should be evaluated for anticholinergic effects, especially dry mouth and constipation, hypotension, and sedation. Patients receiving SSRIs should be monitored for agitation, drug-induced anorexia, nausea, weight loss, and insomnia. The decision to use long-term medication must be based on specific and sustained improvement in the target symptoms already mentioned, balanced against tolerance of adverse effects.

BULIMIA NERVOSA

An individualized treatment and monitoring plan begins with a thorough assessment describing the baseline frequency and severity of treatment-responsive target symptoms and other associated findings. The assessment must be comprehensive, as a patient may hide their illness by shifting from one type of behavior to another. For example, they may switch from compulsive exercise to purging after meals as a way to compensate for bingeing.

◀ A comprehensive assessment includes a description of psychiatric symptoms, physical findings, frequency and severity of binge/purge episodes, laxative and ipecac use, exercise patterns, and laboratory and ECG abnormalities.⁶ Interpersonal and relationship problems should also be evaluated. Some findings indicating a more chronic course of illness, such as salivary gland inflammation or erosion of dental enamel, may take months to reverse or may never normalize, hence these are not sensitive indicators of early treatment

response. Data describing a patient's baseline level of functioning and previous response to treatment should be used to set goals in the current treatment plan.

Antidepressant response usually occurs within 4 to 8 weeks after the onset of treatment. If response does not occur, binge/purge behavior should be considered as a contributing factor. If this behavior is not present, then every attempt should be made to maximize the dose. Serum concentration monitoring, when appropriate as with TCAs, should be done periodically (every 3 to 6 months if a patient is responding and tolerating the medication, or more frequently if clinically indicated). Evaluation of previously described adverse effects also should be part of the monitoring plan. If the patient responds, they should be followed for 6 to 12 months, then the need for ongoing medication should be reassessed. If the patient relapses upon medication discontinuation, then the medication should be restarted.

Ambulatory eating disorder patients present a particular challenge to clinicians. Impulsivity associated with BN may increase the risk for suicide. Prescriptions should be limited to small supplies. In addition, pharmacists should be alert to persons who make large or frequent purchases of laxatives or ipecac syrup, as this is an indicator of possible bulimic behaviors.

CONCLUSIONS

Our understanding of the pathophysiology and symptomatology of eating disorders has improved significantly over the past several years. Medication serves an adjunctive role to a variety of psychosocial therapies in AN, whereas it plays a more central role in BN and BED treatment. By gaining a greater understanding of the underlying physiologic changes and the psychosocial complications associated with eating disorders, treatment plans can be specifically designed for an individual patient with the goal of improving their quality of life.

ABBREVIATIONS

AN: anorexia nervosa
 BED: binge eating disorder
 BN: bulimia nervosa
 CBT: cognitive behavioral therapy
 IP: interpersonal psychotherapy
 SSRI: selective serotonin reuptake inhibitor
 TCA: tricyclic antidepressant

ALZHEIMER'S DISEASE

Jennifer D. Faulkner, Jody Bartlett, and Paul Hicks

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The prevalence of Alzheimer's disease (AD) increases with each decade of life and is more common in females.
- 2 The etiology of AD is unknown, and pharmacotherapy neither cures nor arrests the pathophysiology.
- 3 Neuritic plaques and neurofibrillary tangles are the pathologic hallmarks of AD; however, the definitive cause of this disease is yet to be determined.
- 4 AD affects multiple areas of cognition and is characterized by a gradual onset with a slow progressive decline.
- 5 A thorough physical and neurologic exam, as well as laboratory and imaging studies, are required to rule out other disorders and diagnose AD before considering drug therapy.
- 6 Early initiation and continued, uninterrupted treatment provide the optimal cognitive benefit.
- 7 Pharmacotherapy for AD focuses on impacting three domains: cognition, psychiatric symptoms, and activities of daily living.
- 8 Nondrug therapy and social support for the patient and family are the primary treatment interventions for AD.
- 9 Cholinesterase inhibitors and memantine are used to treat cognitive symptoms of AD; other medications have been suggested to be beneficial because of their potential preventive or cognitive effects.
- 10 Slow medication dosage titration with careful monitoring should be done to minimize the incidence of troubling adverse drug reactions.
- 11 A thorough behavioral assessment and plan with careful examination of environmental factors should be conducted before initiating drug therapy for behavioral symptoms.
- 12 Pharmacotherapy may reduce the total cost of treating AD by delaying cognitive decline and time to nursing home placement.

I now begin the journey that will lead me into the sunset of my life.

Ronald Reagan

Alzheimer's disease (AD), first characterized by Alois Alzheimer in 1907, is a gradually progressive dementia affecting both cognition and behavior. The exact pathophysiologic mechanisms underlying AD are not entirely known, and no cure exists.¹ Although drugs may reduce AD symptoms for a time, the disease is eventually fatal.

AD profoundly affects the family as well as the patient. The need for supervision and assistance increases until the late stages of the disease, when AD patients become totally dependent on a family member, spouse, or other caregiver for all of their basic needs. These are the all-too-common experiences of the millions of people in the United States who have AD.

EPIDEMIOLOGY

AD is the most common cause of dementia, accounting for over 60% of cases of late-life cognitive dysfunction.¹ Table 63–1 lists etiology-based subclasses of dementia. This chapter focuses exclusively on dementia of the Alzheimer's type. However, the reader is encouraged

to use the nonpharmacologic approaches and management of behavioral problems outlined in this chapter to assist in the general treatment approach to other types of dementia that may share similar features with AD.

Approximately 4.5 million Americans have AD.² By the year 2050, one of five people will be over age 65 years, and the number of AD patients is projected to be 13.2 million (Fig. 63–1). AD is generally associated with the elderly because most cases present in persons older than age 65, but in about 5% of cases onset can be as early as age 40, resulting in the arbitrary age classifications of early-onset (ages 40 to 64 years) and late-onset (age 65 years and older).^{3,4}

1 The prevalence of AD increases exponentially with age, affecting approximately 7% of individuals aged 65 to 74 years, 53% aged 75 to 84, and 40% of persons aged 85 years and older.² AD affects two times as many women as men, and family history of AD may increase the risk of inheriting the disease by up to fourfold.³ Although genetic inheritance is a significant factor in its transmission, other factors may contribute. Factors determining age of onset and rate of progression remain largely undefined.

Survival following AD onset is estimated to be 3 to 20 years, with an average of 8 years after the onset of symptoms.³ Approximately 100,000 individuals with AD die every year. AD is the eighth leading cause of death in United States.⁵ This is somewhat of a misrepresentation, as AD does not cause death directly, but indirectly by

TABLE 63–1. Classification of Dementia

| |
|--|
| Dementia of the Alzheimer’s type |
| Vascular dementia |
| Dementia due to human immunodeficiency viral disease |
| Dementia due to head trauma |
| Dementia due to Parkinson’s disease |
| Dementia due to Huntington’s disease |
| Dementia due to Pick’s disease |
| Dementia due to Creutzfeldt-Jakob disease |
| Dementia due to other general medical condition (e.g., normal-pressure hydrocephalus, hypothyroidism, brain tumor, vitamin B ₁₂ deficiency, intracranial radiation) |
| Substance-induced persisting dementia (e.g., alcohol, inhalant, sedative, hypnotic, anxiolytic, or other substance) |
| Dementia due to multiple etiologies |
| Dementia not otherwise specified |

predisposing patients to sepsis, pneumonia, choking and aspiration, nutritional deficiencies, and trauma.⁶

ETIOLOGY

2 The exact etiology of AD is unknown; however, several genetic and environmental causes have been explored as potential causes of AD.

GENETICS

Genetic factors have been investigated in both early- and late-onset AD. Almost all early-onset cases of AD can be attributed to alterations on chromosomes 1, 14, or 21. The majority and most aggressive early-onset cases are attributed to mutations of an Alzheimer’s gene located on chromosome 14, which produces a protein called presenilin 1.⁷ Similar in structure to presenilin 1 is a protein produced by a gene on chromosome 1 called presenilin 2. Presenilin 2 is responsible for early-onset AD in a family of Germans living in Russia’s Volga Valley.⁸ Both presenilin 1 and presenilin 2 encode

for membrane proteins that may be involved in amyloid precursor protein (APP) processing. It has been suggested, but not proven, that presenilins are either γ -secretase or that presenilins affect γ -secretase activity.⁷ APP is encoded on chromosome 21. Only a small number of early-onset familial AD cases have been associated with mutations in the APP gene, resulting in overproduction of beta-amyloid protein (β AP).^{7,8}

Genetic susceptibility to late-onset AD is thought to be primarily influenced by the apolipoprotein E (apo E) genotype. The gene responsible for the production of apo E is located on chromosome 19 in a region previously associated with late-onset AD. Three major subtypes or alleles of apo E occur, and are termed apo E2, apo E3, and apo E4.^{7,8} Humans inherit one copy of the apo E gene from each parent. Apo E3 is the most common type, occurring in 40% to 90% of the population, with apo E2 and apo E4 occurring less frequently.⁷ However, rather than being causative, the apo E4 allele is a risk factor for development of AD.

Inheritance of the apo E4 isoform increases risk for late-onset AD; however, the degree of risk depends on such factors as the number of apo E4 copies, age, ethnicity, and gender.^{4,7} Overall, about 40% of patients with late-onset AD have at least one copy of apo E4. Individuals homozygous for apo E4 are at increased risk, and as many as 90% of persons inheriting two copies of apo E4 will develop AD by age 80 years. Moreover, onset of symptoms occurs at a relatively younger age as compared to patients having zero or only one copy of apo E4 in their genotype.^{4,7} In Caucasians, inheriting a single copy of apo E4 increases AD risk, whereas inheriting the apo E2 allele may protect against AD.^{7,9} Differences also exist with regard to gender; inheriting one copy of apo E4 increases risk in females more than in males.³

Although inheritance of the apo E4 allele increases the risk of AD, it is not diagnostic or even essential for disease presence. AD occurs in persons with no copies of apo E4 and not all persons with two alleles of apo E4 develop AD. If a person homozygous for apo E4 does not develop AD by age 80 years, it is unlikely to occur.

Genetic factors have been linked to both early- and late-onset AD. Alterations to chromosomes 1, 14, and 21 have been associated with early-onset AD, whereas the presence of apo E4 alleles increase a person’s risk of developing late-onset AD. However, genetic causes of AD have been associated with only a small percentage of Alzheimer’s patients, and the exact cause of AD remains unknown.

ENVIRONMENTAL AND OTHER FACTORS

A number of environmental factors have been associated with an increased risk of AD, including stroke, alcohol abuse, small head circumference, repeated or severe head trauma, Down syndrome, and lower levels of education.^{10–12} In particular, traumatic head injury in combination with the apo E4 genotype has been associated with an increased risk of AD.¹³

PATHOPHYSIOLOGY

STRUCTURAL CHANGES

AD is defined by both neuropathologic and clinical criteria. Neuropathologically, AD destroys neurons in the cortex and limbic structures of the brain, particularly the basal forebrain, amygdala, hippocampus, and cerebral cortex. These areas are responsible for higher learning, memory, reasoning, behavior, and emotional control. Anatomically, four major alterations in brain structure are seen:

FIGURE 63–1. Our aging population. The percentage of U.S. population over age 65 years and the percentage with AD projected from years 2000 to 2050. (Estimates based on data from Crismon and Eggert¹ and U.S. Census Bureau.¹⁰⁶)

cortical atrophy, degeneration of cholinergic and other neurons, presence of neurofibrillary tangles (NFTs), and the accumulation of **3** neuritic plaques.^{1,7,14} NFTs and neuritic plaques are considered the signature lesions of AD; without them AD does not occur. Plaques and tangles may also be present in other diseases, even in normal aging, but there is a much higher concentration of plaques and tangles in patients with AD. To understand the causes of AD, researchers must discern the circumstances in which these lesions lead to the clinical picture of AD.¹³

NFTs are comprised of paired helical filaments that aggregate in dense bundles. Paired helical filaments are formed from tau protein. Tau protein provides structural support to microtubules, the cell's transportation and skeletal support system.^{7,13} When tau filaments undergo abnormal phosphorylation at a specific site, they cannot bind effectively to microtubules, and the microtubules collapse. Without an intact system of microtubules, the cell cannot function properly and eventually dies.¹³ Overactivity of kinases such as microtubule affinity-regulating kinase, or underactivity of phosphatases could theoretically produce or prevent breakdown of abnormally phosphorylated tau protein.^{7,13} NFTs are found in other dementing illnesses besides AD, and may represent a common method by which various inciting factors culminate in cell death.⁷

Neuritic plaques (also termed amyloid or senile plaques) are extracellular lesions found in the brain and cerebral vasculature (amyloid angiopathy). Plaques are comprised of β AP, and an entwined mass of broken neurites (axon and dendrite projections of neurons).^{1,7,13} Many of these broken neurites contain neuropil filaments made up of the abnormally phosphorylated tau protein found in NFTs.^{7,13} Two types of glial cells, astrocytes and microglia, are also found in plaques.^{1,7,13} Among other functions, glial cells secrete inflammatory mediators and serve as scavenger cells, which may be important in causing the inflammatory processes that occur in the development of AD. While the number of NFTs is strongly correlated with the severity of dementia, the number of neuritic plaques is not.⁷ Clinical development of AD may inversely correlate with the number of normal neurons and synapses remaining despite plaque presence,^{7,13,14} thus introducing the concept of neurologic reserve.

Forming the center of the neuritic plaque are aggregates of a 39- to 43-amino acid protein segment called β AP.⁷ The β AP accumulating in the brain and cerebral blood vessels in AD is different from other disease-producing amyloid proteins.⁷ β AP is cleaved from the APP, a transmembrane protein.^{1,7,13} Proteases cleave APP in several different ways (Fig. 63–2). In the normal secretory pathway APP is cleaved through the β AP region, first using an enzyme called

α -secretase, and then by an enzyme termed γ -secretase. The resulting product, p3, is soluble and harmless.⁷ In the potentially pathologic process, the endosomal pathway cleaves on both sides of β AP, first with β -secretase and then with γ -secretase, resulting in the formation of a β AP fragment which is released into the extracellular space.^{7,13} Most of these β AP strings contain 40 amino acids, but it was recently determined that a version of β AP containing 42 amino acids damages nerve cells. Although it is not known how β AP causes neuronal damage, it does cause dysregulation in calcium and damage to mitochondria.⁷ This in turn may trigger inflammatory mediators. Taken as a whole, these data suggest that β AP deposition occurs early in the disease process, rather than being simply an end-product of neuronal death, and likely initiates the process of plaque formation and nerve cell destruction.

AD is a neuronal degenerative process that is characterized by the presence of NFTs, neuritic plaques, and cellular atrophy in the cortex and limbic structures of the brain. Though the presence of these structural changes are the hallmark of definitive AD diagnosis, the initial precipitating event remains uncertain.

INFLAMMATORY MEDIATORS

Inflammatory mediators and other immune system constituents are present near areas of plaque formation, suggesting that the immune system plays an active role in the pathogenesis of AD. Although perhaps not the disease-initiating event, an immune response generated against some brain insult could facilitate neuronal destruction. Evidence supporting significant involvement of the immune system includes the increased presence of acute-phase proteins, such as α_1 -antichromotrypsin and α_2 -macroglobulin, both in the serum and within amyloid plaques of patients with AD.¹⁵ Glial cells (microglial cells and astrocytes), cytokines (e.g., interleukin-1 and interleukin-6), and components of the classic complement cascade are also markedly increased in plaque-infested areas.¹⁵ These inflammatory mediators increase β AP toxicity and aggregation. Chronic production of cytotoxic agents and free radicals by activated microglia can result in accelerated neurodegeneration.

Microglial cells located around and within amyloid plaques are thought to release inflammatory mediators, which locally destroy neuronal tissue. Glial cells also function as phagocytes, similar to macrophages and monocytes in the periphery. Another component of the complement cascade, the membrane attack complex, is found associated with broken neurites and areas containing NFTs, implicating the membrane attack complex as a promoter of the vast neuronal destruction characterizing AD.¹⁵ As stated earlier, the acute-phase proteins α_1 -antichromotrypsin and α_2 -macroglobulin also act as protease inhibitors, and could influence proteolytic breakdown of APP into β AP.^{7,15} As is the case in many chronic inflammatory illnesses, specific factors responsible for initiating the immune response are not known. One theory is that breaks in the blood-brain barrier caused by trauma, leaky endothelial cells, or other conditions trigger an immune response to brain proteins previously unexposed to the periphery.^{15,16} Another possibility is that the immune system is activated by plaque precursors or by-products of damaged cells, resulting in further destruction of adjacent neurons.¹⁶

THE CHOLINERGIC SYSTEM

Multiple neuronal pathways are destroyed in AD. Damage occurs in any nerve cell population located in or traveling through plaque-laden areas.⁷ Widespread cell destruction results in a variety of

FIGURE 63–2. Representation of two physiologic cleavage sites of APP. APP is pictured as a transmembrane protein, with the β AP subunit anchored within the membrane. In part A, α -secretase and then γ -secretase cut APP through the β AP region. In part B, β -secretase and then γ -secretase cut β AP on either side of the β AP subunit. β AP is then released intact into the extracellular fluid, where it can aggregate, forming insoluble preamyloid plaques. (Adapted from St George-Hyslop⁷ and Mortimer.¹³)

neurotransmitter deficits. Most profoundly damaged are the cholinergic pathways, particularly a large system of neurons located at the base of the forebrain in the nucleus basalis of Meynert, a brain area believed to be involved in thought integration.^{1,7} Axons of these cholinergic neurons project to the frontal cortex and hippocampus, areas strongly associated with memory and cognition.

The discovery of vast cholinergic cell loss led to the development of a cholinergic hypothesis linked to the pathophysiology of AD. The cholinergic hypothesis targeted cholinergic cell loss as the source of memory and cognitive impairment in AD. Therefore it was presumed that increasing cholinergic function would improve symptoms of memory loss. This approach is flawed for two reasons. First, cholinergic cell loss appears to be a secondary consequence of Alzheimer's pathology, not the disease-producing event; second, cholinergic neurons are only one of many neuronal pathways destroyed in AD. It is increasingly clear that simple addition of acetylcholine cannot compensate for the loss of neurons, receptors, and other neurotransmitters lost during the course of the illness. The goal then is to minimize or improve symptoms through augmentation of neurotransmission at remaining synapses.

OTHER NEUROTRANSMITTER ABNORMALITIES

Although the cholinergic system has received the lion's share of attention in AD pharmaceutical research, deficits also exist in other neuronal pathways. For example, serotonergic neurons of the raphe nuclei and noradrenergic cells of the locus ceruleus are lost, while monoamine oxidase type B activity is increased. Monoamine oxidase type B is found predominantly in the brain and in platelets, and is responsible for metabolizing dopamine. In addition, abnormalities appear in glutamate pathways of the cortex and limbic structures, where a loss of neurons leads to a focus on excitotoxicity models as possible contributing factors to AD pathology.

Glutamate is the major excitatory neurotransmitter in the cortex and hippocampus. Many neuronal pathways essential to learning and memory use glutamate as a neurotransmitter, including the pyramidal neurons (a layer of neurons with long axons carrying information out of the cortex), hippocampus, and entorhinal cortex. Glutamate and other excitatory amino acid neurotransmitters have been implicated as

potential neurotoxins in AD.¹⁶ If glutamate is allowed to remain in the synapse for extended periods of time, it can destroy nerve cells. Toxic effects are thought to be mediated through increased intracellular calcium and accumulation of intracellular free radicals.^{1,16} The presence of β AP renders cells more susceptible to glutamate-mediated excitotoxicity in vitro. Dysregulated glutamate activity is thought to be one of the primary mediators of neuronal injury after stroke or acute brain injury. Although intimately involved in cell injury, the role of excitatory amino acids in AD is as yet unclear; however, blockade of N-methyl-D-aspartate (NMDA) receptors decreases activity of glutamate in the synapse and may lessen the degree of cellular injury in AD.

CHOLESTEROL

Research has found multiple links between cholesterol and the occurrence of AD. Some evidence suggests that cellular membranes contain lipid rafts rich in cholesterol. These rafts are small conglomerates of protein and cholesterol that float within the cellular membrane of the lipid bilayer. The APP in the lipid rafts is cleaved by β - and γ -secretases to produce β -amyloid fragments that could eventually form amyloid plaques.^{17,18} It is theorized that cholesterol depletion can inhibit the amyloidogenic pathway and prevent or slow down the plaque formation process. In addition, the APP in the lipid rafts may alter the shape of the membrane, which could promote further amyloid formation via a seeding-type mechanism.^{17,18} Depleting cellular cholesterol appears to decrease this process. Another potential theory linking cholesterol to AD involves the apo E4 allele. The apo E4 allele is thought to be involved in cholesterol metabolism, and neuronal cholesterol levels have been theorized to be increased in the presence of this allele.¹⁷ The elevated cholesterol levels in brain neurons may alter membrane functioning and result in the cascade leading to plaque formation and AD.

ESTROGEN

Estrogen is thought to be involved in promoting neuronal growth, and in preventing oxidative damage, which would benefit cells exposed to β AP.¹⁹ Estrogen receptors are present in the brain, and are

TABLE 63–2. Stages of Cognitive Decline: The Global Deterioration Scale (GDS)

| | | |
|---------|--|---|
| Stage 1 | Normal | No subjective or objective change in intellectual functioning. |
| Stage 2 | Forgetfulness | Complaints of losing things or forgetting names of acquaintances. Does not interfere with job or social functioning. Generally a component of normal aging. |
| Stage 3 | Early confusion | Cognitive decline causes interference with work and social functioning. Anomia, difficulty remembering right word in conversation, and recall difficulties are present and noticed by family members. Memory loss may cause anxiety for patient. |
| Stage 4 | Late confusion (early AD) | Patient can no longer manage finances or homemaking activities. Difficulty remembering recent events. Begins to withdraw from difficult tasks and to give up hobbies. May deny memory problems. |
| Stage 5 | Early dementia (moderate AD) | Patient can no longer survive without assistance. Frequently disoriented with regard to time (date, year, season). Difficulty selecting clothing. Recall for recent events is severely impaired; may forget some details of past life (e.g., school attended or occupation). Functioning may fluctuate from day to day. Patient generally denies problems. May become suspicious or tearful. Loses ability to drive safely. |
| Stage 6 | Middle dementia (moderately severe AD) | Patients need assistance with activities of daily living (e.g., bathing, dressing, and toileting). Patients experience difficulty interpreting their surroundings; may forget names of family and caregivers; forget most details of past life; have difficulty counting backward from 10. Agitation, paranoia, and delusions are common. |
| Stage 7 | Late dementia | Patient loses ability to speak (may only grunt or scream), walk, and feed self. Incontinent of urine and feces. Consciousness reduced to stupor or coma. |

Adapted from Reisberg et al.¹⁰³

distributed in a pattern consistent with areas destroyed in AD.^{19,20} In the hippocampus, cerebral cortex, and basal forebrain, estrogen receptors colocalize with receptors for nerve growth factor on cholinergic nerve terminals.^{20,21} The presence of estrogen increases the number of nerve growth factor receptors. The ability of estrogen to interact with nerve growth factor may explain estrogen's ability to promote synaptic growth, stimulating axons and dendrites to sprout new terminals. Estrogen supplementation also prevents decrements in choline uptake and choline acetyltransferase concentrations, which occurs in rats following ovariectomy. This suggests that estrogen is important in maintaining normal cholinergic neurotransmission.²⁰ Estrogen may also increase NMDA receptor numbers in brain areas involved in recording new memories. In addition to promoting growth, estrogen prevents cell damage by acting as an antioxidant.¹⁹ In culture, estrogen protects hippocampal neurons exposed to glutamate and β -amyloid from cytotoxic and free radical damage.

A single common mechanism for producing AD does not exist. Regardless of the source, however, the features remain the same: degeneration of neurons in higher brain areas; accumulation of NFTs and neuritic plaques; profound destruction of cholinergic pathways; and an insidious dementia, slowly progressive until death.

CLINICAL PRESENTATION

4 The onset of AD is almost imperceptible, without abrupt changes in cognition or function. Deficits occur progressively over time, affecting multiple areas of cognition.^{1,22} For treatment and assessment purposes, it is helpful to divide Alzheimer's symptoms into two basic categories: cognitive symptoms and noncognitive (behavioral) symptoms.²² Cognitive symptoms are present throughout the illness, whereas behavioral symptoms are less predictable.²² Table 63–2 summarizes the stages of AD.

GENERAL

The patient may have vague memory complaints initially, or the patient's significant other may report that the patient is "forgetful." Cognitive decline is gradual over the course of illness. Behavioral disturbances may be present in moderate stages. Loss of daily function is common in advanced stages.

SYMPTOMS

Cognitive: Memory loss (poor recall and losing items); aphasia (circumlocution and anomia); apraxia; agnosia; disorientation (impaired perception of time and unable to recognize familiar people); impaired executive function

Noncognitive: Depression, psychotic symptoms (hallucinations and delusions), behavioral disturbances (physical and verbal aggression, motor hyperactivity, uncooperativeness, wandering, repetitive mannerisms and activities, and combativeness)

Functional: Inability to care for self (dressing, bathing, toileting, and eating)

LABORATORY TESTS

- Rule out vitamin B₁₂ and folate deficiency
- Rule out hypothyroidism with thyroid function tests

OTHER DIAGNOSTIC TESTS

- CT or MRI scans may aid diagnosis

DIAGNOSIS

A family member rather than the patient often first brings memory complaints to the attention of a primary care clinician. Up to 50% of patients who meet criteria for dementia are not given a diagnosis in the primary care setting, leading some to believe that an appropriate screening tool may be helpful in aiding diagnosis and leading to earlier treatment.²³ Despite the phenomenon of underdiagnosis, the United States Preventative Services Task Force recently concluded that there are insufficient data to recommend for or against cognitive screening for AD because it could not be determined if the benefits outweigh the risks.²⁴ Similarly, the Quality Standards Subcommittee of the American Academy of Neurology (AAN) recommended against screening in asymptomatic patients; however, screening and monitoring were useful in patients who were classified as having mild cognitive impairment (patients do not meet criteria for dementia, but do have some impairment of memory), because they are at increased risk for developing dementia.²⁵

At present the only way to definitively diagnose AD is through direct examination of brain tissue at autopsy or biopsy. In 1984 the National Institute of Neurological and Communicative Disorders and Stroke (NINCDS) and the Alzheimer's Disease and Related Disorders Association (ADRDA) developed criteria for diagnosing patients with probable AD, reducing the percentage of erroneously diagnosed AD cases to less than 10%. The NINCDS-ADRDA criteria (Table 63–3) remain the standard.²⁶ *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed., Text Revision (DSM-IV-TR) criteria are also considered appropriate for making the diagnosis.^{27,28} Other recommendations from the AAN include noncontrast computed

TABLE 63–3. NINCDS-ADRDA Criteria and Diagnostic Work-Up for Probable Alzheimer's Disease

- I. History of progressive cognitive decline of insidious onset
 - In-depth interview of patient and caregivers
- II. Deficits in at least two or more areas of functioning
- III. No disturbance of consciousness
 - Confirmation with use of dementia rating scale (e.g., Mini-Mental Status Exam [MMSE] or Blessed Dementia Scale)
- IV. Age between 40 and 90 years (usually >65 years)
- V. No other explainable cause of symptoms
 - Normal laboratory tests including hematology, full chemistries, B₁₂ and folate, thyroid function tests, Venereal Disease Research Lab test (to rule out venereal disease or syphilis)
 - Normal electrocardiogram and electroencephalogram
 - Normal physical exam, including thorough neurologic exam
 - Neuroimaging: CT or MRI scanning: No focal lesions signifying other possible causes of dementia are present. Abnormalities which are common, but not diagnostic for AD include general cerebral wasting, widening of sulci, widening of the ventricles, and lesions of white matter surrounding the ventricle deep in the brain

The Mini-Mental Status Exam is a commonly used scale that measures orientation, recall, short-term memory, concentration, constructional praxis, and language. The MMSE is scored from 0 to 30, with a score of 10–26 typical of mild to moderate Alzheimer's disease.

Adapted from Mckhann et al.²⁶

tomography (CT) or magnetic resonance imaging (MRI) scanning, which can be useful neuroimaging tests for initial evaluation; screening and treatment of depression, B₁₂ deficiency, and hypothyroidism are also recommended.²⁸ Other tests such as linear or volumetric MRI or CT, positron emission tomography, single photon emission com-

puted tomography, apo E genotyping, cerebrospinal fluid or other biomarkers, or syphilis serology are not recommended at this time.²⁸ Following diagnosis, functional assessment can be obtained from the patient and caregiver using the functional activities questionnaire (FAQ).²⁹

▶ TREATMENT: Alzheimer's Disease

■ DESIRED OUTCOMES

2 None of the current treatments for AD are curative or are known to directly reverse or halt the pathophysiologic processes of the disorder. Therefore the primary goal of treatment in AD is to symptomatically treat cognitive difficulties and preserve patient function as long as possible. Secondary goals include treating the psychiatric and behavioral sequelae that occur as a result of the disease.

■ GENERAL TREATMENT APPROACH

6 Clinical trials have consistently shown the need for early and continuous treatment with cholinesterase inhibitors.^{30–32}
7 Following this approach allows for maximum gain and maintenance of cognition and activities of daily living. A symptomatic approach is used to treat psychiatric symptoms as they arise.

Also essential to treatment is the provision of education to the patient and family at the time of diagnosis. Discussion of the course of illness, treatment options, as well as legal and financial decisions allows the family to plan for these more effectively. Good communication skills are important to maintain a therapeutic environment and minimize stress.

■ NONPHARMACOLOGIC THERAPY

Treatment of AD must include both nonpharmacologic and pharmacologic approaches because AD has a profound effect on both the patient and family. It is emphasized that nonmedication interventions are the current primary interventions for management of AD, and medications should be used in the context of multimodal interventions. Upon initial diagnosis, the patient and caregiver should be educated on the course of illness, prognosis, available treatments, legal decisions, and quality-of-life issues. Education, including short- and long-term programs, has been demonstrated to improve caregiver knowledge and confidence and in some cases delay time to nursing home placement.³³ Table 63–4 lists basic principles of care for the AD patient. Communication between the patient and family members is essential in order to minimize stress on everyone.

While encouraging as much function and self-reliance as possible, life for the AD patient must become progressively more simple and structured in order to compensate for the deficits in cognition and to ensure safety. Education and guidance need to be provided regarding the patient's independence in conducting activities of daily living, including use of power tools, household repairs, cooking, and especially driving. Latches may need to be installed on doors and cabinets

TABLE 63–4. Basic Principles of Care for the Alzheimer's Patient

- Keep requests and demands of the patient simple, and avoid complex tasks that might lead to frustration.
- Avoid confrontation, and defer requests that lead to frustration.
- Remain calm, firm, and supportive if the patient becomes upset.
- Maintain a consistent environment and avoid unnecessary changes.
- Provide frequent reminders, explanations, and orientation cues.
- Recognize declines in capacity and adjust expectations for patient performance.
- Bring sudden declines in function and the emergence of new symptoms to professional attention.

Adapted from Rabins.³⁴

to prevent wandering or rummaging through household items. The patient will need frequent reminders in the beginning, but increasing assistance later with personal hygiene and other personal activities of daily living. A night light and a bedside commode may help prevent confusion and wandering when the patient awakens in the middle of the night for toileting.

Caregiver communication is essential at all stages of AD. For example, overly technical or detailed directions may confuse and upset patients. Family members may not realize at first the degree of impairment of the Alzheimer's patient's memory and ability to reason. Simple instructions or a demonstration of the desired activity improves patient understanding. Caregivers with good intentions may try to push patients to continue doing familiar tasks in the hope that this will preserve existing function as long as possible. As the patient becomes increasingly unable to accomplish a task because of disease progression, the patient may easily become frustrated and upset. A simple change to a less demanding lifestyle may decrease agitated behaviors substantially. For example, the patient may accuse a family member of stealing an item that has been misplaced. The family member becomes upset at this accusation and attempts to rationalize or argue with the patient. This frequently causes agitated behavior to escalate. Although difficult, the caregiver may find that by ignoring accusations or changing the subject, the patient will calm down.

The caregiver must be prepared to face the changes in life that will occur, and acceptance of this does not come easily. Denial on the part of the patient and rationalization on the part of the family are common. The clinician should encourage the family to address legal and financial matters and designate a durable power of attorney for execution of financial and medical decisions once the patient is incompetent. The caregiver will need to address issues such as respite services to provide time for rest, relaxation, and conduct of personal business. Eventually the caregiver will need to face critical questions with respect to institutionalization. The two primary reasons for institutionalization of patient with AD are behavioral disturbances and incontinence, problems that most caregivers find difficult to manage in the home. This is probably the most difficult decision for the caregiver.

Clinician support and referral to social services is vitally important in assisting the caregiver at that moment. The family should also be referred to local resources, such as the Alzheimer's Association, that can provide detailed information regarding support services. Table 63–5 lists some referral sources and references for caregivers.

Education, communication, and planning are the key nonpharmacologic components of caring for an AD patient. Preparation in the early stages of illness will lessen some of the caregiver stress as the illness progresses.

PHARMACOLOGIC THERAPY**PHARMACOTHERAPY FOR COGNITIVE SYMPTOMS**

9 The cholinesterase inhibitors are indicated for treatment of mild to moderate AD. None of the agents in this class have been compared in head-to-head clinical trials; therefore no conclusions on the effectiveness of one agent versus another can be made. The latest treatment guidelines, which were written prior to memantine becoming available, recommend the use of cholinesterase inhibitors as beneficial treatment for AD, and no preference has been suggested for a specific agent.^{33–35}

CLINICAL CONTROVERSIES

Several cholinesterase inhibitors are now available, raising the question of whether it is appropriate to switch a patient from one to another if the first is not considered effective. Theoretical differences exist in their mechanisms of action, but some clinicians feel that these differences will not be clinically meaningful; therefore switching is not helpful. Switching is recommended if a patient is not tolerating the initial treatment. Most clinicians probably switch to another agent, and initial data seem to indicate that some patients do respond to an alternative cholinesterase inhibitor.

Disagreement exists about how to determine effectiveness of cholinesterase inhibitors. Selection of qualitative versus quantitative assessment may bias a clinician's impression of response. Subtle changes are often detected only by psychometric testing rather than with routine questioning. No standard has been suggested to define the effectiveness of these medications; therefore great variation exists between clinicians, and the duration of treatment ranges from months to years.

Additionally, two of these guidelines recommend consideration for concomitant treatment with vitamin E.^{33,34} The AAN guidelines consider selegiline as an option for treatment, recommend against estrogen, and feel evidence is insufficient to support anti-inflammatory agents.³³ In practice, with the exception of tacrine, any of the cholinesterase inhibitors are appropriate as initial treatment. Some clinicians prefer donepezil because more data are available on long-term use, and it can be given once daily.

Cholinesterase inhibitors should be used throughout the course of illness because of the cognitive benefits, possible treatment of behavioral symptoms, and economic factors. Additionally, vitamin E should be used adjunctively with the cholinesterase inhibitors throughout treatment. Vitamin E is recommended solely based on the results of one study that showed no cognitive benefit, but a delayed requirement for nursing home placement with vitamin E. Figure 63–3 shows pharmacotherapeutic treatment algorithms for AD. These recommendations are made based on available efficacy, safety, and tolerability data.

Unfortunately, clinical trials have failed to provide answers to key questions in treating AD patients. Information from clinical trials is insufficient to know if a cholinesterase inhibitor dose-response relationship exists, or if additional cognitive improvement may be gained by increasing to the maximum tolerated dose, rather than continuing with the usual recommended daily dosage. Guidance in extrapolating data related to changes in cognition is needed so that a reasonable duration of clinical treatment with cholinesterase inhibitors can be determined.

In natural disease progression studies, scores on the Alzheimer's Disease Assessment Scale—Cognition (ADAS-COG) have been shown to worsen (increase) by an average of four points over 6 months and seven points over 1 year. Based on these findings, the general consensus is that a four-point change in the ADAS-COG represents a clinically significant change. Therefore if a pharmacotherapeutic agent decreases the ADAS-COG by four points, one could think of this as having reversed progression of disease symptoms by 6 months. The utility of the ADAS-COG in clinical practice is limited due to the time required for administration; it is much more practical to assess changes in disease severity using the mini-mental

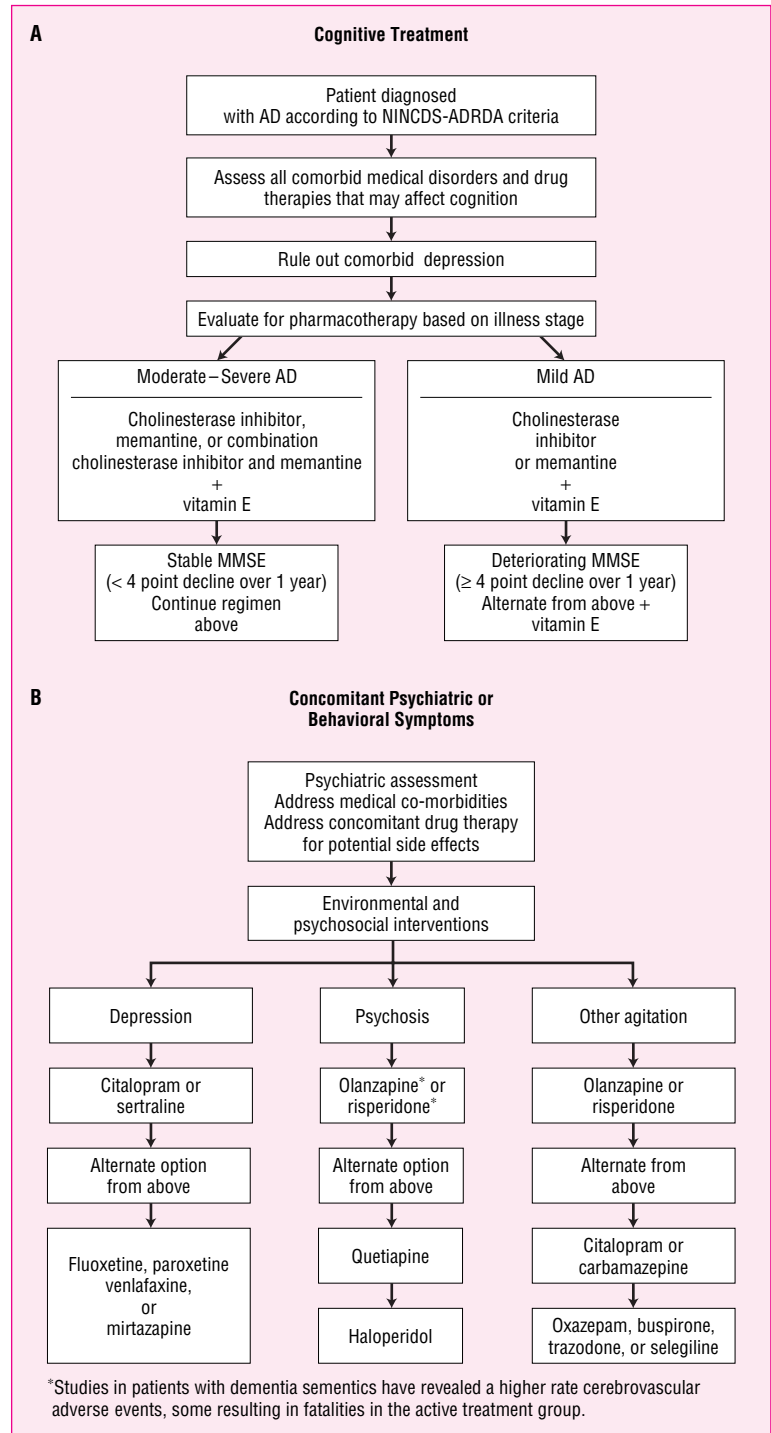

FIGURE 63–3. Proposed treatment algorithms for Alzheimer’s disease. A. Cognitive treatment. B. Concomitant psychiatric or behavioral symptoms.

status exam (MMSE). An untreated patient has an average decline of 2 to 4 points in MMSE score per year. Successful treatment would therefore reflect a decline of less than 2 points a year. It is reasonable to change to a different cholinesterase inhibitor if the decline in MMSE score is greater than 2 to 4 points after 1 year with the initial agent.

▶ The AAN has also provided guidelines for treatment of noncognitive symptoms of AD. For agitation and psychosis, atypical and traditional antipsychotics are effective; however, the atypicals are better tolerated. Selective serotonin reuptake inhibitors (SSRIs), monoamine oxidase type B inhibitors, and selected tricyclic antidepressants are recommended for treatment of depression.³³

CLINICAL CONTROVERSY

Disagreement exists about the utility of cholinesterase inhibitors in advanced stages of AD. Some clinicians feel that patients should be taken off cholinesterase inhibitors once they have reached severe stages of AD, while others believe that these medications may continue to be helpful with managing psychiatric symptoms and maintaining function. Most clinicians probably discontinue cholinesterase inhibitors once the AD patient is bedridden and unable to perform activities of daily living.

TABLE 63–6. Recommended Dosing Strategies for Cholinesterase Inhibitors

| | Tacrine | Donepezil | Rivastigmine | Galantamine |
|------------------------------|---------------------------|---------------|--------------------|---------------------|
| Starting dose | 10 mg four times a day | 5 mg daily | 1.5 mg twice a day | 4 mg twice a day |
| Maintenance dose | 20–40 mg four times a day | 5–10 mg daily | 3–6 mg twice a day | 8–12 mg twice a day |
| Time between dose adjustment | 4–6 weeks | 4–6 weeks | 2 weeks | 4 weeks |

■ Cholinesterase Inhibitors

9 Just as levodopa was developed as replacement therapy for dopaminergic deficiency in Parkinson's disease, in the early 1980s researchers began to examine means to enhance cholinergic activity in patients with AD. Tacrine was the first such drug to be examined in a systematic fashion. However, tacrine is fraught with significant side effects, including hepatotoxicity, that severely limit the ability of patients to adhere to treatment. For all practical purposes the use of tacrine has been replaced by the use of safer, more tolerable cholinesterase inhibitors.

■ **Donepezil.** Donepezil³⁶ is a piperidine cholinesterase inhibitor with specificity for inhibition of acetylcholinesterase as compared to butyrylcholinesterase. This specificity is claimed to result in fewer peripheral side effects (such as nausea, vomiting, and diarrhea) than with nonspecific cholinesterase inhibitors such as tacrine.³⁷

Donepezil is approved for treatment of cognitive impairment in mild to moderately severe AD (MMSE score 10 to 26) at doses of 5 mg and 10 mg daily. Preliminary evidence suggests that it may also be beneficial in patients with moderate to severe AD.³⁸ Cognitive improvement is generally modest with a sustained cognitive benefit of 6 to 9 months, followed by a gradual decline thereafter.³⁹

10 Donepezil should be initiated at a 5-mg/day dose in the morning and titrated to 10 mg/day after 4 to 6 weeks if it is well tolerated. Table 63–6 summarizes cholinesterase inhibitor dosing recommendations. The most common donepezil side effects are nausea, vomiting,

and diarrhea—typical cholinergic side effects; however, the medication is well tolerated in most patients.³⁷ Table 63–7 compares the side effects of various AD medications.

Few drug interactions have been reported with donepezil. Pharmacokinetic studies in healthy male patients revealed increased donepezil concentrations when administered with either ketoconazole or cimetidine, inhibitors of the cytochrome P450 (CYP450) 3A4 system.⁴⁰ Four case reports in AD patients have cited potential interactions with paroxetine, risperidone, or tiapride.⁴⁰ The effects of enzyme inducers on donepezil kinetics have not been studied. Though highly protein bound (96%), donepezil has no effect on the kinetics of theophylline, warfarin, or digoxin.⁴⁰ Clinically significant interactions are unlikely with donepezil; however, monitoring for possible increased peripheral cholinergic side effects such as nausea, vomiting, or diarrhea is advisable when adding a CYP450 2D6 or 3A3/4 inhibitor to a donepezil regimen.

■ **Rivastigmine.** Butyrylcholinesterase is thought to play an important role in acetylcholine degradation following the depletion of acetylcholinesterase. Additionally, acetylcholinesterase is found in two forms: globular G4 and globular G1. The highest concentrations of globular G1 can be found in the hippocampus and cortex, two regions known to be affected in AD. Interestingly, although the globular G4 form is significantly depleted in postmortem studies, globular G1 remains abundant. By blocking this particular form of the acetylcholinesterase enzyme, higher concentrations of acetylcholine may be obtained.⁴¹

NR, not reported.

Compiled from package inserts for Aricept (donepezil),³⁶ Reminyl (galantamine),⁴⁵ Namenda (memantine),⁴⁷ Exelon (rivastigmine),¹⁰⁴ and Cognex (tacrine).¹⁰⁵

Rivastigmine has central activity at acetylcholinesterase and butyrylcholinesterase, but low activity at these sites in the periphery. At least theoretically, this should result in a lower incidence of peripheral side effects.³⁷ Rivastigmine activity at the acetylcholinesterase globular G1 site is higher than at G4, and this may be theoretically advantageous because it may prevent degradation of acetylcholine via this enzyme over the course of the disease as compared to other cholinesterase inhibitors without this activity. It is difficult to say what this means clinically, and long-term head-to-head trials with other cholinesterase inhibitors are needed.

Rivastigmine is efficacious at doses of 6 to 12 mg/day.^{31,42,43} Cognitive improvement was modest and sustained for 6 to 12 months in the treatment groups. Improvement in activities of daily living have also been demonstrated in this dosing range.⁴³ Rivastigmine has not been evaluated in patients with severe dementia or for treatment of behavioral symptoms.

Rivastigmine should be initiated at a dose of 1.5 mg twice daily and titrated upward at a minimum of 2-week intervals to a maximum daily dose of 12 mg. In addition to capsules, rivastigmine is also available as a 2-mg/mL oral solution (Table 63–6 provides dosing guidelines). Tolerability and absorption are improved when rivastigmine is given with food. The potential for drug interactions is low because of low protein binding, and it is not metabolized through the CYP450 enzyme system.⁴⁰ Cholinergic side effects are the most common adverse effects with rivastigmine, but they were well tolerated in clinical studies.^{31,42,43}

■ **Galantamine.** Galantamine is the fourth approved cholinesterase inhibitor, and it also has activity as an allosteric nicotinic receptor agonist. Though galantamine has been shown to be efficacious at dosages of 16 mg/day, 24 mg/day, and 32 mg/day, the maximum dosage recommended by the manufacturer at this time is 24 mg/day.^{32,44,45} Cognitive improvement was similar to that of other cholinesterase inhibitors, producing modest and sustained improvement for approximately 9 months. It is recommended that a patient be continued on the maximum tolerated dosage, as accelerated cognitive deterioration has been seen with dosage reductions.³² Improvement in activities of daily living has also been demonstrated with galantamine.³² Psychiatric and behavioral symptoms have been shown to remain stable, but not improved.⁴⁴

Galantamine should be initiated at 8 mg/day with dosage titration of 8 mg/day occurring at 4-week intervals. This slower titration rate resulted in better patient tolerance and fewer reported adverse drug reactions; therefore adjustment at 4-week intervals is recommended in clinical practice. Galantamine is also available as a 4-mg/mL oral solution.

Galantamine is metabolized through the CYP450 2D6 and CYP450 3A4 pathways, and pharmacokinetic studies with inhibitors of these systems have resulted in increased galantamine concentrations or reductions in clearance.⁴⁰ Studies with CYP450 3A4 inducers have not been conducted. As with donepezil, monitoring for increased cholinergic side effects is recommended if inhibitors of these enzyme systems are added to galantamine.

Cholinesterase inhibitors are the primary treatment for patients with AD. Early and continued use seem to offer patients the optimal benefit. While no differences in effectiveness have been demonstrated to date, tolerability, dosing frequency, and ease of titration may be used for selection of the initial agent. The MMSE may be helpful as a monitoring tool for changes in severity of illness. Unless patients are not tolerating the initial medication, it is recommended to continue for at least a year before considering an alternative agent.

■ Other Agents

9 ■ **Memantine.** Memantine, an NMDA-antagonist, is a novel agent for treating AD. By blocking NMDA receptors, excitotoxic reactions, which ultimately lead to cell death, may be prevented.⁴⁶

Memantine has been studied in patients with vascular dementia, and in patients with moderate and severe AD as monotherapy and in combination with donepezil with favorable results.⁴⁶ It is currently indicated for use in AD patients with moderate to severe illness.

Memantine has 100% bioavailability regardless of administration with or without food. Protein binding is low. Metabolism is minimal, and memantine is excreted renally unchanged. The half-life ranges from 60 to 100 hours. Based on its pharmacologic profile, memantine should be associated with few drug interactions. Preliminary in vitro tests did not reveal any CYP450 inhibition or any effect on acetylcholinesterase inhibitors.⁴⁶

Overall, memantine has been well tolerated in clinical trials. The most frequent adverse events associated with memantine include constipation, confusion, dizziness, headache, coughing, and hypertension.⁴⁷ As some of these side effects are also reported with cholinesterase inhibitors, caution should be used when administering memantine with this class of medications.⁴⁶

Memantine is likely to be used as monotherapy and also in combination with cholinesterase inhibitors, particularly in patients with moderate to severe AD. Memantine should be initiated at 5 mg once a day and increased weekly by 5 mg a day to the effective dose of 10 mg twice daily.⁴⁷ It may be given with or without food. Dosing of 10 mg daily is recommended in patients with creatinine clearance of 40 to 60 mL/min and patients with severe renal impairment (creatinine clearance <40 mL/min) should not receive memantine.⁴⁶

CLINICAL CONTROVERSY

Because of its potential effectiveness, tolerability, and low cost, some clinicians recommend the addition of vitamin E. However, some feel that there is insufficient evidence to broadly recommend this as an additive treatment.

9 ■ **Vitamin E and Selegiline.** Based on pathophysiologic theories involving free radicals, significant interest has evolved regarding the use of antioxidants in the treatment of AD. Vitamin E is often recommended as adjunctive treatment for AD patients. This recommendation is based on data from the only published clinical trial to date, which evaluated the time to critical endpoints (i.e., death, institutionalization, loss of ability to perform activities of daily living, or severe dementia) in patients treated with vitamin E, selegiline, the combination, or placebo.⁴⁸ Although vitamin E and selegiline were superior to placebo, this study has been criticized because of differences in baseline cognitive severity, calling the validity of the results into question. Nonetheless, vitamin E's potential effectiveness, favorable side effect profile, and low cost have perpetuated its use as adjunctive therapy. Although potential benefits of vitamin E combined with a cholinesterase inhibitor have not been evaluated, there are no known complications from their combined use. Vitamin E should be titrated to a maintenance dose of 1000 international units twice a day.⁴⁸

Additional clinical data are lacking in support of selegiline, and it is not recommended as adjunctive therapy in AD.⁴⁹

9 ■ **Estrogen.** Interest in estrogen use has increased over the last decade. Most, but not all, epidemiologic studies show a lower incidence of AD in women who took estrogen replacement therapy

postmenopausally. Results from these epidemiologic trials prompted researchers to look at the use of estrogen preventively and as a treatment for cognitive decline.

Recent clinical trials have not supported the use of estrogen as a treatment for cognitive decline. Two studies evaluating the potential benefit of conjugated estrogens as a treatment for cognitive decline did not show any benefit^{50,51}; behavioral and functional outcomes were not improved either.

The Women's Health Initiative Memory Study, the largest trial to date, enrolled over 4500 healthy women 65 and older to evaluate the incidence of dementia and mild cognitive impairment in patients taking estrogen plus progestin versus placebo.⁵² The mean time from entry until final cognitive assessment was 4 years, with the number of probable dementia cases in the estrogen plus progestin group almost double that of the placebo group (45 versus 22, respectively). Overall, the incidence of probable dementia was low (67 total cases), but suggests 23 more cases of dementia for every 10,000 women per year if they are treated with combination estrogen and progestin. The risk of developing mild cognitive impairment was no different between the treatment and placebo groups. These studies do not support a role for estrogen in treating symptoms of AD. Ongoing clinical trials are being conducted to determine the potential role of estrogen as a preventive treatment for AD.

Other health risks of estrogen use have also been raised recently. The estrogen plus progestin arm of the Women's Health Initiative was terminated early because this treatment group exceeded the threshold for breast cancer risk.^{53,54} Average follow-up was 5.2 years and showed increased risk in coronary heart disease, breast cancer, stroke, and pulmonary embolism. Benefits included reduced risk of colorectal cancer and hip fracture. The effect of estrogen in AD as a treatment of cognition has not been established, and other health risks are also of concern; therefore estrogen should only be used in those patients who have another medical reason for estrogen replacement therapy.

9 ■ Anti-Inflammatory Agents. Epidemiologic studies have also suggested a protective effect against AD in patients who have taken nonsteroidal anti-inflammatory drugs (NSAIDs).^{55–57} Treatment for less than 2 years has been associated with a lower relative risk of AD; however, longer treatment duration lowered this risk further.^{56,57}

The benefits of anti-inflammatory agents on cognition have been less compelling in clinical studies. Indomethacin, prednisone, and diclofenac/misoprostol administration have had no cognitive benefit in AD patients.^{58–60} Tolerability was also problematic.^{58,59} Additionally, prednisone treatment was associated with worsening behavioral symptoms,⁵⁹ and data from other patient populations suggest that prednisone may be associated with cognitive impairment.⁶¹ Because there is a lack of compelling data and also a significant incidence of adverse effects, particularly gastritis and the possibility of gastrointestinal bleeds, NSAIDs and prednisone are not recommended for general use in the treatment or prevention of AD at the present time.

Recent attention has shifted to the potential benefit of the cyclooxygenase-2 inhibitors in light of their anti-inflammatory properties. Rofecoxib has been compared to naproxen and placebo with no demonstrated cognitive benefit after 1 year.⁶² Perhaps the duration of treatment has been inadequate in clinical trials studying anti-inflammatory agents and longer-term exposure as seen in epidemiologic trials is necessary. Until clinical trials establish clinical benefit of the cyclooxygenase-2 inhibitors, their general use as preventive treatment for AD cannot be recommended. Market withdrawal of rofecoxib and other safety concerns within this class may limit further study in AD.

9 ■ Lipid-Lowering Agents. Interest in the potential protective effects in AD patients of lipid-lowering agents, particularly the 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA)-reductase inhibitors, is growing based on animal and recent epidemiologic studies. Longitudinal population-based studies have suggested an association between elevated midlife total cholesterol levels and AD.^{63,64} Other studies suggested that the incidence of AD is lower in patients who have taken either a statin^{65,66} or another lipid-lowering agent,⁶⁷ but not in patients who were taking other cardiovascular medications.⁶⁶ Interestingly, pravastatin and lovastatin, but not simvastatin, were associated with a lower prevalence of AD,⁶⁶ suggesting that individual agents rather than a class effect impact AD prevalence. Although these studies have linked cholesterol levels to increased risk of AD, others have yielded conflicting results.⁶⁸

Prospective clinical trials will need to address the cognitive benefit, duration of treatment, class effect versus effectiveness of individual agents, and optimal dosing. Simvastatin has been studied in one clinical trial showing a reduction in β -amyloid in patients with milder AD, but not in those with severe illness.⁶⁹ Mixed results were also seen in cognitive outcomes.⁶⁹ Atorvastatin is currently being studied in clinical trials. Further studies, including randomized prospective statin trials, are needed to determine cholesterol's role, if any, in the pathogenesis of AD. For now these agents should be reserved for patients who have other indications for their use.

9 ■ Ginkgo Biloba. Egb 761, an extract of ginkgo biloba, is claimed to improve memory. Although it is thought to be an antioxidant and to affect inflammation and neuromodulation, the mechanisms of the multiple compounds in Egb 761 have not been elucidated. A recent meta-analysis determined that only 4 of 57 ginkgo biloba studies that were identified met minimal scientific standards for clinical trials; however, cognitive benefit, though modest, has been demonstrated.⁷⁰ Standardized doses of ginkgo ranged from 120 to 240 mg/day. No significant adverse events were reported; however, some case reports have shown an association with hemorrhaging.

Even if the herbal extract is effective, significant problems exist with its use. The content of herbal products is poorly standardized, and significant variation in supposed active ingredient content for some herbals exists from lot to lot and between manufacturers. Until these products are better standardized and their manufacturing and stability better assured, it is recommended that they be used with caution. Furthermore, little is known about potential adverse reactions, drug interactions, or long-term toxicity with their use.

Because the effects of cholinesterase inhibitors are modest, there is great interest in developing alternative or additional treatments for AD. Most of these alternatives have shown promise in epidemiologic studies; however, benefit in prospective clinical trials has been limited or insufficiently studied. Memantine is the first non-cholinesterase inhibitor approved for AD treatment. Its role in treatment will become more clearly defined in the next several years.

■ PHARMACOTHERAPY OF NONCOGNITIVE SYMPTOMS

The majority of patients with AD manifest noncognitive symptoms at some point in the illness.²² These symptoms can be roughly divided into three categories: psychotic symptoms, inappropriate or disruptive behavior, and depression. Effective management of these problems is important because behavioral symptoms are distressing to both the patient and the caregiver, necessitate increased caregiver supervision and patience, and are a leading reason for nursing home placement.

TABLE 63–8. Medications Used in Treating Noncognitive Symptoms of Dementia

| Drugs | Suggested Dosage in Dementia (mg/day) | Indications |
|-----------------|---------------------------------------|--|
| Antipsychotics | | Psychosis: hallucinations, delusions, suspiciousness Disruptive behaviors: agitation, aggression |
| Haloperidol | 0.5–4 mg | |
| Olanzapine | 2.5–10 mg | |
| Quetiapine | 12.5–200 mg | |
| Risperidone | 0.25–2 mg | |
| Antidepressants | | Depression: poor appetite, insomnia, hopelessness, anhedonia, withdrawal, suicidal thoughts, agitation |
| Citalopram | 10–20 mg | |
| Fluoxetine | 5–20 mg | |
| Mirtazapine | 15–45 mg | |
| Paroxetine | 10–40 mg | |
| Sertraline | 50–200 mg | |
| Trazodone | 75–400 mg ^a | |
| Venlafaxine | 37.5–150 mg | |
| Anticonvulsants | | Agitation or aggression |
| Carbamazepine | 100–1,000 mg ^{ab} | |
| Others | | |
| Bupirone | 10–45 mg | Disruptive behaviors |
| Oxazepam | 10–60 mg ^a | Disruptive behaviors |
| Selegiline | 10 mg | Disruptive behaviors, agitation, anxiety, depression |

^aAdminister in divided doses.

^bDosage adjustment should be guided by drug serum concentrations.

Adapted from Borson and Raskind,⁷¹ Defilippi and Crismon,⁷⁹ and Rabins et al.⁸⁷

In fact, presence of neuropsychiatric symptoms increases caregiver burden more than loss of cognition or self-care.

11 Strategies for treatment of psychotic or behavioral symptoms should include both environmental and pharmacologic interventions (e.g., antipsychotics, antidepressants, mood stabilizers, and anxiolytics). The potential harm to the patient or caregiver should be used as a guide for selecting the appropriate intervention. For example, hallucinations or delusions that are of a nonstressful, non-threatening nature can generally be ignored or redirected by family members. Nonaggressive behaviors can generally be managed with environmental interventions, such as distracting the patient from the behavior, creating a structured environment, providing reassurance to calm the patient, and attending support groups for the caregiver. Patients with aggressive behaviors should be approached similarly; however, pharmacologic treatment is often an additional necessity.

Despite the widespread nature of noncognitive symptoms in AD, until recently little research has been conducted in these patients. Data from clinical trials of antidepressants and antipsychotics are now emerging, although more research is needed. Because of limited clinical data, side-effect profiles have been used as a guide in selecting the appropriate treatment. Psychotropic medications with anticholinergic effects should be avoided because they may actually worsen cognition. Other side effects in the elderly include sedation, medication-induced postural instability, and extrapyramidal side effects, which can decrease the clinical utility of traditional psychotropic agents.

General guidelines governing therapy can be summarized as follows: Use reduced doses, monitor closely, titrate dosage slowly, and document carefully. Caregivers often have erroneous expectations regarding the effects of psychotropic medications, and the anticipated benefits and risks of therapy should be clearly explained. Disruptive behaviors and delusions wax and wane with disease progression. Attempts to slowly taper and discontinue antipsychotic medication should be undertaken in minimally symptomatic patients at least every 3 months, because many patients who initially respond to these medications show no change in symptoms and occasionally improve

on medication withdrawal.⁷¹ Table 63–8 outlines suggested doses of medications.

■ Antipsychotics

Antipsychotic medications have traditionally been used to treat disruptive behaviors and psychosis in AD patients. Symptoms responding to antipsychotics include assaultiveness, extreme agitation, hyperexcitability, hallucinations, delusions, suspiciousness, hostility, and uncooperativeness; whereas withdrawal, apathy, cognitive deficits, wandering, and incontinence are not responsive.⁷²

Until the advent of the atypical antipsychotics, conventional agents were widely used, although available placebo-controlled studies suggested that they were moderately effective at best.^{72,73} More recently, risperidone has been shown to have modest effects in patients with psychotic symptoms or behavioral disturbances associated with dementia.^{74–76} It is recommended to begin with 0.25 mg daily and to titrate in 0.25- to 0.5-mg increments to 1 mg daily, which is usually considered the optimal dose. If response is inadequate, further titrating to a maximum of 2 mg daily may be necessary if the patient is tolerating the medication; however, side effects, particularly extrapyramidal effects, somnolence, and orthostasis, increase with increased dose.

Olanzapine has been studied in AD patients with modest results on psychiatric symptoms at doses of 5 and 10 mg/day. It should be noted that 15 mg/day has also been studied and was no more effective than placebo.⁷⁷ Because the pharmacologic profile of olanzapine includes cholinergic blockade, some concern has been raised as to the utility of this agent in the AD population. Clinical studies have not shown any deleterious cognitive effects in the short-term; however, these results cannot be extrapolated over the long-term.

No placebo-controlled trials are currently available evaluating quetiapine, ziprasidone, or aripiprazole in psychosis of dementia. An open-label study suggests possible effect and good tolerability with quetiapine.⁷⁸ For patients who respond inadequately, have elevated cardiovascular risk, or who have unacceptable side effects

with risperidone or olanzapine, quetiapine is a reasonable alternative. Ziprasidone and aripiprazole require formal study in this population prior to recommending their use.

Patients with AD are more sensitive to antipsychotic side effects than other patient groups. Increased sensitivity to antipsychotic side effects in the elderly appears to be the result of altered pharmacodynamics rather than altered pharmacokinetics.⁷⁹ Particularly problematic side effects are extrapyramidal side effects, postural hypotension caused by α -adrenergic blockade, and anticholinergic effects, including increased confusion, urinary retention, constipation, and dry mouth.⁷⁹ For a more detailed description of antipsychotic side effects see Chap. 66 on schizophrenia. Overall, fewer side effects are seen with the newer atypical antipsychotics, making them a preferred choice for treatment of psychosis or aggression in the AD patient.⁷⁹ Effective doses of antipsychotic medications are much lower than those typically used to treat schizophrenia (see Table 63–8). The rule of thumb is to “start low and go slow.”

■ Antidepressants

Prevalence estimates of depression in AD differ widely, ranging from less than 10% to 80%. Actual prevalence rates of major depression in AD are probably 5% to 15% in community-based patients and 15% to 20% among institutionalized patients.⁷¹ The inconsistency in these figures is largely attributed to symptom overlap, diagnostic differences, and the patient population sampled. Early in the course of AD, depression presents much the same as in other elderly persons, but later in the disease course, diagnosis can be difficult. Apathy, decreased initiative and socialization, decreased concentration, psychomotor retardation, agitation, and changes in appetite and sleep patterns are all symptoms intrinsic to both dementia and depression.⁷¹ Because of the inherent difficulty and variation in diagnosing depression in AD, criteria have recently been suggested to facilitate uniformity in diagnosis.⁸⁰ These criteria were based on DSM-IV-TR criteria for major depression with the following differences: presence of only three or more symptoms, symptoms need not be present nearly every day, irritability and social isolation or withdrawal were added as symptoms, and finally loss of interest or pleasure were revised to a decreased positive affect or pleasure. In determining whether or not a patient with these symptoms is depressed, it is particularly important to assess the patient's affect and ability to experience pleasure. Affective signs of depression might include crying spells, staying in bed, decreased food intake, asking to be killed, moaning, or sorrowful facial expression. An interview with the patient's caregiver can be helpful in obtaining a more accurate record of symptoms. Depression may be more common in the early stages of AD as the patient attempts to adjust to limitations associated with cognitive loss.

The bulk of literature examining antidepressant use in AD is made up of case reports and uncontrolled studies. Most of these report a favorable response to antidepressants,⁷² but several placebo-controlled trials have demonstrated mixed results. Of the antidepressants studied, citalopram, sertraline, clomipramine, and moclobemide (a monoamine oxidase inhibitor not marketed in the U.S.) were considered efficacious in at least one study⁸¹; but fluoxetine and imipramine were no better than placebo. It should be noted that citalopram and sertraline have both been studied in other placebo-controlled trials in this population with no difference over placebo.⁸¹

A controlled comparator trial of fluoxetine 10 mg/day and amitriptyline 25 mg/day found that both were equally effective; however, the fluoxetine group tolerated the medication much better and had significantly lower dropout rates.^{81,82} Similarly, a study com-

paring paroxetine 40 mg/day and imipramine 100 mg/day showed equal effectiveness.⁸¹ The available literature also suggests that antidepressant response, as measured by reductions in Hamilton Depression Rating scores, is not as dramatic as in depressed nondemented patients. Because depressive target symptoms are difficult to distinguish from dementia, it is unclear whether this modest decrease in Hamilton Depression Rating scores is a result of poor drug response or of difficulty in assessing symptoms in this population.^{80,81} Some clinicians have noted that a longer duration of treatment (e.g., up to 12 weeks) is required before elderly patients experience an antidepressant effect.

It is desirable to document symptoms of depression for several weeks prior to initiating antidepressant therapy in a patient with AD. A significant nonspecific treatment response occurs in this population, and it is possible that simply visiting with a clinician or increasing the patient's activity level may be sufficient to improve symptoms. Should this approach fail, a trial of an antidepressant may be initiated. Pharmacotherapy should be initiated with an antidepressant possessing a favorable side-effect profile. Citalopram and sertraline have been recommended as first-line agents because of demonstrated efficacy in placebo-controlled trials.⁸¹ Other SSRIs such as fluoxetine, paroxetine, or serotonin/norepinephrine reuptake inhibitors such as venlafaxine or mirtazapine may be alternatives.⁸¹ While tricyclics have antidepressant efficacy in the dementia population, their very significant anticholinergic effects, which could exacerbate confusion and memory disturbances, should preclude their use unless other alternatives have been exhausted.

In addition to their demonstrated effectiveness, SSRIs also have a low propensity to cause anticholinergic effects, orthostatic hypotension, and sedation, and can usually be dosed once daily. These medications are not risk free, however. Gastrointestinal adverse effects, confusion, agitation, dizziness, and insomnia have been reported in patients with AD taking fluoxetine, especially at higher doses (>20 mg of fluoxetine daily).⁸³ Paroxetine reportedly causes more anticholinergic effects than other SSRIs. For a more complete discussion of treatment of depression refer to Chap. 67 on depressive disorders.

■ Miscellaneous Therapies

Because antipsychotic therapy has shown only modest efficacy and poses a substantial risk of undesirable side effects, medications traditionally used to treat disruptive behaviors and aggression in other psychiatric and neurologic disorders have been suggested as potential alternatives. These alternatives include benzodiazepines, buspirone, carbamazepine, selegiline, and SSRIs.

In addition to antipsychotics, citalopram (10 to 20 mg/day) and carbamazepine (mean dose of 300 mg/day) have been shown to decrease psychosis and behavioral disturbances of dementia.^{84,85} Carbamazepine was well tolerated in AD patients.⁸⁶

Benzodiazepines, particularly oxazepam, have been used to treat anxiety, agitation, and aggression, but they generally show inferior efficacy when compared to antipsychotics. Because benzodiazepines impair cognition, can result in disinhibition, and may increase the risk of falls in AD patients, their routine use is not advised.⁸⁷ Conversely, the 5-HT_{1A} partial agonist buspirone has shown benefit in treating agitation and aggression in a limited number of patients with minimal adverse effects.^{88,89} Selegiline decreases anxiety, depression, and agitation in open-label and controlled studies.^{90,91} Trazodone reportedly decreases insomnia, agitation, and dysphoria in AD patients, and is often used to treat sundowning.

Should antipsychotics fail to manage noncognitive behaviors, available evidence suggests that a trial of citalopram or carbamazepine may be appropriate second-line alternatives. Only minimal evidence exists to support the use of valproate in this population. Lithium has shown no benefit and frequent toxicity.⁸⁷ Clearly, more rigorous placebo-controlled studies are needed to determine the relative efficacy and place in therapy for these medication alternatives.

Interest has grown regarding the potential use of cholinesterase inhibitors for treatment of psychiatric symptoms in AD. Studies assessing noncognitive symptoms in clinical trials with tacrine, donepezil, and galantamine suggest that these agents have positive effects on psychiatric and behavioral symptoms.⁹² Unfortunately, these have been post-hoc analyses or small open-label trials, making

it difficult to draw conclusions. Significant differences were seen in hallucination and apathy scores. Additional research is needed in this area before specific treatment recommendations can be made with confidence.

Noncognitive symptoms are often the most difficult aspect of AD for the caregiver. Without effective treatment, nursing home placement is often needed. Selected antipsychotics and antidepressants have been useful for effective management of behavioral, psychotic, and depressive symptoms; this helps to ease caregiver burden and allow the patient to spend additional time at home. Alternative treatments are also available in case initial choices are not successful. Improved tolerability with newer medications should also make treatment easier for these patients.

PHARMACOECONOMIC CONSIDERATIONS

The economic and social costs of AD are staggering. It is the third most expensive illness in the United States after heart disease and cancer, and the majority of medical and caregiving expenses are left to the patients' families. The total national cost of Alzheimer's disease is estimated at approximately \$100 billion annually.^{93,94} Annual Medicare costs in 2000 were estimated at \$31.9 billion and Medicaid costs for institutionalized AD patients were estimated at \$18.2 billion.⁹⁵ With life expectancy and the number of AD cases increasing, the cost of AD is projected to quadruple over the next 50 years.⁹³ The potential financial burden of this disease on the health care system could reach crisis proportions in the near future unless more effective avenues are developed to provide care for these individuals, to prevent the disease from occurring, or to slow its progression.

Seventy-five percent of care for AD patients is provided by family and friends.³ Lifetime cost of care for AD is estimated at \$174,000.³ Higher levels of home care have been associated with poorer health and higher rates of emotional stress in caregivers, increasing the likelihood of placing patients in institutionalized care, which is considered the greatest financial cost in treating patients with AD.³ On average, the cost of yearly nursing home care is \$42,000.³ Clearly, the economic burden for the home-living AD patient is the time spent in caring for the patient, whereas in the nursing home the burden is the cost for others to provide care.

12 Economic data in AD are increasing, and several studies have evaluated the cost benefits of medications. The Assessment of Health Economics in Alzheimer's Disease trial projected health and economic outcomes of AD patients treated with galantamine in the Netherlands over a 10-year period.⁹⁶ Full-time patient care was predicted to be delayed by 10% in AD patients treated with galantamine. Studies with donepezil and rivastigmine have also predicted decreases in total costs of therapy and delayed nursing home placement.^{84,97,98}

Studies with agents other than cholinesterase inhibitors are rare but should increase in number as the understanding of AD and its potential treatments improve. A 28-week placebo-controlled trial with memantine reported cost savings and a lower incidence of institutionalization than in the placebo group.⁹⁹ Caregiver costs decreased by \$824/month and societal costs by \$1090/month with memantine therapy. However, direct medical costs to the patient treated with memantine were higher than placebo due to cost of the medication.

Other trials have suggested that patients may require longer treatment with medication therapy before cost savings become apparent. In a study of Medicare-managed patients, 204 AD patients receiving donepezil were compared with 204 AD patients receiving no medication therapy.⁸⁴ Health care costs were \$3891 lower in patients receiving donepezil than those with no medications, and greater savings

were reported with longer therapy (>270 days). A study with rivastigmine estimated cost savings to be \$1595 per patient after projecting 3 years of continuous medication therapy.¹⁰⁰ Cost reductions were reported as higher when treatment was begun earlier in the course of the illness.

Caregiver time has been difficult to quantify into actual dollar amounts, but several studies have shown a decrease in caregiver time associated with medication treatment. A 1-year prospective double-blind trial of 286 patients receiving donepezil or placebo reported a decrease of 66 minutes per day of assisting with activities of daily living.¹⁰¹ This resulted in \$1033 of cost savings per patient in the donepezil group. A study with memantine reported a 103-minute-per-day reduction in caregiver time over 28 weeks of therapy.⁹⁹ Depending on the severity of illness, caregivers may spend up to 8 hours or more per day providing care to AD patients. Medication therapy that can reduce caregiver time or improve patient functioning may help with caregiver burden and delay time to nursing home placement.

Other pharmacoeconomic studies have evaluated cholinesterase inhibitor effects on cognitive functioning. Ernst and associates modeled potential cost savings of cholinesterase inhibitor treatment, and found potential cost savings for most mild or severely ill patients to be small. However, for home-dwelling patients with a baseline MMSE score of 7, potential cost savings from treatment were significant, with prevention of a 2-point decline saving \$3700 annually.¹⁰² The extent to which these types of studies predict economic outcomes in real practice is unclear.

Data from current pharmacoeconomic studies in AD suggest that medication therapy may reduce costs of treating this illness; however, the true cost effectiveness of these therapies has yet to be established. If AD treatments delay cognitive decline and time to nursing home placement, then they not only have potential economic benefit, but significant effects on the quality of life of patients and caregivers. Future studies, including prospective pharmacoeconomic trials of longer duration and more detailed cost evaluation modeling, are needed to determine the role and benefits of pharmacotherapy on AD.

EVALUATION OF THERAPEUTIC OUTCOMES

An evaluation of therapeutic outcomes in the patient with AD begins with a thorough assessment at baseline and a clear definition of therapeutic goals. Cognitive status, physical status, functional performance, mood, thought processes, and behavior all need to be evaluated before initiation of drug therapy. The clinician should interview both the patient and the caregiver to assess response to drug therapy. Because caregivers often have difficulty giving honest and frank information about their loved one's condition in his or her presence, it

is often necessary to interview family caregivers separately. In evaluating response to cognitive agents, the clinician should ask questions about the patient's ability to perform daily functional tasks and about mood and behavior, as well as questions about memory and orientation. Objective assessments such as the MMSE for cognition and the FAQ for activities of daily living, should be used to quantify changes in symptoms and function.⁸⁵

Because target symptoms of psychiatric disorders may respond differently in demented patients, a detailed list of symptoms to be treated should be documented in the pharmacotherapy plan to aid in monitoring. These could include, for example, "striking at spouse because patient believes spouse is an impostor," "verbal threats and refusal to allow clothes to be changed," and so on, as opposed to documenting vague symptoms such as "aggression" or "delusions." To make an accurate assessment of depression, multiple symptoms (e.g., sleep, appetite, and activity and interest levels) need to be assessed in addition to the patient's stated mood.

The patient should be observed carefully for potential side effects of drug therapy. Depending on the therapeutic agent being employed, patients should be assessed for potential side effects such as diarrhea, gastrointestinal distress, dizziness, sedation, extrapyramidal side effects, or worsening of behavior. The specific side effects to be monitored and the method and frequency of monitoring should be documented. Periodic assessments for drug effectiveness, side effects, compliance, need for dosage adjustment, or change in treatment should occur at least monthly. However, patients need to be treated for an adequate duration to see a therapeutic effect from a given intervention. Because the effects of cognition-enhancing medications are not great, a treatment period of several months to a year may be necessary before it can be determined whether therapy is beneficial. Cognitive effects of the drug are often noticed only as a plateauing during treatment or as deterioration following drug discontinuation. In general, cognitive agents should be continued if the patient is demonstrating no change in clinical status. However, if there is doubt, the medication can be slowly tapered and discontinued, and the patient monitored off the drug for 4 to 6 weeks to determine the need for continued therapy.

SUBSTANCE-RELATED DISORDERS: OVERVIEW AND DEPRESSANTS, STIMULANTS, AND HALLUCINOGENS

Paul L. Doering

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Problems related to abuse of chemical substances can occur acutely (e.g., respiratory arrest from using heroin) or after some length of time (e.g., dependence or withdrawal from continued use of an opiate). The treatment approach is distinctly different depending on the type of problem.
- 2 Pharmacotherapy of substance-related disorders is most often adjunctive to other modes of therapy such as counseling and intense psychotherapy.
- 3 Withdrawal from certain classes of drugs (e.g., benzodiazepines or barbiturates) can be life-threatening, and steps must be taken to ensure that withdrawal is gradual and that it takes place in closely supervised settings.
- 4 While there is much research focusing on drugs to treat the underlying addictive processes, to date the successes have been few. Whereas methadone, levo-alpha-acetylmethadol (LAAM), and now buprenorphine are used for narcotic maintenance, the logical approach at present should center on prevention. Because of their knowledge of pharmacology and the actions of drugs on the body, health professionals can play a key role in education of young people on the dangers of recreational drug use.

Abuse of alcohol, tobacco, and other drugs (ATOD) is the nation's number one health problem, according to a Robert Wood Johnson health care report prepared by the Institute for Health Policy, Brandeis University.¹ There are more deaths, illnesses, and disabilities from substance abuse than from any other preventable health condition. The economic cost of substance abuse to the U.S. economy each year is staggering, and it is estimated at over \$414 billion.¹ A heavy smoker will stay 25% longer when hospitalized than a nonsmoker, and a problem drinker will stay four times as long as a nondrinker.¹ According to the Robert Wood Johnson health report, "Without a reduction in ATOD abuse, health care costs cannot be curtailed effectively." Of the more than 2 million deaths each year in the United States, approximately one in four is attributable to alcohol, illicit drug, or tobacco use: 100,000 people die as a result of alcohol, 16,000 die from illicit drug use and deaths related to the acquired immune deficiency syndrome, and 430,700 from tobacco-related illnesses.

In addition, one-half to two-thirds of homicides and serious crimes involve alcohol. Nearly one-half of men arrested for homicide and assault actually test positive for an illegal drug.¹ ATOD abuse contributes to family problems, with one in four Americans reporting that alcohol has been a cause of trouble in the family, and alcohol abuse plays a part in one of three failed marriages.¹

Since publication of the last edition of this textbook, a disturbing new trend in drug abuse has emerged: increase in the use of medicinal drugs for nonmedicinal purposes. Between 1995 and 2002 there was a 163% increase in the number of emergency room visits tied to

the abuse of prescription drugs, according to the Substance Abuse & Mental Health Services Administration (SAMHSA).² SAMHSA estimates that 9 million people now abuse prescription drugs, meaning that they use them for nonmedical, and often recreational, purposes. Three million abusers are children between the ages of 12 and 17 years old. The abuse of such drugs can be deadly. Prescription drugs now are a factor in a quarter of all overdose deaths reported in the United States.

This chapter and the next focus on the problems associated with the abuse of chemical substances and the things clinicians can do to help deal with these problems.

TERMINOLOGY

The lack of a common vocabulary in substance abuse treatment and prevention leads to several problems. There is a wide array of terms in common use, many without precise meaning. A number of professional disciplines are involved in research, treatment, and education regarding alcohol and other drug-related problems, and each discipline tends to use its own terminology. This lack of universal agreement on language hampers effective communication among professionals and leads to difficulties in formulating public policy and administering third-party reimbursement programs. The Liaison Committee on Pain and Addiction, a collaborative effort of the American Academy of Pain Medicine, the American Pain Society, and the

American Society of Addiction Medicine has developed definitions related to the use of medications for the treatment of pain that purport to be consistent with current understanding of relevant neurobiology, pharmacology, and appropriate clinical practice. The ultimate goal of their project was to achieve acceptance and use of uniform definitions by clinicians, regulators, and the public, both nationally and internationally, in order to promote appropriate treatment of pain throughout the world. The definitions have been approved by each of the three collaborating organizations. The following definitions resulted from this particular consensus development committee:³

- *Addiction* is a primary, chronic, neurobiologic disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following 5Cs: chronicity, impaired control over drug use, compulsive use, continued use despite harm, and craving.
- *Physical dependence* is a state of adaptation that is manifested by a drug class–specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist.
- *Tolerance* is a state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more of the drug's effects over time.

EPIDEMIOLOGY

NATIONAL SURVEY ON DRUG USE & HEALTH

The National Survey on Drug Use & Health (NSDUH) (formerly called the National Household Survey on Drug Abuse)⁴ is the primary source of statistical information on the use of illegal drugs by the U.S. population. Conducted by the federal government since 1971, the survey collects data from a representative sample of the population at their place of residence.

In 2002, there were 19.5 million Americans (8.3% of the population ages 12 or older) who currently used illicit drugs. An estimated 22 million Americans suffered from substance dependence or abuse due to drugs, alcohol, or both. The 2002 survey found that marijuana is the most commonly used illicit drug, used by 14.6 million Americans. The second most popular category of drug use after marijuana is the nonmedical use of prescription drugs. An estimated 6.2 million people, 2.6% of the population ages 12 or older, were current users of prescription drugs taken nonmedically. Of these, an estimated 4.4 million used narcotic pain relievers, 1.8 million used antianxiety medications, 1.2 million used stimulants, and 0.4 million used sedatives.⁴

THE MONITORING THE FUTURE STUDY

Every year the Institute for Social Research of the University of Michigan conducts its Monitoring the Future Study (MTFS), supported under a series of research grants from the National Institute on Drug Abuse.⁵ The project has many purposes. Among them is to study changes in the beliefs, attitudes, and behavior of young people in the United States. This study focuses on youth because of their significant involvement in today's social changes, and most importantly because youth in a very literal sense will constitute our future society.⁵

In 2002, 43,700 eighth, tenth, and twelfth grade students in 394 public and private secondary schools were surveyed. Use of a

number of illicit drugs showed broad declines (most notably in the use of ecstasy) for the first time, cigarette smoking dropped sharply in all grades, and drinking alcohol and getting drunk were also down in all grades. For eighth graders the annual prevalence of marijuana use in 2002 of 14.6% is down from the recent peak of 18.3% in 1996. At 30.3% in 2002, the annual prevalence of use of marijuana in tenth graders is now somewhat below the recent 1997 peak of 34.8%; but twelfth graders are down only modestly, from the recent 1997 peak of 38.5% to 36.2% in 2002. The rates of daily use in 2002 are approximately where they stood in 2000 in all five populations. Among twelfth graders 6% are now current daily marijuana users, as are 4.1% of college students and 4.5% of all young adults. Daily use among eighth graders is considerably lower, at 1.2%. Other interesting trends have emerged for the following drugs:

- *Ecstasy*. Use of this so-called club drug showed a decline over previous years. The rates of annual prevalence in 2002 for ecstasy were: 2.9%, 4.9%, and 7.4% among eighth, tenth, and twelfth graders, respectively, 6.8% among college students, and 6.2% among all young adults.
- *Inhalants*. Inhalants, the only class of drug that tends to be more popular among younger teens than older ones, include a wide variety of common household products that youngsters inhale or “huff” in order to get high, such as glues, solvents, butane, gasoline, and aerosols. Some 7.7% of the 2002 eighth graders and 5.8% of the tenth graders indicated inhalant use in the prior 12 months, making inhalants the second most widely used class of illicitly used drugs for eighth graders (after marijuana), and the third most widely used (after marijuana and amphetamines) for tenth graders. The annual prevalence rate among twelfth-grade students was 6.5% in 1979, but only 1.1% in 2002.
- *Amphetamine and methamphetamine*. For eighth graders, inhalant use is followed closely in the rankings by amphetamines, with a lifetime prevalence of use rate of 8.7%. But amphetamine use comes ahead of inhalant use in the rankings for tenth and twelfth graders, with 15% of tenth graders and 17% of twelfth graders reporting some use in their lifetime.
- *Prescription drugs*. In 2002 data were gathered for the first time on two prescription drugs in the narcotic class: Vicodin (hydrocodone with acetaminophen) and OxyContin (oxycodone controlled-release). MTFS results found that Vicodin had attained surprisingly high prevalence rates in the five populations under study—an annual prevalence of 2.5% in eighth graders, 6.9% in tenth graders, 9.6% in twelfth graders, 6.9% among college students, and 8.2% among young adults. Considerably lower rates were found for OxyContin, but considering that it is a highly addictive narcotic drug when used inappropriately, the rates are not inconsequential—1.3%, 3%, 4%, 1.5%, and 1.9% in the same five populations, respectively.

TRENDS IN SUBSTANCE ABUSE EMERGENCIES: THE DAWN PROGRAM

Since the early 1970s, the Drug Abuse Warning Network (DAWN),² an ongoing national survey of hospital emergency departments (EDs), has collected information on patients seeking hospital ED treatment related to their use of an illegal drug or the nonmedical use of a

legal drug. DAWN serves as an early warning system to the ever-changing patterns of use of illegal drugs. These data allow health care professionals to be better prepared to react to medical emergencies arising from illegal drug use and to target prevention and education programs to specific drug-using groups or populations.

DAWN defines a *drug-related episode* as an ED visit that was induced by or related to the use of an illegal drug(s) or the nonmedical use of a legal drug for patients aged 6 to 97 years. A *drug mention* refers to a substance that was mentioned during a drug-related ED episode.

In 2002, there were 670,307 drug abuse–related ED episodes in the coterminous United States, with 1,209,938 drug mentions (on average, 1.8 drug mentions per episode). Cocaine-related episodes constituted 30% of all ED drug-related episodes in 2002, more than any other illicit substance measured by DAWN. About one-fifth of the cocaine mentions in 2002 (21%, 42,146 mentions) were attributed to crack cocaine. No significant changes from 2001 to 2002 were evident for the club drugs ecstasy (MDMA) (4,026 mentions in 2002), γ -hydroxybutyrate (GHB) (3,330 mentions), or ketamine (260 mentions). Heroin accounted for 14% (93,519 mentions) in 2002, and amphetamines and methamphetamine were each mentioned in 3% of drug abuse–related ED episodes (21,644 mentions of amphetamines; 17,696 mentions of methamphetamine). When considered together, narcotic analgesics and combinations comprised 119,185 mentions or 10% of ED mentions estimated for the coterminous United States in 2002. From 2001 to 2002, ED mentions of narcotic analgesics and combinations rose 20% (from 99,317 to 119,185 mentions). From 2000 to 2002, the increase was 45% (from 82,373), and over the 8-year period from 1995 to 2002, mentions of narcotic analgesics and combinations rose 163% (from 45,254).

ECONOMIC IMPACT OF SUBSTANCE ABUSE

Substance abuse and addiction have an enormous impact on the economy. Over the years, the Center on Addiction and Substance Abuse (CASA) at Columbia University has conducted numerous studies aimed at quantifying the costs to local, state, and federal governments and agencies. CASA recently reported the results⁶ of an intensive 3-year analysis of the impact of substance abuse on state budgets. They discovered that in 1998 states spent \$620 billion of their own funds to operate state government and provide public services such as education, Medicaid, child welfare, mental health, and highway safety. Of this amount, a full 13.1%—\$81.3 billion—went to dealing with the aftermath of substance abuse and addiction.⁶ This figure does not include the financial toll such abuse extracts from federal or local spending or the private costs such as lost productivity or premature death. Each American paid \$277 per year in state taxes to deal with the burden of substance abuse and addiction in their social programs and only \$10 a year for prevention and treatment. Of every dollar states spend on substance abuse, 95.8 cents goes to pay for the burden of this problem on public programs. For example, untreated substance abuse increases the cost of every state’s criminal justice system; elementary and secondary schools; Medicaid; child welfare, juvenile justice and mental health systems, highways, and state payrolls. These costs totaled \$77.9 billion in 1998.⁶

The majority of the substance abuse–related diseases in the Medicaid population are linked to tobacco and illicit drugs, many related to birth complications resulting from cocaine use. More than 60 Medicare ailments are attributable to ATOD abuse. The majority of the substance abuse–related diseases in the Medicare population are

associated with tobacco, which accounts for 80% of these diseases. If substance abuse and addiction do not decrease, it will cost the Medicare program alone more than \$1 trillion over the next 20 years.⁹ Needless to say, reducing the problem of substance abuse and dependence would result in tremendous savings for local, state, and federal governments and would have a net positive impact on the quality of life of our citizens.

ACUTE VERSUS CHRONIC PROBLEMS

1 Misuse of chemical substances causes problems of two types: those that occur acutely and those that arise after continued use of a drug. Acute problems are usually predictable, given the pharmacology of the drug. Acute drug intoxications usually occur at doses in excess of that normally taken. Chronic abuse of chemical substances can cause a wide array of physical, psychological, and psychiatric ailments. The substance-induced disorders to be discussed here mainly include intoxication and withdrawal. Psychiatric problems associated with substance abuse, including dementia, psychosis, mood disorders, and anxiety, are discussed elsewhere. Physical illnesses associated with chronic use of chemicals (e.g., alcoholic liver disease) are likewise covered in other chapters.

The essential feature of substance dependence is the continued use of the substance despite adverse substance-related problems. The criteria for substance dependence are the same for each of the drugs or drug classes, varying only to fit the unique pharmacologic properties of each drug. Patients who take prescribed drugs for appropriate medical indications and in correct doses may still show tolerance, physical dependence, and withdrawal symptoms if the drug is stopped abruptly rather than being tapered. Tolerance and physical dependence are inevitable consequences of chronic treatment with opioids and certain other drugs, but by themselves, tolerance and physical dependence do not imply “addiction.” To meet *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed., Text Revision (DSM-IV-TR) criteria⁷ for the diagnosis of substance dependence, at least three of the following must be present at any time in a 12-month period:

1. Tolerance
2. Withdrawal, indicated by the appearance of the characteristic withdrawal syndrome or the use of the same or related drug to relieve or avoid withdrawal symptoms
3. Substance taken in larger amounts or over a longer period of time than was intended
4. Persistent desire or unsuccessful efforts to cut down or control substance use
5. Time spent in activities necessary to obtain the substance, use the substance, or recover from its effects
6. Social, occupational, or recreational activities given up or reduced because of substance use
7. Substance use continued despite knowledge of having a persistent or recurrent physical or psychological problem caused or exacerbated by the substance

The characteristic feature of *substance abuse* is a maladaptive pattern of substance use indicated by repeated adverse consequences related to the repeated use of the substance. Examples include failure to fulfill important obligations at work, school, or home; repeated use in situations in which it is physically dangerous, such as driving under the influence; legal problems; and social or interpersonal problems such as arguments and fights.⁷ *Intoxication* refers to the

development of a substance-specific syndrome after recent ingestion and presence in the body of a substance, and it is associated with maladaptive behavior during the waking state caused by the effect of the substance on the central nervous system (CNS). Examples include belligerence, mood lability, impaired judgment, and impaired social or occupational functioning. Evidence for recent intake of the substance can be obtained from the history, physical examination, or laboratory examination. The most common changes involve disturbances in perception, wakefulness, attention, thinking, judgment, motor behavior, and interpersonal behavior.

In addition to the previous definition, *withdrawal* can be further described as the development of a substance-specific syndrome after cessation of or reduction in intake of a substance that was used regularly by the individual to induce a state of intoxication. Withdrawal causes significant distress to the individual and is associated with impairment in social, occupational, or other areas of functioning. Withdrawal is usually associated with substance dependence. Withdrawal generally is also associated with a craving to readminister the drug to relieve the symptoms.

As with most illnesses, the course and prognosis of the disorders of substance use and dependence are variable. Untreated physical withdrawal from the CNS depressants is potentially life-threatening, but withdrawal almost always can be managed successfully with proper medical care. Getting patients who are drug dependent to stop using drugs is very difficult, and many patients return to drug use even after treatment. As many as 75% of treated substance-dependent patients relapse at least once. Many patients, however, are able to obtain recovery with treatment and continued care in programs such as Alcoholics Anonymous (AA) or Narcotics Anonymous (NA). Substance dependence or addiction can be viewed as a chronic illness that can be controlled successfully with treatment, but cannot be cured and is associated with a high relapse rate. Without treatment, the course can progress to life-threatening severity, resulting from the effects of the drug, drug contaminants, or medical complications of use.⁷ Although an in-depth discussion of the mechanism of drug addiction is beyond the scope of this chapter, the interested reader is directed to a recent concise review article that presents the current understanding of the biology of drug addiction.⁸

CNS DEPRESSANTS

BENZODIAZEPINES AND OTHER SEDATIVE-HYPNOTICS

The past several years have witnessed a sharp rise in the abuse of prescription drugs. In 2002, an estimated 6.2 million persons were current users of prescription-type drugs nonmedically.⁴ Benzodiazepines are among the most popular “party drugs” both on college campuses and in the population at large. DAWN estimates show that from 1995 to 2002, increases were evident for the most frequently mentioned benzodiazepines, alprazolam (62%, from 17,082 to 27,659), clonazepam (33%, from 12,802 to 17,042), and unnamed benzodiazepines (199%, from 11,587 to 34,697).²

In clinical practice, the benzodiazepines largely have replaced the short-acting barbiturates and other nonbarbiturate sedative-hypnotics. Benzodiazepines with faster onset (e.g., diazepam) tend to be preferred by the recreational drug user because they are reinforcing. Flunitrazepam emerged in the mid-1990s as an illegal drug in the United States that was predominantly abused recreationally and associated with sexual assaults.⁹ Medically, this benzodiazepine is used in the short-term treatment of insomnia and as a preanesthetic

medication. As with other benzodiazepines, flunitrazepam is most commonly ingested orally, frequently in conjunction with alcohol or other drugs. The drug’s effects begin within 30 minutes, peak within 2 hours, and may persist for up to 8 hours or more depending on the dosage.⁹

Adverse effects associated with the use of benzodiazepines include decreased blood pressure, memory impairment, drowsiness, visual disturbances, dizziness, confusion, gastrointestinal disturbances, and urinary retention.

Even when used alone, benzodiazepines can cause users to appear extremely intoxicated, with slurred speech, poor coordination, swaying, and bloodshot eyes, with no odor of alcohol. When surreptitiously slipped into a drink, young women have reported waking up in strange surroundings having been sexually assaulted while under the influence of the drug.¹⁰ For this reason, flunitrazepam has come to be called the “date rape drug.”

A dramatic drop in cases of flunitrazepam abuse followed the legal reclassification of the drug as a schedule I substance in Florida in February 1997. A recent rise in alprazolam and clonazepam cases coincides with the decreased use of flunitrazepam and represents a new trend in abuse of the benzodiazepines. Alprazolam (Xanax) has become particularly popular and is known on the street by its slang names, Z-Bars, Zandy bars, footballs, and Zannies, among others. Young people will often take alprazolam or other benzodiazepines before going to the bar or dance club, ostensibly to lower the amount of alcoholic beverage needed to attain the desired level of intoxication. Unfortunately, this “pre-partying” is especially popular among women who do not like the taste of beer or find the caloric burden of drinking to be limiting. Sadly, whether taking it intentionally or being given the drug without their knowledge or consent, these women become targets for sexual predators who know that the victim will have diminished recall of the events that take place. When a victim is unable to give precise details of what happened and when it happened, and is unable to identify the perpetrator, the chances of successful prosecution are greatly diminished.

Because all benzodiazepines have abuse and dependence liability, patients cannot be switched from one benzodiazepine to another in hopes of decreasing a pattern of drug abuse or dependence behavior. Zolpidem, a nonbenzodiazepine nonbarbiturate sedative, has been suggested to have little liability for physical dependence, but tolerance and withdrawal have been reported in association with its use as well.¹¹

Benzodiazepines generally do not cause life-threatening respiratory depression, as do the barbiturate-like drugs.¹² Long-term use of even therapeutic doses of benzodiazepines may cause physical dependence and withdrawal symptoms after abrupt discontinuation.¹³ Signs and symptoms of withdrawal are similar in many respects to those of alcohol withdrawal, but the time courses may be quite different. While withdrawal from shorter-acting agents (e.g., lorazepam and alprazolam) has an onset within 12 to 24 hours of the last dose, others (e.g., diazepam, chlorthalidopoxide, clorazepate, phenobarbital, and amobarbital) have elimination half-lives or active metabolites with elimination half-lives of 24 to over 100 hours. As a result, the onset of withdrawal symptoms may be delayed for several days after discontinuation of the drug.¹³ The likelihood and severity of withdrawal are a function of both dose and duration of exposure. Gradual tapering of dosage is also associated with less withdrawal and rebound anxiety than abrupt discontinuation. Dependence on sedative-hypnotics and benzodiazepines is summarized in Table 64–1.

Occurrence of hallucinations or seizures would indicate severe physical withdrawal. For additional information on benzodiazepine withdrawal, refer to Chap. 69.

TABLE 64-1. Dependence on Sedative-Hypnotics

| Generic Name | Common Trade Names (Manufacturer) | Oral Sedating Dose (mg) | Physical Dependence Dose and Time Needed to Produce Dependence | Time Before Onset of Withdrawal (h) | Peak Withdrawal Symptoms (d) |
|---|--|-------------------------|---|-------------------------------------|------------------------------|
| Benzodiazepines | | | | | |
| Diazepam | Valium (Roche) | 5–10 | 40–100 mg × 42–120 days | 12–24 | 5–8 |
| Chlordiazepoxide | Librium, Libritabs (Roche) | 10–25 | 75–600 mg × 42–120 days | 12–24 | 5–8 |
| Clorazepate | Tranxene (Abbott) | 7.5–15 | 45–180 mg × 42–120 days (est.) | 12–24 | 5–8 |
| Alprazolam | Xanax (Upjohn) | 0.25–8 | 8–16 mg × 42 days (est.) | 8–24 | 2–3 |
| Flunitrazepam | Rohypnol (Roche) | 1–2 | 8–10 mg × 42 days (est.) | 24–36 | 2–3 |
| Barbiturates | | | | | |
| Secobarbital | Seconal, Seco-8 (Lilly) | 100 | 800–2200 mg × 35–37 days | 6–12 | 2–3 |
| Pentobarbital | Nembutal (Abbott) | 100 | Same | 6–12 | 2–3 |
| Equal parts of secobarbital and amobarbital | Tuinal (Lilly) | 100 | Same | 6–12 | 2–3 |
| Amobarbital | Amytal (Lilly) | 65–100 | Same | 8–12 | 2–5 |
| Nonbarbiturate sedative-hypnotics | | | | | |
| Ethchlorvynol | Placidyl (Abbott) | 200 | 1–1.5 g × 30 days | 6–12 | 2–3 |
| Chloral hydrate | Noctec (various) | 250 | Exact dose unknown; 12 g/day chronically has led to delirium upon sudden withdrawal | 6–12 | 2–3 |
| Meprobamate | Equanil, Miltown, Mepro tabs (various) | 400 | 1.6–3.2 g × 270 days | 8–12 | 3–8 |

Withdrawal symptoms are tremor, tachycardia, diaphoresis, nausea, vomiting, elevated blood pressure, delirium, seizures, and hallucinations.

γ-HYDROXYBUTYRATE

γ-Hydroxybutyrate (GHB) is a chemical compound structurally similar to the inhibitory brain neurotransmitter γ-aminobutyric acid. Powdered forms of GHB were marketed in health food stores as a nutritional supplement before being removed from the retail market by the Food and Drug Administration (FDA) in 1991. At that time it was used primarily by body builders for its purported ability to increase growth hormone, but it proved to cause serious illness and death when taken in excess doses or in combination with alcohol or other drugs. Primary groups using GHB include party and nightclub attendees. Like flunitrazepam, GHB is also characterized as a date rape drug.¹⁰ Manifestations of acute GHB toxicity include coma, seizures, respiratory depression, and vomiting. Other documented effects of GHB include amnesia and hypotonia (associated with doses of 10 mg/kg of body weight), abnormal sequence of rapid eye movement (REM) and non-REM sleep (doses of 20 to 30 mg/kg), and anesthesia (doses of approximately 50 mg/kg). Doses greater than 50 mg/kg can decrease cardiac output and produce severe respiratory depression, seizure-like activity, and coma^{14,15}; coma and respiratory depression may be potentiated by concomitant use of alcohol.¹⁵ There is no antidote for GHB overdose, and treatment is restricted to nonspecific supportive care. Figure 64-1 shows a protocol recommended for treating suspected GHB overdose.

In the United States, GHB has been produced clandestinely in widely varying degrees of purity. Today GHB is sold mostly as a liquid under such names as “grievous bodily harm,” “Georgia home boy,” “liquid ecstasy,” “scoop,” “easy lay,” “salty water,” and “organic quaalude.”

In March 2000, GHB was placed into schedule I of the Controlled Substances Act. Until recently, the majority of GHB sold on

the streets was manufactured using inexpensive kits obtained over the Internet. It is mixed largely by nonchemists from recipes that can be flawed or incomplete, and finished products are often of questionable purity, and more important, unknown potency. Improper preparation of GHB can result in a mixture of GHB and sodium hydroxide that can be severely toxic because of the combined effects of the GHB and the direct caustic effects of sodium hydroxide. Since there is no way to tell the strength of homemade GHB, what might be a safe dose today (e.g., “one capful”) could produce a toxic dose tomorrow if a different batch is used. Fortunately, crackdowns in 1997 by the FDA, the Department of Justice, and other enforcement groups has led to decreased availability of ready-made kits on the Internet. Despite the FDA’s action, GHB remains available to consumers.

The decreased Internet availability of kits to make GHB has been accompanied by an increased availability of chemical precursors to GHB as well as GHB analogs. Also available in gyms and health food stores, these substances include γ-butyrolactone (GBL) and 1,4-butanediol.¹⁶ GBL is converted in the body to GHB. Labels of marketed products may use unfamiliar synonyms to disguise the actual content. GBL is also known by the chemical names 2(3H)-furanone dihydro, butyrolactone, 4-butyrolactone, dihydro-2(3H)-furanone, 4-butanolide, 2(3H)-furanone, dihydro, tetrahydro-2-furanone, and butyrolactone-γ.

Withdrawal resulting in severe agitation, mental status changes, elevated blood pressure, and tachycardia has been reported hours after stopping chronic use of GHB. In one case the patient admitted to substantial GHB abuse on a daily basis for 2.5 years. Previous attempts at cessation reportedly resulted in diaphoresis, tremors, and agitation. The patient required 507 mg lorazepam and 120 mg diazepam over 90 hours to control agitation.¹⁷

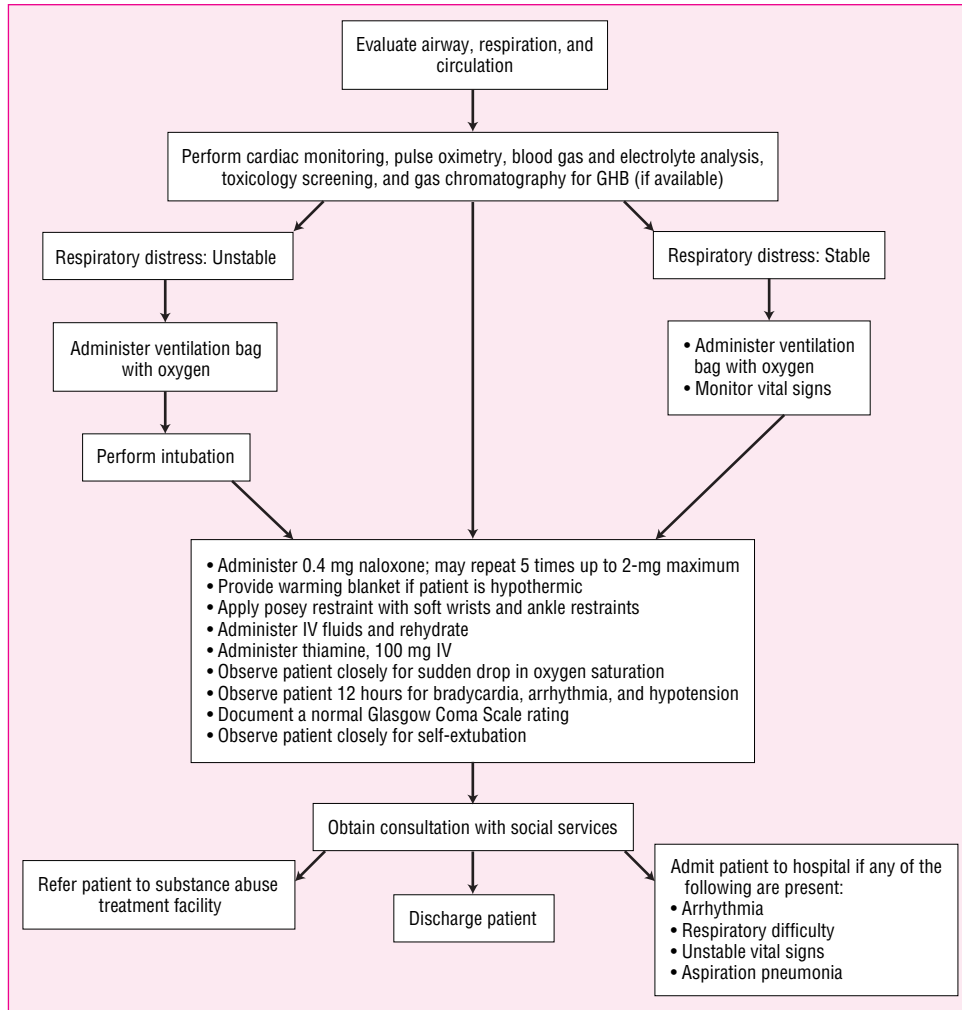

FIGURE 64–1. Protocol for treatment of suspected GHB overdose.

OPIATES

Incidence and prevalence of opiate use are widely variable depending on the drug. In 2002, there were 166,000 current heroin users. Collectively, use of opiates other than heroin is far more common. An estimated 4.4 million people used narcotic pain relievers and 1.9 million persons ages 12 or older used what SAMHSA classified as “OxyContin” nonmedically at least once in their lifetime.⁴

Signs and symptoms of opioid intoxication and withdrawal are summarized in Table 64–2. Onset of the acute phase of withdrawal varies with the drug consumed, but ranges from a few hours after stopping heroin to 3 to 5 days after stopping methadone. The duration of withdrawal ranges from 3 to 14 days. Opioid withdrawal is significantly different from withdrawal from alcohol or other sedative-hypnotics. The biggest difference is that opioid withdrawal is not fatal unless there is a concurrent medical problem of major concern. This has significant treatment implications. Although patients in opioid withdrawal may be in great discomfort and incapacitated, they are not delirious. The presence of delirium should raise the question of concurrent withdrawal from another drug, such as alcohol, or another cause of delirium possibly secondary to drug use.

Many of the complications of opiate use, especially intravenous use, are related not only to the drug itself, but also to varying purity, contaminants, and techniques of administration such as dirty equipment and use of shared needles. Overdoses, anaphylactic reactions

to impurities, nephrotic syndrome, septicemia, endocarditis, and acquired immune deficiency syndrome are examples.

Increased recreational use of pharmaceutical dosage forms of opiates has sparked nationwide debate on both the illegal and legal use of these drugs. OxyContin has been a target of much of this criticism. Introduced in 1995, OxyContin is a controlled-release dosage form of oxycodone that gradually releases steady amounts of narcotics for 12 hours. By crushing the OxyContin tablets, drug abusers can get the full 12-hour narcotic effect almost immediately. Snorting or injecting

TABLE 64–2. Signs and Symptoms of Opioid Intoxication and Withdrawal

| Intoxication | Withdrawal |
|----------------------|---------------|
| Euphoria | Lacrimation |
| Dysphoria | Rhinorrhea |
| Apathy | Mydriasis |
| Motor retardation | Piloerection |
| Sedation | Diaphoresis |
| Slurred speech | Diarrhea |
| Attention impairment | Yawning |
| Miosis | Fever |
| | Insomnia |
| | Muscle aching |

the crushed tablet can lead to overdose and death. Abuse of this drug has caused a nationwide discussion on whether drugs of this nature should be more closely regulated. In September 2003 a federal drug advisory panel rejected requests from members of Congress and drug enforcement officials that sales of OxyContin be severely restricted. According to testimony at the hearings, OxyContin is responsible for 500 to 1000 deaths a year.¹⁸ But these data are refuted in a careful examination of data from an oxycodone postmortem database.¹⁹ Created from 1243 solicited cases from medical examiner and coroner offices in 23 states in the United States, the database included information collected from August 27, 1999 through January 17, 2002. Researchers examined records of the 919 deaths related to oxycodone and discovered that in only 12 of the cases was OxyContin the only agent found at autopsy. The remaining victims had taken either an overdose of other oxycodone-containing drugs (for example, Percocet) or a combination of drugs. In fact, 97% had at least three other drugs in their systems, mostly alcohol, benzodiazepines, cocaine, antidepressants, or other narcotics like heroin. From these data, the authors concluded that oxycodone-related deaths overwhelmingly occur in drug-abusing individuals, and rarely is OxyContin an exclusive cause of death.

Various groups have weighed in on the pros and cons of prescribing opiates for chronic pain and the debate at times is emotional. Various position statements and points of view have been expressed, but the limited space here precludes an exhaustive review of the issues. An excellent review of the appropriate use of opioid therapy for chronic pain has recently been published, and the interested reader is directed there for more information.²⁰

CLINICAL CONTROVERSY

There is considerable debate about the appropriate use of prescribed opiates and how this might contribute to the overuse or abuse of these same drugs for nonmedicinal purposes. Some clinicians believe that use of opiates in patients with chronic pain is inappropriate because it leads to physical dependence and addiction. Practitioners should strive to balance the therapeutic imperative that says “Always use analgesics when they are appropriate for a patient” against the regulatory imperative that says “Never use analgesics when they are inappropriate for a patient.”

CNS STIMULANTS

COCAINE

Cocaine is perhaps the most behaviorally reinforcing of all drugs of abuse. Clinicians estimate that approximately 10% of people who begin to use the drug recreationally will go on to serious, heavy use. Once having tried cocaine, an individual cannot predict or control the extent to which he or she will continue to use the drug.

The most characteristic systemic effect of cocaine is stimulation of the CNS.²¹ In the CNS, cocaine appears to mediate its effects primarily by blocking reuptake of catecholamine neurotransmitters such as norepinephrine and dopamine. The most common clinical manifestations of cocaine stimulation of the CNS are intense euphoria, decreased fatigue, and increased alertness.

In 2002, an estimated 2 million persons (0.9% of the U.S. population) were current cocaine users, 567,000 of whom used crack during the same time period (0.2%).⁴ About half of these meet the criteria for dependence on cocaine.

Cocaine is absorbed rapidly from virtually all sites of application. For many years, cocaine has been administered as the hydrochloride

salt form, usually by inhalation, but also by injection. In the last 15 to 18 years, as the purity of cocaine hydrochloride obtained on the street declined, many users converted the cocaine hydrochloride to cocaine base, also known as “crack” or “rock.” Smoking the drug leads to almost instant absorption and intense euphoria. Peak plasma concentrations of more than 900 ng/mL have been achieved following inhalation of cocaine base vapors, compared with concentrations of only 150 to 200 ng/mL achieved after inhalation of similar amounts of pure cocaine hydrochloride powder.²¹

The high from snorting may last 15 to 30 minutes, whereas that from smoking may last 5 to 10 minutes. Increased use can reduce the period of stimulation. Some users of cocaine report feelings of restlessness, irritability, and anxiety. An appreciable tolerance to the high may be developed, and many addicts report that they seek but fail to achieve as much pleasure as they did from their first exposure. Scientific evidence suggests that the powerful neuropsychological reinforcing property of cocaine is responsible for an individual's continued use despite harmful physical and social consequences. In rare instances, sudden death can occur on the first use of cocaine or unexpectedly thereafter. However, there is no way to determine who is prone to sudden death.

High doses of cocaine and/or prolonged use can trigger paranoia. Smoking crack cocaine can produce a particularly aggressive paranoid behavior in users. When addicted individuals stop using cocaine they often become depressed. This may lead to further cocaine use to alleviate depression. Prolonged cocaine snorting can result in ulceration of the mucous membranes of the nose and can damage the nasal septum enough to cause it to collapse. Cocaine-related deaths are often a result of cardiac arrest or seizures followed by respiratory arrest.

Recent research has helped clarify certain patterns of cocaine use such as combining cocaine and alcohol. Such drug use would seem counterintuitive because cocaine is a CNS stimulant and alcohol a CNS depressant. In the presence of alcohol, cocaine is metabolized to cocaethylene, a longer-acting but potent psychoactive compound as compared with the parent drug.²² The risk of death from cocaethylene is greater than from cocaine.²³ The cocaine-alcohol combination is one of the most commonly identified among individuals who come to hospital emergency departments with acute substance abuse problems.

Cocaine is metabolized and eliminated rapidly. The elimination half-life of cocaine is approximately 1 hour, and the duration of effect is very short.²¹ The short duration of effect provides a powerful incentive for repeated use of the drug. Many users experience intense drug use cycling, sometimes lasting days, characterized by rapidly repeating doses of cocaine until their supply is exhausted. Laboratory monkeys, given a choice between food and cocaine around the clock for 8 days, consistently choose cocaine.²⁴

Complications of cocaine use frequently involve cardiovascular events.²⁵ At higher doses it increases heart rate because of an overall systemic increase in sympathetic tone. At toxic doses, cocaine causes cardiac failure due to a direct effect on myocardial contractility. Cocaine is also pyrogenic, and hyperthermia is observed frequently in cocaine poisoning. Death is usually related to arrhythmias, shock, or convulsions.

Cocaine is a psychotomimetic drug, sometimes even at systemically nontoxic doses. A kindling phenomenon has been described with cocaine in which neuronal function becomes altered with each dose of the drug. This causes a type of reverse tolerance with increased receptor sensitivity to cocaine, and psychosis may be caused by doses that formerly did not cause psychosis. The toxic psychosis is characterized by auditory, visual, and frequently tactile hallucinations, paranoid thinking, and looseness of associations. The psychosis is qualitatively very similar to a paranoid schizophrenic psychosis.²⁶

TABLE 64–3. Signs and Symptoms of Cocaine Intoxication and Withdrawal

| Intoxication | Withdrawal |
|------------------------------------|--------------------|
| Motor agitation | Fatigue |
| Elation/euphoria | Sleep disturbance |
| Grandiosity | Nightmares |
| Loquacity | Depression |
| Hypervigilance | Increased appetite |
| Tachycardia | |
| Mydriasis | |
| Elevated or lowered blood pressure | |
| Sweating or chills | |
| Nausea and vomiting | |

Signs and symptoms of cocaine intoxication are summarized in Table 64–3. Although there is some controversy as to whether cocaine is associated with physical withdrawal on abrupt discontinuation, most clinicians feel that there is a characteristic syndrome of withdrawal effects, although they are not life-threatening.^{13,27} Cocaine withdrawal consists primarily of fatigue, sleep disturbance, nightmares, and depression; it begins within hours of discontinuing the drug and lasts up to several days.

AMPHETAMINE, METHAMPHETAMINE, AND OTHER STIMULANTS

During the 1940s the Japanese government distributed amphetamines to soldiers, sailors, and pilots, as well as to arms factory workers, to mobilize all their reserves for the war effort. Pilots routinely used the drug to remain awake and alert for long periods on long-distance bombing missions. After 1945 large quantities of the drug from looted military supplies flooded the market. In the United States in the 1950s and 1960s, legally manufactured tablets of methamphetamine were used nonmedically by college students, truck drivers, and athletes, who usually did not become severely addicted. This pattern changed drastically in the later 1960s with the increased availability of injectable methamphetamine.

There were an estimated 378,000 new methamphetamine users in 1998, up from 149,000 in 1990.⁴ Street methamphetamine is referred to by many names, such as “speed,” “meth,” and “crank.” Methamphetamine hydrochloride, clear chunky crystals resembling ice which can be inhaled by smoking, is referred to as “ice,” “crystal,” and “glass.”

The physiologic and psychological effects of amphetamines and other stimulants are qualitatively similar to those of cocaine—they diminish fatigue, increase alertness, and suppress appetite. Pharmacologically, amphetamines increase the activity of catecholamine neurotransmitters (e.g., norepinephrine and dopamine) by blocking reuptake, increasing release of neurotransmitters, and inhibiting the degradative enzyme monoamine oxidase.²⁸ The longer duration of effect of methamphetamine has led to a shift away from cocaine and toward the longer-acting drug.

Methamphetamine is taken orally or intranasally, by intravenous injection, and by smoking. Immediately after inhalation or intravenous injection, the methamphetamine user experiences an intense sensation, called a “rush” or “flash,” that lasts only a few minutes and is described as extremely pleasurable.

Because methamphetamine elevates mood, people who experiment with it tend to use it with increasing frequency and in increasing doses, although this was not their original intent. The CNS actions that result from taking even small amounts of methamphetamine include increased wakefulness, increased physical activity, decreased

appetite, increased respiration, hyperthermia, and euphoria. Other CNS effects include irritability, insomnia, confusion, tremors, convulsions, anxiety, paranoia, and aggressiveness. Hyperthermia and convulsions can result in death.

Cardiovascular side effects, which include chest pain and hypertension, also can result in cardiovascular collapse and death. In addition, methamphetamine causes increased heart rate and blood pressure and can cause irreversible damage to blood vessels in the brain, producing strokes. Other effects of methamphetamine include respiratory problems, irregular heartbeat, and extreme anorexia.

Methamphetamine can be injected, smoked, snorted, or ingested orally or anally. The timing and intensity of the “rush” that accompanies the use of methamphetamine, which is a result of the release of high levels of dopamine into the brain, depends in part on the method of administration. Specifically, the effect is almost instantaneous when smoked or injected, while it takes approximately 5 minutes after snorting or 20 minutes after oral ingestion. Immediate physiologic changes associated with the use of methamphetamine are similar to those produced by the fight-or-flight response and include increased blood pressure, body temperature, heart rate, and respiratory rate. Negative side effects include high body temperature, stroke, cardiac arrhythmias, stomach cramps, and shaking, as well as increased anxiety, insomnia, aggressive tendencies, paranoia, and hallucinations.

Prolonged use of methamphetamine may result in a tolerance for the drug and increased use at higher dosage levels, creating dependence. Such continual use of the drug with little or no sleep leads to an extremely irritable and paranoid state. Discontinuing use of methamphetamine often results in a state of depression, as well as fatigue, anergia, and some types of cognitive impairment that last anywhere from 2 days to several months.²⁹

Both short- and long-term health effects have also been documented. Negative consequences of methamphetamine abuse range from anxiety and insomnia to convulsions, paranoia, and brain damage, but in addition to the many direct effects on methamphetamine users are the indirect impacts on individuals and society. Children of methamphetamine abusers are at high risk of neglect and abuse, and pregnant women’s use of methamphetamine can cause growth retardation, premature birth, and developmental disorders in neonates. Extensive evidence indicates that in many Western U.S. cities, methamphetamine is used extensively by gay males and is frequently associated with high-risk sexual behavior, a major factor in the transmission of the human immunodeficiency virus (HIV). Within this particular group, effective treatment for methamphetamine dependence may be one of the most important strategies in reducing the spread of HIV and other associated communicable diseases.³⁰ Treatment for methamphetamine dependence is very difficult, with a low success rate.³¹

The expanding global market is fed by an increase in clandestine manufacture of methamphetamine. Not only are there more laboratories in more countries, but their size and sophistication is also increasing. The number of clandestine methamphetamine laboratories seized nationwide by the U.S. Drug Enforcement Administration (DEA) increased from 263 in 1994 to 1815 in 2000, a 590% increase. In addition, state and local police agencies seized almost 4,600 clandestine laboratories in the United States during 2000. So-called “kitchen” laboratories are still detected, but today clandestine laboratories with 100-kilogram capacities per week are also found. Initially the clandestine manufacture of methamphetamine was based primarily in the West and Southwest. Today methamphetamine can be found in cities across the United States. Methamphetamine is manufactured using the ephedrine or pseudoephedrine reduction method. In this process, ephedrine or pseudoephedrine is extracted from over-the-counter cold and allergy tablets. Pharmacists should be wary of persons wishing

to purchase large quantities of products containing nonprescription sympathomimetic products.

Prices for methamphetamine vary throughout different regions of the United States, ranging from \$3500 per pound in parts of California and Texas to \$21,000 per pound in southeastern and northeastern regions of the country. Retail prices range from \$400 to \$3000 per ounce.³² This corresponds to a cost of \$10 to \$60 per dosage unit.³³

ECSTASY AND OTHER METHAMPHETAMINE ANALOGS

Several dozen analogs of amphetamine and methamphetamine are hallucinogenic. Two methamphetamine analogs of most concern are 3,4-methylenedioxyamphetamine (MDA) and especially 3,4-methylenedioxymethamphetamine (MDMA or ecstasy). Use of this latter drug has skyrocketed in recent years. The drug is particularly popular among young people at all-night dance parties referred to as “raves,” and the drug is classified among the “club drugs.” As stated earlier, among high school seniors annual use rates have actually declined from 9.2% to 7.4%.⁵

Decreased usage of a drug is usually tied to increases in the perceived risk of using that drug. Disapproval of ecstasy use rose sharply in all three grades in 2002, indicating that peer norms against the use of this drug are strengthening. In 2000, only 38% of twelfth graders said there was a great risk of harm associated with trying ecstasy. That figure jumped to 46% in 2001 and again in 2002 to 52%.⁵

The vast majority of ecstasy consumed domestically is produced in Europe. It costs as little as 25 to 50 cents to manufacture an ecstasy tablet in Europe, but the street value of that same ecstasy tablet can be as high as \$40, with a tablet typically selling for between \$20 and \$30.³⁴ A limited number of ecstasy laboratories operate in the United States. Law enforcement seized 17 clandestine ecstasy laboratories in the United States in 2001 compared to 7 seized in 2000.³⁴ United States Customs Service statistics show a dramatic increase in seizures of MDMA tablets. In fiscal year 1997, approximately 400,000 MDMA tablets were seized, compared to approximately 7.2 million tablets seized in fiscal year 2001. On July 22, 2000, approximately 2.1 million tablets worth an estimated \$40 million were seized in Los Angeles. To date this is the largest seizure of MDMA tablets in the United States.³⁵

MDMA is structurally similar to methamphetamine and mescaline and stimulates the CNS, producing a mild hallucinogenic effect. Known most commonly on the street as ecstasy, it is also called “Adam,” “X,” “X-TC,” “Stacy,” “beans,” “e,” or simply “pills.” Users under the influence of MDMA are said to be “rolling.” Those taking both MDMA and lysergic acid diethylamide (LSD) are referred to as “trolling,” a combination of the slang terms “tripping” and “rolling.” MDMA is usually taken by mouth in tablet, capsule, or powder form, but it also may be smoked, snorted, or injected.

The effects of MDMA usually last approximately 4 to 6 hours. Users of the drug say that it produces profoundly positive feelings, empathy for others, elimination of anxiety, and extreme relaxation. MDMA is also said to suppress the need to eat, drink, or sleep, enabling users to endure 2- to 3-day parties. Consequently MDMA use sometimes results in severe dehydration or exhaustion. MDMA generally reduces inhibitions and creates a sense of euphoria, but it also can evoke anxiety and paranoia. Heavier doses generate depression, irrationality, and psychosis. Users claim they experience feelings of closeness with others and a desire to touch them.

MDMA use can result in a variety of acute psychiatric disturbances, including panic, anxiety, depression, and paranoid thinking.³⁶ Physical symptoms include muscle tension, nausea, blurred vision, faintness, chills, and sweating. MDMA also increases the heart rate and blood pressure. Other effects include hyperthermia, dehydration,

vomiting, tremors, loss of control over body movements, insomnia, convulsions, rapid eye movements, and teeth and jaw clenching.

MDMA is perceived to be a harmless drug by many of its users, based in part on the fact that the risk of death is low compared with other drugs like heroin and cocaine. However, mounting evidence points to neurotoxic effects of MDMA, involving a complex and incompletely understood mechanism. MDMA has been clearly shown to destroy serotonin-producing neurons in animals.³⁷ Doses of MDMA that produce neurotoxicity are only two or three times more than the minimum dose needed to produce a psychotropic response. This suggests that individuals who are self-administering the drug may be getting a neurotoxic dose.³⁸

Researchers have found that heavy MDMA users have memory problems that persist for at least 2 weeks after they have stopped using the drug.³⁹ The authors compared 24 abstinent MDMA users and 24 control subjects on several standardized tests of memory, after matching subjects for age, gender, educational level, and vocabulary score (a surrogate of verbal intelligence). The authors also explored correlations between changes in memory function and decrements in cerebrospinal fluid (CSF) 5-hydroxyindoleacetic acid (5-HIAA), which serves as a marker of central serotonin neural function. These researchers were able to show that greater use of MDMA (total milligrams per month) was associated with greater impairment in immediate verbal memory and delayed visual memory. Furthermore, lower vocabulary scores were associated with stronger dose-related effects, with men having greater dose-related deficits than women. Lastly, lower concentrations of CSF 5-HIAA were associated with poorer memory performance. The authors concluded that abstinent MDMA users have impairment in verbal and visual memory, and that the extent of memory impairment correlates with the degree of MDMA exposure and the reduction in brain serotonin, as indexed by CSF 5-HIAA.

McCann and colleagues⁴⁰ conducted a study to determine the effects of MDMA use on cognitive performance. Twenty-two MDMA users who had not used MDMA for at least 3 weeks and 23 control subjects were tested repeatedly with a computerized cognitive performance assessment battery while participating in a 5-day controlled inpatient study. CSF measures of monoamine metabolites also were collected as an index of brain monoaminergic function. MDMA users and controls were found to perform similarly on several cognitive tasks. However, MDMA subjects had significant performance deficits on a sustained-attention task requiring arithmetic calculations, a task requiring complex attention and incidental learning, a task requiring short-term memory, and a task of semantic recognition and verbal reasoning. MDMA users also had significant selective decreases in CSF 5-HIAA. The authors believe that their data provide further evidence that MDMA is neurotoxic to brain serotonin neurons in humans, and the behavioral data suggest that brain serotonin injury is associated with subtle but significant cognitive deficits. Additional evidence has been accruing.⁴¹

Manufacturers of illicit drugs sometimes substitute other, potentially more dangerous substances for the one the buyer is expecting. Other suppliers produce products adulterated with chemical by-products of the incomplete synthesis of active ingredients. One such chemical, *para*-methoxyamphetamine, is a drastically more potent hyperthermic agent than MDMA.⁴² Deaths from the drug likely will rise as a result of these poor-quality tablets.

PHENCYCLIDINE AND KETAMINE

Phencyclidine (PCP), commonly referred to as “angel dust” and “crystal,” was popular in the 1970s, but as its adverse effects became better known, use declined. PCP is most often a substitute for or contaminant of other drugs, and its most common pattern of use may now

TABLE 64–4. Signs and Symptoms of Phencyclidine Intoxication

| | |
|--------------------------|--------------------------------|
| Nystagmus | Euphoria |
| Increased blood pressure | Motor agitation |
| Tachycardia | Anxiety and emotional lability |
| Paresthesias | Hostility |
| Ataxia | Delusions |
| Slurred speech | Hallucinations |
| Muscle rigidity | |

be unintentional. The actual extent of its use is unclear. It is often misrepresented as LSD or Δ^9 -tetrahydrocannabinol (THC). With the exception of the pharmaceutical dosage form of dronabinol, THC is virtually unavailable on the street because it is highly unstable when isolated from the marijuana plant. When used intentionally, PCP is commonly smoked with marijuana and referred to as a “crystal joint,” but it also may be taken orally or intravenously.

PCP has widely varied actions including CNS stimulation, depression, and hallucinogenic properties. Pharmacologically, it is known to block reuptake of serotonin, dopamine, and norepinephrine, but neurotransmitter antagonists do not effectively block its effects. In low doses, PCP causes sedation, ataxia, nystagmus, slurred speech, and paresthesias. At higher doses, users experience an increase in heart rate, blood pressure, temperature, diaphoresis, and muscle rigidity. At acutely toxic doses, coma and seizures may occur.⁴³

Behavioral effects of PCP range from sleep to catatonic detachment to paranoid psychosis to violent hostility. Users are sometimes amnesic for events that occur under the influence of the drug. Psychoses sometimes last for weeks. Users with a previous history of schizophrenia are especially susceptible to the psychotomimetic effects of the drug. The only truly characteristic behavioral effect of PCP use is its high unpredictability. The signs and symptoms of PCP intoxication are summarized in Table 64–4.

Ketamine, a compound chemically related to PCP, is used primarily as a veterinary anesthetic but has gained popularity recently as a recreational drug.⁴⁴ Once used extensively in human medicine, it has fallen out of favor because of “emergence delirium,” characterized by hallucinations, delirium, vivid dreams, and other psychiatric effects. This untoward effect as a medicinal agent is precisely the effect that recreational users are seeking.

Known as “special K,” “jet,” “green,” and other names on the street, ketamine is sometimes injected, but can be evaporated to solid crystals, powdered, and smoked, snorted, or swallowed. Marijuana cigarettes are sometimes soaked in the ketamine solution, allowed to dry, and then smoked. Ketamine has become popular as a “rave” club drug. Side effects include significant transient increases in blood pressure and heart rate, respiratory depression, airway obstruction, apnea, muscular hypertonia, psychomotor and psychotomimetic effects, and acute dystonic reactions. Following overdose, seizures, polyneuropathy, increased intracranial pressure, respiratory arrest, and cardiac arrest may occur.^{45,46}

The effects of a ketamine “high” usually last an hour, but they can last for 4 to 6 hours, and 24 to 48 hours are generally required before the user will feel completely normal again. Effects of chronic use of ketamine may take from several months to 2 years to disappear completely. Low doses (25 to 100 mg) produce psychedelic effects quickly. Large doses can produce vomiting and convulsions and may lead to hypoxia of the brain and muscles; 1 g can cause death. Flashbacks may even occur 1 year after use. Long-term effects include tolerance and possible physical and/or psychological dependence.

Since its emergence as a drug of abuse in the late 1960s, PCP has been described as one of the most dangerous of all synthetic hallucinogens. Its niche in the drug world is usually one characterized by

abusers exhibiting hostile behavior that manifests itself in extremely violent episodes.^{45,46}

Despite the negative effects associated with PCP, there remains an illicit market for the drug. Illicit organizations producing and distributing PCP are still active in the United States.⁴⁷ These organizations, operating mainly in Los Angeles and to a lesser extent in Houston, supply most of the PCP available in the nation. The recent emergence of large PCP laboratories in other locations, such as Indiana and Maryland, are cause for concern because this may be an indication that the demand for PCP is on the rise. Lending support to this claim is a DAWN survey indicating that the number of PCP-related ED visits increased 78% from 1998 to 2001; mentions of PCP increased 25% (from 6,102 to 7,648) from 2001 to 2002.²

HALLUCINOGENS

The drugs commonly classified as hallucinogens are LSD, psilocybin, dimethyltryptamine (DMT), mescaline, and other related compounds. LSD is one of the most potent mood-changing chemicals. It is manufactured from lysergic acid, which is found in ergot, a fungus that grows on rye and other grains.

Pharmacologically, LSD and related drugs stimulate both presynaptic (5-HT_{1A} and 5-HT_{1B}) and postsynaptic (5-HT₂) serotonin recognition sites in the brain, which functionally may cause either agonist or antagonist effects on serotonin activity.⁴⁸ Precisely how the hallucinogens exert their effects remains unclear. LSD, often referred to as “acid,” is an extraordinarily potent compound, producing observable CNS effects at doses as low as 25 mcg.⁴⁸

LSD is sold on the street in tablets, capsules, and occasionally in liquid form. It is odorless, colorless, and tasteless and usually is taken by mouth. Often LSD is added to absorbent paper, such as blotter paper, and divided into small decorated squares, with each square representing one dose.

The DEA reports that the strength of LSD samples obtained recently from illicit sources ranges from 20 to 80 mcg of LSD per dose. This is considerably less than the levels reported during the 1960s and early 1970s, when the dosage ranged from 100 to 200 mcg or higher per unit.

The effects of LSD are unpredictable. They depend on the amount taken; the user’s personality, mood, and expectations; and the surroundings in which the drug is used. Usually the user feels the first effects of the drug 30 to 90 minutes after taking it. The physical effects include dilated pupils, higher body temperature, increased heart rate and blood pressure, sweating, loss of appetite, sleeplessness, dry mouth, and tremors.

Sensations and feelings change much more dramatically than the physical signs. The user may feel several different emotions at once or swing rapidly from one emotion to another. If taken in a large enough dose, the drug produces delusions and visual hallucinations. The user’s sense of time and self changes. Sensations may seem to “cross over,” giving the user the feeling of hearing colors and seeing sounds. These changes can be frightening and can cause panic.

Many LSD users experience flashbacks, or recurrence of certain aspects of a person’s experience, without the user having taken the drug again. A flashback occurs suddenly, often without warning, and may occur within a few days or more than a year after LSD use. Flashbacks usually occur in people who use hallucinogens chronically or have an underlying personality problem; however, otherwise healthy people who use LSD occasionally also may have flashbacks.

Most users of LSD voluntarily decrease or stop its use over time. LSD is not considered an addictive drug because it does not

TABLE 64–5. Signs and Symptoms of Hallucinogen Intoxication

| Psychologic | Physical |
|----------------------------|----------------|
| Perceptual intensification | Mydriasis |
| Depersonalization | Tachycardia |
| Derealization | Diaphoresis |
| Illusions | Palpitations |
| Hallucinations | Blurred vision |
| Synesthesias | Tremor |
| | Incoordination |
| | Dizziness |
| | Weakness |
| | Drowsiness |
| | Paresthesias |

produce compulsive drug-seeking behavior. However, as with many of the addictive drugs, LSD use produces tolerance, so some users who take the drug repeatedly must take progressively higher doses to achieve the state of intoxication that they had achieved previously.

Signs and symptoms of hallucinogen intoxication are summarized in Table 64–5. Psychological symptoms of intoxication include a subjective intensification of perceptions, depersonalization, illusions, hallucinations, and synesthesias, the overflow of one sensory modality to another (colors are heard, sounds are seen). Among the hallucinogenic drugs, LSD is the most potent and long acting; it is hundreds of times more potent than both psilocybin and mescaline. DMT is inactive when ingested orally but can be smoked, inhaled, or injected. There is cross-tolerance among LSD, psilocybin, and mescaline. There is no observable physical withdrawal syndrome after abrupt discontinuation of hallucinogenic drugs.⁴⁹

Complications from hallucinogen use are primarily psychological. Users sometimes experience prolonged episodes of panic—the so-called “bad trip.” The flashbacks noted above are common, occurring in approximately 15% of users and occurring episodically up to several years after the last exposure to the drug. Flashbacks may occur spontaneously but are also triggered by other drugs, including marijuana, and by anxiety-provoking stimuli. Physical effects of hallucinogen use are relatively nontoxic. Contrary to a widely held notion in the 1960s and early 1970s, there is no reliable evidence that hallucinogen use causes chromosome damage or genetic defects.⁴⁸

Few LSD laboratories have ever been seized in the United States because of infrequent and irregular production cycles. In 2000, the DEA seized one LSD laboratory that was located in a converted missile silo in Kansas. This was the largest LSD lab seizure ever made by the DEA, and agents seized approximately 41.3 kilograms (90.86 pounds) of LSD and approximately 23.6 kilograms (51.92 pounds) of iso-LSD, a by-product of the manufacture of LSD.⁵⁰

MARIJUANA

Marijuana, referred to as “reefer,” “pot,” “grass,” or “weed,” remains the most commonly used illicit drug. In 2002, it was used by 75% of current illicit drug users. Approximately 55% of current illicit drug users used only marijuana, 20% used marijuana and another illicit drug, and the remaining 25% used an illicit drug but not marijuana in the past month. Ninety-five million people 12 years and older (40.4%) have tried marijuana at least once.⁴ There were an estimated 2.6 million new marijuana users in 2001. In 2001, about two-thirds (67%) of new marijuana users were under age 18. This proportion has generally increased since the 1960s, when less than half of initiates were under

18. The average age of marijuana initiates was around 19 in the late 1960s and 17.1 in 2001.

Most users smoke marijuana in hand-rolled cigarettes called joints, among other names; some use pipes or water pipes called bongs. Marijuana cigars called blunts have also become popular. To make blunts, users slice open cigars and replace the tobacco with marijuana, often combined with another drug, such as crack cocaine. Marijuana also is used to brew tea and is sometimes mixed into foods.⁵¹

Marijuana’s effects begin immediately after the drug enters the brain and last from 1 to 3 hours. If marijuana is consumed in food or drink, the short-term effects begin more slowly, usually in 1/2 to 1 hour, and last longer, for as long as 4 hours. Smoking marijuana deposits several times more THC into the blood than does eating or drinking the drug.⁵¹

Within minutes of inhaling marijuana smoke, the heart rate increases, the bronchial passages relax and become enlarged, and blood vessels in the eyes dilate, causing the eyes to appear bloodshot. As THC enters the brain, it causes a user to feel euphoric, activating the reward system by stimulating brain cells to release dopamine. A marijuana user may experience pleasant sensations, colors and sounds may seem more intense, and time appears to pass very slowly. The user’s mouth feels dry, and he may suddenly become very hungry and thirsty. The hands may tremble and grow cold. The euphoria passes after awhile, and then the user may feel sleepy or depressed. Occasionally, marijuana use produces anxiety, fear, distrust, or panic.⁵¹

Marijuana use impairs a person’s ability to form memories, recall events, and shift attention from one thing to another.⁵² THC also disrupts coordination and balance by binding to receptors in the cerebellum and basal ganglia. Through its effects on the brain and body, marijuana intoxication can cause accidents. Studies show that approximately 6% to 11% of fatal accident victims test positive for THC. In many of these cases alcohol is detected as well.

In a study conducted by the National Highway Traffic Safety Administration, a moderate dose of marijuana alone was shown to impair driving performance; however, the effects of even a low dose of marijuana combined with alcohol were markedly greater than for either drug alone. Driving indices measured included reaction time, visual search frequency (driver checking of side streets), and the ability to perceive and/or respond to changes in the relative velocity of other vehicles.⁵³

Marijuana users who have taken high doses of the drug may experience acute toxic psychosis, which includes hallucinations, delusions, and depersonalization—the persistent or recurrent feelings of being detached from one’s body or mental processes and usually a feeling of being an outside observer of one’s own life. Although the specific causes of these symptoms remain unknown, they appear to occur more frequently when a high dose of cannabis is consumed in food or drink rather than smoked.⁵¹

The principal psychoactive component of marijuana is THC. Hashish, the dried resin of the top of the plant, is much more potent than the plant itself. Increasingly sophisticated growing techniques have resulted in plants of greater potency. In a recent study, the amount of Δ^9 -THC found in the samples ranged from 1.41% to 12.62% by dry weight. The average Δ^9 -THC content was 6.20%, which is almost identical to the 2002 value reported by The University of Mississippi’s Potency Monitoring Project.⁵²

Marijuana has been used widely and is believed by many to be a relatively harmless, nonaddictive intoxicant. Chronic low doses of marijuana usually are not associated with significant physical withdrawal on abrupt discontinuation, but many chronic users exhibit compulsive drug-seeking and drug-use behaviors characteristic of addiction or dependence. Acutely, marijuana has many of the effects of

TABLE 64–6. Signs and Symptoms of Marijuana Intoxication

| | |
|-------------------------|-------------------------|
| Tachycardia | Euphoria |
| Conjunctival congestion | Sensory intensification |
| Increased appetite | Apathy |
| Dry mouth | Hallucinations |

alcohol—sedation, a decrease in reactivity and ability to perform complex tasks, and disinhibition. Marijuana also causes hallucinations with high enough doses. Chronic use is associated with all the risks of tobacco smoking, although marijuana smokers are commonly also tobacco smokers, and thus differentiation of effects is often difficult. Endocrine effects including amenorrhea, decreased testosterone production, and inhibition of spermatogenesis have been demonstrated. Marijuana is associated with an amotivational syndrome characterized by a behavioral pattern of apathy, dullness, impaired judgment, decreased concentration and memory, loss of interest in personal hygiene, and a general reduction of goal-directed behavior.⁵⁴

The signs and symptoms of marijuana intoxication are summarized in Table 64–6. Although the duration of effect of marijuana may be only several hours, THC is detectable on toxicologic screening for up to 4 to 5 weeks, especially in chronic users.

Marijuana smoke is irritating to the lungs. Researchers have found that the daily use of one to three marijuana joints appears to produce approximately the same lung damage and potential cancer risk as smoking five times as many cigarettes.⁵⁵ The study results suggest that the way smokers inhale marijuana, in addition to its chemical composition, increases the adverse physical effects. The study findings refute the argument that marijuana is safer than tobacco because users smoke only a few joints a day.

Clearly, there is much more work to be done before the precise health and psychological effects of marijuana use are well understood. In fact, many of these health issues remain the subject of much debate. Undoubtedly, opinions on its risks are polarized along the lines of proponents' views on what its legal status should be. This polarization of opinion has prevented the development of any consensus on what health information the medical profession should give to patients who are users or potential users of marijuana. There is conflicting evidence about many of the effects of marijuana use. Readers are referred to an excellent article that attempts to summarize in a dispassionate way the evidence on the most probable adverse health and psychological consequences of acute and chronic use of marijuana.⁵⁶

INHALANTS

Inhalants are a diverse group of substances that include volatile solvents, gases, and nitrites that are sniffed, snorted, huffed, or bagged

to produce intoxicating effects similar to those of alcohol. These substances are found in common household products like glues, lighter fluid, cleaning fluids, paint products, nail polish remover, gasoline, rubber glue, waxes, and varnishes. Chemicals found in these products include toluene, benzene, methanol, methylene chloride, acetone, methylethyl ketone, methylbutyl ketone, trichloroethylene, and trichlorethane. The gas used as a propellant in canned whipped cream and in small metallic containers called “whippets” (used to make whipped cream) is nitrous oxide or “laughing gas.” Tiny cloth-covered ampules called “poppers” or “snappers” by abusers contain amyl nitrite, a medication used to dilate blood vessels. Butyl nitrite, sold as tape head cleaner and referred to as “rush,” “locker room,” or “climax,” is often sniffed or huffed to get high.

The easy accessibility, low cost, legal status, and ease of transport and concealment make inhalants one of the first substances abused by children. Survey data indicate that about 15% to 20% of junior and senior high school students have tried inhalants, with about 2% to 6% reporting current use. The highest incidence of use is among 10- to 12-year-old children, with rates of use declining with age.⁵ Parents worry about alcohol, tobacco, and drug use, but may be unaware of the hazards associated with products found throughout their homes.

Inhalants may be sniffed directly from an open container or huffed from a rag soaked in the substance and held to the face. Alternatively, the open container or soaked rag can be placed in a bag where the vapors can concentrate before being inhaled. Although inhalant abusers may prefer one particular substance because of taste or odor, a variety of substances may be used because of similar effects, availability, and cost. Once inhaled, the extensive capillary surface area of the lungs allows rapid absorption of the substance and blood levels peak rapidly. Entry into the brain is fast, and the intoxicating effects are intense but short-lived. Intoxication is often accompanied by headache and nausea, and users may experience hallucinations and delusions. The most serious physical risk of acute use is sudden death, usually from cardiac arrhythmias. Some users die from suffocation by plastic bags that contain the solvent. With chronic use, the drugs are toxic to virtually all organ systems. Psychological impairment; impaired pulmonary, renal, and hepatic function; neuropathies; encephalopathy; and brain damage have all been observed.⁵⁷

Inhalants depress the CNS, producing decreased respiration and blood pressure. Users report distortion in perceptions of time and space. Many users experience headaches, nausea, slurred speech, and loss of motor coordination. Mental effects may include fear, anxiety, or depression. A rash around the nose and mouth may be seen, and the abuser may start wheezing. An odor of paint or organic solvents on clothes, skin, and breath is sometimes a sign of inhalant abuse. Other indicators of inhalant abuse include slurred speech or staggering gait; red, glassy, watery eyes; and excitability or unpredictable behavior.

► TREATMENT: Substance-Related Disorders

■ ACUTE DRUG INTOXICATIONS

Treatment of drug intoxication, summarized in Table 64–7, is primarily supportive. Vital functions are maintained while waiting for the drug to be eliminated. When absolutely necessary, physical restraint may be required temporarily while a diagnostic evaluation is initiated to rule out other causes for the behavior (e.g., metabolic or fluid and electrolyte disturbances). Whenever possible, drug therapy should be avoided because psychotropic drug therapy has the potential

for worsening a toxic reaction to another psychoactive agent; however, when patients are agitated, combative, assaultive, hallucinatory, or delusional, drug therapy may be required. Drug therapy also may be indicated in the treatment of an acute, potentially fatal drug overdose. Toxicology screens are useful in the evaluation and treatment process, but knowledge of the metabolism of the suspected drug and its excretion patterns is important for proper interpretation of test results. When toxicology screens are desired, blood or urine should be collected immediately upon the patient's arrival.

TABLE 64–7. Treatment of Substance Intoxication

| Drug Class | Pharmacologic Therapy | Nonpharmacologic Therapy |
|--|---|---|
| Benzodiazepines | Flumazenil 0.2 mg/min IV initially, repeat up to 3 mg maximum | Support vital functions |
| Alcohol, barbiturates, and sedative-hypnotics (nonbenzodiazepines) | None | Support vital functions |
| Opiates | Naloxone 0.4–2 mg IV every 3 min | Support vital functions |
| Cocaine and other CNS stimulants | Lorazepam 2–4 mg IM every 30 min to 6 h as needed for agitation Haloperidol 2–5 mg (or other antipsychotic agent) every 30 min to 6 h as needed for psychotic behavior | Monitor cardiac function |
| Hallucinogens, marijuana, and inhalants | Lorazepam and/or haloperidol as above | Reassurance; “talk-down therapy”; support vital functions |
| Phencyclidine | Lorazepam and/or haloperidol as above | Minimize sensory input |

For alcohol and barbiturate intoxication, supportive treatment is the rule. For benzodiazepine intoxication, the benzodiazepine antagonist flumazenil can be used to reverse toxic effects. However, it is not indicated in all cases of suspected drug overdose, and is specifically contraindicated in cases in which cyclic antidepressant involvement is known or suspected because of the risk of seizures. In addition, it should be used with caution in patients when benzodiazepine physical dependence is suspected because of the risks of induction of benzodiazepine withdrawal. In the case of opiate intoxication, if the patient is unconscious and respiration is depressed, the opiate antagonist naloxone can be used to revive the patient. The usual dosage for naloxone in acute opiate toxicity is 0.4 to 2 mg intravenously, given approximately every 3 minutes as necessary.⁵⁸ Although naloxone is effective in reversing opiate overdose, it also may precipitate physical withdrawal in physically dependent patients. Patients who fail to respond to a total dosage of 10 mg naloxone probably have a cause of acute intoxication other than an opiate.

Intoxication with stimulants, including cocaine, is treated pharmacologically only if the patient is overtly psychotic and agitated. Injectable benzodiazepines, usually lorazepam 2 to 4 mg intramuscularly every 30 minutes to 6 hours as necessary, can be used for agitation. As a back-up to lorazepam, antipsychotic drugs can be used on a short-term basis, primarily in patients with psychotic symptoms, and usually at relatively low doses, such as haloperidol 2 to 5 mg intramuscularly every 30 minutes to 6 hours as necessary, followed by 5 to 15 mg orally per day in single or divided doses if the patient is still psychotic after initial treatment.²⁷ Cardiovascular complications are treated symptomatically with antiarrhythmic agents or other interventions as necessary. Seizures generally are treated supportively. Intravenous lorazepam or diazepam can be used if seizures progress to status epilepticus.

Hallucinogen intoxication is treated in a manner similar to stimulant intoxication. Drug therapy often can be avoided because patients may respond to careful reassurance, or so-called talk-down therapy. When necessary, short-term antianxiety and/or antipsychotic drug therapy can be used, as described previously. The same approach applies to marijuana and inhalant intoxication.

PCP intoxication is more unpredictable and more difficult to treat than other psychosis-producing drugs. Most clinicians suggest that sensory input be minimized to the extent possible; thus talk-down therapy is not recommended and may in fact make the patient worse. If PCP intoxication is suspected, patients should be left alone in a quiet, dimly lit room. If behavior is uncontrollable, antianxiety and/or antipsychotic drug therapy may be necessary.

WITHDRAWAL

3 Treatment of drug withdrawal is the primary indication for drug therapy in substance-related disorders. Goals of drug therapy include prevention of progression of withdrawal to life-threatening severity, enabling the patient to be sufficiently comfortable and functional in order to participate in a behavioral treatment program, and supportive drug therapy. The clinician should remember that withdrawal is usually part of a substance dependence disorder. Patients with drug dependence generally cope with almost any stress through the use of a drug. In drug therapy for withdrawal, it is important to avoid reinforcing the patient’s drug-seeking and drug-use behavior to the extent possible. Drug withdrawal in the best of circumstances is uncomfortable. Patients must be educated to deal with the stress of withdrawal without seeking drugs. The use of drugs as needed for anxiety or insomnia should be avoided. A recent review on the management of drug and alcohol withdrawal has been published.¹³ Treatment of drug withdrawal is summarized in Table 64–8.

CNS DEPRESSANT WITHDRAWAL

Benzodiazepines

3 Treatment of benzodiazepine withdrawal is very similar to the treatment of alcohol withdrawal, and the same drugs and dosages may be used.⁵⁹ The major difference in management is the length of treatment. The onset of withdrawal symptoms in patients physically dependent on the long-acting benzodiazepines may be delayed up to 7 days after discontinuation of the drug.¹³ A common approach in detoxification of such patients is to initiate treatment at usual dosages (chlordiazepoxide 50 mg three times a day; lorazepam 2 mg three times a day) and to maintain the initial dosage for 5 days, with gradual tapering over an additional 5 days. Detoxification in patients physically dependent on shorter-acting benzodiazepines is similar to treatment of alcohol withdrawal. Among the benzodiazepines, alprazolam has been suggested to be more difficult to taper and discontinue than the other benzodiazepines. Whether the difficulty is related to a different patient population commonly treated with alprazolam (e.g., panic disorder) or to intrinsic differences between alprazolam and other benzodiazepines is not clear. A longer, more gradual taper of the benzodiazepine used for detoxification may be needed. With all benzodiazepines, protracted minor abstinence symptoms—such as

TABLE 64–8. Treatment of Withdrawal from Some Common Drugs of Abuse

| Drug or Drug Class | Pharmacologic Therapy |
|-------------------------------|---|
| Benzodiazepines | |
| Short- to intermediate-acting | Chlordiazepoxide 50 mg three to four times a day or lorazepam 2 mg three to four times a day; taper over 5–7 days |
| Long-acting | Chlordiazepoxide 50 mg three to four times a day or lorazepam 2 mg three to four times a day; taper over additional 5–7 days |
| Barbiturates | Pentobarbital tolerance test; initial detoxification at upper limit of tolerance test; decrease dosage by 100 mg every 2–3 days |
| Opiates | Methadone 20–80 mg orally daily; taper by 5–10 mg daily or clonidine 2 mcg/kg three times a day × 7 days; taper over additional 3 days |
| Mixed-substance withdrawal | |
| Drugs are cross-tolerant | Detoxify according to treatment for longer-acting drug used |
| Drugs are not cross-tolerant | Detoxify from one drug while maintaining second drug (cross-tolerant drugs), then detoxify from second drug |
| CNS stimulants | Supportive treatment only; pharmacotherapy often not used; bromocriptine 2.5 mg three times a day or higher may be used for severe craving associated with cocaine withdrawal |

anxiety, insomnia, irritability, sensitivity to light and sound, and muscle spasms—may remain for several weeks in patients with a history of long exposure, even after the acute phase of benzodiazepine withdrawal is complete.

■ Barbiturates and Other Sedative-Hypnotic Drugs

3 While once used extensively, barbiturates and other nonbenzodiazepine sedating medications have been largely replaced by safer and more effective medications. Abuse problems with barbiturates resemble those seen with benzodiazepines in many ways. Withdrawal from barbiturates should be handled similarly to interventions for the abuse of alcohol and benzodiazepines.¹¹

■ Opiates

Opiate withdrawal syndrome is similar to a severe case of influenza.¹³ Opiate withdrawal is not life-threatening unless there is a concurrent life-threatening medical condition. Although most patients complain of symptoms of withdrawal such as cramping or insomnia, these symptoms are tolerable, and initiation of drug therapy may be avoided in many cases. Because opiate withdrawal is not life-threatening, observable signs of withdrawal, such as mydriasis, piloerection, diaphoresis, or diarrhea should be noted before initiation of drug therapy. Characteristic signs and symptoms of opiate withdrawal include pupillary dilatation, lacrimation, rhinorrhea, piloerection (“gooseflesh”), yawning, sneezing, anorexia, nausea, vomiting, and diarrhea. Seizures do not occur. Onset and duration of withdrawal symptoms and the time of peak occurrence depends on the half-life of the drug involved. Typically heroin withdrawal reaches a peak within 36 to 72 hours of discontinuation and can last for 7 to 10 days. For methadone, symptoms peak at 72 hours but can last for 2 weeks or more.¹³

The conventional drug therapy for opioid withdrawal has been methadone, a synthetic opiate. Recently, buprenorphine has been approved for opioid withdrawal and will be discussed in detail below. In detoxification treatment, methadone is administered in decreasing doses over a period not exceeding 30 days (short-term detoxification) or 180 days (long-term detoxification). There are many tapering schedules recommended in the literature. Most patients in withdrawal

continue to complain of mild symptoms after detoxification is completed. Some patients who are unable to discontinue methadone completely or habitually return to drug use when methadone is discontinued are placed in methadone-maintenance treatment programs and receive methadone chronically.⁶⁰

Levo-alpha-acetylmethadol (LAAM) was approved by the FDA in 1993 as a potential alternative to methadone maintenance. LAAM forms two long-acting metabolites which allow three-times-a-week dosing.⁵⁸

Typically, opioid dependency is treated initially with detoxification, usually as an inpatient. Except in a few individuals who remain drug free, detoxification is followed by long-term maintenance therapy. In the past, opioid-dependent patients relied on methadone or levomethadyl acetate, but federal restrictions limited distribution of these drugs to a small number of methadone clinics, which are not only inconvenient, but also expose patients to other drug users, and can stigmatize patients if friends, family, or coworkers are aware of their trips to the clinic. There were limited provisions for take-at-home dosing of methadone or levomethadyl because of concern about the diversion of these drugs to illicit use.

In October 2003, the FDA approved two new products for treatment of opiate dependence. These products represent two new formulations of buprenorphine. The first of these formulations, Subutex, contains only buprenorphine and is intended for use at the beginning of treatment for opiate abuse. The other, Suboxone, contains both buprenorphine and the opiate antagonist naloxone, and is intended to be the formulation used in maintenance treatment of opiate addiction. Naloxone has been added to Suboxone to guard against intravenous abuse of buprenorphine by individuals physically dependent on opiates.

These drugs represent the first therapy for in-office prescribing for opioid dependence under the federal Drug Addiction Treatment Act (DATA) of 2000.⁶¹ Prior to the passage of the DATA, office-based management of opioid therapy was illegal because existing federal laws prohibited physicians from prescribing narcotics for the sole purpose of maintaining a patient in a narcotic-addicted state. However, not every physician is permitted to prescribe these new drugs.

To qualify, physicians must be board certified in addiction medicine/psychiatry or hold other special credentials, and physicians are required to obtain 8 hours of authorized training before they can prescribe medications for office-based treatment of opioid dependence. They also must agree to treat no more than 30 opioid-dependent

patients at any one time, and they must obtain special DEA numbers indicating that they are authorized to prescribe under the provisions of the DATA.

The two formulations of the drug have been placed into schedule III by the DEA. Each product is available in two dosage strengths, 2 mg and 8 mg. Once-daily doses are titrated to a target of 16 mg/day of buprenorphine, but the dosing range extends from 4 mg/day to 24 mg/day.

Office-based maintenance therapy is well studied for patients who are already receiving treatment.^{62–65}

In a multicenter, randomized, placebo-controlled trial,⁶² 326 opiate-addicted persons were assigned to office-based treatment with sublingual tablets consisting of buprenorphine (16 mg) in combination with naloxone (4 mg), buprenorphine alone (16 mg), or placebo given daily for 4 weeks. The primary outcome measures were the percentage of urine samples negative for opiates and the subjects' self-reported craving for opiates. Safety data were obtained on 461 opiate-addicted persons who participated in an open-label study of buprenorphine and naloxone (at daily doses of up to 24 mg and 6 mg, respectively), and another 11 persons who received this combination only during the trial. The double-blind trial was terminated early because buprenorphine and naloxone in combination and buprenorphine alone were found to have greater efficacy than placebo. The proportion of urine samples that were negative for opiates was greater in the combined-treatment and buprenorphine groups (17.8% and 20.7%, respectively) than in the placebo group (5.8%; $p < 0.001$ for both comparisons); the active-treatment groups also reported less opiate craving ($p < 0.001$ for both comparisons with placebo). Rates of adverse events were similar in the active-treatment and placebo groups. During the open-label phase, the percentage of urine samples negative for opiates ranged from 35.2% to 67.4%. Results from the open-label follow-up study indicated that the combined treatment was safe and well tolerated. The authors concluded that buprenorphine and naloxone in combination and buprenorphine alone are safe and reduce the use of opiates and the craving for opiates among opiate-addicted persons who receive these medications in an office-based setting.

To check to see if the prescriber is authorized to treat patients under the DATA, pharmacists can call 1-866-BUP-CSAT or send an e-mail message to info@buprenorphine.samhsa.gov. Physicians generally use Subutex during induction and give a small supply of the product directly to the patient (clinical studies used buprenorphine-only tablets for the first 2 days). If patients present prescriptions for either agent from more than one prescriber for the same time period, a pharmacist should assume that diversion or abuse is occurring, refuse to fill the prescriptions, and notify both prescribers. Likewise, prescriptions for Subutex should be verified with prescribers, as the Suboxone formulation is preferred for long-term therapy.⁶⁵

A rapid detoxification (RD) technique has been developed that is designed to shorten detoxification by precipitating withdrawal through the administration of opioid antagonists such as naloxone hydrochloride or naltrexone.⁶⁶ This approach is thought to have the advantage of getting patients through detoxification rapidly, minimizing the risk of relapse, and initiating treatment more quickly with naltrexone maintenance combined with suitable psychosocial interventions. Ultrarapid detoxification (URD) represents a variant of this technique in which patients undergo opioid antagonist-precipitated withdrawal while under general anesthesia or heavy sedation. Although it is difficult to estimate the extent of their clinical use, these techniques are becoming increasingly available in response to rising demand for opioid-dependence treatment services. In the United States there has been a rapid proliferation of programs offering URD, with some programs charging up to \$7500 per treatment.⁶⁶

A recent meta-analysis was performed to assess the evidence for the efficacy of both RD and URD to determine their role among the available treatment options for opioid dependence. Analysis was performed on 12 studies of RD and 9 studies of URD. The authors concluded that more research is needed using more rigorous research methods, longer-term outcomes, and comparisons with other methods of treatment for opioid dependence before these techniques can gain widespread acceptance.⁶⁶

CLINICAL CONTROVERSY

Ultrarapid detoxification from opiates remains somewhat controversial in terms of its efficacy, safety, and cost. Before consenting to such treatment, patients should inquire of the practitioner regarding previous experience with this technique, including success rates of patients remaining drug-free, and also rates of complications that have occurred.

WITHDRAWAL FROM OTHER SUBSTANCES

Withdrawal from other drugs, including cocaine and other stimulants, is primarily supportive. However, pharmacotherapy recently has assumed a greater role in treating cocaine withdrawal and dependence. Bromocriptine, a dopamine antagonist at low dosages and an agonist at high dosages, is usually used in the treatment of parkinsonism and hyperprolactinemia and has been used to treat cocaine withdrawal symptoms and to reduce the craving for cocaine. Use of bromocriptine is based on the hypothesis that chronic use of cocaine causes dopamine depletion; therefore higher dosages should be used (i.e., 2.5 mg three times daily or higher). Despite initially promising pilot studies, recent evidence does not support the efficacy of bromocriptine to reduce cocaine use or craving.⁶⁷

SUBSTANCE DEPENDENCE

2 The treatment of drug dependence is primarily behavioral. The patient generally is taught that complete abstinence is the only realistic alternative to a life of uncontrollable drug use and despair that ultimately will end in death, and that there is no intermediate, controllable level of drinking or use of another drug. However, complete and permanent abstinence as the sole route to recovery is controversial. There may be an extremely few individuals who can return to controllable levels of drinking alcohol, but it is impossible to predict who these individuals are; thus most treatment programs continue to advocate complete abstinence. The prospect of life without alcohol or other drugs is incomprehensible to many patients. Entry into treatment often is facilitated by some type of leverage that the drug-dependent person associates with negative consequences, such as potential loss of job, divorce, legal problems, or deteriorating physical health. Early treatment is directed at penetrating the denial of a problem that is always present. The patient must be educated as to the disease of addiction, the effects of drugs, and the permanence of the condition.

As evidenced by the approval of the two buprenorphine products, there has been a trend toward outpatient treatment for drug dependence, due in part to cost-containment efforts. Inpatient treatment programs can cost as much as \$20,000 for a 4-week stay. When withdrawal symptoms are mild to moderate and there are no other medical indications for hospitalization, outpatient treatment may be an attractive alternative to inpatient treatment. One critical criterion for

outpatient treatment is the patient's compliance with complete abstinence from the dependence-producing drug during the treatment experience.

Families must be involved in treatment. The course of the patient's illness often has a devastating effect on other family members. Severely depleted self-esteem, denial of the family member's addiction, feelings of responsibility for the family member's drug use, and other behaviors that parallel the addiction process are often present. Treatment must be a lifelong process. Aftercare, or what is now being called *continued care*, should include regular and

frequent treatment in some form. Most drug-dependence treatment programs embrace a treatment approach based on the twelve steps to recovery. Alcoholics Anonymous (AA) is one of the most successful of all self-help groups. Associated groups include Alanon (a group for family members of alcoholics), Narcotics Anonymous (self-help groups based on the AA concept for users of other drugs), Overeaters Anonymous (a group for individuals with eating disorders), Gamblers Anonymous, and several other similar programs. Among chemically dependent health care professionals, treatment that incorporates both AA and peer-led self-help groups may be most effective.⁶⁸

CONCLUSIONS

Substance use disorders remain one of the great public health issues of contemporary society. Dependence on drugs is a powerful emotional and political issue. Because we live in a chemically oriented society, everyone is affected in some way by drug abuse and drug dependence. Health care professionals must be particularly vigilant for problems associated with drug use, not only for our patients, but also for ourselves.

SUBSTANCE-RELATED DISORDERS: ALCOHOL, NICOTINE, AND CAFFEINE

Paul L. Doering

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Tobacco is the number one preventable cause of death in the United States.
 - 2 Between 12 and 16 million Americans report current heavy alcohol use or alcohol abuse.
 - 3 Pharmacogenomics studies have identified genotypic and functional phenotypic variants that either serve to protect patients or predispose them toward alcohol dependence.
 - 4 Alcohol is a central nervous system depressant that shares many pharmacologic properties with the nonbenzodiazepine sedative hypnotics.
 - 5 The metabolism of alcohol is considered to follow zero-order pharmacokinetics, and this has important implications for the time course in which alcohol can exert its effects.
 - 6 Benzodiazepines are the treatment of choice for alcohol withdrawal.
 - 7 Disulfiram and naltrexone are the only two drugs FDA approved for the treatment of alcohol dependence, although the clinical utility of these agents remains controversial.
 - 8 More than three-quarters of smokers are nicotine dependent. Tobacco dependence is a chronic condition that requires repeated interventions.
 - 9 Use of nicotine replacement therapy along with behavioral counseling doubles cessation rates.
 - 10 Bupropion is efficacious alone and in combination with nicotine replacement therapy for smoking cessation.
 - 11 Caffeine's pharmacologic actions are similar to those of other stimulant drugs. As such, abstinence from caffeine induces a distinct withdrawal syndrome that includes headache, drowsiness, and fatigue.
- 1 Alcohol, nicotine, and caffeine are considered by most to be socially acceptable drugs, yet they impose an enormous social and economic cost on our society. More than 440,000 deaths each year are attributable to tobacco use, making tobacco the number one preventable cause of death and disease in this country.¹ Smoking is responsible for 85% of all lung cancer deaths, approximately 80% of all chronic obstructive pulmonary disease deaths, and 30% of overall health disease deaths.²
- 2 Approximately 12.9 million persons in the United States report current heavy use of alcohol or alcohol abuse.³ Almost one-half of these persons meet *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed., Text Revision (DSM-IV-TR) criteria for alcohol dependence,⁴ and more than 700,000 persons are in treatment for alcoholism at any one time.⁵ Population-based surveys of current drinkers have found rates of 7% to 16% for alcohol abuse or dependence.⁶ In 1995, 2.7% of the annual emergency department visits were related to alcohol abuse. These alcohol-related visits were 1.6 times as likely to be associated with injuries and with a chief complaint of pain. Alcohol dependence was diagnosed in 20% of these cases.⁷ According to the Drug Abuse Warning Network 2002 survey, ED visits related to drug abuse most frequently involved alcohol, and included 31% of the observed cases.⁸
- An estimated 100,000 U.S. citizens die each year because of alcohol-related causes, including traffic collisions and cirrhosis of the liver.⁹ Direct and indirect health and social costs of alcoholism to the nation are estimated to be \$180 billion annually.¹⁰
- Caffeine is currently the most widely used psychoactive substance in the world.¹¹ In the United States, 80% to 90% of adults regularly consume behaviorally active doses of caffeine.¹¹ Although research has shown that caffeine can cause a compulsive pattern of use, the prevalence of caffeine dependence and its clinical significance are difficult to determine.
- The subjects of alcohol, tobacco, and caffeine abuse deserve much more attention than space permits in this chapter. Therefore the information here should serve as a brief overview of these topics, and the reader desiring more details is urged to consult one or more of the many textbooks and articles devoted to these subjects.

ALCOHOL

EPIDEMIOLOGY OF ALCOHOL USE

Roughly half (51%) of Americans ages 12 and older reported being current drinkers of alcohol according to the National Survey on

TABLE 65–1. Genotypic, Phenotypic, and Environmental Factors that Affect Alcohol Dependence Risk

| Susceptibility Genes | Phenotype | Environment |
|--|---|---|
| Regions on chromosomes 1 and 4 that code for the following receptors: GABA _A Serotonin 1b DRD4 (dopamine 2) Tryptophan hydroxylase Neuropeptide Y Gene that codes for: ALDH2 (alcohol dehydrogenase, type 2; on chromosome 12) 5HTTLPR (serotonin transporter promoter) | Personality traits that include: Novelty seeking Impulsivity Aggression Depression Maximum number of alcoholic drinks consumed per day | Religious background Urban residence vs. rural History of sexual abuse Being single Having deceased parents |

Drug Use & Health (formerly called the National Household Survey on Drug Abuse).³ This translates to an estimated 120 million people. Approximately one-fifth of persons 12 years of age and older (54 million people) participated in binge drinking, defined as having five or more drinks on the same occasion, at least once in the 30 days prior to the survey. In 2002 there were 15.9 million heavy drinkers, meaning that they drank five or more drinks on the same occasion on at least five different days in the past month.³

Among youths aged 12 to 17 years, an estimated 22.9% used alcohol in the month prior to the survey interview. The prevalence of current alcohol drinking increases with increasing age, from 2% among youths aged 12 to a peak of 70.9% for persons 21 years of age. In 2002, 57.4% of males (age 12 and older) were current drinkers compared with 44.9% of females. In contrast to the pattern for illicit drugs, the higher the level of educational attainment, the more likely was the current use of alcohol. In 2002, 67.4% of adults with college degrees were current drinkers compared with only 37.8% of those having less than a high school education.³

THE DISEASE MODEL OF ADDICTION AS APPLIED TO ALCOHOLISM

Individuals who are drug dependent frequently are regarded as constitutionally weak people who have brought their problems on themselves and deserve the consequences of their behavior. Even when the lay public and health care professionals acknowledge addiction as a disease process, it is often felt to be self-induced. The disease concept of addiction, using alcoholism as a model, states that addiction is a disease and that individuals who suffer from the disease do not choose to contract the disease any more than someone who suffers from heart disease or diabetes mellitus chooses to contract that illness. A *disease* is defined as “any deviation from or interruption of the normal structure or function of any part, organ, or system (or combination thereof) of the body that is manifested by a characteristic set of symptoms and signs and whose etiology, pathology, and prognosis may be known or unknown.”⁴ Alcoholism, which is discussed as a prototype, meets all the definitional criteria. Diagnostic criteria for alcoholism do not specify frequency of drinking or amount of alcohol consumed. The key determinant is whether drinking is compulsive, out of control, and consequential when one drinks.

It has long been recognized that alcoholism is heritable, since 50% to 60% of first-degree relatives of alcoholics become alcohol dependent themselves.¹² Past discussions have focused on whether this heritable risk is due to genetics, environment, or both. Recent

research has identified several traits (or phenotypes), that attenuate one’s risk of alcohol dependence. Initially based on data from pre-clinical studies, pharmacogenomics studies have identified genotypic and functional phenotypic variants that either serve to protect patients, or predispose them toward alcohol dependence.¹³ Large-scale pharmacoepidemiologic studies have further elucidated the environmental risk factors that are associated with either protective effects or predisposition toward alcoholism.¹⁴ This is referred to as the “genome x” environment interaction effect. The known susceptibility genes, phenotypic characteristics, and environmental risk factors are summarized in Table 65–1. Interplay between the nonmodifiable interpatient variability due to functional polymorphisms that directly influence alcohol metabolism, as well as those functional genetic variants of proteins involved in the physiologic response to alcohol has increased our understanding of alcohol pharmacokinetics and pharmacodynamics. Yet, further elucidation of the gene-environment interactions are needed before these data are used to (1) create alcohol abuse prevention programs that target high-risk populations, and (2) to develop targeted treatments to prevent and treat alcohol dependence.¹⁵

Based on this and other information, the belief that addiction is a self-induced disease or a constitutional weakness has been dismissed by clinicians in the addiction treatment field. Willpower and self-discipline cannot control genetics or environment. Since most patients will consume alcohol at some point in their lives, and over half drink alcohol regularly, the determination of who becomes alcoholic must be multifactorial.

PHARMACOLOGY AND PHARMACOKINETICS OF ALCOHOL

ALCOHOL AS A DRUG

Alcohol is a central nervous system (CNS) depressant that shares many pharmacologic properties with the nonbenzodiazepine sedative-hypnotic drugs. It affects the CNS in a dose-dependent fashion, producing sedation that progresses to sleep, unconsciousness, coma, surgical anesthesia, and finally fatal respiratory depression and cardiovascular collapse. Alcohol affects endogenous opiates and several neurotransmitter systems in the brain, including γ -aminobutyric acid (GABA), glutamine, and dopamine. Alcohol intake results in an increase in endogenous opioids,¹⁶ and this may be responsible for the euphoria experienced with alcohol consumption. Currently there are no clinically useful antagonists that can reverse all the pharmacologic effects of alcohol.

Alcohol is available in a variety of concentrations in various alcoholic beverages. There are approximately 14 g of alcohol in a 12-oz can of beer (approximately 5%), 4 oz of nonfortified wine (approximately 10% to 14%), or one shot (1.5 oz) of 80-proof whiskey (40%). This amount will cause an increase in blood alcohol level of about 20 to 25 mg/dL in a healthy 70-kg male, although this varies with the time frame over which the alcohol is consumed, the type of alcoholic beverage, whether food is consumed along with it, and many patient variables. The lethal dose of alcohol in humans is variable, but deaths generally occur when blood alcohol levels are greater than 400 to 500 mg/dL.¹⁷

PHARMACOKINETICS

Absorption of alcohol begins in the stomach within 5 to 10 minutes of oral ingestion. The onset of clinical effects follows fairly rapidly. It is absorbed primarily from the duodenum, but in smaller amounts from the stomach, esophagus, and mucous membranes. Peak serum concentrations of alcohol usually are achieved 30 to 90 minutes after finishing the last drink, although it is quite variable depending on the type of alcoholic beverage consumed, what and when the person last ate, and other factors.¹⁸

Over 90% of alcohol in the plasma is metabolized in the liver by three enzyme systems that operate within the hepatocyte. The remainder is excreted by the lungs and in urine and sweat. Alcohol is metabolized to acetaldehyde by alcohol dehydrogenase in the cell. In turn, acetaldehyde is metabolized to carbon dioxide and water by the enzyme aldehyde dehydrogenase. A second pathway for oxidation of alcohol uses catalase, an enzyme located in the peroxisomes and microsomes. The third enzyme system, the microsomal alcohol oxidase system, has a role in the oxidation of alcohol to acetaldehyde. These last two mechanisms are of lesser importance than the alcohol dehydrogenase-aldehyde dehydrogenase system.

5 The metabolism of alcohol generally is said to follow zero-order pharmacokinetics.¹⁸ This may in fact be an oversimplification because at very high or very low concentrations of alcohol the metabolism may follow first-order pharmacokinetics.¹⁹ On average, the blood alcohol concentration is lowered from 15 to 22.2 mg/dL per hour in the nontolerant individual, assuming that the individual is in the postabsorptive state. Alcohol has a volume of distribution of 0.6 to 0.8 L/kg, representing the total body water.¹⁸

ACUTE EFFECTS OF ALCOHOL

At lower serum concentrations, euphoria and disinhibition may be noted. Slurred speech, altered perception of the environment, impaired judgment, ataxia, incoordination, nystagmus, and hyperreflexia may occur. As plasma levels increase or in different individuals, combative and destructive behavior may occur. With higher levels still, somnolence and respiratory depression may ensue. The typical effects of various blood alcohol concentrations (BACs) are shown in Table 65–2, although effects vary from individual to individual.

ALCOHOL POISONING

If the BAC gets high enough, death becomes a very real possibility, especially if there is coadministration of other sedative-hypnotics. Acute alcohol poisoning usually occurs with rapid consumption of large quantities of alcoholic beverages, because this type of drinking

TABLE 65–2. Specific Effects of Alcohol Related to the Blood Alcohol Concentration (BAC)

| BAC (%) | Effect |
|------------|---|
| 0.02–0.03 | No loss of coordination, slight euphoria and loss of shyness. Depressant effects are not apparent. |
| 0.04–0.06 | Feeling of well-being, relaxation, lower inhibitions, sensation of warmth. Euphoria. Some minor impairment of reasoning and memory, lowering of caution. |
| 0.07–0.09 | Slight impairment of balance, speech, vision, reaction time, and hearing. Euphoria. Judgment and self-control are reduced, and caution, reason, and memory are impaired. It is illegal to operate a motor vehicle in some states at this level of intoxication. |
| 0.10–0.125 | Significant impairment of motor coordination and loss of good judgment. Speech may be slurred; balance, vision, reaction time, and hearing will be impaired. Euphoria. It is illegal to operate a motor vehicle at this level of intoxication. |
| 0.13–0.15 | Gross motor impairment and lack of physical control. Blurred vision and major loss of balance. Euphoria is reduced and dysphoria is beginning to appear. |
| 0.16–0.20 | Dysphoria (anxiety, restlessness) predominates, nausea may appear. The drinker has the appearance of a “sloppy drunk.” |
| 0.25 | Needs assistance in walking; total mental confusion. Dysphoria with nausea and some vomiting. |
| 0.30 | Loss of consciousness. |
| ≥0.40 | Onset of coma, possible death due to respiratory arrest. |

Grams of ethyl alcohol per 100 mL of whole blood.

delivers a large bolus of alcohol to the gastrointestinal (GI) tract. Normally, one passes out before a toxic dose of alcohol can be ingested, and/or the person vomits to rid the stomach of its toxic reservoir. With rapid drinking as described, the person may fall asleep or pass out without vomiting, allowing continued absorption from the GI tract until fatal BACs are achieved.

In the clinical setting, it is important to differentiate acute alcohol intoxication from certain other medical or surgical illnesses. Mental status changes may result from head trauma, and if the diagnosis is missed, the consequences could be disastrous. Appropriate diagnostic measures such as computed tomography (CT) should be performed on any patient with deteriorating mental status, focal neurologic findings, failure to improve over time, new-onset seizures, or mental status out of proportion to the degree of intoxication.

LABORATORY STUDIES

In the emergency room, a BAC should be ordered in any patient in whom alcohol ingestion is suspected, regardless of the presenting complaint. For clinical purposes, most laboratories report BAC in units of milligrams per deciliter. In legal cases, results are reported in percent (grams of ethyl alcohol per 100 mL of whole blood). For example, a whole blood alcohol level of 150 mg/dL reported in the hospital corresponds to 0.15% BAC obtained by law enforcement.

If the diagnosis is unclear, if the intoxication seems atypical, or when there is suspicion of multiple drug ingestions, a complete toxicologic screen to rule out the presence of other substances may be useful.

► **TREATMENT: Alcohol-Related Disorders**

■ **ALCOHOL WITHDRAWAL**

The DSM-IV-TR definition of alcohol withdrawal includes two main components.⁴ The first component is a history of cessation or reduction in heavy and prolonged alcohol use. The second includes the presence of two or more of the symptoms of alcohol withdrawal. Signs and symptoms of alcohol withdrawal as well as acute alcohol intoxication are shown in Table 65–3.

Goals for alcohol-dependent persons trying to decrease or discontinue alcohol intake include (1) the prevention and treatment of withdrawal symptoms (including seizures and delirium tremens) and medical or psychiatric complications, (2) long-term abstinence after detoxification, and (3) entry into ongoing medical and alcohol-dependence treatment.

CLINICAL CONTROVERSY

The use of phenobarbital for acute alcohol withdrawal remains controversial. Despite its time-honored place in therapy, there is a lack of published evidence-based support for its efficacy and safety for acute alcohol withdrawal.

■ **PHARMACOLOGIC THERAPY**

6 A meta-analysis was performed to provide evidence-based recommendations on the pharmacologic management of alcohol withdrawal.²⁰ Trials comparing different benzodiazepines demonstrated that all appear similarly efficacious in reducing signs and symptoms of withdrawal. However, there is some evidence that longer-acting agents may be more effective in preventing seizures. Evidence shows, however, that longer-acting agents contribute to an overall smoother withdrawal course with fewer breakthrough or rebound symptoms.

Another consideration in the choice of benzodiazepine is their potential for abuse. Individuals with addictive disorders prefer certain agents to others. Agents with rapid onset of action, such as diazepam or alprazolam, demonstrate higher abuse potential because of their reinforcing effects. Those with slower onset of action, such as chlordiazepoxide, oxazepam, and halazepam, are less likely to be abused. This consideration may be relevant in an outpatient setting or for patients with a history of benzodiazepine or other substance abuse.²⁰

TABLE 65–3. Signs and Symptoms of Alcohol Intoxication and Withdrawal

| Intoxication | Withdrawal |
|--------------------|-----------------------|
| Slurred speech | Tremor |
| Ataxia | Tachycardia |
| Nystagmus | Diaphoresis |
| Sedation | Labile blood pressure |
| Flushed face | Anxiety |
| Mood change | Nausea and vomiting |
| Irritability | Hallucinations |
| Euphoria | Seizures |
| Loquacity | Hyperthermia |
| Impaired attention | Delirium |

Although barbiturates are used by approximately 10% of detoxification programs in the United States, there is less evidence-based support for their use versus the benzodiazepines.²¹ Their use is, however, supported by uncontrolled studies, including a recent randomized open-label pilot study that compared phenobarbital with valproic acid. Both were found to have similar efficacy for decreasing withdrawal symptoms.²² Unlike other barbiturates, phenobarbital has low abuse potential. It is long acting; it can be administered reliably by oral, intramuscular, and intravenous routes; it has well-documented anticonvulsant activity; and it is inexpensive. However, the barbiturates (including phenobarbital) pose a greater risk of respiratory depression, particularly when combined with alcohol, and an overall lower safety profile than benzodiazepines when used in high doses.

Although phenothiazines, clonidine, carbamazepine, γ -hydroxybutyric acid, and valproic acid may reduce symptoms of alcohol withdrawal, their ability to prevent seizures or delirium tremens has yet to be proven,²³ and in fact, the phenothiazines may lower the seizure threshold. Other drugs used to treat symptoms of alcohol withdrawal include other barbiturates, alcohol itself, sympatholytics such as atenolol, thiamine, magnesium, and other neuroleptics such as haloperidol. At the time of this writing, gabapentin is being compared to lorazepam for acute alcohol withdrawal in a phase II clinical trial.

■ **Treatment Regimens**

■ **Fixed-Schedule Therapy.** Over the years, benzodiazepines given regularly at a fixed dosing interval have been considered the gold standard therapy for alcohol withdrawal. Chlordiazepoxide 50 to 100 mg orally every 6 hours for 1 day followed by 2 days at 25 to 50 mg every 6 hours is known to prevent delirium tremens and seizures.

The treatment guideline,²⁰ however, takes exception with this rigid approach, urging clinicians to allow for some degree of individualization within fixed-schedule therapy. Patients should be monitored and given additional medication when indicated by symptoms. This type of regimen is useful in patients with a history of seizures, patients with acute medical or surgical illness, or patients with a history of delirium tremens. It also may be preferable for pregnant women.²⁰

■ **Front Loading.** *Front loading* refers to regimens in which frequent, high doses of medication are given to treat the early signs and symptoms of withdrawal. Diazepam is given in 20-mg doses every 2 hours until resolution of withdrawal symptoms. A total of 60 mg typically is required. Because of the long half-life of diazepam and its active metabolites, further doses are not required. This regimen also has been shown to decrease the incidence of seizures. Advantages of front loading are that medication administration and intensive monitoring are limited to the early symptomatic period of withdrawal.²⁰

■ **Symptom-Triggered Therapy.** With symptom-triggered therapy, medication is given only when the patient has symptoms. This approach results in treatment that is shorter, potentially avoiding over-sedation and allowing the physician to focus on specific therapy for alcohol dependence.²⁰ A typical regimen would include diazepam 10 to 20 mg administered every hour when a structured assessment scale such

as the Clinical Institute Withdrawal Assessment-Alcohol—Revised indicates that symptoms are moderate to severe.²⁴

■ Treatment of Alcohol Withdrawal Seizures

Alcohol withdrawal seizures do not require treatment with an anticonvulsant drug unless they progress to status epilepticus because seizures usually end before diazepam or another drug can be administered.^{20,23} Phenytoin, which is not cross-tolerant to alcohol, does not prevent or treat withdrawal seizures, and without an intravenous loading dose, therapeutic blood levels of phenytoin are not reached until acute withdrawal is complete. Patients experiencing seizures should be treated supportively. An increase in the dosage and slowing of the tapering schedule of the benzodiazepine used in detoxification or a single injection of a benzodiazepine may be necessary to prevent further seizure activity. Patients with a history of withdrawal seizures can be predicted to experience an especially severe withdrawal syndrome. In such patients, a higher initial dosage of a benzodiazepine and a slower tapering period of 7 to 10 days are advisable.

■ Treatment Settings

Alcohol withdrawal treatment can take place in hospitals, inpatient detoxification units, or outpatient settings. Inpatient treatment may be necessary when there are coexisting acute or chronic medical (including pregnancy), surgical, or psychiatric conditions that would complicate alcohol withdrawal. Only patients with mild to moderate symptoms should be considered for outpatient treatment, and it is a good idea to have a responsible, sober person available to help the patient monitor symptoms and administer medications. Patients with a strong craving for alcohol, those concurrently using other drugs, and those with a history of seizures or delirium tremens are not good candidates for outpatient treatment.

■ ALCOHOL DEPENDENCE

■ PHARMACOLOGIC MANAGEMENT

7 In the United States, disulfiram and naltrexone are the only two drugs specifically indicated for the treatment of alcohol dependence. Disulfiram acts as a deterrent to the resumption of drinking, and naltrexone is a competitive opioid antagonist that has been shown to reduce cravings for alcohol. Other drugs, including nalmefene,²⁵ acamprostate,²⁶ bupropion, various serotonergic agents (including selective serotonin reuptake inhibitors and serotonin₃ receptor antagonists), and lithium also have been used either abroad or in the United States for off-label indications.²⁷ Recently, an evidence-based review of the pharmacologic treatment of alcohol dependence was published.²⁷ Recommendations from this report will be incorporated into the discussion that follows.

CLINICAL CONTROVERSY

The theory behind deterrent therapy with disulfiram is intuitively simple, and thus it would seem to be an attractive treatment option for chronic alcoholism. However, many clinicians question its overall role in achieving long-term absti-

nence. Studies have failed to prove it effective, and it is poorly tolerated. For this reason, most clinicians rarely recommend the use of disulfiram.

■ Disulfiram

Disulfiram deters a patient from drinking by producing an aversive reaction if the patient drinks. Note that although disulfiram appeared to be effective in a series of small-scale studies, these were largely uncontrolled.²⁷ In the absence of alcohol, disulfiram has minimal effects. It inhibits the liver enzyme aldehyde dehydrogenase in the biochemical pathway for alcohol metabolism, allowing acetaldehyde to accumulate. The resulting increase in acetaldehyde causes severe facial flushing, throbbing headache, nausea and vomiting, chest pain, palpitations, tachycardia, weakness, dizziness, blurred vision, confusion, and hypotension. Severe reactions including myocardial infarction, congestive heart failure, cardiac arrhythmia, respiratory depression, convulsions, and death can occur, particularly in vulnerable individuals.

The disulfiram-alcohol interaction sometimes can be intense, causing serious problems for patients with cerebrovascular, cardiovascular, or severe pulmonary disease or chronic renal failure. The use of disulfiram in patients who may have occult vascular disease, such as those over 60 years of age and patients with diabetes, also should be avoided.²⁷ Vomiting during a disulfiram reaction can cause severe bleeding in a patient with esophageal varices, and for this reason disulfiram is contraindicated in patients with cirrhosis with portal hypertension. Disulfiram can lower the seizure threshold and cause peripheral neuropathy and should be avoided in patients with these conditions. It has been linked to birth defects and therefore should not be used during pregnancy. Because disulfiram can cause drowsiness, it should be taken first on the weekend at bedtime and discontinued if the patient continues to be drowsy on awakening after 2 to 3 days of medication.

A rare but potentially fatal idiosyncratic hepatotoxicity can occur with disulfiram. As a result, baseline liver function tests should be obtained and the patient monitored for hepatotoxicity by monitoring for symptoms and by repeating the liver function tests at 2 weeks, 3 months, 6 months, and then twice yearly thereafter.

The prescriber should wait at least 24 hours after the last drink before starting disulfiram, usually at a dose of 250 mg/day. At this dose there are fewer side effects than at 500 mg, although some research suggests that higher doses are needed to reliably produce an aversive reaction if the patient drinks.²⁷

■ Naltrexone

Naltrexone, an opiate antagonist that has been available in the United States since 1984 for the treatment of opioid dependence, blocks the effects of exogenous opioids. In 1994 the Food and Drug Administration (FDA) approved its use in the treatment of alcohol dependence. Naltrexone is thought to attenuate the reinforcing effects of alcohol,²⁸ and those who consume alcohol while taking naltrexone report feeling less intoxicated and having less craving for alcohol.²⁸

The efficacy of naltrexone for use in alcohol dependence has been investigated in three placebo-controlled clinical trials, and is currently being evaluated in several phase IV clinical trials. Patients randomized to receive 50 mg naltrexone daily for 12 weeks were more likely to remain abstinent and to avoid relapse to heavy

drinking; 31% of placebo-treated patients remained abstinent compared with 54% of patients on naltrexone; 48% of placebo-treated patients avoided heavy drinking, whereas 75% of naltrexone-treated patients avoided drinking to excess successfully. Craving for alcohol also was significantly lower for patients on naltrexone.

Naltrexone should not be given to patients currently dependent on opiates because it can precipitate a severe withdrawal syndrome. Naltrexone is associated with dose-related hepatotoxicity, but this generally occurs at doses higher than those recommended for treatment of alcohol dependence. Nevertheless, it is considered contraindicated in patients with hepatitis or liver failure, and liver function tests should be monitored monthly for the first 3 months and every 3 months thereafter.

Nausea is the most common side effect of naltrexone, occurring in about 10% of patients. Other side effects are headache, dizziness, nervousness, fatigue, insomnia, vomiting, anxiety, and somnolence.

Naltrexone should be given in a dose of 50 mg/day, which effectively blocks μ opioid receptors. Documentation is lacking to support routine use of higher doses.²⁹

Other Drugs

Nalmefene is a newer opioid antagonist that is structurally similar to naltrexone, but with a number of potential pharmacologic advantages for the treatment of alcohol dependence, including no dose-

dependent association with liver toxicity, greater oral bioavailability, longer duration of antagonist action, and more competitive binding with opioid receptor subtypes that are thought to reinforce drinking.²⁹ A meta-analysis of controlled clinical trials that include naltrexone, nalmefene, and other opioid antagonists evaluated efficacy in alcoholic abstinence maintenance versus placebo. Naltrexone decreased the number of patients that returned to drinking significantly, yet short-term dropout rates were high for both naltrexone and placebo groups. The other opioid antagonists did not differ from placebo.

Acamprosate is a drug that has been studied extensively in Europe, but is also not commercially available in the United States. Clinical trial results with this drug have been consistently positive for reducing drinking frequency, with some evidence of enhancing abstinence. Its future impact on U.S. practice is not yet clear.^{26,27} At the time of this writing, acamprosate was in phase III clinical trials alone and in combination with naltrexone to enhance abstinence.

Using the limited data on serotonergic agents in the evidence-based analysis,²⁷ these drugs were deemed not very promising, although most studies were confounded by high rates of comorbid mood disorders. Topiramate, a fructopyranose derivative that is FDA approved for seizure prevention, looks promising as a treatment for alcohol dependence. A recent randomized, double-blind, 12-week trial demonstrated topiramate efficacy for preventing alcoholic relapse in patients who have already been detoxified from alcohol. Pharmacologically, this therapy is quite rational since topiramate binds to a nonbenzodiazepine site on the GABA_A receptor.³⁰

NICOTINE

Cigarette smoking is an enormous national health problem, and as health care professionals, we are not doing enough to help people quit smoking. A telephone survey of adult cigarette smokers was conducted to determine the types of smoking cessation counseling interventions they received during their physician office visits in the past year. Only about one-half of the current smokers surveyed reported that their doctors talked with them about their smoking, less than half were advised to stop smoking, 15% were offered smoking cessation assistance in the form of education and support groups, and only 9% were prescribed drug therapies to assist smoking cessation efforts.³¹ A second observational study was conducted to determine the effects of community-based academic detailing interventions on the quit rates of a sample of smokers ($n = 4295$). Detailed interventions were delivered to physicians that encouraged smoking cessation efforts with patients to comply with the National Cancer Institute and the Agency for Healthcare Quality and Research smoking intervention standards.^{31,32} A small, significant effect was observed in a subgroup of patients residing in the intervention area.³² Other health care professionals did an even poorer job, with only 22% of dentists, 24% of nurses, and 4% of pharmacists helping their patients to quit smoking.³³

EPIDEMIOLOGY OF TOBACCO USE

An estimated 71.5 million Americans reported current use (past month use) of a tobacco product in 2002, a prevalence rate of 30.4% for the population aged 12 or older.³⁴ Among that same population, 61.1 million (26% of the total population aged 12 or older) smoked cigarettes, 12.8 million (5.4%) smoked cigars, 7.8 million (3.3%) used smokeless tobacco, and 1.8 million (0.8%) smoked tobacco in pipes.

The rate of lifetime cigarette use among youths aged 12 to 17 has remained between 29% and 39% for every year since 1965. Although

the rate increased during the 1990s from 30.3% in 1990 to 37.8% in 1999, there was a significant decline from 2001 to 2002 (from 37.3% to 33.3%). One of the national health objectives for 2010 is to reduce the prevalence of cigarette smoking among adults to less than 12%.³⁴

ECONOMIC IMPACT OF SMOKING

The direct medical costs associated with smoking total more than \$75 billion per year, and the costs associated with lost productivity are estimated to be \$80 billion. About 14% of all Medicaid expenditures are for smoking-related illnesses. This estimate does not include the costs of smoking-related neonatal disorders.

HEALTH RISKS OF SMOKING

Each year more than 440,000 deaths, or 20% of the total deaths in the United States, are caused by smoking.³⁵ Cigarette smoking substantially increases the risk of (1) cardiovascular diseases such as stroke, sudden death, and heart attack, (2) nonmalignant respiratory diseases including emphysema, asthma, chronic bronchitis, and chronic obstructive pulmonary disease, (3) lung cancer, and (4) other cancers (e.g., mouth, pharynx, larynx, esophagus, stomach, pancreas, uterus, cervix, kidney, ureter, and bladder).

Exposure to environmental tobacco smoke (*passive exposure*) has been cited as the cause of 3,000 lung cancer deaths and 35,000 to 40,000 heart disease deaths in the United States every year.³⁵ When children are exposed to environmental smoke, they have a higher risk of respiratory infection, asthma, and middle ear infections than those who are not exposed. Sudden infant death syndrome occurs more often in infants whose mothers smoked during pregnancy than in offspring of nonsmoking mothers.³⁵ The harmful effects of smoking on reproduction and pregnancy include reduced fertility and fetal

growth, as well as increased risk of ectopic pregnancy and spontaneous abortion.³⁵

PHARMACOLOGY OF NICOTINE

Nicotine is a ganglionic cholinergic receptor agonist whose pharmacologic effects are highly dependent on dose. These effects include central and peripheral nervous system stimulation and depression, respiratory stimulation, skeletal muscle relaxation, catecholamine release by the adrenal medulla, peripheral vasoconstriction, and increased blood pressure, heart rate, cardiac output, and oxygen consumption.³⁶ Cigarette smoking or low doses of nicotine produce an increased alertness and increased cognitive functioning by stimulating the cerebral cortex. At higher doses, nicotine stimulates the “reward” center in the limbic system of the brain.³⁶

Chronic nicotine ingestion may lead to physical and psychological dependence and tolerance to some of its pharmacologic effects. Abrupt smoking cessation in physically dependent smokers results in

TABLE 65–4. Withdrawal Symptoms of Nicotine

| | |
|---|------------------------------------|
| Anxiety | Gastrointestinal disturbances |
| Craving for tobacco | Headache |
| Decreased blood pressure and heart rate | Hostility |
| Depression | Increased appetite and weight gain |
| Difficulty concentrating | Increased skin temperature |
| Drowsiness | Insomnia |
| Frustration, irritability, impatience | Restlessness |

withdrawal symptoms (Table 65–4). Onset of these symptoms usually occurs within 24 hours and may last for days, weeks, or longer. The craving for tobacco may last for years.

8 Although some smokers do not develop physical or psychological dependence, most people who smoke 10 to 15 cigarettes daily for several weeks or longer do. Between 77% and 92% of smokers are addicted to nicotine in cigarettes.³⁷

► TREATMENT: Nicotine Dependence

■ AGENCY FOR HEALTHCARE RESEARCH AND QUALITY CLINICAL PRACTICE GUIDELINE: TREATING TOBACCO USE AND DEPENDENCE

The Agency for Healthcare Research and Quality (AHRQ) periodically convenes expert panels to develop clinical guidelines for health care practitioners when the need dictates. Because of the widespread prevalence of smoking-related illnesses, its related morbidity and mortality, and the economic burden imposed, the agency convened a panel of experts in 1994 to develop guidelines on the treatment of tobacco addiction. The resultant guideline for smoking cessation was released in 1996. In June 2000, an updated version of the 1996 Smoking Cessation Clinical Practice Guideline was issued by AHRQ.³⁸

The revised guideline suggests strategies for providing appropriate treatments for every patient. The panel reminds us that effective treatments for tobacco dependence now exist and that every

patient should receive at least minimal treatment every time he or she visits a clinician. The first step in this process, identification and assessment of tobacco use status, separates patients into three treatment categories:

1. Patients who use tobacco and are willing to quit should be treated using the 5 A's (*ask, advise, assess, assist, and arrange*).
2. Patients who use tobacco but are unwilling to quit at this time should be treated with the 5 R's of motivational intervention (*relevance, risks, rewards, roadblocks, and repetition*).
3. Patients who have quit using tobacco recently should be provided relapse-prevention treatment.

Figure 65–1 shows an overall approach to evaluating patients' needs and desires to quit smoking. Figure 65–2 is an algorithm for treating tobacco use.

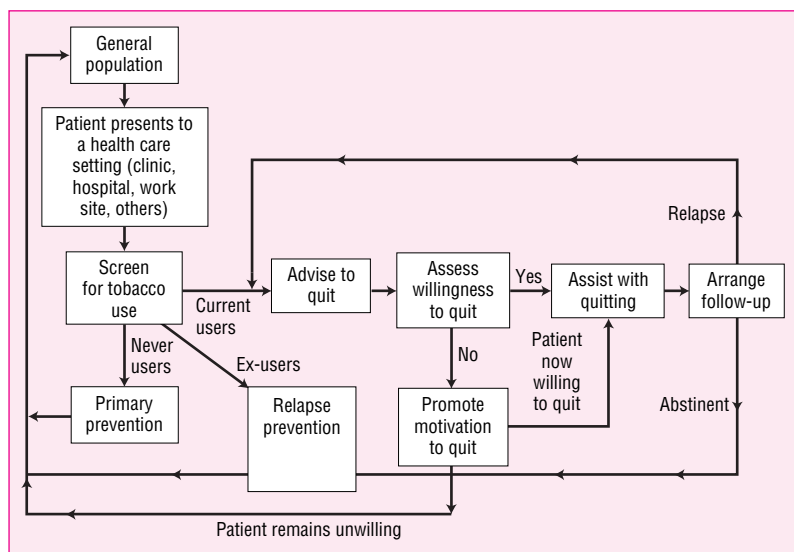

FIGURE 65–1. Model for treatment of tobacco use and dependence.

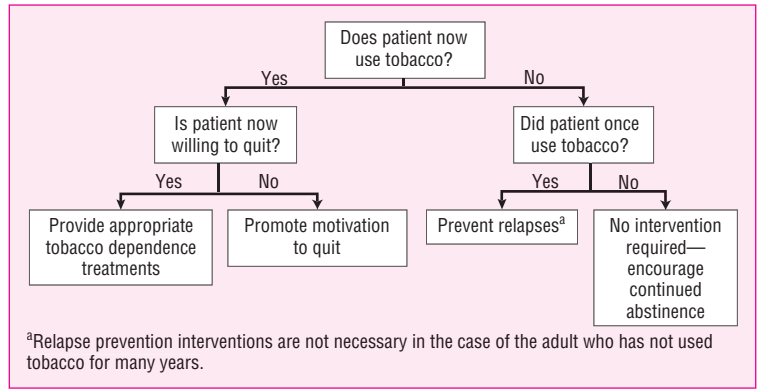

FIGURE 65–2. Algorithm for treating tobacco use.

KEY FINDINGS

The guideline identified a number of key findings that clinicians should use:

1. **8** Tobacco dependence is a chronic condition that often requires repeated intervention. However, effective treatments exist that can produce long-term or even permanent abstinence.
2. Because effective tobacco dependence treatments are available, every patient who uses tobacco should be offered at least one of these treatments:
 - Patients willing to try to quit tobacco use should be provided with treatments that are identified as effective in the guideline.
 - Patients unwilling to try to quit tobacco use should be provided with a brief intervention that is designed to increase their motivation to quit.
3. It is essential that clinicians and health care delivery systems (including administrators, insurers, and purchasers) institutionalize the consistent identification, documentation, and treatment of every tobacco user who is seen in a health care setting.
4. Brief tobacco dependence treatment is effective, and every patient who uses tobacco should be offered at least brief treatment.
5. There is a strong dose-response relationship between the intensity of tobacco dependence counseling and its effectiveness. Treatments involving person-to-person contact (via individual, group, or proactive telephone counseling) are consistently effective, and their effectiveness increases with treatment intensity (e.g., minutes of contact).
6. Three types of counseling and behavioral therapies were found to be especially effective and should be used with all patients who are attempting tobacco cessation:
 - Provision of practical counseling (problem-solving/skills training).
 - Provision of social support as part of treatment (intra-treatment social support).
 - Help in securing social support outside treatment (extra-treatment social support).

7. Numerous effective pharmacotherapies for smoking cessation now exist. Except in the presence of contraindications, these should be used with all patients who are attempting to quit smoking. Five first-line pharmacotherapies were identified that reliably increase long-term smoking abstinence rates:

- Bupropion sustained-release (SR)
- Nicotine gum
- Nicotine inhaler
- Nicotine nasal spray
- Nicotine patch

Two second-line pharmacotherapies were identified as efficacious and may be considered by clinicians if first-line pharmacotherapies are not effective:

- Clonidine
- Nortriptyline

8. Tobacco dependence treatments are both clinically effective and cost-effective relative to other medical and disease-prevention interventions. As such, insurers and purchasers should ensure that

- All insurance plans include as a reimbursed benefit the counseling and pharmacotherapeutic treatments that are identified as effective in this guideline.
- Clinicians are reimbursed for providing tobacco dependence treatment just as they are reimbursed for treating other chronic conditions.

OTHER FACTORS IMPORTANT TO THE SUCCESS OF A SMOKING-CESSATION STRATEGY

The AHRQ expert panel emphasized the importance of the type and intensity of the contact with the counselor to the success of the intervention. When interventions last for more than 10 minutes, the increase in cessation rates is much better than when interventions do not involve contact with a professional. Group and individual counseling is more effective than no intervention in increasing abstinence rates, but self-help materials (e.g., handouts, pamphlets, and brochures) are not. Interventions are more successful when they include social support and training in general problem-solving skills, stress management, and relapse prevention.³⁸ The number of treatment sessions offered is also important. Providing at least four to seven sessions significantly increased cessation rates, independent of the treatment's intensity.³⁸

Comprehensive behavioral interventions are more effective in helping people quit smoking and remain abstinent, but less intensive treatments are beneficial as well. Even minimal contacts lasting less than 3 minutes and simple advice to quit are more successful in increasing cessation rates than intervention involving no contact.³⁸

9 Counseling efficacy is further augmented by the addition of nicotine-replacement products. The cessation rates of nicotine patch users are approximately double the cessation rates of smokers who receive placebos, according to a meta-analysis.³⁹ Although absolute quit rates have varied greatly, abstinence rates for the nicotine patch are estimated at 27% (ranging from 14% to 69%) at the end of treatment and 22% (ranging from 13% to 34%) at 6 months posttreatment.³⁹

Although comprehensive programs are most effective, few smokers (10% to 15%) seek formal assistance in quitting.³⁹ A health care professional who merely advises his or her patient to quit smoking is providing at least minimal assistance in the efforts.

■ PHARMACOLOGIC THERAPY FOR SMOKING CESSATION

All patients attempting to quit should be encouraged to use effective pharmacotherapies for smoking cessation except in the presence of special circumstances. Long-term smoking-cessation pharmacotherapy should be considered as a strategy to reduce the likelihood of relapse. As with other chronic diseases, the most effective treatment of tobacco dependence encompasses multiple modalities. Pharmacotherapy is a vital element of a multicomponent approach. The clinician should encourage all patients initiating a quit attempt to use one or a combination of efficacious pharmacotherapies, although pharmacotherapy use requires special consideration with some patient groups (e.g., those with medical contraindications, those smoking fewer than 10 cigarettes a day, pregnant or breast-feeding women, and adolescent smokers). The role of pharmacotherapy is summarized in Table 65–5.

TABLE 65–5. Summary of Clinical Guidelines for Prescribing Pharmacotherapy for Smoking Cessation

| | |
|--|--|
| Who should receive pharmacotherapy for smoking cessation? | All smokers trying to quit, except in the presence of special circumstances. Special consideration should be given before using pharmacotherapy with selected populations: those with medical contraindications, those smoking fewer than 10 cigarettes/day, pregnant/breast-feeding women, and adolescent smokers. |
| What are the first-line pharmacotherapies recommended in this guideline? | All five of the FDA-approved pharmacotherapies for smoking cessation are recommended, including bupropion SR, nicotine gum, nicotine inhaler, nicotine nasal spray, and the nicotine patch. |
| What factors should a clinician consider when choosing among the five first-line pharmacotherapies? | Because of the lack of sufficient data to rank order these five medications, choice of a specific first-line pharmacotherapy must be guided by factors such as clinician familiarity with the medications, contraindications for selected patients, patient preference, previous patient experience with a specific pharmacotherapy (positive or negative), and patient characteristics (e.g., history of depression, concerns about weight gain). |
| Are pharmacotherapeutic treatments appropriate for lighter smokers (e.g., 10–15 cigarettes/day)? | If pharmacotherapy is used with lighter smokers, clinicians should consider reducing the dose of first-line nicotine replacement pharmacotherapies. No adjustments are necessary when using bupropion SR. |
| What second-line pharmacotherapies are recommended in this guideline? | Clonidine and nortriptyline. |
| When should second-line agents be used for treating tobacco dependence? | Consider prescribing second-line agents for patients unable to use first-line medications because of contraindications or for patients for whom first-line medications are not helpful. Monitor patients for the known side effects of second-line agents. |
| Which pharmacotherapies should be considered with patients particularly concerned about weight gain? | Bupropion SR and nicotine replacement therapies, in particular nicotine gum, have been shown to delay, but not prevent, weight gain. |
| Are there pharmacotherapies that should be especially considered in patients with a history of depression? | Bupropion SR and nortriptyline appear to be effective with this population. |
| Should nicotine replacement therapies be avoided in patients with a history of cardiovascular disease? | No. The nicotine patch in particular is safe and has been shown not to cause adverse cardiovascular effects. |
| May tobacco-dependence pharmacotherapies be used long term (e.g., 6 months or more)? | Yes. This approach may be helpful with smokers who report persistent withdrawal symptoms during the course of pharmacotherapy or who desire long-term therapy. A minority of individuals who successfully quit smoking use ad libitum nicotine replacement medications (gum, nasal spray, inhaler) long term. The use of these medications long term does not present a known health risk. Additionally, the FDA has approved the use of bupropion SR for long-term maintenance. |
| May pharmacotherapies ever be combined? | Yes. There is evidence that combining the nicotine patch with either nicotine gum or nicotine nasal spray increases long-term abstinence rates over those produced by a single form of nicotine replacement therapy. |

■ NICOTINE-REPLACEMENT THERAPY

■ A Systematic Review of Nicotine Replacement Therapy

In 2002 a systematic review³⁹ of published studies was performed to determine the effectiveness of the different forms of nicotine replacement therapy (NRT; e.g., chewing gum, transdermal patches, nasal spray, inhalers, and tablets) in achieving abstinence from cigarettes or a sustained reduction in the amount smoked. The review was also designed to determine whether the effect is influenced by the clinical setting in which the smoker is recruited and treated, the dosage and form of the NRT used, or the intensity of additional advice and support offered to the smoker; to determine whether combinations of NRT are more effective than one type alone; and to determine its effectiveness compared to other pharmacotherapies.

The review was limited to randomized trials in which NRT was compared to placebo or no treatment, or where different doses of NRT were compared. The main outcome measure was abstinence from smoking after at least 6 months of follow-up. For each trial, researchers used the most rigorous definition of abstinence, and confirmation with biochemical markers where available. The review includes 110 studies, 96 of which included a placebo or non-nicotine control arm. These studies were used in the primary analysis. In this group there were 51 trials of nicotine gum, 34 of transdermal nicotine patch, 4 of intranasal nicotine spray, 4 of inhaled nicotine, and 3 of an oral tablet. Five trials compared combinations of two forms of nicotine therapy with only one form (patch with gum to patch alone; patch with gum to gum alone; patch with nasal spray to patch alone; patch with inhaler to inhaler alone; and patch with inhaler to either one alone).³⁹

The odds ratio (OR) for abstinence with NRT compared to control was 1.74 (95% confidence interval [CI] 1.64 to 1.86). The ORs for the different forms of NRT were 1.66 for gum, 1.74 for patches, 2.27 for nasal spray, 2.08 for inhaled nicotine, and 2.08 for nicotine sublingual tablet/lozenge. These odds were not a function of the duration of therapy, the intensity of additional support provided, or the setting in which the NRT was provided. The 4-mg gum provided a significant benefit over 2-mg gum (OR 2.67; 95% CI 1.69 to 4.22) in highly dependent smokers. Higher doses of nicotine patch may produce additional small increases in quit rates compared to lower doses. Only one study directly compared NRT to another pharmacotherapy, in which bupropion was significantly more effective than nicotine patch or placebo.³⁹

The authors of this review concluded that all of the commercially available forms of NRT (nicotine gum, transdermal patch, the nicotine nasal spray, nicotine inhaler, and nicotine sublingual tablets/lozenges) are effective as part of a strategy to promote smoking cessation. They increase quit rates approximately 1.5- to twofold regardless of setting.³⁹

The percentage of smokers who were abstinent after 12 months (excluding trials with shorter follow-up; data not shown) was 18% (95% CI 17% to 19%) among smokers who had been allocated to receive nicotine gum, and 14% (95% CI 13% to 15%) among those who had used transdermal patches. For intranasal spray, nicotine inhaler, and sublingual tablet, the corresponding figures were 24% (95% CI 20% to 28%), 17% (95% CI 14% to 21%), and 20% (95% CI 15% to 25%), respectively.

The AHRQ guidelines recommend use of NRT in the forms of transdermal nicotine patches, nicotine gum, nicotine sprays, and nicotine inhalers.³⁸ The use of NRT is relatively safe, but it is not recommended for all smokers. Although cardiovascular disease is not an independent risk factor for acute myocardial events, NRT should

be used with caution among particular cardiovascular patient groups: those in the immediate (within 2 weeks) post-myocardial infarction period, those with serious arrhythmias, and those with serious or worsening angina pectoris.³⁸

In a recent study of survey data from California,⁴⁰ use of NRT increased short-term cessation success in moderate to heavy smokers in each survey year. However, a long-term cessation advantage was only observed before NRT became widely available over the counter (August 1996). In 1999, no advantage for pharmaceutical aid users was observed in either the short or long term for the nearly 60% of California smokers classified as light smokers (<15 cigarettes/day). Authors contend that since becoming available over the counter, NRT appears no longer effective in increasing long-term successful cessation in California smokers.

■ Nicotine Gum

Clinicians should offer 4-mg rather than 2-mg nicotine gum to highly dependent smokers. The 2-mg nicotine gum improves long-term abstinence rates by approximately 30% to 80% as compared with placebo. The 2-mg gum is recommended for patients smoking less than 25 cigarettes per day, whereas the 4-mg gum is recommended for patients smoking 25 or more cigarettes per day. Generally, the gum should be used for up to 12 weeks, no more than 24 pieces chewed per day. The dosage and duration of therapy should be tailored to meet the needs of each patient.

Nicotine gum currently is available exclusively as an over-the-counter medication and is packaged with important instructions on correct use, including chewing instructions. There is currently little evidence to suggest that combined use of the patch and gum increases abstinence beyond 24 weeks.

Gum should be chewed slowly until a peppery or minty taste emerges and then “parked” between cheek and gums to facilitate nicotine absorption through the oral mucosa. It should be chewed slowly and intermittently and parked for about 30 minutes or until the taste dissipates. Acidic beverages (e.g., coffee, juices, or soft drinks) interfere with the buccal absorption of nicotine, so eating and drinking anything except water should be avoided for 15 minutes before and during chewing. Patients often do not use enough gum to get the maximum benefit: They chew too few pieces per day, and they do not use the gum for a sufficient number of weeks. Instructions to chew the gum on a fixed schedule (at least one piece every 1 to 2 hours) for at least 1 to 3 months may be more beneficial than ad libitum use.

■ Nicotine Patch

9 The nicotine patch approximately doubles long-term abstinence rates over those produced by placebo interventions. The nicotine patch is available both as an over-the-counter medication and as a prescription medication. Treatment of 8 weeks or less has been shown to be as efficacious as longer treatment periods. The 16- and 24-hour patches are of comparable efficacy.³⁸ Clinicians should consider individualizing treatment based on specific patient characteristics, such as previous experience with the patch, amount smoked, and degree of addiction, among others. Finally, clinicians should consider starting treatment on a lower patch dose in patients smoking 10 or fewer cigarettes per day.³⁸

At the start of each day, the patient should place a new patch on a relatively hairless location, typically between the neck and waist. There are no restrictions on activity while using the patch. Patches

should be applied as soon as the patient wakes on the quit day. Patients who experience sleep disruption should remove the 24-hour patch prior to bedtime or use the 16-hour patch.

■ Nicotine Nasal Spray

Nicotine nasal spray more than doubles long-term abstinence rates when compared with a placebo spray. Nicotine nasal spray is available exclusively as a prescription medication. A dose of nicotine nasal spray consists of one 0.5-mg delivery to each nostril (1 mg total). Initial dosing should be one to two doses per hour, increasing as needed for symptom relief. The minimum recommended treatment is 8 doses per day, with a maximum limit of 40 doses per day (5 doses per hour). Each bottle contains approximately 100 doses. Recommended duration of therapy is 3 to 6 months. Patients should not sniff, swallow, or inhale through the nose while administering doses because this increases irritating effects. The spray is best delivered with the head tilted slightly back.³⁸

■ Instructing Patients in the Use of NRT

Compliance with NRT improves when the patient is presented a clear rationale for its use and a realistic expectation about the response.⁴¹ It should be explained to the patient that nicotine is responsible for addiction and that discontinuation of the nicotine causes craving for cigarettes, tension, irritability, sadness, problems with sleep, and difficulty concentrating. These are partly due to nicotine withdrawal. The patient should be told that using the patch results in less desire to smoke and provides an opportunity for a new nonsmoker to practice all the new nonsmoking skills without being burdened by craving. The patient should understand that with smoking, there are naturally peaks and valleys in the amount of nicotine in the bloodstream. With the patch there is a steady gradual rise in the blood nicotine concentration that levels off and remains constant for much of the day and then gradually decreases while the person is asleep. Maintaining an adequate blood level of nicotine lessens withdrawal symptoms.⁴²

A similar rationale can be used if patients are using gum. It should be emphasized that NRT is not a “magic bullet” and that the use of coping skills is essential for abstinence. The patch or the gum only buys time by reducing withdrawal symptoms and giving individuals a chance to figure out alternatives that they can use in place of smoking.⁴³

CLINICAL CONTROVERSY

Some clinicians are hesitant to prescribe nicotine replacement therapy for smoking cessation during pregnancy because the safety and efficacy of nicotine replacement therapy has not been established in controlled clinical trials in this population.

■ Side Effects

Nicotine replacement products have relatively few side effects. Nausea and light-headedness are possible signs of nicotine overdose that warrant a reduction of the nicotine dose.

The most frequent side effect with the nicotine patch is skin irritation related to the adhesive or the medium containing nicotine and not to the nicotine itself. About 50% of patients report skin irritation during the course of treatment with the patch. The patch site can be

rotated to diminish this problem. The use of over-the-counter hydrocortisone cream (1%) or triamcinolone cream (0.5%) is recommended as a local treatment for patch-related skin irritations. Switching to a different brand of patch also may alleviate the problem because different products use different adhesives or media. The gum can be used instead of the patch when the skin irritation is severe. Less than 5% of patients were forced to discontinue therapy because of skin reactions.

About 23% of patients using the patch report sleep disturbances, but the insomnia is hard to differentiate from the sleeplessness that often accompanies withdrawal itself, especially during the first few weeks of quitting.

More research regarding the safety and efficacy of pharmacotherapy during pregnancy is needed to define the risk/benefit profile of smoking cessation medications in this population.⁴⁴ Clearly, exposure of the fetus to nicotine delivered by smoking is known to be detrimental to the fetus. Because total nicotine levels are lower with NRT than smoking, if the alternative is active smoking, NRT is almost certainly safer if cessation can be achieved. Nicotine does cross the placenta, whether delivered by cigarette smoking or through nicotine replacement. Nicotine transdermal systems and inhalers are classified as FDA pregnancy risk category D, and nicotine gum is classified as FDA pregnancy category C, but there are conflicting data regarding pregnancy safety ratings of nicotine replacement products, and the pregnancy categories cannot be used in isolation from other information sources. Nicotine replacement is not contraindicated and could be appropriately used in well-selected pregnant patients.

A recent study⁴⁵ of women using various doses of transdermal nicotine while breast-feeding confirms that nicotine is transferred via milk to the infant. The absolute infant dose of nicotine and its metabolite cotinine decreases by about 70% while using the 7-mg patch compared to when they were smoking or using the 21-mg patch. The use of the nicotine patch had no significant influence on milk intake by the breast-fed infant. The authors conclude that undertaking maternal smoking cessation with the nicotine patch is therefore a safer option than continued smoking. Ultimately, the choice of whether to use pharmacotherapy for smoking cessation should be made jointly by the pregnant or breast-feeding smoker and her health care provider.

■ Duration

Those who commit to quitting smoking using the nicotine patch should be told to expect a minimum of 6 to 8 weeks of treatment. Using the therapy beyond 8 weeks is not associated with better success rates.³⁸ However, some patients will experience severe withdrawal even beyond 8 weeks, and these people may need to use the patch longer.

The duration of therapy with the gum should be at least 1 to 3 months on a fixed schedule rather than when one has the urge to smoke.³⁹ Studies have found, however, that 15% to 20% of abstainers continue to use the gum for longer than 12 months. Patients should be encouraged to stick with the patch and/or gum for the minimally acceptable duration of treatment.

■ Economic and Pharmacoeconomic Considerations

Most health insurers provide coverage for the chronic illnesses caused by smoking (e.g., chronic obstructive pulmonary disease, cancer, and myocardial infarction), yet few provide coverage for treating the nicotine addiction that caused those ailments.³⁸ For each of the approximately 22 billion packs of cigarettes sold in the United States in

1999, \$3.45 was spent on medical care attributable to smoking, and \$3.73 in productivity losses were incurred, for a total cost of \$7.18 per pack.¹ Even after adding the cost of the nicotine patch to physician counseling, costs from the standpoint of a third-party payer range from \$1441 to \$3445 per quality-adjusted life year saved for NRT (based on 15 minutes of physician counseling and 1 to 2 months of NRT).⁴⁶ Treating tobacco dependence is particularly important economically in that it can prevent a variety of costly chronic diseases, including heart disease, cancer, and pulmonary disease. A recent meta-analysis conducted by the Cochrane Collaboration determined that a 36% reduction in risk of death from coronary heart disease was obtained by quitting smoking. This decrease in risk is comparable, if not greater, than that obtained from lowering LDL cholesterol or blood pressure lowering.⁴⁷ This is but one reason why smoking cessation treatment is referred to as the gold standard of preventive interventions.

It is important to note that smoking cessation is also cost effective in special populations such as hospitalized patients and pregnant women. For hospitalized patients, successful tobacco abstinence not only reduces general medical costs in the short term, but also reduces the number of future hospitalizations.³⁸ Smoking cessation interventions for pregnant women are especially cost effective because they result in fewer low-birth-weight babies and perinatal deaths; result in fewer physical, cognitive, and behavioral problems during infancy and childhood; and also yield important health benefits for the mother.³⁸

The failure of a health plan to cover tobacco dependence treatment could reduce the number of people seeking and receiving these services.

■ BUPROPION

 In 1997, the antidepressant drug bupropion, available since 1989 under the brand name Wellbutrin, was approved by the FDA in a sustained-release formulation (Zyban) for use as an aid in smoking cessation. Bupropion inhibits neuronal reuptake and potentiates the effects of norepinephrine and dopamine. Although its precise mechanism in smoking cessation is not well understood, dopamine has been associated with the rewarding effects of addictive substances. Withdrawal symptoms may be decreased by virtue of bupropion inhibition of norepinephrine uptake. The AHRQ panel concluded that sustained-release (SR) bupropion is an efficacious smoking cessation treatment that patients should be encouraged to use.³⁸ Two large multicenter studies met selection criteria and were included in the meta-analysis comparing bupropion SR with placebo. The use of bupropion SR approximately doubles long-term abstinence rates when compared with placebo.

Bupropion requires a prescription and is contraindicated in patients with a seizure disorder, a current or prior diagnosis of bulimia or anorexia nervosa, use of a monoamine oxidase inhibitor within the previous 14 days, or in patients on another medication that contains bupropion. Bupropion SR can be used in combination with NRT.

One study compared the effects of 100, 150, or 300 mg/day of bupropion SR or placebo for 7 weeks in 615 patients who visited the clinic each week for evaluation and counseling.⁴⁸ When the study was concluded, smoking cessation rates were 19% with placebo and 28.8%, 38.6%, and 44.2% with the respective doses of the drug. The differences between the 150- and 300-mg doses and placebo were statistically significant. After 1 year, the respective rates were 12.4%, 19.6%, 22.9%, and 23.1%, indicating a fairly high rate of relapse in all groups.

Bupropion at a dose of 150 mg twice daily of sustained-release tablets was compared with the 21-mg nicotine patch separately and as combined therapy and with placebo in nearly 900 patients studied for 9 weeks. At the 10-week mark, smoking cessation had been accomplished in 20% of the placebo group, 32% of the group using the patch alone, 46% of the group using bupropion alone, and 51% of the group using combined therapy. All three active treatments were significantly better than placebo.⁴⁹ Unlike its use as an antidepressant, no seizures occurred with bupropion in smoking cessation trials. Insomnia and dry mouth were the most frequent adverse effects. Other side effects noted in the trials were tremor, rash, and a few anaphylactoid reactions characterized by pruritus, urticaria, angioedema, and dyspnea. Insomnia also was reported.⁴⁹

 For smoking cessation, the manufacturer recommends a dosage of 150 mg once daily for 3 days and then twice daily for 7 to 12 weeks or longer, with or without nicotine replacement. Patients are instructed to stop smoking during the second week of treatment and are encouraged to use counseling and support services along with the medication. For maintenance therapy, consider bupropion SR 150 mg twice daily for up to 6 months.³⁸ In addition, bupropion SR appears to be effective for smokeless tobacco cessation.⁵⁰

Cost per quality-adjusted life year saved after smoking cessation ranged from \$920 to \$2150 for bupropion alone, and \$1282 to \$2836 for NRT plus bupropion.⁴⁶

■ SECOND-LINE MEDICATIONS

Second-line medications are pharmacotherapies for which there is evidence of efficacy for treating tobacco dependence, but they have a more limited role than first-line medications because (1) the FDA has not approved them for a tobacco-dependence treatment indication and (2) there are more concerns about potential side effects than exist with first-line medications.³⁸ Second-line treatments should be considered for use on a case-by-case basis after first-line treatments have been used or considered.

■ Clonidine

Clonidine, a prescription drug, is an efficacious smoking cessation treatment. It may be used under a clinician's supervision as a second-line agent to treat tobacco dependence. A recent meta-analysis of six trials showed that clonidine increased smoking cessation rates by 11% (OR 1.89; CI 1.30 to 2.14). There was a high incidence of dose-dependent side effects, particularly dry mouth and sedation.⁵¹ It should be noted that abrupt discontinuation of clonidine can result in symptoms such as nervousness, agitation, headache, and tremor, accompanied or followed by a rapid rise in blood pressure and elevated catecholamine levels.

Because clonidine is used primarily as an antihypertensive medication and has not been approved by the FDA as a smoking cessation medication, clinicians need to be aware of the specific warnings regarding this medication as well as its side-effect profile. Additionally, a specific dosing regimen for the use of clonidine in smoking cessation has not been established. Because of the warnings associated with clonidine discontinuation, the variability in dosages used to test this medication, and a lack of FDA approval, the guideline panel chose to recommend clonidine as a second-line agent. Doses used in various clinical cessation trials have varied significantly, from 0.15 to 0.75 mg/day orally to 0.10 to 0.20 mg/day transdermally, without a clear dose-response relation to cessation. Initial dosing typically is

0.1 mg orally twice daily or 0.1 mg/day transdermally, increasing by 0.1 mg/day each week if needed. The dose duration also varied across the clinical trials, ranging from 3 to 10 weeks. Most commonly reported side effects include dry mouth, drowsiness, dizziness, sedation, and constipation. As an antihypertensive medication, clonidine can be expected to lower blood pressure in most patients. Therefore clinicians may need to monitor blood pressure when using this medication.³⁸

Nortriptyline

Nortriptyline is also considered to be efficacious as a second-line agent to treat tobacco dependence. Based on very limited data, the use of nortriptyline appears to increase abstinence rates when compared with placebo.

Nortriptyline should be considered for smoking cessation under a clinician’s direction in patients unable to use first-line medications because of contraindications or in patients who failed using first-line medications. Therapy is initiated 10 to 28 days before the quit date to allow nortriptyline to reach steady state at the target dose. Smoking cessation trials have initiated treatment at a dose of 25 mg/day, increasing gradually to a target dose of 75 to 100 mg/day. Duration of treatment used in smoking cessation trials has been approximately 12 weeks. Most commonly reported side effects include sedation, dry mouth, blurred vision, urinary retention, light-headedness, and shaky hands.

Trials have investigated the use of other antidepressants for smoking cessation, including other tricyclics and selective serotonin reuptake inhibitors. Because of a paucity of data, the AHRQ panel drew no conclusions about the use of other antidepressants for smoking cessation.³⁸

CAFFEINE

Caffeine is the most widely consumed behaviorally active substance in the world.⁵² *Caffeinism* is the term coined to describe the clinical syndrome produced by acute or chronic overuse of caffeine.⁵³ The syndrome usually is characterized by CNS and peripheral manifestations, most notably anxiety, psychomotor alterations, sleep disturbances, mood changes, and psychophysiologic complaints. Table 65–6 summarizes typical manifestations of caffeine overuse syndrome.

As many as one in five adults consumes doses of caffeine generally considered large enough to cause clinical symptoms.^{54–55} Controlled double-blind studies demonstrate that caffeine has reinforcement properties in most people with a history of heavy prior use⁵⁶ and that this reinforcement is a function of dose and prior exposure.

Pharmacologically, the risk of developing some meaningful clinical manifestations becomes high when intake exceeds 500 mg/day. This places 20% to 30% of North Americans at risk.⁵⁴ Recognizing that there are individual variations and accepting a conservative approach, these data suggest that perhaps 10% to 20% of the North American adult population probably has meaningful clinical symptoms consistent with a diagnosis of caffeinism, a prevalence rate exceeding that of most other substances of abuse.

Caffeine has been proposed as a “model of drug abuse” despite the facts that its sale is largely unrestricted and that heavy consumption of caffeine-containing beverages is not considered to be drug abuse. A recent exhaustive review of caffeine dependence focused on the potential for abuse of caffeine and the nature of tolerance and withdrawal and presents a symposium of current knowledge as to the site(s) and mechanism of action of caffeine.⁵⁵ A second comprehensive review of human and animal data on coffee and caffeine consumption and caffeine dependence, withdrawal, and reinforcement also has been published.⁵⁴ The information below represents a broad overview of these topics, and the reader interested in more detail is urged to consult these two reviews.^{54,55}

EPIDEMIOLOGY OF CAFFEINE USE AND ABUSE

Caffeine is used by 80% of the population of the United States,⁵⁷ and its use can be problematic for some people. In 1999 there were 108,000,000 coffee consumers in the United States spending approximately \$9.2 billion in the retail sector and \$8.7 billion in the food service sector every year.⁵⁸ It can be inferred, therefore, that a coffee drinker spends on average \$164.71 per year on coffee. The National Coffee Association found in 2001 that 52% of the adult population of the United States drinks coffee daily.⁵⁹ More than 107 million Americans drink an average of 3.3 cups of coffee per day.

Average caffeine consumption in humans can range in different cultures and nations from 80 to 400 mg per person per day. In the United States caffeine consumption exceeds several billion kilograms annually. Per capita intake for the entire world’s population approximates 70 mg/day. In the United States this figure is considerably larger, at 210 to 238 mg. The majority of caffeine users progress to a pattern of frequent or daily consumption. Approximately one-fourth eventually begin consuming large quantities, exceeding 500 mg/day, and conservatively, 10% of all adults then progress to develop the syndrome of caffeinism. Mean daily consumption of caffeine in American children is surprisingly high. The Framingham Children’s Study⁶⁰ looked at the amounts of caffeine consumed each day by children between the ages of 6 and 10 years (mean 8.4 years for boys and 8.1 years for girls). Mean intake of caffeine was 16.0 ± 9.6 mg/day. Caffeinated soft drinks and chocolate furnished almost all of the caffeine.

Caffeine is an added ingredient in approximately 70% of soft drinks consumed in the United States.⁵⁷ Soft drink manufacturers’ justification to regulatory agencies and the public for adding caffeine to soft drinks is that caffeine is a flavoring agent. In a recent study, only 8% of a group of regular cola soft drink consumers could detect the taste effect of the caffeine concentration found in most cola soft drinks. Thus soft drinks serve as a major source of caffeine intake without any apparent purpose beyond its stimulant effects.⁵⁷

DIFFERENTIAL DIAGNOSIS

Caffeine intoxication is the only official diagnosis associated with caffeinism in the DSM-IV-TR. Caffeine-induced anxiety may manifest as restlessness, nervousness, excitement, insomnia, diuresis, flushing, gastrointestinal disturbance, muscle twitching, irritability, and jitteriness. If caffeine-induced insomnia requires specific treatment, caffeine-induced sleep disorder (DSM-IV-TR) is an appropriate diagnosis.^{4,53}

TABLE 65–6. Signs and Symptoms of Excessive Caffeine Intake

| | |
|--------------|------------------------------------|
| Restlessness | Gastrointestinal disturbances |
| Nervousness | Muscle twitching |
| Excitement | Rambling flow of thought or speech |
| Insomnia | Tachycardia or cardiac arrhythmia |
| Flushed face | Periods of inexhaustibility |
| Diuresis | Psychomotor agitation |

Because excessive caffeine consumption is so widespread, a thorough history of caffeine use should be included in the routine assessment of all new patients in primary care medical settings. In this manner, the practitioner can use the information gathered to uncover high levels of caffeine intake and then use the information to pinpoint the cause of clinical signs and symptoms typical of caffeinism. Clinical manifestations of caffeinism almost always will lessen in intensity or disappear completely within 1 to 2 weeks after removing the drug.⁴

PHARMACOLOGY OF CAFFEINE

Caffeine is rapidly and completely absorbed from the gastrointestinal tract, reaching a peak blood level within 30 to 45 minutes of oral ingestion. It easily crosses the blood-brain barrier, and levels achieved in the brain are proportional to the dose administered.

The half-life of caffeine in humans is approximately 3.5 to 5 hours. It is metabolized extensively according to a complex metabolic pathway occurring primarily in the liver. Serious problems rarely result from overdoses of caffeine. In fact, the amount of caffeine needed to cause death in an average adult male is 5 to 10 g, the equivalent of 50 to 100 cups of regular brewed coffee. Thus the risk of overdose from dietary sources of caffeine is virtually nonexistent.

☛ Caffeine increases the heart rate and force of contraction. It also has a strong diuretic effect. The key factor promoting caffeine use and dosage increases may be the drug's reinforcing effect on pleasure and reward centers of the brain. Caffeine's pharmacologic actions appear comparable (although less potent) in some aspects with those of other stimulants, such as amphetamines and cocaine. After years of uncertainty, it is apparent from both preclinical research and human studies that regular caffeine use does induce tolerance.

CAFFEINE DEPENDENCE

Research has shown that abstinence from caffeine induces a distinct withdrawal syndrome. Evidence for the existence of a caffeine dependence syndrome was presented by Strain and associates.⁵² In a structured psychiatric interview, subjects self-identified as having problems with caffeine use were evaluated for features of a DSM-IV-TR diagnosis of drug dependence. Those judged as caffeine dependent manifested at least three of four criteria (i.e., tolerance, withdrawal, persistent desire, or an unsuccessful attempt to reduce consumption and persistent use despite adverse psychological or physical consequences). Of 99 people screened, 27 were evaluated by means of a structured psychiatric interview modified for the diagnosis of caffeine dependence; 16 of those subjects (59%) met the criteria. In a second phase of the study, 11 of the 16 caffeine-dependent individuals participated in a 2-day double-blind crossover study of caffeine deprivation. Nine showed evidence of caffeine withdrawal during the placebo phase, a finding that validated one of the criteria for the diagnosis of dependence.

CAFFEINE WITHDRAWAL

☛ The frequency of the caffeine withdrawal syndrome is not well known, but it may be common. Withdrawal can occur when individuals who previously have been consuming caffeine on a regular basis suddenly discontinue its intake.⁴ The syndrome can be characterized by the occurrence of headache, drowsiness, fatigue, and sometimes impaired psychomotor performance, difficulty concentrating, nausea, excessive yawning, and craving. These symptoms usually appear within 18 to 24 hours of discontinuation of intake, corresponding to the time required for the drug to leave the body.

TABLE 65–7. Signs and Symptoms of Caffeine Withdrawal

| | |
|----------------------------------|--------------------------|
| Headache | Difficulty concentrating |
| Drowsiness | Nausea |
| Fatigue | Excessive yawning |
| Impaired psychomotor performance | Craving |

The caffeine withdrawal headache is somewhat unique, starting with a sense of fullness in the head and progressing to throbbing and diffuse pain that is made worse by movement. The maximum intensity of the pain occurs 3 to 6 hours after beginning. Symptoms of caffeine withdrawal are summarized in Table 65–7.

In an effort to understand the relationship between caffeine dosing conditions and the emergence of withdrawal, Evans and Griffiths⁶¹ performed a series of double-blind experiments in independent groups of healthy participants to assess the conditions under which withdrawal symptoms occur on cessation of low to moderate doses of caffeine. Their results show that significant caffeine withdrawal symptoms can occur reliably when individuals are maintained on as little as 100 mg caffeine each day, and the severity of caffeine withdrawal is an increasing function of the caffeine maintenance dose. Administration of caffeine as a single daily dose produces physical dependence similar to that produced by three divided doses over the day, suggesting that the daily dose of caffeine consumed is more relevant to the development of caffeine dependence than the pattern of caffeine intake within the day. They showed that caffeine withdrawal occurs after as little as 3 consecutive days of caffeine exposure, with a somewhat increased severity of withdrawal observed after a week of caffeine exposure. Finally, when individuals were maintained on 300 mg caffeine per day, a substantial reduction in caffeine consumption or complete elimination is necessary for the manifestation of the full, classic withdrawal symptoms.

When caffeine is reintroduced, relief of withdrawal symptoms tends to occur within 30 to 60 minutes. At present, this appears to be the most effective “treatment” for the caffeine-withdrawal syndrome.

EFFECT ON SLEEP

Caffeine interferes with sleep in most nontolerant individuals.^{4,53} Once tolerance has developed, people are much less likely to self-report sleep abnormalities, or they may sense that the insomnia has disappeared altogether. To illustrate, 53% of those consuming less than 250 mg/day agreed that caffeine before bedtime would prevent sleep, compared with 43% of those consuming 250 to 749 mg/day, and only 22% of those taking 750 mg/day or more. Even though the higher-level consumers denied that caffeine interferes with their sleep, studies done in the sleep laboratory confirm that caffeine consumers do have greater sleep latency, more frequent awakenings, and altered sleep architecture, and that these effects are dose related.

CAFFEINE-RELATED SOMATIC MANIFESTATIONS

Caffeine can cause other problems in addition to anxiety and nervousness. Users of high doses of caffeine often experience one or more of the following problems: urinary frequency and diuresis, headache, tachycardia, arrhythmias, tremulousness, diarrhea, gastrointestinal pain or discomfort, and light-headedness. Less frequent symptoms include seeing “spots” in front of the eyes, ringing in the ears, a feeling of being unable to breathe, tingling in fingers and toes, and excessive perspiration. Caffeine also may precipitate a true panic attack.

COMORBID SUBSTANCE-RELATED DISORDERS

It is not uncommon for heavy users of caffeine to also be taking a variety of other psychoactive medications, mostly of the CNS depressant variety. Sedative-hypnotics and antianxiety agents are used

significantly more often in those consuming high doses of caffeine than in those consuming low or moderate amounts. Approximately two-thirds of heaviest caffeine users reported using an antianxiety agent within the past month. Similar effects on the brain reward pathways may help explain why excessive caffeine, alcohol, and tobacco use tend to occur in the same individuals.

TREATMENT: Caffeinism

Caffeinism is treated by reducing or discontinuing the drug. It may be necessary to wean the patient off the drug because going “cold turkey” may produce such serious symptoms that the drug must be restarted. Decaffeinated beverages may be substituted slowly for the caffeinated type. However, relapses are less likely to occur when the drug is discontinued all at once, probably due to the considerable self-discipline required to continue weaning the drug when one knows that an increase in dose will cause the symptoms to abate.

It may be possible for some individuals simply to reduce their dosage of caffeine rather than discontinue it altogether. Others may be particularly sensitive to the drug, and they may not be able to handle even reduced intake of caffeine. Patients with cardiovascular disease, especially arrhythmias, should refrain totally, as should people with prior stroke or transient ischemic attacks. Peptic ulcer patients and those with bipolar mood disorder and schizophrenia should be encouraged to avoid caffeine altogether.

CONCLUSIONS

Use of alcohol, tobacco, and caffeine is so commonly accepted in our society that people take notice only when their use causes serious problems. When these problems do occur, the human and economic costs are enormous. Health professionals must be committed to helping people free themselves of the addictions that can occur with these common drugs.

SCHIZOPHRENIA

M. Lynn Crismon and Peter F. Buckley

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The pathophysiology of schizophrenia may occur in one or more different neurotransmitter systems.
- 2 The clinical presentation of schizophrenia is characterized by positive symptoms, negative symptoms, and impairment in cognitive functioning.
- 3 Comprehensive care for individuals with schizophrenia must occur in the context of a multidisciplinary mental health care environment that offers psychotropic medication management and comprehensive psychosocial services.
- 4 A thorough patient evaluation (e.g., history, mental status exam, physical exam, and laboratory analysis) should occur to establish a diagnosis of schizophrenia and to identify potential co-occurring disorders, including substance abuse and general medical disorders.
- 5 Given that one cannot distinguish among the newer second-generation antipsychotics based upon efficacy, side-effect profiles become important in choosing an antipsychotic for an individual patient.
- 6 Pharmacotherapy algorithms should emphasize monotherapies with antipsychotics of optimal efficacy:side-effect ratios and progress to medications with greater side-effect risks and to combination regimens in treatment-resistant patients.
- 7 Adequate time on a given medication at a therapeutic dose is the most important variable in predicting medication response.
- 8 Long-term maintenance antipsychotic treatment is necessary for the vast majority of patients with schizophrenia in order to prevent relapse.
- 9 Thorough patient and family psychoeducation should occur, including education about the illness, symptoms, prognosis, medication, psychosocial treatments, and methods to improve adaptive functioning.
- 10 Pharmacotherapy decisions should be guided by systematic monitoring of patient symptoms, preferably with the use of brief symptom rating scales.

Schizophrenia is one of the most complex and challenging of psychiatric disorders. It represents a heterogeneous syndrome of disorganized and bizarre thoughts, delusions, hallucinations, inappropriate affect, and impaired psychosocial functioning. From the time that Kraepelin first described dementia praecox in 1896 until publication of the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, Text Revision (DSM-IV-TR) in 2000, the description of this illness has continuously evolved.¹ Scientific advances that increase our knowledge of central nervous system (CNS) physiology, pathophysiology, and genetics will likely improve our understanding of schizophrenia in the future.

EPIDEMIOLOGY

According to the Epidemiologic Catchment Area Study, the U.S. lifetime prevalence of schizophrenia ranges from 0.6% to 1.9%, with an average of approximately 1%.² With only a few possible exceptions, the worldwide prevalence of schizophrenia is remarkably similar among all cultures. Schizophrenia most commonly has its onset in late adolescence or early adulthood and rarely occurs before adolescence or after the age of 40 years. Although the prevalence of schizophrenia is equal in males and females, the onset of illness tends

to be earlier in males. Males most frequently have their first episode during their early twenties, whereas with females it is usually during their late twenties to early thirties.^{1,2}

ETIOLOGY

Although the etiology of schizophrenia is unknown, research has demonstrated various abnormalities in brain structure and function.³ However, these changes are not consistent among all individuals with a diagnosis of schizophrenia, and much has yet to be learned about its pathogenesis. The cause of schizophrenia is likely multifactorial; that is, multiple pathophysiologic abnormalities may play a role in producing the similar but varying clinical phenotypes we refer to as schizophrenia.

A neurodevelopmental model has been evoked as one possible explanation for the etiology of schizophrenia.⁴ This model proposes that schizophrenia has its origins in some as yet unknown in utero disturbance, possibly occurring during the second trimester of pregnancy. Evidence for this is provided by the abnormal neuronal migration demonstrated in most studies of schizophrenic brains. This “schizophrenic lesion” may result in abnormalities in cell shape, position, symmetry, and connectivity, and functionally to the development

of abnormal brain circuits.^{3,4} Changes are consistent with a cell migration abnormality during the second trimester of pregnancy, and some studies associate upper respiratory infections during the second trimester of pregnancy with a higher incidence of schizophrenia.⁵ Other studies show a relationship between obstetric complications or neonatal hypoxia and schizophrenia. Some studies also associate low birth-weight (<2,500 g) with schizophrenia.² The resulting secondary “synaptic disorganization” associated with such insults is thought not to produce overt clinical manifestations of psychosis until adolescence or early adulthood because this is the corresponding time period of neuronal maturation.

Additional support for a developmental model is provided by the fact that although studies have shown decreased cortical thickness and increased ventricular size in the brains of many patients with schizophrenia, this occurs in the absence of widespread gliosis.³ Gliosis, or the proliferation of glial cells, is thought to occur as a compensatory change in degenerative diseases of the brain. One hypothesis is that obstetric complications and hypoxia, in combination with a genetic predisposition, could activate a glutamatergic cascade that results in increased neuronal pruning. It is hypothesized that this genetic predisposition may be related to genes controlling N-methyl-D-aspartate (NMDA) receptor activity. As a part of the normal neurodevelopmental process, pruning of dendrites occurs. In the normal individual, about 35% of the peak number of dendrites at 2 years of age are pruned by midadolescence. Some studies have shown a higher percentage of pruning in individuals with schizophrenia. Furthermore, synaptic pruning predominantly involves glutamatergic dendrites. Hypoxia or other prenatal insult may result in a decreased number of basal neurons from which to start, and glutamatergic activation may exaggerate the pruning process. This is consistent with studies showing perinatal hypoxia being associated with earlier age of onset of schizophrenia. Others have suggested that altered membrane phospholipid metabolism may result in a cascade of effects leading to the expression of schizophrenia.⁶

Numerous studies have shown neuropsychological abnormalities as early as 4 years of age in individuals who later develop schizophrenia.^{1,2} Impairment in reaching normal motor milestones, and abnormal movements in children as young as 8 months of age, have been associated with the development of schizophrenia.² These findings indicate abnormalities in brain function long before the onset of psychotic symptomatology and provide empiric evidence for schizophrenia being a neurodevelopmental disorder.⁷ However, the progressive clinical deterioration in some patients suggests that this illness may also have a neurodegenerative component. This is consistent with recent brain imaging studies that show deteriorative brain changes in patients whose illness course is of frequent relapses.^{8,9} This had led our field not so much to consider schizophrenia as *either* neurodevelopmental *or* neurodegenerative in origin, but rather to reconceptualize the illness as exhibiting neurodegenerative propensity based upon a vulnerable neurodevelopmental substrate.¹⁰ This notion has substantial implications for early detection and treatment of this debilitating condition.¹¹

GENETICS

Although a specific abnormality has not been discovered, increasing evidence suggests a genetic basis for schizophrenia. Although the risk of developing schizophrenia is 0.6% to 1.9% in the general population, this increases to approximately 10% if a first-degree relative has the illness and to 3% if a second-degree relative has the illness.¹² If both parents have schizophrenia, the risk of producing a

schizophrenic offspring increases to approximately 40%. Twin studies in dizygotic twins report that the risk of the second twin developing schizophrenia if one twin has the illness is between 12% and 14%. However, in monozygotic twins the risk increases to 48%.¹² Numerous adoption studies indicate that the risk for schizophrenia lies with the biologic parents, and change in the environment during the child’s developmental stages does not alter this. If schizophrenia occurs in siblings, the onset of illness tends to occur at the same age in each, thus lessening the possibility of an environmental precipitant. A search for a genetic linkage in schizophrenia has been difficult, and any genetic etiologies in schizophrenia are likely heterogeneous, but present with similar phenotypes. Potential loci have been identified on chromosomes 6, 8, 13, and 22.¹² Beyond traditional familial and twin association studies, the study of the genetics of schizophrenia has become increasingly molecular in focus.^{3,12} Recent work has shown that polymorphism in the VAL/MET alleles of the catecholamine-o-methyl transferase gene may explain some of the frontal lobe functional deficits in patients with schizophrenia.¹² Other recent studies have shown abnormalities in several genes that code for neurodevelopment and for trophic factors.^{12–14}

PATHOPHYSIOLOGY

Computed axial tomography (CAT) scans and magnetic resonance imaging (MRI) studies show increased ventricular size, particularly in the third and lateral ventricles, in subtypes of schizophrenics. Recent studies also show a small but definite decrease in brain size as compared to matched controls. These changes appear to be consistent with brain asymmetry, the ventricular enlargement being most pronounced in the left temporal horn, and the decreased cortical size being most obvious in the left temporal lobe.^{3,8} Not only does pre-morbid lower hippocampal volume predict onset of symptoms in high-risk individuals, these changes may progress throughout the course of the illness.¹⁵ Changes in hippocampal volume may correspond with impairment in neuropsychological testing, and these patients may have poorer response to first-generation antipsychotics (FGAs).⁸ Rather than a decrease in the number of neurons in affected brain areas, a decrease in axonal and dendritic communications between cells may result in a loss of connectivity that may be important with respect to neuronal adaptivity and CNS homeostasis.³ These changes are likely consistent with the evidence for abnormal neuronal pruning.⁴

NEUROTRANSMITTER CHANGES

Since the discovery of the role of dopamine (DA) as a neurotransmitter in 1958, and the observations that antipsychotic drugs are postsynaptic DA-receptor antagonists, interest in a dopaminergic hypothesis for the pathophysiology of schizophrenia has existed. However, these theories may be more appropriately oriented toward the treatment of psychosis with antipsychotics.

Four dopaminergic tracts are of primary interest. Table 66–1 outlines the origin, innervation, and primary functional activity of each tract, as well as the effects of dopamine antagonists.⁷

Increasing evidence supports the presence of a DA-receptor defect in schizophrenia. Numerous positron emission tomography (PET) studies have shown regional brain abnormalities, including increased glucose metabolism in the caudate nucleus, and decreased blood flow and glucose metabolism in the frontal lobe and left temporal lobe.^{2,3}

TABLE 66–1. Dopaminergic Tracts and Effects of Dopamine Antagonists

| Dopamine Tract | Origin | Innervation | Function | Dopamine Antagonist Effect |
|--------------------|--|--|---|---------------------------------------|
| Nigrostriatal | Substantia nigra (A9 area) | Caudate nucleus Putamen | Extrapyramidal system, movement | Movement disorders |
| Mesolimbic | Midbrain ventral tegmentum (A10 area) | Limbic areas (e.g., amygdala, olfactory tubercle, septal nuclei), cingulate gyrus | Arousal, memory, stimulus processing, motivational behavior | Relief of psychosis |
| Mesocortical | Midbrain ventral tegmentum (A10 area) | Frontal and prefrontal lobe cortex | Cognition, communication, social function, response to stress | Relief of psychosis Akathisia? |
| Tuberoinfundibular | Hypothalamus | Pituitary gland | Regulates prolactin release | Increased prolactin concentrations |

This may indicate dopaminergic hyperactivity in the head of the caudate nucleus and dopaminergic hypofunction in the frontotemporal regions. PET studies using D₂-specific ligands provide data suggesting increased densities of D₂ receptors in the head of the caudate nucleus with decreased densities in the prefrontal cortex.^{2,3} PET studies assessing D₁ function suggest that subpopulations of schizophrenics may have decreased densities of D₁ receptors in the caudate nucleus and the prefrontal cortex. Hypofrontality may be associated with lack of volition, one of the core negative symptoms seen in schizophrenia. It is important to emphasize that it is unknown whether these changes represent a primary event or whether they are secondary processes related to other pathophysiologic abnormalities in schizophrenia. Because of the heterogeneity in the clinical presentation of schizophrenia, it has also been suggested that the DA hypothesis may be more applicable to “neuroleptic-responsive psychosis,” with multiple different etiologies possibly being responsible for causing schizophrenia.¹⁶ Attempts have been made to develop relationships between these abnormal findings and behavioral symptoms present in schizophrenic patients. The positive symptoms are possibly more closely associated with DA-receptor hyperactivity in the mesocaudate, whereas negative symptoms are most closely related to DA-receptor hypofunction in the prefrontal cortex. Presynaptic D₁ receptors in the prefrontal cortex are thought to be involved in modulating glutamatergic activity, and this may be important with regard to working memory in individuals with schizophrenia.¹⁵

Glutamatergic dysfunction has been suggested as being etiologic in schizophrenia. The glutamatergic system is one of the most widespread excitatory neurotransmitter systems in the brain. Alterations in its function, either hypo- or hyperactivity, can result in toxic neuronal reactions.^{2,3,15} Dopaminergic innervation from the ventral striatum decreases the limbic system’s inhibitory activity (perhaps through γ -aminobutyric acid [GABA] interneurons); thus, dopaminergic stimulation increases arousal. The corticostriatal glutamate pathways have the opposite effect, inhibiting dopaminergic function from the ventral striatum, therefore allowing the limbic system to have increased inhibitory activity. Descending glutamatergic tracts interact with dopaminergic tracts directly as well as through GABA interneurons. Glutamatergic deficiency produces symptoms similar to those of dopaminergic hyperactivity and possibly those seen in schizophrenia. Clinical support for this hypothesis comes from the fact that phencyclidine, a potent psychotomimetic, is a noncompetitive antagonist at the NMDA receptor, a major glutamate receptor. It is proposed that schizophrenia may involve some currently unknown in utero assault that leads to a developmental defect in NMDA receptor function—so-called NMDA hypofunction. This defect is proposed

to have latent clinical expression with neuropsychological pathology from NMDA hypofunction not being seen until late adolescence or early adulthood. It has been shown that excess D₂ stimulation can impair NMDA transmission via GABAergic neurons. Thus the use of antipsychotic drugs could potentially enhance glutamatergic transmission.¹⁵

Serotonergic receptors are present on dopaminergic axons, and it is known that stimulation of these receptors will decrease DA release, at least in the striatum.⁷ Although somewhat more diffuse, the distribution of serotonergic neurons is similar to that of dopaminergic neurons, thus allowing these two neurotransmitter systems to innervate the same areas. In fact, 5-hydroxytryptamine₂ (serotonin₂; 5-HT₂) receptors and D₄ receptors have been found to be colocalized in the cortex.^{3,7,15} Patients with schizophrenia with abnormal brain scans have higher whole-blood 5-HT concentrations, and these concentrations are correlated with increased ventricular size.¹⁷ Atypical antipsychotics with potent 5-HT₂ receptor antagonist effects reverse worsening of symptomatology induced by 5-HT agonists in patients with schizophrenia.¹⁷

◀ The primary pathophysiologic abnormality in schizophrenia may occur in one of a number of different neurotransmitters (e.g., dopaminergic, glutamatergic, or serotonergic systems), with changes in other neurotransmitters occurring secondarily. For example, a primary defect resulting in abnormal presynaptic release of DA from the neuron and ineffective feedback mechanisms could lead to postsynaptic DA receptor hypersensitivity. The NMDA hypofunction model is another approach that could lead to dysregulation among neurotransmitter systems.

Schizophrenia is a complex disorder, and multiple etiologies likely exist for the clinical syndrome we refer to as schizophrenia. Based on current knowledge, it is naive to think that any currently proposed etiology can adequately explain the genesis of this complex disease. Molecular research involving genetically determined subtle changes in G proteins, protein metabolism, and other subcellular processes may well identify the biologic disturbances associated with schizophrenia.^{3,7,15}

CLINICAL PRESENTATION

Schizophrenia is the most common functional psychosis, and there are as many clinical presentations of schizophrenia as there are individuals with the disorder. Despite numerous attempts to portray a stereotype in movies and on television, the stereotypic schizophrenic essentially does not exist. Moreover, schizophrenia does not mean

“split personality.” Schizophrenia is a chronic disorder of thought and affect with the individual having a significant disturbance in interpersonal relationships and ability to function in society on a daily basis.

The first psychotic episode may be sudden in onset with few premorbid symptoms, or commonly may be preceded by withdrawn, suspicious, peculiar behavior (schizoid). During the acute psychotic episodes, the patient loses touch with reality, and in a sense, the brain creates a false reality to replace it. The patient experiences a variety of acute psychotic symptoms, such as hallucinations (especially hearing voices), delusions (fixed false beliefs), and ideas of influence (beliefs that one’s actions are controlled by external influences). Thought processes are disconnected (loose associations), the patient may not be able to carry on logical conversation (alogia), and may have simultaneous contradictory thoughts (ambivalence). The patient’s affect may be flat (no emotional expression), or it may be inappropriate and labile. The patient is often withdrawn and inwardly directed (autism). Uncooperativeness, hostility, and verbal or physical aggression may be seen because of the patient’s misperception of reality. Self-care skills are impaired, and the patient is frequently dirty, unkempt, and in general has poor hygiene. Sleep and appetite are often disturbed. When the acute psychotic episode remits, the patient typically has residual features. This is an important point in differentiating schizophrenia from other psychotic disorders. Although residual symptoms and their severity vary, patients may have difficulty with anxiety management, suspiciousness, and lack of volition, motivation, insight, and judgment. Therefore they often have difficulty living independently in the community. Because of poor anxiety management and suspiciousness, they are frequently withdrawn socially, and have difficulty forming close relationships with others. In addition, impaired volition and motivation contribute to poor self-care skills and make it difficult for the patient with schizophrenia to maintain employment.

Patients with schizophrenia frequently experience a lack of historicity, or difficulty in learning from their experiences. They may repeatedly make the same mistakes in social conduct and situations requiring judgment. They have difficulty understanding the importance of treatment, including medications, in maintaining their ability to function in society. Therefore they tend to discontinue medications and other treatments, and this increases the risk of relapse and rehospitalization.

Although the course of the illness is variable, the long-term prognosis for many schizophrenic patients is poor. The disease is marked by intermittent acute psychotic episodes and impaired psychosocial functioning between acute episodes, with most of the deterioration in psychosocial functioning occurring within 5 years after the first psychotic episode.¹⁸ By late life, the patient may appear “burned out,” that is, the patient ceases to have acute psychotic episodes, but residual symptoms, as previously described, persist. However, functional skills may actually improve compared with earlier in the patient’s life. In a subpopulation of patients, probably 5% to 15%, psychotic symptoms are nearly continuous, and response to typical antipsychotics is poor.¹⁹

The DSM-IV-TR places a greater emphasis on the chronicity of schizophrenia and negative symptoms than do previous editions. Schizophrenia is a chronic disorder, and the patient’s history must be carefully assessed for dysfunction that has persisted for longer than 6 months. After their first episode, patients with schizophrenia rarely have a level of adaptive functioning as high as before the onset of the disorder. Table 66–2 summarizes the DSM-IV-TR criteria, and this reference should be consulted for a more detailed discussion of the differential diagnosis.¹

TABLE 66–2. DSM-IV-TR Diagnostic Criteria for Schizophrenia

- A. Characteristic symptoms: Two or more of the following, each persisting for a significant portion of at least a 1-month period:
 - (1) delusions
 - (2) hallucinations
 - (3) disorganized speech
 - (4) grossly disorganized or catatonic behavior
 - (5) negative symptoms

Note: Only one criterion A symptom is required if delusions are bizarre or if hallucinations consist of a voice keeping a running commentary on the person’s behavior or two or more voices conversing with each other.
- B. Social/occupational dysfunction: For a significant portion of the time since onset of the disorder, one or more major areas of functioning such as work, interpersonal relations, or self-care are significantly below the level prior to onset.
- C. Duration: Continuous signs of the disorder for at least 6 months. This must include at least 1 month of symptoms fulfilling criterion A (unless successfully treated). This 6 months may include prodromal or residual symptoms.
- D. Schizoaffective or mood disorder has been excluded.
- E. Disorder is not due to a medical disorder or substance use.
- F. If a history of a pervasive developmental disorder is present, there must be symptoms of hallucinations or delusions present for at least 1 month.

Adapted from American Psychiatric Association.¹

2 The DSM-IV-TR classifies the symptoms of schizophrenia into two categories: positive and negative. Recently greater emphasis has been placed on a third symptom category, cognitive dysfunction (Table 66–3).¹⁹ The areas of cognition found to be abnormal in schizophrenia include attention, working memory, and executive function. Positive symptoms have traditionally attracted the most attention and are the ones most affected by traditional antipsychotic drugs. However, negative symptoms and impairment in cognition are more closely associated with poor psychosocial function. This fact merits attention when one is examining pharmacologic options for treatment.

Numerous authors have attempted to construct subtypes of schizophrenia, and it has been suggested that symptom complexes may correlate with prognosis, cognitive functioning, structural abnormalities in the brain, and response to antipsychotic drugs. Negative symptoms and cognitive impairment may be more closely associated with prefrontal lobe dysfunction and positive symptoms with temporolimbic abnormalities. Many patients demonstrate both positive and negative symptoms. Patients with negative symptoms frequently have more antecedent cognitive dysfunction, poor premorbid adjustment, low level of educational achievement, and a poorer overall prognosis.¹⁹

TABLE 66–3. Schizophrenia Symptom Clusters

| Positive | Negative | Cognitive |
|-------------------------------------|----------------------|-----------------------------|
| Suspiciousness | Affective flattening | Impaired attention |
| Unusual thought content (delusions) | Alogia | Impaired working memory |

▶ **TREATMENT: Schizophrenia**

■ **DESIRED OUTCOME**

Pharmacotherapy is the mainstay of treatment in schizophrenia, and it is essentially impossible in most patients to implement effective psychosocial rehabilitation programs in the absence of antipsychotic treatment.¹⁹ Elements of the comprehensive care of patients with schizophrenia are listed in Table 66–4. A pharmacotherapeutic treatment plan should be developed that delineates drug-related aspects of therapy. Because most deterioration in psychosocial functioning occurs within the first 5 years of the initial psychotic episode, treatment interventions should be particularly assertive during this period.¹⁸ Explicit endpoints should be defined, including realistic goals of the target symptoms most likely to respond, and the relative time course for response.^{2,19} Other goals include avoiding unwanted side effects, using the minimum effective dose, emphasizing adequate time as a primary variable in determining response, and limiting augmentation medications to nonresponsive patients.

■ **NONPHARMACOLOGIC THERAPY**

Psychosocial rehabilitation programs oriented toward improving patients’ adaptive functioning are the mainstay of nondrug treatment for schizophrenia. These programs may include basic living skills, social skills training, basic education, work programs, and supported housing. In particular, programs aimed at employment and housing have been the more effective interventions and are considered “best practices” for persons with serious and persistent mental disorders. Programs that involve families in the care and life of the patient have also been shown to decrease rehospitalization and to improve functioning in the community. For particularly low-functioning patients, assertive intervention programs referred to as active community treatment (ACT) are effective in improving patients’ functional outcomes. ACT teams are available on a 24-hour basis and work in the patient’s home and place of employment to provide comprehensive treatment, including medication, crisis intervention, daily living skills, and supported employment and housing.^{2,19} A listing of psychotherapeutic approaches to the treatment of schizophrenia is given in Table 66–5.

■ **PHARMACOLOGIC THERAPY**

■ **ASSESSMENT PRIOR TO TREATMENT**

◀⁴ The importance of initial assessment for accurate diagnosis cannot be overemphasized in a patient presenting with acute

psychosis. A thorough mental status examination, physical and neurologic examination, complete family and social history, and laboratory work-up must be performed to confirm the diagnosis and exclude general medical or substance-induced causes of psychosis, such as acute or chronic drug ingestion. Laboratory tests, biologic markers, and commonly available brain imaging techniques do not assist in diagnosis or selection of medication. A pretreatment patient work-up is not only important in excluding other pathology, but in serving as a baseline for monitoring potential medication-related side effects, and should include: vital signs, complete blood count, electrolytes, hepatic function, renal function, electrocardiogram, fasting serum glucose, serum lipids, thyroid function, and urine drug screen.

■ **ANTIPSYCHOTIC MEDICATION CHOICES**

■ **Second-Generation Antipsychotics**

Second-generation antipsychotics (SGAs) (with the exception of clozapine) have become the agents of first choice in the treatment of schizophrenia, and most practice guidelines and consensus statements support this recommendation.^{19–21} The nomenclature for these drugs is at present confusing. No absolute criterion distinguishes atypical (second-generation) from typical (traditional or conventional first-generation) antipsychotics, and no universally accepted definition exists for an atypical antipsychotic.¹⁷ Thus in many respects, “second-generation antipsychotic” is a more appropriate term. Common to all definitions is the ability of the drug to produce antipsychotic response with few or no acutely occurring extrapyramidal side effects (EPS). Other attributes that have been ascribed to SGAs include enhanced efficacy, particularly for negative symptoms and cognition; absence or near absence of tardive dyskinesia; and lack of effect on serum prolactin.¹⁹ To date, the only approved SGA that fulfills all of these criteria is clozapine, the prototypical agent.¹⁷ Growing, but still controversial, evidence suggests that SGAs have superior efficacy for the treatment of negative symptoms, cognition, mood, and general psychopathology.^{19–21} Whether these differences are a result of differences in core efficacy or differences in side-effect profile is unknown. The major advantage of atypical antipsychotics may be in their side-effect profiles with respect to motor effects, as they generally have better overall tolerability than the FGAs. While information from maintenance studies is beginning to accrue, there is still a relative lack of information to adequately define the long-term clinical outcomes resulting from their widespread use. However, some experts believe that their use during the first 5 years of onset of the

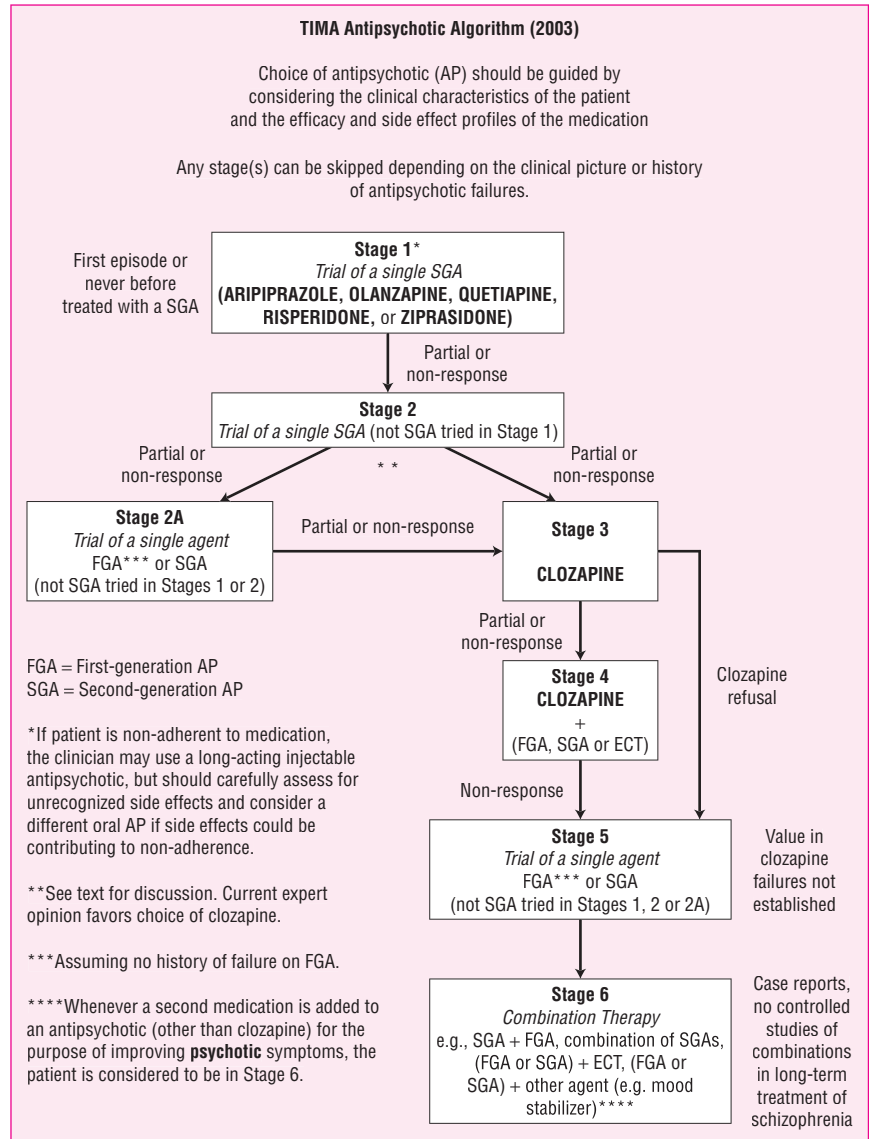

FIGURE 66–1. Patient entry into the algorithm is determined by individual patient history and clinical presentation. Algorithm stages can be skipped if clinically appropriate, and one may go back stages if indicated. In general, inadequately responding patients should not remain in stages 1 or 2 longer than 12 weeks at therapeutic doses. Stage 3 may be up to 6 months. TIMA = Texas Implementation of Medication Algorithms. (From Miller et al.²⁰ and Miller et al.²² This figure is in the public domain and may be reproduced with appropriate citation of the authors and source. Algorithm updates may be obtained at <http://www.mhmr.state.tx.us/centraloffice/medicaldirector/timasczman.pdf>.)

illness could help prevent some of the deterioration associated with the disease.^{18,22} However, adequate psychosocial rehabilitation programs must be used in conjunction with atypical antipsychotics if patients are to achieve their maximum functional capacity.

Risperidone fulfills the atypical criterion of having a low incidence of EPS at low to moderate doses. The mean optimal dose in parallel, fixed-dose studies was 4 to 6 mg daily. At doses greater than 6 mg daily, risperidone’s profile is more similar to that of an FGA.^{22,23} Because risperidone appears to lose its atypical profile at higher doses, the lowest possible dose should be used in treatment. This may include gradual dose titration downward if patients do not respond initially, rather than upward titration as has been the traditional approach to dosing antipsychotics.^{19,22}

Olanzapine has a very low incidence of EPS when used within the approved dose range of 10 to 20 mg daily.^{2,19,22} However, many patients are being treated at doses above the currently recommended limit in the approved product labeling of 20 mg/day. Quetiapine is an efficacious antipsychotic with an excellent EPS profile.^{22,24} Although contrary to efficacy studies, doses above 500 mg are often used to achieve optimal effects, with dose titration to 800 mg/day being a

common occurrence. From a clinical perspective, the optimal daily quetiapine dose appears unclear.

Ziprasidone 40 to 160 mg/day appears to have efficacy similar to other SGAs, with response rates increasing at doses greater than 80 mg daily.^{2,22,25} Aripiprazole has established efficacy at 15 to 30 mg/day.^{19,20,26} Both aripiprazole and ziprasidone have significantly less potential to produce weight gain than other SGAs.

5 The side-effect profiles of individual atypical antipsychotics and individual patient characteristics should be used in deciding which drug to use in an individual patient. Information from the algorithm (Fig. 66–1) and the adverse effects sections should be utilized in arriving at this decision.

■ First-Generation or Typical Antipsychotics

Because of the risk of EPS, particularly tardive dyskinesia, FGAs are not usually considered first-line treatments.^{19,20,21} All FGAs are equal in efficacy when used in equipotent doses. Selection of medication should be based on the need to avoid certain side effects and

TABLE 66–6. Available Antipsychotics: Doses and Dosage Forms

concurrent medical or psychiatric disorders. No differences exist in efficacy between low- and high-potency FGAs, and high-potency drugs (e.g., haloperidol) are as effective in treating acute agitation as low-potency, highly sedating FGAs (e.g., chlorpromazine).

Previous patient or family history of response to an antipsychotic is helpful in the selection of an agent. Traditional dosage equivalents (expressed in “chlorpromazine equivalent dosages”—the equipotent dosage of any traditional FGA compared with 100 mg of chlorpromazine) may assist in determining the effective dosage range if the need arises to treat a patient with a different FGA. However, because SGAs differ in mechanism of action, the dose equivalents have little relevance when comparing dosages of SGAs. Table 66–6 lists antipsychotics and their usual dosage ranges.

■ Pharmacotherapeutic Algorithm

6 Figure 66–1 outlines a suggested pharmacotherapeutic algorithm for schizophrenia.^{20,22} Newer SGAs are recommended as first-line treatment (i.e., stages 1, 2, and 2A) because of a lower incidence of acutely occurring EPS and tardive dyskinesia, and some evidence for a superior effect on negative symptoms and cognition. Although it is unclear how many newer SGAs to try before proceeding to clozapine, because of safety concerns and the need for white blood cell (WBC) monitoring, it is generally recommended that patients be tried on two newer SGAs as monotherapy before proceeding to a trial of clozapine (stage 3).^{20,22} Clozapine has been shown to have superior efficacy in decreasing suicidal behavior, and it should also be considered as a higher treatment option in the suicidal patient.²⁷ If a patient will not consent to taking clozapine, then a trial of a different SGA or an FGA is recommended (stage 2A).

Treatment algorithm recommendations after clozapine (stages 4, 5, and 6) are based more on anecdotal experiences and clinical opinions than on empirical research.^{20,22} These combination strategies are aimed at a small percentage of patients who have responded poorly to

stages 1 through 3. These interventions should be implemented with careful evaluation of a patient's symptom response and discontinuation of the combination if improvement does not occur. See the later section on the treatment-resistant patient for a discussion of these strategy options.

If partial or poor adherence contributes to inadequate clinical improvement, then long-acting or depot injectable antipsychotics should be considered.¹⁹ Risperidone long-acting injection is currently the only long-acting SGA available. Because of a lower risk of EPS compared to fluphenazine or haloperidol depot injection, it is a preferred agent. In addition to individuals who are identified as partially adherent, some other patients may elect a once-every-2-week injection instead of taking daily oral medications. Long-acting injectable antipsychotics can be substituted for an oral antipsychotic at any point in the algorithm where they are thought to be indicated.

CLINICAL CONTROVERSY

Some effectiveness studies and meta-analyses of SGA efficacy studies have shown minimal superiority of these medications in improving psychotic symptoms (especially positive symptoms), particularly when compared with lower doses of haloperidol. However, other studies have reported that SGAs are superior to FGAs in improving negative symptoms. Nearly all studies have demonstrated a lower incidence of EPS with SGAs than FGAs. Tension exists between policy decision makers who are responsible for managing finite resources and clinicians who see clinical benefits of the SGAs in the patients they treat.

The use of antipsychotic combinations is controversial, as no research evidence supports increased efficacy for combination antipsychotic treatment. Combination antipsychotics are frequently used by clinicians, and testimonies attest to clinical benefits when a second SGA is added.

■ PREDICTORS OF RESPONSE

Obtaining a thorough medication history is important, and previous antipsychotic treatment should help guide the selection of current drug therapy, in that either a good prior response favors the use of the same agent or a negative prior response suggests the selection of a dissimilar drug. Nonprescription and illicit drug use may influence psychiatric presentation and thus diagnosis or antipsychotic response. Amphetamine and other CNS stimulants, cocaine, corticosteroids, digitalis glycosides, indomethacin, marijuana, pentazocine, phencyclidine, and other drugs can induce psychosis in susceptible individuals or exacerbate psychosis in patients with preexisting psychiatric illness.²⁸ Schizophrenic patients who continue to abuse alcohol or drugs usually have a poor response to medications and a poor prognosis. Alcohol, caffeine, and nicotine use potentially results in drug interactions.

Individual differences in patient response have been either proposed or identified, which may be clinically useful predictors of response.²⁹ Acute onset and short duration of illness, presence of acute stressors or precipitating factors, later age of onset, family history of affective illness, and good premorbid adjustment as reflected in stable interpersonal relationships or employment are all predictors of good response.²⁹

Negative schizophrenic symptoms are generally less responsive to antipsychotic therapy. Although controversial, affective symptoms may correlate with an overall good response. However, other than these caveats, few data support a relationship between drug response and schizophrenic subtypes. Neuropsychological deficits related to cognition and neurologic soft signs may correlate with poor antipsychotic response.²⁹ A patient's subjective response within the first 48 hours after being administered an FGA may be associated with drug responsiveness.³⁰ An initial dysphoric response, demonstrated by stating a dislike of the medication, or feeling worse or zombie-like, combined with anxiety or akathisia-like symptoms, is associated with poor drug response, and likely adverse effects. If continued on the same medication, the patient will likely be nonadherent.

The importance of developing a therapeutic alliance between the patient and the clinician cannot be underestimated. Patients who form positive therapeutic alliances are more likely to be adherent with all aspects of therapy, experience a better outcome at 2 years, and generally require smaller antipsychotic doses.

A certain minority of patients fail to benefit from antipsychotic therapy, and their psychosocial functioning may actually worsen. Unfortunately, no accepted method is available to identify these people before treatment.²⁹

■ INITIAL TREATMENT IN AN ACUTE PSYCHOTIC EPISODE

Initial dosing should follow the goals described in the individualized pharmacotherapeutic treatment plan. The goals during the first 7 days should be decreased agitation, hostility, combativeness, anxiety, tension, and aggression, and normalization of sleep and eating patterns. The usual recommendation is to initiate therapy and to titrate over the first few days to an average effective dose, unless the patient's physiologic status or history indicates that this dose may result in unacceptable adverse effects. Table 66–6 lists the usual dosage range, and an average dose is typically midrange. If “cheeking” of medication is suspected, liquid formulations and orally disintegrating tablets of different antipsychotics are available (see Table 66–6). If a patient has shown absolutely no improvement after 3 to 4 weeks at therapeutic doses, then an alternative antipsychotic should be considered (i.e., moving to the next treatment stage in the algorithm; see Fig. 66–1).^{20,22}

Although some clinicians believe that larger daily doses are necessary in more severely symptomatic patients, data are not available to support this practice. Some symptoms, such as agitation, tension, aggression, and increased motor activity, may respond more quickly, but side effects may be more common with higher doses. However, interindividual differences in dosage and patient response do occur. In partial but inadequate responders who are tolerating the chosen antipsychotic well, it may be reasonable to titrate above usual dose ranges. However, this tactic should be time-limited (i.e., 2 to 4 weeks), and if the patient does not achieve further improvement, the dose should either be decreased, or an alternative treatment strategy tried.^{19,22} In general, rapid titration of antipsychotic dosage is not indicated.^{19,22} However, intramuscular antipsychotic administration (e.g., ziprasidone 10 to 20 mg IM, olanzapine 2.5 to 10 mg IM, or haloperidol 2 to 5 mg IM) can be used to assist in calming a severely agitated patient. Agitation can be manifested by loud, physically or verbally threatening behavior, motor hyperactivity, or physical aggression. Although this technique may assist in calming an acutely agitated psychotic patient, it does not improve the extent of or time to remission, or the length of hospitalization. If IM haloperidol is used, the occurrence of EPS may eliminate some of the advantages of using an SGA. If the patient is receiving an antipsychotic within the usual therapeutic range, the use of lorazepam 2 mg IM as needed in combination with the maintenance antipsychotic is a rational alternative to an injectable antipsychotic.

CLINICAL CONTROVERSY

Minimal research evidence supports the use of antipsychotic doses beyond the dose range in the Food and Drug Administration (FDA) approved product labeling. Clinicians frequently titrate doses above the approved range, and often attest to symptom improvement when this is done.

■ STABILIZATION THERAPY

Improvement is usually a slow but steady process over 6 to 12 weeks or longer. During the first 2 to 3 weeks, goals should include increased socialization and improvement in self-care habits and mood. Improvement in formal thought disorder should follow and may take an additional 6 to 8 weeks to respond. Patients who are early in the course of their illness may experience a more rapid resolution of symptoms than individuals who are more chronically ill. In general, if a patient has not received a robust decrease in positive and negative symptoms within 8 to 12 weeks at adequate doses, then an alternate monotherapy antipsychotic in the algorithm should be considered. In a more chronically ill patient, symptoms may continue to improve for 3 to 6 months. During acute stabilization, usual labeled doses of SGAs are recommended (see Table 66–6); with FGAs, a range of 300 to 1,000 mg of chlorpromazine equivalents daily is recommended.^{19,22}

▶ An optimum dose of the chosen drug should be estimated in the initial treatment plan. If the patient begins to show adequate response before or at this dosage, then the patient should remain at this dosage as long as symptoms continue to improve. In general, adequate time on a therapeutic antipsychotic dose is the most important factor in predicting medication response. However, if necessary, dose titration may continue within the therapeutic range every week or two as long as the patient has no side effects.

Before changing medications in a poorly responding patient, the following should be considered: Were the initial target symptoms indicative of schizophrenia or did they represent manifestations of a different diagnosis, a long-standing behavioral problem, a substance

abuse disorder, or a general medical condition? Is the patient adherent with pharmacotherapy? Are the persistent symptoms poorly responsive to antipsychotics (e.g., impaired insight or judgment, or fixed delusions)? How does the patient's current status compare with response during previous exacerbations? Would this patient potentially benefit from a change to a different treatment stage (see Fig. 66-1)? Does this patient have a treatment-refractory schizophrenic illness?

The conclusion that a partially responding patient has achieved as much symptomatic improvement as possible is one that must be made with great care and after considering all possible treatment alternatives. However, treatment goals must be realistic. Medications are effective at decreasing many of the symptoms of schizophrenia (and are thus referred to as *palliative*), but they are not curative, and all symptoms may not abate. This being said, the treatment approach should be assertive. While one should expect none to minimal residual positive symptoms with effective treatment, it is still unclear what a realistic goal is with regard to maximum improvement in negative symptoms.

It is important to screen patients for co-occurring mental disorders, and their presence may become more apparent during the stabilization or maintenance phases of schizophrenia treatment. Examples include substance abuse disorders, depression, obsessive-compulsive disorder, and panic disorder. As co-occurring disorders will limit symptom and functional improvement and increase the risk of relapse, it is critical that they be appropriately treated. Pharmacological and nonpharmacological interventions specific for the co-occurring disorder should be implemented in combination with evidence-based treatment for schizophrenia.

■ MAINTENANCE TREATMENT

Maintenance drug therapy prevents relapse, as shown in numerous double-blind studies. The average relapse rate after 1 year is 18% to 32% with active drug (including some nonadherent patients) versus 60% to 80% for placebo.^{19,23,31}

Available evidence suggests that the 1-year relapse rate may be lower with SGAs, with an average 1-year relapse rate of 15%.^{23,31} After treatment of the first psychotic episode in a schizophrenic patient, medication should be continued for at least 12 months after remission.^{19,22} Although maintenance treatment in patients with multiple acute episodes is more difficult to define, good medication responders should be treated for at least 5 years. It is still unknown thereafter whether low-dose strategies or complete drug tapering and withdrawal should be considered in an effort to determine the need for continued treatment. Continuous or lifetime pharmacotherapy is necessary in the majority of patients to prevent relapse. This should be approached with the lowest effective dose of the antipsychotic that is likely to be tolerated by the patient.³² Targeted medication administration based on prodromal symptoms was historically recommended as an alternative to continuous antipsychotic treatment in stabilized patients. However, studies show continuous medication to be more effective than targeted medication in preventing decompensation, in decreasing need for hospitalization, and in improving the extent and quality of employment.^{2,19} Therefore the approach of intermittent or targeted therapy has now been abandoned.

Antipsychotics should be tapered slowly before discontinuation. Abrupt discontinuation of antipsychotics, especially low-potency FGAs and clozapine, can result in withdrawal symptoms, felt to be a manifestation of rebound cholinergic outflow. Insomnia, nightmares, headaches, gastrointestinal symptoms (e.g., abdominal cramps, stomach pain, nausea, vomiting, and diarrhea), restlessness, increased

salivation, and sweating are reported. In general, when switching from one antipsychotic to another, the first antipsychotic should be tapered and discontinued over at least 1 to 2 weeks after the second antipsychotic is initiated.^{19,20,33} Tapering often needs to occur more slowly, especially with clozapine.^{19,20}

■ LONG-ACTING OR DEPOT INJECTABLE ANTIPSYCHOTICS

Depot or long-acting antipsychotics are recommended for patients who are unreliable in taking oral medication on a daily basis, and thus are not usually used as first-line therapy. Before a long-acting antipsychotic is initiated, it should be determined whether the patient's medication nonadherence is because of side effects. If so, an alternative medication with a more favorable side-effect profile should be considered before a long-acting injectable antipsychotic.

The patient's motivation for treatment is a major factor influencing outcome. Conversion from oral therapy to a long-acting injectable is most successful in patients who have been stabilized on oral therapy. The ideal patient for a long-acting injectable is the individual who does not like the daily reminder of oral medication or is unreliable in taking medications. Risperidone recently became available as the first long-acting injectable formulation of an SGA.³⁴ Long-acting risperidone has demonstrated efficacy, with an optimum dose range likely between 25 and 50 mg given IM every 2 weeks. Doses above 50 mg every 2 weeks are not recommended, as results from one study showed no greater efficacy but more EPS.³⁵ The pattern of adverse effects, especially low propensity to induce EPS and tardive dyskinesia, is similar to that of oral risperidone, and it appears to be well tolerated by patients.^{34,35}

Conversion from an oral antipsychotic to a long-acting medication should start with stabilization on an oral dosage form of the same agent, or at least a short trial (3 to 7 days), to determine whether the patient tolerates the medication without significant side effects. Long-acting risperidone is a suspension of drug in glycolic acid-lactate copolymer microspheres that must be reconstituted before administration. The microspheres are degraded via hydrolysis with significant risperidone serum concentrations being measurable approximately 3 weeks after single-dose administration. Thus it is important that the oral antipsychotic be administered for at least 3 weeks after beginning the injections. Dose adjustments are recommended to be made no more often than once every 4 weeks.³⁵

For fluphenazine decanoate, the simplest dosing conversion method recommends 1.2 times the oral fluphenazine daily dose for stabilized patients, rounding up to the nearest 12.5-mg interval, administered in weekly doses for the first 4 to 6 weeks; or 1.6 times the oral daily dose for more acutely ill patients.³⁶ Subsequently, fluphenazine decanoate may be administered once every 2 to 3 weeks. Oral fluphenazine may be overlapped for 1 week. For haloperidol decanoate, a factor of 10 to 15 times the oral haloperidol daily dose is commonly recommended, rounding up to the nearest 50-mg interval, administered in a once-monthly dose with an oral haloperidol overlap for the first month. A more assertive conversion method recommends 20 times the oral daily dose, but dividing the injection into consecutive doses of 100 to 200 mg every 3 to 7 days until the entire amount is given.³⁷ With this method, oral medication overlap was unnecessary. The haloperidol decanoate dose is decreased by 25% at the second and third months.

Injection site reactions have been reported with the haloperidol decanoate 100 mg/mL preparation, consisting of painful pruritic swelling at the injection site.³⁸ Acute EPS can be seen following injections of either fluphenazine or haloperidol decanoate. These

effects are minimized with the use of risperidone microspheres. Both haloperidol and fluphenazine decanoate should be administered by a deep, “Z-tract” intramuscular method. Long-acting risperidone is injected by deep IM injection in the gluteus maximus, but Z-tracting is not necessary. For patients not exposed to the oral drug, an oral test dose of the medication is recommended before administering the first IM dose of the long-acting antipsychotic.

■ METHODS TO ENHANCE PATIENT ADHERENCE

It is often a challenge for individuals with chronic illnesses to maintain high levels of medication adherence, and partial compliance is thus a reality in the treatment of all chronic illnesses.³⁹ Individuals with serious mental disorders have somewhat higher nonadherence rates than those with general medical disorders, with the following explanations provided: denial of illness, lack of insight, grandiosity or paranoia, no perceived need for medication, perceived lack of input into choice of medication or dosage, side effects, misperceived “allergies,” or the number of medications prescribed or doses received daily. In fact, clinicians should expect partial compliance to be the norm with regard to medication-taking behavior. This should be approached in a non-judgmental manner, with the clinician actively engaging the patient in care as a mechanism to enhance therapeutic alliance and patient adherence.

9 Education geared toward patients becoming more informed about their illness and the effectiveness and risks of treatment may help to increase adherence.⁴⁰ These programs should be staged so that patients initially receive basic information about their disorder and its symptoms and basic information about their medication and self-monitoring techniques. As the patient is capable of dealing with more complex information, more detailed information regarding schizophrenia, psychosocial treatments, and prognosis should be discussed. Patients and families should be taught self-monitoring techniques and when to report symptom exacerbation or medication side effects to the clinician.⁴⁰ Psychoeducation strategies should involve individual counseling as well as group activities.

Recent evidence suggests that the use of cognitive behavioral therapy that focuses on medication adherence can improve patient outcome.⁴¹ This approach is called *compliance therapy*. Groups facilitated by trained individuals who have the illness may be more effective in enhancing awareness and acceptance of schizophrenia and necessary treatment than groups led only by professionals. Active involvement of family members further increases the likelihood of patient adherence with treatment. In addition to programs provided by community mental health centers, support groups operated by consumer groups such as the National Alliance for the Mentally Ill (NAMI) are available in most urban areas. Contact information for local NAMI chapters can be accessed at http://www.nami.org/Template.cfm?Section=Your_Local_NAMI. In the hospital, self-medication administration often reinforces the patient’s perception of their active role in their own treatment. When patients miss outpatient appointments, active outreach interventions must be implemented to enhance patient engagement in treatment. These include both phone calls and home visits.^{19,40,42}

■ MANAGEMENT OF TREATMENT-RESISTANT SCHIZOPHRENIA

An official definition of “treatment resistance” does not exist.¹⁹ In general, it reflects a patient who has had inadequate symptom response

from multiple antipsychotic trials. Traditionally, treatment resistance has been defined as lack of improvement in positive symptoms, but it can be defined by poor improvement in negative symptoms, or even by medication intolerance. Between 10% and 30% of patients receive minimal symptomatic improvement after multiple FGA monotherapy trials.¹⁹ An additional group of patients (30% to 60%) has partial but inadequate improvement in symptoms or unacceptable side effects associated with antipsychotic use.^{19,20}

■ Atypical Antipsychotics

Only clozapine has shown superiority over other antipsychotics in randomized clinical trials for the management of treatment-resistant schizophrenia. Most other SGAs have either not been studied in treatment-refractory patients or evaluated in small open trials. In a seminal study, clozapine was effective in approximately 30% of patients with treatment-resistant schizophrenia, compared with only 4% treated with a combination of chlorpromazine and benztropine.⁴³ The results of this study not only demonstrated the efficacy of clozapine in this population, but provided a definition for treatment-resistant schizophrenia. This definition includes treatment failures on three different FGAs from at least two different chemical classes and a history of poor social functioning for the past 5 years.⁴³ It is significant that when using these criteria for treatment resistance, almost no patients improved with trials of haloperidol and chlorpromazine. These criteria have been subsequently modified to require only two treatment failures, and includes both FGAs and SGAs. Other treatment candidates for clozapine include those patients who cannot tolerate even conservative doses of other antipsychotics.

Symptomatic improvement with clozapine in the treatment-resistant patient often occurs slowly, and as many as 60% of patients may improve if clozapine is used for up to 6 months.⁴⁴ This, in combination with clozapine’s adverse effects profile, provides sufficient information to conclude that clozapine is not a panacea for schizophrenia. However, as an SGA with proven efficacy in the treatment-resistant population, a therapeutic trial of clozapine is recommended at algorithm stage 3 for those patients who consent to its use and are willing to have the weekly to biweekly blood draws for WBCs. Polydipsia and hyponatremia (psychogenic water drinking) is a frequent problem among treatment-resistant patients, and clozapine reportedly decreases water drinking and increases serum sodium in such patients.⁴⁵

Because of the risk of orthostatic hypotension, clozapine is usually titrated more slowly than other antipsychotics, particularly on an outpatient basis. If a 12.5-mg test dose does not produce hypotension, then clozapine 25 mg at bedtime is recommended, increased to 25 mg twice a day after 3 days, and then increased in 25- to 50-mg/day increments every 3 days until a dose of at least 300 mg/day is reached. Because high doses are associated with significantly increased side effects, including seizures, a clozapine serum concentration is recommended before exceeding 600 mg/day. Although some clinicians add valproate when exceeding this dose to prevent the occurrence of seizures, no evidence supports this intervention, and it is more prudent to start valproate if a seizure occurs.

■ Augmentation and Combination Strategies

Little empirical evidence exists to guide treatment decisions for patients who do not respond to clozapine.^{19,46} Numerous suggestions

have been made regarding augmentation of clozapine or other SGAs and using combinations of antipsychotics (see Fig. 66–1).^{20,47} Augmentation therapy involves the addition of a nonantipsychotic drug to an antipsychotic drug in a poorly or partially responsive patient, whereas combination treatment involves using two antipsychotics simultaneously. Several guidelines should be followed regarding augmentation: (a) augmentation should be used only in inadequately responding patients; (b) augmentation agents are rarely effective for schizophrenic symptoms when used alone; (c) augmentation responders usually improve rapidly; and (d) if augmentation does not improve symptomatology, the augmenting agent should be discontinued.^{22,47}

Mood stabilizers are frequently used as an augmentation strategy. Lithium does not enhance antipsychotic effect, but may improve labile affect and agitated behavior in selected patients. However, a recent meta-analysis showed its effects as an augmenting agent to be inconclusive.⁴⁸ Valproic acid and carbamazepine have also been used. A large placebo-controlled trial supports faster symptom improvement when divalproex was used in combination with either olanzapine or risperidone.⁴⁹ Enzyme induction with carbamazepine may cause a decrease in antipsychotic serum concentrations and potentially worsen psychotic symptoms in some patients. Dosing of mood stabilizers in treatment-resistant schizophrenia is similar to dosing in bipolar disorder¹⁹ (see Chap. 68).

Selective serotonin (5-HT) reuptake inhibitors (SSRIs), particularly fluoxetine and fluvoxamine, have reasonable evidence for improving negative symptoms when used as augmentation of FGAs. Potential benefits of combining SSRIs with SGAs require more study.⁵⁰ Consistently positive results have been reported when using SSRIs to treat obsessive-compulsive symptoms that worsen or arise during clozapine treatment.

β -Blockers such as propranolol, pindolol, and nadolol have been reported to have an antiaggression effect when used in a variety of psychiatric disorders, but particularly in the organic aggressive syndrome.¹⁹ Doses are typically higher than those required for cardiovascular β -blockade, but patients should be monitored carefully for β -blocker-related side effects. Patients may need to be treated with adequate doses for 6 to 8 weeks in order to evaluate an antiaggression response.

Combining an FGA with an SGA and combining different SGAs have been suggested as intervention strategies for treatment-resistant patients. These treatments are based on the hypothesis that using antipsychotics with different mechanisms of action will result in greater efficacy than using any medication individually. Critics argue that combining an FGA with an SGA will negate the advantages of the SGA (e.g., fewer EPS). Pharmacodynamically, no clear rationale exists for explaining how combinations of antipsychotics would produce enhanced efficacy, and increased side effects is a possible result. Increased EPS, elevated prolactin levels, and increased D₂ binding were demonstrated in one small study after the addition of haloperidol 4 mg/day to stable doses of clozapine.⁵¹ In general, a series of antipsychotic monotherapies, including clozapine, are preferred over antipsychotic combinations.²⁰ However, when this fails to produce desired outcomes, a time-limited combination trial may be attempted (see Fig. 66–1, stages 4 or 6).^{19,20,22} As is evidenced in Figure 66–1, this is usually indicated only after inadequate response to clozapine, or in a patient who refuses to give consent for clozapine treatment. Such antipsychotic combination treatment trials should be time limited (6 to 12 weeks) and the patient carefully evaluated with rating scales for changes in symptomatology. If no apparent improvement is observed, then one of the medications should be tapered and discontinued.

■ ANTIPSYCHOTIC DRUG MECHANISMS OF ACTION

The exact mechanism of action of antipsychotic medications is unknown. Research has centered on antipsychotics' relative affinities to block various neurotransmitter receptors, with recent work focusing on the relative affinity to block D₂ versus 5-HT_{2A} receptors. It has been suggested that current antipsychotics be classified into three different categories: (a) typical or traditional (high D₂ antagonism and low 5-HT_{2A} antagonism); (b) atypical (moderate to high D₂ antagonism and high 5-HT_{2A} antagonism); and (c) atypical clozapine-like (low D₂ antagonism and high 5-HT_{2A} antagonism).^{52,53} With the exception of aripiprazole, all current SGAs have a greater affinity for 5-HT_{2A} receptors than D₂ receptors. Aripiprazole is a potent 5-HT_{1A} agonist, and it has been suggested that 5-HT_{1A} agonism may produce a clinical effect similar to 5-HT_{2A} blockade, resulting in an atypical clinical profile.^{26,53}

Studies of antipsychotic receptor binding in humans have utilized PET scans to examine neurotransmitter receptor binding at 12 hours postdose in small numbers of individuals who have been dosed to steady state. Using this methodology, at least 60% to 65% occupation of D₂ receptors has been thought necessary to decrease positive psychotic symptoms, whereas blockade of approximately 77% or more of D₂ receptors is associated with EPS.^{52,54} FGAs are dopaminergic antagonists with high affinity for D₂ receptors. During chronic treatment with these agents, between 70% and 90% of D₂ receptors in the striatum are usually occupied. Thus treatment with FGAs frequently exceeds the threshold for production of EPS. In contrast, during clozapine treatment only 38% to 47% of D₂ receptors are occupied. Even with doses as high as 900 mg daily, less than 50% of D₂ receptors are occupied.^{52,55} Newer SGAs have variable D₂ binding. With low-dose risperidone (2 to 5 mg/day), D₂ binding ranges from 60% to 79%, but with doses greater than 6 mg daily, binding commonly exceeds the 77% threshold associated with the development of EPS. Risperidone 2 mg/day produces 5-HT_{2A} binding greater than 70%, and with 4 mg/day it is nearly 100%.^{52,55}

Olanzapine 10 to 20 mg/day produces D₂ binding ranging from 71% to 80%, while at 30 to 40 mg/day, it ranges from 83% to 88%. At 5 mg/day, 5-HT_{2A} receptors are near saturation of binding.⁵² Thus risperidone 6 mg and olanzapine 20 mg/day have similar D₂ binding, while both drugs have high 5-HT_{2A} occupancy even at the lower end of the usual therapeutic dose range.⁵⁵

Ziprasidone has the highest 5-HT_{2A}:D₂ affinity ratio of any of the currently available antipsychotics. It is also a potent 5-HT_{1A} agonist.⁵⁶

Quetiapine has the lowest D₂ binding. At doses of 300 to 600 mg/day, D₂ binding ranges from 0% to 27%. Even at quetiapine 800 mg/day, only 30% of D₂ receptors are occupied. At these same daily doses, 45% to 90% of 5-HT_{2A} receptors are occupied. However, when quetiapine D₂ binding is examined 2 to 3 hours postdose, 58% and 64% of receptors were occupied with 400 mg and 450 mg, respectively. This led to the conclusion that transient blockade of dopamine receptors may be adequate to produce antipsychotic effect (and transient rise in serum prolactin concentrations), but long-term D₂ blockade is required for production of EPS and sustained hyperprolactinemia. It was further concluded that low D₂ binding, and thus atypicality, may be directly associated with how rapidly the antipsychotic disassociates from the D₂ receptor.^{52,55}

The recent availability of aripiprazole, a partial agonist at D₂ receptors, represents a further elaboration of the dopamine hypothesis of antipsychotic action.^{26,53} Based on extensive preclinical studies, it is proposed that aripiprazole works as a functional partial agonist in the hypodopaminergic state, and as a functional but weak dopamine antagonist in the hyperdopaminergic state. Aripiprazole is a rather

weak 5-HT_{2A} antagonist, but a potent 5-HT_{1A} agonist, which is also thought to contribute to its atypicality.^{26,53} Thus it is clear that the SGAs differ in their mechanisms of action and most likely in the manner in which they produce an atypical clinical profile.

The primary therapeutic effects of FGAs are thought to occur in the limbic system, including the ventral striatum, whereas EPS are thought to be related to DA blockade in the dorsal striatum. Tolerance often develops to the acutely occurring EPS within a few weeks, but tolerance to the antipsychotic effects appears to be less common, if not rare. 5-HT_{2A} antagonism in combination with modest D₂ blockade leads to release of dopamine in the prefrontal cortex, and this is one explanation for the decrease in negative symptoms and improvement in cognition reported with atypical antipsychotics. It has also been suggested that polymorphism in the 5-HT_{2A} receptor gene may explain some of the variance in response to clozapine.⁵³

Antipsychotics vary in their effects on other neurotransmitter receptor systems, including the antagonism of D₁, D₄, 5-HT_{2C}, 5-HT₆, 5-HT₇, muscarinic, α₁-adrenergic, and histaminic receptors.^{52,53,55} Additionally, clozapine is a partial agonist at D₁ receptors, and ziprasidone is a modest inhibitor of the presynaptic reuptake of NE and 5-HT.⁵³ Although any potential effects of these different mechanisms on differential efficacy is unclear, they do explain some potential differences in the side-effect profiles among antipsychotics. For example, this offers an explanation for side effects such as dry mouth, constipation, sinus tachycardia, and orthostatic hypotension with some antipsychotics. These differences in pharmacodynamic profiles also point out that the SGAs are not all alike, and that patients obtaining an inadequate clinical response (either efficacy or side effects) with one antipsychotic may have a superior response on an alternate drug. Thus serial SGA monotherapy trials should be tried in patients receiving a suboptimal clinical response (see Fig. 66–1).

■ PHARMACOKINETICS

As a class, antipsychotics are highly lipophilic and highly bound to membranes and plasma proteins. They distribute readily into most tissues with a high blood supply and may accumulate in tissues;

therefore they have large volumes of distribution.⁵⁷ Most antipsychotics are largely metabolized, primarily through the cytochrome P450 pathways in the liver, except for ziprasidone, which is largely metabolized by aldehyde oxidase. Risperidone and its active metabolite 6-OH-risperidone are both metabolized through CYP 2D6, and thus are susceptible to polymorphic metabolism. This should be considered in individuals who experience side effects at low doses. In particular, 30% to 35% of Africans and Asians are slow to intermediate metabolizers, in addition to about 7% and 2%, respectively, who are poor metabolizers.⁵⁸ Thus approximately 40% of patients in these racial/ethnic groups may have increased sensitivity to side effects with drugs such as risperidone that are primarily metabolized through CYP 2D6. Table 66–7 outlines the prominent metabolic pathways of selected antipsychotics.

Most antipsychotics have fairly long elimination half-lives, in the range of 20 to 40 hours, with the exception of quetiapine and ziprasidone, which have short half-lives.^{26,57,59} Thus after dosage stabilization most antipsychotics can be dosed once daily. Although not systematically studied, brain receptor kinetics are different than peripheral kinetics, and it may be possible to dose these SGAs less often than their plasma kinetics would suggest. Efforts to develop relationships between antipsychotic plasma concentrations and clinical response have been hampered by several factors, including the variable lag time between beginning antipsychotic treatment and symptom change, the subjective and relatively imprecise methods of measuring drug effect or symptom change in schizophrenia, the presence of multiple metabolites, and perhaps differences between receptor kinetics and peripheral pharmacokinetics. Among the SGAs, only clozapine has an established therapeutic range, with efficacy being associated with a clozapine plasma concentration greater than 250 to 350 ng/mL. A 12-hour postdose clozapine serum concentration of at least 250 ng/mL is recommended if the patient is receiving divided clozapine doses, or 350 ng/mL if the patient is being dosed once daily. Whether increased symptom improvement occurs with continued dosage increases above these serum concentrations, and a potential maximum therapeutic clozapine serum concentration exists, are poorly defined. However, side effects do increase with increased clozapine serum concentrations. It is likely not cost effective to

TABLE 66–7. Pharmacokinetic Parameters of Selected Antipsychotics

| Drug | Bioavailability (%) | Half-life (h) | Major Metabolic Pathways | Active Metabolites |
|---|---------------------|------------------------------|---------------------------|---------------------------------------|
| <i>Selected first-generation antipsychotics</i> | | | | |
| Chlorpromazine | 10–30 | 8–35 | FMO3, CYP 3A4 | 7-hydroxy, others |
| Fluphenazine | 20–50 | 14–24 | CYP 2D6 | ? |
| Fluphenazine decanoate | | 14.2 ± 2.2 ^a days | | |
| Haloperidol | 40–70 | 12–36 | CYP 1A2, 2D6, 3A4 | Reduced haloperidol |
| Haloperidol decanoate | | 21 days | | |
| <i>Second-generation antipsychotics</i> | | | | |
| Aripiprazole | 87 | 48–68 | CYP 3A4, 2D6 | Dehydroaripiprazole |
| Clozapine | 12–81 | 11–105 | CYP 1A2, 3A4, 2C19 | Desmethylclozapine |
| Olanzapine | 80 | 20–70 | CYP 1A2, 3A4, FMO3 | N-glucuronide; 2-OH-methyl; 4-N-oxide |
| Quetiapine | 9 ± 4 | 6.88 | CYP 3A4 | 7-OH-quetiapine |
| Risperidone | 68 | 3–24 | CYP 2D6 | 9-OH-risperidone |
| Risperidone Consta | | 3–6 days | CYP 2D6 | 9-OH-risperidone |
| Ziprasidone | 59 | 4–10 | Aldehyde oxidase, CYP 3A4 | None |

^aBased on multiple-dose data. Single-dose data indicate a β half-life of 6–10 days.

Adapted from De Leon et al,²⁶ Harrison and Goa,³⁵ Ereshefsky et al,³⁶ Ereshefsky et al,³⁷ Ereshefsky,⁵⁷ and ziprasidone package insert.⁵⁹

routinely monitor clozapine serum concentrations in all patients. However, they should be monitored before exceeding 600 mg daily; in patients who develop unusual or severe adverse side effects; in patients who are taking concomitant medications that may cause drug interactions; in patients who have age or pathophysiologic changes suggesting a change in pharmacokinetics; or for assessment of patient adherence.³¹

Long-acting risperidone is a suspension of drug in glycolic acid-lactate copolymer microspheres.³⁵ After IM injection the polymer is slowly hydrolyzed, and significant risperidone begins being released after about 3 weeks, with therapeutic concentrations achieved in weeks 3 and 4. The apparent β -phase half-life is 3 to 6 days.³⁵ With dosing every 2 weeks, steady-state risperidone concentrations are achieved after approximately 2 months. Steady-state risperidone concentrations have been reported to be similar in elderly and younger individuals.³⁵

The depot FGAs fluphenazine decanoate (also available in an enanthate salt) and haloperidol decanoate are esterified drugs formulated in sesame seed oil for deep intramuscular injection. Their absorption from the muscle and metabolism to the free base is sufficiently slow to cause absorption to be the rate-limiting step in determining their respective apparent half-lives.³⁶

■ ADVERSE EFFECTS

Table 66–8 presents the relative incidence of common categories of antipsychotic side effects. The precise incidence of many of these side effects has not been systematically evaluated. Side effects are discussed below with respect to organ system affected. A general approach to monitoring and assessing side effects requires prospective monitoring by clinicians, preferably using a thorough review of systems approach. Patient-oriented self-rated side-effect scales may also be helpful, because many patients with schizophrenia do not readily complain of side effects, because of a lack of volition, a lack of perception of having input into their treatment, poor understanding, or because of the actual interference of side effects themselves (e.g., sedation).

With the variety of antipsychotics currently available, using an alternative drug should be considered in patients who complain of poorly tolerated side effects. Because medication side effects are one of the primary predictors of patient nonadherence, the clinician should take advantage of the treatment options currently available in an

attempt to improve patient outcomes. As new antipsychotics become available, side effects and risks associated with different drugs should be re-evaluated. As we learn more about relative side-effect risks (e.g., weight gain, glucose intolerance, QTc prolongation, acute extrapyramidal side effects, and tardive dyskinesia), it will be necessary to regularly reconsider which antipsychotics should be considered first-line treatment alternatives.

■ Endocrine System

DA blockade in the tuberoinfundibular tract results in increased prolactin levels, because DA is the major prolactin-inhibiting factor. Galactorrhea may occur in up to 57% of women, and menstrual irregularities or amenorrhea in up to 97%. These effects may be dose related and are more common with the use of FGAs and risperidone. Gynecomastia and galactorrhea are reported in men as well. Tolerance does not appear to develop to these effects.⁶⁰ Switching to the SGAs olanzapine, quetiapine, ziprasidone, or aripiprazole, which have no appreciable sustained effect on prolactin, is the most reasonable treatment option. Bromocriptine in doses up to 15 mg daily, or amantadine in doses up to 300 mg daily, has been used to treat prolactin-related symptoms.

The potential risk of osteoporosis is of concern with the long-term use of medications that cause osteoporosis. Inadequate evidence is currently available regarding the potential effects on bone density of long-term antipsychotic-related hyperprolactinemia.

Weight gain is frequently reported in both adults and children receiving antipsychotics.^{61,62} Although the exact mechanism is uncertain, weight gain has been associated with antihistaminic effects, antimuscarinic effects, and blockade of 5-HT_{2C} receptors. However, dietary factors and activity levels may play a significant role in this population, as does renourishment after a period of poor self-care. Weight gain may be seen with most atypical antipsychotics. In particular, significant weight gain, as defined by $\geq 7\%$ of the baseline body weight, is associated with clozapine and olanzapine therapy in 40% or more of patients.^{61,63} Risperidone and quetiapine may cause weight gain, but much less than that caused by clozapine or olanzapine. Ziprasidone and aripiprazole both have been associated with minimal weight gain.

The clinical significance of weight gain during antipsychotic therapy is substantial. The risk of cardiovascular-related mortality is higher in individuals with schizophrenia,^{64,65} and this is further

TABLE 66–8. Relative Side Effect Incidence of Commonly Used Antipsychotics

| | Sedation | EPS | Anticholinergic | Orthostasis | Weight Gain | Prolactin |

EPS, extrapyramidal side effects; Relative side-effect risk: ±, negligible; +, low; ++, moderate; +++, moderately high; +++++, high.

aggravated by drug-related weight gain. Additionally, obesity is a risk factor for diabetes mellitus.⁶⁶ Weight gain during treatment is a major reason for poor patient medication adherence, and patients commonly report weight gain as being a concern.⁶⁷

As in all patient populations, interventions for weight reduction in persons with schizophrenia are far from perfect. A number of pharmacological interventions have been attempted for antipsychotic-related weight gain, but in general these should be discouraged. Switching patients to an SGA less likely to cause weight gain, dietary restriction, exercise, and behavior modification programs are reported to be successful in small short-term studies.⁶⁸ An American Diabetes Association consensus task force recommends consideration of a change in antipsychotic if a patient gains more than 5% of baseline body weight after starting the drug.⁶⁹

Schizophrenic patients have a higher prevalence of type II diabetes than the nonschizophrenic population. Beyond this, antipsychotics may adversely affect glucose levels in diabetic patients. The extent to which these effects are related to drug-induced weight increase is unclear.^{63,70,71} A single-dose study suggests that SGAs impair glucose tolerance and increase insulin secretion, which supports a potential effect on glucose regulation independent of weight increase. A naturalistic study of patients taking clozapine found a 5-year rate of new-onset diabetes totaling 52%.⁷¹ New-onset diabetes has been reported during treatment with risperidone, olanzapine, quetiapine, and ziprasidone; aripiprazole is too new in clinical practice to draw conclusions regarding any association with diabetes. Although there are more reports of diabetes during treatment with clozapine or olanzapine, epidemiologic studies provide conflicting data regarding the relative risk of different SGAs to produce diabetes mellitus.⁷⁰ At present, the overall incidence, relative occurrence across agents, and treatment-patient related risk factors for diabetes during antipsychotic therapy are unknown. In March 2004 the FDA issued a safety alert requiring revisions in the labeling of all SGAs, that describes the increased risk of diabetes mellitus in patients taking atypical antipsychotics.⁷² Given the public health significance of diabetes, clarifying the diabetogenic effect of SGAs is a major focus of current research. Moreover, designing care models and standards for managing diabetes in patients with schizophrenia is another major consideration. Clozapine and olanzapine should be used with caution in patients with preexisting diabetes.

CLINICAL CONTROVERSY

The relative role of individual SGAs in precipitating diabetes mellitus is unclear. Clinicians are increasingly concerned about the escalating number of new cases of diabetes mellitus being reported in patients taking SGAs. It is clear, however, that obesity is associated with an increased risk of type II diabetes mellitus; olanzapine and clozapine have been shown to cause more weight gain than other SGAs.

■ Cardiovascular System

■ **Orthostatic Hypotension.** Postural or orthostatic hypotension, defined as a greater than 20-mm Hg drop in systolic pressure, is caused by α -adrenergic blockade, which inhibits reflex vasoconstriction when rising to a sitting or standing position; this appears to be a combination of local vasodilatory effects and central inhibition of the vasomotor center, as well as sympatholysis leading to an unopposed β -adrenergic effect.⁷³ Patients may experience light-headedness or syncope. Associated with lower potency FGAs and SGAs (especially

on intramuscular or intravenous administration), orthostatic hypotension can occur in any patient, but diabetic patients with preexisting cardiovascular disease and the elderly seem particularly predisposed. For mild cases, patient education should address slow changes in posture to allow for adaptation and/or the use of support hose. For most patients, tolerance to this effect occurs within 2 to 3 months. If tolerance does not occur, lower doses or a change to an antipsychotic with less α -blockade can be attempted.

■ **Electrocardiographic Changes.** Among the antipsychotics, thioridazine, mesoridazine, clozapine, and ziprasidone are most likely to cause electrocardiogram (ECG) changes. ECG changes include increased heart rate (through sinus tachycardia from anticholinergic effects, or reflex tachycardia from α -adrenergic blockade), flattened T waves, ST segment depression, and prolongation of QT and PR intervals. The most clinically important of these potential changes is prolongation of the QTc interval, which has been associated with ventricular arrhythmias, including torsades de pointes syndrome. Thioridazine has been shown to prolong the QTc interval on average about 20 milliseconds (ms) longer than haloperidol, risperidone, olanzapine, or quetiapine.^{63,74} Thioridazine's effects on QTc prolongation appear to be dose related. For this reason, thioridazine and mesoridazine (an active metabolite of thioridazine) have a black box warning in the FDA-approved product labeling with regard to this effect. Torsades de pointes has been reported with thioridazine, which may cause cardiac sudden death. Given the number of antipsychotic options currently available, few reasons exist to use either thioridazine or mesoridazine. In the same study, ziprasidone prolonged the QTc interval about 10 ms longer than did haloperidol, risperidone, olanzapine, or quetiapine—about one-half of the effect of thioridazine.⁶³ Ziprasidone effects were not dose related. Widespread clinical use suggests that ziprasidone's effects on the ECG are not associated with clinical sequelae, unless the patient has baseline risk factors.²⁰ Although the precise point at which QTc prolongation becomes clinically dangerous is unclear, it has been recommended to discontinue a medication associated with QTc prolongation if the interval consistently exceeds 500 ms.

Greater caution regarding antipsychotic choice and use is necessary in the elderly, in patients with preexisting cardiac disease, and in patients taking diuretics or medications that may prolong the QTc interval.^{20,59,63} In patients older than 50 years of age, a pretreatment ECG is recommended, as are baseline serum potassium and magnesium levels. These factors should be considered in antipsychotic selection.⁵⁹

■ Lipid Changes

Treatment with at least some SGAs and phenothiazines appears associated with elevations in serum triglycerides and cholesterol. As with diabetes, the extent to which this adverse event differs among agents is unclear, although less risk for change in serum lipid or cholesterol levels may occur with risperidone, ziprasidone, or aripiprazole.⁶⁵

The occurrence of weight gain, diabetes, and lipid abnormalities during antipsychotic therapy is consistent with the development of metabolic syndrome (i.e., syndrome X). The metabolic syndrome consists of raised triglycerides (≥ 150 mg/dL), low HDL cholesterol (≤ 40 mg/dL for males, ≤ 50 mg/dL for females), elevated fasting glucose (≥ 100 mg/dL), blood pressure elevation ($\geq 130/85$ mm Hg), and weight gain (abdominal circumference > 102 cm for males, > 88 cm in females).⁶⁵ These abnormalities, either alone or in combination, dictate an important role for general health screening and monitoring

in patients with schizophrenia, and prompt intervention when such abnormalities occur. The propensity of individual antipsychotics to produce metabolic disturbances should be considered in the context of individual patient risk factors at the time of drug selection, and in patient monitoring during treatment.

■ Autonomic Nervous System

Patients receiving antipsychotics, or antipsychotics in combination with anticholinergics, may experience anticholinergic side effects (e.g., dry mouth, constipation, tachycardia, blurred vision, inhibition or impairment of ejaculation, urinary retention, or impaired memory). This is particularly so with low-potency FGAs, and the elderly are especially sensitive to these effects. Of the SGAs, clozapine and olanzapine have moderately high rates of anticholinergic effects. System-specific effects are discussed under the appropriate heading. Dry mouth can be managed with increased intake of fluids, oral lubricants (Xerolube), ice chips, or use of sugarless chewing gum or hard candy. Constipation, caused by slowed peristaltic movement and decreased intestinal fluid content, should be closely monitored and treated, especially in the elderly. Paralytic ileus and necrotizing enterocolitis may also occur. Constipation can be treated with increases in fluid and dietary fiber intake, and exercise.

■ Central Nervous System

■ Extrapyramidal System

■ DYSTONIA

Dystonia is defined as a state of abnormal tonic, sometimes described simplistically as a severe “muscle spasm.”⁷⁵ Dystonias may be dramatic, frightening, and painful. More accurately, they are prolonged tonic contractions, with a rapid onset, usually within 24 to 96 hours of dosage initiation or dosage increase. They may be life-threatening, as in the case of pharyngeal-laryngeal dystonias, and can contribute to patient nonadherence. Types of dystonic reactions include trismus, glossospasm, tongue protrusion, pharyngeal-laryngeal dystonia, blepharospasm, oculogyric crisis, torticollis, and retrocollis. Dystonic reactions occur primarily with FGAs. Risk factors include younger patients (especially males), the use of high-potency agents, and high dosage. The overall incidence from the 1960s through the mid-1970s ranged from 2.3% to 10%, but as higher-potency traditional antipsychotics became more widely used, the rate increased to as high as 64%.

Intramuscular or intravenous anticholinergics (Table 66–9) or benzodiazepines are the treatments of choice for dystonia. Benzotropine mesylate 2 mg or diphenhydramine 50 mg may be given intramuscularly or intravenously. Diazepam 5 to 10 mg by slow IV push or lorazepam 1 to 2 mg intramuscularly are treatment alternatives. Relief is typically seen within 15 to 20 minutes of an intramuscular injection and within 5 minutes of intravenous administration. If no response is seen within 15 minutes of intravenous injection or within 30 minutes of intramuscular injection, the dose can be repeated. The antipsychotic may be continued, with concomitant short-term use of oral anticholinergic agents. In general, prophylactic anticholinergic medications are not recommended routinely with all FGAs. However, prophylaxis is reasonable when using high-potency FGAs (e.g., haloperidol or fluphenazine) in young men, and in patients with a history of dystonia.⁷⁵ Dystonias may also be minimized by the use

TABLE 66–9. Agents Used to Treat Extrapyramidal Side Effects

| Generic Name | Equivalent Dose (mg) | Daily Dosage Range (mg) |
|------------------------------|----------------------|-------------------------|
| Antimuscarinics | | |
| Benzotropine ^a | 1 | 1–8 ^b |
| Biperiden ^a | 2 | 2–8 |
| Trihexyphenidyl | 2 | 2–15 |
| Antihistaminic | | |
| Diphenhydramine ^a | 50 | 50–400 |
| Dopamine agonist | | |
| Amantadine | N/A | 100–400 |
| Benzodiazepines | | |
| Lorazepam ^a | N/A | 1–8 |
| Diazepam | N/A | 2–20 |
| Clonazepam | N/A | 2–8 |
| β -Blockers | | |
| Propranolol | N/A | 20–160 |

^aInjectable dosage form can be given intramuscularly for relief of acute dystonia.
^bDosage may be titrated to 12 mg/day with care; nonlinear pharmacokinetics have been demonstrated.

of lower initial FGA doses. Anticholinergics are good choices for prophylaxis, whereas amantadine has not been proved effective for this purpose. The risk of dystonia is greatly reduced with SGAs. The availability of olanzapine and ziprasidone injectables introduces a rapid-acting injection with a low risk of dystonia.

■ AKATHISIA

Akathisia is defined as the inability to sit still and as being functionally motor restless. The most accurate diagnosis is made by combining subjective complaints with objective symptoms (pacing, shifting, shuffling, or tapping feet). Subjectively, patients may describe a feeling of inner restlessness or disquiet or a compulsion to move or remain in constant motion. Akathisia occurs in 20% to 40% of patients treated with high-potency FGAs.⁷⁵ The majority of patients receiving FGAs may actually experience akathisia, but the reported incidence reflects only patients who can verbalize their feelings or recognize akathisia as being different from psychosis. Akathisia is frequently accompanied by dysphoria. Detection of akathisia requires a high degree of interviewer sensitivity, and symptoms can be quantified by use of the Barnes Akathisia Scale.

Many treatments for akathisia, although accepted to be effective, are based on anecdotal data. Treatment with anticholinergic agents, usually considered the standard treatment for all acute extrapyramidal side effects, is disappointing for akathisia, but may be helpful in patients with concomitant pseudoparkinsonism.⁷⁵ Traditionally, reduction in antipsychotic dosage has been considered the best intervention; however, this may not be a realistic goal in an acutely psychotic patient. A logical alternative is to switch to an SGA, an SGA with a lower risk of akathisia, or an antipsychotic previously used in the patient without adverse effect. Akathisia may occasionally occur with SGAs, and this seems to be the most common EPS-like symptom reported with SGAs. Although head-to-head comparisons are not widely available, quetiapine and clozapine appear to have the lowest risk of producing akathisia.^{22,59}

Benzodiazepines have been used for treatment of akathisia, but the high prevalence of co-occurring substance abuse in schizophrenia discourages their prescribing.⁷⁵ The β -blockers propranolol in doses up to 160 mg daily, nadolol in doses up to 80 mg daily, and metoprolol in β_2 -selective doses of 100 mg daily or less are reported as effective.⁷⁵

Clonidine has also been investigated, and hypotension and sedation were the only observed side effects. Preventive measures for akathisia include using the lowest possible FGA dose, or preferably, the use of SGAs.

■ PSEUDOPARKINSONISM

Pseudoparkinsonism, produced by D₂ blockade in the nigrostriatum, resembles idiopathic Parkinson's disease. A patient with pseudoparkinsonism may present with any of four cardinal symptoms: (1) akinesia, bradykinesia, or decreased motor activity including difficulty initiating movement, as well as extreme slowness, mask-like facial expression, micrographia, slowed speech, and decreased arm swing; (2) tremor, known as pill-rolling type, that is predominant at rest and decreases with movement, usually involving the fingers and hands, although tremors may also be seen in the arms, legs, neck, head, and chin (it may often be activated in resting body parts by having the patient perform mechanical movements with one extremity); (3) cogwheel rigidity, seen as the patient's limbs yielding in jerky, ratchet-like fashion when passively moved by the examiner (a mild form may present as stiffness); and (4) postural abnormalities and instability manifested as stooped posture, difficulty in maintaining stability when changing body position, and a gait that ranges from slow and shuffling to festinating (a result of autonomic dysfunction combined with a shift in the center of gravity due to the stooped posture). Accessory symptoms include the autonomic manifestations seborrhea, sialorrhea, and hyperhidrosis.⁷⁵ Fatigue and weakness may be noted, as well as oral abnormalities including dysphagia and dysarthria, and abnormal palmomental and glabellar reflexes. A variant of pseudoparkinsonism is rabbit syndrome, a perioral tremor. The overall incidence of pseudoparkinsonism from FGAs ranges from 15.4% to 36%, depending on the drug and dose. Akinesia alone can be seen in 59% of patients on high-potency FGAs. Other risk factors include increasing age and possibly female gender. The onset of symptoms is typically 1 to 2 weeks after initiation of antipsychotic therapy or a dose increase.

The efficacy of anticholinergic medications in alleviating or attenuating symptoms of pseudoparkinsonism is well established.⁷⁵ Benztropine is advantageous in that its longer half-life allows once- to twice-daily dosing. Typical dosing is 1 to 2 mg twice a day up to a usual maximum dosage of 8 mg daily, although some patients will continue to respond to doses up to 12 mg. Dosage titration should be slow, as benztropine displays nonlinear pharmacokinetics, and side effects may become unacceptable. Trihexyphenidyl (2 to 5 mg three times a day), diphenhydramine (25 to 50 mg three times a day), and biperiden (2 mg three times a day) usually require thrice-daily administration. Diphenhydramine produces more sedation than the other agents. Although it has been suggested that trihexyphenidyl is more likely to be abused, all of the anticholinergics have been abused for their euphoriant effects.⁷⁶ With all of these agents, symptoms typically begin to resolve within 3 to 4 days after initiation of treatment, but a minimum of at least 2 weeks of treatment is normally required for full response. Amantadine is generally as efficacious for pseudoparkinsonism as anticholinergics, with significantly less effect on memory function.⁷⁵ Its mechanism of action involves enhancement of dopaminergic tone in the striatum. Excessive doses may produce anxiety, agitation, restlessness, or uncommonly exacerbation of psychosis. Dosage adjustment is necessary with renal insufficiency. The need for prophylactic use of these agents against pseudoparkinsonism is less convincing than with dystonias, and is unnecessary when using SGAs.⁷⁵ The long-term treatment of pseudoparkinsonism with antiparkinsonism medication

is somewhat controversial, and an attempt should be made to taper and discontinue these agents 6 weeks to 3 months after symptom resolution. If symptoms reappear, then switching to an SGA should be considered. The risk of pseudoparkinsonism with SGAs is extremely low. When risperidone is used in doses greater than 6 mg/day, the risk of pseudoparkinsonism symptoms approaches that with FGAs. However, in doses lower than 6 mg/day, the risk of pseudoparkinsonism appears similar to that of olanzapine or ziprasidone.²⁰ Quetiapine, aripiprazole, or clozapine are reasonable alternatives in a patient experiencing extrapyramidal side effects with other SGAs.^{20,22,26,75}

■ TARDIVE DYSKINESIA

Tardive dyskinesia is a syndrome characterized by abnormal involuntary movements occurring late in onset in relation to initiation of antipsychotic therapy. Tardive dyskinesia is sometimes irreversible and continues to be a controversial issue, clinically, legally, and ethically.

The classic description of tardive dyskinesia is the buccolingual-masticatory (BLM) syndrome, or orofacial movements. The onset of BLM movements is usually insidious. Typically, they are the first detectable signs of tardive dyskinesia, and begin with mild forward, backward, or lateral movements of the tongue. As the disorder progresses, more obvious or frank BLM movements appear, including tongue thrusting, rolling, or fly-catching movements, and chewing or lateral jaw movements. Tardive dyskinesia symptoms may interfere with the patient's ability to chew, speak, or swallow. Further complications include oral ulcerations, inability to wear dentures, and inflammation and loosening of mandibular joints. Eating difficulties and malnutrition may be primary physical complications of tardive dyskinesia. Weight loss may be seen in patients with esophageal or respiratory manifestations but not in those with truncal movements. Facial movements include frequent blinking, brow arching, grimacing, upward deviation of the eyes, and lip smacking. Involvement of the extremities sometimes occurs, with the appearance of restless choreiform (irregular spasmodic) and distal athetosis (slow, writhing movement) of limbs including twisting, spreading, flexion (bending) and extension of fingers, toe tapping, and toe dorsiflexion (upward turning). Unusual posture, hyperextension, pelvic thrusting, axial hyperkinesia (excessive muscular activity of head and trunk), ballismus (jerking or shaking), exaggerated lordosis (bending backward), rocking, and swaying are occasionally observed. Among the more common differential diagnoses are withdrawal dyskinesias occurring after short-term use of antipsychotics, spontaneous orofacial dyskinesias in the elderly, orofacial dyskinesias in the edentulous, stereotypic movements in schizophrenics, Huntington's disease, and congenital torsion dystonia. Orofacial movements are reported more commonly in older patients, whereas the truncal axial movements are classically reported in young adults. Movements may worsen with stress, decrease with sedation, and disappear during sleep. Concentration on motor tasks or attempts to suppress the movements voluntarily may actually increase them.

Early signs of tardive dyskinesia may be reversible, but if allowed to persist or if not detected in the early stages, they may become irreversible, even with drug discontinuation. When the antipsychotic dose is decreased or tapered and discontinued, there is often a worsening of abnormal movements and then possibly a slow improvement after months or years if the patient remains on lower doses or discontinues treatment. No standardized diagnostic criteria for tardive dyskinesia are available. Abnormal involuntary movements can be detected early through physical assessment and the use of rating scales. Available

rating scales include the abnormal involuntary movement scale (AIMS) and the Dyskinesia Identification System: Condensed User Scale.^{75,77} Neither scale is diagnostic in itself.

Risk factors include increasing age, the occurrence of acute extrapyramidal side effects, poor antipsychotic drug response, diagnosis of organic mental disorder, diabetes mellitus, mood disorders, and possibly female gender.^{78,79} Duration of antipsychotic therapy, daily dosage, and possibly total cumulative dosage are probably the most significant risk factors. However, persistent dyskinesias may occur with as little as 6 months of therapy. Overall morbidity and mortality are greater in tardive dyskinesia patients, and patients with tardive dyskinesia show a greater incidence of respiratory tract infections and cardiovascular illness.

With FGAs, the reported incidence of tardive dyskinesia ranges from 0.5% to 62%.⁷⁸ In a first episode of schizophrenia, the incidence is estimated at about 5% per year, with the overall prevalence ranging from 20% to 25% with long-term treatment. Among the elderly, the overall risk of tardive dyskinesia is higher, with the 3-year FGA treatment prevalence estimated at 53%.⁷⁹ Tardive dyskinesia is not always permanent, with remission of symptoms observed in 25% of patients after 5 years of continued treatment.^{75,78,79}

The risk of tardive dyskinesia with SGAs is significantly lower. A systematic review of 11 studies with SGAs lasting 1 year or more found an overall risk of tardive dyskinesia to be about 0.8% per year in nonelderly adults and 5.3% per year in the elderly. For individual agents, the annual incidence rates ranged from zero to 0.5% for olanzapine to 0.6% to 0.7% for risperidone or quetiapine. Given that most of the patients in these studies had been previously treated with FGAs, the true risk of tardive dyskinesia with SGAs could potentially be lower.⁸⁰ To date, there are no reports of tardive dyskinesia with clozapine monotherapy. Although introduced in the United States in 1990, it has been used in some European countries since the early 1970s.

Prevention of tardive dyskinesia is important, as treatment of the movements once they occur is difficult. Because of data suggesting a lower risk of tardive dyskinesia with SGAs, these agents are considered treatments of first choice^{19,20,22,80} (see Fig. 66–1). Regular neurologic examinations (AIMS or other scales) should be performed at baseline and at least quarterly to assess for early signs of tardive dyskinesia. At the first signs of tardive dyskinesia, the need for continuing antipsychotic treatment should be reassessed. In such situations, if the patient is taking an FGA and continuing treatment is indicated, the medication should be switched to an SGA.

Numerous drugs have been used in an attempt to treat tardive dyskinesia, representing various strategies affecting CNS neurotransmission. In two controlled trials lasting 22 to 52 weeks, clozapine decreased abnormal involuntary movements.^{79,81} Switching antipsychotic therapy to clozapine is a favored first-line pharmacotherapeutic strategy, particularly in patients with moderate to severe dyskinesias.^{78,79,81} Limited evidence suggests that olanzapine may decrease symptoms, and no data are available with other SGAs.⁸¹ A systematic review of studies with vitamin E suggest that it may help prevent deterioration in tardive dyskinesia symptoms, but have no effect on symptom improvement.⁸²

■ **Sedation and Cognition.** Sedation must be recognized as an antipsychotic side effect and not as an indication of therapeutic effect. It occurs more frequently with antipsychotics with antihistaminic properties. Chlorpromazine, thioridazine, mesoridazine, clozapine, olanzapine, and quetiapine are most frequently implicated. Administration of most or all of the daily dosage at bedtime (depending on the drug half-life) can decrease daytime sedation and in some patients eliminate the need for hypnotic agents. Sedation occurs early in treatment

and may decrease over time.⁷³ Oversedation may play a large role in cognitive, perceptual, and motor dysfunction. With acute dosing, tasks requiring vigilance, attention, or motor behavior may be impaired. However, the positive effects of medication are seen with chronic administration, evidenced by improvements in tasks involving visual-motor skills, attention to task, and working memory. Compared with FGAs, several studies have shown cognitive benefits of SGAs. Comparative effects of different SGAs on cognition are as yet unclear, but available studies suggest that different SGAs may have effects on varying cognitive domains.⁸³ An algorithm-driven disease management program utilizing SGAs as first-line treatment was shown to improve cognition over a 9-month period.⁸⁴ Since SGAs appear to have beneficial effects on cognition, ongoing research is evaluating the clinical significance of this effect, and the relative effects of different SGAs.

■ **Seizures.** Antipsychotics lower the seizure threshold through GABA depletion, changes in CNS permeability leading to enhanced conduction of a discharge, disruption of DA-acetylcholine balance, or the activation of a latent seizure focus. There is an increased risk of drug-induced seizures in all patients treated with antipsychotics. However, this risk is greater if the following predisposing factors are present: preexisting seizure disorder, history of drug-induced seizure, abnormal electroencephalogram (EEG), and preexisting CNS pathology or head trauma. Seizures are more closely associated with the use of higher doses, rapid dosage increases, and upon initiation of treatment. When an isolated seizure occurs, a dosage decrease is first recommended; anticonvulsant therapy is not recommended. Although spontaneously occurring seizures have been reported with most antipsychotics, the highest potential risk for an antipsychotic-related seizure is with clozapine or chlorpromazine. Based on EEG findings, olanzapine may also be associated with greater risk. If a change in antipsychotic therapy is required because of a drug-induced seizure, risperidone, molindone, thioridazine, haloperidol, pimozide, trifluoperazine, and fluphenazine are associated with the lowest potential.⁸⁵

■ **Thermoregulation.** Poikilothermia, the body temperature adjusting to the ambient temperature, can be a serious side effect of antipsychotic therapy in temperature extremes.⁸⁶ Hyperpyrexia can be a danger in hot weather or during exercise. Inhibition of sweating, a result of anticholinergic properties impairing the peripheral mechanisms of heat dissipation, can also contribute to this problem, which in its severest form can lead to heat stroke. Hypothermia is also a risk, particularly in the elderly and in cold climates. All patients receiving antipsychotics should be educated about these potential problems. Thermoregulatory problems are reportedly more common with the use of low-potency FGAs and may occur with the more anticholinergic SGAs.

■ **Neuroleptic Malignant Syndrome.** Neuroleptic malignant syndrome (NMS) occurs in 0.5% to 1% of patients receiving FGAs. The rate of NMS has diminished since the introduction of SGAs, and reliable current estimates are not available. NMS may occur more frequently in patients receiving high-potency FGAs, injectable or depot FGAs, and in patients who are dehydrated, with physical exhaustion, or organic mental disorders. Although less common than with FGAs, NMS has been reported with SGAs, including clozapine. The onset of symptoms varies from early in treatment to months later. It develops rapidly, over the course of 24 to 72 hours. NMS may occur after antipsychotic discontinuation, especially when depot agents are used. Possible mechanisms of NMS include disruption of the central

thermoregulatory process or excess production of heat secondary to skeletal muscle contractions. The differential diagnosis includes heat stroke, lethal catatonia, anesthetic-associated malignant hyperthermia, anticholinergic toxicity, and monoamine oxidase inhibitor drug interactions. Cardinal signs and symptoms of NMS are body temperature exceeding 38°C (100.4°F), altered level of consciousness, autonomic dysfunction (tachycardia, labile blood pressure, diaphoresis, tachypnea, or urinary or fecal incontinence), and rigidity. Laboratory evaluation, although considered nonspecific, frequently shows leukocytosis with or without a left shift, increases in creatine kinase (CK), aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, and myoglobinuria.^{87,88}

Treatment should always begin with antipsychotic discontinuation and supportive care. In many cases that alone is effective. The role of adjunctive agents is unclear, yet they are often practical in clinical settings. The DA agonist bromocriptine, used in theory to reverse DA blockade, reduces rigidity, fever, or CK in up to 94% of patients, whereas the use of another DA agonist, amantadine, has been successfully used in up to 63% of patients. Dantrolene has been used as a skeletal muscle relaxant, with effects on temperature, heart rate, respiratory rate, and CK in up to 81% of patients.^{87,88} Wide recognition and rapid antipsychotic discontinuation has drastically reduced mortality from 20% 15 years ago to 4% in the mid-1990s.

Many patients with schizophrenia, despite having had NMS, will require future antipsychotic pharmacotherapy. Patient selection for rechallenge is important, as only those patients in need of reinstitution of antipsychotics should receive future trials. A review of antipsychotic rechallenges suggests that the risk of rechallenge is acceptable in most patients, provided that the patient is observed for an extended period of time (2 weeks or more is suggested) without antipsychotics, that there is careful monitoring and slow dose titration, and that the patient is maintained on the lowest possible dose.⁸⁷ Only SGAs should be used for rechallenge following an episode of NMS. Neither patient-specific demographic variables nor antipsychotic agent used assist in predicting recurrence.

■ **Psychiatric Side Effects.** Antipsychotic-induced akathisia, akinesia, and dysphoria may have unfortunate sequelae, resulting in what has been termed “behavioral toxicity.”³⁰ Akathisia has resulted in impulsivity and in extreme cases, violence and suicide. Akinesia, characterized by “diminished spontaneity,” results in symptoms of apathy and withdrawal, often mistaken for the negative symptoms of schizophrenia; these patients may actually appear depressed on formal evaluation.

Delirium and psychosis are reported with larger doses of FGAs or combinations of anticholinergics with FGAs. Chronic confusion and disorientation can occur in the elderly as a result of antipsychotic treatment.⁸⁹ Unfortunately, the link is not always made between initiation of antipsychotic therapy, and the patient may be misdiagnosed with an organic mental disorder. This clinical presentation, called a “pseudodementia,” is easily reversible on discontinuation of the antipsychotic.

Exacerbation and new onset of obsessive-compulsive symptoms have been reported with clozapine, and has anecdotally been reported to improve with addition of an SSRI.⁹⁰

■ **Ophthalmologic Effects.** Anticholinergic effects of antipsychotics or concomitant antiparkinson medications can exacerbate narrow-angle (angle closure) glaucoma. Antipsychotics with low anticholinergic effects should be used in such individuals, and they should be appropriately monitored.⁹¹

Opaque deposits in the cornea and lens occur with chronic phenothiazine treatment, most frequently with chlorpromazine. Although visual acuity is not usually affected, periodic slit-lamp ophthalmologic examinations are frequently recommended in patients receiving long-term treatment with phenothiazines.

Because of cataract development and lenticular changes in animals, baseline and periodic eye exams are recommended in the product labeling for patients receiving quetiapine.⁹² However, clinical experience with quetiapine since marketing has not supported a significant risk of cataracts.^{22,92} Retinitis pigmentosa can result from use of thioridazine doses greater than 800 mg daily. It is caused by melanin deposits, and can result in permanent visual impairment or blindness. There is no evidence that it is a function of cumulative dose.⁹¹

■ Hepatic System

Cholestatic hepatocellular jaundice has been reported in up to 2% of patients receiving phenothiazines. Additionally, liver function test (LFT) abnormalities (elevated aminotransferases and alkaline phosphatase), often asymptomatic, were reported in up to 50% of patients.⁹³ If aminotransferases are greater than three times the upper limit of normal, antipsychotic therapy should be changed to a chemically unrelated antipsychotic.

Overall, LFT abnormalities are uncommon with SGAs. However, cholestatic hepatitis has been reported with risperidone,⁹⁴ and LFT abnormalities, mostly transient, have been reported to be more frequent with clozapine than haloperidol.⁹⁵

■ Genitourinary System

Urinary hesitancy and retention is reported with low-potency FGAs and with clozapine. Anticholinergic effects cause smooth muscle slowing and paralyze the detrusor muscle of the bladder, requiring greater urine volume to evoke muscle contraction. Men with benign prostatic hypertrophy are especially prone to this effect.⁸⁹

Urinary incontinence is thought to be caused by α -blockade, and among the SGAs, it appears to be particularly problematic with clozapine. The incidence has been reported to be as high as 44%, and it may be persistent in 25% of patients.⁹⁶

Numerous different mechanisms have been suggested to cause sexual dysfunction, including dopaminergic blockade, hyperprolactinemia, histaminergic blockade (sedation), anticholinergic effects, and α -adrenergic blockade. This area is inadequately studied, and multiple mechanisms are likely responsible for producing sexual dysfunction. Unmedicated individuals with schizophrenia report decreased libido. However, to varying degrees antipsychotics produce decreased libido and sexual dysfunction. Most but not all studies have shown a relationship between hyperprolactinemia and sexual dysfunction, including decreased libido, erectile dysfunction, difficulty achieving orgasm, and ejaculatory abnormalities. While risperidone produces at least as much sexual dysfunction as FGAs, other SGAs, which have weak effects on prolactin or are “prolactin-sparing,” produce less sexual dysfunction. It is unclear whether hyperprolactinemia directly impairs sexual functioning, reflects high dopaminergic blockade from risperidone and FGAs, or is associated with other mechanisms of producing sexual dysfunction. Some evidence suggests that hyperprolactinemia may be associated with low testosterone concentrations, which could be associated with altered sexual functioning. Patients experiencing sexual dysfunction with FGAs or risperidone should be switched to an SGA with less effect on prolactin.⁹⁷

■ Hematologic System

Transient leukopenia may occur during initial treatment with antipsychotics; however, it typically does not progress to clinically significant parameters.⁹⁸ If the WBC count is less than 3,000/mm³, or if the absolute neutrophil count (ANC) is less than 1,000/mm³, the antipsychotic should be discontinued, and the WBC monitored closely until it returns to normal. Agranulocytosis reportedly occurs in 0.01% of patients receiving FGAs, and more frequently with chlorpromazine and thioridazine. The onset is usually within the first 8 weeks of therapy. Agranulocytosis may initially manifest clinically as a local infection, with sore throat, leukoplakia, erythema, and ulcerations of the pharynx. These symptoms in any patient receiving antipsychotics should signal the immediate need for a WBC count. If either the WBC or ANC falls below these parameters, the drug should be discontinued immediately and the patient monitored closely for the development of secondary infections. Isolated rare cases of thrombocytopenia and eosinophilia have been reported.

Agranulocytosis with clozapine significantly limits the clinical utility of this agent. Data on the incidence since the release of clozapine in February 1990 following stringent monitoring guidelines reveal that the 1-year treatment risk of developing agranulocytosis with clozapine is approximately 0.8%, and the 18-month risk is 0.91%.⁹⁹ Increasing age and female gender are associated with greater risk. Based on available data, the time period for greatest risk appears to be between months 1 and 6 of treatment, and weekly WBC monitoring for the first 6 months of therapy is mandated in the FDA-approved product labeling.¹⁰⁰ After the first 6 months, the labeling allows the frequency of WBC monitoring to be decreased to every 2 weeks. If the total WBC count drops to less than 2,000/mm³, or the ANC is less than 1,000/mm³, clozapine should be discontinued and the patient monitored closely. Some clinicians have used the granulocyte colony-stimulating factor filgrastim with hopes of improving the outcome by hastening resolution or decreasing morbidity. One case series that used filgrastim (starting dose of 300 mcg/day SC, increased by 300 mcg/day until 900 mcg/day is reached, and then continued until the agranulocytosis is resolved) demonstrated a decrease in time to resolution and decreased intensive care bed costs when compared to historical controls.¹⁰¹ In cases of mild to moderate neutropenia (granulocytes between 2,000/mm³ and 3,000/mm³, or ANC between 1,000/mm³ and 500/mm³), which occurs in up to 2% of patients, clozapine should be discontinued with daily monitoring of complete blood counts until values return to normal.

■ Dermatologic System

Allergic reactions are rare and usually occur within 8 weeks of initiating therapy, manifesting as maculopapular, erythematous, pruritic rashes that are evident on the face, neck, trunk, or extremities. Drug discontinuation and topical steroids are recommended. Contact dermatitis, including the oral mucosa, may occur in patients or medical personnel. For patients, mixing the antipsychotic concentrate in a sufficient quantity of a nonacidic liquid and swallowing it quickly decreases problems in susceptible patients. Care should be taken in the handling and preparation of liquid FGAs.

Phenothiazine structures can absorb ultraviolet light and energy, resulting in the formation of free radicals, which can have damaging effects on the skin. Both SGAs and FGAs cause photosensitivity. Erythema and severe sunburns can occur. Exposure to sunlight should be limited, and patients should be educated about the use of a maximally blocking sunscreen, hats, protective clothing, and sunglasses.¹⁰²

Blue-gray or purplish skin coloration in areas exposed to sunlight occurs in patients receiving higher doses of low-potency phenothiazines during long-term administration, especially with chlorpromazine. It commonly occurs with concurrent corneal or lens pigmentation.

■ Miscellaneous Adverse Effects

A particularly curious and sometimes troubling side effect with clozapine is sialorrhea, which may occur in up to 54% of patients taking clozapine. The mechanism of clozapine-induced drooling is unclear, although α -adrenergic blockade and muscarinic₄ receptor agonism have been suggested as potential etiologies. α -Agonists such as clonidine and antimuscarinics such as benztropine have been suggested as potential treatments.¹⁰³

■ TOXICITY WITH OVERDOSE

Acute overdose with antipsychotics rarely results in serious symptomatology. Mild intoxication manifests as sedation, hypotension, and miosis, whereas with severe intoxication, agitation and delirium may typically progress to motor retardation, seizures, cardiac arrhythmias, respiratory arrest, and coma. Dystonias and pseudoparkinsonism symptoms also occur. Supportive measures, gastric lavage, and activated charcoal are recommended. Induction of emesis may be difficult because of effects on the chemoreceptor trigger zone, and dialysis is ineffective because of the degree of drug-protein binding. Phenytoin or sodium bicarbonate are useful in the treatment of quinidine-like cardiac conduction effects on the QRS or QTc intervals. Physostigmine is not generally recommended to reverse anticholinergic toxicity because of deleterious effects on arrhythmias and seizure threshold.¹⁰⁴

■ USE IN PREGNANCY AND LACTATION

Minimal data exist regarding the effects of pregnancy on schizophrenia. However, the disorganized thought processes, impaired cognition, and negative symptoms can have a detrimental effect on the functioning and self-care of the mother, and therefore adversely affect the fetus.¹⁰⁵ Currently available data assessing the risk of teratogenesis with antipsychotic agents are insufficient. Epidemiologic studies show a slightly increased risk of birth defects with low-potency FGAs. Haloperidol is the best studied of all antipsychotics, and no relationship between its use and teratogenicity has been found. SGAs have been inadequately studied. However, concern has been expressed regarding the use of clozapine in pregnancy.¹⁰⁶ The weight gain associated with olanzapine and clozapine and potential risk of gestational diabetes should be considered in drug selection.

The risk of antipsychotic use must be weighed against the benefits of pharmacotherapy in pregnant women who may be experiencing disorganized thoughts, delusions about change in body image or pregnancy, or who are unable to provide adequate prenatal care.¹⁰⁵ Other potential but largely unknown risks of antipsychotics throughout pregnancy are the possibility of behavioral teratogenicity on the neonate, receptor changes, perinatal effects (e.g., tonicity, strength, and sucking), extrapyramidal side effects, jaundice, respiratory depression, and intestinal obstruction.

Antipsychotics appear in breast milk with milk:plasma ratios of 0.5 to 1. However, 1 week after delivery, clozapine milk

concentrations have been found to be as much as 279% of serum concentrations. Its use during breast-feeding is not recommended.¹⁰⁶ Overall, little is known about breast-feeding and the potential effects of antipsychotics on the neonate. Although not contraindicated, the lowest dosage should be used in the mother, and the infant should be carefully monitored.

■ DRUG INTERACTIONS

Although drug interactions may occur through a variety of mechanisms, most occur because of pharmacodynamic or pharmacokinetic interactions. Common examples of pharmacodynamic interactions resulting in enhanced effect include the excess sedation that can occur when antipsychotics are used concomitantly with other medications that have sedative side effects (e.g., mood stabilizers, hypnotics, alcohol, antidepressants, anxiolytics, or antihistamines).

Additive antimuscarinic effects of antipsychotics used with other medications with antimuscarinic effects (e.g., antihistamines, antidepressants, or antiparkinsonism agents) may result in urinary retention, constipation, blurred vision, or other anticholinergic side effects.³⁰ Both combined sedative and anticholinergic effects from multiple medications may result in impaired cognition, particularly in the elderly and other patients predisposed to such problems.⁶³ Patients may be more likely to experience symptomatic orthostatic hypotension when an antipsychotic is used with other medications that cause orthostasis (e.g., antidepressants with α -blockade, antihypertensive agents, or diuretics). Although metoclopramide is a commonly prescribed medication for treating esophageal reflux, it is a DA antagonist, and patients are more likely to experience akathisia and other extrapyramidal side effects if it is used concomitantly with antipsychotics.⁶³ Although some SSRIs may interact with antipsychotics through enzyme inhibition, they may also interact through pharmacodynamic mechanisms. 5-HT₂ receptors are present on the presynaptic dopaminergic neuron, and their activation leads to decreased dopamine release from the presynaptic terminal. Increased availability of serotonin through SSRI effect may activate these receptors, decrease dopamine release, and add to the dopaminolytic effects of antipsychotic agents.⁶³ Thus in the absence of enzyme inhibition, SSRIs may still precipitate akathisia or extrapyramidal side effects when added to a patient stabilized on an antipsychotic medication. A potentially more dangerous interaction may occur when medications that slow myocardial conduction (e.g., quinidine, procainamide, or tricyclic antidepressants), and thus prolong the QTc interval, are used in combination with antipsychotics that significantly prolong the QTc interval, such as ziprasidone, thioridazine, or mesoridazine.^{63,74,107} Medications that prolong the QTc interval should also be monitored carefully in patients taking concomitant diuretics.⁵⁹ These effects may all increase the risk of clinically significant side effects.

Although atypical antipsychotics may be affected to varying degrees by enzyme inhibitors and inducers, none of the available atypical antipsychotics have been shown to significantly affect the pharmacokinetics of other medications. Table 66–7 lists the major pathways thought to be involved in the metabolism of SGAs. Risperidone is metabolized primarily by CYP 2D6 to its active metabolite, 9-OH-risperidone, which is metabolized by the same pathway.⁵⁷ 9-OH-risperidone is thought to have a pharmacodynamic profile similar to risperidone. Paroxetine has been reported to increase the total risperidone plus active metabolite concentrations by 76% over the baseline. This was also associated with EPS in some individuals.¹⁰⁸ As indicated, SSRIs may also interact with antipsychotics through pharmacodynamic mechanisms. Carbamazepine has been reported to decrease risperidone plasma concentrations.¹⁰⁸

After single-dose administration, the mean bioavailability of quetiapine is 9% with significant interindividual variation.⁵⁷ If a CYP 3A4 inhibitor (e.g., cimetidine, ketoconazole, nefazodone, grapefruit juice, or erythromycin) is added to quetiapine, increased side effects (e.g., sedation or orthostasis) may occur. Fluoxetine may also decrease clearance of a medication such as quetiapine metabolized through CYP 3A4. However, with fluoxetine, it is the long-acting metabolite norfluoxetine, and not fluoxetine, that is the primary inhibitor of 3A4 metabolism. If an enzyme inducer such as carbamazepine or St. John's wort is added to quetiapine, then decreased antipsychotic effects may occur.^{108,109}

Based on current information, inhibitors of CYP 1A2 have the greatest potential for causing interactions with olanzapine.¹⁰⁹ Examples include cimetidine, fluvoxamine, and fluoroquinolone antibiotics (e.g., ciprofloxacin) to varying degrees. To date, however, no serious inhibition interactions have been reported with olanzapine, which may be a result of olanzapine's wide therapeutic index. Carbamazepine has been reported to increase olanzapine elimination by as much as 50%.¹¹⁰ Cigarette smoking is a potent inducer of CYP 1A2, and one would expect lower mean olanzapine serum concentrations in smokers compared to nonsmokers.

Because of the risk of seizures with higher clozapine tissue concentrations, inhibition interactions with clozapine are potentially significant. In particular, fluvoxamine has been reported to increase clozapine serum concentrations by an average of two- to threefold and up to fivefold.^{111,112} Fluoxetine and erythromycin may increase clozapine serum concentrations in some patients, but to a lesser degree.¹¹⁰ Mean clozapine serum concentrations are reported to be 32% lower in smokers compared with nonsmokers.¹¹⁰ Carbamazepine may also induce clozapine metabolism and lead to lower serum concentrations.¹¹⁰

A study with the potent CYP 3A4 inhibitor ketoconazole showed minimal effects on ziprasidone single-dose pharmacokinetics, with only a 33% mean increase in the ziprasidone area under the time-versus-concentration curve.^{59,74} These results are consistent with data suggesting that aldehyde oxidase is the major metabolic pathway for ziprasidone, with only 30% to 35% being metabolized by CYP 3A4.^{59,113}

Modest elevations of aripiprazole serum concentration occur in the presence of ketoconazole or quinidine, which inhibit CYP 2D6 and 3A4, respectively. Carbamazepine has been reported to decrease aripiprazole serum concentrations.²⁶

Antidepressants are commonly used in combination with antipsychotics to treat depressive symptoms in individuals with schizophrenia. Different antidepressants have been reported to inhibit metabolism of different P450 pathways.¹¹⁰ Table 66–10 summarizes the potential metabolic drug interactions between antidepressants and SGAs. Potential enzyme inhibitor interactions with clozapine are the most clinically significant. Increased clozapine serum concentrations with a CYP 1A2 inhibitor such as fluvoxamine may precipitate seizures.¹¹⁰ With the newer atypical antipsychotics, enzyme inhibitors are more likely to cause side effects such as increased sedation, orthostatic hypotension, or increased risk of akathisia and other extrapyramidal side effects.

■ PHARMACOECONOMIC CONSIDERATIONS

It is estimated that approximately 80% of individuals suffering their first schizophrenic break will have recurrent episodes and significant lifetime psychosocial dysfunction. In 1994, the direct cost of treating schizophrenia in the United States was estimated to be \$45 billion.¹¹⁴ The public mental health care sector provides the majority of services for individuals with schizophrenia. Mental health care costs

TABLE 66–10. Antidepressant/Antipsychotic P450 Inhibitor Drug Interactions

| Inhibitor (Inhibits Substrate) | Substrate (Drug Metabolized By Pathway) | | |
|--|--|--|--|
| | 1A2 | 2D6 | 3A3/4 |

| Paroxetine (Paxil) | | PHENOTHIAZINES, Risperidone, Aripiprazole Phenothiazines | |
| Sertraline (Zoloft) | | | Clozapine, Quetiapine, Ziprasidone ^a |

The inhibitor drug inhibits the metabolism of the substrate drug; therefore increasing the amount of substrate drug in the body, and the potential for side effects from the substrate drug. Bold type and capital letters reflect the relative potential for the interaction to be clinically significant (i.e., **HIGH, Moderate, Low**).

^aIndicates that this is a minor pathway for this substrate, and therefore the possibility of a clinically significant interaction through this pathway is decreased.

for schizophrenia represent disproportionate expenditures for crisis intervention and hospitalization as compared to comprehensive outpatient services oriented toward maintaining remission and improving psychosocial functioning. The suboptimal or inadequate funding provided for efficient ambulatory mental health services further increases the demand for hospitalization, which diverts additional revenues that might be available for outpatient services. This has created a vicious revolving door cycle and is a major challenge facing public mental health care.

The advent of more expensive SGAs, accompanied by limited resources, has forced mental health care organizations to examine the outcomes and related economics of treating patients with the SGAs compared with the traditional, largely generic FGAs. Although medication costs are higher with SGAs than with FGAs, studies with various SGAs have fairly consistently shown total mental health costs

to be no higher or even lower with SGAs.¹¹⁴ Similarly, some studies have shown clozapine to result in lower overall mental health care costs, while others have shown no difference in costs compared to FGAs. Additionally, clozapine decreases suicidality more than comparator antipsychotics, and it is more effective in treatment-resistant schizophrenia.^{115,116}

Of greater debate is whether differences in cost-effectiveness exist among the SGAs. Significant differences in acquisition costs among the SGAs have produced controversy regarding formulary decisions in organized health care settings.¹¹⁴ For example, although olanzapine has a higher acquisition cost, some studies have found no difference in total mental health care direct costs (i.e., medications plus services) when comparing olanzapine and risperidone.^{114,117} However, these findings are inconsistent, and the comparative pharmacoeconomics of SGAs remain controversial.¹¹⁴

EVALUATION OF THERAPEUTIC OUTCOMES

Assessment of response has traditionally been done subjectively or empirically (a relative sense of how the clinician feels the patient is doing). A formal mental status examination (MSE) is used to structure the patient interview and focus on items related to appearance, mood, sensorium, intellectual functioning, and thought processes. However, the MSE is not specific for the measurement of drug response. Clinicians should be trained to use simple, standardized psychiatric rating scales to assist in objectively rating patient drug responses.^{20,22,118} The brief psychiatric rating scale (BPRS) and the Positive and Negative Symptom Scale (PANSS) were developed for use in clinical trials as research tools to quantify symptoms and improvement seen with antipsychotic treatment.¹¹⁸ Objectively, the use of a numeric indicator (e.g., 20%, 30%, or 40% reduction in BPRS score) has been used to quantify overall symptom reduction and classify patients according to different degrees of response. However, these types of rating scales are too long and unwieldy to be routinely used within the time constraints of most clinical practices. Symptom scales used in clinical practice must be sufficiently brief to be used during an ordinary clinic visit (e.g., 15 to 30 minutes) while measuring both positive and negative symptoms, and being sufficiently

representative of overall symptomatology. The four-item Positive Symptom Rating Scale and the Brief Negative Symptom Assessment are brief scales that meet such criteria (Fig. 66–2).^{22,118} It is increasingly recognized that clinicians should be examining cognition as an outcome in treatment of schizophrenia. Although multiple lengthy research batteries are available, brief, simple assessments have not been readily available. However, a brief cognition battery has recently been developed and validated, and it can be completed in 15 to 20 minutes.¹¹⁹

Similarly, the pharmacotherapeutic plan should include specific monitoring parameters for potential side effects. The plan should include the side effects to be monitored (e.g., EPS and weight increase), how the potential side effect will be evaluated, and the frequency of assessment (e.g., daily or weekly). Given the risk of weight gain, diabetes, and lipid abnormalities associated with many of the SGAs, a consensus task force led by the American Diabetes Association recommends the following baseline parameters before beginning antipsychotics: family history, weight, height, body mass index, waist circumference, blood pressure, fasting plasma glucose, and fasting lipid profile.⁶⁹ They also recommend follow-up monitoring of these parameters after beginning or changing SGAs. Weight should be monitored monthly for the first 3 months, and quarterly thereafter. The

FIGURE 66–2. Brief clinical assessments for monitoring antipsychotic response in schizophrenia. To enhance consistency in ratings, the structured probes in the administration manual should be used each time the scales are used. (Data from Miller et al²² and Miller et al.¹¹⁸ The complete administration manual for the Positive Symptom Rating Scale and the Brief Negative Symptom Assessment can be accessed from the appendices in the TIMA Procedure Manual: Schizophrenia Module at <http://www.dshs.state.tx.us/mhprograms/timaszman.pdf>. This rating scale is in the public domain and may be reproduced with appropriate citation of the authors and source.)

other parameters should be assessed at the end of 3 months and then annually. If normal, serum lipids can be monitored less often.

Self-assessments can be a useful adjunct in treating the patient. Although the patient with schizophrenia may not always be accurate in evaluating symptom severity (in fact, just the opposite may occur), the use of patient self-assessments increases patient engagement in care, enhances therapeutic alliance, and gives the clinician an opportunity to identify misconceptions the patient may have regarding symptoms associated with the illness, medication side effects, and the like.^{40,42,118} Traditionally, clinicians have often accepted partial symptom response in schizophrenia as success, and have not been aggressive in attempting to achieve greater symptomatic remission. In many respects the side-effect profile of FGAs encouraged the acceptance of partial response and a tendency to not “rock the boat” in a patient with partial improvement. However, the advent of multiple different SGAs with varying, but overall favorable, side-effect profiles should encourage clinicians to be more assertive in attempting to achieve symptom remission.

CONCLUSIONS

Schizophrenia is a complex disease with multiple ramifications for patients and their families. Treatment issues remain clouded by the fact that the etiology of the illness is unknown. It is clear, however, that no single treatment modality is adequate to properly manage a patient with schizophrenia. Antipsychotics are the bedrock of treatment. SGAs have substantially advanced the care of people with schizophrenia. However, notwithstanding such advances, the SGAs are not a panacea and have multiple adverse effects in addition to the limitations of their efficacy. However, when used within the context of multidisciplinary treatment, SGAs improve positive and negative symptoms and cognition so that patients can appropriately participate in psychosocial rehabilitation programs. Scientific advances continue to expand our understanding of CNS physiology and the abnormali-

ties present in schizophrenia. Advances in our understanding of the pathophysiology of schizophrenia should, in turn, result in the development of treatments that are more specific and more effective. In practice, it is mandatory that clinicians appropriately use their expanding armamentarium. It is important that clinicians appreciate the pharmacodynamic basis for treatment interventions so that they can effectively design and implement rational pharmacotherapeutic regimens. Finally, it is critical that clinicians more objectively evaluate individual patient response to medication so that treatment can be optimized. With these strategies, the gap between practice and science can be narrowed and patients’ lives benefited.

DEPRESSIVE DISORDERS

Judith C. Kando, Barbara G. Wells, and Peggy E. Hayes

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 When counseling patients with depression who are receiving pharmacotherapeutic interventions, the patient should be informed that adverse effects might occur immediately, while resolution of symptoms may take 2 to 4 weeks.
- 2 When evaluating a patient for the presence of depression, it is essential to rule out medical causes of depression and drug-induced depression.
- 3 The goal of pharmacological treatment of depression is the resolution of current symptoms and the prevention of further episodes of depression.
- 4 When determining if a patient has been nonresponsive to a particular pharmacotherapeutic intervention, it must be determined whether the patient has received an adequate dose for an adequate duration. If tricyclic antidepressants are being used, a serum level may be useful, especially in special populations such as the elderly, and those with concurrent medications that may alter the pharmacokinetic profile of the TCAs.
- 5 Childhood depression occurs commonly and can present with nonspecific symptoms. The dosage range, titration, and adverse effects of fluoxetine, imipramine, and sertraline are similar in children and adults.
- 6 An assessment of compliance should be made with every patient interaction. Remember that accurate capsule or tablet counts do not mean the patient has consumed the medication or consumed it in the manner prescribed.
- 7 If a patient exhibits a partial response to a pharmacotherapeutic agent, augmentation therapy should be considered before the trial is abandoned and the patient is treated with an alternative therapeutic agent.
- 8 When evaluating response to an antidepressant agent, in addition to target signs and symptoms, consider quality-of-life issues such as role, social functioning, and occupational function. In addition, the tolerability of the agent should be assessed because the occurrence of side effects may lead to nonadherence to the regimen.

Major depressive disorder is a disorder of mood in which the individual experiences one or more major depressive episodes without a history of manic, mixed, or hypomanic episodes. A major depressive episode is defined by the criteria listed in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed., Text Revision (DSM-IV-TR), published by the American Psychiatric Association.¹ Depression is associated with significant functional disability, morbidity, and mortality.

Newer generations of antidepressants have provided pharmacological interventions that are effective and better tolerated than older agents like the tricyclic antidepressants (TCAs) and the monoamine oxidase inhibitors (MAOIs). In addition, substantial efforts have been undertaken to improve the ability of clinicians to recognize the signs and symptoms of depression and to treat. This chapter focuses exclusively on the diagnosis and treatment of major depressive disorder.

EPIDEMIOLOGY

The true prevalence of depressive disorders in the United States is unknown. The National Comorbidity Survey Replication recently found that 16.2% of the population studied had a history of major depressive disorder in their lifetime, and more than 6.6% had an episode within the past 12 months.² Women are at increased risk of depression from early adolescence until their mid-50s, with a lifetime rate of depres-

sion that is 1.7 to 2.7 times greater than for men.³ Although depression can occur at any age, adults 25 to 44 years of age experience the highest rates of major depression.⁴ The estimated lifetime prevalence of major depression in individuals aged 65 to 80 recently was reported to be 20.4% in women and 9.6% in men.⁵ Depressive disorders are common during adolescence, with comorbid substance abuse, suicide attempts, and deaths occurring frequently in these young patients.^{6,7} Depressive disorders and suicide tend to occur within families, and first-degree relatives of patients with depression are 1.5 to 3 times more likely to develop depression than normal controls.^{1,8,9} Approximately 8% to 18% of patients with major depression have at least one first-degree relative (father, mother, brother, or sister) with a history of depression, compared with 5.6% of the first-degree relatives of a normal control group.⁸ A twin study found that the heritability of liability for major depression was 39% and was the same in men and women, whereas the remaining 61% of the variance in liability was due to individual-specific environment.¹⁰ Therefore major depressive disorder is relatively common, occurs more frequently in women than men, and prevalence is influenced by both genetic and environmental factors.

ETIOLOGY

The etiology of depressive disorders is too complex to be totally explained by a single social, developmental, or biologic theory. Several

factors appear to work together to cause or precipitate depressive disorders. The symptoms reported by patients with major depression consistently reflect changes in brain monoamine neurotransmitters, specifically norepinephrine (NE), serotonin (5-HT), and dopamine (DA).^{11–13}

PATHOPHYSIOLOGY

BIOGENIC AMINE HYPOTHESIS

The biogenic amine hypothesis evolved as a result of several observations made in the early 1950s. It was noted that the antihypertensive drug reserpine depleted neuronal storage granules of NE, 5-HT, and DA and produced clinically significant depression in 15% or more of patients.¹⁴ In addition, it was discovered that the hallucinogen lysergic acid diethylamide blocked peripheral serotonin receptors, and it was proposed that the mind-altering effects of lysergic acid diethylamide were secondary to similar effects on central nervous system (CNS) serotonin receptors.¹³

Therefore, several years before the introduction of antidepressants, the cause of depression was linked to decreased brain levels of the neurotransmitters NE, 5-HT, and DA, although the actual cause remains unknown. Although the reuptake blockade of monoamines (e.g., NE and 5-HT) occurs immediately upon administration of an antidepressant, the clinical antidepressant effects generally are not observed until after 4 weeks of dosing.¹⁵ The reason for this delay in onset of action has caused researchers to focus on the adaptive changes induced by antidepressants, as discussed below.¹²

THEORIES OF POSTSYNAPTIC CHANGES IN RECEPTOR SENSITIVITY

A more perplexing aspect of the observed effects of antidepressants is the discrepancy between monoamine reuptake blockade (immediate) and any measurable improvement in depressive symptoms (delayed therapeutic response). Accordingly, theories that focus on adaptive (or chronic) changes in amine receptor systems compared with acute changes have emerged over the past decade.

In the mid-1970s it was recognized that chronic, but not acute, administration of antidepressants to animals caused desensitization of NE-stimulated cyclic adenosine monophosphate synthesis. In fact, for most antidepressants, downregulation of β -adrenergic receptors accompanies this desensitization.¹⁶

Studies of many antidepressants have demonstrated that either desensitization or downregulation of NE receptors corresponds to a clinically relevant time course for antidepressant effects.¹¹ Other studies have revealed downregulation of 5-HT₂ receptors following chronic administration of antidepressants.^{17,18} Thus a theory based on postsynaptic changes in receptor sensitivity provides a cogent explanation of the delayed onset of activity of antidepressant drugs.¹¹

DYSREGULATION HYPOTHESIS

The dysregulation hypothesis incorporates the diversity of antidepressant activity with the adaptive changes occurring in receptor sensitization over several weeks.¹⁹ In this theory, emphasis is placed on a failure of homeostatic regulation of neurotransmitter systems rather than on absolute increases or decreases in their activities.¹⁵ According to this hypothesis, effective antidepressant agents restore efficient regulation to the dysregulated neurotransmitter system.^{19,20}

5-HT/NE LINK HYPOTHESIS

It is apparent that no single neurotransmitter theory of depression is adequate. The 5-HT/NE link hypothesis maintains that both the serotonergic and noradrenergic systems need to be functional for an antidepressant effect to be exerted.^{12,17} The 5-HT/NE link hypothesis is also consistent with the rationale of the postsynaptic alteration theory of depression, which emphasizes the importance of β -adrenergic receptor downregulation for achieving an antidepressant effect.¹⁶ Again, it has been proposed that both NE and 5-HT are necessary for homologous desensitization of central β -adrenergic receptors by antidepressants.¹⁷

ROLE OF DA IN DEPRESSION

Traditional explanations of the biologic basis of depressive disorders have focused largely on NE and 5-HT; however, most of the evidence that coalesced into the biogenic amine hypothesis of depression does not clearly distinguish between NE and DA.²¹

Several reviews suggest that increased DA neurotransmission in the nucleus accumbens may represent a final common pathway for at least part of the mechanism of action of antidepressant medications.²² The mechanisms by which antidepressant drugs sensitize DA transmission remain unclear, but may be mediated indirectly by primary actions at NE or 5-HT terminals.

The evidence supporting a dopaminergic mechanism of antidepressant action is entirely preclinical, and clinical studies evaluating the role of DA mechanisms in the action of classical antidepressants have not been conducted.²¹

The complexity of the interaction between 5-HT, NE, and possibly DA is gaining greater appreciation, but a more in-depth understanding of the precise mechanism is needed.

BIOLOGIC MARKERS

Investigators continue to search for biologic or pharmacodynamic markers to assist in the diagnosis and treatment of depressed patients. Although no biologic marker has been discovered, several biologic abnormalities are present in many depressed patients. Approximately 45% to 60% of patients with major depression have a neuroendocrine abnormality, including hypersecretion of cortisol, lack of cortisol suppression after dexamethasone administration (i.e., a positive dexamethasone suppression test), or an abnormal or diminished thyroid-stimulating hormone response to the administration of thyrotropin-releasing hormone. The dexamethasone suppression test is the most specific measure of hypothalamic-pituitary-adrenal axis overactivity. Dexamethasone administration suppresses adrenal corticosteroid production in normal subjects for 24 hours. Failure of dexamethasone to suppress plasma cortisol concentrations indicates overactivity or dysregulation of the hypothalamic-pituitary-adrenal axis. Unfortunately, the high rate of false-positive and false-negative results limits the usefulness of testing for these markers, and has led to their relative lack of use in clinical practice.

Sleep studies in patients with major depression have identified several abnormalities that become more pronounced with advancing age. In depressed patients, the onset of rapid eye movement (REM) sleep occurs earlier during sleep (decreased REM latency) and there is a shift of REM sleep to the first half of the night. There also may be a decrease in slow-wave sleep (stages 3 and 4), increased awakenings during sleep, and early morning awakening.²³ Sleep abnormalities occur in other psychiatric disorders and are not diagnostic for major depression.

CLINICAL PRESENTATION

2 When a patient has depressive symptoms, it is necessary to investigate the possibility of a medical, psychiatric, and/or drug-induced cause (Table 67–1).²⁴ Up to 25% of patients with chronic medical conditions (e.g., diabetes, myocardial infarction, carcinoma, or stroke) develop major depression during the course of their medical condition, and the depression often is not accurately diagnosed, especially in the elderly.²⁵

All depressed patients should have a complete physical examination, mental status examination, and basic laboratory work-up, including a complete blood count with differential, thyroid function tests, and electrolyte determinations to identify any potential medical problems. A complete medication review should be performed because many drugs may precipitate or worsen a depressive episode (see Table 67–1).

A patient diagnosed with major depressive disorder can expect to have one or more episodes of major depression during their lifetime. According to the DSM-IV-TR a single major depressive episode is characterized by five or more of the symptoms described in Table 67–2. At least one of the symptoms is depressed mood (often an irritable mood in children or adolescents) or loss of interest or pleasure in nearly all activities.¹ These symptoms must have been present nearly every day for at least 2 weeks and must represent a change from the patient’s previous level of functioning. The clinician must consider presenting symptoms, their duration, and the patient’s current level of social, occupational, or other important areas of functioning. Significant stressors or life events may trigger depression in some individuals but not others; and there may be an important precipitant at the beginning of the disorder.^{1,13}

EMOTIONAL SYMPTOMS

A major depressive episode is characterized by a persistent, diminished ability to experience pleasure. A loss of interest and pleasure in usual activities, hobbies, or work is common. Patients appear sad or

depressed, and they are often pessimistic and believe that nothing will help them feel better. The presence of intense hopelessness and complete or near-total loss of interest and pleasure in usual activities may identify patients at risk for suicide.²⁶ Anxiety symptoms are present in almost 90% of depressed outpatients.

Patients often have guilt feelings that are unrealistic, and these may reach delusional proportions. Patients may feel that they deserve punishment and may view their present illness as a punishment. A patient suffering from major depression with psychotic features may hear voices (auditory hallucinations) saying that he or she is a bad person and that he or she should commit suicide. Depression with psychotic features may require hospitalization, especially if the patient becomes a danger to self or others.

PHYSICAL SYMPTOMS

Physical symptoms often motivate patients, especially the elderly, to seek medical attention. Chronic fatigue is a common complaint, with a decreased ability to perform normal daily tasks. Fatigue often appears worse in the morning and does not improve with rest. Complaints of pain, especially headache, often accompany fatigue.

Sleep disturbances generally present as frequent early morning awakening (terminal insomnia), with difficulty returning to sleep. This may coexist with difficulty falling asleep (initial insomnia) and frequent nighttime awakening. Less frequently, depressed patients complain of increased sleep (hypersomnia), although they experience daytime exhaustion or fatigue.

Appetite disturbances, including complaints of decreased appetite, often result in substantial weight loss, especially in the elderly.²⁵ Some patients lose 2 pounds or more per week without dieting. Other patients, especially in the ambulatory setting, may overeat and gain weight, although they actually may not enjoy eating. They may crave specific foods.

Some patients exhibit gastrointestinal complaints, others cardiovascular complaints, especially palpitations. Patients frequently present with a loss of sexual interest or libido.

TABLE 67–1. Common Medical Disorders, Psychiatric Disorders, and Drug Therapy Associated With Depression

| Medical disorders | Metabolic disorders | Psychiatric disorders |
|-------------------------------|--------------------------|--------------------------------------|
| Endocrine diseases | Electrolyte imbalance | Alcoholism |
| Hypothyroidism | Hypokalemia | Anxiety disorders |
| Addison’s disease | Hyponatremia | Eating disorders |
| Cushing’s disease | Hepatic encephalopathy | Schizophrenia |
| Deficiency states | Cardiovascular disease | Drug therapy |
| Pernicious anemia | Coronary artery disease | Antihypertensives |
| Wernicke’s encephalopathy | Congestive heart failure | Clonidine |
| Severe anemia | Myocardial infarction | Diuretics |
| Infections | Neurologic disorders | Guanethidine sulfate |
| AIDS | Alzheimer’s disease | Hydralazine hydrochloride |
| Encephalitis | Epilepsy | Methyldopa |
| Influenza | Huntington’s disease | Propranolol |
| Mononucleosis | Multiple sclerosis | Reserpine |
| Sexually transmitted diseases | Pain | Hormonal therapy |
| Tuberculosis | Parkinson’s disease | Oral contraceptives |

TABLE 67–2. DSM-IV-TR Criteria for Major Depressive Episode

- A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.
- Note:** Do not include symptoms that are clearly due to a general medical condition or mood-incongruent delusions or hallucinations.
1. Depressed mood most of the day nearly every day
 2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day nearly every day
 3. Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day
 4. Insomnia or hypersomnia nearly every day
 5. Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down)
 6. Fatigue or loss of energy nearly every day
 7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day
 8. Diminished ability to think or concentrate, or indecisiveness, nearly every day
 9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide
- B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- C. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hypothyroidism).
- D. The symptoms are not better accounted for by bereavement (i.e., after the loss of a loved one), the symptoms persist for longer than 2 months or are characterized by marked functional impairment, morbid preoccupation with worthlessness, suicidal ideation, psychotic symptoms, or psychomotor retardation.

Modified and reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, 4th ed., Text Revision. Washington, American Psychiatric Association, 2000.

INTELLECTUAL OR COGNITIVE SYMPTOMS

Intellectual or cognitive symptoms include a decreased ability to concentrate, slowed thinking, and a poor memory for recent events. Patients may appear confused and indecisive. Depression should be considered when cognitive symptoms are present in the elderly.²⁵

PSYCHOMOTOR DISTURBANCES

Patients may appear noticeably slowed or retarded in physical movements, thought processes, and speech (psychomotor retardation). Conversely, depression may be accompanied by psychomotor agitation, manifesting as purposeless, restless motion (e.g., pacing, wringing of hands, or outbursts of shouting).

SUICIDE RISK EVALUATION AND MANAGEMENT

Suicide is the eighth leading cause of death in the United States, and most patients who committed suicide were suffering from depression around the time of their death.²⁷ All patients suffering from major depression should be assessed for suicidal thoughts. Widely held myths regarding suicide include the belief that people are more likely to commit suicide if they are asked about it, that people who attempt or talk about suicide are just looking for attention and are not serious, that suicidal people are crazy, and that most suicides are caused by a sudden traumatic event.

Factors that increase the risk for suicide include increasing age, being widowed, being unmarried, being unemployed, living alone, a history of a previous psychiatric admission, substance abuse, depression, feelings of hopelessness, prior attempts, family history of suicide, anniversary of a loss, presence of a serious medical problem, lack of a social support system, and refusal to seek help.²⁶ The presence of a very detailed plan with the intention and ability to carry it out indicates a high risk of suicide. Although women attempt suicide two to three times more often than men, men succeed about three times more frequently. Suicide is almost twice as common in the elderly as in the general population.²⁸ This appears to be a result of more determination, carefully planned acts, and fewer warning signs.²⁸ To assess the severity of suicidal thoughts, the clinician must be sensitive to hints of suicidal ideation, including a change in personality, a sudden decision to make a will or give away possessions, and any recent purchase of a gun or obtaining (or hoarding) a large supply of medications or other potentially toxic substances. It is important to remember that the risk of suicide in those recovering from major depression may increase as they develop the energy and capacity to act on a plan made earlier in a course of illness. It is not always possible to predict whether or when a depressed person will attempt suicide.

When suicidal intent is suspected, it is important to ask, “Are you thinking about harming or killing yourself?” If the risk is significant, the patient must be referred immediately to an appropriate health care professional.

► TREATMENT: Depressive Disorders

■ DESIRED OUTCOME

◀ The goals of treatment are to reduce the symptoms of acute depression, facilitate the patient’s return to a premorbid level (before the onset of the illness) of functioning, and prevent further episodes of depression. Whether or not to hospitalize the patient is often the first decision that is made in consideration of the patient’s risk of suicide, physical state of health, social support system, and presence of a psychotic and/or catatonic depression.

■ GENERAL APPROACH TO TREATMENT

Studies have found that antidepressants are of equivalent efficacy when administered in comparable doses. Because one cannot predict which antidepressant will be the most effective in an individual patient, the initial choice is made empirically. Factors that often influence the choice of an antidepressant include the patient’s history of response, pharmacogenetics (history of familial antidepressant response), subtype of depression, patient’s concurrent medical history,

potential for drug-drug interactions, adverse events profile, and drug cost.

Although the pathophysiology of major depression remains elusive, the clinician can now select from multiple drug therapies with different mechanisms of action.²⁹ Failure to respond to one antidepressant class or one antidepressant drug within a class does not predict a failed response to another drug class or another drug within the class.

Approximately 65% to 70% of patients with varying types of depression improve with drug therapy, compared with 30% to 40% who improve with placebo. A preferential response to MAOIs has been reported in patients with atypical depression.³⁰ In atypical depression, two or more of the following are present: (1) weight gain or increase in appetite, (2) hypersomnia, (3) heavy feelings in arms or legs, and (4) interpersonal rejection sensitivity. Depressed individuals with psychotic symptoms should be treated with an antidepressant plus an antipsychotic agent or electroconvulsive therapy (ECT).³¹

■ NONPHARMACOLOGIC THERAPY

In addition to pharmacologic interventions, psychotherapy should be employed whenever the patient is able and willing to participate. Psychotherapy alone is not recommended for the acute treatment of patients with severe and/or psychotic major depressive disorder. However, if the depressive episode is mild to moderate in severity, psychotherapy may be the first-line therapy.³² The effects of psychotherapy and antidepressant medications are considered to be additive. Combined treatment may be advantageous for patients with partial responses to either treatment alone and for those with a chronic course of illness. However, for uncomplicated, nonchronic major depressive disorder, combined treatment may provide no unique advantage.³² Although not extensively evaluated, cognitive therapy, behavioral therapy, and interpersonal psychotherapy appear equally effective.³² Maintenance psychotherapy as the sole treatment to prevent recurrence generally is not recommended. Often, medication alone may prevent a depressive recurrence during the maintenance phase.³²

ECT is a safe and effective treatment for certain severe mental illnesses, including all subtypes of major depressive disorder as well as other selected psychiatric illnesses.

Patients are candidates for ECT when a rapid response is needed, risks of other treatments outweigh potential benefits, there is a history of poor response to drugs and a good response to ECT, and the patient expresses a preference for ECT.³³

A course of ECT generally consists of 6 to 12 treatments administered either unilaterally or bilaterally two to three times weekly. A rapid therapeutic response (10 to 14 days) has been reported. Although there are no absolute contraindications to the use of ECT, several conditions are associated with increased risk. These include increased intracranial pressure, cerebral lesions, recent myocardial infarction, recent intracerebral hemorrhage, bleeding, or otherwise unstable vascular condition. The use of an anesthetic as well as a nondepolarizing neuromuscular blocking agent decreases the morbidity associated with ECT.³³

Adverse effects of ECT include cognitive dysfunction, cardiovascular dysfunction, prolonged apnea, treatment-emergent mania, headache, nausea, and muscle aches. Cognitive changes associated with ECT include confusion immediately after the seizure and retrograde and anterograde memory disturbance. Most cognitive disturbances are transient, but some patients may report permanent loss of

memory for events occurring over the months before, after, or during treatment.³³

Relapse rates during the year immediately following ECT are high unless maintenance antidepressant medication is prescribed. Guidelines developed by the American Psychiatric Association include indications and contraindications for the appropriate use of ECT, procedures for obtaining informed consent, and issues in administering ECT.³³

Some individuals experience depressive episodes during a particular season of the year. This condition is referred to as *seasonal affective disorder* (SAD) and occurs most commonly in the winter, with remission in spring or summer.³⁴ Reduced environmental light may be the main precipitating factor of winter depression,³⁴ and may result from a disturbance of the circadian rhythm caused by desynchronization between the solar clock and the human biologic clock during short photoperiods.³⁴ Bright-light therapy is used to resynchronize the disturbed rhythm,^{35–37} and requires the patient to gaze into a light box in the morning or evening for approximately 2 hours.³⁶ Some individuals will require antidepressant therapy in addition to light therapy or antidepressants for nonseasonal episodes of major depression.

Light therapy is well tolerated, with minor visual complaints being the most frequently reported event.³⁶ Consequently, anyone undergoing light therapy should receive baseline and periodic eye examinations.

■ PHARMACOLOGIC THERAPY

4 Antidepressants can be classified in several ways, including by chemical structure and the presumed mechanism of antidepressant activity. Although the link between the presumed mechanism of drug action and antidepressant response is tenuous, this classification has the advantage of being based on established pharmacology and clearly explains some of the common, but expected, adverse effects. The knowledgeable clinician can use these facts to tailor treatment to individual patient needs and thereby optimize treatment outcome. Currently available antidepressants and initial dosages are shown in Table 67–3.

■ MIXED SEROTONIN AND NOREPINEPHRINE REUPTAKE INHIBITORS

Although TCAs are effective in treating all depressive subtypes, especially the severe melancholic subtype of major depressive disorder, their use has diminished greatly due to the availability of equally effective therapies that are much safer and better tolerated. All TCAs potentiate the activity of NE and 5-HT by blocking their reuptake. However, the potency and selectivity of TCAs for the inhibition of reuptake of NE and 5-HT vary greatly among these agents (Table 67–4). Because TCAs affect other receptor systems including the anticholinergic, neurologic, and cardiovascular systems, adverse events are reported frequently during TCA therapy.³⁸

Venlafaxine, a structurally novel antidepressant, is a potent inhibitor of 5-HT and NE reuptake and a weak inhibitor of dopamine reuptake. Unlike the TCAs, it has virtually no affinity for muscarinic, histaminergic, and α_1 -adrenergic receptors.³⁹

Maprotiline and amoxapine are both inhibitors of NE reuptake, with less effect on 5-HT reuptake. Maprotiline is associated with

TABLE 67–3. Adult Dosages for Currently Available Antidepressant Medications^a

| Generic Name | Trade Name | Suggested Therapeutic Plasma Concentration (ng/mL) | Initial Dose (mg/day) | Usual Dosage Range (mg/day) |

a higher incidence of seizures than imipramine or amitriptyline.¹⁹ Amoxapine, while less sedating than some antidepressants, blocks cholinergic receptors, causing clinically significant anticholinergic effects.

■ **SELECTIVE SEROTONIN REUPTAKE INHIBITORS**

The efficacy of SSRIs is superior to placebo and equal to the TCAs in treating patients with major depression, and the SSRIs cause minimal anticholinergic effects.²⁹

■ **TRIAZOLOPYRIDINES**

Trazodone and nefazodone have dual actions on serotonergic neurons, acting as both 5-HT₂ antagonists and 5-HT reuptake inhibitors,⁴⁰ and they may enhance 5-HT_{1A}-mediated neurotransmission. These drugs have negligible affinity for cholinergic and histaminergic receptors. Trazodone’s use as an antidepressant agent has diminished secondary

to side effects (e.g., dizziness and sedation) and increased availability of alternative better-tolerated agents. Nefazodone also has low affinity for α₁-adrenergic receptors. The triazolopyridines are effective agents in treating major depression with no substantial evidence to support a unique spectrum of therapeutic activity.

■ **AMINOKETONE**

Bupropion, the only marketed aminoketone antidepressant, appears to have a unique mechanism of drug action.⁴¹ It has no appreciable effect on the reuptake of NE or 5-HT, and its most potent neurochemical action is blockade of DA reuptake.

■ **MIXED SEROTONIN-NOREPINEPHRINE EFFECTS**

Mirtazapine, a TCA, enhances central noradrenergic and serotonergic activity through the antagonism of central presynaptic α₂-adrenergic autoreceptors and heteroreceptors.⁴²

MONOAMINE OXIDASE INHIBITORS

MAOIs increase the concentrations of NE, 5-HT, and DA within the neuronal synapse through inhibition of the MAO enzyme. Studies have demonstrated that similarly to TCAs, chronic therapy causes changes in receptor sensitivity (i.e., downregulation of β-adrenergic, α-adrenergic, and serotonergic receptors).^{43,44} The MAOIs currently marketed in the U.S., phenelzine and tranlycypromine, are nonselective inhibitors of MAO A and MAO B.

ST. JOHN’S WORT

Increasingly, consumers are choosing alternative forms of therapy, such as herbal medications including St. John’s wort.^{45,46} Some evaluations have found that the active ingredient in St. John’s wort, hypericum, is a safe and effective treatment for mild to moderate depression^{45,46} when compared with placebo, TCAs, and fluoxetine.^{47,48} In most cases, side effects appear to be mild. St. John’s wort is available as an over-the-counter medication. Although this

may allow certain advantages such as reduced cost of therapy and self-treatment, it also has the potential to result in circumvention of the health care system. St. John’s wort has been found to have several significant drug interactions with medications used to treat human immunodeficiency virus (e.g., indinavir) and digoxin.⁴⁹ Perhaps most disconcerting is the fact that herbal medications are not regulated by the Food and Drug Administration (FDA), and manufacturers are not required to adhere to good manufacturing practices. St. John’s wort should be administered under the guidance of a clinician trained in the treatment of depression, and a single-source product should be used continuously from a reputable and trusted manufacturer.

CLINICAL CONTROVERSY

The treatment of depression with herbal agents or nutraceuticals remains controversial. Studies evaluating the efficacy of therapies such as St. John’s wort have been conflicting. In addition, concerns regarding the safety and integrity of the products have been raised.

■ ADVERSE EFFECTS

■ TCAs and Other Heterocyclics

The most commonly reported adverse effects of antidepressant therapy are summarized in Table 67–4. The TCAs affect several neurotransmitters and produce a wide range of pharmacologic actions, including many unwanted, but expected, adverse effects. The side effects most frequently associated with the TCAs (e.g., dry mouth, constipation, blurred vision, urinary retention, dizziness, tachycardia, memory impairment, and at higher doses, delirium) may result from blockade of cholinergic receptors.⁴³ These adverse effects often have an impact on patient compliance, particularly in the elderly and those receiving long-term maintenance therapy. A common and potentially problematic effect, orthostatic hypotension, has been attributed to the affinity of the TCAs for adrenergic receptors.⁵⁰ TCAs also cause cardiac conduction delays and may even induce heart block in patients with a preexisting conduction disorder. TCA overdose can produce severe arrhythmias.⁵⁰ Therefore caution should be exercised when prescribing these agents to patients with clinically significant cardiac disease. Other adverse effects that lead to patient non-compliance include weight gain, excessive perspiration, and sexual dysfunction.⁵⁰

Abrupt withdrawal of TCAs is often associated with symptoms suggestive of cholinergic rebound (e.g., dizziness, nausea, diarrhea, insomnia, and restlessness), especially if the daily dose exceeds 300 mg.^{51,52} Therefore the dose should be tapered over several days.

Amoxapine, the demethylated metabolite of loxapine, has intermediate sedative and anticholinergic potency.⁵¹ Because of its postsynaptic receptor DA-blocking effects, extrapyramidal side effects, including pseudoparkinsonism, dystonia, akathisia, and tardive dyskinesia have been reported.¹⁹ Amoxapine offers no advantage over standard TCAs or other antidepressants.

Maprotiline, a tetracyclic drug, blocks reuptake of NE with minimal effect on 5-HT. It has intermediate sedative and anticholinergic effects and may cause less orthostatic hypotension than imipramine; however, an exanthematous rash occurs in approximately 4% of patients.¹⁹ Maprotiline is also associated with a higher incidence of seizures than standard TCAs and is contraindicated in patients with a history of a seizure disorder.

■ Venlafaxine

The most commonly reported adverse effects with venlafaxine include nausea, constipation, somnolence, dry mouth, dizziness, nervousness, sweating, asthenia, abnormal ejaculation/orgasm, and anorexia.^{44,53} These side effects may be dose related. Venlafaxine may cause a dose-related increase in diastolic blood pressure, and baseline blood pressure is not a useful predictor of the occurrence of this phenomenon. Blood pressure should be monitored regularly during venlafaxine therapy, and dosage reduction or discontinuation may be necessary if sustained hypertension occurs.^{53,54}

■ Selective Serotonin Reuptake Inhibitors

The SSRIs include fluoxetine, citalopram, sertraline, paroxetine, escitalopram, and fluvoxamine. The SSRIs have a low affinity for histaminic, α_1 -adrenergic, and muscarinic receptors, and therefore produce fewer anticholinergic and cardiovascular adverse effects than the TCAs, and are not associated with weight gain.^{55,56} The most

common adverse effects, which generally are mild and short lived, are gastrointestinal symptoms (i.e., nausea, vomiting, and diarrhea), sexual dysfunction in both males and females, headache, insomnia, and fatigue.⁵⁶

Although the SSRIs are known to improve the anxiety symptoms associated with depression, a few patients experience an increase in anxiety symptoms or agitation early in treatment.

■ Triazolopyridines

Trazodone and nefazodone have minimal anticholinergic effects and 5-HT agonist side effects, but they can cause orthostatic hypotension. Sedation, cognitive slowing, and dizziness are the most frequent dose-limiting side effects associated with trazodone.⁴³ Prescribing information for nefazodone was recently updated to include a black box warning related to cases of life-threatening hepatic failure. Treatment with nefazodone should not be initiated in individuals with active liver disease or with elevated baseline serum transaminases.⁵⁷ Common adverse effects associated with nefazodone include light-headedness, dizziness, orthostatic hypotension, somnolence, dry mouth, nausea, and asthenia.⁴⁵

A rare but potentially serious adverse effect of trazodone is priapism, which is reported to occur in approximately 1 in 6000 male patients. Some cases have required surgical intervention (1 in 23,000), and permanent impotence may result.⁵⁸ There have been no reports of priapism associated with nefazodone use in men, but there is a published case report of nefazodone-induced clitoral priapism.⁵⁹

■ Aminoketone

Adverse effects associated with bupropion include nausea, dizziness, tremor, insomnia, vomiting, constipation, dry mouth, and skin reactions. The occurrence of seizures in patients taking bupropion appears to be strongly associated with dose, and may be increased by predisposing factors such as history of head trauma and CNS tumor. At daily doses of 450 mg (the FDA-approved ceiling dose) or less, the incidence of seizures is 0.4%.^{60,61}

■ Mixed Serotonin-Norepinephrine Effects

The most common adverse effects of mirtazapine are somnolence, weight gain, dry mouth, and constipation. In premarketing clinical trials, both agranulocytosis and liver function test (LFT) elevations were noted. However, the incidence appears to be rare, and therefore routine laboratory monitoring is not recommended.⁴⁷ Additionally, LFT elevations were observed 1.4 times more frequently than with other antidepressants and 1.6 times more frequently than with placebo. Prescribers should consider obtaining baseline LFTs and monitoring these periodically throughout the course of therapy.⁴⁷

■ Monoamine Oxidase Inhibitors

The most common adverse effect of MAOIs is postural hypotension; this is more likely to occur with phenelzine than with tranylcypromine.⁴⁸ Hypotensive reactions may be minimized through divided dosage scheduling. Anticholinergic side effects, especially dry mouth and constipation, are common but are milder in severity compared with those associated with the TCAs.

^bUp to 2 oz daily is acceptable.

^c3 oz white wine or a single cocktail is acceptable.

^dUp to 2 oz daily is acceptable; larger amounts of decaffeinated coffee are acceptable.

Phenelzine, the most frequently prescribed MAOI, has mild to moderate sedating effects. Tranylcypromine may exert a stimulating effect, and insomnia may occur, so the last dose of the day should be administered in the early afternoon. Dose-related impotence and anorgasmia in males and orgasmic inhibition in females have been reported.^{62,63} In addition, fever, myoclonic jerking, and brisk deep tendon reflexes may occur.^{48,64}

Hypertensive crisis, a potentially fatal but rare adverse reaction, may occur when MAOIs are taken concurrently with certain foods, especially those high in tyramine (Table 67-5) or drugs (Table 67-6). Ten milligrams of tyramine can cause a marked pressor effect, and 25 mg can result in serious hypertensive crisis,⁶⁵ and these incidents may culminate in cerebrovascular accident and death.⁴⁸ Symptoms of hypertensive crisis include occipital headache, stiff neck, nausea, vomiting, sweating, and sharply elevated blood pressure. Hypertensive crises were previously treated with sublingual nifedipine, but recent reports of adverse events secondary to an uncontrollable fall in blood pressure and resulting rebound catecholamine release have led to concerns.⁶⁶ Alternative agents, such as captopril, should be considered.⁶⁷

Education of patients taking MAOIs regarding dietary and medication restrictions is extremely important. Printed and verbal patient instructions should be provided. Patients unable to read and those with difficulty understanding or remembering medication instructions should not be prescribed MAOIs unless they have competent caregivers. Patients should be instructed to consult a health care professional before taking over-the-counter medications. Patients should

be taught to recognize the symptoms of hypertensive crisis and to seek treatment should those symptoms occur.

PHARMACOKINETICS

The pharmacokinetics of the antidepressants are summarized in Table 67-7. In general, the TCAs are absorbed rapidly after oral administration. Bioavailability is low (30% to 70% for most TCAs) as a result of the first-pass effect, which shows great interindividual variation.⁶⁸

The TCAs have a large volume of distribution and concentrate in brain and cardiac tissue in laboratory animals. They are bound extensively and strongly to plasma albumin, erythrocytes, α_1 -acid glycoprotein, and lipoprotein.⁶⁸

The major metabolic pathways are demethylation, aromatic and aliphatic hydroxylation, and glucuronide conjugation. Enterohepatic cycling has been described.^{68,69} Metabolism of TCAs appears to be linear within the usual dosage range. The elimination half-lives of the TCAs vary greatly among individual patients, and this may be determined genetically.⁶⁸

The diversity of the SSRIs is evident not only in their chemical structures, but also in their pharmacokinetic profiles.⁷⁰ Fluoxetine has an elimination half-life of 2 to 3 days (4 to 5 days with multiple dosing). The single-dose half-life of norfluoxetine, the active metabolite, is 7 to 9 days. Paroxetine and sertraline have half-lives of approximately 24 hours. Unlike paroxetine, sertraline has an active metabolite, but the metabolite contributes minimally to the pharmacologic effects. Escitalopram has a half-life of approximately 30 hours. Peak plasma concentrations of citalopram are observed within 2 to 4 hours after dosing, and the elimination half-life is about 30 hours. The SSRIs, with the exception of fluvoxamine, escitalopram, and citalopram, are extensively bound to plasma proteins (94% to 99%). The SSRIs are extensively distributed to the tissues, and all, with the possible exception of citalopram, may have a nonlinear pattern of drug accumulation with long-term administration.⁷⁰

Mirtazapine undergoes biotransformation via demethylation and hydroxylation followed by glucuronide conjugation.⁴⁷ The 1A2 and the 2D6 isoenzymes of the cytochrome P450 system may be responsible for the formation of the hydroxymetabolite, whereas the 3A4 isoenzyme may be responsible for the formation of the *N*-desmethyl and the *N*-oxide metabolite.⁴⁷ Although these metabolites are

TABLE 67–7. Pharmacokinetic Properties of Antidepressants

| Generic Name | Elimination Half-Life (h) ^a | Time of Peak Plasma Concentration (h) | Plasma Protein Binding (%) | Percentage Bioavailable | Clinically Important Metabolites |

theoretically active, they are present at such low plasma concentrations as to contribute little to the overall pharmacologic profile of mirtazapine.

■ Altered Pharmacokinetics

Factors reported to influence TCA plasma concentrations include disease states, genetics, age, cigarette smoking, and concurrent drug administration. Hepatic disease may reduce metabolic clearance of TCAs.⁷⁷ Renal failure does not alter nortriptyline metabolism, but the 10-hydroxy metabolite may accumulate, and protein binding may be diminished, with resulting enhanced sensitivity to the drug.⁶⁸ Clinicians should be alert to the possibility of higher-than-expected plasma concentrations of some TCAs in the elderly. Because dose-related

kinetics cannot be ruled out in the elderly, dosage adjustments based on plasma concentration monitoring may be difficult.

In cirrhotics, the half-lives of fluoxetine and norfluoxetine increased to 7.6 and 12 days, respectively.⁷⁰ Patients with hepatic impairment had a twofold increase in plasma concentrations of paroxetine.⁷¹ Similarly, in patients with mild stable cirrhosis, the half-life of sertraline was 2.5 times greater than in patients without liver disease.⁷² Patients with renal impairment had a two- to fourfold increase in paroxetine plasma concentrations compared with normal volunteers.⁷¹ Plasma concentrations of SSRIs in the elderly are reported to be greater than in younger patients.⁷⁰

The area under the curve of nefazodone and hydroxynefazodone is 25% greater in cirrhotics than in normal volunteers.⁷³ Patients with cirrhosis accumulate metabolites of bupropion to concentrations two to three times those seen in normal individuals.

■ **Plasma Concentration and Clinical Response**

Studies in acutely depressed patients have demonstrated a correlation between antidepressant effect and plasma concentrations for some TCAs. The patient’s clinical response, not plasma concentration, dictates dosage adjustments. Some patients with plasma concentrations outside the suggested therapeutic plasma concentration range respond, whereas others are nonresponsive regardless of their plasma concentration. See Table 67–3 for a listing of suggested therapeutic plasma concentration ranges.

For four TCAs (nortriptyline, desipramine, imipramine, and amitriptyline) there is more consistent evidence to support a minimal plasma concentration for clinical response. The best established therapeutic range is for nortriptyline.⁷⁴ Studies suggest a curvilinear plasma concentration-response relationship for nortriptyline, with a suggested therapeutic range of 50 to 150 ng/mL. Using logistic regression analysis of data from multiple published studies, it was found that within this range, 70% of patients with major depression responded versus only 29% of patients with plasma concentrations outside this range. Interestingly, the response rate generally was higher at the lower end of this range than at the upper limit.⁷⁴

For the newer antidepressants, a correlation has not been established between plasma concentration and clinical response or adverse effects.

■ **Plasma Concentration Monitoring**

Because of interindividual variations in plasma concentrations achieved by a given dose, approximately 40% of patients receiving standard doses of TCAs may not obtain plasma concentrations within the desired therapeutic range.⁷⁵ Although plasma level monitoring is not performed routinely, some indications include inadequate response, relapse, serious or persistent adverse effects, use of higher-than-standard doses, suspected toxicity, elderly patients, pregnant patients, patients of African or Asian descent (because of slower metabolism), cardiac disease, suspected noncompliance, suspected pharmacokinetic drug interactions, and when the manufacturer of the product changes. Plasma concentration monitoring of TCAs, when used appropriately, can improve efficacy and minimize drug-related problems. Plasma concentrations should be obtained at steady state, usually after a minimum of 1 week at constant dosage. Sampling should be performed during the drug elimination phase, usually in the morning, 12 hours after the last dose. Samples collected in this manner are comparable for patients on once-, twice-, or thrice-daily regimens.⁶⁸

■ **DRUG INTERACTIONS**

■ **TCAs**

Because the TCAs are metabolized in the liver through the cytochrome P450 system, they may interact with other drugs that modify hepatic enzyme activity or hepatic blood flow. TCAs are also extensively protein bound, which can cause drug interactions through displacement from protein-binding sites. Many commonly used medications can interact when given concurrently with TCAs. Pharmacokinetic and pharmacodynamic drug interactions involving TCAs are shown in Tables 67–8 and 67–9, respectively.

TCAs may reverse the hypotensive effects of certain sympatholytic antihypertensives (e.g., guanethidine, methyl dopa, and clonidine) because of inhibition of presynaptic uptake of the

TABLE 67–9. Pharmacodynamic Drug Interactions Involving Tricyclic Antidepressants

| Interacting Drug | Effect |
|------------------------------|---|
| Alcohol | Increased CNS depressant effects |
| Amphetamines | Increased effect of amphetamines |
| Androgens | Delusions, hostility |
| Anticholinergic agents | Excessive anticholinergic effects |
| Bepredil | Increased antiarrhythmic effect |
| Clonidine | Decreased antihypertensive efficacy |
| Disulfiram | Acute organic brain syndrome |
| Estrogens | Increased or decreased antidepressant response; increased toxicity |
| Guanadrel | Decreased antihypertensive efficacy |
| Guanethidine | Decreased antihypertensive efficacy |
| Insulin | Increased hypoglycemic effects |
| Lithium | Possible additive lowering of seizure threshold |
| Methyl dopa | Decreased antihypertensive efficacy; tachycardia; CNS stimulation |
| Monoamine oxidase inhibitors | Increased therapeutic and possibly toxic effects of both drugs; hypertensive crisis; delirium; seizures; hyperpyrexia; serotonin syndrome |
| Oral hypoglycemics | Increased hypoglycemic effects |
| Phenytoin | Possible lowering of seizure threshold and reduced antidepressant response |
| Sedatives | Increased CNS depressant effects |
| Sympathomimetics | Increased pharmacologic effects of direct-acting sympathomimetics; decreased effects of indirect-acting sympathomimetics |
| Thyroid hormones | Increased therapeutic and possibly toxic effects of both drugs; CNS stimulation; tachycardia |

Compiled from Wells.⁶⁸

antihypertensive or desensitization of the α_2 -adrenergic receptor.⁷⁶ Similarly, because of inhibition of presynaptic uptake, TCAs may increase the vasopressor response to direct-acting sympathomimetics such as phenylephrine, epinephrine, and NE. The vasopressor response to indirect-acting sympathomimetics such as ephedrine is decreased.⁷⁶ Adverse effects of any TCA would be additive with those of other drugs with similar pharmacologic effects (e.g., anticholinergic, sedative, or hypotensive drugs).⁷⁶

Although MAOIs and TCAs may be coadministered safely in refractory patients with apparent increased efficacy compared with monotherapy, severe reactions and fatalities have occurred. These reactions include hypertensive crises, hyperpyrexia, excitation, and convulsions, and they usually occur when TCAs are added to established MAOI therapy.⁷⁶

■ SSRIs

Table 67–10 summarizes the drug interactions of non-TCA antidepressants. Drug-drug interactions may occur when an SSRI is coadministered with another drug metabolized through the cytochrome P450 system.⁷⁶ Two of the isoenzymes of the cytochrome P450 system, 2D6 and 3A4, are responsible for the metabolism of over 80% of currently marketed drugs.⁷⁷ The ability of an SSRI, or any antidepressant, to inhibit or induce the activity of these enzymes will be a significant contributory factor in determining its capability to cause a pharmacokinetic drug interaction when administered concomitantly.^{77,78} Table 67–11 shows the cytochrome P450 enzyme inhibitory, potential of the second- and third-generation antidepressant agents.⁷⁷

The long half-lives of fluoxetine (2 to 5 days in young healthy subjects) and of its active metabolite, norfluoxetine (7 to 9 days), ensure that following discontinuation of the drug, active compounds persist in the body for weeks. The very slow elimination of fluoxetine makes it critical to ensure a 5-week washout after fluoxetine discontinuation before starting an MAOI.⁷⁷ For all other SSRIs, a 2-week washout is recommended. Serious and potentially fatal reactions may occur when any SSRI is coadministered with an MAOI, and coadministration is contraindicated.⁷⁶

Patients prescribed concomitant phenytoin or carbamazepine with fluoxetine may have increased anticonvulsant plasma concentrations and symptoms of toxicity.⁷⁶ Markedly increased plasma concentrations of TCAs with resulting symptoms of toxicity have been reported in patients taking fluoxetine.

Although no significant pharmacokinetic changes were present with the coadministration of warfarin and fluoxetine, altered anticoagulation effects, including bleeding, have been documented.⁷⁹ Similar findings have been noted with paroxetine and sertraline, and consequently careful monitoring of prothrombin time is recommended when warfarin and an SSRI are administered concomitantly. The risk of using SSRIs in combination with other CNS-active medications has not been evaluated systematically. Although coadministration appears relatively safe, caution should be used when prescribing an SSRI and other CNS-active drugs such as benzodiazepines.⁵⁵ There are case reports of elevated levels of TCAs when administered concomitantly with fluoxetine, sertraline, and paroxetine. In a patient on a stable dose of a TCA in whom therapy with an SSRI is being initiated, it is recommended that a blood level of the TCA be obtained. Therapy with the SSRI should be initiated carefully and conservatively. Consideration of a dose reduction of the TCA is appropriate for susceptible populations such as the elderly or those with cardiovascular disease.

Data to date suggest that citalopram may cause only moderate or no pharmacokinetic interactions when coadministered with TCAs.

Coadministration of cimetidine reduced citalopram oral clearance by 29%, whereas the addition of fluvoxamine caused a significant increase in plasma concentrations of citalopram.⁸⁰ At this time, escitalopram is considered unlikely to be involved in clinically important pharmacokinetic interactions, although coadministration of escitalopram and desipramine resulted in a doubling of the area under the curve for desipramine.⁸¹

■ Other Agents

Venlafaxine and its active metabolite, *O*-desmethylvenlafaxine, are only 30% protein bound, permitting coadministration with other highly protein-bound drugs.⁵³ Venlafaxine did not cause any significant change in the pharmacokinetics of ethanol, diazepam, or lithium.⁵³ Venlafaxine is metabolized to its active metabolite by the cytochrome P450 2D6 isoenzyme, which is the source of the genetic polymorphism present in the metabolism of many antidepressants. Venlafaxine does not have an inhibitory effect on isoenzymes 1A2, 2C9, 2D6, or 3A4.⁸² Although nefazodone is highly protein bound in vitro, nefazodone does not alter the in vitro protein binding of chlorpromazine, desipramine, diazepam, phenytoin, lidocaine, prazosin, propranolol, verapamil, or warfarin. However, it is unknown whether or not displacement of either nefazodone or other drugs occurs in vivo.⁷³ Triazolobenzodiazepines, such as triazolam and alprazolam interacted significantly with nefazodone. When triazolam is coadministered with nefazodone, a 75% reduction in the dose of triazolam is recommended. If alprazolam is coadministered with nefazodone, a 50% reduction in the dose of alprazolam is recommended.⁷³ Astemizole is metabolized by the cytochrome P450 3A4 isoenzyme. Ketoconazole, erythromycin, and other inhibitors of 3A4 can block the metabolism of terfenadine and astemizole, resulting in an increased plasma concentration of parent drug. Increased plasma concentrations of terfenadine and astemizole are associated with QT prolongation and with rare cases of serious cardiovascular adverse events, including death. Nefazodone is an in vitro inhibitor of 3A4. The concurrent use of mirtazapine and the MAOIs should be avoided. In addition, 14 days should elapse between the discontinuation of an MAOI and the initiation of mirtazapine, and vice versa. Mirtazapine is metabolized by cytochrome P450 isoenzymes 1A2, 2D6, and 3A4.

■ SPECIAL POPULATIONS

■ Elderly Patients

Depression in the elderly is a major public health problem. Many elderly depressed patients are often inadequately treated, or depression is missed or mistaken for another disorder, such as dementia. In the elderly, depressed mood, the typical signature symptom of depression, may be less prominent than other depressive symptoms such as loss of appetite, cognitive impairment, sleeplessness, anergia, and loss of interest in and enjoyment of the normal pursuits of life.⁸³ Somatic (physical) complaints are quite frequently the presenting symptoms in elderly depressed patients. The increased suicidal attempts present in the depressed elderly may be due to access to firearms, diminished cognitive functions, sleep disruptions, poor social interactions, and inattention among primary caregivers.⁸⁴ Approximately every 95 minutes an elderly person commits suicide.⁸⁴

Before initiating antidepressant treatment, a complete physical examination should be performed. In prescribing antidepressants, elderly patients may be either over- or undertreated. Overtreatment

TABLE 67–10. Drug Interactions of Non-TCA Antidepressants

| Non-TCA | Interacting Drug/Drug Class | Effect |
|--|---|---|
| Dibenzoxazepine | | |
| Amoxapine | Many of the drugs that interact with the TCAs | Similar response to that seen with TCA interaction |
| Tetracyclines | | |
| Maprotiline | Many of the drugs that interact with the TCAs | Similar response to that seen with TCA interaction |
| Mirtazapine | MAOIs | Theoretically central serotonin syndrome could occur |
| Triazolopyridines | | |
| Nefazodone | Alprazolam | Increased plasma concentrations of alprazolam |
| | Astemizole | Theoretically increased plasma concentrations of astemizole with potentially serious cardiovascular adverse effects |
| | Digoxin | Increased C_{max} , C_{min} , and AUC of digoxin by 29%, 27%, and 15%, respectively |
| | Haloperidol | Decreased clearance of haloperidol by 35% |
| | MAOIs | Hypertensive crisis; serotonin syndrome; delirium; coma; seizures; hyperpyrexia |
| | Propranolol | Decreased C_{max} and AUC of propranolol; increased C_{max} , C_{min} , and AUC of m-CCP metabolite of nefazodone |
| | Ritonavir | Increased AUC of ritonavir with potential for increased adverse events: headaches, dry mouth, nausea, somnolence, dizziness |
| | Terfenadine | Theoretically increased plasma concentrations of terfenadine with potentially serious cardiovascular adverse effects |
| | Triazolam | Increased plasma concentrations of triazolam; increased psychomotor impairment |
| Trazodone | CNS depressants | Increased CNS depression |
| | Digoxin | Increased serum concentrations of digoxin |
| | Ethanol | Additive impairment in motor skills |
| | Fluoxetine | Increased plasma concentrations of trazodone |
| | MAOIs | Theoretically central serotonin syndrome could occur |
| | Neuroleptics | Increased hypotension |
| | Phenytoin | Increased serum concentrations of phenytoin |
| | Tryptophan | Agitation, restlessness, poor concentration, nausea |
| | Warfarin | Decreased hypoprothrombinemic response |
| Aminoketone | | |
| Bupropion | MAOIs | Increased toxicity of bupropion |
| | Medications that lower seizure threshold | Increased incidence of seizures |
| | Levodopa | Increased incidence of adverse experiences |
| | Ritonavir | Increased blood level of bupropion with increased risk of seizures |
| Selective serotonin reuptake inhibitors | | |
| Citalopram | Cimetidine | Reduced oral clearance of citalopram |
| | Fluvoxamine | Increased plasma concentrations of citalopram |
| | TCAs | Possible increased AUC of TCA |
| Fluoxetine | Alprazolam | Increased plasma concentrations and half-life of alprazolam; increased psychomotor impairment |
| | Anticoagulants | Possible increased risk of bleeding |
| | β -Adrenergic blockers | Increased metoprolol serum concentrations and bradycardia; possible heart block |
| | Buspirone | Decreased therapeutic response to buspirone |
| | Carbamazepine | Increased plasma concentrations of carbamazepine with symptoms of carbamazepine toxicity |
| | Dextromethorphan | Visual hallucinations (one patient only) |
| | Haloperidol | Increased haloperidol concentrations and increased extrapyramidal side effects |
| | Lithium | Neurotoxicity—confusion, ataxia, dizziness, tremor, absence, seizures |
| | MAOIs | Severe or fatal reactions—confusion, nausea, double vision, hypomania, hypertension, tremor, serotonin syndrome |
| | Phenytoin | Increased plasma concentrations of phenytoin and symptoms of phenytoin toxicity |
| | TCAs | Markedly increased TCA plasma concentration with symptoms of TCA toxicity |
| | Terfenadine | Arrhythmias, shortness of breath, and orthostasis |
| | Trazodone | Headaches, dizziness, sedation |
| | Tryptophan | Agitation, restlessness, poor concentration, nausea |
| | Valproate | Increased valproate serum concentrations |

TABLE 67–10. (Continued)

| Non-TCA | Interacting Drug/Drug Class | Effect |
|---|------------------------------|---|
| Fluvoxamine | Alprazolam | Increased AUC of alprazolam by 96%, increased alprazolam half-life by 71%, and increased psychomotor impairment |
| | Astemizole | Theoretically increased plasma concentrations of astemizole with potentially serious cardiovascular effects |
| | β -Adrenergic blockers | Fivefold increase in propranolol serum concentration; bradycardia and hypotension with combined fluvoxamine and metoprolol |
| | Carbamazepine | Possible carbamazepine toxicity, although a controlled study did not support this |
| | Clozapine | Increased clozapine serum concentrations and increased risk for seizures and orthostatic hypotension |
| | Diazepam | Decreased clearance of diazepam and its active metabolite |
| | Diltiazem | Bradycardia |
| | Haloperidol | Increased haloperidol plasma concentrations |
| | Lithium | Increased serotonergic effects; seizures, nausea, tremor |
| | MAOIs | Potential for hypertensive crisis, serotonin syndrome, seizures, delirium |
| | Methadone | Increased methadone plasma concentrations with symptoms of methadone toxicity |
| | TCAs | Increased TCA plasma concentration |
| | Terfenadine | Theoretically increased plasma concentrations of terfenadine with potentially serious cardiovascular effects |
| | Theophylline | Increased serum concentrations of theophylline with symptoms of theophylline toxicity |
| | Paroxetine | Tryptophan |
| Warfarin | | Increased hypoprothrombinemic response to warfarin |
| Cimetidine | | Increased paroxetine serum concentrations |
| Desipramine | | Increased plasma concentrations and half-life of desipramine |
| MAOIs | | Potential for hypertensive crisis, serotonin syndrome, seizures, delirium |
| Sertraline | Warfarin | Possible increased risk for bleeding |
| | Carbamazepine | Increased plasma concentrations of carbamazepine |
| | Diazepam | Small decrease in clearance of diazepam |
| | MAOIs | Serotonin syndrome, myoclonus, violent shaking |
| | TCAs | Increased plasma concentrations of secondary amine TCAs (desipramine, nortriptyline) |
| Serotonin/norepinephrine reuptake inhibitor | Tolbutamide | Decreased clearance of tolbutamide (16%) |
| | Warfarin | Increased prothrombin time |
| Venlafaxine | Cimetidine | Reduced clearance of venlafaxine by 43% |
| | MAOIs | AUC and peak serum concentration of venlafaxine increased by 60% Potential for hypertensive crisis, serotonin syndrome, seizures, delirium |

AUC, area under the curve; C_{max} , maximum concentration; C_{min} , minimum concentration; MAOI, monoamine oxidase inhibitor. Compiled from Wells,⁶⁸ Hansten and Hon,⁷⁶ and Mitchell.⁷⁷

occurs when age-related pharmacokinetic and pharmacodynamic factors are overlooked. Undertreatment results from an overly conservative approach as a result of the patient's advanced age or concurrent medical problems. The SSRIs are usually selected as first-choice antidepressants in the elderly, and may enable the clinician to avoid some of the problematic adverse effects commonly associated with the TCAs (e.g., sedative, anticholinergic, and cardiovascular side effects). Nefazodone, bupropion, and venlafaxine are also chosen because of milder anticholinergic and less frequent cardiovascular side effects.⁸³ If a TCA is prescribed, a secondary amine (e.g., desipramine or nortriptyline) should be selected because of the defined therapeutic plasma concentration ranges and lower incidence of side effects compared to the tertiary amines. Plasma concentration monitoring can be a useful tool for managing drug therapy in this patient population.⁸³

Although the MAOI phenelzine may be used in carefully selected patients, in general, MAOIs are usually reserved for treatment-resistant patients because of the hypotensive side effects of the MAOIs

and the availability of newer, better tolerated drugs. Dietary and medication restrictions are also a concern.⁸³

■ Pediatric Patients

5 Accumulating evidence indicates that childhood depression occurs quite commonly. Symptoms of depression in the young may vary from accepted diagnostic criteria and include several non-specific symptoms such as boredom, anxiety, failing adjustment, and sleep disturbance.⁸⁵

Data collected under controlled conditions that support the efficacy of antidepressants in children and adolescents are sparse, and no antidepressant, except fluoxetine, is FDA-approved for the treatment of depression in patients less than 18 years of age. In fact, the FDA now requires all antidepressants to carry a black box warning linking the antidepressants to increased suicidal thoughts and behavior

in children and adolescents. The FDA also recommends specific monitoring parameters when antidepressants are used in children and adolescents. Detailed information is available from the FDA or from the FDA-approved labeling of these agents. Conversely, a recent report of two double-blind placebo-controlled trials of sertraline in the treatment of children and adolescents with major depressive disorder found that sertraline-treated patients did better than patients on placebo.⁸⁶ In addition, sertraline was well-tolerated with the major side effects being diarrhea, vomiting, anorexia and agitation.⁸⁶ In a double-blind study by Preskorn and associates, imipramine was superior in efficacy to placebo only through the first 3 weeks of treatment.⁸⁷ Demonstration of efficacy in this population is confounded by a high placebo response rate. However, the TCAs and several of the SSRIs remain viable treatment options. Toxicity in overdose is important in the adolescent population, where suicide is a major concern and must be considered when prescribing TCAs.⁸⁸

Antidepressants are used to treat depressed children and adolescents because no other definitive effective therapies are currently available. Plasma concentration monitoring of TCAs is important to ensure safety. As in the adult population, plasma concentrations above 450 ng/mL are associated with increased risk of serious adverse effects including delirium, seizures, delayed cardiac conduction, and sudden death.⁸⁹

Several cases of sudden death have been reported in children and adolescents taking desipramine. A baseline electrocardiogram (ECG) is recommended before initiating treatment with a TCA in children and adolescents, and many clinicians recommend an additional ECG when steady-state plasma concentrations are achieved.⁸⁹

Although several antidepressants are FDA-approved for use in children, only one, fluoxetine, is currently approved for childhood depression. Imipramine is approved for the treatment of enuresis, clomipramine for obsessive-compulsive disorder in children 12 years and older, and fluvoxamine along with fluoxetine is approved for obsessive-compulsive disorder in children.⁹⁰ The treatment of depression in children remains challenging, as depression can be difficult to diagnose and treat once identified. The studies involving imipramine, sertraline, and fluoxetine found that the dose range and titration as well as adverse effects were similar to those in adults.^{86,90–92}

■ Pregnant and Lactating Patients

Approximately 10% of pregnant women develop a serious depression during pregnancy. No major teratogenic effects are currently

associated with the SSRIs or TCAs.^{93–94} Studies have been conducted evaluating birth anomalies, growth impairment, and behavioral teratogenicity. A meta-analysis of first-trimester exposure to TCAs found no significant association between exposure to TCAs and congenital malformations.⁹³ An additional evaluation compared birth defects in neonates born to women who were exposed to fluoxetine, TCAs, and agents felt not to increase baseline teratogenic risk (such as penicillin or dental x-rays). Comparable rates of malformations were found across all three groups. However, a higher rate of miscarriages was present in the fluoxetine- and TCA-treated groups (13.5% and 12.2%, respectively) compared with the control group (6.8%). This raised questions about the effect of both depression and antidepressant treatment on the rate of miscarriage.⁹⁴ Some studies, but not all, have reported higher rates of perinatal complications associated with third-trimester use of fluoxetine.⁹⁵

Studies evaluating the development of children exposed prenatally to TCAs, fluoxetine, or nonteratogens found no important differences in the rates of prenatal complications, incidence of major malformations, and mean global IQ scores.⁹⁵

Concern regarding the use of fluoxetine arose as a result of an evaluation of neonates exposed to fluoxetine before 25 weeks of gestation only (early exposure) versus exposure during the third trimester (late exposure) versus exposure to nonteratogens. Premature birth occurred in 14.3% of late-exposure neonates versus 4.1% of early-exposure neonates, and 5.9% in the control group.⁹³ Additionally, birth weight, birth length, and maternal weight gain were less in the late-exposure group compared with the early-exposure and control groups. Evaluations to date do not support any teratogenic effects of fluoxetine, but do raise questions regarding premature birth and fetal growth rate.⁹⁴

If a TCA is withdrawn during pregnancy, it should be tapered gradually to avoid maternal or fetal withdrawal symptoms. If possible, drug tapering is usually begun 5 to 10 days before the estimated day of confinement.⁹⁴ Although MAOIs have demonstrated teratogenicity in animals, there are insufficient data in humans to permit firm conclusions. Similarly, there are inadequate data on the use of other antidepressants during pregnancy.

In summary, the risks and benefits of drug therapy during pregnancy must always be weighed, and concerns about the risks of untreated depression during pregnancy should be considered. These include the possibility of low birth weight secondary to poor maternal weight gain, suicidality, potential for hospitalization, potential for marital discord, inability to engage in appropriate obstetric care, and difficulty caring for other children.⁹⁵ Several different approaches

exist for dealing with pregnancy and antidepressant use.⁹⁵ First, discontinuation of an antidepressant before conceptions is an option for women who are stable and appear likely to remain well while not taking antidepressant medication. Secondly, continuation of the antidepressant until conception may be reasonable. For those who have a history of depressive relapse after medication discontinuation, the antidepressant should be continued throughout pregnancy. Further evaluations of the newer antidepressant agents are needed to fully understand the risks associated with their use at various stages of the gestational period. Additionally, the risks of not treating depression in a pregnant woman should not be underestimated or minimized.

■ Refractory Patients

6 The majority of “treatment resistant” depressed patients are likely the result of inadequate therapy (relative resistance).²⁹ Issues to be addressed in assessing the patient who has not responded to treatment include the following:

1. Is the diagnosis correct?
2. Does the patient have a psychotic depression?
3. Has the patient received an adequate dose and adequate duration of treatment?
4. Do adverse effects preclude adequate dosing?
5. Has the patient adhered to the prescribed regimen?
6. Was a stepwise approach to treatment used?
7. Was treatment outcome adequately measured?
8. Is there a coexisting or preexisting medical or psychiatric disorder?
9. Are there other factors that interfere with treatment?

7 When a patient has failed to respond, nondrug modalities including environmental manipulation, family counseling, cognitive therapy, or interpersonal psychotherapy are often beneficial.²⁹

Three primary pharmacologic approaches are used when dealing with treatment nonresponse. The current antidepressant may be stopped and a trial with an unrelated agent initiated. For example, the patient may be switched from a TCA to an SSRI or an MAOI. Second, the current antidepressant can be augmented (potentiated) by the addition of lithium, liothyronine, or an anticonvulsant such as carbamazepine or valproic acid. A recently published study evaluated the efficacy of high-dose fluoxetine (40 to 60 mg/day), fluoxetine plus lithium, and fluoxetine plus desipramine in a group of patients who had failed to respond to 8 weeks of treatment with fluoxetine 20 mg per day.⁹⁶ There was no significant difference in response rates or drop rates across the three treatment groups, although the high-dose fluoxetine group was associated with a numerically greater response (42.4% vs. 29.4% vs. 23.5%, respectively). More recent evaluations have explored the addition of a novel antipsychotic agent (e.g., olanzapine or risperidone) to an antidepressant agent.⁹⁷ A third approach to the treatment-resistant patient is to use two different classes of antidepressants concurrently (e.g., a TCA plus an MAOI).²⁹ As discussed previously, the combination of an SSRI and an MAOI should never be used.

There are accumulating data to support that 50% to 60% of previously treatment-resistant depressed patients respond to adequate doses of SSRIs. MAOIs can be considered in the truly treatment-resistant population, especially for the patient with atypical features.²⁹

Augmenting strategies, such as the addition of lithium to a TCA regimen, have been found to benefit some previously unresponsive patients. Several older trials support that addition of liothyronine to a TCA regimen may induce antidepressant response.²⁹

Only a prescriber experienced in the use of such combinations should undertake concurrent use of a TCA and an MAOI. When this is undertaken, the MAOI is slowly added to the TCA. Desipramine is not recommended to be used in combination with an MAOI. When the combination is discontinued, the MAO inhibitor should be stopped first. Patients with psychotic depression usually require the combination of an antidepressant and an antipsychotic.²⁹

The American Psychiatric Association practice guideline for the treatment of patients with major depressive disorder offers guidelines for managing patients who fail to respond. This publication advises that if patients fail to respond to medication after 6 to 8 weeks, a reappraisal of the treatment regimen should be considered.²⁹ For those with no response, options include changing to a second antidepressant or the addition of psychotherapy or ECT. Partial responders should consider changing the dose, augmenting the antidepressant, or adding psychotherapy or ECT. Comorbid medical or psychiatric conditions should be identified and treated because they may complicate treatment. Before changing a patient’s treatment, the clinician is advised to evaluate the adequacy of the medication dosage and compliance with the prescribed regimen. A combination of two drugs should not be used when one drug will suffice.

CLINICAL CONTROVERSY

There are no universally agreed upon algorithms or guidelines for individuals experiencing treatment-resistant depression. Approaches include discontinuing the current antidepressant and initiating treatment with a different agent, augmenting the current treatment, or beginning a trial of combination antidepressant therapy (see Fig. 67–1).

■ CLINICAL APPLICATION

A suggested algorithm for the management of depression is shown in Figure 67–1.

■ Dosing

Recommended initial doses and dosage ranges are shown in Table 67–3. The usual initial adult dose of most TCAs is 50 mg at bedtime, and the dose may be increased by 25 to 50 mg every third day. The recommended initial dose for the SSRIs is fluoxetine, 10 to 20 mg; paroxetine, 20 mg; sertraline, 50 mg; citalopram, 20 mg; and escitalopram 10 mg.

Bupropion is usually initiated at 100 mg twice daily, and this dose may be increased to 100 mg three times daily after 3 days. Most patients will respond at 300 mg/day; however, an increase to 450 mg/day, given as 150 mg three times daily, may be considered in patients with no clinical response after several weeks of treatment at 300 mg/day. Additionally, a sustained-release formulation of bupropion is currently available and may be given as 200 mg twice a day in those individuals requiring higher dosages.

Typically, phenelzine is initiated at 15 mg in the morning and then increased by 15 mg every third day up to 60 mg/day. The dose should be given three times daily to minimize postural hypotension, with the last dose given in the early afternoon to lessen the likelihood of insomnia. Maintenance doses may be as low as 15 mg/day.

The usual starting dose of venlafaxine is 75 mg/day given in two or three divided doses and taken with food. Depending on tolerability, the dose is then increased to 150 mg/day. If needed, the dose

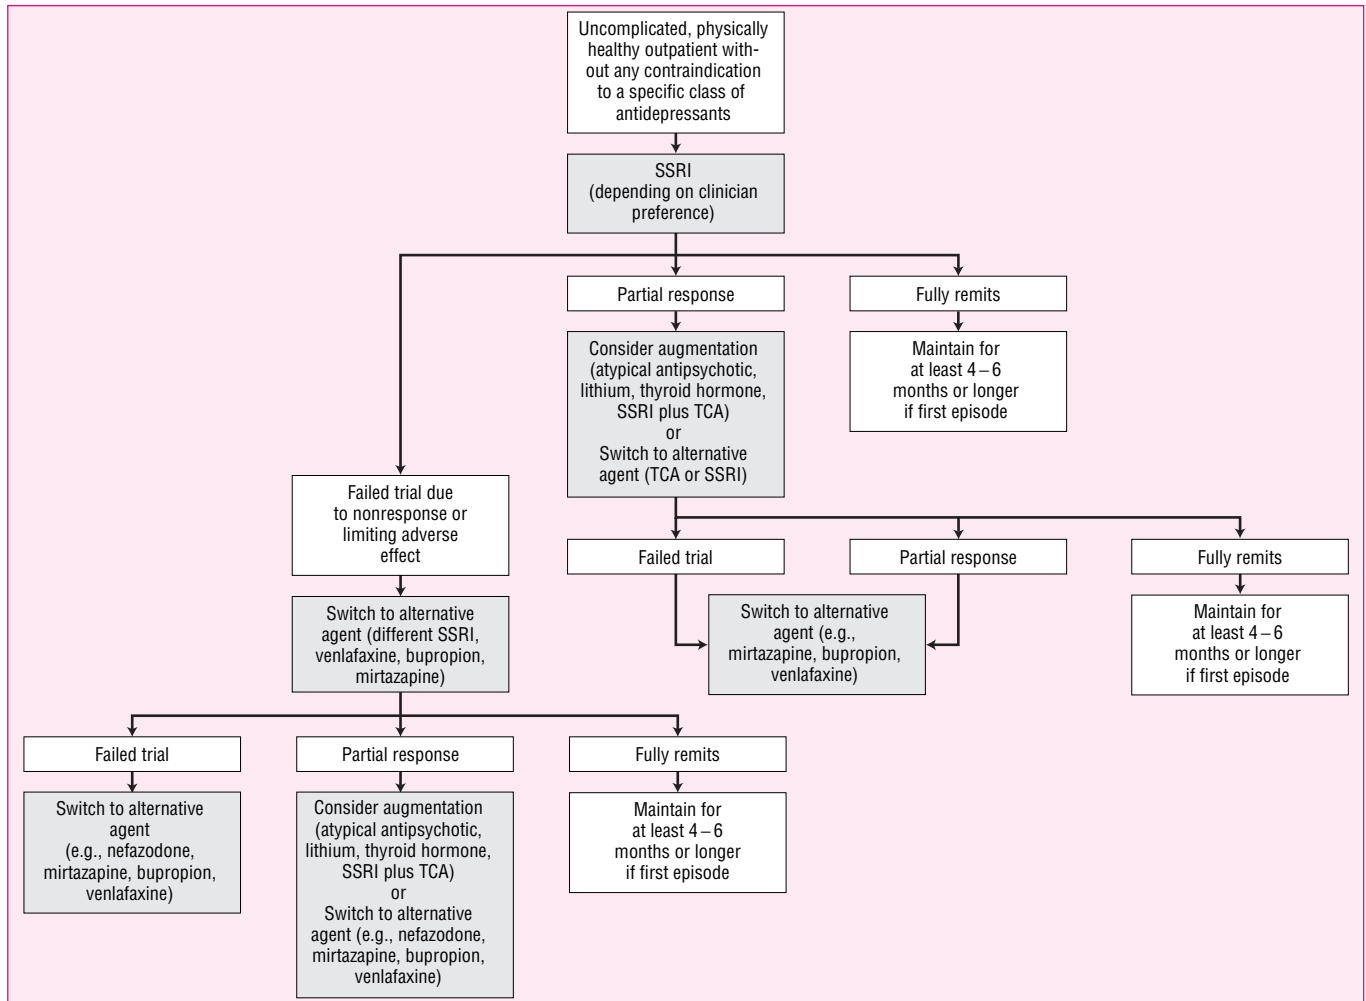

FIGURE 67-1. Algorithm for treatment of uncomplicated major depression.

may be further increased to 225 mg/day. Certain patients, including severely depressed patients, may need a dose up to 375 mg/day. A sustained-release formulation of venlafaxine is also available. The recommended starting dose is 75 mg/day administered with food. Dosage increases should occur in 75-mg/day increments with a maximum daily dose of 225 mg.

The starting dose of nefazodone is 100 mg given twice daily. Dose increases should occur in increments of 100 mg/day, on a twice-daily schedule, at intervals of no less than 1 week, with the usual effective dose range between 300 and 600 mg/day.

The recommended starting dose of mirtazapine is 15 mg/day administered in a single dose at bedtime. The maximum dose recommended is 45 mg/day. Dosage increases should occur every 1 to 2 weeks as indicated.

Caution is urged when switching from one antidepressant to another. It is important to remember that 3 to 4 weeks is usually required before a mood-elevating response is seen. A 6-week trial at a maximum dosage is considered an adequate trial.²⁹ It is crucial to explain to the patient about the expected lag time before the onset of clinical response. Patients uneducated in this regard often fail to comply with their prescribed regimens.

In elderly patients, as a general rule dosing is initiated at half the initial dose administered to younger adults, and the dose is increased at a slower rate. Thus desipramine or nortriptyline may be initiated at

10 to 25 mg/day, or fluoxetine at 10 to 20 mg/day, or alternatively 20 mg every second or third day. Six to twelve weeks of treatment may be required to achieve the desired antidepressant response in elderly patients. A remission is achieved when symptoms of depression are no longer present. A relapse is a return of symptoms within 6 months after remission. To prevent relapse, antidepressants should be continued at full therapeutic doses for 4 to 9 months after remission.²⁹ This period of treatment is termed *continuation therapy*. A recurrence is a separate episode of depression, which may occur after years of normal functioning. Five years after the first episode of depression, only 25% of patients had recovered and remained well.⁹⁸ The risk of recurrence increases as the number of past episodes and age at onset of the first episode increase. The duration of antidepressant therapy depends on the risk of recurrence. Some investigators recommend lifelong maintenance therapy for persons at greatest risk for recurrence (persons below 40 years of age with two or more prior episodes and persons of any age with three or more prior episodes).²⁹

PHARMACOECONOMIC CONSIDERATIONS

Drug costs account for only about 1% to 2% of total costs of the treatment of depression and about 10% to 12% of direct costs of depression.⁹⁹ Other costs associated with depression primarily

include the indirect costs associated with lost earnings/productivity and premature death.⁹⁹ Therefore when evaluating the cost of treating depression, more must be considered than just the cost of medications. For example, if lack of response to an antidepressant leads to an overdose and subsequent treatment in the intensive care unit, the cost of treating depression will be increased dramatically. Likewise, if the patient suffers intolerable side effects, becomes noncompliant, and relapses requiring hospitalization, the cost of treating the depression becomes very expensive quite rapidly.

When SSRIs were introduced, many managed care organizations restricted these medications to those who had failed treatment with the TCAs or been unable to tolerate these agents, with the belief that the SSRIs represented a more expensive approach to the treatment of depression. Subsequent evaluations have shown that in fact the SSRIs represent a more economic approach to the treatment of depression when compared with TCAs when all treatment costs are considered.^{100,101} A more recent review concluded that cost differences between those receiving TCAs and those receiving fluoxetine were minimal. There were few differences in medical costs, depression outcomes, and health-related quality of life.¹⁰² The larger question seems to center around whether one SSRI is more economic

than another. Initial findings suggest that fluoxetine may offer an overall cost advantage when compared with other SSRIs, but additional longer-term data are necessary before a final conclusion can be reached.¹⁰³

A number of studies of venlafaxine have found a lower expected cost than comparable treatment with SSRIs and TCAs.¹⁰⁴ In addition, an evaluation of nine health care plans in the United States of resource use and the cost of venlafaxine instead of TCAs, after switching from an SSRI, showed that overall costs did not vary markedly between venlafaxine and TCAs. The clinician must always determine the applicability of these data to his or her individual practice setting.¹⁰⁴

Additional longer-term studies in more diverse populations are necessary before judgments can be made regarding which of the newer antidepressant agents offers a cost advantage. It would be extremely useful if subpopulations and special populations (e.g., the elderly, those with comorbid substance abuse, those with comorbid anxiety disorders, and children) were studied and cost-effective agents in these subpopulations were identified. Also, the pharmacoeconomics of the medication management of depression in various health care environments such as public, private psychiatry, or primary care needs evaluation.

EVALUATION OF THERAPEUTIC OUTCOMES

8 Several monitoring parameters, in addition to plasma concentrations, are useful in managing patients. Patients must be monitored for adverse effects, such as sedation, anticholinergic effects, and sexual dysfunction, and for remission of previously documented target symptoms. The presence of side effects does not necessarily indicate adequate dosage. In addition, changes in social and occupational functioning should be assessed. Patients receiving venlafaxine should have their blood pressure monitored at regular intervals. Patients older than 40 should receive a pretreatment ECG before starting TCA therapy, and follow-up ECGs should be performed periodically. Patients should be monitored for the emergence of suicidal ideation after initiation of any antidepressant.

In addition to the clinical interview, psychometric rating instruments (e.g., patient-rated and clinician-rated scales) allow for rapid and reliable measurement of the nature and severity of depressive and associated symptoms (see Chap. 60). It is helpful to administer the rating scales prior to treatment, 6 to 8 weeks after initiation of therapy, and periodically thereafter. Interviewing a family member or friend (with the patient's permission) regarding symptoms and daily functioning also can assist in assessment of progress. Patients should be monitored at more frequent intervals early in treatment. Monitoring is then continued at regular intervals throughout the continuation and maintenance phases of treatment. Regular monitoring for re-emergence of side effects should be continued for several months after antidepressant therapy is discontinued.

COLLABORATIVE PRACTICE

Significant evidence exists to show that depression is common, chronic, and causes significant morbidity and mortality.¹⁰⁵ Pharmacists in conjunction with other health care providers can play a crucial role in the screening, recognition, and treatment of this disorder. In fact, the United States Preventive Services Task Force has recommended that clinicians "maintain an especially high index of suspicion for depressive symptoms in adolescents and young adults, persons

with a family history or personal history of depression, those with chronic illnesses, those who perceive or have experienced a recent loss, and those with sleep disorders, chronic pain or multiple unexplained somatic complaints."¹⁰⁶ In addition, pharmacists and other health care clinicians play a crucial role in ensuring adherence to medication regimens through assessment of a patient's willingness and ability to take a medication, including an assessment of financial viability, through patient education regarding dosing, side effects and drug interactions, and guidance regarding follow-up appointments with prescribing clinicians.¹⁰⁷

CONCLUSIONS

Major depressive disorder remains one of the most commonly occurring mental illnesses in adults, and it is often undiagnosed and untreated. Pharmacologic intervention is the cornerstone of antidepressant treatment. Antidepressant medications have a broad spectrum of neurochemical effects and influence a variety of receptors peripherally and centrally. Safe and effective use of antidepressants requires a thorough understanding of the pharmacology of these drugs and of the principles of monitoring efficacy and adverse effects. In addition, clinicians must have a thorough understanding of antidepressant drug interactions and other factors that may influence the pharmacokinetics of antidepressant drugs. Plasma concentration monitoring is unnecessary for most patients, but can improve the outcome in some situations. The search for more effective antidepressants with more favorable adverse-effect profiles must continue.

BIPOLAR DISORDER

Martha P. Fankhauser and Marlene P. Freeman

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Bipolar disorder is a cyclic mental illness with recurrent mood episodes that occur over a person's lifetime. The symptoms, course, severity, and response to treatment differ among individuals.
- 2 Bipolar disorder is likely caused by genetic factors, environmental triggers, and the dysregulation of neurotransmitters, neurohormones, and secondary messenger systems in the brain.
- 3 The goal of therapy for bipolar disorder should be to eliminate mood episodes, maximize adherence to therapy, improve the functioning of the patient, and limit adverse effects.
- 4 Patients and family members should be educated about bipolar disorder and treatments. Long-term monitoring and adherence to treatment are major factors in obtaining stabilization of the disorder.
- 5 Lithium and valproate are the mainstays of treatment for both acute mania and prophylaxis for recurrent manic and depressive episodes. Anticonvulsants such as lamotrigine, carbamazepine, and oxcarbazepine and atypical antipsychotics such as aripiprazole, olanzapine, risperidone, queti-
- 6 Practice guidelines have been developed for bipolar disorder and are generally based on available efficacy and safety data and on opinions from a consensus panel of experts. Algorithms help the clinician select treatment options based on the type of mood episode, response to treatment, and patient-specific characteristics.
- 7 Some patients can be stabilized on one mood stabilizer, but others may require combination therapies or adjunctive agents for the acute treatment of mood episodes and for the continuation phase. If possible, adjunctive agents should be tapered and discontinued when the acute mood episode remits and the patient is stabilized.
- 8 Baseline and follow-up laboratory tests are required for some medications to monitor for adverse effects. Serum drug concentrations (applicable for lithium, carbamazepine, and valproate) help to adjust the dose and are used for both the acute and maintenance phase of treatment.

1 Bipolar disorder (manic-depressive illness) is one of the most common of the severe chronic psychiatric disorders. The cyclic mood disorder is characterized by recurrent fluctuations in mood, energy, and behavior encompassing the extremes of human experiences.¹⁻⁴ Bipolar disorder differs from recurrent major depression (or unipolar depression) in that a manic, hypomanic, or mixed episode occurs during the course of the illness.² Bipolar disorder is a lifelong illness with a variable course and requires both nonpharmacologic and pharmacologic treatments for mood stabilization.^{2,3}

EPIDEMIOLOGY

Approximately 1% to 3% of the adult population has either bipolar I or II disorder, but broader definitions suggest prevalence rates up to 5% if the full spectrum of recurrent mood disorders are included.^{2-4,6} A national comorbidity survey reported that the lifetime prevalence rate of a manic episode is 1.6% ± 0.3% for men and 1.7% ± 0.3% for women in the United States (approximately 4 million people).⁷ The

lifetime prevalence of bipolar I disorder (one or more manic or mixed episodes) is 0.4% to 1.6%; that for bipolar II disorder (recurrent major depressive episodes with hypomanic episodes) is approximately 0.5%.^{2,3} Bipolar I disorder occurs equally in men and women, whereas bipolar II disorder is more common in women.^{2,3} Of the 1.9 million Americans who have either bipolar I or II disorder, it is estimated that only 50% of these individuals are receiving any type of treatment for their illness.¹

ETIOLOGY

2 The exact etiology of bipolar disorder is unknown. Bipolar disorder is thought to be genetically based, environmentally influenced, and caused by a wide range of biological abnormalities. Stressful life events, alcohol or substance use, and changes in the sleep-wake cycle may elicit the expression of genetic or biological vulnerabilities that cause dysregulation of neurotransmitters, neuroendocrine pathways, and secondary messenger systems.⁴ Table 68-1 summarizes the etiologic theories of bipolar disorder.^{1,4,8-12}

TABLE 68–1. Etiologic Theories of Bipolar Disorder**Genetic factors**

80–90% of patients with bipolar disorder have a biologic relative with a mood disorder (e.g., bipolar disorder, major depression, cyclothymia, or dysthymia).

First-degree relatives of bipolar patients have a 15–35% lifetime risk of developing any mood disorder and a 5–10% lifetime risk for developing bipolar disorder.

The concordance rate of mood disorders is 60–80% for monozygotic twins and 14–20% for dizygotic twins.

Linkage studies suggest that certain loci on genes and the X chromosome may contribute to genetic susceptibility of bipolar disorder.

Nongenetic factors*Perinatal insult**Head trauma**Environmental factors*

Dysynchronization of circadian or seasonal rhythms cause diurnal variations in mood and sleep patterns and may result in seasonal recurrences of mood episodes.

Changes in the sleep-wake cycle or light-dark cycle may precipitate episodes of mania or depression.

Bright light therapy may be used for the treatment of winter depression, and may precipitate hypomania, mania, or mixed episodes.

Psychosocial or physical stressors

Stressful life events often precede mood episodes and may increase recurrence rates and prolong time to recovery from mood episodes.

Nutritional factors

Deficiency of essential amino acid precursors in the diet may cause a dysregulation of neurotransmitter activity (e.g., L-tryptophan deficiency causes a decrease in 5-HT and melatonin synthesis and activity).

Deficiency in essential fatty acids (e.g., omega-3 fatty acids) may cause a dysregulation of neurotransmitter activity.

Neurotransmitter/neuroendocrine/hormonal theories

Dysregulation between excitatory and inhibitory neurotransmitter systems; excitatory: NE, DA, glutamate, and aspartate; inhibitory: 5-HT and GABA.

Monoamine hypothesis

An excess of catecholamines (primarily NE and DA) cause mania.

Agents that decrease catecholamines are used for the treatment of mania (e.g., DA antagonists and α_2 -adrenergic agonists).

Deficit of neurotransmitters (primarily NE, DA, and/or 5-HT) cause depression.

Agents that increase neurotransmitter activity are used for the treatment of depression (e.g., 5-HT and NE/DA reuptake inhibitors and MAOIs).

Dysregulation of amino acid neurotransmitters

Deficiency of GABA or excessive glutamate activity causes dysregulation of neurotransmitters (e.g., increased DA and NE activity).

Agents that increase GABA activity or decrease glutamate activity are used for the treatment of mania and for mood stabilization (e.g., benzodiazepines, lamotrigine, lithium, or valproic acid).

Cholinergic hypothesis

Deficiency of acetylcholine causes an imbalance in cholinergic-adrenergic activity and may increase the risk of manic episodes.

Agents that increase acetylcholine activity may decrease manic symptoms (e.g., use of cholinesterase inhibitors or augmentation of muscarinic cholinergic activity).

Increased central acetylcholine levels may increase the risk of depressive episodes.

Agents that decrease acetylcholine activity may alleviate depressive symptoms (i.e., anticholinergic agents).

Secondary messenger system dysregulation

Abnormal G protein functioning dysregulates adenylate cyclase activity, phosphoinositide responses, sodium/potassium/calcium channel exchange, and activity of phospholipases. Abnormal cyclic adenosine monophosphate and phosphoinositide secondary messenger system activity.

Abnormal protein kinase C activity and signaling pathways.

Hypothalamic-pituitary-thyroid axis dysregulation

Hyperthyroidism may precipitate a mania.

Hypothyroidism may precipitate a depression and be a risk factor for rapid cycling; thyroid supplementation used for refractory rapid cycling and augmentation of antidepressants in unipolar depression.

Positive antithyroid antibody titers reported in patients with bipolar disorder.

Hormonal changes during the female life cycle may cause dysregulation of neurotransmitters (e.g., premenstrual, postpartum, and perimenopause).

Membrane and cation theories

Abnormal neuronal calcium and sodium activity and homeostasis causes neurotransmitter dysregulation.

Hypocalcemia associated with causing anxiety, mood irritability, mania, psychosis, and delirium.

Hypercalcemia associated with causing depression, stupor, and coma.

Extracellular and intracellular calcium concentrations may affect the synthesis and release of NE, DA, and 5-HT, as well as the excitability of neuronal firing.

Sensitization and kindling theories

Recurrences of mood episodes causes behavioral sensitivity and electrophysiologic kindling (similar to the amygdala-kindling models for seizures in animals) and may result in rapid or continuous mood cycling.

Anticonvulsants with antikingling properties are effective for stabilizing mood (e.g., carbamazepine, valproic acid).

DA, dopamine; GABA, γ -aminobutyric acid; 5-HT, serotonin; MAOI, monoamine oxidase inhibitor; NE, norepinephrine.

Compiled from Torrey and Knable,¹ Goldberg and Harrow,⁴ Kelso,⁸ Manji et al,⁹ Lenox et al,¹⁰ Baron,¹¹ Bezchlibnyk and Young,¹² Goodnick,¹⁸ Soares,¹⁹ Manji et al,²⁰ Gould and Manji,²¹ Sobczak et al,²² Freeman et al,²³ Ketter and Wang,²⁴ White,²⁵ Rasgon et al,²⁶ and Mahmood and Silverstone.²⁷

TABLE 68–2. Secondary Causes of Mania**Medical conditions that induce mania**

- CNS disorders (brain tumor, strokes, head injuries, subdural hematoma, multiple sclerosis, systemic lupus erythematosus, temporal lobe seizures, Huntington’s disease)
- Infections (encephalitis, neurosyphilis, sepsis, human immunodeficiency virus)
- Electrolyte or metabolic abnormalities (calcium or sodium fluctuations, hyper- or hypoglycemia)
- Endocrine or hormonal dysregulation (Addison’s disease, Cushing’s disease, hyper- or hypothyroidism, menstrual-related or pregnancy-related or perimenopausal mood disorders)
- Vitamin and nutritional deficiencies (essential amino acids, essential fatty acids, vitamin B₁₂)

Medications or drugs that induce mania

- Alcohol intoxication
- Drug withdrawal states (alcohol, α_2 -adrenergic agonists, antidepressants, barbiturates, benzodiazepines, opiates)
- Antidepressants (MAOIs, TCAs, 5-HT and/or NE and/or DA reuptake inhibitors, 5-HT antagonists)
- DA-augmenting agents (CNS stimulants: amphetamines, cocaine, sympathomimetics; DA agonists, releasers, and reuptake inhibitors)
- Hallucinogens (LSD, PCP)
- Marijuana intoxication precipitates psychosis, paranoid thoughts, anxiety, and restlessness
- NE-augmenting agents (α_2 -adrenergic antagonists, β -agonists, NE reuptake inhibitors)
- Steroids (anabolic, adrenocorticotrophic hormone, corticosteroids)
- Thyroid preparations
- Xanthines (caffeine, theophylline)
- Over-the-counter weight loss agents and decongestants (ephedra, pseudoephedrine)
- Herbal products (St. John’s wort)

Somatic therapies that induce mania

- Bright light therapy
- Sleep deprivation

CNS, central nervous system; DA, dopamine; 5-HT, serotonin; LSD, lysergic acid diethylamide; MAOI, monoamine oxidase inhibitor; NE, norepinephrine; PCP, phencyclidine; TCA, tricyclic antidepressant.

Compiled from Torrey and Knable,¹ American Psychiatric Association,² American Psychiatric Association,³ and Goodnick.¹⁸

SECONDARY CAUSES

Several medical, medication-induced, or substance-related causes of mania and depression have been identified (see Table 68–2 for causes of mania and Table 67–1 in Chap. 67 on depressive disorders for causes of depression).^{1–3} A complete medical, psychiatric, and medication history; physical examination; and laboratory testing are necessary to rule out any organic causes of mania or depression.³ An accurate diagnosis is important because some psychiatric and neurologic disorders present with manic-like symptoms.^{3,4} For example, attention-deficit/hyperactivity disorder and a manic episode have similar characteristics; thus individuals with bipolar disorder may be misdiagnosed and prescribed central nervous system stimulants.^{13,14} Use of any substance that affects the central nervous system (e.g., alcohol, antidepressants, caffeine, central nervous system stimulants, hallucinogens, or marijuana) can worsen symptoms and decrease the response to treatment.^{3,15–18}

PATHOPHYSIOLOGY

2 Many theories have been proposed regarding the pathophysiology of mood disorders.⁴ Family, twin, and adoption studies report an increased lifetime prevalence risk of having mood disorders among first-degree relatives of patients with bipolar disorder.^{3,5} Genetic linkage studies suggest multiple gene loci may be involved in the heredity of mood disorders.^{8–11,18} Neuroimaging studies have found neurochemical, anatomic, and functional abnormalities in bipolar patients.^{18,19} Environmental or psychosocial stressors, nutritional deficiencies, infections, immunologic reactions, sleep deprivation, and disruption of circadian rhythms may cause dysregulation in neurotransmitters, hormones, endocrine function, neuropep-

tides, cations, intracellular second messengers, and signal transduction pathways.^{3,4,9,18–24}

NEUROCHEMICAL THEORIES

The kindling and behavioral sensitization model postulates that psychosocial stressors can result in manic or depressive episodes because various brain networks are sensitized for exaggerated and spontaneous reactions secondary to neurotransmitter imbalances or dysregulation and voltage-gated ion channel abnormalities.^{4,25} Dysregulation between neurotransmitters, neuropeptides, hormones, and secondary messenger systems may produce a cyclic rhythm disturbance in the central nervous system.^{1,4,9,18,25} Abnormal calcium, potassium, and sodium homeostasis may alter neurotransmitter release and the secondary messenger system.^{9,25} Hormonal changes during the menstrual cycle, postpartum period, and perimenopausal phase may contribute to mood dysregulation.^{23,26}

The “permissive serotonin hypothesis” proposes that serotonin (5-hydroxytryptamine or 5-HT) plays a critical role in modulating brain activity (e.g., stabilization of the catecholamine system and inhibition of dopamine [DA] release), and is low in both mania and depression.^{18,27} L-tryptophan or 5-HT deficiency and changes in the light-dark cycle may result in reduced melatonin secretion from the pineal gland that disrupts the sleep-wake cycle, alters circadian rhythms, and causes seasonal affective changes.^{1,18,27}

The catecholamine hypothesis of mood disorders suggests that increased DA and norepinephrine (NE) activity contribute to hyperactivity and psychosis associated with the severe stages of mania, and reduced activity causes depression.^{4,18} A γ -aminobutyric acid (GABA) deficiency theory has been proposed for mania since it inhibits NE and DA activity.^{4,9,18} Glutamate and aspartate, excitatory amino

acid neurotransmitters, may be overactive and involved in causing manic episodes.⁹ Cholinergic underactivity has been proposed to cause mania and overactivity of acetylcholine to cause depression.^{9,18} Acetylcholine is an antagonist of the catecholamine system and contributes to the interaction between phosphatidylinositol and phosphatidylcholine secondary messenger systems.⁹

CLINICAL PRESENTATION

1 The essential feature of bipolar disorder is a history of mania or hypomania that is not caused by any other medical condition, substance, or psychiatric disorder (see Table 68–2 for secondary causes of mania).^{2,3} The *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed., Text Revision (DSM-IV-TR) of the American Psychiatric Association (APA) details the present understanding of mood disorders.² Bipolar disorder is divided into four subtypes based on the identification of specific mood episodes: bipolar I, bipolar II, cyclothymic disorder, and bipolar disorder not otherwise specified. See Table 68–3 for a definition of mood disorders by type of episode. The mood states are further separated into four subcategories to differentiate the current or most recent mood episode: major depressive, manic, hypomanic, or mixed. See Table 68–4 for the evaluation and diagnostic criteria of mood episodes. A new concept of “bipolar spectrum disorder” has been suggested that broadens the diagnosis to include dysthymia, cyclothymia, drug-induced hypomania, and recurrent unipolar depression.^{4,28} Comorbid psychiatric disorders associated with bipolar disorder include alcohol and substance abuse, personality disorders, and anxiety disorders such as panic disorder, social anxiety, and obsessive-compulsive disorder.^{2–4,15,17,18,29,30}

MAJOR DEPRESSIVE EPISODE

Bipolar depression is often underdiagnosed and is frequently misdiagnosed as major depressive disorder.^{3,31} Compared to manic episodes, depressive episodes are more frequent, longer lasting, and occur more often in bipolar II than in bipolar I disorder.^{4,32} Over a person’s lifetime, depressive episodes may account for up to 80% of all mood episodes. Compared to men, women have twice the lifetime risk

for major depression and a higher prevalence of seasonal affective disorder.^{2,23} In bipolar depression, patients have an increased suicide risk and often have mood lability, hypersomnia, low energy, psychomotor retardation, cognitive impairment, anhedonia, decreased sexual activity, slowed speech, carbohydrate craving, and weight gain (also called atypical depressive features).^{4,32,33} Delusions, hallucinations, and suicide attempts are more common in bipolar depression than in unipolar depression.⁴

MANIC EPISODE

For a diagnosis of mania, the symptoms must last at least 1 week, the mood must be elevated (expansive or irritable), and there must be an impairment in functioning.² Acute mania usually begins abruptly and symptoms escalate over several days. Common symptoms of mania include grandiosity, decreased need for sleep or food, pressured speech, flight of ideas (racing thoughts), distractibility, increased activity, poor judgment, and involvement in pleasurable activities with potentially negative consequences.² The severe stages of a manic episode resemble paranoid schizophrenia with bizarre behavior, hallucinations, and paranoid or grandiose delusions. Seasonal changes, stressors, sleep deprivation, antidepressants, central nervous system stimulants, or bright light can precipitate a manic episode. Bipolar patients may use cocaine or other stimulants during a manic phase to intensify and prolong mania.⁴

HYPOMANIC EPISODE

Hypomania is a less severe form of mania, and by definition does not cause a marked impairment in social or occupational functioning, and no delusions or hallucinations are present.^{2,4} Patients with hypomania often do not seek treatment until they have a depressive episode, thus hypomania may not be recognized or reported.³ Symptoms found in hypomanic episodes are similar to those of cocaine- or antidepressant-induced mood disorders; thus the differential diagnosis should rule out any substance-induced or medical conditions that present with elevated mood.¹⁷ Hypomanic states should be closely monitored, because 5% to 15% of patients may rapidly switch to a manic episode.⁴

TABLE 68–3. Mood Disorders Defined by Episodes

| Disorder Subtype | Episode(s) ^a |
|--|---|
| Major depressive disorder, single episode | Major depressive episode |
| Major depressive disorder, recurrent | Two or more major depressive episodes |
| Bipolar disorder, type I ^b | Major depressive episode + manic or mixed episode |
| Bipolar disorder, type II ^c | Major depressive episode + hypomanic episode |
| Dysthymic disorder | Chronic subsyndromal depressive episodes |
| Cyclothymic disorder ^d | Chronic fluctuations between subsyndromal depressive and hypomanic episodes (2 years for adults and 1 year for children and adolescents) |
| Mood disorder due to a general medical condition | Disturbance in mood that is secondary to a general medical condition (see Table 68–2) |
| Substance-induced mood disorder | Disturbance in mood that is secondary to the effects of a substance (e.g., medication, toxin, drug abuse, somatic treatments; see Table 68–2) |
| Bipolar disorder not otherwise specified | Mood states do not meet criteria for any specific bipolar disorder |

^aThe length and severity of a mood episode and the interval between episodes varies from patient to patient. Manic episodes are usually briefer and end more abruptly than major depressive episodes. The average length of untreated manic episodes ranges from 4 to 13 months. Episodes may occur regularly (at the same time or season of the year) and often cluster at 12-month intervals. Women have more depressive episodes than manic episodes, whereas men have a more even distribution of episodes.

^bFor bipolar I disorder, 90% of individuals who experience a manic episode later have multiple recurrent major depressive, manic, hypomanic, or mixed episodes alternating with a normal mood state.

^cApproximately 5–15% of patients with bipolar II disorder will develop a manic episode over a 5-year period. If a manic or mixed episode develops in a patient with bipolar II disorder, the diagnosis is changed to bipolar I disorder.

^dPatients with cyclothymic disorder have a 15–50% risk of later developing a bipolar I or II disorder.

Compiled from American Psychiatric Association,² Goldberg and Harrow,⁴ and Goodnick.¹⁸

TABLE 68–4. Evaluation and Diagnostic Criteria of Mood Episodes

| | |
|--|--|
| Diagnostic work-up depends on clinical presentation and findings | <ul style="list-style-type: none"> • Mental status examination • Psychiatric, medical, and medication history • Physical and neurological examination • Basic laboratory tests: complete blood count, blood chemistry screen, thyroid function, urinalysis, urine drug screen • Psychological testing • Brain imaging: magnetic resonance imaging and functional scan; alternative: computed tomography scan, positron emission tomography scan • Lumbar puncture • Electroencephalogram |
|--|--|

| Diagnosis | | |
|------------------|--|--|
| Episode | Impairment of Functioning or Need for Hospitalization ^a | DSM-IV-TR Criteria ^b |
| Major depressive | Yes | >2-Week period of either depressed mood or loss of interest or pleasure in normal activities, associated with at least five of the following symptoms: <ul style="list-style-type: none"> • Depressed, sad mood (adults); may be irritable mood in children • Decreased interest and pleasure in normal activities • Decreased appetite, weight loss • Insomnia or hypersomnia • Psychomotor retardation or agitation • Decreased energy or fatigue • Feelings of guilt or worthlessness • Impaired concentration and decision making • Suicidal thoughts or attempts |
| Manic | Yes | >1-Week period of abnormal and persistent elevated mood (expansive or irritable), associated with at least three of the following symptoms (four if the mood is only irritable): <ul style="list-style-type: none"> • Inflated self-esteem (grandiosity) • Decreased need for sleep • Increased talking (pressure of speech) • Racing thoughts (flight of ideas) • Distractible (poor attention) • Increased activity (either socially, at work, or sexually) or increased motor activity or agitation • Excessive involvement in activities that are pleasurable but have a high risk for serious consequences (buying sprees, sexual indiscretions, poor judgment in business ventures) |
| Hypomanic | No | At least 4 days of abnormal and persistent elevated mood (expansive or irritable); associated with at least three of the following symptoms (four if the mood is only irritable): <ul style="list-style-type: none"> • Inflated self-esteem (grandiosity) • Decreased need for sleep • Increased talking (pressure of speech) • Racing thoughts (flight of ideas) • Increased activity (either socially, at work, or sexually) or increased motor activity or agitation • Excessive involvement in activities that are pleasurable but have a high risk for serious consequences (buying sprees, sexual indiscretions, poor judgment in business ventures) |
| Mixed | Yes | Criteria for both a major depressive episode and manic episode (except for duration) occur nearly every day for at least a 1-week period |
| Rapid cycling | Yes | >4 Major depressive or manic episodes (manic, mixed, or hypomanic) in 12 months |

^aImpairment in social or occupational functioning; need for hospitalization due to potential self-harm, harm to others, or psychotic symptoms.
^bThe disorder is not due to a medical condition (e.g., hypothyroidism) or substance-induced disorder (e.g., antidepressant treatment, medications, electroconvulsive therapy).
 Compiled from Torrey and Knable,¹ American Psychiatric Association,² American Psychiatric Association.³

MIXED EPISODE

Bipolar “mixed episode” (previously known as mixed state, dysphoric mania, or depressive mania) is defined as the simultaneous occurrence of manic and depressive symptoms.^{2,4} Mixed mood states occur in up to 40% of all episodes, and are more common in younger and older patients and in females.⁴ Mixed episodes are often difficult to diagnose and treat because of the fluctuating clinical presentation. Patients with mixed states often have comorbid alcohol and substance abuse, severe anxiety symptoms, a higher suicide rate, and a poorer prognosis.^{4,17}

COURSE OF ILLNESS

1 Bipolar disorder is frequently not recognized and treated for many years because of its fluctuating course and episodic mood states.^{3,4,18} The onset of bipolar disorder is rare before puberty, but its incidence increases during late adolescence and into early adulthood (usually between the ages of 15 and 30).² The average age of onset of a first manic episode is 21 for both men and women.³ The first episode in females is more likely to be a major depressive episode, whereas males are more likely to first experience a manic episode.^{2,3}

Women are more likely to have mixed states, depressive episodes, and rapid cycling compared to men.^{2,3} Onset of manic episodes after the age of 60 is rare and is likely caused by a medical or neurological condition (e.g., stroke, tumor, or dementia), medications, or substance use.³

Approximately 95% of patients with bipolar disorder experience episodes of depression during their lifetime.^{2,4} Recurrent depressive episodes are more common in women compared to men.⁴ Unipolar mania (i.e., with no depressive episodes) occurs in less than 5% to 9% of patients. More than 80% of patients have more than four mood episodes during their lifetime; untreated patients may have ten or more episodes during their lifetime.³ There may be a longer duration of episodes and more frequent episodes with aging.³ Usually there is a period of normal functioning between episodes, but approximately 20% to 30% of patients with bipolar I type and 15% with bipolar II type have no period of euthymia because of mood lability, residual mood symptoms, or a direct switch to the opposite polarity.²

Rapid cycling (more than four mood episodes per year) occurs in approximately 10% to 20% of bipolar I and II disorder patients, and 70% to 90% of rapid-cycling patients are women.^{1-4,16,23} Frequent and severe episodes of depression appear to be the most common hallmark of rapid cycling. Use of alcohol, stimulants such as cocaine and antidepressants, sleep deprivation, hypothyroidism, and seasonal changes may play a role in rapid cycling.^{4,16,34} Seasonal patterns of mania in the summer and depression during the winter have been observed.¹ A rare form of bipolar disorder is characterized by “ultrarapid” cycles (e.g., every 24 to 48 hours) or “continuous” cycles with no free interval between episodes.⁴ Rapid-cycling patients have a poorer long-term prognosis and often require combination therapies.⁴

Bipolar disorder affects an estimated 1% of children and adolescents and is often harder to recognize, diagnose, and treat than in a typical adult patient.^{2,3,16,18,35} Late adolescence (ages 15 to 19) is a period with increased vulnerability for the onset of bipolar disorder.¹⁸ Approximately 10% to 15% of adolescents with recurrent major depressive episodes have a subsequent episode of mania or hypomania.² Stimulants, hallucinogens, and excessive caffeine can precipitate a mania or mixed state.¹⁸ Early stressful experiences in childhood (e.g., physical or sexual abuse) may precipitate an earlier onset and result in faster cycling, increased suicide risk, and alcohol or substance abuse.^{4,18} Before the onset of mania, adolescents may exhibit irritability, hyperactivity, impulsivity, emotional lability, poor judgment, marked anxiety, insomnia, depression, and psychosis.^{2,14,18} Acute mania often has psychotic symptoms, thus adolescents may be misdiagnosed as having schizophrenia.¹⁸

Early-onset bipolar disorder (before age 7 years) often presents similarly to attention-deficit/hyperactivity disorder with extreme irritability or rages.³⁶ The misdiagnosis of attention-deficit/hyperactivity disorder and use of central nervous system stimulants may be a factor in causing treatment-refractory mixed states or rapid cycling. Child-onset bipolar disorder is associated with a higher genetic loading for affective illness, a high comorbidity of disruptive behavior and attention disorders, an increased risk of anxiety and psychotic features, more frequent mood recurrences (mixed states and rapid cycling), a more chronic course, and a less favorable response to treatment.^{3,4,13,18,35,36}

Fluctuations in hormones and neurotransmitters during the luteal phase of the menstrual cycle, postpartum period, and during perimenopause (starting approximately 10 years before menopause) may precipitate mood changes and increase cycling that resembles bipolar II disorder.^{2,23,26} Women with bipolar I disorder are at greater risk for relapse into mania, depression, or psychosis during the

postpartum period.³ If a severe mood episode occurs postpartum, there is an increased risk for recurrences during subsequent postpartum periods.³ Prophylactic medications such as lithium or valproate may prevent postpartum episodes in women with bipolar disorder.³

Alcohol and substance abuse is common among patients with bipolar disorder and may have a significant impact on the age of onset, course of the illness, and response to treatment.^{4,15,18,30} Alcohol and drug abuse or dependence has been reported in 46% and 41% of bipolar patients, respectively.^{3,18} Patients with substance use disorders are more likely to have an earlier onset of their illness, mixed states, higher rates of relapse, a poorer response to treatment, comorbid personality disorders, increased suicide risk, and more psychiatric hospitalizations.⁴ Bipolar patients may self-medicate during episodes (e.g., cocaine during mania and alcohol during depression), resulting in further impairment of judgment, poor impulse control, treatment nonadherence, and a worsening of the clinical course.^{3,4,17}

More than one-half (55% to 65%) of bipolar I patients have some degree of functional disability after the onset of their illness, and approximately 10% to 20% of bipolar patients have severe impairment in their psychosocial and occupational functioning.^{1-4,37} In a 1-year longitudinal study in 258 bipolar patients, two-thirds had four or more mood episodes a year despite comprehensive pharmacologic treatment, and approximately 33.2% of the year was spent being depressed compared to 10.8% of the time in a manic phase.³⁷

Compared with the general population, individuals with bipolar disorder have a 2.3-times higher mortality rate.¹ Suicide attempts occur in up to 50% of patients with bipolar disorder, and approximately 10% to 19% of individuals with bipolar I disorder commit suicide.^{2-4,38} Recent studies suggest patients with bipolar II disorder have more suicide attempts than bipolar I patients.³³ Suicidal ideation and attempts are most likely to occur in a depressive or mixed state and in patients with personality disorders, psychotic features, and/or a comorbid alcohol and substance use disorder.^{3,4,39} Accidental deaths are more frequent during manic episodes when the person has grandiosity, hallucinations, or delusions that result in risk-taking behaviors.^{1,3} In addition, bipolar patients have a higher mortality from endocrine, respiratory, and cardiovascular disease that may be related to higher rates of obesity, smoking, alcohol and substance abuse, infections, and lack of medical care.^{1,3}

Acutely manic or depressed patients may need protection (or hospitalization) because they are suicidal, have violent or aggressive behavior, or lack appropriate judgment and insight.³ Nonadherence with pharmacologic treatment and alcohol or substance abuse are major factors in relapse and hospitalizations.^{3,4} Medication discontinuation occurs in up to 50% of patients secondary to intolerance of drug-induced side effects.⁴⁰ The best predictor for level of functioning during a person's lifetime is adherence with medication treatment. Because of failure to recognize the disorder, reluctance to acknowledge it, or poor adherence with treatment, an estimated two-thirds of patients with bipolar disorder do not receive appropriate treatment.¹

Severe psychiatric illnesses such as bipolar disorder often manifest themselves during adolescence and young adulthood, and result in disruption of educational, occupational, marital, and other pursuits. Residual symptoms are often common between mood episodes, and more than one-half of bipolar patients manifest some degree of functional disability after the onset of the illness. Poorer outcome is associated with rapid cycling, mixed states, concurrent alcohol and substance abuse, nonadherence to treatment, and poor psychosocial support.

▶ TREATMENT: Bipolar Disorder

■ DESIRED OUTCOME

3 The desired outcome for bipolar disorder is to alleviate or shorten the duration of an acute manic, hypomanic, or depressive episode, to maintain good functioning, and to prevent further cycles of mania or depression.^{1,3,4} The general principles and goals for the management of bipolar disorder are found in Table 68–5.

■ GENERAL APPROACH TO TREATMENT

4 Treatment of bipolar disorder must be individualized because the clinical presentation, severity, and frequency of episodes vary widely among patients. Treatment approaches should include both nonpharmacologic and pharmacologic strategies (Table 68–6).⁴ Patients and family members should be educated about bipolar disorder (e.g., symptoms, causes, and course) and treatment options. Long-term adherence to treatment is the most important factor in achieving stabilization of the disorder.

■ NONPHARMACOLOGIC THERAPY

4 The basics of nonpharmacologic approaches should address issues of adequate nutrition, sleep, exercise, and stress reduction.^{1,4} Sleep deprivation, high stress, and deficiencies in dietary essential amino acids, fatty acids, vitamins, and minerals may exacerbate mood episodes and result in poorer outcomes.⁴ Another effective treatment is to combine medications with adjunctive psychoeducational programs, supportive counseling, insight-oriented psychother-

apy (individual or group), couples or family therapy, cognitive behavioral therapy, and communication enhancement training.^{1,3,4,18,41}

Most communities have self-help, support groups, and mental health organizations that provide information, educational materials, and support. For public information, individuals may contact the Depression and Bipolar Support Alliance at 800-826-3632 and www.dbsalliance.org; the National Alliance for the Mentally Ill (NAMI) at 800-950-6264 (helpline) and www.nami.org; the National Foundation for Depressive Illness at 800-248-4344 or 800-239-1265 and www.depression.org; National Mental Health Association at 800-433-5959 or 800-969-6642 (resource center) and www.nmha.org; and National Institute of Mental Health at 866-615-6464 or www.nimh.nih.gov.^{1,3} A recently published book for patients, families, and providers called *Surviving Manic Depression* is an excellent educational resource about the disorder.¹

Several nonpharmacologic treatment strategies (e.g., electroconvulsive therapy [ECT], high-intensity bright light therapy, phase-advanced sleep schedule, and partial or complete sleep deprivation) have been used for bipolar disorder.^{1,3,4} Bilateral ECT is an effective treatment for severe mania, psychotic depression, rapid cycling, and mixed states with high suicidal risk (approximately an 80% response rate).³ Repetitive transcranial magnetic stimulation has been reported to be effective in depression, but the effectiveness in bipolar disorder is unknown.^{3,4,42}

■ PHARMACOLOGIC THERAPY

5 Pharmacotherapy is crucial for the acute and maintenance treatment of bipolar disorder and includes lithium, valproate, carbamazepine, oxcarbazepine, lamotrigine, atypical antipsychotics, and adjunctive agents such as antidepressants and benzodiazepines.

TABLE 68–5. General Principles for the Management of Bipolar Disorder

Goals of treatment

- Eliminate mood episode with complete remission of symptoms (i.e., acute treatment)
- Prevent recurrences or relapses of mood episodes (i.e., continuation phase treatment)
- Return to complete psychosocial functioning
- Maximize adherence with therapy
- Minimize adverse effects
- Use medications with the best tolerability and fewest drug interactions
- Treat comorbid substance use and abuse
 - Eliminate alcohol, marijuana, cocaine, amphetamines, and hallucinogens
 - Minimize nicotine use and stop caffeine intake at least 8 hours prior to bedtime
- Avoidance of stressors or substances that precipitate an acute episode

Monitor for:

- Mood episodes: document symptoms on a daily mood chart (document life stressors, type of episode, length of episode, and treatment outcome); monthly and yearly life charts are valuable for documenting patterns of mood cycles
- Medication adherence (missing doses of medications is a primary reason for nonresponse and recurrence of episodes)
- Adverse effects, especially sedation and weight gain (manage rapidly and vigorously to avoid noncompliance)
- Suicidal ideation or attempts (suicide completion rates with bipolar I disorder are 10–15%; suicide attempts are primarily associated with depressive episodes, mixed episodes with severe depression or presence of psychosis)

Frequency of visits:

- Severely ill patients should be seen more often (i.e., weekly) compared with less ill patients who are symptomatic (i.e., every 2 weeks)
- When starting new medications or switching therapies, frequent monitoring is recommended (e.g., every 2 weeks) to assess adherence, efficacy, dosing, and adverse effects
- When a patient is stabilized on medication, less frequent monitoring is possible during the continuation phase (e.g., every month for the first 3 months, then every 2–3 months)
- Patients should be encouraged to call their clinician if any problems or adverse events occur or if mood episodes occur between scheduled appointments; rapidly identifying and correcting potential problems or making dosage adjustments is essential in achieving mood stabilization

TABLE 68–6. General Guidelines for Nonpharmacologic and Pharmacologic Treatments for Bipolar Disorder**Nonpharmacologic therapies**

- Psychoeducation about bipolar disorder, treatment, and monitoring for the patient and family
 - Early signs and symptoms of mania and depression and charting mood changes
 - Importance of compliance with therapy
 - Psychosocial or physical stressors that may precipitate an episode
 - Limiting substances and drugs that can trigger mood episodes
 - Strategies for coping with stressful life events
 - Development of a crisis intervention plan
- Psychotherapy (e.g., individual, group, and family), interpersonal therapy, and/or cognitive behavioral therapy
- Stress reduction techniques, relaxation therapy, massage, yoga, etc.
- Sleep (regular bedtime and awake schedule; avoid alcohol or caffeine intake prior to bedtime)
- Nutrition (regular intake of protein-rich foods or drinks and essential fatty acids; supplemental vitamins and minerals)
- Exercise (regular aerobic and weight training at least three times a week)

Pharmacologic treatments

- Use an established mood stabilizer for the treatment of an acute mood episode and for continuation therapy (see Table 68–7 for efficacy ratings and recommendations based on clinical trials, guidelines, and algorithms)
 - If a patient responded well to a specific pharmacologic agent in the past and it was well tolerated, then use the same treatment again
 - If a patient had intolerance or adverse reactions to a specific pharmacologic agent in the past or has a strong preference against an agent, then do not use it
 - It is preferable to slowly taper off a medication than to abruptly discontinue it
- There are no specific guidelines for when to switch therapies or when combination approaches should be started
 - In general, if a patient with mania or mixed states has not responded within 2 to 4 weeks with an established mood stabilizer (e.g., lithium, lamotrigine, or valproate), a second first-line agent can be added to the regimen for augmentation; alternative treatment options include adding carbamazepine, oxcarbazepine, or an atypical antipsychotic in lieu of a first-line agent
 - Patients who are nonresponsive or intolerant to adverse effects of first-line pharmacologic approaches should be switched to another agent; when necessary, electroconvulsive therapy may be used to rapidly reduce manic or depressive symptoms and may be used for maintenance treatment
 - Changes in medication therapies and doses should be based on treatment response (or change in symptoms), tolerability of side effects, serum drug levels when applicable, and avoidance of drug interactions
- For patients with rapid cycling (>4 mood episodes per year):
 - Evaluate and treat underlying hypothyroidism, hormonal imbalance, or drug or alcohol abuse
 - For antidepressant-induced rapid cycling, taper off antidepressant and other agents that increase norepinephrine or dopamine activity (e.g., central nervous system stimulants, sympathomimetics, and caffeine)
- Use combination therapies for patients who are partially responsive or unresponsive to monotherapy with an established mood stabilizer
 - Combination therapies may be needed for the treatment of acute mania or mixed episodes, breakthrough depression, and rapid cycling
 - Reassessment of combination and adjunctive therapies should be done routinely and unnecessary medications should be tapered off gradually and discontinued
 - Use antidepressants or stimulants cautiously in patients with rapid cycling or with a history of antidepressant-induced mania; patients with recurrent depressive episodes may need long-term antidepressant therapy to minimize relapses
- Some mood stabilizers have an increased teratogenic risk during the first trimester (e.g., carbamazepine, lithium, oxcarbazepine, and valproate); this risk is greater if the patient is on multiple agents
 - Prenatal monitoring suggested: maternal serum α -fetoprotein screening for neural tube defects before the twentieth week of gestation and high-resolution ultrasound at 16–18 weeks' gestation to detect cardiac abnormalities; fetal echocardiography is recommended if lithium is used during the first trimester
 - Routine serum level monitoring of medications (when applicable) is recommended during pregnancy, with dosage adjustments if indicated
- Electroconvulsive therapy may be considered for patients with severe or treatment-resistant mania or depression and in pregnant women; maintenance drug therapy may be considered for patients whose acute episodes responded to electroconvulsive therapy
- After the resolution of the mood episodes, maintenance treatment is generally recommended for both bipolar I and II disorder: lithium or valproate (first choices) and carbamazepine, lamotrigine, and oxcarbazepine (alternative choices)
 - Patients should be maintained on a 6-month continuation phase of the mood stabilizer while the adjunctive treatment(s) are tapered and discontinued if possible
 - Patients who have had only one manic episode and who have responded to treatment should be continued on a mood stabilizer for 12 months, then gradually tapered off over several months (usually after 6 months of complete remission)
- Lifetime prophylaxis with a mood stabilizer is recommended for:
 - Bipolar I: after two manic episodes, after one severe manic episode, in the presence of a strong family history of bipolar disorder or major depressive disorder, with frequent episodes (more than one per year), or with rapid onset of manic episodes
 - Bipolar II: after three hypomanic episodes or if the patient becomes hypomanic with antidepressant therapy

| Haloperidol | A: monotherapy or adjunctive | D | D |
| Olanzapine | A+: monotherapy or adjunctive | B: adjunctive with fluoxetine | D |
| Risperidone | A+: monotherapy or adjunctive | B: adjunctive | D |
| Quetiapine | A+: monotherapy or adjunctive | D | D |
| Ziprasidone | A+: monotherapy | D | D |

Definition of Ratings:

A = Efficacy established by two or more randomized, double-blind, placebo-controlled or comparator trials and/or recommended as a first-line agent by APA Practice Guidelines for the Treatment of Patients with Bipolar Disorder (Revision) or Texas Consensus Panel on Medication Treatment of Bipolar Disorder; + = approved by the FDA.
 B = Efficacy suggested by one randomized, double-blind, placebo-controlled or comparator trial; recommended as a second-line (alternative) agent by APA Practice Guidelines for the Treatment of Patients with Bipolar Disorder (Revision) or Texas Consensus Panel on Medication Treatment of Bipolar Disorder; not approved by the FDA.
 C = Efficacy suggested by two or more open-label and/or non-placebo-controlled trials; not approved by the FDA.

D = No controlled clinical trials and/or efficacy not established for monotherapy in bipolar disorder.

X = Not recommended due to negative results or no significant difference from placebo on a randomized, placebo-controlled or comparator trial.

APA, American Psychiatric Association, FDA, Food and Drug Administration.

Compiled from American Psychiatric Association,³ Suppes et al,⁴⁵ Sachs,⁴⁷ Keck and McElroy,⁵⁰ and Kuskumar.⁶⁴

this may not be accurate since some medications are more effective for acute mania, some for the depressive episode, and others for the maintenance phase.^{3,50,51} Lithium, divalproex sodium (or valproate), and olanzapine are currently approved by the Food and Drug Administration (FDA) for the treatment of acute mania in bipolar I disorder, and only lithium and lamotrigine are approved for the maintenance treatment of bipolar I disorder. Lithium is the drug of choice for classic bipolar disorder, whereas valproate has better efficacy for mixed states and rapid cycling compared to lithium.³ Carbamazepine and oxcarbazepine are not approved for bipolar disorder, but are often alternative treatments (or adjunctive agents) for acute mania and maintenance therapy.^{3,52}

Several atypical antipsychotics (e.g., aripiprazole, quetiapine, risperidone, and ziprasidone) have been approved by the FDA for acute mania (e.g., monotherapy and adjunctive with lithium or valproate) and are under investigation for maintenance treatment of bipolar I disorder. Combination therapies (e.g., lithium plus valproate or carbamazepine; lithium or valproate plus an atypical antipsychotic) may provide better acute response and long-term prevention of relapse and recurrence than monotherapy in some bipolar patients with mixed states or rapid cycling.^{3,4,52} Controlled efficacy and safety studies addressing the combination of specific antidepressants with mood-stabilizing agents for acute versus long-term therapy are lacking.^{3,4,49}

6 Several guidelines and algorithms have been published regarding the treatment of bipolar disorder, and these are generally based on the best available data and the clinical consensus of experts.

One excellent reference is the Practice Guideline for the Treatment of Patients with Bipolar Disorder (Revision) that was published in 2002 by the APA.³ The APA guidelines address the diagnosis, clinical course, epidemiology, and treatment strategies for adults, but are not intended to be used as a standard of psychiatric care. Texas has developed and implemented algorithms in the public mental health system to improve treatment outcomes with bipolar I disorder.^{45,53} In addition, an international task force of the World Federation of Societies of Biological Psychiatry has published guidelines for the treatment of bipolar depression and mania.^{46,54}

There are few controlled studies in children and adolescents with bipolar disorder, thus little is known about the long-term efficacy and safety of specific agents or for combination therapies in this population.^{3,4,13,35,55} The only published guidelines for children and adolescents are the Practice Parameters for the Assessment and Treatment of Children and Adolescents with Bipolar Disorder by the American Academy of Child and Adolescent Psychiatry,¹³ and a proposed treatment algorithm for pediatric bipolar disorder.⁵⁵ A more complete review of using mood stabilizers and antipsychotics in children and adolescents can be found elsewhere.⁵⁶

6 Based on the APA guidelines,³ the Texas algorithms for bipolar disorder,⁴⁵ available research, and current marketing of medications, an example of treatment algorithms and guidelines for acute mood episodes in adult patients with bipolar I disorder are listed in Table 68–8.⁴⁷ Because newer anticonvulsants, atypical antipsychotics, and combination therapies are under investigation for bipolar disorder, published guidelines, algorithms, and decision trees may be

| | <p>Fifth, if response is inadequate, consider adding adjunctive therapies^e</p> | | <p>Fifth, if response is inadequate, consider adding adjunctive therapies^e</p> |

^aUtilize standard therapeutic serum concentration ranges; if partial response or breakthrough episode, adjust dose to achieve higher serum concentrations without causing intolerable adverse effects; valproate is preferred over lithium for mixed episodes and rapid cycling; lithium and/or lamotrigine is preferred over valproate for bipolar depression.

^bLamotrigine is not approved for the acute treatment of depression, and the dose must be started low and slowly titrated up to decrease adverse effects if used for maintenance therapy of bipolar I disorder. A drug interaction and a severe dermatologic rash may occur when lamotrigine is combined with valproate (i.e., lamotrigine doses must be halved from standard dosing titration).

^cAntidepressant monotherapy is not recommended for bipolar depression. Bupropion, selective serotonin reuptake inhibitors (SSRIs; e.g., citalopram, escitalopram, or sertraline), and serotonin-norepinephrine reuptake inhibitors (SNRIs; e.g., venlafaxine) have shown good efficacy and fewer adverse effects in the treatment of unipolar depression; monoamine oxidase inhibitors (MAOIs) and tricyclic antidepressants (TCAs) have more adverse effects (e.g., weight gain) and may have a higher risk of causing antidepressant-induced mania; fluoxetine, fluvoxamine, nefazodone, and paroxetine inhibit liver metabolism and should be used with caution in patients on concomitant medications that require cytochrome P450 clearance; paroxetine and venlafaxine have a higher risk for causing a discontinuation syndrome.

^dElectroconvulsive therapy (ECT) is used for severe mania or depression during pregnancy and for mixed episodes; prior to treatment, anticonvulsants, lithium, and benzodiazepines should be tapered off to maximize therapy and minimize adverse effects.

^eThere are minimal or no efficacy data for some adjunctive (add-on) therapies: α_2 -adrenergic agonists, calcium channel blockers, gabapentin, tiagabine, topiramate, and zonisamide; topiramate may have efficacy as an adjunctive agent with standard agents for maintenance therapy, based on initial trials.

Compiled from American Psychiatric Association,³ Suppes et al,⁴⁵ Sachs,⁴⁷ Keck and McElroy,⁵⁰ and Kusmakar.⁶⁴

out of date as new scientific knowledge evolves. Selection of treatments for acute mood episodes (e.g., manic or mixed, depressive, or rapid cycling) and for maintenance strategies to prevent relapses of mood episodes should be individualized. Treatment plans should be based on patient-specific characteristics, comorbid psychiatric and medical conditions, and avoidance of drug interactions and adverse effects.³

■ **General Information Regarding Efficacy and Safety.** Lithium was first utilized in 1949 as a treatment for mania and was approved in 1972 in the United States for the treatment of acute mania and for maintenance therapy. Lithium was the first established mood stabilizer, and is still considered a first-line agent for acute mania and continuation treatment of bipolar I and II disorder.^{50,57,58} Lithium is the only bipolar medication approved for children and adults aged 12 and older. Long-term lithium treatment has been shown to reduce suicide risk in several studies.^{3,59} Patients with rapid cycling or mixed states may not respond as well to lithium monotherapy compared to some anticonvulsants.^{34,57} Lithium requires regular assessment of renal and thyroid functioning and lithium blood level monitoring to minimize adverse effects.³

In the 1980s, anticonvulsants were investigated for manic-depressive illness since the disorder had similar characteristics to episodic neurological disorders like epilepsy and migraines. Divalproex sodium (known as sodium valproate) was marketed in 1995 for the acute treatment of mania in adults and is now the most prescribed mood stabilizer in the United States. Although carbamazepine has been used for both acute and maintenance therapy, it is not approved in the United States for bipolar disorder and may cause more adverse effects and drug interactions compared to oxcarbazepine, a 10-keto analogue of carbamazepine that is used extensively in Europe.^{3,4} Valproate, carbamazepine, and oxcarbazepine each have a wide range of neurological, gastrointestinal, electrolyte, and hematologic adverse effects that requires regular assessment as well as routine blood level monitoring (for valproic acid and carbamazepine).

Lamotrigine, a newer anticonvulsant, was approved in 2003 in the United States for the maintenance treatment of bipolar I disorder.^{60,61} Lamotrigine add-on or monotherapy has been used for treatment-refractory bipolar depression without increasing cycling or inducing a switch to mania.^{3,60} Lamotrigine is associated with causing hypersensitivity reactions and rare life-threatening skin rashes and requires slow dosage titration.³

Atypical antipsychotics such as aripiprazole, olanzapine, quetiapine, risperidone, and ziprasidone are effective as monotherapy or adjunctive therapy with lithium and valproate in the treatment of acute mania.⁶² Some antipsychotics have the potential to cause adverse effects such as extrapyramidal reactions, sedation, depression, emotional blunting, sexual dysfunction, weight gain, and orthostatic hypotension.^{18,63} Prophylactic use of antipsychotics may be needed for some patients with recurrent mania or mixed states, but the risks versus benefits must be weighed because of long-term adverse effects (e.g., obesity, type 2 diabetes, hyperlipidemia, hyperprolactinemia, cardiac disease, and tardive dyskinesia).^{64,65}

Few randomized controlled trials have been done to evaluate different approaches for the treatment of acute and recurrent bipolar depression.^{3,51,66,67} Nonpharmacologic treatment that may have augmenting effects include phototherapy for seasonal-pattern depression and sleep deprivation for rapid cycling.^{4,68} The use of ECT for severe episodes of mania/mixed episodes, depression, psychotic features (e.g., hallucinations or delusions), or rapid cycling is still considered the best acute treatment approach for those patients who do not respond to first-line mood stabilizers such as lithium and valproate.^{3,4}

Alternative Drug Treatments

➤ Although monotherapy with an established mood stabilizer is preferred for long-term maintenance, combinations of different types of medications may be necessary for patients with acute depressive, manic, or mixed episodes who have partial or nonresponse to monotherapy, and for those who experience rapid cycling.^{3,64,69}

■ **Benzodiazepines.** High potency benzodiazepines such as clonazepam and lorazepam are common alternatives to antipsychotics when patients are experiencing acute mania, agitation, anxiety, panic, and insomnia, or cannot take mood stabilizers (e.g., during the first trimester of pregnancy).^{3,4,29,70,71} Lorazepam is available for intramuscular injection and is useful in the acute management of agitation. Benzodiazepines cause minimal adverse effects compared to antipsychotics, and at higher doses, rapidly sedate agitated patients.⁴ Benzodiazepines may cause central nervous system depression, sedation, cognitive and motor impairment, dependence, and withdrawal reactions. Relative contraindications for long-term therapy with benzodiazepines are drug or alcohol abuse or dependency. When no longer required, benzodiazepines should be gradually tapered over several weeks and discontinued to avoid withdrawal symptoms.

■ **Antidepressants.** Antidepressants are routinely added for the treatment of acute depression, but some studies have reported that specific classes such as the tricyclic antidepressants may cause an increased risk of inducing mania in bipolar I disorder and possibly cause rapid cycling.^{3,4} Some guidelines recommend avoiding antidepressants in the treatment of bipolar depression or limiting their use to brief intervals, but recent evidence suggests that the coadministration of mood stabilizers can reduce the risk of antidepressant-induced switching.⁵¹ Before the addition of an antidepressant, the patient should be on a therapeutic dosage or blood level of a primary mood stabilizer.³ Patients who have a history of mania after a depressive episode or who have frequent cycling should be treated cautiously with antidepressants.^{3,4} In general, the antidepressant should be gradually withdrawn 2 to 6 months after remission, and the patient maintained on a mood-stabilizing agent.^{32,44} For patients with recurrent depressive episodes, the use of long-term adjunctive treatment with antidepressants may be required to avoid relapses, particularly in bipolar II disorder.^{3,64,72} Treatment-resistant depression is often associated with using inadequate dosages and duration of treatment for mood-stabilizing agents and antidepressants, alcohol and substance abuse, poor compliance, and rapid cycling. For more information, see Chapter 67 for comparisons between antidepressants.

Alternative augmenting or adjunctive treatments for depression include: atypical antipsychotics such as olanzapine for mixed states, psychotic features, or rapid cycling; estradiol replacement therapy for perimenopausal women with rapid cycling; thyroid hormones for rapid cycling or augmentation of antidepressants; calcium channel blockers (e.g., nimodipine) for rapid cycling; and DA agonists (e.g., pramipexole) for augmentation of DA.^{3,4}

■ **Calcium Channel Antagonists.** Calcium channel antagonists inactivate voltage-sensitive calcium channels, thus inhibiting neurotransmitter synthesis and release and neuronal signal transmission.^{9,18} Verapamil, a nondihydropyridine, has demonstrated mood stabilizing properties in some studies but negative results were found in other trials.^{3,4,18,75} Nimodipine, a dihydropyridine, may be more effective than verapamil for rapid-cycling bipolar disorder because of its anticonvulsant properties, high lipid solubility, and good penetration into the brain.^{3,4,9,18,34,75} Calcium channel blockers are generally well

tolerated, and the most common adverse effects are bradycardia and hypotension. The low teratogenic effects of these agents may make them a preferable choice over lithium or anticonvulsants during pregnancy and breastfeeding.¹⁸

■ **Newer Anticonvulsants.** Third-generation anticonvulsants have been investigated for treating bipolar disorder with the hope that a different mechanism of action would be beneficial for mood stabilization.^{1,76,77} Despite early reports of efficacy based on open-label trials, agents such as gabapentin and topiramate were not effective for acute mania in double-blind comparator trials.^{78–80} Both gabapentin and topiramate require slow dosing titration to avoid initial adverse effects, thus they may have a delayed onset of efficacy until therapeutic doses can be attained.^{81,82} Gabapentin has virtually no drug interactions but requires three-times-daily dosing because of a short half-life.⁴ Gabapentin causes sedation, dizziness, and weight gain with high-dose therapy.^{65,74} Topiramate may cause drug interactions and has dose-related adverse effects (e.g., sedation, fatigue, psychomotor slowing, dizziness, speech and language disorders, difficulty with memory and concentration, paresthesia, nystagmus, tremor, nausea, anorexia, and weight loss).^{3,82} Although topiramate has been used as an add-on weight-reduction medication, there are no randomized controlled trials supporting its use in bipolar disorder.^{65,74} The effectiveness of gabapentin and topiramate as adjunctive agents for bipolar depression, comorbid anxiety and insomnia, refractory patients, or for the maintenance phase still needs to be evaluated in controlled studies.^{4,77–79}

Newer anticonvulsants such as levetiracetam and zonisamide have several published case reports or open trials showing efficacy in mania and treatment-refractory rapid cycling, but it is too early to predict whether they have a place in either acute or maintenance therapy.^{49,77,79} Tiagabine has caused seizures in patients with bipolar disorder and has two negative open-label trials, thus there is little support for its safety and efficacy as a mood stabilizer.

■ **Novel Agents and Dietary Intake.** Disturbances in 5-HT neurotransmission secondary to inadequate dietary L-tryptophan or abnormalities in tryptophan hydroxylase, 5-HT transporters, and 5-HT receptors was implicated in the pathophysiology of manic-depressive illness as early as 1958.¹⁸ Low 5-HT activity may be a trait marker for bipolar disorder.²⁷ If available 5-HT is low, the synthesis and secretion of melatonin may be disrupted, thus causing circadian rhythm changes.¹⁸ Acute tryptophan depletion has been shown to reverse the antidepressant effects of 5-HT reuptake inhibitors in depressed patients in remission, but may not negatively affect mood changes in lithium-stabilized bipolar patients.⁸³ Randomized controlled studies of L-tryptophan or 5-hydroxytryptophan have shown positive results in the acute treatment and prophylaxis of bipolar disorder.¹⁸ Because 5-HT synthesis in the brain is dependent on dietary L-tryptophan intake, the importance of adequate and regular ingestion of animal-derived protein should be discussed with patients.¹⁸

A dietary deficiency in essential fatty acids (found in certain fish oils and flaxseed oil that contains α -linolenic acid) has been proposed as a potential cause of mood disorders.^{84,85} Omega-3 fatty acids have been shown to suppress neuronal pathways and inhibit kindling processes by several mechanisms (e.g., inhibition of phosphatidylinositol and G-protein secondary messengers and blocking L-type calcium channels). Seafood and fish are rich dietary sources of omega-3 essential fatty acids, specifically docosahexaenoic acid and eicosapentaenoic acid. A relationship between greater seafood consumption and lower prevalence rates of bipolar disorders has been reported.⁸⁴ A double-blind, placebo-controlled study with high doses of omega-

3 fatty acids reported some positive benefits in patients with bipolar disorder.⁸⁵

Several novel agents have been tried in bipolar disorder, but randomized controlled trials are needed to determine their efficacy and safety.³ High doses of levothyroxine sodium (0.15 to 0.4 mcg/day) have been reported to have mood-stabilizing properties in rapid-cycling bipolar patients when combined with traditional mood-stabilizing agents.³

■ SPECIAL POPULATIONS

Approaches for treating bipolar disorder in special populations (e.g., comorbid medical or psychiatric disorders, pregnancy, or breastfeeding) are found in Table 68–9. Patients with comorbid medical conditions or concomitant substance abuse, those over 65 years of age, and pregnant patients may require different treatment approaches. Approximately 20% to 50% of women with bipolar disorder relapse postpartum; therefore prophylaxis with mood stabilizers is recommended immediately postpartum to decrease the risk of relapse.⁸⁶

■ DRUG CLASS INFORMATION

ⓘ Product information, dosing and administration, clinical use, and proposed mechanism of action for agents used in the treatment of bipolar disorder are found in Table 68–10. Pharmacokinetics and therapeutic serum concentrations of lithium and selected anticonvulsants are listed in Table 68–11. Table 68–12 includes recommendations for baseline and routine laboratory testing for patients receiving carbamazepine, lamotrigine, lithium, olanzapine, oxcarbazepine, and valproate.

■ Antipsychotics

■ **Pharmacology and Mechanism of Action.** Typical (conventional) antipsychotic agents that block DA₂ receptors and newer atypical antipsychotics that block both DA₂ and 5-HT_{2A} receptors are used to decrease DA activity in the treatment of mania and mixed states.

■ **Pharmacokinetics.** A summary of pharmacokinetic parameters and metabolism pathways for antipsychotics is found in Chapter 66.

■ **Efficacy.** Typical antipsychotic agents are effective in up to 70% of patients with acute mania, particularly those with psychosis and psychomotor agitation. Atypical antipsychotics such as olanzapine, quetiapine, and risperidone have demonstrated similar efficacy and fewer side effects than typical antipsychotics (e.g., chlorpromazine and haloperidol) for the treatment of acute mania associated with agitation, aggression, and psychosis.^{3,62,63,87,88} Currently aripiprazole, olanzapine, quetiapine, risperidone, and ziprasidone are FDA approved for the treatment of acute manic episodes in bipolar I disorder. Depot antipsychotics (e.g., haloperidol decanoate, fluphenazine decanoate, and risperidone long-acting injection) may have a place in the maintenance of patients with noncompliance or treatment-resistant bipolar disorder.³ Controlled studies in acute mania with lithium or valproate plus an antipsychotic suggest greater efficacy with combination therapies compared with any of these agents alone.^{3,62} Adjunctive atypical antipsychotics may be beneficial in the treatment of breakthrough manic episodes or if there is incomplete response to monotherapy with lithium or valproate.

Olanzapine has shown efficacy in the treatment of acute manic, mixed, and depressive phases with or without psychotic features in

TABLE 68–9. Approaches to Treating Bipolar Disorder in Special Populations and with Comorbidities

| Population Type or Comorbid Condition | First-Line Therapies | Second-Line Therapies |
|---|---|--|
| Aggression/violence/homicidal | Hospitalization: optimize dose and/or serum concentrations of lithium or valproate, then lithium or valproate ± atypical antipsychotic ^a Alternative: carbamazepine or oxcarbazepine ± atypical antipsychotic ^a | Lithium ± valproate ± atypical antipsychotic ^a ± benzodiazepines Alternative: carbamazepine or oxcarbazepine ± atypical antipsychotic ^a ± benzodiazepines |
| Anxiety disorders (panic or obsessive-compulsive disorder) | Valproate or add antidepressant (e.g., 5-HT reuptake inhibitor) | Adjunctive: benzodiazepine (short-term) |
| Attention deficit hyperactivity disorder | Add bupropion or atomoxetine; DA or NE augmenting agents may exacerbate mood changes and make it difficult to monitor bipolar disorder | CNS stimulants (use cautiously): amphetamine, dextroamphetamine, methylphenidate |
| Breast-feeding | All medications used in the treatment of bipolar disorder are secreted in breast milk, thus the risks versus benefits must be weighed. | There are no recommendations or treatment guidelines at this time. Valproate or carbamazepine are compatible with breast-feeding, but potential risks should be considered. |
| Cardiac disease/heart failure | Valproate: monitor for hypertension, tachycardia, peripheral edema | Calcium channel blocker: monitor for bradycardia, hypotension, peripheral edema |
| Catatonia (mutism, motor excitement, and stereotypic movements) | Benzodiazepines (lorazepam) for acute treatment | ECT for acute treatment |
| Children and adolescents | Lithium or valproate: maintenance treatment should continue for a minimum of 18 months after stabilization to decrease risk of relapse | Carbamazepine or oxcarbazepine. Alternative: atypical antipsychotics (for psychosis) or combination therapies |
| Geriatric patients (over 65 years of age and in good health) | Rule out general medical conditions, medications, or substance use that may cause a manic syndrome; valproate and lithium require lower doses, regular laboratory and serum concentration monitoring; concomitant medications and medical conditions may alter the metabolism and excretion of medications | Carbamazepine or oxcarbazepine induce liver enzymes and may affect the metabolism and blood levels of concomitant medications; lithium, antipsychotics, and benzodiazepines increase the risk of adverse effects and cognitive impairment |
| Liver disease | Lithium: not metabolized by the liver Alternative: gabapentin (no efficacy data) | All anticonvulsants (except gabapentin), atypical antipsychotics, benzodiazepines, and calcium channel blockers require liver metabolism, and dosage adjustments may be needed (e.g., 25–50% reduction of normal doses) |
| Neurologic disorders (migraine, seizures) | Valproate | Carbamazepine or oxcarbazepine Alternative: lamotrigine |
| Pregnancy ^b | Pregnancy should be planned in consultation with a psychiatrist and obstetrician to weigh risks versus benefits of treatment options (e.g., discontinuing medications before conception or at the beginning of pregnancy, discontinuing medications only for the first trimester, or continuing medications throughout pregnancy). Medications should be tapered off slowly to avoid recurrent mood episodes. Prophylactic medications such as lithium or valproate may prevent postpartum mood episodes. Alternative: ECT used for patients with severe mania, mixed states, depression, or psychosis. | Acute mania or mixed episode: first choice: lithium After first trimester: carbamazepine, lamotrigine, oxcarbazepine, or valproate Second choice: benzodiazepine (lorazepam) Third choice: calcium channel blocker With psychosis: first choice: adjunctive high-potency typical antipsychotic (haloperidol, perphenazine, thiothixene, or trifluoperazine) Second choice: adjunctive atypical antipsychotic ^b Acute depression: First choice: adjunctive 5-HT or 5-HT/NE reuptake inhibitors Second choice: adjunctive bupropion ECT |
| Psychosis (delusions, hallucinations) | Optimize dose and/or serum concentrations of lithium or anticonvulsant Alternative: add atypical or typical antipsychotic for short-term adjunctive therapy | |
| Renal disease or impairment | Carbamazepine and valproate: if creatinine clearance is <10 mL/min, administer 75% of standard dose; combining medications in patients with renal impairment should be done cautiously; use agents that have a therapeutic serum concentration range for blood level monitoring | Oxcarbazepine: initiate dosing at one-half the usually starting dose (300 mg/day) and increase slowly |

TABLE 68–9. (Continued)

| Population Type or Comorbid Condition | First-Line Therapies | Second-Line Therapies |
|---|--|--|
| Substance use disorders (e.g., alcohol, cocaine, methamphetamine) | Dual-diagnosis treatment program: substance abuse plus standard pharmacologic/nonpharmacologic treatments for bipolar disorder; hepatic dysfunction from chronic alcohol abuse or from hepatitis may alter the metabolism of some agents | Lithium or valproate Alternative: carbamazepine or oxcarbazepine or topiramate (alcohol dependence) |
| Suicidal behavior or attempts | Lithium: long-term treatment associated with reduction of suicide risk and mortality | |

^aOlanzapine, quetiapine, and risperidone are preferred; alternative atypicals: aripiprazole and ziprasidone are newer agents and may initially cause akathisia-like reactions; clozapine is usually reserved for treatment-resistant mania or mixed states.

^bTeratogenic ratings: gabapentin, lamotrigine, olanzapine, oxcarbazepine, quetiapine, risperidone, topiramate, and verapamil are category C; carbamazepine, clonazepam, lithium, lorazepam, and valproate are category D. Lithium may have fewer teratogenic effects than previously thought and may be considered during the first trimester. Carbamazepine, oxcarbazepine, and topiramate increase the metabolism of oral contraceptives and may make them ineffective.

DA, dopamine; ECT, electroconvulsive therapy; 5-HT, serotonin; NE, norepinephrine.

Compiled from American Psychiatric Association,³ Goldberg and Harrow,⁴ Goodnick,¹⁸ and Suppes et al.⁴⁵

double-blind trials (compared with placebo, lithium, valproate, and haloperidol).^{62,87} Patients with a younger onset of illness, no prior substance abuse, and those who are antipsychotic naïve may respond better to olanzapine.⁸⁹ Olanzapine is under investigation for the long-term maintenance treatment of bipolar disorder.⁵¹

Clozapine monotherapy has acute and long-term mood-stabilizing effects in refractory bipolar disorder, including conditions with mixed mania and rapid cycling, but requires regular white blood cell monitoring for agranulocytosis.^{3,18,62,86} Risperidone, in combination with other mood-stabilizing agents (lithium or valproate), and as monotherapy (versus haloperidol, lithium, and placebo) has demonstrated efficacy in several double-blind acute mania trials.^{3,18,62,90} Quetiapine at higher doses (e.g., 400 to 800 mg/day) has been reported to be effective for monotherapy and as an adjunctive agent with standard mood stabilizers in acute mania in a double-blind, placebo-controlled trial.⁶² Ziprasidone was more effective than placebo in a double-blind, placebo-controlled study in acute mania, but has been associated with inducing mania or hypomania.^{3,62} Aripiprazole, a partial agonist at the DA₂ receptor, has been evaluated in two randomized, placebo-controlled studies in bipolar I disorder patients with an acute manic or mixed episode and in one comparative trial with haloperidol in acute mania.⁶² Aripiprazole was significantly better than placebo in one 3-week study at doses of 30 mg/day (but was no different from placebo in the second study), and was significantly better than haloperidol by week 12.⁶²

The long-term safety and efficacy of antipsychotics for monotherapy or as an adjunctive treatment for bipolar depression and as a prophylactic agent in bipolar disorder still needs to be evaluated.^{3,51,87,88}

■ **Adverse effects.** Low-potency typical antipsychotics (chlorpromazine and thioridazine) are more sedating and cause more orthostatic hypotension and weight gain, but have the advantage of causing fewer extrapyramidal side effects.³ The high-potency typical agents (haloperidol and fluphenazine) and moderate-potency agents (perphenazine and thiothixene) cause less sedation and fewer blood pressure changes, but are more likely to cause extrapyramidal side effects such as akathisia and pseudoparkinsonism.³ Patients with bipolar disorder may be at increased risk of developing extrapyramidal side effects, tardive dyskinesia, and depression from antipsychotic agents.^{4,18}

Atypical antipsychotics cause fewer extrapyramidal side effects and may have a lower risk of causing tardive dyskinesia than typ-

ical agents.^{3,87} At dosages under 6 mg/day, risperidone has few extrapyramidal side effects; however, the incidence increases with higher dosages, and several cases of tardive dyskinesia have occurred. Although olanzapine and clozapine have a lower incidence of extrapyramidal side effects than risperidone, they may cause sedation, dry mouth, constipation, orthostatic hypotension, increased appetite, weight gain, and hepatic transaminase elevations.^{3,18} Weight gain may lead to obesity, impaired glucose tolerance, hyperglycemia, an increased risk of type 2 diabetes, elevation of cholesterol and triglyceride levels, hypertension, and mortality.⁷⁴ Elevated plasma prolactin concentrations have been reported with risperidone and olanzapine, and may result in sexual dysfunction, galactorrhea, menstrual disorders, impaired fertility, and decreased bone density.³

Quetiapine has sedative effects and may cause weight gain, but it causes minimal extrapyramidal side effects or prolactin elevations. Ziprasidone causes few extrapyramidal side effects, does not significantly increase prolactin levels, and has a lower risk of causing weight gain. Aripiprazole has low extrapyramidal side effects (except for initial akathisia), minimal effect on prolactin levels, and is considered to be weight neutral.

■ **Drug-Drug Interactions.** Combining antipsychotics with other agents with antimuscarinic, antihistaminic, α_1 -adrenergic blockade, and DA blockade may result in additive adverse effects.¹ DA-augmenting agents may reverse the effect of DA receptor blockade, and 5-HT-augmenting agents may work against the 5-HT_{2A} receptor blockade, thus decreasing DA release and worsening extrapyramidal side effects. Several atypical antipsychotic agents may be affected by enzyme inhibitors or inducers. Cigarette smoking is a potent inducer of cytochrome P450 1A2 and can significantly lower clozapine and olanzapine serum concentrations. Agents that inhibit the cytochrome P450 1A2 or 3A/4 pathways may significantly increase clozapine serum concentrations and result in toxicity and an increased risk of seizures. A summary of drug interactions with antipsychotics can be found in Chapter 66.

■ **Dosing and Administration.** For acute mania, higher initial doses of antipsychotics may be required (e.g., olanzapine 15 mg/day was more effective than 10 mg/day in hospitalized patients).³ Once acute mania is controlled (usually within 7 to 28 days), the antipsychotic can be gradually tapered and discontinued, and the patient maintained on the mood stabilizer alone.

TABLE 68–10. Product Formulations, Dosage and Administration, Clinical Use, and Proposed Mechanism of Action of Agents Used in the Treatment of Bipolar Disorder

| Generic Name | Trade Name | Formulations | Dosage and Administration | Clinical Use | Proposed Mechanism of Action |
|---|-------------|--|--|---|--|
| Lithium salts: FDA-approved for bipolar disorder | | | | | |
| Lithium carbonate | Eskalith | Capsule: 300 mg | 900–2400 mg/day in 2–4 divided doses, preferably with meals. There is wide variation in the dosage needed to achieve therapeutic response and trough serum lithium concentration (i.e., 0.6–1.2 mEq/L for maintenance therapy and 1.0–1.2 mEq/L for acute mood episodes taken 8–12 hours after the last dose). | Use alone or in combination with other drugs (e.g., valproate, carbamazepine, antipsychotics) for the acute treatment of mania and for maintenance treatment. | <ul style="list-style-type: none"> • Normalizes or inhibits secondary messenger systems (e.g., inhibits phosphoinositide and adenylate cyclase signaling; normalizes guanine nucleotide-binding protein [G protein] signal transduction system) • Decreases 5-HT reuptake and increases postsynaptic 5-HT receptor sensitivity • Inhibits the synthesis of DA, decreases the number of β-adrenergic receptors and inhibits DA₂ and β-adrenergic receptor supersensitivity • Enhances GABAergic activity and normalizes GABA levels • Reduces glutaminergic activity (e.g., increases glutamate uptake) with chronic therapy • Decreases Ca⁺ transport into cells, interferes with Ca⁺-Na⁺ active transport system, increases renal tubular reabsorption of Ca⁺ and increases serum Ca⁺ and parathyroid concentrations • Increases choline in red blood cells and potentiates the cholinergic secondary messenger system |
| | Eskalith CR | Extended-release tablet: 450 mg | | | |
| | Lithobid | Extended-release tablet: 300 mg | | | |
| | Generic | Tablet: 300 mg (scored) Capsule: 150, 300, 600 mg | | | |
| Lithium citrate | Cibalith-S | 8 mEq/5 mL | | | |
| Anticonvulsants: FDA-approved for bipolar disorder | | | | | |
| Divalproex sodium | Depakote | Enteric-coated, delayed-release tablet: 125, 250, 500 mg Sprinkle capsule: 125 mg | 750–3000 mg/day (20–60 mg/kg per day) in 2–3 divided doses for delayed-release divalproex or valproic acid. Extended-release divalproex may be given once daily at bedtime after stabilization. | Use alone or in combination with other drugs (e.g., lithium, carbamazepine, antipsychotics) for the acute treatment of mania and for maintenance treatment. | <ul style="list-style-type: none"> • Increases GABA levels in plasma and CNS; inhibits GABA catabolism, increases synthesis, and release; may prevent GABA reuptake; enhances the action of GABA at the GABA_A receptor |
| | Depakote ER | Enteric-coated extended release tablet: 250, 500 mg | | | |
| Valproic acid | Depakene | Capsule: 250 mg | A loading dose of divalproex (20–30 mg/kg per day) can be given, then 20 mg/kg per day and titrated to a serum concentration of 50–125 mcg/mL. | Use caution when combining with lamotrigine due to potential drug interaction. | <ul style="list-style-type: none"> • Normalizes Na⁺ and Ca⁺ channels • Reduces intracellular inositol and protein kinase C isozymes • May modulate gene expression • Antikindling properties may decrease rapid cycling and mixed states |
| Valproate sodium | Depakene | Syrup: 250 mg/5 mL | | | |

TABLE 68–10. (Continued)

| Generic Name | Trade Name | Formulations | Dosage and Administration | Clinical Use | Proposed Mechanism of Action |
|---|--|--|--|---|--|
| Lamotrigine | Lamictal | Tablet: 25, 100, 150, 200 mg Chewable tablet: 2, 5, 25 mg | 50–400 mg/day in divided doses. Dosage should be slowly increased (e.g., 25 mg/day for 2 weeks, then 50 mg/day for weeks 3 and 4, then 50-mg/day increments at weekly intervals up to 200 mg/day). When combined with valproate, initial and titration dosing should be decreased by 50% to minimize the risk of a serious rash. | Use alone or in combination with other drugs (e.g., lithium, carbamazepine) for long-term maintenance treatment for bipolar I disorder. Lamotrigine may have efficacy for prevention of bipolar depression. | <ul style="list-style-type: none"> Blocks voltage-sensitive Na⁺ and Ca⁺ channels Modulates or decreases presynaptic aspartate and glutamate release Antikindling properties may decrease rapid cycling and mixed states |
| Anticonvulsants: Not FDA-approved for bipolar disorder | | | | | |
| Carbamazepine | Tegretol, Epitol Tegretol Tegretol-XR Carbatrol | Tablet: 200 mg Chewable tablet: 100 mg Suspension: 100 mg/5 mL Extended-release tablet: 100, 200, 400 mg Extended-release capsule: 200, 300 mg | 200–1800 mg/day in 2–4 divided doses. Dosage should be slowly increased according to response and adverse effects (e.g., 100–200 mg twice daily and increase by 200 mg/day at weekly intervals). Administer conventional tablets and suspension with meals. Extended-release tablets should be swallowed whole and not be broken or chewed. Carbatrol capsules may be opened and contents sprinkled over food. | Use alone or in combination with other drugs (e.g., lithium, valproate, antipsychotics) for the acute and long-term maintenance treatment of mania or mixed episodes for bipolar I disorder. APA guidelines recommend reserving it for patients unable to tolerate or who have inadequate response to lithium or valproate. | <ul style="list-style-type: none"> Blocks voltage-sensitive Na⁺ channels Stimulates the release of antidiuretic hormone and decreases Na⁺ serum concentrations Blocks Ca⁺ influx through the NMDA glutamate receptor and decreases Ca⁺ serum concentrations Modulates presynaptic aspartate and glutamate release Antikindling properties may decrease rapid cycling and mixed states |
| Oxcarbazepine | Trileptal | Tablet: 150, 300, 600 mg Suspension: 300 mg/5 mL | 300–1200 mg/day in two divided doses. Dosage should be slowly adjusted up and down according to response and adverse effects (e.g., 150–300 mg twice daily and increase by 300–600 mg/day at weekly intervals). | May have fewer adverse effects and be better tolerated than carbamazepine | <ul style="list-style-type: none"> Oxcarbazepine and its monohydroxy metabolite increase K⁺ conductance; modulates the activity of high-voltage activated Ca⁺ channels; and blocks Na⁺ channels |
| Clonazepam | Klonopin | Tablet: 0.5, 1, 2 mg | 0.5–20 mg/day in divided doses or one dose at bedtime. Dosage should be slowly adjusted up and down according to response and adverse effects. | Use in combination with other drugs (e.g., antipsychotics, lithium, valproate) for the acute treatment of mania or mixed episodes. Use as a short-term adjunctive sedative-hypnotic agent. | <ul style="list-style-type: none"> Binds to the benzodiazepine site and augments the action of GABA_A by increasing the frequency of Cl⁻ channel opening, which causes hyperpolarization (a less excitable state) and inhibits neuronal firing |
| Lorazepam | Ativan | Tablet: 0.5, 1, 2 mg Oral solution: 2 mg/mL Injection: 2, 4 mg/mL | 2–40 mg/day in divided doses or one dose at bedtime. Dosage should be slowly adjusted up and down according to response and adverse effects. | | |

TABLE 68–10. (Continued)

| Generic Name | Trade Name | Formulations | Dosage and Administration | Clinical Use | Proposed Mechanism of Action |
|--|----------------|---|---|---|--|
| Gabapentin | Neurontin | Capsule: 100, 300, 400 Solution: 250 mg/5 mL Tablets: 600, 800 mg | 900–3600 mg/day in 3–4 divided doses. Dosage should be slowly increased to minimize adverse effects (e.g., 300 mg three times daily, and increase by 300 mg/day every 3–7 days up to 1800 mg/day). | Not recommended for the acute treatment of mania or mixed episodes for bipolar I disorder due to lack of efficacy. Used as an adjunctive agent for comorbid anxiety states and insomnia. | <ul style="list-style-type: none"> Exact mechanism is unknown; although gabapentin is structurally related to GABA, it does not interact with GABA receptors May modulate the action of the GABA synthetic enzyme (glutamic acid decarboxylase) and the glutamate synthetic enzyme; alters the synthesis and release of GABA; increases GABA levels |
| Topiramate | Topamax | Tablet: 25, 100, 200 mg Sprinkle capsule: 15, 25 mg | 50–200 mg/day in divided doses. Dosage should be slowly increased to minimize adverse effects (e.g., 25 mg at bedtime for 1 week, then 25–50 mg/day increments at weekly intervals). | Not recommended for the acute treatment of mania or mixed episodes due to lack of efficacy; used as an adjunctive agent with established mood stabilizers | <ul style="list-style-type: none"> Modulates voltage-sensitive Na⁺ channels Inhibits Ca⁺ channels Blocks glutamate activity Potentiates GABAergic activity and levels Inhibits protein kinases A and C Weak carbonic anhydrase inhibitor |
| Atypical antipsychotics: FDA-approved for bipolar disorder | | | | | |
| Aripiprazole | Abilify | Tablet: 5, 10, 15, 20, 30 mg | 10–30 mg/day once daily | Use in combination with lithium or valproate for the acute treatment of mania or mixed states (primarily with psychotic features) for bipolar I disorder. Only olanzapine is FDA-approved at this time. | <ul style="list-style-type: none"> Antagonist of postsynaptic DA₂ receptors; atypical agents also block 5-HT_{2A} receptors that increase the presynaptic release of DA, thus lowering the risk of extrapyramidal symptoms and prolactin release Receptor blockade varies by agent: DA_{1–4}, 5-HT_{2A–2C}, α_{1–2}-adrenergic, muscarinic, and histamine₁ |
| Olanzapine | Zyprexa | Tablet: 2.5, 5, 7.5, 10, 15, 20 mg | 5–20 mg/day in 1 or 2 doses | | |
| | Zyprexa Zydis | Tablet, orally disintegrating: 5, 10, 15, 20 mg | | | |
| Quetiapine | Seroquel | Tablet: 25, 100, 200, 300 mg | 50–800 mg/day in divided doses or once daily when stabilized | | |
| Risperidone | Risperdal | Tablet: 0.25, 0.5, 1, 2, 3, 4 mg Oral solution: 1 mg/mL | 0.5–6 mg/day in 1 or 2 doses | | |
| Ziprasidone | Geodon | Capsule: 20, 40, 60, 80 mg | 40–160 mg/day in divided doses | | |
| Calcium channel blockers: Not FDA-approved for bipolar disorder | | | | | |
| Nimodipine | Nimotop | Capsule: 30 mg | 30–120 mg/day | Use as third-line agent for combination with other drugs (e.g., carbamazepine, valproate, antipsychotics). | <ul style="list-style-type: none"> Blocks Ca⁺ influx through L-type Ca⁺ channels Alters Ca⁺-Na⁺ exchange Decreases 5-HT, DA, and endorphin activity |
| Verapamil | Verelan | Capsule: 120, 180, 240, 360 mg | 80–480 mg/day | | |
| | Calan, Isoptin | Film-coated tablet: 40, 80, 120 mg Extended-release tablet: 120, 180, 240 mg | | | |

■ Carbamazepine

■ **Pharmacology and Mechanism of Action.** Carbamazepine, a dibenzazepine derivative, is structurally related to tricyclic antidepressants.^{18,91} The precise mechanism of action of carbamazepine in affective disorders remains to be elucidated.⁹ Proposed mechanisms of action for carbamazepine are listed in Table 68–10.

■ **Pharmacokinetics.** A summary of the absorption, distribution, metabolism, and elimination data for carbamazepine is found in Table 68–11.

■ **Efficacy.** Carbamazepine is not a first-line agent for bipolar disorder, and is generally reserved for lithium-refractory patients, rapid cyclers, or for mixed states.^{1,3,18} Carbamazepine has acute antimanic

TABLE 68–11. Pharmacokinetics and Therapeutic Serum Concentrations of Lithium and Anticonvulsants Used in the Treatment of Bipolar Disorder

| | Lithium | Carbamazepine | Oxcarbazepine | Divalproex (DVPX) Sodium/ Valproic Acid (VPA) | Lamotrigine |
|---|--|---|--|---|--------------------------------------|
| Gastrointestinal absorption | | | | | |
| Regular release | Rapid: 95–100% within 1–6 hours | Slow and erratic: 85–90% | Slow and complete: 100% | Rapid and complete (VPA) | Rapid: 98% |
| Syrup/suspension/solution | Faster rate of absorption: 100% | Faster rate of absorption | Unknown | Faster rate of absorption than tablets | NA |
| Extended-release/enteric-coated tablets | Delayed absorption: 60–90% | Delayed absorption: 89% of the suspension; and less than regular-release tablets | NA | Extended release: 90% of intravenous dose Delayed release: 81–90% of intravenous dose Delayed absorption with delayed-release tablets; valproate is rapidly converted to VPA in the stomach, then is rapidly and almost completely absorbed from the GI tract | NA |
| Delay in absorption by food | Yes | No; reports of increased rate of absorption with fatty meals (extended-release capsule) | Unknown | Yes; food slows the rate of absorption but not the extent for DVPX | Bioavailability not affected by food |

effects comparable to lithium and chlorpromazine, but its long-term effectiveness is unclear.^{3,18} One comparison trial in hospitalized manic patients indicated that carbamazepine was less effective and needed more rescue adjunctive medications than valproate.³ Other comparison studies with lithium have reported carbamazepine to be less effective than lithium for maintenance therapy.³ In a double-blind, placebo-controlled crossover study and in an open study, carbamazepine showed efficacy in the treatment of bipolar depression.^{3,18} Studies with treatment-refractory patients have reported that carbamazepine has both acute and long-term prophylactic effects.^{4,18} A gradual loss of efficacy over time (similar to lithium and valproate) has been reported in some patients.^{4,18}

The combination of carbamazepine with lithium, valproate, and antipsychotics is often utilized for treatment-resistant manic patients.¹⁸ Carbamazepine increases the hepatic metabolism of antie-

pressants, anticonvulsants, and antipsychotics; thus dosage increases may be necessary (see drug-drug interactions).^{18,91} Calcium channel blockers (i.e., verapamil and diltiazem) increase carbamazepine blood levels; thus combination therapy should be closely monitored.⁹¹ The combination of carbamazepine with nimodipine for treatment-refractory bipolar illness may have potential benefit.

■ **Adverse Effects.** The most common adverse effects of carbamazepine involve central nervous system toxicity, which occurs in up to 60% of patients.^{3,91} Neurologic side effects include drowsiness, dizziness, fatigue, clumsiness, ataxia, vertigo, blurred vision, diplopia, nystagmus, dysarthria, confusion, and headache.^{3,18,91} These side effects usually occur during the first few weeks of therapy, so initiating therapy with low doses, gradually increasing the dose, changing to a slow-release product, or giving a larger bedtime dose may

^aScreen for drug abuse and serum pregnancy.
^bComplete blood cell count (CBC) with differential and platelets.
^cFasting glucose, serum lipids, weight.
^dLactate dehydrogenase, aspartate aminotransferase, alanine aminotransferase, total bilirubin, alkaline phosphatase.
^eSerum creatinine, blood urea nitrogen, urinalysis, urine osmolality, specific gravity.
^fTriiodothyronine, total thyroxine, thyroxine uptake, and thyroid-stimulating hormone.
^gSerum sodium.
^hRashes, hair thinning, alopecia.
ⁱAtypical antipsychotics: Monitor for increased appetite with weight gain (primarily in patients with initial low or normal body mass index); monitor closely if rapid or significant weight gain occurs during early therapy; cases of hyperlipidemia and diabetes reported.
^jCarbamazepine: Manufacturer recommends CBC and platelets (and possibly reticulocyte counts and serum iron) at baseline, and that subsequent monitoring be individualized by the clinician (e.g., CBC, platelet counts, and liver function tests every 2 weeks during the first 2 months of treatment, then every 3 months if normal). Monitor more closely if patient exhibits hematologic or hepatic abnormalities or if the patient is receiving a myelotoxic drug; discontinue if platelets are <100,000/mm³, if white blood cell (WBC) count is <3,000/mm³ or if there is evidence of bone marrow suppression or liver dysfunction. Serum electrolyte levels should be monitored in the elderly or those at risk for hyponatremia. Carbamazepine interferes with some pregnancy tests.
^kLamotrigine: If renal or hepatic impairment, monitor closely and adjust dosage according to manufacturer’s guidelines. Serious dermatologic reactions have occurred within 2–8 weeks of initiating treatment and are more likely to occur in patients receiving concomitant valproate, with rapid dosage escalation, or using doses exceeding the recommended titration schedule.
^lLithium: Obtain baseline electrocardiogram for patients over age 40 or if preexisting cardiac disease (benign, reversible T-wave depression may occur). Renal function tests should be obtained every 2–3 months during the first 6 months, then every 6–12 months; if impaired renal function, monitor 24-hour urine volume and creatinine every 3 months; if urine volume >3L/d, monitor urinalysis, osmolality, and specific gravity every 3 months. Thyroid function tests should be obtained once or twice during the first 6 months, then every 6–12 months; monitor for signs and symptoms of hypothyroidism; if supplemental thyroid therapy is required, monitor thyroid function tests and adjust thyroid dose every 1–2 months until thyroid function indices are within normal range, then monitor every 3–6 months.
^mOxcarbazepine: Hyponatremia (serum sodium concentrations <125 mEq/L) has been reported and occurs more frequently during the first 3 months of therapy; serum sodium concentrations should be monitored in patients receiving drugs that lower serum sodium concentrations (e.g., diuretics or drugs that cause inappropriate antidiuretic hormone secretion) or in patients with symptoms of hyponatremia (e.g., confusion, headache, lethargy, and malaise). Hypersensitivity reactions have occurred in approximately 25–30% of patients with a history of carbamazepine hypersensitivity and requires immediate discontinuation.
ⁿValproate: Weight gain reported in patients with low or normal body mass index. Monitor platelets and liver function during first 3–6 months if evidence of increased bruising or bleeding. Monitor closely if patients exhibit hematologic or hepatic abnormalities or in patients receiving drugs that affect coagulation, such as aspirin or warfarin; discontinue if platelets are <100,000/mm³/L or if prolonged bleeding time. Pancreatitis, hyperammonemic encephalopathy, polycystic ovary syndrome, increased testosterone, and menstrual irregularities have been reported; not recommended during first trimester of pregnancy due to risk of neural tube defects.
 Compiled from American Psychiatric Association,³ Goodnick,¹⁸ McEvoy et al,⁹¹ McEvoy et al,⁹⁴ McEvoy et al,⁹⁶ McEvoy et al,⁹⁸ and McEvoy et al.⁹⁹

minimize these effects.⁹¹ Gastrointestinal side effects (nausea, vomiting, abdominal pain, diarrhea, constipation, and anorexia) occur early in therapy in up to 15% of patients.^{3,18} Hyponatremia occurs in 6% to 31% of patients and may be related to fluid retention secondary to carbamazepine’s antidiuretic effect.^{3,91} Carbamazepine has been noted to produce weight gain, although it occurs less frequently than with valproate.^{3,66,74}

Mild asymptomatic leukopenia may occur in 25% of patients and return to normal with dosage reduction or with discontinuation.³ Patients with low- or below-normal pretreatment white blood cell and neutrophil counts should be monitored more closely because of their increased risks of developing leukopenia. Mild thrombocytopenia has been reported and may respond to dosage reduction.^{3,18} Serious hematologic dyscrasias such as agranulocytosis and aplastic anemia are rare. Patients should be educated about the signs and symptoms of leukopenia and thrombocytopenia (oral ulcers, sore throat, easy bruising, bleeding, and fever).^{1,18}

Other side effects of carbamazepine include hypersensitivity and dermatologic reactions (e.g., pruritic and erythematous rashes, urticaria, photosensitivity reactions, and a systemic lupus

erythematosus–like syndrome).^{18,91} Patients should be instructed to seek medical attention if they develop a rash. A mild transient elevation of liver enzyme levels occurs in 5% to 15% of patients; hepatitis and a significant increase in liver enzyme levels can occur.^{3,91} Carbamazepine may decrease total and free thyroxine levels and increase free cortisol levels.³

Acute overdoses of carbamazepine are potentially lethal, and serum levels above 15 mcg/mL are associated with ataxia, choreiform movements, diplopia, nystagmus, cardiac conduction changes, seizures, and coma.³ Gastric lavage, hemoperfusion, and symptomatic treatment are recommended for the management of carbamazepine toxicity.

Because the safe use of carbamazepine during pregnancy has not been established, caution should be used in prescribing carbamazepine during the first trimester of pregnancy or in women of reproductive age.⁹² Carbamazepine may cause craniofacial deformities, spina bifida (0.5% to 1%), and low birth weight.^{18,91} Carbamazepine is excreted in breast milk (the milk-to-maternal plasma ratio of carbamazepine is about 0.4).⁴ There are two case reports of transient cholestatic hepatitis and jaundice in nursing infants.

■ **Drug-Drug Interactions.** Carbamazepine induces the hepatic cytochrome P450 isoenzymes (1A2, 3A4, 2C9/10, and 2D6), which increases the metabolism of many medications, such as anticonvulsants (i.e., lamotrigine, topiramate, and valproate), antidepressants (i.e., tricyclics and bupropion), antipsychotics (i.e., clozapine, haloperidol, fluphenazine, olanzapine, and thiothixene), benzodiazepines, oral contraceptives, and protease inhibitors.^{3,4,91} Women who receive carbamazepine require higher dosages of oral contraceptives or alternative contraceptive methods.⁴

Carbamazepine is metabolized to an active 10,11-epoxide metabolite, thus medications that inhibit 3A4 isoenzymes may result in carbamazepine toxicity (e.g., cimetidine, diltiazem, erythromycin, fluoxetine, fluvoxamine, isoniazid, itraconazole, ketoconazole, nefazodone, propoxyphene, and verapamil).^{3,4,18,91} When carbamazepine is combined with valproate, the carbamazepine dose should be reduced because valproate displaces carbamazepine from protein binding sites, thus increasing free levels.^{4,18} Combining clozapine and carbamazepine is not recommended because of the possibility of bone marrow suppression with both agents.¹⁸

■ **Dosing and Administration.** Carbamazepine must be titrated up gradually to avoid adverse effects. During an acute manic episode, carbamazepine can be started at 200 to 400 mg/day in divided doses with meals and increased by 200 mg/day every 2 to 4 days up to 10 to 15 mg/kg per day.⁹¹ If there is no response after 2 weeks, then the dosage can be gradually increased to obtain serum concentrations between 6 and 10 mcg/mL. During the first month of therapy, serum concentrations of carbamazepine may decrease due to its autoinduction of cytochrome P450 3A4 enzymes, and the dose may need to be increased to maintain serum concentrations.⁹¹ Carbamazepine should be withdrawn slowly to avoid precipitating the recurrence of bipolar symptoms.

Carbamazepine serum levels are usually obtained every 1 to 2 weeks during the first 2 months, and then every 3 to 6 months during maintenance therapy. Serum levels should be drawn 10 to 12 hours after the dose (trough levels) and at least 5 to 7 days after a dosage change. Although there is no correlation between carbamazepine serum concentration and degree of antimanic or antidepressant response, most clinicians attempt to maintain levels between 6 and 10 mcg/mL (although some treatment-resistant patients may require serum concentrations of 12 to 14 mcg/mL).¹ Recommended baseline and routine laboratory tests for carbamazepine are listed in Table 68–12.

■ Lamotrigine

■ **Pharmacology and Mechanism of Action.** Lamotrigine blocks voltage-sensitive sodium channels, modulates or decreases glutamate and aspartate release, and has anticonvulsant properties (see Table 68–10).^{4,9,61,93,94}

■ **Pharmacokinetics.** Lamotrigine is rapidly and completely absorbed (with little first-pass metabolism), has 55% protein binding, is metabolized predominantly by hepatic glucuronic acid conjugation, and is renally excreted.^{93,94} The normal half-life is approximately 25 hours; with concomitant valproic acid it increases to 59 hours, and with carbamazepine it decreases to 15 hours (see Table 68–11).^{18,61}

■ **Efficacy.** The effectiveness of lamotrigine for the maintenance treatment of bipolar I disorder in adult patients was established in two multicenter double-blind, placebo-controlled studies.³ Doses of

200 mg/day were more effective than lower doses and there were no advantages to using 400 mg/day. Lamotrigine has both antidepressant and mood-stabilizing effects, it may have augmenting properties when combined with lithium or valproate, and has low rates of switching patients to mania.^{73,93} Although lamotrigine is less effective for acute mania compared to standard mood stabilizers, it may be beneficial in the maintenance therapy of treatment-resistant bipolar I and II disorders, in rapid-cycling dysphoric mania, and in mixed states.^{3,4,80,93}

■ **Adverse Effects.** Lamotrigine has fewer side effects with slow titration during the initiation of therapy.^{93,94} Common adverse effects include headache, nausea, dizziness, ataxia, diplopia, drowsiness, tremor, rash, and pruritus.^{93,94} Lamotrigine is considered to be weight-neutral compared to lithium and valproate.⁷⁴ Approximately 10% of patients in premarketing clinical trials developed a maculopapular rash and required discontinuation of therapy.^{93,94} Although most rashes are self-limiting and resolve with continued treatment, some cases progressed to life-threatening conditions such as Stevens-Johnson syndrome. The incidence of rash appears to be greatest with coadministration of valproate, with higher than recommended initial doses, and with rapid dose escalation.⁹⁴ If a slow titration schedule is used, the incidence of a serious rash is 0.01% in adults. Patients should be warned about the rash, and the need for discontinuing lamotrigine if the rash is diffuse, involves mucosal membranes, and is accompanied by a fever or sore throat.

■ **Drug-Drug Interactions.** Valproate decreases the clearance of lamotrigine (i.e., more than doubles the half-life) and lamotrigine must be administered at a reduced dosage (approximately half the standard dose).⁹⁴ Carbamazepine, phenytoin, and phenobarbital increase the clearance of lamotrigine. Lamotrigine has no effect on the pharmacokinetics of lithium and does not inhibit the cytochrome P450 isoenzymes.

■ **Dosing and Administration.** For the maintenance treatment of bipolar disorder, the usual dosage range of lamotrigine is 50 to 300 mg/day. The target dose is generally 200 mg/day (100 mg/day in combination with valproate and 400 mg/day in combination with carbamazepine).^{93,94} For patients not taking medications that affect lamotrigine's clearance, the dose is 25 mg/day for the first 2 weeks of therapy, 50 mg/day for weeks 3 and 4, 100 mg/day for week 5, and 200 mg/day for week 6 and beyond.^{3,93,94} Lamotrigine should not be abruptly discontinued, and doses should be reduced by approximately 50% per week over 2 weeks when discontinued. Patients who stop lamotrigine therapy for more than a few days should be restarted on the recommended dosage escalation titration schedule.

■ Lithium

■ **Pharmacology and Mechanism of Action.** Despite numerous investigations into the biologic and clinical properties of lithium, there is no unified theory for its mechanism of action (see Table 68–10).^{9,18,20,95} Chronic lithium administration may modulate gene expression and have neuroprotective effects.

■ **Pharmacokinetics.** Lithium has unique pharmacokinetics because it is a monovalent cation. Lithium is rapidly absorbed, is widely distributed with no protein binding, is not metabolized, and is excreted unchanged in the urine and in other body fluids (see Table 68–11).⁹⁶

■ **Efficacy.** Early placebo-controlled studies with lithium reported up to a 78% response rate in aborting an acute manic or hypomanic

episode, but more recent studies suggest a slower onset of action and a more moderate effectiveness when compared to other agents.^{3,4,58} Lithium has displayed efficacy in acute mania trials similar to that of valproate, carbamazepine, risperidone, olanzapine, chlorpromazine, and other typical antipsychotics.³ In placebo-controlled studies in bipolar depression, lithium has been found to have efficacy, but there may be a 6- to 8-week delay for its antidepressant effects.³ Lithium is more effective for pure or elated (classic) mania, and may be less effective for severe mania with psychotic features, mixed episodes, rapid or continuous cycling, alcohol and drug abuse, and in organic-induced mood states.^{3,4,57}

Long-term lithium therapy is more effective in patients with fewer prior episodes, with a history of euthymia or good functioning between episodes, and with a family history of bipolar illness with a positive response to lithium.^{4,18} Lithium produces a prophylactic response in up to two-thirds of patients and reduces suicide risk by 8- to 10-fold.^{3,57-59}

Patients maintained on standard serum concentrations of lithium (between 0.8 and 1 mEq/L) may have fewer relapses than patients maintained on lower serum concentrations (0.4 to 0.6 mEq/L).^{3,4} Abrupt discontinuation or noncompliance with lithium therapy may increase the risk of relapse.^{3,4} Discontinuation-induced refractoriness has been reported in approximately one-fifth of patients who previously were stabilized on lithium.^{3,4}

Lithium augmentation of antidepressants, carbamazepine, lamotrigine, and valproate may improve treatment response in bipolar I disorder.^{3,97} Concomitant use of lithium with valproate or carbamazepine appears to be well tolerated, but may increase the risk of sedation, weight gain, gastrointestinal complaints, and tremor. Initial reports of combining lithium and lamotrigine suggest that the combinations are safe and effective, but further studies are necessary.

Lithium is frequently combined with both traditional and atypical antipsychotics in euphoric acute mania with psychotic features. Case reports of neurotoxicity (e.g., delirium, cerebellar dysfunction, extrapyramidal symptoms, and severe tremors) have been reported in elderly patients receiving lithium and traditional antipsychotics.⁹⁶ Combining lithium with calcium channel blockers is not recommended because of reports of neurotoxicity and severe bradycardia with verapamil and diltiazem.⁹⁶ Acute neurotoxicity and delirium have been reported in patients receiving ECT with lithium (even at reduced dosages); therefore lithium should be withdrawn and discontinued at least 2 days before ECT and should not be resumed until 2 to 3 days after the last treatment.

■ **Adverse Effects.** Approximately 35% to 93% of patients treated with lithium will experience adverse effects. These are divided into those that occur early in therapy but are generally innocuous and transient, those that occur with long-term therapy and are usually not dose-related, and toxic effects that occur with high serum concentrations.^{1,3,96}

Initial side effects are often dose-related and are worse at peak serum concentrations (1 to 2 hours postdose).³ Standard approaches for minimizing adverse effects include lowering the dose, taking smaller doses with food, using extended-release products, and trying once-daily dosing at bedtime.³ Gastrointestinal distress (e.g., nausea, vomiting, dyspepsia, and diarrhea) can be minimized by the standard approaches or by adding antacids or antidiarrheal agents.³ Muscle weakness and lethargy develop in about 30% of patients, but these symptoms are usually transient. Polydipsia with polyuria and nocturia occurs in up to 70% of patients and can be managed by changing to once-daily bedtime dosing.

As many as 40% of patients complain of headache, memory impairment, confusion, poor concentration, and impaired motor performance.¹⁸ A fine hand tremor may be evident in up to 50% of patients. Stress, concomitant use of antidepressants or antipsychotics, caffeine, sympathomimetics, and impending toxicity may exacerbate the tremor. Strategies to reduce the tremor include standard approaches or adding a β -adrenergic antagonist (e.g., propranolol 20 to 120 mg/day, atenolol 50 mg/day, or metoprolol 20 to 80 mg/day).

Lithium reduces the kidney's ability to concentrate urine and may cause a nephrogenic diabetes insipidus characterized by low urine specific gravity and a low osmolality polyuria (urine volumes >3 L/day).^{3,96} Lithium-induced nephrogenic diabetes insipidus is treated with loop diuretics, thiazide diuretics, or triamterene. If a thiazide diuretic is used (e.g., hydrochlorothiazide 50 mg/day), lithium doses should be decreased by 50%, and potassium levels need to be monitored.³ Amiloride, a potassium-sparing diuretic, has weaker natriuretic effects than thiazides and appears to be relatively safe with minimal effect on lithium clearance. Potassium supplements have been suggested as another treatment for lithium-induced polyuria.¹⁸ Fluid restriction is not recommended because dehydration increases the risk of lithium toxicity. If edema occurs, treatment approaches include lowering sodium intake or using a diuretic (e.g., spironolactone); close monitoring for lithium toxicity is necessary because these treatments often increase lithium concentrations.

Patients on long-term lithium therapy have a 10% to 20% risk of developing morphological renal changes (e.g., glomerular sclerosis, tubular atrophy, and interstitial nephritis) that is associated with impairment of water resorption and increased serum creatinine concentrations.³ Lithium rarely causes nephrotoxicity if patients are maintained on the lowest effective dose, if once-daily dosing is used, if adequate hydration is maintained, and if toxicity is avoided.¹⁸ Lithium should be avoided in patients with preexisting renal disease unless there is frequent monitoring.

Lithium is concentrated in the thyroid gland, interferes with thyroid hormone synthesis, and may induce the formation of thyroid antibodies.⁹⁶ Up to 30% of patients on maintenance lithium therapy develop transiently elevated thyroid-stimulating hormone concentrations, and 5% to 35% of patients develop a goiter and/or hypothyroidism.³ Lithium-induced hypothyroidism is not dose-related, is observed 10 times more frequently in women (particularly in those with rapid cycling), and usually occurs after 6 to 18 months of therapy.³ Hypothyroidism does not require discontinuation of lithium, because exogenous thyroid hormone (i.e., levothyroxine) can be added to the regimen. When lithium is discontinued, the need for exogenous thyroid hormone should be reassessed, because hypothyroidism is almost always reversible.

Lithium may cause a variety of benign and reversible cardiac effects, particularly T-wave flattening or inversion (in up to 30% of patients), atrioventricular block, and bradycardia.^{3,18,96} Lithium rarely causes myocarditis, sinus node dysfunction, or sinoatrial block, but may aggravate ventricular arrhythmias and atrial premature contractions. If a patient has significant preexisting cardiac disease, consultation with a cardiologist and an electrocardiogram is recommended at baseline and during lithium therapy.

Other late-appearing lithium side effects include benign reversible leukocytosis and a variety of dermatologic effects (e.g., acne and acneiform eruptions, alopecia, exacerbation of psoriasis, pruritic dermatitis, maculopapular rashes, and folliculitis).^{3,18} Weight gain is common (approximately 20% of patients gain more than 10 kg) and may be related to fluid retention, the consumption of high-calorie beverages as a result of polydipsia, or to a decreased metabolic rate due to hypothyroidism.^{18,66,74} Decreased libido, sexual dysfunction,

dry mouth, alterations in taste, changes in glucose tolerance, hypercalcemia, and hyperparathyroidism have been reported.^{3,18,96} Severe neurologic disturbances such as coarse hand tremors, ataxia, slurred speech, myasthenia gravis, extrapyramidal syndrome, pseudotumor cerebri, and papilledema are occasionally observed.

Lithium is an extremely toxic drug if accidentally or intentionally taken in overdose. Lithium toxicity can occur with blood levels greater than 1.5 mEq/L, but elderly patients may have symptoms at therapeutic levels.³ Severe lithium intoxication occurs when concentrations are higher than 2 mEq/L, and there is a worsening in several key symptoms: *gastrointestinal* (e.g., vomiting, diarrhea, or incontinence); *coordination* (e.g., severe fine to coarse hand tremor, unstable gait, slurred speech, and muscle twitching); and *cognition* (e.g., poor concentration, drowsiness, disorientation, apathy, and coma).³ Several reports of seizures, cardiac dysrhythmia, permanent neurologic impairments with ataxia and deficits in memory, and kidney damage with reduced glomerular filtration rate have been reported after lithium intoxication.³

Situations that predispose patients to lithium toxicity include: sodium restriction, dehydration, vomiting, diarrhea, and drug interactions that decrease lithium clearance. Heavy exercise, sauna baths, hot weather, and fever may promote sodium loss. Patients should be cautioned to maintain adequate sodium and fluid intake (2.5 to 3 quarts per day of fluids) and to avoid the excessive use of coffee, tea, cola, and other caffeine-containing beverages and alcohol.

If lithium toxicity is suspected, the person should go to an emergency room to be monitored, and lithium should be discontinued.³ Gastric lavage and intravenous fluids may be needed, and the patient should be monitored for fluid balance, renal and electrolyte status, and neurologic changes. In cases of overdose with sustained-release lithium products, the development and duration of toxicity can be prolonged.³ When lithium concentrations are above 3.5 to 4 mEq/L, intermittent hemodialysis (12 hours on and 12 hours off) can be started and continued until the lithium concentration is below 1 mEq/L when taken 12 hours after the last dialysis. Hemodialysis is generally required when serum lithium levels are above 4 mEq/L for patients on long-term treatment, and greater than 6 to 8 mEq/L after acute poisoning.³ Rebound increases in serum lithium concentrations may occur 5 to 8 hours after dialysis, thus repeat dialysis may be needed.³

Infants whose mothers took lithium during the first trimester of pregnancy may have a lower incidence of cardiovascular defects (particularly Epstein's anomaly) than was previously thought.^{3,18} Lithium freely crosses the placenta and is found in equal concentrations in maternal and fetal blood.⁹⁶ When lithium is used during pregnancy, it should be tapered down to the lowest effective dose necessary to decrease the risk of relapse. Lithium may cause a "floppy" infant syndrome (e.g., low Apgar scores, lethargy, hypotonia, bradycardia, cyanosis, shallow respiration, and poor sucking), hypothyroidism, and nontoxic goiters. Milk concentrations of lithium range from 30% to 50% of the mother's serum concentration, and serum concentrations in the nursing infant are 10% to 50% of the mother's; thus breastfeeding is usually discouraged.^{3,18,92}

■ **Drug-Drug Interactions.** Neurotoxicity may occur when lithium is combined with carbamazepine, diltiazem, losartan, methyl-dopa, metronidazole, phenytoin, and verapamil.^{3,96} Thiazide diuretics, nonsteroidal anti-inflammatory drugs, cyclooxygenase-2 inhibitors, angiotensin-converting enzyme inhibitors, fluoxetine, and salt-restricted diets can elevate lithium levels.^{1,3} Analgesics such as acetaminophen or aspirin and loop diuretics are less likely to interfere with lithium clearance. Caffeine and theophylline may enhance the renal elimination of lithium. Because lithium has no effect on the

hepatic metabolizing enzymes, it has fewer drug-drug interactions compared with carbamazepine, oxcarbazepine, and valproate.

■ **Dosing and Administration.** Lithium dosing depends on the patient's age and weight, tolerance to adverse effects, and the acuity of the illness. Dosing is generally titrated up to achieve steady-state serum lithium concentrations of 0.6 to 1.2 mEq/L.³ Lithium therapy is usually initiated with low to moderate doses (600 mg/day) for prophylaxis and higher doses (900 to 1,200 mg/day) for acute mania, using a two- to three-times-a-day dosing regimen.^{3,96} Immediate-release lithium preparation should be given in two or three divided daily doses, whereas extended-release products may be given once or twice daily. If lithium is discontinued, a gradual tapering down of the dose by 300 mg/day each month has been recommended to reduce the risk of relapse.

When lithium is first started, a non-steady-state serum concentration is recommended every 2 to 3 days in patients prone to toxicity.⁹⁶ Once a desired serum concentration has been achieved, levels should be drawn every 1 to 2 weeks for 2 months or until lithium concentrations are stabilized.

Maintenance lithium serum concentrations are usually measured every 3 months, but can be adjusted to every 6 months for stabilized patients, and every 1 to 2 months for patients with frequent mood episodes.³ Lithium clearance rates increase by 50% to 100% during pregnancy and return to normal postpartum; thus lithium levels should be determined monthly during pregnancy and weekly the month before delivery. At delivery, rapid fluid changes may significantly increase lithium levels, thus a reduction to prepregnancy lithium doses and adequate hydration are recommended.³

The recommended guidelines for baseline and routine laboratory testing for lithium are listed in Table 68–12. The 12-hour post-dose lithium serum concentration may be 12% to 33% higher with extended-release preparations and lower with regular-release tablets with divided dosage schedules. The dose should be adjusted based on the steady-state serum concentration drawn 12 hours (± 30 minutes) after the last dose.⁹⁶ A therapeutic trial (lithium serum concentrations of 0.6 to 1.2 mEq/L) should last a minimum of 4 to 6 weeks. Acutely manic patients may require serum concentrations of 1 to 1.2 mEq/L, and some need up to 1.5 mEq/L to achieve a therapeutic response. Although serum concentrations less than 0.6 mEq/L are associated with higher rates of relapse, some patients may do well at 0.4 to 0.7 mEq/L.³ For bipolar prophylaxis in elderly patients, serum concentrations of 0.4 to 0.6 mEq/L are recommended because of increased sensitivity to adverse effects.³

■ Oxcarbazepine

■ **Pharmacology and Mechanism of Action.** Oxcarbazepine, a 10-keto analog of carbamazepine, blocks voltage-sensitive sodium channels, modulates voltage-activated calcium currents, and increases potassium conductance.⁹⁸

■ **Pharmacokinetics.** A summary of the absorption, distribution, metabolism, and elimination data for oxcarbazepine is found in Table 68–11.⁹⁸

■ **Efficacy.** Initial trials suggest oxcarbazepine has mood-stabilizing effects similar to those of carbamazepine, as well as the advantages of milder adverse effects, no autoinduction of liver enzymes, and fewer drug interactions.³

■ **Adverse Effects.** Oxcarbazepine has dose-related adverse effects of dizziness, sedation, headache, ataxia, fatigue, vertigo, abnormal vision, diplopia, nausea, vomiting, and abdominal pain.⁹⁸ Hyponatremia has been reported in up to 3% of patients.

■ **Drug-Drug Interactions.** Oxcarbazepine, a cytochrome P450 2C19 enzyme inhibitor and a 3A3/4 enzyme inducer, has the potential for causing drug interactions.⁹⁸ Oxcarbazepine induces the metabolism of oral contraceptives, thus alternative contraceptive measures are required.³

■ **Dosing and Administration.** Initial dosing is usually 150 to 300 mg twice daily and doses may be increased by 300 to 600 mg/day every 3 to 6 days up to 1,200 mg/day in divided doses (with or without food).⁹⁸

■ Valproate Sodium and Valproic Acid

■ **Pharmacology and Mechanism of Action.** The exact mechanism of action of valproic acid is not known (see Table 68–10).^{9,18,20,99}

■ **Pharmacokinetics.** Valproate sodium is rapidly converted to valproic acid in the stomach, whereas divalproex sodium delayed-release and extended-release tablets must pass into the small intestine to be converted to valproic acid.⁹⁹ Valproic acid is highly bound to albumin and other plasma proteins, and it is extensively metabolized in the liver.¹⁸ A summary of the absorption, distribution, metabolism, and elimination data for valproate is found in Table 68–11.⁹⁹

■ **Efficacy.** Valproic acid is a branched chain fatty acid and was originally utilized as an organic solvent before it was discovered in the 1960s to have anticonvulsant properties. Valproate has antimigraine, mood-stabilizing, antianxiety, antipanic, and antiaggressive effects.⁹⁹ In 1995 the enteric-coated formulation divalproex sodium (valproate) was approved for the acute treatment of mania. Several controlled studies have shown valproate to be as effective as lithium and olanzapine in patients with pure mania, and it may be more effective than lithium in certain subtypes of bipolar disorder (e.g., rapid cycling, mixed states, secondary bipolar disorder, and comorbid substance abuse).^{3,4,16,18,100} Placebo- and lithium-controlled and open studies report that valproate reduces or prevents recurrent manic, depressive, and mixed episodes.^{3,4,18} Although valproate is not approved for bipolar disorder in children and adolescents, studies suggest that it is effective and well tolerated.^{18,35}

Predictors of a positive response with valproate include rapid cycling, mixed episodes, comorbid panic disorder, organic mental disorders (e.g., head trauma), and mental retardation.^{1,4,18} Low-dose valproate (125 to 500 mg/day) has been reported to be effective in reducing mood cycling in bipolar II disorder and cyclothymia. Oral loading with divalproex sodium, 20 mg/kg per day, may produce a rapid reduction in manic and psychotic symptoms within 4 days without causing major side effects, although there may be a lag time to obtain full antimanic efficacy. Development of tolerance and loss of efficacy with valproate occurs in some patients after several years of treatment.⁴

Giving lithium, carbamazepine, antipsychotics, or benzodiazepines with valproate may augment its antimanic effects. The addition of valproate to lithium may have synergistic effects in treatment-refractory rapid cycling and mixed states, and the combination has demonstrated efficacy in maintenance therapy for bipolar I disorder.¹⁶

Combinations of valproate and carbamazepine may have synergistic effects, but the potential drug interactions make blood level monitoring of both agents essential.¹⁸ Valproate has been combined with traditional and atypical antipsychotics (e.g., olanzapine and risperidone) for patients with mixed state, depression, rapid cycling, or psychotic features.⁵¹ Adding adjunctive atypical antipsychotics to valproate may be effective for breakthrough mania or if there is incomplete or partial response to monotherapy. Clozapine and olanzapine may increase the risk of sedation and weight gain when combined with valproate. The combination of valproate and lamotrigine may be effective, but there is an increased risk of rashes, ataxia, tremor, sedation, and fatigue.^{93,99}

■ **Adverse Effects.** The most frequent dose-related adverse effects with valproate are gastrointestinal complaints (anorexia, nausea, indigestion, vomiting, mild diarrhea, and flatulence), fine hand tremors, and sedation.^{3,18,99} The gastrointestinal complaints are usually transient, but giving the drug with food, using lower initial doses with gradual increases in doses, switching to divalproex sodium extended-release tablets, or adding a histamine₂ antagonist such as famotidine or ranitidine can minimize them.^{3,18} Reduction of the dose or the addition of a β -blocker may alleviate tremors, and giving the total daily dose at bedtime may minimize daytime sedation.^{3,18}

Other adverse effects of valproate include ataxia, lethargy, alopecia, changes in the texture or color of hair, pruritus, prolonged bleeding due to inhibition of platelet aggregation, transient increases in liver enzymes, and hyperammonemia.^{18,99} Increased appetite and weight gain occurs in approximately 50% of patients on long-term valproate therapy. Weight gain may be related to changes in metabolic rates and not to excessive food intake; excessive weight gain may result in obesity-induced hyperinsulinemia and insulin resistance.^{66,74} Valproate may chelate trace metals such as selenium or zinc, which contributes to hair loss; therefore supplementation of selenium and zinc may help to manage hair thinning.¹⁸

Mild cases of asymptomatic leukopenia and rare cases of agranulocytosis and hepatitis have been reported with valproate.^{3,18,99} Thrombocytopenia may occur at higher doses, and patients should be monitored for bleeding and bruising. Lowering the valproate dose may restore platelet counts to normal levels.³ Fatal necrotizing hepatitis is a rare idiosyncratic, non-dose-related adverse effect that has occurred in children with epilepsy receiving multiple anticonvulsants.^{18,99} Children receiving valproate should be monitored for the signs and symptoms of hepatitis (nausea, vomiting, abdominal pain, malaise, lethargy, fever, and jaundice).¹⁸ A life-threatening hemorrhagic pancreatitis has been reported in both children and adults.^{3,18,99} Patients should be warned that nausea, vomiting, abdominal pain, and anorexia can be symptoms of pancreatitis, which requires prompt medical attention. Polycystic ovarian syndrome, menstrual irregularities, hyperandrogenemia, and peripheral insulin resistance (possibly associated with significant weight gain) have been reported in women taking valproate.^{3,74,99,100}

Valproate has a wide therapeutic range, so toxicity from overdoses is uncommon.³ Signs of overdose include coma, visual hallucinations, deep sleep, and heart block. Hemodialysis can be used to remove unbound valproic acid in overdose situations.^{3,99}

Valproate is usually not recommended during the first trimester of pregnancy due to a 1% to 5% risk of neural tube birth defects, primarily spina bifida.^{92,99} Administration of folate may reduce the risk of neural tube defects; therefore the risks versus benefits of using valproate during pregnancy must be discussed with the patient.¹⁸ Valproic acid is excreted into human breast milk in low concentrations (less than 1% to 10% of the mother's serum level), so is considered to be compatible with breast-feeding.⁴ One case report of

thrombocytopenia and anemia from valproate exposure has been reported in a nursing infant. If the mother receives valproate during breast-feeding, the infant should have routine blood level and laboratory monitoring like the mother.

■ **Drug-Drug Interactions.** There are several complex interactions between valproate and other medications.⁹⁹ Valproic acid is a weak inhibitor of liver enzymes, it may displace other drugs that are highly protein-bound (e.g., warfarin), and it may be displaced from protein binding sites by aspirin.^{3,4,18,99} The antiplatelet effects of valproic acid may potentiate the anticoagulant effects of warfarin and aspirin. Valproate tends to increase serum concentrations of other anticonvulsants and tricyclic antidepressants.¹⁸ Valproic acid may displace carbamazepine from serum protein binding sites and inhibit the metabolism of carbamazepine 10,11-epoxide, thereby causing carbamazepine toxicity.⁴ Hepatic metabolism induced by carbamazepine may decrease valproic acid serum concentrations. Chlorpromazine, cimetidine, erythromycin, felbamate, and fluoxetine may inhibit liver metabolism of valproic acid and result in toxicity.¹⁸ Valproic acid inhibits the metabolism of lamotrigine by competing with the glucuronidation enzyme site in the liver, thus lamotrigine should be initiated at half the starting dose and titrated up more slowly to 50% of the standard dose.^{3,93}

■ **Dosing and Administration.** For acute mania, the initial starting dosage of valproate is 500 to 1,000 mg/day (5 to 10 mg/kg per day) in divided doses, and the dose is adjusted up by 250 to 500 mg/day every 1 to 3 days (based on clinical response and tolerability) to 1,000 to 3,000 mg/day (i.e., 15 to 20 mg/kg per day up to 60 mg/kg per day) (see Table 68–10).^{3,18,99} For outpatients who are hypomanic, euthymic, or for elderly patients, the initial starting dose can be lower and gradually titrated to avoid adverse effects.³ Once an optimal dosage has been achieved, the total daily dose may be given twice daily or at bedtime if tolerated.^{3,18,99} Extended-release divalproex can be administered once daily, but bioavailability may be 15% lower than immediate-release products, thus requiring slightly higher doses.³ Higher initial loading doses of divalproex sodium (20 to 30 mg/kg per day in divided doses) have been used in acutely agitated manic inpatients, resulting in therapeutic serum levels within 5 days.^{3,4}

Recommended baseline and routine laboratory tests for valproate are listed in Table 68–12. Data from clinical trials in acutely manic patients indicated that there was an earlier response when trough serum levels were greater than 45 mcg/mL during the first week of treatment.⁴ Although therapeutic serum concentrations of valproic acid have not been established in bipolar disorder, most clinicians use the anticonvulsant therapeutic range of 50 to 125 mcg/mL taken 12 hours after the last dose.^{3,18} Patients with cyclothymia or mild bipolar II disorder may have a therapeutic response to lower doses and blood levels, whereas some patients with a more severe form of bipolar disorder may require up to 150 mcg/mL. Serum valproic acid levels are usually determined every 1 to 2 weeks during the first 2 months, and then every 3 to 6 months during maintenance therapy.⁹⁹

■ PHARMACOECONOMIC CONSIDERATIONS

Bipolar disorder is one of the leading causes of chronic disability worldwide and shares characteristics of both major depressive disorder and schizophrenia.^{4,101} Bipolar disorder is primarily treated in the public mental health sector, and a majority of patients receive life-long disability coverage because of compromised functioning.⁴ The total cost to society for bipolar disorder is enormous and is exceeded only by the costs for treating individuals with schizophrenia.¹⁸ It is estimated that the total economic impact of bipolar disorder in the United States is approximately \$45 billion.¹

Despite the prevalence, morbidity, mortality, and costs associated with the illness, there are few pharmacoeconomic or evidence-based outcome studies.^{4,102,103} To address some of these issues, The Stanley Foundation Bipolar Network was created to obtain longitudinal data (among five core sites and a number of affiliated sites) from double-blind, randomized controlled trials using consistent methodology and reliable and validated instruments.¹⁰⁴ A Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) is a 5-year outpatient study funded by the National Institute of Mental Health (www.stepbd.org) to determine which treatments or combination of treatments are most effective for bipolar disorder. The results from these controlled studies will help to provide the data for evidence-based outcomes and pharmacoeconomic considerations. Recently published data from a 12-month outpatient bipolar study (the Texas Algorithm Project) suggested that an algorithm-driven treatment had better initial and long-term improvement on outcome measures compared to a treat-as-usual group.⁵³

CLINICAL CONTROVERSIES

The place in therapy of the newer anticonvulsants, such as gabapentin, levetiracetam, tiagabine, topiramate, and zonisamide, is controversial. Many clinicians consider these agents to be less effective than established mood stabilizers based on initial studies and avoid them for monotherapy in bipolar disorder.

No published algorithms and guidelines have addressed the long-term use of combination therapies; thus the concurrent use of psychotropic agents from different classes remains controversial. At present the best approach is to maximize the dose and/or blood levels of the established mood stabilizer, and if possible, to taper off any adjunctive agent once the mood episode has resolved.

The issue of medication-induced weight gain in psychiatric patients has received considerable attention in the literature because of the medical complications of obesity. The management of weight gain and its consequences on physical and mental health remains controversial. Clinicians must strive to reduce weight gain because it decreases adherence to treatment and results in increased morbidity and mortality.

EVALUATION OF THERAPEUTIC OUTCOMES

4 The establishment and maintenance of a therapeutic alliance with a clinician is essential in monitoring a patient's psychiatric status and safety; enhancing treatment adherence; promoting good nutrition, sleep, and exercise; identifying stressors; recognizing new mood episodes; and minimizing adverse reactions and drug

interactions.^{1,3} Patients who have a partial response or nonresponse to established bipolar therapies should be reassessed for an accurate diagnosis, concomitant medical or psychiatric conditions, and medications or substances that exacerbate mood symptoms. Nonadherence to medication treatment, delusional symptoms, alcohol or substance abuse, rapid cycling, or mixed states are often associated with poorer treatment outcomes.

The evaluation of therapeutic outcomes for bipolar disorder requires regular monitoring by a clinician. More frequent office visits, telephone calls, and intensive outpatient programs are first-line strategies to prevent hospitalization during the acute treatment phase of a manic or depressive episode.³ Patients (and family members if needed) should be actively involved with their treatment and help to monitor target symptoms, efficacy of treatment, and adverse effects.^{1,3}

Standardized rating scales for mania and depression are used to measure severity and changes in symptoms in clinical trials (e.g., Young Mania Rating Scale, brief bipolar disorder symptoms scale, Hamilton Rating Scale for Depression, and Montgomery-Asberg Depression Rating Scale). Patient-rated life mood charts, a timeline of stressful life events, and a graphic display of sleep patterns are helpful in recognizing early symptoms of mood episodes and in documenting patterns and lengths of episodes.³ A mood disorder questionnaire, a 13-item self-reported screening tool, was recently developed to differentiate bipolar disorder from other mood disorders (www.dbsalliance.org/questionnaire/screening_intro.asp).^{3,28} Health-related quality of life scales such as the Short Form (SF)-36 and the Psychological General Well Being Scale have been recommended to assess the quality of life in individuals with bipolar disorder.¹⁰⁵

ABBREVIATIONS

DA: dopamine

ECT: electroconvulsive therapy

GABA: γ -aminobutyric acid

5-HT: serotonin

NE: norepinephrine

SSRI: selective serotonin reuptake inhibitor

ANXIETY DISORDERS I: GENERALIZED ANXIETY, PANIC, AND SOCIAL ANXIETY DISORDERS

Cynthia K. Kirkwood and Sarah T. Melton

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The long-term goal in generalized anxiety disorder is remission with minimal or no anxiety symptoms and no functional impairment.
- 2 Antidepressants are the agents of choice for long-term management of generalized anxiety disorder.
- 3 Antidepressants have a lag time of 2 to 4 weeks or longer before antianxiety effects occur in generalized anxiety disorder.
- 4 When monitoring the effectiveness of antidepressants in panic disorder, it is important to allow an adequate amount of time (8 to 12 weeks) to achieve full therapeutic response.
- 5 Clonazepam and alprazolam extended-release are alternatives to alprazolam immediate-release for patients with panic disorder having breakthrough panic symptoms at the end of a dosing interval.
- 6 The optimal duration of panic therapy is unknown; 12 to 24 months of pharmacotherapy is recommended before gradual drug discontinuation over 4 to 6 months is attempted.
- 7 Social anxiety disorder is a chronic long-term illness requiring extended therapy. After improvement, at least a 1-year maintenance period is recommended to maintain response and decrease the rate of relapse.
- 8 The selective serotonin reuptake inhibitors or venlafaxine are considered first-line pharmacotherapy for social anxiety disorder, especially in patients with comorbid depression, other anxiety disorders, or substance abuse.
- 9 An adequate trial of antidepressants in generalized social anxiety disorder lasts at least 8 weeks, and maximal benefit may not be seen until 12 weeks.
- 10 The three principal domains in which improvement should be observed in generalized social anxiety disorder include symptoms, functionality, and well being or overall improvement.

Anxiety is an emotional state commonly caused by the perception of real or perceived danger that threatens the security of an individual. It allows a person to prepare for or react to environmental changes. Everyone experiences a certain amount of nervousness and apprehension when faced with a stressful situation. This is an adaptive response, and is transient in nature.

Anxiety can produce uncomfortable and potentially debilitating psychological (e.g., worry or feeling of threat) and physiological arousal (e.g., tachycardia or shortness of breath) if it becomes excessive. Some individuals experience persistent, severe anxiety symptoms and possess irrational fears that significantly impair normal daily functioning. These persons often suffer from an anxiety disorder.¹

Anxiety disorders are among the most frequent mental disorders encountered in clinical practice. Health care professionals often mistake anxiety disorders for physical illnesses, and only 23% of patients receive appropriate treatment.² Failure to diagnose and manage anxiety disorders results in negative outcomes including overuse of health care resources, increased morbidity, and mortality.³ Individuals with anxiety disorders develop cardiovascular, cerebrovascular, gastroin-

testinal, and respiratory disorders at a significantly higher rate than the general population.⁴

To treat anxiety appropriately, the clinician must make a reliable diagnosis. It is essential that the distinction between short-term symptoms of anxiety and anxiety disorders be understood. Common or situational anxiety is a normal response to a stressful circumstance. Although symptoms can be severe, they are temporary and usually last no more than 2 or 3 weeks. While short-term, “as needed” treatment with an anxiolytic agent such as a benzodiazepine is common and may provide some symptomatic relief, prolonged drug therapy is unnecessary.⁵

EPIDEMIOLOGY

The prevalence rates of anxiety disorders was recently adjusted to reflect clinically significant disorders in the community.⁶ According to the revised prevalence estimates of mental disorders in the

United States, the 1-year prevalence rate for anxiety disorders was 13.3% in persons aged 18 to 54 years and 10.6% in those over age 55 years.⁶ Specific phobias were the most common anxiety disorder, with a 12-month prevalence of 8%; however, patients were not seriously impaired in terms of daily functioning, and few persons sought treatment.^{1,6} The 1-year prevalence of generalized anxiety disorder (GAD) was 2.8%, that of panic disorder was 1.7%, and that of social anxiety disorder (SAD) was 3.7%.⁶

In general, anxiety disorders are a group of heterogeneous illnesses that develop before age 30 and are more common in women, individuals with social issues, and those with a family history of anxiety and depression. Patients often develop another anxiety disorder, major depression, or substance abuse.^{1–3} The clinical picture of mixed anxiety and depression is much more common than an isolated anxiety disorder.^{7,8}

ETIOLOGY

The differential diagnosis of anxiety disorders includes medical and psychiatric illnesses and certain drugs.⁸ Family studies show that SAD can be inherited, with a threefold increase in the rate of SAD in relatives of patients.⁹ Behavioral inhibition, characterized by wariness, decreased social interaction, and withdrawal, is a genetic trait that may contribute to SAD.¹⁰ Patients with SAD commonly report having overprotective parents. Parental dysfunction and abuse are potential risk factors for developing SAD.¹⁰

MEDICAL DISEASES ASSOCIATED WITH ANXIETY

Anxiety symptoms are an inherent part of the initial clinical presentation of several diseases, thus complicating the distinction between anxiety disorders and medical disorders.⁷ If the anxiety symptoms are secondary to a medical illness, they usually will subside as the medical situation stabilizes. However, the knowledge that one has a physical illness (e.g., cancer and diabetes) can trigger anxious feelings and further complicate therapy. Persistent anxiety subsequent to a physical illness requires further assessment for an anxiety disorder.⁷ Symptoms of anxiety frequently present in medical disorders include palpitations, tachycardia, chest pain or tightness, shortness of breath, and hyperventilation. Medical disorders most closely associated with anxiety are listed in Table 69–1.^{7,8,11} About 50% of patients with GAD have irritable bowel syndrome.¹²

TABLE 69–1. Common Medical Illnesses Associated with Anxiety Symptoms

Cardiovascular

Angina, arrhythmias, congestive heart failure, ischemic heart disease, myocardial infarction

Endocrine and metabolic

Cushing's disease, hyperparathyroidism, hyperthyroidism, hypothyroidism, hypoglycemia, hyponatremia, hyperkalemia, pheochromocytoma, vitamin B₁₂ or folate deficiencies

Neurologic

Dementia, migraine, Parkinson's disease, seizures, stroke, neoplasms, poor pain control

Respiratory system

Asthma, chronic obstructive pulmonary disease, pulmonary embolus, pneumonia

Others

Anemias, systemic lupus erythematosus, vestibular dysfunction

Compiled from House and Stark,⁷ Gliatto,⁸ and Chen et al.¹¹

TABLE 69–2. Drugs Associated with Anxiety Symptoms

Anticonvulsants: carbamazepine

Antidepressants: selective serotonin reuptake inhibitors, tricyclic antidepressants

Antihypertensives: felodipine

Antibiotics: quinolones, isoniazid

Bronchodilators: albuterol, theophylline

Corticosteroids: prednisone

Dopa agonists: levodopa

Herbals: ma huang, ginseng, ephedra

Nonsteroidal anti-inflammatory drugs: ibuprofen

Stimulants: amphetamines, methylphenidate, caffeine, cocaine

Sympathomimetics: pseudoephedrine

Thyroid hormones: levothyroxine

Toxicity: anticholinergics, antihistamines, digoxin

Withdrawal: alcohol, sedatives

Compiled from American Psychiatric Association,¹ House and Stark,⁷ and Chen et al.¹¹

PSYCHIATRIC DISEASES ASSOCIATED WITH ANXIETY

Anxiety can be a presenting feature of several major psychiatric illnesses. Anxiety symptoms are extremely common in patients with mood disorders, schizophrenia, delirium, dementia, and substance-use disorders. Most psychiatric patients will have two or more concurrent psychiatric disorders (comorbidity) within their lifetime.⁶ It is important to diagnose and treat all comorbid psychiatric conditions in patients with anxiety disorders.

DRUG-INDUCED ANXIETY

Drugs are a common cause of anxiety symptoms (Table 69–2). Anxiety occurs during the use of central nervous system (CNS) stimulating drugs in a dose-dependent manner, but ingestion of minimal amounts can result in marked anxiety, including panic attacks, in some individuals. The onset of drug-induced anxiety is usually rapid after the initiation of therapy; look for a recent drug or dosage change to rule out drug etiologies for anxiety.

Anxiety occurs occasionally during the use of CNS depressants, especially in children and the elderly; however, anxiety complaints are more common as complications of drug withdrawal after the abrupt discontinuation of these agents.^{7,11}

PATHOPHYSIOLOGY

Data from biochemical and neuroimaging studies indicate that the modulation of normal and pathologic anxiety states is associated with multiple regions of the brain and abnormal function in several neurotransmitter systems, including norepinephrine (NE), γ -aminobutyric acid (GABA), and serotonin (5-HT). Current neuroanatomic models of fear (i.e., the response to danger) and anxiety (i.e., the feeling of fear that is disproportionate to the actual threat) include some key brain areas. The amygdala, a temporal lobe structure, plays a critical role in the assessment of fear stimuli and learned response to fear.¹³ The locus ceruleus (LC), located in the brain stem, is the primary NE-containing site in the brain, with widespread projections to areas responsible for implementing fear responses (e.g., vagus, lateral and paraventricular hypothalamus). The hippocampus is integral in the consolidation of traumatic memory, and along with the entorhinal cortex, contextual fear conditioning that is involved in overgeneralization

of the fear response. The hypothalamus is the principal area for integrating neuroendocrine and autonomic responses to a threat.¹³

NEUROCHEMICAL THEORIES

NORADRENERGIC MODEL

The basic premise of the noradrenergic theory is that the autonomic nervous system of anxious patients is hypersensitive and overreacts to various stimuli. Many anxious patients clearly display symptoms of peripheral autonomic hyperactivity. In response to threat or fearful situations, the LC serves as an alarm center, activating NE release and stimulating the sympathetic and parasympathetic nervous systems. Chronic central noradrenergic overactivity downregulates α_2 -adrenoreceptors in patients with GAD. This receptor is hypersensitive in some patients with panic disorder.¹³ Patients with SAD appear to have a hyperresponsive adrenocortical response to psychological stress.¹⁴

By administering drugs that have a relatively specific effect on the LC, researchers have further explored the NE theory of anxiety and panic disorder. Drugs with anxiogenic effects (e.g., yohimbine [an α_2 -adrenergic receptor antagonist]) stimulate LC firing and increase noradrenergic activity. NE in turn increases glutamate release (an excitatory neurotransmitter).¹³ This produces subjective feelings of anxiety and can precipitate a panic attack in those with panic disorder, but not in normal volunteers or those with other psychiatric illnesses.¹⁵ Drugs with anxiolytic or antipanic effects (e.g., benzodiazepines, antidepressants, and clonidine) inhibit LC firing, decrease noradrenergic activity, and block the effects of anxiogenic drugs.¹³

GABA RECEPTOR MODEL

There are two superfamilies of GABA protein receptors: GABA_A and GABA_B. Drugs to reduce anxiety and produce sedation target the GABA_A receptor. The GABA_B receptor is a G-protein coupled receptor postulated to be involved in the presynaptic inhibition of GABA release.¹³ GABA_A receptors are ligand-gated ion channels. The opening of the channel is composed of five peptide subunits (i.e., α , β , γ , δ , or ρ subunits) that surround a central pore that crosses the neuronal cell membrane and is permeable to chloride. Benzodiazepine ligands either enhance or diminish the inhibitory effects of GABA.¹³ GABA, the major inhibitory neurotransmitter in the CNS, has a strong regulatory or inhibitory effect on the 5-HT, NE, and dopamine (DA) systems. When GABA binds to the GABA_A receptor, the chloride ion channel opens and permits the influx of negatively charged chloride ions; this results in hyperpolarization of the cell membrane and decreases nerve cell excitability.

The specific role of the GABA receptors in anxiety disorders has not been established. The number of GABA_A receptors can change with alterations in the environment (e.g., chronic stress) and the subunit expression can be altered by hormonal changes.¹⁶ In patients with GAD, benzodiazepine binding in the left temporal lobe is reduced.¹⁶ Abnormal sensitivity to antagonism of the benzodiazepine binding site and decreased binding was demonstrated in panic disorder.^{13,16} This is consistent with the suggestion that panic disorder is secondary to a lack of central inhibition that results in uncontrolled elevations in anxiety during panic attacks.¹⁶ Growth hormone response to baclofen in patients with generalized SAD suggests an abnormality of central GABA_B receptor function.¹⁷ Antidepressant potentiation of the GABA_A modulatory effects of neurosteroids may contribute to their mechanism of action in anxiety disorders.¹⁶

SEROTONIN MODEL

Although there are data suggesting that the 5-HT system is dysregulated in patients with anxiety disorders, definitive evidence that shows a clear abnormality in 5-HT function is lacking. 5-HT is primarily an inhibitory neurotransmitter that is used by neurons originating in the raphe nuclei of the brain stem and projecting diffusely throughout the brain (e.g., cortex, amygdala, hippocampus, and limbic system). The diverse actions of 5-HT are regulated by at least 14 different postsynaptic receptor subtypes.¹³ Abnormalities in serotonergic functioning through release and uptake at the presynaptic autoreceptors (5-HT_{1A/1D}), the serotonin reuptake transporter site (SERT), or effect of 5-HT at the postsynaptic receptors (e.g., 5-HT_{1A}, 5-HT_{2A}, and 5-HT_{2C}) may play a role in anxiety disorders.¹³ Preclinical models suggest that greater 5-HT function facilitates avoidance behavior; however, primate studies show that reducing 5-HT increases aggression.¹³ It is postulated that greater 5-HT activity reduces NE activity in the LC, inhibits defense/escape response via the periaqueductal gray region, and reduces hypothalamic release of corticotropin-releasing factor. The selective serotonin reuptake inhibitors (SSRIs) acutely increase 5-HT levels by blocking the SERT to increase the amount of 5-HT available postsynaptically, and are efficacious in blocking the manifestations of panic and anxiety.¹³ The precise role of 5-HT in panic disorder is unclear; however, 5-HT may play a role in the development of anticipatory anxiety.¹⁵

Low 5-HT activity may lead to a dysregulation of other neurotransmitters. NE and 5-HT systems are closely linked, and interactions between the two are reciprocal and vary. NE may act at presynaptic 5-HT terminals to decrease 5-HT release, and its activity at postsynaptic receptors can cause increased 5-HT release. Stimulation of the postsynaptic 5-HT_{2A} receptors in the limbic system results in anxiety and avoidance behavior.

Buspirone is a selective 5-HT_{1A} partial agonist that is effective for GAD but not for panic disorder. Because the selective 5-HT_{1A} partial agonists reduce serotonergic activity, GAD symptoms may reflect excessive 5-HT transmission or overactivity of the stimulatory 5-HT pathways. Patients with SAD have greater prolactin response to bupirone challenge compared with healthy controls, indicating an enhancement of central serotonergic response.¹⁸

NEUROIMAGING STUDIES

Functional neuroimaging studies suggest that frontal and occipital brain areas are integral to the anxiety response. There is some evidence that patients with panic disorder have abnormal activation of the parahippocampal region and prefrontal cortex at rest. Panic anxiety is associated with activation of brain stem and basal ganglia areas.¹⁵ In GAD patients there is an abnormal increase in cortical activity and a decrease in basal ganglia activity. After benzodiazepine treatment, basal ganglia activity increases, and cortical activity is reduced.¹⁵ Neuroimaging studies implicate abnormalities in the amygdala, hippocampus, and varied cortical regions in patients with SAD.¹⁹

CLINICAL PRESENTATION

The *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision classifies anxiety disorders into several categories: GAD, panic disorder (with or without agoraphobia), agoraphobia, SAD, specific phobia, obsessive-compulsive disorder, posttraumatic stress disorder, and acute stress disorder.¹ The characteristic features of these illnesses are anxiety and avoidance behavior.

TABLE 69–3. Presentation of Generalized Anxiety Disorder**Psychological and cognitive symptoms**

- Excessive anxiety
- Worries that are difficult to control
- Feeling keyed up or on edge
- Poor concentration or mind going blank

Physical symptoms

- Restlessness
- Fatigue
- Muscle tension
- Sleep disturbance
- Irritability

Impairment

- Social, occupational, or other important functional areas
- Poor coping abilities

Screening questions

- What is going on in your life?
- How do you feel about it?
- What troubles you the most?
- How are you handling that?

Compiled from American Psychiatric Association¹ and Hildago and Davidson.²⁰

Obsessive-compulsive disorder and posttraumatic stress disorder are discussed in Chap. 70.

GENERALIZED ANXIETY DISORDER

The diagnostic criteria for GAD require persistent symptoms for most days for at least 6 months.¹ The essential feature of GAD is unrealistic or excessive anxiety and worry about a number of events or activities.¹ The clinical presentation of GAD appears in Table 69–3. The anxiety or apprehensive expectation is accompanied by at least three psychological or physiological symptoms. Anxiety and worry are not confined to features of another psychiatric illness (e.g., having a panic attack, being embarrassed in public). The persistent worry must cause significant distress, and impairment in social, occupational, or other important areas of functioning. Anxiety and worry should not be secondary to a drug or illicit substance or a general medical disorder, and not occur solely as part of another psychiatric disorder (e.g., mood disorder).¹

The onset, course of illness, and comorbid conditions of GAD are important considerations. GAD has a gradual onset with an average age of 21 years; however, there is a bimodal distribution. If GAD is the primary disorder, the patient can present in their teens. If it develops secondary to another anxiety disorder, the onset can be as late as age 30 years and even extend into the mid-50s. Most patients report onset of symptoms in childhood or adolescence. The median duration of illness at the time of diagnosis is 15.6 years.²⁰ GAD can be exacerbated or precipitated in later life by severe psychological stressors. Tense life events also can play a role in the persistence of symptoms. The course of the illness is chronic (i.e., episodes can last for a decade or longer); there is a high percentage of relapse and low rates of recovery. The likelihood of remission at 2 years is 25%.^{1,20} Patients report substantial interference with their lives and have a high probability of seeking treatment.³ The majority of patients with GAD eventually will develop another mental disorder. GAD is usually the primary disorder in patients with comorbid anxious depression.

PANIC DISORDER

Panic disorder begins as a series of unexpected (spontaneous) panic attacks involving an intense, terrifying fear similar to that caused by life-threatening danger. The unexpected panic attacks are followed

TABLE 69–4. Symptoms of a Panic Attack**Psychological symptoms**

- Depersonalization
- Derealization
- Fear of losing control
- Fear of going crazy
- Fear of dying

Physical symptoms

- Abdominal distress
- Chest pain or discomfort
- Chills
- Dizziness or light-headedness
- Feeling of choking
- Hot flushes
- Palpitations
- Nausea
- Paresthesias
- Shortness of breath
- Sweating
- Tachycardia
- Trembling or shaking

From American Psychiatric Association.¹

by at least 1 month of persistent concern about having another panic attack, worry about the possible consequences of the panic attack, or a significant behavioral change related to the attacks.¹ During an attack, patients often describe an overwhelming sense of doom, a fear of dying or losing control, and at least four physical symptoms (Table 69–4).¹ Panic attacks usually last no more than 20 to 30 minutes, with the peak intensity of symptoms within the first 10 minutes. Often patients seek help at a physician's office or emergency department, only to have their symptoms resolve before or on arrival. Because panic symptoms mimic those present in several medical conditions, patients often are misdiagnosed, and multiple referrals are common.¹

Secondary to the panic attacks, many patients eventually develop agoraphobia. Agoraphobia is anxiety about being in places or situations in which escape might be difficult or where help might not be available in the event of a panic attack.¹ As a result, patients often avoid specific situations (e.g., flying or elevators) in which they fear a panic attack might occur.¹

Panic disorder has an adverse impact on the patient's quality of life (QOL), including a significant degree of social and work impairment. Complications include depression (10% to 65% have major depressive disorder), alcohol abuse, and high use of health services and emergency rooms.¹ Patients with panic disorder have a high lifetime risk for suicide attempts compared with the general population.²¹ The usual course is chronic but waxing and waning.

SOCIAL ANXIETY DISORDER

SAD is characterized by an intense, irrational, and persistent fear of being negatively evaluated or scrutinized in at least one social or performance situation. Exposure to the feared circumstance usually provokes an immediate situation-related panic attack. Symptoms of SAD are found in Table 69–5. Blushing is the principal physical indicator and distinguishes SAD from other anxiety disorders. Adults with SAD usually recognize their fear is excessive and unreasonable; however, they are unable to overcome it without treatment. If necessary, the feared situation is avoided or endured with significant distress.¹ The avoidance, anxious anticipation, or distress in the feared social or performance situation must interfere significantly with the person's normal routine, occupational or academic functioning, or social activities or relationships, or cause significant distress about having

TABLE 69–5. Presentation of Social Anxiety Disorder**Fears**

- Being scrutinized by others
- Being embarrassed
- Being humiliated

Some feared situations

- Addressing a group of people
- Eating or writing in front of others
- Interacting with authority figures
- Speaking in public
- Talking with strangers
- Use of public toilets

Physical symptoms

- Blushing
- “Butterflies in the stomach”
- Diarrhea
- Sweating
- Tachycardia
- Trembling

Types

- Generalized type: fear and avoidance extend to a wide range of social situations
- Nongeneralized type: fear is limited to one or two situations

Screening questions

- Are you uncomfortable or embarrassed at being the center of attention?
- Do you find it hard to interact with people?

Compiled from American Psychiatric Association¹ and Ballenger et al.²²

the phobia. In individuals under 18 years of age, the duration of symptoms is at least 6 months. The fear or avoidance is not caused by a drug or other substance (e.g., cocaine), or a general medical or psychiatric disorder.¹

The mean age of onset of SAD is during the mid-teens. Rates of SAD are slightly higher among women than men and more frequent in younger cohorts. It is a chronic disorder with a mean duration of 20 years.¹

Differentiating SAD from other anxiety disorders can be difficult. Panic attacks occur in both SAD and panic disorder, but the distinction between the two is the rationale behind fear; fear of anxiety symptoms is characteristic of panic disorder, while fear of embarrassment from social interaction typifies SAD.¹ GAD is likely the diagnosis if anxiety regarding social situations are part of a pattern of worries about multiple life areas or numerous potential negative outcomes. A majority of SAD patients have a comorbid mood, anxiety, or substance abuse disorder.²² The SAD typically precedes the development of comorbid disorders, which is associated with increased suicidal ideation.²²

SPECIFIC PHOBIA

Specific phobia is marked and persistent fear of a circumscribed object or situation (e.g., insects, heights, blood, or public transportation). Apart from contact with the feared object or situation, the patient is usually free of symptoms. Most persons simply avoid the feared object and adjust to certain restrictions on their activities.¹

► TREATMENT: Generalized Anxiety Disorder**■ DESIRED OUTCOME**

The short-term goals of therapy in the acute management of GAD are to reduce the severity and duration of the anxiety symptoms and ◀1 to improve overall functioning. The long-term goal in GAD is remission with minimal or no anxiety symptoms and no functional impairment.²³ Patients with comorbid depression should have minimal depressive symptoms.²³

■ GENERAL APPROACH TO TREATMENT

Once GAD is diagnosed, a patient-oriented treatment plan, which usually consists of both psychotherapy and drug therapy, is devel-

oped. The plan depends on the patient’s degree of emotional distress, age, drug history, medical status, and the potential outcomes of pharmacologic treatment. Psychotherapy is the least invasive and safest treatment modality.⁸ Antianxiety medication is indicated for patients experiencing anxiety symptoms severe enough to produce functional disability. Table 69–6 lists drug choices for GAD, panic disorder, and SAD. Many questions remain unanswered regarding how to manage treatment-resistant GAD.

■ NONPHARMACOLOGIC THERAPY

Nonpharmacologic treatment modalities in GAD include psychoeducation, short-term counseling, stress management, psychotherapy, meditation, or exercise. Psychoeducation includes information on the

TABLE 69–6. Drug Choices for Anxiety Disorders

| Anxiety Disorder | First-Line Drugs | Second-Line Drugs | Alternatives |
|-------------------------|--|---|---------------------------------------|
| Generalized anxiety | Venlafaxine XR Paroxetine Escitalopram | Benzodiazepines Imipramine Buspirone | Hydroxyzine |
| Panic disorder | SSRIs | Imipramine Clomipramine Alprazolam Clonazepam | Phenelzine |
| Social anxiety disorder | Paroxetine Sertraline Venlafaxine XR | Citalopram Escitalopram Fluvoxamine Clonazepam | Buspirone Gabapentin Phenelzine |

SSRI, selective serotonin reuptake inhibitor; XR, extended-release.

Compiled from Ballenger et al,¹² Ballenger et al,²² Bandelow et al,²⁴ and Work Group on Panic Disorder.²⁵

etiology and management of GAD. Anxious patients should be instructed to avoid caffeine, nonprescription stimulants, diet pills, and excessive use of alcohol. Most patients with GAD require psychological therapy, alone or in combination with anti-anxiety drugs, to overcome fears and to learn to manage their anxiety and worry.⁵ Cognitive behavioral therapy (CBT) is the most effective psychological therapy in GAD patients. Controlled trials comparing the efficacy of combining CBT with medication or using it alone are lacking.²⁴ The current literature is not clear regarding when to use CBT. Certified therapists can be identified through the Web sites of the Academy of Cognitive Therapy (www.academyofct.org) or the American Board of Professional Psychology (www.abpp.org).¹²

PHARMACOLOGIC THERAPY

The benzodiazepines are the most effective, safe, and commonly prescribed drugs for the rapid relief of acute anxiety symptoms. They are also used intermittently or adjunctively for acute GAD exacerbations and for sleep disturbances at the outset of antidepressant therapy.¹²

All benzodiazepines are equally effective anxiolytics, and consideration of pharmacokinetic properties and the patient’s clinical situation will assist in the selection of the most appropriate agent. Pharmacokinetic differences vary, and the clinician must monitor response to the initial treatment regimen after 2 to 4 weeks.⁵

Because of the lack of dependency and tolerable adverse effect profile, antidepressants have emerged as the treatment of choice for the long-term management of chronic anxiety, especially in the presence of comorbid depressive symptoms. Buspirone is an additional anxiolytic option (Table 69–7) in patients without comorbid depression or other anxiety disorders (e.g., panic disorder and SAD). Because of the high risk of adverse effects and toxicity, barbiturates, antipsychotics, antipsychotic-antidepressant combinations, and antihistamines generally are not indicated in the treatment of GAD.^{12,24} The benzodiazepines are more effective in treating the somatic and autonomic symptoms of GAD as opposed to the psychic symptoms (e.g., apprehension and worry), which are reduced by antidepressants.⁵

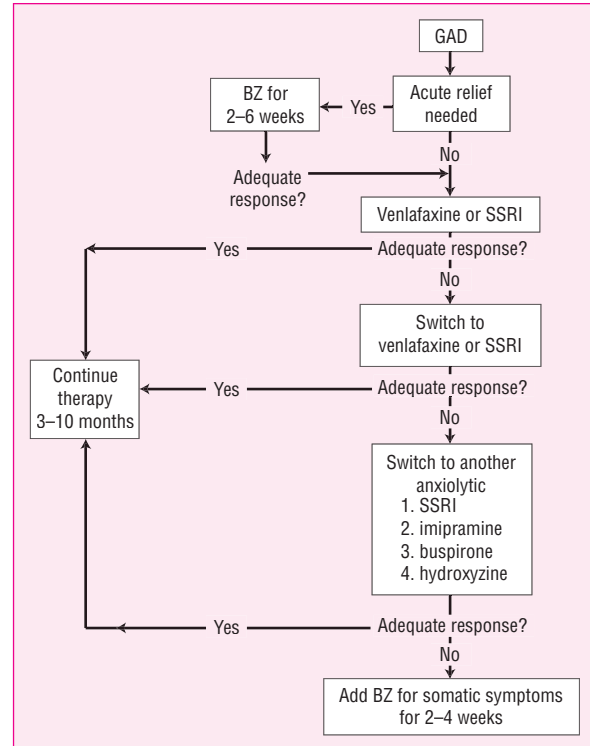

FIGURE 69–1. Algorithm for the pharmacotherapy of GAD. SSRI = selective serotonin reuptake inhibitor, BZ = benzodiazepine. (Compiled from Rickels and Rynn,⁵ Ballenger et al,¹² and Bandelow et al.²⁴)

Two published algorithms outline the pharmacotherapy of GAD⁵ and management of anxiety disorders in patients with chemical dependency.³⁰ A consensus report on the management of anxiety in primary care¹² and guidelines on the pharmacological treatment of GAD from the World Federation on Societies of Biological Psychiatry were published.²⁴ An algorithm for the pharmacological management of GAD is shown in Figure 69–1, but the current literature is not conclusive on the optimal sequence of pharmacologic therapies.

TABLE 69–7. Nonbenzodiazepine Antianxiety Agents for Generalized Anxiety Disorder

| Generic Name | Trade Name | Starting Dose | Dosage Range (mg/day) ^a |
|------------------------------|------------------|------------------------------|------------------------------------|
| <i>Antidepressants</i> | | | |
| Escitalopram ^b | Lexapro | 10 mg per day | 10–20 |
| Imipramine ^c | Tofranil | 50 mg per day | 75–200 |
| Paroxetine ^{b,c} | Paxil | 20 mg per day | 20–50 |
| Venlafaxine ^b | Effexor XR | 37.5 or 75 per day | 75–225 ^d |
| <i>Azapirones</i> | | | |
| Buspirone ^{b,c} | BuSpar | 7.5 mg twice per day | 15–60 ^d |
| <i>Diphenylmethane</i> | | | |
| Hydroxyzine ^{b,c,e} | Vistaril, Atarax | 25 or 50 mg four times daily | 200–400 |

^aElderly patients are usually treated with approximately one-half of the dose listed.

^bFDA-approved for generalized anxiety disorder.

^cAvailable generically.

^dNo dosage adjustment is required in elderly patients.

^eFDA-approved for anxiety and tension in children in divided daily doses of 50–100 mg.

Compiled from Bandelow et al,²⁴ Lexapro package insert,²⁶ Paxil package insert,²⁷ Effexor XR package insert,²⁸ and Vistaril package insert.²⁹

■ ALTERNATIVE DRUG TREATMENTS

Hydroxyzine and kava kava are two alternatives. Patients with GAD demonstrated continued efficacy for 3 months with hydroxyzine or bromazepam (not marketed in the United States), but not with placebo.³¹ Efficacy was maintained in 86% of the hydroxyzine group and 88% of the bromazepam group.³¹ A meta-analysis of randomized trials comparing the herbal preparation kava kava found it was more effective than placebo for anxiety during trial durations of 1 to 24 weeks. Many patients experienced CNS effects (e.g., tremors, drowsiness, restlessness, and headaches) and abdominal discomfort during short-term treatment.³² Because of recent reports of hepatotoxicity, kava kava is not recommended as an anxiolytic.³³

■ SPECIAL POPULATIONS

The management of anxiety in pregnancy, children, elderly patients, and those with hepatic impairment requires special consideration in the choice of anxiolytic. The literature is unclear if the potential risks of anxiolytic therapy outweigh the benefits of treating anxiety during pregnancy. Clinical practice guidelines for anxiety disorders indicate that the use of SSRIs or tricyclic antidepressants (TCAs) in pregnancy does not pose increased risk; however, neonatal complications and prematurity were reported.²⁴ Cleft lip, cleft palate, and other teratogenic effects are associated with benzodiazepine use, but a causal relationship is inconclusive.²⁴ Diazepam and chlordiazepoxide are the two benzodiazepines with the longest safety records. Diazepam should not be used if the mother is nursing because infants can experience sedation, lethargy, and weight loss.³⁴ Clinicians should avoid benzodiazepine use during the first trimester, use the lowest dosage for the shortest period of time, divide the total daily dosage into two or three doses to prevent high peak plasma levels, and use the agent as monotherapy.³⁴

In the elderly, secondary to a decreased capacity for oxidation and alterations in the volume of distribution, drug accumulation can result. Patients with hepatic disease also are at risk for drug accumulation and subsequent complications. Therefore, intermediate- or short-acting benzodiazepines without active metabolites are preferred for chronic use in the elderly and those with liver disorders. Elderly patients are also sensitive to the CNS adverse effects of benzodiazepines (regardless of half-life) and their use is associated with a high frequency of falls and hip fractures.³⁵

There are few controlled clinical trials of drugs in children and adolescents with GAD. CBT alone or in conjunction with antidepressants can have long-term benefits.³⁶ Randomized controlled trials of sertraline and fluvoxamine, and open trials of alprazolam, clonazepam, and fluoxetine indicate short-term efficacy;^{36–38} however, behavioral activation was reported with clonazepam.^{36,37} To date, fluoxetine is FDA-indicated for treatment of both depression and OCD, and fluvoxamine and sertraline are FDA-indicated for OCD in children and adolescents. Other SSRIs and venlafaxine have not been proved safe and effective in children and adolescents.³⁹ There are reports of hostility, suicidal ideation, and self-harm with paroxetine in children with major depression, and venlafaxine in children with major depression or GAD.^{40,41} Increased monitoring for behavioral activation with benzodiazepines and suicide-related adverse effects with SSRIs is necessary if these agents are prescribed for anxiety in children and adolescents. The FDA recently placed a black box warning on the use of all antidepressants in children and adolescents, and specific monitoring parameters were defined. The reader is

referred to the official approved labeling for each antidepressant and to the FDA for additional information.

■ ANTIDEPRESSANT THERAPY

2 Antidepressants are considered first-line agents in the long-term management of GAD. Venlafaxine extended-release, paroxetine, and escitalopram are FDA-approved antidepressants for GAD. Imipramine is considered when patients fail to respond to SSRIs 3 or venlafaxine (see Table 69–7). The anti-anxiety response of antidepressants is delayed by 2 to 4 weeks or longer.²⁴ The pharmacokinetics and drug interactions of the antidepressants are reviewed in the chapter on depressive disorders (Chap. 67).

■ Efficacy

Venlafaxine extended-release, a serotonin-norepinephrine reuptake inhibitor (SNRI), alleviates anxiety in patients with and without comorbid depression. The reduction in psychic symptoms of anxiety and tension is not accompanied by significant reductions in somatic symptoms. Venlafaxine (dosed once daily) was effective at doses of 150 and 225 mg for 2 months in patients with GAD, and efficacy was maintained for an additional 6 months of therapy.⁴² Paroxetine was significantly more effective than placebo at achieving response in 62% and 68% of patients at 20 and 40 mg daily, respectively, after 2 months. Remission occurred in 30% and 36% of patients taking 20 and 40 mg of paroxetine, respectively.⁴³ Escitalopram was more efficacious than placebo in three 8-week trials in patients with GAD.²⁶ In a four parallel-group comparison, diazepam and trazodone were found to be equivalent in anxiolytic activity (remission rates of 66% and 69%, respectively) compared with placebo (47% remission rate), but imipramine's rate of remission (73%) exceeded that of the other three treatments.³⁷

■ Mechanism of Action

The mechanism of action of antidepressants in anxiety disorders is not fully understood. Research indicates that antidepressants modulate receptor activation of neuronal signal transduction pathways connected to the neurotransmitters 5-HT, DA, and NE. As a result these cascades modify the expression of certain genes and the proteins that are produced (e.g., increase messenger RNA for glucocorticoid receptors and brain-derived neurotrophic factor for trkB receptors, and reduce mRNA expression for corticotropin-releasing hormone).⁴⁴ It is theorized that by activating stress-adapting pathways, SSRIs and SNRIs reduce the somatic anxiety symptoms and the general distress experienced by patients.⁴⁴

■ Adverse Effects

The most common adverse events of venlafaxine in patients with GAD were nausea, somnolence, and dry mouth.⁴² Paroxetine was associated with a high rate of somnolence, nausea, abnormal ejaculation, dry mouth, decreased libido, and asthenia compared with placebo.⁴³ Escitalopram caused nausea, insomnia, fatigue, decreased libido, ejaculation disorders, and decreased libido at a higher rate than placebo in patients with GAD.²⁶ The use of TCAs may be limited by troublesome adverse events (e.g., sedation, orthostatic hypotension,

TABLE 69–8. Benzodiazepine Antianxiety Agents

| Generic Name | Brand Name | Approved Dosage Range (mg/day) ^a | Approximate Equivalent Dose (mg) |
|-------------------------------|------------|---|----------------------------------|

anticholinergic effects, and weight gain) in some patients and the risk of toxicity in overdose.⁵ However in a meta-analysis of antidepressant trials there was no difference in dropout rates between antidepressants (i.e., paroxetine, venlafaxine, and imipramine) compared with placebo, suggesting equivalent tolerability between antidepressants.³⁷

■ Dosing and Administration

The antidepressants can be dosed once a day (see Table 69–7). The initial dose of venlafaxine extended-release is 75 mg once a day; 37.5 mg can be used in some patients. The dose can be increased every 4 days up to a maximum of 225 mg once daily, although a dose-response relationship has not been established.²⁸ Paroxetine is administered in a single daily dose (with or without food) of 20 mg. Doses greater than 20 mg/day have not been found to be more effective, but it can be increased by 10 mg/day every week.²⁷ Escitalopram dosing begins with 10 mg daily.²⁶

■ BENZODIAZEPINE THERAPY

The benzodiazepines are the most frequently prescribed drugs for treating anxiety.⁸ Although all benzodiazepines possess anxiolytic properties, only 7 of the 13 currently marketed agents have Food and Drug Administration (FDA) approval for the treatment of GAD (Table 69–8). Estazolam, flurazepam, temazepam, quazepam, and triazolam are marketed as sedative-hypnotic agents. Clonazepam is marketed as an antipanic agent and anticonvulsant,⁴⁶ and midazolam is labeled for preoperative sedation. Alprazolam is indicated for the treatment of panic disorder with or without agoraphobia, as well as GAD, and is also available in once-daily dosed extended-release tablets.⁴⁷

■ Pharmacology and Mechanism of Action

The GABA receptor model of anxiety (described in the pathophysiology section) theorizes that benzodiazepines ameliorate anxiety through potentiation of the inhibitory activity of GABA.¹³ The GABA receptor is composed of protein subunits arranged in a pentamer with a chloride ion channel in the center. Benzodiazepines bind on the GABA_A receptor at the α_1 , α_2 , α_3 , and α_5 sites; the anxiolytic effects of benzodiazepines are mediated at the α_2 site.¹³ When benzodiazepines bind to the GABA_A receptor, the frequency of the chloride ion channels opening and the influx of chloride ions into the neuronal cell are increased. The resulting negatively charged hyperpolarized

membrane prevents further depolarization by excitatory neurotransmitters. Other neurotransmitters (e.g., 5-HT, NE, and DA) may be involved in benzodiazepine activity.

■ Pharmacokinetics

A wide difference in milligram potency exists between the benzodiazepine compounds; however, when dosage adjustments are made, all agents share similar anxiolytic and sedative-hypnotic activity. The variations in lipid solubility between compounds influence the pharmacokinetic properties of benzodiazepines. Different pharmacokinetic and pharmacodynamic properties can assist the clinician in choosing an appropriate anxiolytic (Table 69–9). After a single dose, the onset, intensity, and duration of pharmacological effects are important factors to consider when using benzodiazepines for the short-term, intermittent, or as-needed treatment of anxiety.

The primary determinant of a drug's onset of effect after a single oral dose is the rate of drug absorption. Because of high lipophilicity, diazepam and clorazepate are absorbed rapidly and distributed quickly into the CNS. Therefore the onset of anxiolytic effect occurs within 30 to 60 minutes, which results in a rapid and intense relief of anxiety. High lipophilicity increases the extent of drug redistribution into the periphery, particularly adipose tissue, resulting in a shorter duration of effect after a single dose than indicated by single-dose elimination half-life studies.⁴⁸ Clinically, patients perceive a rapid onset of action, but some experience an unpleasant feeling of drowsiness or loss of control. This “rush” can be euphoric and contribute to abuse. Chlordiazepoxide's onset of action is much slower because of decreased lipophilicity, slower absorption, and delayed passage into the CNS.

Compared with diazepam, lorazepam and oxazepam are relatively less lipophilic and have a slower onset of effect. These benzodiazepines have smaller volumes of distribution and a resulting longer duration of action.⁴⁸ Oxazepam absorption is slow, and peak levels are not obtained until 2 to 4 hours after a single dose; however, like lorazepam, oxazepam's anxiolytic effects are long lasting because extensive distribution does not occur.

Parenteral administration via the intramuscular route should be avoided with diazepam and chlordiazepoxide secondary to variability in the rate and extent of drug absorption. Intramuscular lorazepam provides rapid, reliable, and complete absorption; however, the preparation requires refrigeration.

After multiple dosing, the rate and extent of drug accumulation are functions of the drug's elimination half-life in relation to dosing intervals, clearance, and formation of active metabolites. Differences

TABLE 69–9. Pharmacokinetics of Benzodiazepine Antianxiety Agents

| Generic Name | Time to Peak Plasma Level (h) | Elimination Half-Life, Parent (h) | Metabolic Pathway | Clinically Significant Metabolites | Protein Binding (%) |

Compiled from Bailey et al.⁴⁸

in clinical effects that occur during and after repeated dosages with the benzodiazepines are related in part to variability in metabolism and metabolite accumulation.⁴⁸

The benzodiazepines undergo two primary metabolic processes, hepatic oxidation (catalyzed by cytochrome P450 3A4) and glucuronide conjugation. With the exception of lorazepam and oxazepam (which are conjugated only) and clonazepam (which undergoes nitroreduction), all benzodiazepines are oxidized first and then conjugated and excreted renally.^{48,49} Diazepam's metabolism is also catalyzed by cytochrome P450 2C19.⁴⁹ Oxidation can be impaired in patients with liver disease, in the elderly, and in those who simultaneously use drugs that inhibit oxidation. Impaired oxidation results in higher levels of the parent drug and/or an active metabolite.

Many benzodiazepines are converted to desmethyldiazepam (DMDZ), an active metabolite with a long elimination half-life of about 100 hours⁴⁸ (see Table 69–9). DMDZ is further oxidized to oxazepam and then conjugated and excreted. After multiple dosing, accumulation of DMDZ is slow and extensive, providing a long-lasting antianxiety effect. If oxidation of DMDZ is impaired, the half-life is prolonged, and drug accumulation can result with repeated dosing.

Clorazepate is a prodrug and possesses no anxiolytic effects until metabolism to DMDZ. Before absorption, clorazepate is metabolized rapidly in the stomach through a pH-dependent process under acidic conditions.

Benzodiazepines with shorter half-lives (e.g., alprazolam, lorazepam, and oxazepam) reach steady-state plasma concentrations rapidly, and drug accumulation after repeated dosing is minimal. Oxazepam and lorazepam are not converted into active metabolites.

Benzodiazepine protein binding is extensive, especially for the drugs with a long elimination half-life. After a single dose of a benzodiazepine with a long elimination half-life, the expected duration of clinical activity may not parallel the drug's pharmacokinetic half-life because of drug redistribution.⁴⁸ After multiple dosing, drugs with long elimination half-lives and active metabolites require 1 to 2 weeks to reach steady state.

■ Efficacy

Clinical trials of benzodiazepines show that 65% to 75% of patients with GAD have a marked to moderate response, with most of the improvement occurring in the first 2 weeks of therapy.⁵⁰ Benzodiazepines are more effective on the somatic symptoms of anxiety and fail to obviate the cognitive or psychic symptoms (e.g., worry).

■ Adverse Effects

The most common adverse events associated with benzodiazepine therapy involve CNS depression. This is manifested clinically as drowsiness, sedation, psychomotor impairment, and ataxia.⁵¹ A transient mild drowsiness is experienced commonly by patients during the first few days of treatment; however, tolerance often develops. Disorientation, depression, confusion, irritability, aggression, and excitement are reported.⁵²

Impairment of memory and recall also may occur during benzodiazepine treatment. The memory loss induced by the benzodiazepines typically is limited to events occurring after drug ingestion (anterograde amnesia).⁵² Anterograde amnesia is secondary to disordered consolidation processes that store information and is not impairment in the perception or retrieval of information.⁷ Benzodiazepines with high affinity for binding to the benzodiazepine receptor (e.g., lorazepam) appear to possess a higher potential for amnesia.

■ Abuse, Dependence, Withdrawal, and Tolerance

Two serious complications of benzodiazepine therapy are the potential for abuse and development of physical dependence. Benzodiazepine abuse is rare in the general population of users; however, individuals with a history of multiple drug abuse (e.g., alcohol or sedatives) are at the greatest risk for becoming benzodiazepine abusers.²⁶

Because of the chronicity of illness, persons with GAD and panic disorder are at high risk of developing benzodiazepine dependence.⁵⁰ Benzodiazepine dependence is a physiologic phenomenon demonstrated by the appearance of a predictable abstinence syndrome (withdrawal symptoms) on abrupt discontinuation of therapy. Withdrawal symptoms may result because of the sudden dissociation of a benzodiazepine from its receptor site. After abrupt discontinuation, an acute decrease in GABA neurotransmission results, producing a less inhibited CNS.

■ Benzodiazepine Discontinuation

After benzodiazepine therapy is discontinued suddenly, several events can occur. Rebound anxiety represents an immediate but transient return of original symptoms having an increased intensity compared with baseline. Recurrence or relapse is the return of original symptoms with similar intensity as before treatment. About half of the patients

using benzodiazepines relapse within 6 weeks of discontinuation, so some patients will be able to taper the benzodiazepine at this point in therapy.⁵⁰

Withdrawal symptoms are the emergence of new symptoms and a worsening of pre-existing symptoms after benzodiazepine discontinuation. Symptoms may persist for days to weeks and resolve gradually over months.

Common symptoms of benzodiazepine withdrawal include anxiety, insomnia, restlessness, muscle tension, and irritability. Less frequently occurring symptoms are nausea, malaise, coryza, blurred vision, diaphoresis, nightmares, depression, hyperreflexia, and ataxia. Tinnitus, confusion, paranoid delusions, hallucinations, seizures, and psychosis occur rarely. Seizures may occur with both therapeutic and high doses of benzodiazepines with a short elimination half-life, usually within 3 days of drug discontinuation. They may occur approximately 1 week after discontinuation of agents with a long elimination half-life. High benzodiazepine doses, a long duration of therapy, and concurrent ingestion of drugs that lower the seizure threshold are risk factors for withdrawal seizures.

The onset of withdrawal symptoms in patients ingesting benzodiazepines with short elimination half-lives occurs much earlier (within 24 to 48 hours) than in those taking benzodiazepines with long elimination half-lives (within 3 to 8 days). Other factors associated with an increased incidence and severity of benzodiazepine withdrawal include high doses and long-term benzodiazepine therapy.

Several strategies to minimize the severity of benzodiazepine withdrawal include a 25% per week reduction in dosage until 50% of the dose is reached, and then dosage reduction by one-eighth every 4 to 7 days. If therapy exceeds 8 weeks, a slow dosage taper over 2 to 3 weeks is recommended; however, if the duration of treatment is 6 months, a taper over 4 to 8 weeks should ensue.⁵ Long-term use of benzodiazepines (i.e., 1 year or longer) requires a 2 to 4 month slow taper.⁵ Tapering will not eliminate the emergence of withdrawal symptoms entirely, but will prevent severe withdrawal. Slow drug taper is extremely important for the drugs with a short elimination half-life because some individuals have greater difficulty with discontinuation. Adjunctive use of certain drugs (e.g., imipramine, valproic acid, or buspirone) or CBT can help to reduce withdrawal symptoms during the benzodiazepine taper.⁵ If patients experience difficulties, especially with the agents with a short elimination half-life, then substitution of an agent with a long elimination half-life should be considered. Using this approach, diazepam can be initiated as a loading dose (40% of daily consumption), followed by daily tapering of 10%. Clonazepam is an alternative agent.

Although tolerance develops to the sedative, muscle relaxant, and anticonvulsant activities, the benzodiazepines do not appear to lose anxiolytic or antipanic efficacy.²⁴ The anxiolytic efficacy of benzodiazepines in long-term clinical trials (>6 to 8 months of chronic use) has not been reported.⁵

■ Drug Interactions

Drug interactions with the benzodiazepines generally fall into two categories: pharmacodynamic and pharmacokinetic (Table 69–10).⁴⁹ Simultaneous use of alcohol and a benzodiazepine results in additive CNS depressant effects and lowers the therapeutic index of the benzodiazepine. In addition, concurrent use of a benzodiazepine and drugs with CNS depressant properties (e.g., narcotic agonists, antipsychotics, and antihistamines) can potentiate the adverse sedative effects. When ingested alone in an overdose attempt, benzodiazepines are rarely life-threatening; however, the combination of

TABLE 69–10. Pharmacokinetic Drug Interactions with the Benzodiazepines

| Drug | Effect |
|---------------------|---|
| Alcohol (chronic) | Increased CI of BZs |
| Carbamazepine | Decreased CI of alprazolam |
| Cimetidine | Decreased CI of alprazolam, diazepam, chlordiazepoxide, and clorazepate and increased $t_{1/2}$ |
| Disulfiram | Decreased CI of alprazolam and diazepam |
| Erythromycin | Decreased CI of alprazolam |
| Fluoxetine | Decreased CI of alprazolam and diazepam |
| Fluvoxamine | Decreased CI of alprazolam and prolonged $t_{1/2}$ |
| Itraconazole | Potentially decreased CI of alprazolam and diazepam |
| Ketaconazole | Potentially decreased CI of alprazolam |
| Nefazodone | Decreased CI of alprazolam, AUC doubled, and $t_{1/2}$ prolonged |
| Omeprazole | Decreased CI of diazepam |
| Oral contraceptives | Increased free concentration of chlordiazepoxide and slightly decreased CI; decreased CI and increased $t_{1/2}$ of diazepam and alprazolam |
| Paroxetine | Decreased CI of alprazolam |
| Phenobarbital | Increased CI of clonazepam and reduced $t_{1/2}$ |
| Phenytoin | Increased CI of clonazepam and reduced $t_{1/2}$ |
| Probenecid | Decreased CI of lorazepam and prolonged $t_{1/2}$ |
| Propranolol | Decreased CI of diazepam and prolonged $t_{1/2}$ |
| Ranitidine | Decreased absorption of diazepam |
| Rifampin | Increased metabolism of diazepam |
| Theophylline | Decreased alprazolam concentrations |
| Valproate | Decreased CI of lorazepam |

AUC, area under the plasma concentration curve; BZ, benzodiazepine; CI, clearance; $t_{1/2}$, elimination half-life.
Compiled from Tanaka.⁴⁹

benzodiazepines with alcohol or other CNS depressant agents is potentially fatal. SSRIs can affect benzodiazepine metabolism by inhibition of cytochrome P450 3A4 and 1A2 enzymes.⁴⁹ Nefazodone and fluvoxamine increase alprazolam concentrations; thus the alprazolam dose should be reduced by 50% when these agents are added.⁴⁹

■ Dosing and Administration

Benzodiazepine dosage requirements vary widely among patients and must be individualized. Therapy should be initiated using low doses (e.g., diazepam 2 mg three times daily, alprazolam 0.25 mg three times a day or equivalent doses of other benzodiazepines) and titrated upward to relieve anxiety symptoms and avoid adverse events. After an initial treatment response is achieved, agents with long elimination half-lives can be dosed at bedtime. Dosage adjustments should be made weekly. Three to four weeks of a daily dose at the maximum dose constitutes an adequate clinical trial.⁵

The duration of benzodiazepine therapy for the acute management of anxiety generally should not exceed 2 to 4 weeks. Benzodiazepines can be prescribed on an as-needed basis, and if several acute courses are necessary a benzodiazepine-free period of 2 to 4 weeks should be implemented between courses.⁵ Individuals with persistent symptoms should be managed with antidepressants or buspirone because of the risk of dependence with continued benzodiazepine therapy.¹²

Patient education should include the anticipated length of drug therapy, potential side effects, and consequences of the ingestion of alcohol and other CNS depressants. Patients should understand that benzodiazepines provide symptomatic relief but do not solve underlying psychological problems. Patients should be instructed not to decrease or discontinue benzodiazepine usage without contacting their prescriber.

■ BUSPIRONE THERAPY

Buspirone is a nonbenzodiazepine anxiolytic that lacks anticonvulsant, muscle relaxant, hypnotic, motor impairment, and dependence properties. It is considered to be a second-line agent for GAD because of inconsistent reports of efficacy, delayed onset of effect (i.e., 2 weeks or longer), and lack of efficacy for other potential comorbid depressive and anxiety disorders (e.g., panic disorder or SAD).^{12,24}

■ Pharmacology and Mechanism of Action

Buspirone's anxiolytic mechanism of action is unknown. It is thought to exert its anxiolytic effect through 5-HT_{1A} partial agonist activity at the presynaptic 5-HT receptors by reducing the firing of 5-HT neurons.⁵¹ Unlike benzodiazepines, buspirone is effective for the cognitive symptoms of anxiety.⁵¹

■ Pharmacokinetics

After an oral dose, buspirone is absorbed rapidly and completely and undergoes extensive first-pass metabolism. The mean elimination half-life is 2.5 hours and it must be dosed 2 to 3 times daily, which adversely affects adherence to the drug regimen.⁵¹

■ Adverse Effects

A major advantage of buspirone is its lack of sedative properties. Adverse events include dizziness, nausea, and headaches.⁵¹

■ Drug Interactions

Drugs that inhibit cytochrome P450 3A4 (e.g., verapamil, diltiazem, itraconazole, fluvoxamine, nefazodone, and erythromycin) can increase buspirone levels. Rifampin caused a 10-fold reduction in buspirone levels. Buspirone reportedly increases haloperidol levels and elevates blood pressure in patients taking a monoamine oxidase inhibitor (MAOI).

■ Dosing and Administration

The recommended initial dose of buspirone is 7.5 mg two times daily with dosage increments of 5 mg/day every 2 to 3 days as needed.⁵⁰ The usual therapeutic dose of buspirone is 30 to 60 mg/day.^{24,50} The onset of improvement in cognitive symptoms (2 weeks or longer) precedes the relief of somatic symptoms; maximum therapeutic benefit may not be evident for 4 to 6 weeks.

Buspirone is an agent of choice in the management of uncomplicated GAD, in patients who fail other anxiolytic therapies, or in patients with a history of substance abuse. It is not useful in clinical

situations requiring immediate anxiolysis or for situations requiring as-needed anxiolytic therapy. The use of benzodiazepines within the previous month of initiation of buspirone therapy was associated with reduced efficacy because of its delayed onset in the reduction of somatic symptoms.⁵⁰ Patients who responded to benzodiazepines in the past often perceive that buspirone is ineffective because they do not experience the same effect on their somatic symptoms of anxiety.⁵⁰

■ PHARMACOECONOMIC CONSIDERATIONS

The annual economic burden of anxiety disorders in the United States was estimated to be \$42.3 billion in 1990 (\$63.1 billion in 1998 dollars).³ Nonpsychiatric medical treatment costs represented more than half of this figure (\$23 billion), with expenses of \$13.3 billion for psychiatric treatment, \$4.1 billion for indirect workplace costs, and \$1.2 billion in mortality costs.

GAD is associated with high rates of health care use and disability. The number of days missed increases when GAD is comorbid with one or more other psychiatric disorders. Patients with GAD tend to use family practitioners and gastroenterologists more frequently than healthy controls.¹² GAD ranks third among anxiety disorders in the rate of use of primary care physician time and it is the leading cause of disability in the workplace in the United States.¹² Pharmacoeconomic analyses in the management of GAD have not been conducted.

CLINICAL CONTROVERSIES

The optimal duration of treatment with antidepressants in patients with GAD is controversial. The longest study duration (6 months) occurred with venlafaxine extended-release. Many clinicians recommend treating patients for up to 1 year.

The role of combined benzodiazepines and antidepressants in the first few weeks of GAD therapy has not been resolved. In practice, despite a lack of evidence of clinical benefits, many clinicians combine a benzodiazepine and an antidepressant for the first few weeks of therapy until the antidepressant begins to work.

■ EVALUATION OF THERAPEUTIC OUTCOMES

The goals of treatment and expected duration of therapy should be discussed with the patient at the beginning of therapy. Initially, anxious patients should be monitored twice weekly for a reduction in the frequency, duration, and severity of anxiety symptoms and improvement in occupational, social, and interpersonal functioning. The clinician should assess the patient for response to treatment by asking about specific target symptoms of anxiety and emergence of adverse events. Ideally, the patient should have no or minimal anxiety or depressive symptoms and no functional impairment. After achieving an optimal drug dosage, the patient can be evaluated monthly until drug discontinuation. Use of an objective measurement of remission of GAD (e.g., Hamilton Rating Scale for Anxiety score <7 to 10 and a Sheehan Disability Scale Score ≤1 on each item) can assist in the evaluation of drug response.²³ If a patient has only a partial response, the dose should be increased after 4 to 6 weeks of antidepressant therapy (or 2 weeks for acute therapy with benzodiazepines). The length of therapy should be individualized, with some patients requiring up to 1 year of antidepressant therapy.⁵

► TREATMENT: Panic Disorder

■ DESIRED OUTCOME

The goal of therapy in panic disorder is remission. Patients should be free of panic attacks, have no or minimal anticipatory anxiety and agoraphobic avoidance, and no functional impairment.²³ Naturalistic studies indicate that after pharmacotherapy, over 50% of patients have occasional panic attacks, 40% experience agoraphobic avoidance, and most continue to take medications.⁵³

■ GENERAL APPROACH TO TREATMENT

Therapeutic options include single or combined pharmacologic agents, concurrent psychotherapy, or psychotherapy followed by pharmacotherapy. Most patients without agoraphobic avoidance will improve with pharmacotherapy alone; however, if avoidance is present, CBT typically is initiated concurrently. With all effective drug therapies, resolution of agoraphobic avoidance tends to occur slowly.

In the most comprehensive study to date, efficacy of imipramine alone and CBT alone were equivalent in acute therapy for 3 months and during 6 months of maintenance therapy. Combined imipramine and CBT therapy was not significantly better than CBT or imipramine alone for acute therapy, but was significantly better during maintenance. At 6 months after discontinuation, only CBT maintained improvement (4% relapse) compared with a 25% relapse rate in patients treated with imipramine.⁵⁴ Patients who failed to respond to CBT and had paroxetine added to therapy had a significant improvement in agoraphobic behavior and anxiety symptoms.⁵⁵

■ NONPHARMACOLOGIC THERAPY

Patients should be educated to avoid substances that can precipitate panic attacks, including caffeine, drugs of abuse, and nonprescription stimulants.^{1,56} CBT focuses on the correction of a patient's maladaptive thoughts and behaviors that initiate, perpetuate, or exacerbate panic symptoms.⁵⁶ Through CBT, the patient learns to decrease the fear and avoidance of internal and external signals associated with panic attacks. The cognitive restructuring and in vivo exposure (to feared stimuli) components of CBT target panic attacks and phobic-avoidance behavior.⁵⁶ For patients who cannot or will not take medications, CBT alone is certainly indicated. CBT is associated with short-term improvement in 80% to 90% of patients and 6-month improvement in 75% of patients.⁵⁶

■ PHARMACOLOGIC THERAPY

Panic disorder is treated effectively with several drugs including the SSRIs, the TCA imipramine, the benzodiazepines alprazolam and clonazepam, and the MAOI phenelzine⁸ (Table 69–11). Alprazolam, clonazepam, sertraline, and paroxetine are approved for this indication. SSRIs are the first-line agents because of their tolerability,^{24,25,53} however, the benzodiazepines are the most commonly used drug for panic disorder.⁵⁹ In a meta-analysis of the pharmacotherapy of panic disorder, the effect size of SSRIs and TCAs did not differ; however, the number of dropouts in the TCA group (31%) was significantly higher than in the SSRI group (18%).⁶⁰ Three practice guidelines^{24,25,53} and one consensus statement for the treatment of panic disorder were

TABLE 69–11. Drugs Used in the Treatment of Panic Disorder

| Class/Generic Name | Brand Name | Starting Dose | Antipanic Dosage ^a Range (mg) |
|---|------------|-------------------------------|---|
| Selective serotonin reuptake inhibitors | | | |
| Citalopram | Celexa | 10 mg per day | 20–60 |
| Escitalopram | Lexapro | 5 mg per day | 10–20 |
| Fluoxetine ^b | Prozac | 5 mg per day | 10–20 |
| Fluvoxamine ^b | Luvox | 25 mg per day | 100–300 |
| Paroxetine ^b | Paxil | 10 mg per day | 20–60 ^c |
| Sertraline | Zoloft | 25 mg per day | 50–200 ^c |
| Benzodiazepines | | | |
| Alprazolam ^b | Xanax | 0.25 mg three times a day | 4–10 ^c |
| | Xanax XR | 0.5–1 mg per day | 1–10 ^c |
| Clonazepam ^b | Klonopin | 0.25 mg once or twice per day | 1–4 ^c |
| Diazepam ^b | Valium | 2–5 mg three times a day | 5–20 |
| Lorazepam ^b | Ativan | 0.5–1 mg three times a day | 2–8 |
| Tricyclic antidepressants | | | |
| Clomipramine ^b | Anafranil | 25 mg twice a day | 75–250 |
| Imipramine ^b | Tofranil | 10–25 mg per day | 75–250 |
| Monoamine oxidase inhibitor | | | |
| Phenelzine | Nardil | 15 mg per day | 45–90 |

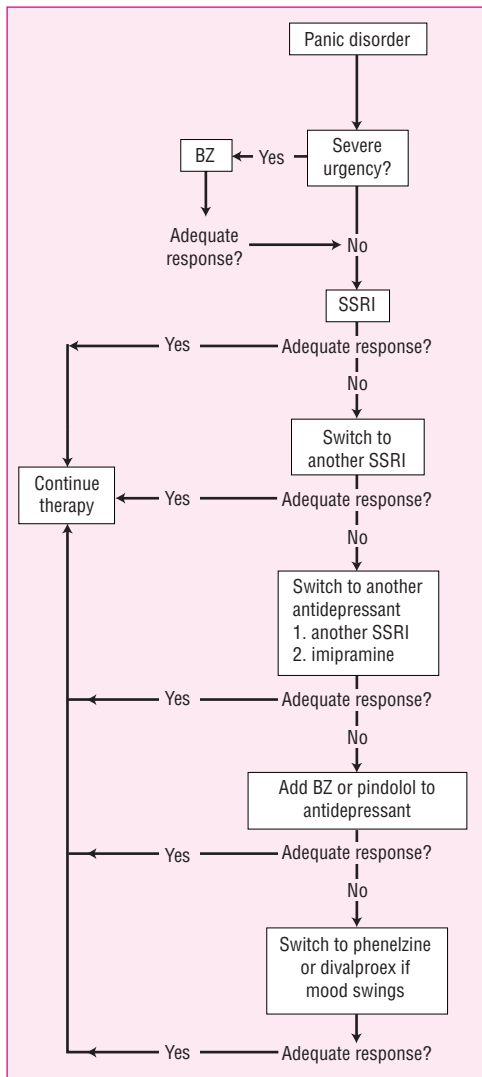

FIGURE 69–2. Algorithm for the pharmacotherapy of panic disorder. SSRI = selective serotonin reuptake inhibitor, BZ = benzodiazepine. (Compiled from Bandelow et al,²⁴ Work Group on Panic Disorder,²⁵ Ballenger et al,⁶¹ and Sheehan.⁶⁹)

published.⁶¹ An algorithm for the pharmacologic therapy of panic disorder appears in Figure 69–2.

Except in instances in which rapid response is required (i.e., loss of a job), benzodiazepines are considered second-line agents. Because of the risk of dependency, benzodiazepines should be used only after several trials of antidepressants have failed.^{24,25} Because of potential emergence of depressive symptoms during treatment, benzodiazepines should not be used as monotherapy in a patient who is clinically depressed or has a history of depression. In patients whose illness is complicated by a history of alcohol or drug abuse, benzodiazepine use should be avoided.^{8,26} Data support the combined use of SSRIs and benzodiazepines in the first weeks of treatment to offset the delay in the SSRI effect.^{62,63}

ALTERNATIVE DRUG TREATMENTS

Buspirone, trazodone, bupropion, and β -blockers are ineffective in panic disorder.^{24,53,55} Venlafaxine was effective in a small trial.²⁴

SPECIAL POPULATIONS

Elderly patients with panic disorder have fewer, less intense symptoms and avoidant behavior than younger patients.⁶⁴ Youth often present with fear that they are dying or being smothered, and agoraphobia can be manifested as a fear of leaving home.³⁹ Antidepressants, especially the SSRIs, are preferred for management of panic disorder in elderly patients and youth.^{39,64} Benzodiazepines are second-line agents because of potential problems with disinhibition in these two populations.

ANTIDEPRESSANT THERAPY

Tricyclic Antidepressants

Efficacy. Imipramine is the most studied TCA, alleviating panic attacks in 75% of patients with panic disorder. Imipramine effectively blocks panic attacks within at least 4 weeks; however, maximal improvement (including antiphobic response) does not occur until 8 to 12 weeks.²⁵ The sequence of patient response is an initial decrease in the number of panic attacks, then diminution of anticipatory anxiety, followed by a reduction in agoraphobic avoidance.²⁵

Adverse Effects. Up to 40% of patients experience stimulant-like side effects, including anxiety, insomnia, jitteriness, and irritability.^{25,63} These side effects often affect patient compliance significantly, prevent medication dosage increases, and interfere with the overall treatment outcome.

Problems with TCA use in panic disorder are well documented and include stimulatory side effects, anticholinergic effects, orthostatic hypotension, delayed onset of antipanic effects, and toxicity in overdose.²⁵ Approximately 25% of patients reportedly discontinue treatment because of side effects.⁶³ Weight gain is a problematic side effect associated with long-term therapy.²⁵

Dosing and Administration. When using imipramine, treatment should be conservatively initiated with 10 mg/day at bedtime and slowly increased by 10 mg every 2 to 4 days as tolerated to 75 to 100 mg/day, and then increased by 25 mg every 2 to 4 days over a 2- to 4-week period.^{56,57} Most patients require at least 150 mg/day of imipramine (or a combined imipramine-desipramine plasma concentration of 100 to 150 ng/mL).⁶³ If this dose is not effective, a higher dose (up to 300 mg/day) can be used.

Selective Serotonin Reuptake Inhibitors

Efficacy. Clinical studies indicate that all SSRIs are effective in panic disorder.^{53,65–68} The percentage of patients who become panic-free ranges between 60% and 80%.²⁵ The antipanic effect of SSRIs is delayed for at least 4 weeks, and some patients do not respond for 8 to 12 weeks.²⁵

Adverse Effects. Typical antidepressant doses of SSRIs can cause side effects of insomnia, jitteriness, restlessness, and agitation, and lead to drug discontinuation in patients with panic disorder. Transient gastrointestinal disturbances occur more frequently with SSRIs than with TCAs. Thus low initial SSRI doses should be prescribed.^{24,57} Sleep disturbances, headaches, and sexual dysfunction often are problematic.²⁴

■ **Dosing and Administration.** Low initial doses of SSRIs are recommended (see Table 69–11) to avoid stimulatory side effects (e.g., insomnia or nervousness). The initial doses are much smaller than those used in depression and should be maintained for the first week of therapy. Paroxetine can be increased by 10 mg weekly; the target dose is 40 mg.⁶⁶ The starting dose of fluoxetine is 5 mg/day, with dosage increases every 2 or 3 days to a dosage range of 10 to 20 mg/day by the end of 2 weeks.⁵⁷ Fluvoxamine can be increased to 150 mg/day in divided doses over 2 weeks.⁶⁷

■ Monoamine Oxidase Inhibitors

■ **Efficacy.** The majority of studies assessing the efficacy of MAOIs in treating panic disorder were open-labeled. These trials lacked sufficient dosage and duration of treatment, adequate sample size, and valid ratings of panic attacks. No maintenance trials of MAOIs are published. The course of response mimics that of TCAs.²⁵ MAOIs are reserved for the most refractory or difficult patients.^{24,57}

■ **Adverse Effects.** Side effects and dietary restrictions adversely affect patient acceptance.²⁵ Anticholinergic side effects are less severe with phenelzine than with TCAs, but orthostatic hypotension and insomnia are often more of a problem. After 3 weeks, most unpleasant side effects subside.

Hypertensive crisis following the ingestion of tyramine-containing foods or sympathomimetic drugs is the most serious, potentially life-threatening event encountered with phenelzine⁵⁷ (see Chapter 67 for food and drug restrictions and side effects). Patients should observe the food, beverage, and drug restrictions for at least 24 hours before starting the first dose of phenelzine and for 2 weeks after stopping therapy.

■ **Dosing and Administration.** The starting dose of phenelzine is 15 mg/day after the evening meal, increasing by 15 mg/day every 3 to 4 days until a minimum dose of 45 mg/day (in two or three divided doses) is reached. Dosages can be increased (up to 90 mg/day) if improvement is not achieved after 8 to 12 weeks. If a patient was on an antidepressant previously, it should be discontinued 2 weeks before phenelzine is started to prevent a potential drug interaction. Fluoxetine must be stopped 5 weeks before phenelzine (or another MAOI) can be started.

■ Benzodiazepines

■ **Efficacy.** Although benzodiazepines are effective antipanic agents, concerns over their use are prevalent. The development of dependency, risk of withdrawal, lack of efficacy for comorbid depression, and the need for multiple daily dosing (i.e., alprazolam immediate-release) with possible interdose rebound anxiety can limit their usefulness. The high-potency benzodiazepines clonazepam and alprazolam are used frequently.⁵⁶ Diazepam and lorazepam are possibly effective in treating panic disorder when taken in sufficiently high doses.²⁵ Therapeutic response to benzodiazepines occurs in 1 to 2 weeks. It is estimated that 60% to 80% of panic disorder patients respond to benzodiazepines.⁶⁹ Alprazolam is an ideal agent for patients who need rapid relief. Relapse rates of 50% or higher are common despite slow drug tapering.²⁵

■ **Adverse Effects.** Patient acceptance of benzodiazepines usually is not a problem, and except for sedation, side effects are reported

rarely. Patients tolerate the initial side effects of alprazolam much better than those of imipramine or phenelzine.⁵⁶

■ **Dosing and Administration.** The starting dose of clonazepam is 0.25 mg twice a day, with an increase to 1 mg by the third day of therapy. Further increases of dose (by 0.25 or 0.5 mg) every 3 days to 4 mg/day can be made if needed.⁴⁶ The starting dose of alprazolam is 0.25 to 0.5 mg three times daily (or 0.5 mg once a day of alprazolam extended-release⁴⁷), slowly increasing over several weeks to reach an **5** ideal dose. The duration of action may be as little as 4 to 6 hours with resulting breakthrough symptoms; use of the extended-release alprazolam or clonazepam will avoid this problem. Most patients require 3 to 6 mg/day of alprazolam, and some need doses of 6 to 10 mg/day to obtain a full therapeutic (antipanic and antiphobic) response.

■ **Treatment Resistance.** Common reasons for treatment failures are comorbid psychiatric disorders, rapid dosage increases with resulting intolerable side effects, and underdosage.^{25,56} All standard treatments should be tried before using augmentation strategies. The most common strategy used in patients with a partial response to one agent is to augment it with low doses of another antipanic agent (e.g., a TCA, benzodiazepine, or an SSRI),^{25,56} or to add pindolol to an SSRI.⁷⁰ Limited data support the use of divalproex sodium as monotherapy in patients with concurrent mood swings.⁷¹

■ Phases of Therapy

■ **Acute Phase.** The main goal of therapy in the acute phase is reduction of symptoms (e.g., resolution of panic attacks, reduction in anxiety and phobic fears, resumption of the patient's usual activities).²⁵ The duration of this phase is generally 1 to 3 months depending on the choice of drug. The duration of the acute phase with antidepressants is about 12 weeks.²⁵ Therapy should be altered if there is no response after 6 to 8 weeks of an adequate dose. The duration of the acute phase with benzodiazepines is approximately 1 month because response is rapid and occurs within 1 to 3 weeks.

The guiding principle for using drugs in panic disorder is to start low, use an adequate dose, and treat for an appropriate period of time.⁵⁷ Side effects with the antidepressants, often from too high an initial dose, may prevent achievement of an optimal dosage, compromise treatment response, and contribute to patient noncompliance.

■ **Maintenance Phase and Discontinuation.** The optimal **6** length of therapy is unknown; however, the total duration of therapy appears to be 12 to 24 months before drug discontinuation over 4 to 6 months is attempted.^{24,25} The dose used in the acute phase is continued into the maintenance phase.²⁴ Successful maintenance with single weekly doses of fluoxetine was described.⁷² Citalopram, clomipramine, fluoxetine, and imipramine maintained clinical effects for up to 1 year of treatment.²⁴ When drugs are discontinued too early, a high rate of relapse occurs; thus longer periods of treatment are associated with more sustained response. Reinstitution of drug usually results in renewed clinical response.²⁵ Patients successfully treated with imipramine for 6 months had the same rate of relapse after discontinuation as those treated for 12 to 30 months.⁷³ Pharmacotherapy, even at long duration, may not prevent relapse, and many patients require long-term therapy.

Patients taking alprazolam, clonazepam, or imipramine for up to 8 months maintained antipanic efficacy without dosage increases, suggesting that tolerance does not develop to the antipanic effects of these agents.^{5,74} The most important determinant of compliance with

maintenance therapy is the tolerability of adverse events.²⁵ Some adverse events which are experienced short term become unbearable during long-term management (e.g., sexual dysfunction and weight gain). The primary risk of long-term benzodiazepine use is the development of dependency and withdrawal reactions on discontinuation. Abuse of benzodiazepines usually is confined to patients with a personal or family history of substance or alcohol use.⁵ Both TCAs and SSRIs can be associated with discontinuation symptoms.

Some patients receiving high-dose alprazolam (>4 mg/day) can have an extremely difficult time with drug taper, and the withdrawal schedule for all patients should be individualized. The taper phase is most successful when it is accomplished over a 4- to 6-month period. Approximately 30% of the patients receiving high doses, even with slow taper, may experience transient, mild to moderate withdrawal symptoms (as discussed in the earlier section on benzodiazepines) and relapse of panic attacks. Adjunctive CBT reportedly facilitates benzodiazepine discontinuation.⁵ If a TCA is discontinued abruptly a substantial number of patients develop severe cholinergic rebound with upset stomach, nausea, vomiting, and abdominal cramping; thus TCAs should be reduced by 25 mg every 2 to 4 weeks.⁵⁶ The dose of phenelzine should be reduced by 15 mg every 2 to 4 weeks.

Patient education is essential. Patients should be informed regarding the lag time before a therapeutic response will occur and any problematic side effects. Many patients are reluctant to take drugs for fear that their illness will worsen or that they will become addicted. Adverse events are often perceived as a worsening of the illness and can contribute to nonadherence or prevent necessary dosage increases. Patients receiving benzodiazepines should be told not to decrease or discontinue therapy unless authorized by their clinician.

■ PHARMACOECONOMIC CONSIDERATIONS

Patients with panic disorder have high rates of unemployment, receiving welfare, disability benefits, and health care services.³ They also have impaired emotional and physical health status and experience poor marital and social functioning.²¹ After 6 weeks of clon-

azepam, work productivity improved (from 71% to 88%), and personal happiness also increased.²¹ Measures of quality of life (QOL) improved with imipramine, clonazepam, and sertraline. Treatment with clomipramine, paroxetine, or fluoxetine improved work, social, and family responsibilities. Improvements in anxiety and phobic avoidance were significantly associated with QOL improvements but not reduction in the frequency of panic attacks, which is used most often as the measure of success in drug efficacy trials.²¹ In a cost comparison, group CBT was more cost-beneficial than pharmacotherapy for the initial 4 months of therapy.⁷⁵

CLINICAL CONTROVERSY

The role of benzodiazepines in the management of panic disorder is controversial. The treatment guidelines for panic disorder recommend SSRIs as first-line agents, especially when long-term therapy is being considered. In clinical practice benzodiazepines are the most commonly prescribed pharmacotherapeutic agents for panic disorder, despite the risk of dependence with long-term therapy.

■ EVALUATION OF THERAPEUTIC OUTCOMES

During the first few weeks of the acute phase of therapy, patients with panic disorder should be seen at least weekly to adjust drug dosages based on improvement in panic symptoms and to monitor for adverse events. Subsequently, monthly visits should suffice. The patient should be counseled to maintain a diary to record the date, time, frequency, and duration of panic episodes and the severity of panic symptoms, anticipatory anxiety, and agoraphobic avoidance. Treatment outcomes can be assessed objectively by use of the Hamilton Rating Scale for Anxiety (score ≤ 7 to 10) for anxiety.²³ At scheduled visits, the clinician can inquire about the level of disability experienced by the patient and have the patient complete the Sheehan Disability Scale (with a goal of ≤ 1 on each item).²³ During drug discontinuation, the frequency of appointments should be increased to evaluate for emergence of withdrawal symptoms and monitor for relapse.

▶ TREATMENT: Social Anxiety Disorder

■ DESIRED OUTCOME

The goals of therapy in the acute phase of treatment are to reduce physiological symptoms of anxiety (e.g., tachycardia, flushing, and sweating), social anxiety, and phobic avoidance. The duration of this phase is 4 to 12 weeks, depending on the drug therapy.

The goals of therapy in the continuation phase are to extend the therapeutic benefits of the acute phase, especially the patient's ability to participate in social activities, and improve QOL. This phase usually lasts 3 to 6 months.

7 SAD is a chronic, long-term illness requiring extended therapy. After improvement, at least a 1-year maintenance period is recommended to maintain improvement and decrease the rate of relapse.²² Situations suggesting a possible need for long-term treatment include the presence of unresolved symptoms or comorbidity, an early onset of disease, and a prior history of relapse.²² The long-

term goal in the treatment of SAD is remission with the disappearance of the core symptoms of social anxiety, little or no anxiety, and no functional impairment or comorbid depressive symptoms.²³

■ GENERAL APPROACH TO TREATMENT

Generalized SAD is associated with significant morbidity, and patients should be treated aggressively. Obstacles to effective treatment include patient avoidance of therapy secondary to fear and shame, treatment directed toward somatic symptoms or comorbid conditions, and financial barriers.⁷⁶ Patients with SAD often respond to treatment more slowly and less completely than patients with other anxiety disorders. Therefore it is important to set reasonable expectations for response to therapy. The patient's symptoms, prior treatments, comorbid conditions, and history of substance abuse direct treatment selections.

CBT and pharmacotherapy are effective in the treatment of SAD.^{77–79} Pharmacotherapy is often the most practical choice because CBT may not be available outside of large urban areas secondary to the lack of trained therapists and high treatment costs. Studies suggest the acute treatment outcomes for CBT and pharmacotherapy are equal; however, they may differ in long-term effects.^{78,79} Drug therapy tends to be superior on some measures in acute treatment (e.g., independent assessment, self-report, and behavior test measures), while CBT can lead to a greater likelihood of maintaining response after treatment termination.⁷⁹ It is not possible to predict which patients will respond best to pharmacotherapy, CBT, or a combination.⁷⁹

There are no data to predict which patients will maintain gains after discontinuing pharmacotherapy. Some patients elect lifelong therapy. Many patients are reluctant to attempt drug discontinuation because of fear of relapse. The relapse rate 12 to 24 weeks after discontinuation of acute paroxetine therapy ranged from 39% to 63%.⁷⁷ Data show that relapse rates after discontinuation of CBT are significantly less than those after discontinuation of effective pharmacotherapy.⁷⁹ Sertraline is the only medication approved for the long-term treatment of SAD, although paroxetine, escitalopram, and venlafaxine are also effective in preventing relapse over an extended time period.^{80–82}

■ NONPHARMACOLOGIC THERAPY

Patients should be educated about SAD, the symptoms they experience, and effective therapeutic options. Support groups are helpful for some patients. Self-help group programs that focus on effective communication can benefit people with public-speaking phobia.

CBT for SAD consists of exposure therapy, cognitive restructuring, relaxation training techniques, and social skills training.⁹ Through CBT, patients learn to overcome anxiety in social situations and change the beliefs and responses that maintain this behavior. Therapy usually lasts several months and often is conducted in a group setting.

■ PHARMACOLOGIC THERAPY

■ SPECIAL POPULATIONS

SAD can present in children of preschool to elementary school age. If the disorder is not treated, it can persist into adulthood and increase the risk of depression and substance abuse. CBT and social skills training are effective nonpharmacological therapies in children.¹⁰ Pharmacological evidence is limited to case studies or open-label trials. SSRIs are considered first-line therapy because of tolerability and effectiveness. Fluoxetine, fluvoxamine, sertraline, and paroxetine were effective in children with SAD.^{10,38} Headache, nausea, drowsiness, insomnia, jitteriness, and stomach aches were reported in children receiving SSRIs.

Benzodiazepines are prescribed in children with SAD after all other types of drugs fail to show improvement.¹⁰ If prescribed, they should be used for the shortest time period possible. The adverse effects of benzodiazepines in children include drowsiness, oppositional behavior, disinhibition, fatigue, and nausea.

Approximately one-fifth of patients with SAD also suffer from an alcohol use disorder (AUD). Many people with SAD report that they use alcohol to cope with their anxiety. Most clinical trials evaluating

pharmacotherapy for SAD excluded patients with AUD. Paroxetine significantly reduced social anxiety and decreased the frequency and severity of alcohol use in patients with SAD and an AUD.⁷⁷ MAOIs and benzodiazepines are not appropriate therapy for these patients. The tyramine present in many alcoholic beverages can precipitate hypertensive crisis in patients on a MAOI. People who abuse alcohol are at risk for abusing or becoming dependent on benzodiazepines. SSRI therapy is the treatment of choice in this patient population.

■ ANTIDEPRESSANT THERAPY

8 The SSRIs and venlafaxine have the benefits of antidepressant activity for comorbid depression and safety when used in patients with substance abuse. Paroxetine, sertraline, and venlafaxine extended-release are approved for the treatment of generalized SAD and are considered first-line agents because of their efficacy and tolerability (Table 69–12). Venlafaxine and paroxetine were equivalent in efficacy for SAD over a 12-week acute period.⁸³ The International Consensus Group on Depression and Anxiety published a consensus statement on SAD.²² An algorithm on the pharmacotherapy of SAD appears in Figure 69–3.

■ Selective Serotonin Reuptake Inhibitors

■ **Efficacy.** The efficacy and safety of paroxetine and sertraline were established in large placebo-controlled trials.^{84,85} Response rates to SSRIs in SAD ranged from at least 50% in controlled trials to up to 80% in open trials.⁷⁷

Patients treated with paroxetine or sertraline showed improvement in anxiety and avoidance symptoms and a decrease in disability.^{84,85} Daily doses up to 60 mg of paroxetine and 200 mg of sertraline were well tolerated, and emergent adverse effects were similar to those of depression trials (e.g., nausea, sexual dysfunction, sweating, and somnolence). The onset of effect was delayed 4 to 8 weeks, and maximum benefit was often not observed until 12 weeks or longer. Sertraline is also effective in disabled patients suffering from the marked to severe form of generalized SAD.⁸⁵ Limited data suggest that citalopram, escitalopram, and fluvoxamine are also effective in treating SAD.^{86–88} Fluoxetine was not effective in SAD.⁸⁹

■ **Dosing and Administration.** SSRIs should be initiated at doses similar to those used for the treatment of depression and administered as a single daily dose with or without food (except for fluvoxamine). If the patient suffers from comorbid panic disorder, the SSRI dose should be started at one-fourth or one-half of the normal antidepressant dose. Patients should receive the starting dose for 2 to 4 weeks before it is increased slowly (i.e., paroxetine 10 mg/day and sertraline 50 mg/day) in weekly intervals as necessary to obtain a response. Safety for paroxetine in SAD was demonstrated in doses up to 60 mg/day, but additional therapeutic benefits above 20 mg/day were not shown.⁹⁰ The maximum dosage of sertraline used in patients with SAD was 200 mg/day.⁸⁵

The starting dose for fluvoxamine is 50 mg/day, which is then increased as tolerated and needed up to 300 mg/day divided into twice-daily doses.⁸⁸ If citalopram is used, the initial dose is 20 mg/day, and it may be increased to 40 mg/day after 2 weeks.⁸⁶ The starting dose for escitalopram is 10 mg/day, and it can be increased to a maximum of 20 mg/day.⁸¹ The dosage should be tapered slowly (i.e., decreasing sertraline by 50 mg/month or paroxetine by 10 mg/month) to decrease

TABLE 69–12. Drugs Used in the Treatment of Social Anxiety Disorder

| Class/Generic Name | Brand Name | Starting Dose | Dosage Range ^a (mg/day) |
|---|------------|--------------------------|------------------------------------|
| Selective serotonin reuptake inhibitors | | | |
| Citalopram ^b | Celexa | 20 mg per day | 20–40 |

^dUsed as augmenting agent.

Compiled from Ballenger et al,²² Paxil package insert,²⁷ Effexor XR package insert,²⁸ Blanco et al,⁹³ and Pollack.⁹⁶

the risk of relapse during discontinuation. Patients should be observed for signs of relapse for several months.⁷⁷

■ Venlafaxine

■ **Efficacy.** Venlafaxine extended-release was significantly better than placebo in improving social interaction, performance, avoidance factors, and some fear factors (e.g., public speaking).⁹¹ Beneficial

effects were seen by week 3. Venlafaxine was effective in patients who failed to respond to therapy with SSRIs.⁹²

■ **Adverse Effects.** Adverse effects included anorexia, dry mouth, nausea, insomnia, and sexual dysfunction.

■ **Dosing and Administration.** The starting dose of venlafaxine extended-release is 75 mg/day administered in a single dose. The dose may be increased in increments of 75 mg/day at an interval of not less

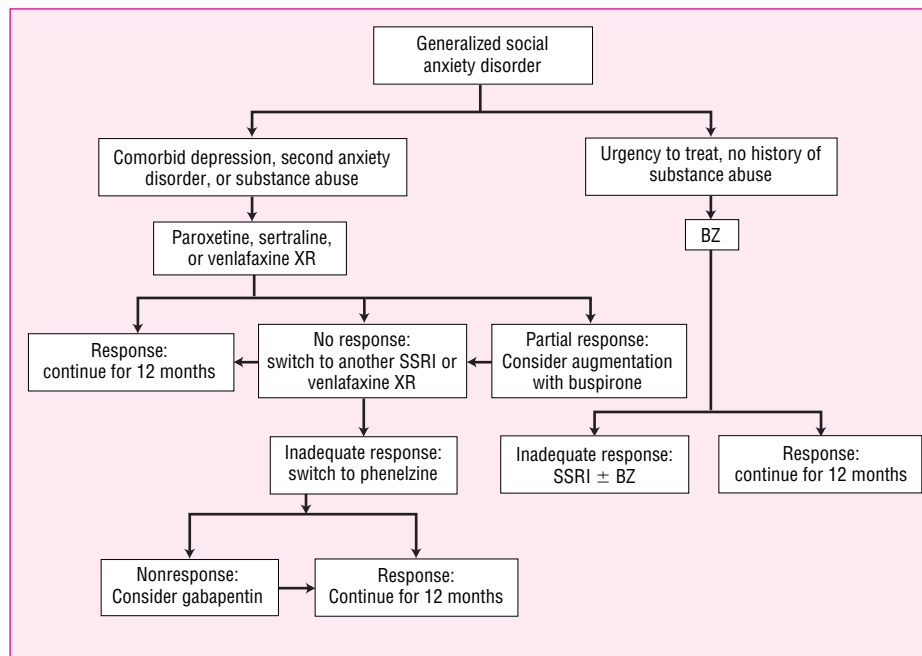

FIGURE 69–3. Algorithm for the pharmacotherapy of social anxiety disorder. SSRI = selective serotonin reuptake inhibitor, BZ = benzodiazepine. (Compiled from Ballenger et al,²² Van Ameringen and Mancini,⁷⁷ and Blanco et al.⁹³)

than 4 days to a maximum of 225 mg/day.^{77,91,93} Venlafaxine should be tapered slowly (i.e., decreasing by 37.5 mg/month) over several months to decrease the risk of relapse during discontinuation.⁷⁷

■ ALTERNATE AGENTS

■ Benzodiazepines

Benzodiazepines are prescribed commonly for SAD. Clonazepam is the most extensively studied benzodiazepine for the treatment of generalized SAD.⁹⁴ Clonazepam improved fear and phobic avoidance, interpersonal sensitivity, fears of negative evaluation, and disability measures.^{78,94} Adverse effects included sexual dysfunction, unsteadiness, dizziness, and poor concentration.⁹⁴ Clonazepam is often prescribed in conjunction with an antidepressant, psychotherapy, or both for initial symptom relief.²² Comorbid alcohol or substance abuse are contraindications to the use of benzodiazepines. Other limitations of clonazepam therapy include lack of efficacy in depression and difficulty with discontinuation. Because of the risk of dependency, benzodiazepines should be reserved for patients at a low risk of substance abuse, those who require rapid relief of symptoms, or those who have not responded to other therapies.

For patients requiring a rapid onset of effect, clonazepam is effective within 1 to 2 weeks. The acute phase of benzodiazepine therapy is about 1 month. The initial dose of 0.25 mg/day can then be increased as tolerated over several weeks up to 3 mg/day. The average daily dose in clinical trials was 2.5 mg.^{77,93} Patients should be instructed not to decrease or discontinue clonazepam without consulting their clinician.

Benzodiazepines must be slowly tapered on discontinuation. Patients on clonazepam for 6 months who were slowly tapered over 5 months maintained their treatment response.⁹⁴

■ Gabapentin

Gabapentin, a nonbenzodiazepine GABA analog, was effective for SAD in a 14-week placebo-controlled trial.⁹⁵ The onset of effect occurred within 2 to 4 weeks. Patients reported dizziness and dry mouth. The effective dose of gabapentin ranged from 900 to 3600 mg daily given in three divided doses.⁹⁵

■ Beta-Blockers

β -Blockers decrease the perception of anxiety by blunting the peripheral autonomic symptoms of arousal (e.g., rapid heart rate, sweating, blushing, and tremor) and are often used to decrease anxiety in performance-related situations. For patients with specific SAD, 10 to 80 mg of propranolol or 25 to 100 mg of atenolol can be taken an hour before a performance situation as needed.⁹⁶ A test dose should be taken at home before the presentation to assure that β -blockade is sufficient and there are no adverse events. Controlled trials with atenolol do not support daily use of β -blockers in generalized SAD.⁷⁷

■ Treatment Resistance

There are no data to guide clinicians in the choice of treatments if there is a lack of response to antidepressants. Patients who have an

incomplete response to a first-line agent may benefit from augmentation with buspirone at an initial dose of 10 mg twice daily. The dose of buspirone can be increased as needed to 45 to 60 mg/day.⁹³

9 An adequate trial usually consists of 8 to 12 weeks (at maximum dosages) to confirm efficacy. Subsequent options include a trial of a second SSRI or venlafaxine extended-release. Some patients experience clinical benefit during the first 4 weeks of therapy.⁷⁷ If nonresponsiveness continues, a trial of an alternative agent is warranted.

■ Phenzelzine

The MAOIs are reserved for treatment-resistant patients. Although phenzelzine is effective in 77% of patients with SAD,^{22,77,93} dietary restrictions, potential drug interactions and adverse effects (e.g., postural hypotension, insomnia, weight gain, sedation, and hypertensive crisis) have limited its use.

The starting dose of phenzelzine is 15 mg/day. It can be increased weekly by 15 mg/day to a maximum of dose of 90 mg (in divided doses).⁹³ Patients must avoid tyramine-containing foods and sympathomimetic drugs to prevent hypertensive crisis. If a patient is switched from another antidepressant to phenzelzine, an appropriate washout period should be followed.

■ PHARMACOECONOMIC CONSIDERATIONS

Generalized SAD is associated with lower health-related QOL, a higher rate of lifetime suicide attempts, diminished educational and occupational attainment, and increased use of health care resources.²² Patients with SAD have a low employment status.

Early intervention is important in the treatment of SAD. Pharmacotherapy can dramatically improve QOL. Patients treated with fluvoxamine, sertraline, paroxetine, or escitalopram showed a significantly greater improvement in functioning, disability, and QOL compared with placebo-treated patients.^{80,81,85,88} In a relapse prevention study, patients treated with escitalopram experienced a better health-related QOL and more cost-effective therapy than placebo.⁸¹ The acquisition cost of escitalopram was more than offset by a decrease in total costs of care. Health care professionals can assist patients who qualify for pharmaceutical manufacturer patient access-to-care programs to ease the burden of drug costs.

CLINICAL CONTROVERSY

The role of benzodiazepines in the treatment of SAD is controversial. Some clinicians prescribe benzodiazepines in combination with an antidepressant in the initial acute management of SAD, then taper the benzodiazepine after 3 to 4 weeks. Others believe that these drugs can be used without risk during continuation and maintenance therapy.

■ EVALUATION OF THERAPEUTIC OUTCOMES

10 The pharmacotherapy of SAD can be monitored in three principal domains. The domains include SAD symptoms (e.g., fears and physical symptoms), functionality, and well being or overall improvement.²² Response to pharmacotherapy in SAD is defined as a stable, clinically meaningful improvement; patients no longer have

the full range of symptoms but typically continue to experience more than minimal symptoms.²²

During the acute phase of treatment, patients should be seen weekly while the drug dosage is titrated. Once the patient responds and the dosage is stabilized, the patient can be seen monthly. At each visit, the patient should be asked about adverse effects and improvement in symptoms. The patient should be instructed to keep a diary to record fear levels, physical symptoms, cognitions, and anxious behaviors in actual exposures to social situations. The Liebowitz Social Anxiety Scale is a clinician-rated scale that rates clinical severity and change in SAD that can be used to monitor response.²² Patients can use the Social Phobia Inventory for self-assessment of SAD symptoms.²² Full remission is a complete resolution of symptoms across the three

SAD domains that is maintained for 3 months²² or a Liebowitz Social Anxiety Scale score of ≤ 30 .²³

Patient counseling is important. The patient should be instructed about the gradual onset of effect and that the full therapeutic effect may not be achieved for up to 12 weeks. Patients should be told that long-term therapy is required. When drug therapy is discontinued, the dosage will need to be gradually decreased over several months, and the patient should be seen more frequently to monitor for signs and symptoms of relapse or withdrawal.

It is important to remember that while pharmacotherapy usually leads to improvement in social and occupational functioning, most patients do not achieve a full remission. Many patients require additional treatment, often in the form of CBT.

► TREATMENT: Specific Phobia

Specific phobia is considered unresponsive to drug therapy, although highly responsive to behavioral therapy. The use of antidepressant drugs can be detrimental in patients with specific phobias.

CONCLUSIONS

Anxiety disorders are common in the population and are commonly comorbid with other psychiatric disorders. The proper management of anxiety disorders begins with the correct diagnosis; not all patients should receive antianxiety agents. Nonpharmacologic interventions often are effective alone or when combined with drug therapy.

There are several subtypes of anxiety disorders, and the diagnosis determines the type of drug and nonpharmacologic intervention selected. Although benzodiazepines remain the drugs of choice for situational anxiety, antidepressants have emerged as first-line therapy for GAD, panic disorder, and SAD. The antidepressants are the drugs of choice for patients who need chronic therapy for GAD. Benzodiazepines are reserved for use in situations requiring immediate anxiety relief or for use on an as-needed basis. Antidepressants, including the SSRIs and the benzodiazepines clonazepam and alprazolam, are used extensively in patients with panic disorder. Research in the area of SAD has resulted in new pharmacologic treatment strategies with antidepressants.

The long-term goal of therapy for GAD, panic disorder, and SAD is remission of core anxiety symptoms with no impairment in functionality, minimal anxiety, and no depressive symptoms. Clinicians can use the pharmacological armamentarium effectively to achieve this goal for patients.

ABBREVIATIONS

AUD: alcohol use disorder
 CBT: cognitive behavioral therapy
 DA: dopamine
 DMDZ: desmethyldiazepam
 GABA: γ -aminobutyric acid
 GAD: generalized anxiety disorder
 5-HT: serotonin
 LC: locus ceruleus
 MAOI: monoamine oxidase inhibitor
 NE: norepinephrine

QOL: quality of life

SAD: social anxiety disorder

SERT: serotonin reuptake transporter site

SNRI: serotonin-norepinephrine reuptake inhibitor

SSRI: selective serotonin reuptake inhibitor

TCA: tricyclic antidepressant

ANXIETY DISORDERS II: POSTTRAUMATIC STRESS DISORDER AND OBSESSIVE-COMPULSIVE DISORDER

Cynthia K. Kirkwood, Eugene H. Makela, and Barbara G. Wells

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The short-term goal in posttraumatic stress disorder is reduction in core symptoms, while the long-term goal is remission.
- 2 Cognitive and behavioral approaches are the most effective nonpharmacologic methods to reduce symptoms of posttraumatic stress disorder.
- 3 The selective serotonin reuptake inhibitors (SSRIs) are considered first-line treatment for posttraumatic stress disorder.
- 4 An adequate trial for an antidepressant in posttraumatic stress disorder is 8 to 12 weeks.
- 5 The duration of pharmacotherapy for posttraumatic stress disorder is at least 12 months.
- 6 The SSRIs are the drugs of choice for the treatment of obsessive-compulsive disorder.
- 7 Clomipramine should be considered after 2 or 3 failed SSRI trials for obsessive-compulsive disorder.
- 8 Antidepressant taper can be considered after 1 to 2 years of treatment for obsessive-compulsive disorder.
- 9 Long-term or lifetime prophylactic maintenance medication is recommended for obsessive-compulsive disorder after 2 to 4 severe relapses or 3 to 4 mild to moderate relapses.

Recent world events (e.g., wars, terrorist attacks, and earthquakes) have placed a renewed focus on posttraumatic stress disorder (PTSD). Initially diagnosed in veterans of war, PTSD is now acknowledged as a significant psychiatric illness in the civilian population.¹ PTSD continues to be poorly recognized and diagnosed in clinical practice.² Because of its co-occurrence with other anxiety disorders, depression, and substance abuse, the overlapping symptoms can lead to diagnostic uncertainty. Advances in the science and treatment of PTSD can assist clinicians in all fields of health care to screen patients for a history of trauma and effectively manage PTSD if it is present.

Obsessive-compulsive disorder (OCD) is one of the ten leading causes of disability.³ Patients with OCD experience significant impairment in their quality of life (QOL), with reductions in social, family, and occupational functioning.⁴ OCD affects far more individuals than was thought in the past. Because of the nature and potential severity of signs and symptoms and the resultant negative effects on QOL, OCD is considered a major medical condition. Clinicians should be able to identify OCD and understand the current treatment options.

EPIDEMIOLOGY

The prevalence rates of anxiety disorders were recently revised to encompass clinically significant cases in the community.⁵ According to the modified prevalence estimates of mental disorders in the United States, the 1-year prevalence rate of PTSD was 3.6%.⁵ The

1-year prevalence rate for obsessive-compulsive disorder was 2.4% in persons aged 18 to 54 years and 1.5% in those over age 55 years.⁵

The epidemiology of PTSD is associated with the incidence of trauma. It is estimated that about 50% of men and 60% of women are exposed to a life-threatening traumatic event. Of these individuals 8.2% of men and 20% of women will develop PTSD.⁶ Previous exposure to a trauma and the intensity of response to the event increase the risk of PTSD.⁶ Individuals with a history of childhood sexual abuse are at higher risk of developing PTSD as adults.⁷ Men tend to be assaulted more frequently, but women have a higher rate of PTSD after assault. The incidence of PTSD is equal between men and women after rape (i.e., 50%) and natural disasters (i.e., <5%).⁶ Genetic factors can increase vulnerability to PTSD if an individual is exposed to a traumatic event. Offspring of Holocaust survivors had a higher lifetime prevalence rate of PTSD compared with a control group.⁶

OCD usually begins early in life, with 20% of cases occurring in childhood, 29% in adolescence, and 49% of cases occurring by age 20. The onset of illness is earlier in men than women. OCD tends to be a chronic disorder.¹ Twin studies revealed significantly higher concordance rates in monozygotic versus dizygotic twins, but OCD probably has nongenetic as well as genetic influences over expression of the illness, because the concordance rate for monozygotic twins is less than 100%. Individuals have an 11% to 12% risk of developing the illness if a first-degree relative has OCD; however, this familial relationship may be age-sensitive. In one epidemiological study, no

cases of OCD were found in relatives of patients developing the illness after 18 years of age.⁸

ETIOLOGY

The exact etiologies of PTSD and OCD are not known. It is likely that abnormalities in several areas of brain functioning interact to cause these chronic anxiety disorders. Genetics may play a role in expression of PTSD and OCD, but environmental factors likely are also involved. A neurodevelopmental model of OCD has been proposed.⁹

OCD has been characterized as a pediatric autoimmune neuropsychiatric disorder associated with streptococcal infections. In response to streptococcal infection, antibodies are produced in some individuals that temporally precipitate sudden onset or exacerbation of symptoms of OCD. Neuroimaging studies suggest that in these patients the antibodies produce inflammation of the basal ganglia. This leads to increased volumes of the caudate, putamen, and the globus pallidus, and subsequently to smaller caudate volumes potentially reflective of scarring or atrophy related to streptococcal infection. Although most patients with OCD do not have a streptococcal etiology, an accurate medical history regarding onset of illness is imperative because specific treatment strategies are indicated.¹⁰

PATHOPHYSIOLOGY

Research findings in the areas of neuroendocrinology, neurobiology, and neuroimaging have advanced a number of theories on the pathophysiology of anxiety disorders. Neuroendocrine changes in the hypothalamic-pituitary-adrenal (HPA) axis are implicated in the pathophysiology of PTSD.⁶ As reviewed in the previous chapter (Chap. 69), data from neurochemical and neuroimaging studies indicate that the modulation of normal and pathologic anxiety states is associated with multiple regions of the brain (e.g., amygdala, hippocampus, thalamus, and prefrontal cortex). Abnormal function in several neurotransmitter systems, including norepinephrine (NE), γ -aminobutyric acid (GABA), glutamate, dopamine (DA), and serotonin (5-HT) may affect the manifestations of anxiety disorders.^{11,12}

NEUROENDOCRINE THEORIES

Neuroendocrine studies provide data that abnormalities occurring pretrauma, during trauma, and posttrauma contribute to PTSD.⁶ Normally the immediate reaction to stress occurs as an automatic response from the amygdala to the sympathetic and parasympathetic systems and the HPA axis. The release of corticotropin-releasing factor stimulates cortisol release from the adrenal gland. Both catecholamines and cortisol levels rise in tandem. Cortisol reduces the stress response by tempering the sympathetic reaction through negative feedback on the pituitary and hypothalamus.⁶ These systems return to normal after a few hours.

Patients with PTSD have a hypersecretion of corticotropin-releasing factor but demonstrate subnormal levels of cortisol at the time of trauma and chronically.⁶ Dysregulation of the HPA axis is postulated to be a risk factor for eventual development of PTSD.⁶

NEUROCHEMICAL THEORIES

Several neurotransmitters may be involved in the pathophysiology of PTSD. 5-HT and NE are associated with the processing of

emotional and somatic contents of memories in the amygdala. The cortex and hippocampus are involved in storing the facts and related cues of memory.¹³ The noradrenergic theory posits that the autonomic nervous system of anxious patients is hypersensitive and overreacts to stimuli. The alarm center, the locus ceruleus, releases NE to stimulate the sympathetic and parasympathetic nervous systems. Patients with PTSD tend to experience sustained elevated heart rates during trauma and enhanced startle effects starting a month after trauma exposure. Patients with chronic central noradrenergic overactivity have downregulated α_2 -adrenoreceptors.¹⁴ Dysregulation of the processing of sensory input and memories may contribute to the dissociative and hypervigilant symptoms in PTSD. Preliminary data indicate that the 5-HT and 5-HT₂ antagonist *meta*-chlorophenylpiperazine (*m*-CPP) causes increased anxiety symptoms in patients with PTSD.¹³ Abnormalities of GABA inhibition may lead to increased awareness or response to stress, as seen in PTSD.¹³

Both 5-HT and DA are implicated in the pathogenesis of OCD. Pharmacologic trials involving selective and potent serotonergic reuptake inhibitors have consistently shown these agents to be effective for symptoms of the illness. Results of challenge studies using 5-HT agonists support a role for this neurotransmitter as well. However, to date there is no specific identified abnormality in the 5-HT system with OCD.¹² DA dysregulation may contribute to some forms of OCD. Neurologic symptoms (e.g., tics) are part of the clinical presentation in some patients with OCD. Tourette's disorder, a disorder of DA dysfunction, is often comorbid with OCD.¹ Patients with OCD and tics benefit from the addition of an antipsychotic drug to their treatment regimen.¹²

NEUROIMAGING STUDIES

Neuroimaging studies suggest that certain areas of the brain are altered by psychological trauma. The most consistent finding is decreased hippocampal volumes in patients with PTSD.¹⁵ In twin studies, the unaffected twin of patients with PTSD also demonstrated smaller hippocampi compared with twins without PTSD.¹⁵ These findings suggest that lower hippocampal volumes in patients with PTSD are likely a precursor associated with vulnerability for subsequent development of PTSD.¹¹

Findings of increased activation of the amygdala after symptom provocation (e.g., via personal trauma script, visual imagery, or audio tape of combat sounds) indicate that this structure plays a role in the formation of emotional memory. Concurrent reductions in the activity in Broca's area (functioning here is required to attach meaning to experiences that can be translated into words) may explain why patients with PTSD have problems in labeling and understanding their extreme emotions.^{16,17} Neuroimaging data suggest that the biological changes after trauma can also involve alterations in brain structure and function.¹⁶

Progress has been made in elucidating the pathophysiologic mechanisms that are the underpinnings of OCD. Functional neuroimaging studies indicate that individuals with OCD show hyperactivity in the ventral prefrontal cortex (VPFC) of the brain. In adult patients with OCD there is a correlation between symptom severity and VPFC and striatal activity. Lesions of the VPFC in patients with OCD result in decreased obsessive-compulsive symptoms. The VPFC dysfunction may be related to a loss of inhibitory processes that results in increased metabolic rates in this region and difficulty in inhibiting thoughts and rituals that otherwise would seem senseless.⁹

CLINICAL PRESENTATION

The *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision classifies anxiety disorders into several categories: generalized anxiety disorder, panic disorder (with or without agoraphobia), social anxiety disorder, specific phobia, OCD, PTSD, and acute stress disorder (ASD).¹ The characteristic features of these illnesses are anxiety and avoidance behavior. Generalized anxiety disorder, panic disorder, and social anxiety disorder are discussed in Chap. 69.

POSTTRAUMATIC STRESS DISORDER

Exposure to a traumatic event is required for a diagnosis of PTSD.¹ The person must have witnessed, experienced, or have been confronted with a situation that involved definite or threatened death or serious injury, or possible harm to themselves or others. The patient's response to the trauma must include intense fear, helplessness, or horror.¹ Some examples of traumatic events include motor vehicle accidents, natural disasters, rape, being held hostage, child sexual abuse, and witnessing a murder or injury of another.

The resulting PTSD symptoms include persistent re-experiencing of the traumatic event, avoidance of stimuli associated with the trauma, numbing of general responsiveness, and persistent symptoms of hyperarousal (Table 70–1). Patients must have at least one re-experiencing symptom that can include recurrent images, thoughts, perceptions, or dreams of the event; dissociative flashbacks,

TABLE 70–1. Presentation of Posttraumatic Stress Disorder

Re-experiencing symptoms

- Recurrent, intrusive distressing memories of the trauma
- Recurrent, disturbing dreams of the event
- Feeling that the traumatic event is recurring (e.g., dissociative flashbacks)
- Physiologic reaction to reminders of the trauma

Avoidance symptoms

- Avoidance of conversations about the trauma
- Avoidance of thoughts or feelings about the trauma
- Avoidance of activities that are reminders of the event
- Avoidance of people or places that arouse recollections of the trauma
- Inability to recall an important aspect of the trauma
- Anhedonia
- Estrangement from others
- Restricted affect
- Sense of a foreshortened future (e.g., does not expect to have a career, marriage)

Hyperarousal symptoms

- Decreased concentration
- Easily startled
- Hypervigilance
- Insomnia
- Irritability or angry outbursts

Subtypes

- Acute: duration of symptoms is less than 3 months
- Chronic: symptoms last for longer than 3 months
- With delayed onset: onset of symptoms is at least 6 months posttrauma

Screening questions

- Have you ever experienced a significant trauma in your life?
- Did this experience have a lasting negative impact or change your life?

Adapted from American Psychiatric Association¹ and Ballenger et al.¹¹

illusions, hallucinations, or a sense of reliving the event; physiologic reactivity (e.g., increased heart rate) on exposure to internal or external cues that symbolize a feature of the trauma.¹ At least three signs or symptoms of persistent avoidance of stimuli associated with the trauma or numbing are required and can include the following: efforts to avoid feelings, conversations, and thoughts about the trauma; avoidance of places, activities, or individuals that stimulate recollections of the event; restricted range of affect; feelings of estrangement from others; anhedonia; dissociative amnesia; and sense that they lack a future.¹ At least two symptoms of increased arousal are present, including insomnia, exaggerated startle response, difficulty concentrating, hypervigilance, and irritability.¹ Symptoms from each category need to be present for longer than 1 month and cause significant distress or impairment in functioning. Most persons diagnosed with PTSD also meet criteria for another mental disorder.¹

Anxiety and dissociative symptoms (e.g., sense of numbing or absence of emotional responsiveness, derealization, depersonalization, inability to recall important features of the event) emerging within 1 month after exposure to a traumatic stressor are classified as ASD. Symptoms of ASD are experienced during or immediately after the trauma, last for at least 2 days, and resolve within 4 weeks.¹

The age of onset and course of PTSD are variable. PTSD can occur at any age. The presentation is not predictable because symptoms are related to the duration and intensity of the trauma, the presence of other psychiatric disorders, and how the patient deals with the trauma. The average duration of symptoms in patients in treatment is about 36 months. In those not receiving treatment, symptoms can last for a mean of 5 years. About one-third of patients with PTSD have a poor prognosis for recovery.⁷ About 80% of patients with PTSD have a concurrent depression or anxiety disorder.⁷ Over half of men with PTSD suffer from comorbid alcohol abuse or dependence.⁷ About 20% of patients with PTSD attempt suicide.⁷

OBSESSIVE-COMPULSIVE DISORDER

Patients with OCD exhibit a great variety of symptoms upon presentation to clinicians (Table 70–2). The diversity and oddity of symptoms that manifest can obscure accurate diagnosis and delay appropriate treatment of the disorder. Patients may be secretive about symptoms and purposefully refuse to report or deny symptoms.¹⁸ Patients can present in a seemingly incongruous manner to nonpsychiatrists for

TABLE 70–2. Presentation of Obsessive-Compulsive Disorder

Obsessions

- Repetitive thoughts (e.g., feeling contaminated after touching an object, doubting whether the stove was turned off)
- Repetitive images (e.g., recurrent sexually explicit pictures)
- Repetitive impulses (e.g., need for symmetry or putting things in specific order, impulse to shout out obscenities in a church)

Compulsions

- Repetitive activities (e.g., hand washing, checking, ordering, need to ask, need to confess)
- Repetitive mental acts (e.g., counting, repeating words silently, praying)

Screening questions

- Do you have repetitive thoughts that make you anxious and that you cannot get rid of?
- Do you check things excessively?
- Do you feel the need to wash your hands frequently?
- Do you keep things exceptionally clean?

Adapted from American Psychiatric Association¹ and Jenike.¹⁸

other complaints—dermatologists for eczema or chapped skin, pediatricians for parental concerns over a child's compulsive hand washing, neurologists for tics, or dentists for gum lesions from compulsive teeth brushing.

The diagnostic criteria for OCD requires the presence of either obsessions and/or compulsions (although most patients have both) that are severe enough to cause marked distress, to be time-consuming (occupy more than 1 hour per day), or to cause significant impairment in social or occupational functioning.¹ An obsession is a recurrent, persistent idea, thought, impulse, or image that is experienced as intrusive and inappropriate and produces marked anxiety. Common obsessions involve thoughts about contamination (e.g., concern with germs, dirt, or toxic chemicals), repeated doubts, and needing to have things in a particular order.¹

Individuals must recognize that their obsessions or compulsions are excessive or unreasonable. Obsessions must be acknowledged as products of the individual's own mind and attempts must be made to ignore or suppress them. The obsessions produce marked feelings of anxiety and are not simply excessive worry about a real life situation.¹

A compulsion is defined as a repetitive behavior or mental act generally performed in response to an obsession. The most common compulsions involve washing and cleaning, counting, checking, and requesting or demanding assurances. Diagnostically, compulsive behavior is not pleasurable and is designed to prevent discomfort or the occurrence of a dreaded event that is often unknown. For example, many patients are obsessed with feelings of doubt (e.g., whether a door was left unlocked), causing them marked distress, and leading to repetitive checking (or compulsive behaviors). These behaviors are usually performed according to certain rules or in a stereotyped fashion. The individual recognizes compulsions as senseless. Because patients recognize their behavior as silly, they become extremely adept at denying symptoms, disguising their rituals, and concealing their illness from friends and family.¹

Patients with OCD often have comorbid depression, anxiety disorders, and alcohol abuse or dependence.¹⁸ It is a chronic illness in most patients, with severity of symptoms varying in intensity over time. Many patients with OCD have significantly impaired QOL and ability to function.¹⁸

► TREATMENT: Posttraumatic Stress Disorder

■ DESIRED OUTCOME

1 The short-term goal of therapy in the management of PTSD is reduction in core symptoms (i.e., intrusive re-experiencing, avoidance, and hyperarousal). Patients should also have improvements in disability, comorbid conditions, and QOL. The long-term goal in PTSD is remission.¹⁹

■ GENERAL APPROACH TO TREATMENT

In general, patients who seek treatment acutely after a trauma and are in intense distress should receive therapy based on their presenting symptoms (e.g., a nonbenzodiazepine hypnotic for difficulty sleeping). Short courses of cognitive behavioral therapy (CBT) can be helpful. If symptoms (e.g., hyperarousal, avoidance, dissociation, sleep difficulties, or depressed mood) persist for 3 to 4 weeks and the patient experiences marked social, occupational, and/or interpersonal impairment, they should be treated with pharmacotherapy, psychotherapy, or both. Many patients with PTSD will improve substantially with pharmacotherapy but retain some symptoms. Treatment regimens usually combine psychoeducation, psychosocial support and/or treatment, and pharmacotherapy.¹¹

■ NONPHARMACOLOGIC THERAPY

Psychotherapy can be used when a patient suffers from mild symptoms, in patients who prefer not to use medications, or in conjunction with drugs in patients with severe symptoms to improve response.¹¹ Patients who have experienced trauma should be educated that they can experience anxiety, depression, nightmares, and even flashbacks as a normal reaction to the event.¹¹ Brief courses of CBT in close proximity to the traumatic event resulted in lower rates of PTSD

3 and 6 months later.¹¹ Single-session critical incident stress debriefing was not shown to be effective in preventing development of PTSD and actually may cause harm.¹¹

2 Psychotherapies for treating PTSD include anxiety management (e.g., stress-inoculation training, relaxation training, biofeedback, distraction techniques), CBT (e.g., exposure therapy, cognitive processing therapy, and eye movement desensitization/reprocessing), insight-oriented therapies (e.g., psychodynamic therapy, and hypnosis), and psychoeducation.^{20,21} Short-term reductions in symptoms can be achieved with anxiety management, group therapy, hypnosis, or psychodynamic therapy.²⁰ Cognitive and behavioral approaches are the most effective nonpharmacologic methods to reduce symptoms of PTSD. Follow-up studies after a 3-month course of CBT demonstrated continued benefit for 3 to 12 months.²² Psychoeducation includes information about the disease state, treatment options, and avoidance of excessive use of alcohol, nicotine, and other substances of abuse.

■ PHARMACOLOGIC THERAPY

3 Antidepressants are the major pharmacotherapeutic treatment for PTSD. In addition to their efficacy in PTSD, these agents are also effective for comorbid depression and anxiety disorders. The selective serotonin reuptake inhibitors (SSRIs) are the first-line pharmacotherapy of PTSD. Other antidepressants (e.g., tricyclic antidepressants [TCAs] and monoamine oxidase inhibitors [MAOIs]) may also be effective, but they have less favorable side-effect profiles (Table 70-3). Sertraline and paroxetine are both approved for the acute treatment of PTSD,^{24,25} and sertraline is approved for the long-term (i.e., 52 weeks) management of PTSD.²⁵ A number of drugs can be used as augmentation agents (e.g., anticonvulsants, antiadrenergic drugs, and antipsychotics).²¹ Benzodiazepines are not effective in the management of PTSD.²³ Two practice guidelines^{20,23} and two consensus statements for the treatment of PTSD are published.^{11,21} An algorithm for the treatment of PTSD appears in Fig. 70-1.

TABLE 70-3. Antidepressants Used in the Treatment of Posttraumatic Stress Disorder

| Class/Generic Name | Brand Name | Starting Dose | Dosage Range ^a (mg/day) |
|---|------------|-------------------|------------------------------------|
| Selective serotonin reuptake inhibitors | | | |
| Citalopram ^C | Celexa | 20 mg per day | 20–40 |
| Escitalopram | Lexapro | 10 mg per day | 10–20 |
| Fluoxetine ^C | Prozac | 10–20 mg per day | 10–60 |
| Fluvoxamine ^C | Luvox | 50 mg per day | 100–250 |
| Paroxetine ^C | Paxil | 10–20 mg per day | 20–60 ^b |
| Sertraline | Zoloft | 25–50 mg per day | 50–200 ^b |
| Other agents | | | |
| Amitriptyline | Elavil | 25–50 mg per day | 75–200 |
| Imipramine | Tofranil | 25–50 mg per day | 75–200 |
| Lamotrigine | Lamictal | 25 mg per day | 50–500 |
| Phenelzine | Nardil | 15 mg every night | 45–75 |

^aDosage used in clinical trials but not FDA-approved.

^bDosage is FDA-approved.

^cAvailable generically.

■ SPECIAL POPULATIONS

Children who experience stress and trauma (e.g., sexual or physical abuse or loss of a parent) are predisposed to develop mood and anxiety disorders. The SSRIs are the initial pharmacologic agents of choice in this patient population. Psychotherapy is also a treatment option (e.g., play therapy).^{21,26}

■ ANTIDEPRESSANT THERAPY

■ Selective Serotonin Reuptake Inhibitors

The SSRIs act pharmacologically to enhance serotonergic functioning. Large prospective studies documented the efficacy of sertraline and paroxetine in the acute management of PTSD. In a 12-week trial sertraline (mean dose 146 mg/day) was effective across the spectrum of PTSD-specific, global, and functional outcome measures. About 60% of the patients improved on symptom clusters of arousal and avoidance/numbing but not on re-experiencing.²⁷ Sixty percent of patients with PTSD receiving a paroxetine dose of

20 mg/day and 54% of patients receiving 40 mg/day responded; response was not related to dose.²⁸ In a flexible-dose trial, paroxetine significantly improved all three PTSD symptom clusters and disability compared with placebo at 12 weeks.²⁹ Fluoxetine showed efficacy in a placebo-controlled trial,³⁰ and fluvoxamine was efficacious in an open trial in acute PTSD.³¹ In a comparison between sertraline and citalopram, PTSD symptoms improved significantly in both groups, but sertraline was significantly better in reducing avoidance/numbing than citalopram.³² In general, the SSRIs reduced the numbing symptoms of PTSD, whereas other drugs have not. Adverse reactions reported in patients with PTSD treated with SSRIs include gastrointestinal symptoms, sexual dysfunction, insomnia, and agitation.

The results of two long-term trials indicate that sertraline (12 months) and fluoxetine (9 months) were effective in preventing relapse.^{30,33} Sertraline also improved QOL compared with placebo.³³

■ Other Antidepressants

The TCAs amitriptyline and imipramine and the MAOI phenelzine can be considered second- or third-line antidepressants if therapeutic

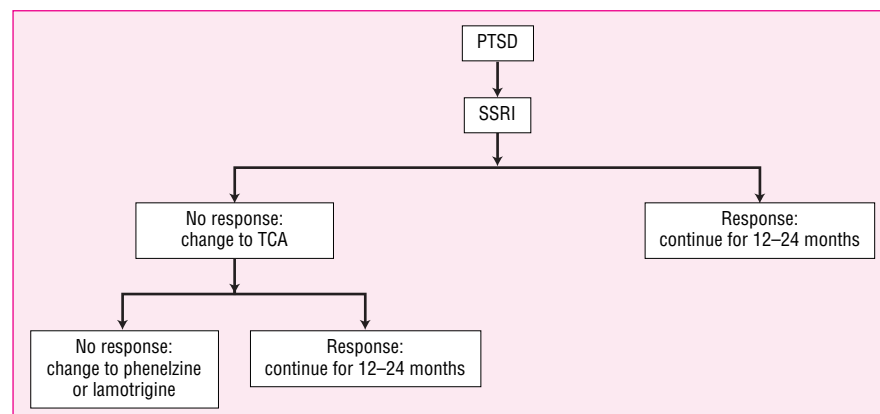

FIGURE 70-1. Algorithm for the pharmacotherapy of posttraumatic stress disorder. (Adapted from Ballenger et al¹¹ and Bandelow et al.²³)

trials of SSRIs have failed. Phenelzine decreased insomnia, nightmares, and flashbacks, and may be an alternative for patients who do not respond to SSRIs. TCAs are associated with a higher burden of adverse effects compared with SSRIs (e.g., daytime drowsiness, toxicity in overdose, and poor compliance).^{21,23}

Other antidepressants have been studied in open-label trials. Trazodone and mirtazapine decreased some symptoms of PTSD.^{34,35} Patients with PTSD who used trazodone in the past reported that it helped to relieve nightmares.³⁴ The sedating effect of trazodone is used frequently to treat insomnia induced by SSRIs. Mirtazapine was effective on global ratings of symptoms in 64% of patients with PTSD in doses up to 45 mg/day.³⁵ Venlafaxine improved PTSD symptom severity and global assessment of functioning in five refugees.³⁶ Although bupropion decreased symptoms of depression and hyperarousal, most PTSD symptoms were unchanged.³⁷ Patients who have failed therapy with other drugs may respond to a trial of nefazodone,³⁸ but the risk of hepatotoxicity must be considered.

■ ALTERNATIVE DRUG TREATMENTS

Mood stabilizers can be used as augmentation therapy in cases of partial response to antidepressant therapy, especially those with prominent irritability or anger.²¹ Anticonvulsants (thought to exert their mechanism in part through antikingling effects) have been effective in treating PTSD. In a retrospective review topiramate reduced nightmares and flashbacks.³⁹ Divalproex sodium was effective in an open trial.⁴⁰

Prazosin, an α_1 -adrenergic antagonist, decreased nightmares and sleep disturbances, and improved the core PTSD symptoms in daily doses of 1 to 4 mg. Its presumed mechanism of action is reduction of noradrenergic transmission.⁴¹

Initial case reports of risperidone's improvement in aggressive behavior, hyperarousal, and flashbacks has led to further investigation into the adjunctive use of atypical antipsychotics in refractory PTSD.⁴² Quetiapine (mean dose 100 mg/day; range, 25 to 300 mg/day) reduced core PTSD symptoms over a 6-week period when added to current therapy.⁴³ Olanzapine (mean dose 15 mg/day) added adjunctively to SSRIs decreased PTSD symptoms and significantly improved sleep compared with placebo. Patients gained an average of 13.2 pounds over the course of the 8-week trial.⁴⁴

Anticonvulsants can be useful in some patients with PTSD. The response rate for patients receiving lamotrigine was twice that of patients receiving placebo (50% and 25%, respectively) over an 8-week period.⁴⁵ However, the slow dosage escalation of lamotrigine needed to avoid the development of a rash may prolong the time required to reach an effective dose.²³

■ DOSAGE AND ADMINISTRATION

■ Acute Phase

PTSD symptoms respond slowly to pharmacotherapy, and some patients may never experience full resolution. SSRIs should be started 3 to 4 weeks after exposure to a trauma in patients with no improvement in their acute stress response.¹¹ The initiation of an SSRI should be at a low dose with gradual titration upward toward antidepressant doses. Eight to twelve weeks is an appropriate duration of antidepressant therapy to determine response.²¹

The initial dose of sertraline is 25 mg given once daily, with an increase to 50 mg/day after 1 week. The dose can be increased in weekly intervals by 50 mg/day up to a maximum dosage of

200 mg/day. Paroxetine can be initiated at 20 mg/day and increased by 10 mg/day in weekly intervals to a target dose of 40 mg/day and a maximum dosage of 60 mg/day. The initial dose of phenelzine is 15 mg given in the evening, and the dose is titrated to 45 to 60 mg/day. Dietary precautions must be followed and drug interactions carefully avoided to prevent hypertensive crisis. The dosing of other antidepressants is shown in Table 70–3.

■ Continuation Phase

Many patients may be undergoing psychotherapy during the continuation phase of therapy, and dosages can vary as patients deal with past traumatic experiences. During this phase symptoms continue to improve, and the maximal drug benefit (i.e., improvement of disability) accrues. Patients who responded to fluoxetine after 3 months of treatment continued to improve at 15 months.⁴⁶ Clinical response at 3 months was identified as a predictor of long-term outcome.⁴⁶

■ Maintenance and Discontinuation

5 Patients with PTSD who respond to pharmacotherapy should continue treatment for at least 12 months.^{21,23} If residual symptoms persist, drug therapy should be continued for at least 24 months.²¹ The decision about when to discontinue therapy is based on response to therapy, presence of ongoing stresses, and adverse effects.²¹ The patient must be confident in the discontinuation plan and requires extra support throughout the process. Drug therapy should be withdrawn and tapered slowly over a period of at least 1 month to reduce the potential for relapse.²¹

CLINICAL CONTROVERSY

The sequence of antidepressant use in PTSD after the first trial of SSRIs fails is controversial. It is not known if a second trial of a different SSRI should be undertaken or if an antidepressant of a different class should be used.

■ PHARMACOECONOMIC CONSIDERATIONS

PTSD compares with depression in the level of disability it imposes on patients with the disorder.⁴⁷ Individuals fail to realize their potentials for career development, marriage, and education. Decreased productivity leads to a financial loss of more than \$3 billion per year. This figure does not include economic loss associated with the failure of patients with PTSD to achieve their educational or career goals.⁴⁷ Women in a health care maintenance organization with high scores on the Posttraumatic Stress Disorder Checklist had more than twice the adjusted total annual median cost (\$1,283) of care (i.e., outpatient, specialty care, primary care, pharmacy and mental health care costs) than those with a low score (\$609).⁴⁸ Treatment with effective pharmacotherapy can improve the QOL of these patients. Sertraline and fluoxetine improved measures of social and occupational functioning as well as the perception of improved QOL in patients with PTSD.^{34,49}

■ EVALUATION OF THERAPEUTIC OUTCOMES

During the acute phase of therapy, patients should be seen weekly for a month and then every other week.²¹ During months 3 to 6 of

therapy, the patient can be seen monthly. In months 6 to 12 of therapy, visits can be extended to every 1 to 2 months. After a year of pharmacotherapy patients can be seen every 3 months. The patient should be asked about target symptoms of PTSD as well as other symptoms including sleep, anger outbursts, irritability, and disability.²¹ The patient should maintain a diary to record the date and presence of symptoms of re-experiencing, avoidance behavior, and hyperarousal, as well as comorbid conditions (e.g., panic attacks, obsessions and compulsions, or suicidal ideation). A remission or good response in patients with PTSD is defined as a greater than 75% reduction in symptoms and response maintained for at least 3 months. Patients who have a 25% to 75% reduction in symptoms are considered partial responders.

Patients who are nonresponsive to therapy have less than 25% reduction in symptoms.²¹ Before deciding that a patient is not responsive to pharmacotherapy, the clinician should ensure that the medication trial has been adequate in both dose and duration.²¹ Use of an objective measurement of remission of PTSD (e.g., a Treatment Outcome PTSD Scale [TOPS-8] score ≤ 5 and a Sheehan Disability Scale ≤ 1 on each item) can assist in the evaluation of drug response.¹⁹

Many patients with PTSD are sensitive to the adverse effects of drugs. They should be monitored carefully for adverse reactions that may delay the escalation of drug dosages or cause the patient distress. When pharmacotherapy is discontinued, patients should be seen more frequently and monitored carefully for signs of relapse or withdrawal.

▶ TREATMENT: Obsessive-Compulsive Disorder

■ DESIRED OUTCOMES

Goals of therapy for OCD include reduction in the frequency of obsessive thoughts and in the time spent performing compulsive acts and reduction in the degree of anxiety. Treatment for OCD may not completely eliminate obsessions or compulsions, but patients may feel remarkably improved with partial resolution of their symptoms. Treatment should provide the patient with an optimal level of psychosocial and occupational functioning and an overall improved QOL. Efforts should be made to minimize adverse drug events and prevent drug interactions.

■ GENERAL APPROACH TO TREATMENT

It is important at the outset of therapy to identify and document the specific target symptoms for pharmacotherapy. Rating scales may be used to measure symptom severity, and a baseline determination is indicated if these tools are used (e.g., Leyton Obsessional Inventory, Symptom Check List 90-OC, and the National Institutes of Mental Health Global Scale). The most widely used scale is the Yale-Brown Obsessive Compulsive Scale (YBOCS).^{50,51}

The Food and Drug Administration (FDA) has approved five antidepressants for the management of OCD: clomipramine, fluoxetine, fluvoxamine, paroxetine, and sertraline. In adolescents with OCD, CBT is generally selected first for mild OCD, but CBT plus an SSRI (e.g., fluoxetine, fluvoxamine, sertraline, or paroxetine) are used for more severe OCD. In adults, CBT is the initial choice for mild OCD, and CBT plus an SSRI or an SSRI alone is selected for more severe OCD. Figure 70–2 is an algorithm for the treatment of OCD.

■ NONPHARMACOLOGIC TREATMENTS

CBT is the treatment of choice for mild OCD in both adolescents and adults. In the management of OCD, CBT involves exposure plus response prevention combined with cognitive therapy. When available, CBT should be offered to every OCD patient.⁵² Exposure involves having the patient perform actions that were formerly avoided. For instance, if a patient avoided touching the flush handle on a bathroom toilet, exposure would involve holding onto the handle. Response

prevention involves having the patient resist the compulsive rituals that are performed. The ritualistic washing behavior often associated with a contamination obsession might be the focus: the patient would be asked to delay the washing behavior as long as possible. At the beginning of CBT treatment patients are often unable to perform these activities, and imaginal exposure is used as the first step in the treatment process. Over time in a gradual manner the patient is exposed to feared objects/activities and is trained to resist rituals for longer periods of time.

Two-thirds to three-fourths of patients who continue in CBT therapy generally respond.⁵⁴ CBT should be added to the regimen when a patient is a nonresponder or a partial responder to SSRI or clomipramine monotherapy. CBT should be used alone if the patient is intolerant to adverse drug effects, is pregnant, or has a medical condition that contraindicates medication.⁵² Behavioral therapy appears to have stronger effects on compulsive rituals than for the associated obsessions.

Exposure and response prevention therapies have longer-lasting effects after discontinuation and produce greater improvement compared with drug therapy.⁵⁵ Techniques such as teaching patients to prevent relapse through self-exposure and self-imposed ritual prevention are suggested to foster optimal nonpharmacologic therapy.⁵⁵ Exposure with response prevention is particularly helpful for contamination or other fears, symmetry rituals, counting/repeating, hoarding, and aggressive urges. Cognitive therapy is beneficial for scrupulosity, moral guilt, and pathologic doubt. Thirteen to twenty sessions are typically required to treat uncomplicated OCD.⁵²

A major barrier to the application of nonpharmacologic therapy is availability of treatment. CBT requires specific training. Many psychiatrists are not adequately trained and/or do not have the time or desire necessary to apply this therapy. Psychologists and social workers may have skills in this discipline; however, the availability of their services is often restricted in certain areas.

■ PHARMACOLOGIC THERAPY

6 The Expert Consensus Panel report reflects the most recent comprehensive opinions of a large number of leading authorities in the field of OCD treatment.⁵² The SSRIs are considered to be the drugs of choice in the treatment of OCD. Drug therapy is reserved for patients with moderate to severe symptoms. Antidepressants may be combined with CBT or used alone in adults with moderate to severe symptoms. An SSRI should be added when there has been no response or partial response to CBT alone. Generally, an SSRI is selected

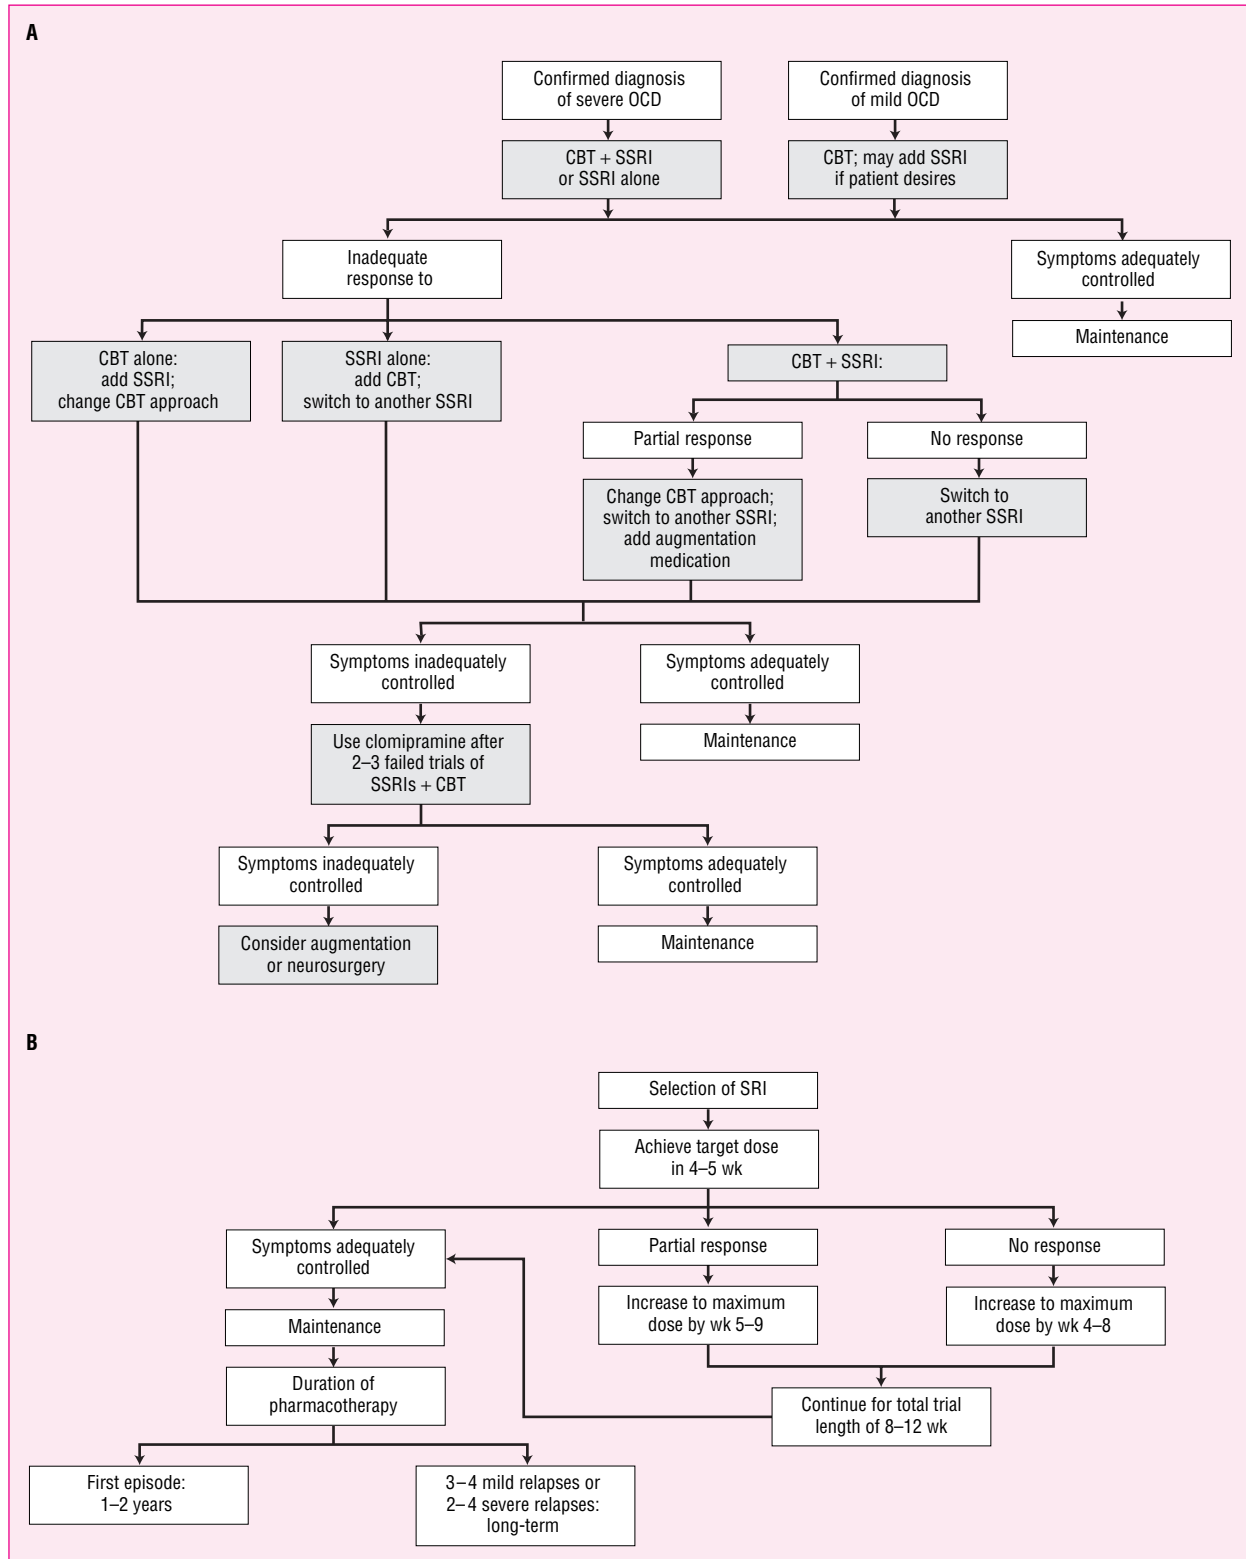

FIGURE 70-2. Algorithm for management of obsessive-compulsive disorder in adults. *A.* Overall approach to treatment. *B.* Pharmacotherapeutic approach to treatment. CBT, cognitive behavioral therapy; SSRI, selective serotonin reuptake inhibitor. (Derived from Expert Consensus Panel for Obsessive-Compulsive Disorder⁵² and American Pharmaceutical Association.⁵³)

before clomipramine, and whenever anticholinergic, cardiovascular, sexual, sedative, or weight gain adverse effects are a major concern. If one SSRI is ineffective, then another SSRI should be tried. Treatment resistance can be defined as failure to achieve at least a 25% reduction  in baseline scores on the YBOCS.^{18,52} Clomipramine may be selected after two to three failed SSRI trials. Clomipramine can be used to augment an SSRI in partially responsive or nonresponsive patients.⁵²

■ SPECIAL POPULATIONS

■ Children and Adolescents

Clomipramine, fluvoxamine, sertraline, and fluoxetine are approved by the FDA for treatment of OCD in children and adolescents.⁵⁶ Childhood and adult OCD appear to respond similarly to drug therapy. The SSRIs appear to be effective and well tolerated in treatment of OCD in children and are generally considered first-line agents.⁵⁷ Treatment with an SSRI produces a favorable response in 75% of children and adolescents with OCD. A combination of SSRIs and CBT is preferred in most cases.⁵⁸ In children, the most commonly described side effects of SSRI therapy include nausea, headache, tremor, gastrointestinal complaints, drowsiness, akathisia, insomnia, disinhibition, and agitation.⁵⁸ Clomipramine was significantly better than placebo in the treatment of OCD in children and adolescents, with 75% of patients having a moderate to marked improvement.⁵⁹ Clomipramine was also more effective than desipramine in children and adolescents.⁶⁰

■ Hepatic and Renal Disease

Clomipramine, fluoxetine, sertraline, paroxetine, fluvoxamine, and citalopram are extensively metabolized in the liver, and patients with significant liver disease should be prescribed these drugs cautiously and in lower doses than those used in healthy subjects. The pharmacokinetics of fluoxetine and fluvoxamine were similar in patients with renal failure and in healthy subjects; however, the manufacturer recommends starting with a lower dose in patients with renal impairment. The pharmacokinetics of sertraline are not altered in patients with significant renal dysfunction, and dosage adjustment is not necessary in these patients.²⁵ Increased plasma concentrations of paroxetine occur in subjects with renal impairment.²⁶ The initial dose of paroxetine should be reduced in patients with severe renal impairment, and upward titration should occur more slowly.²⁶ No dosage adjustment is necessary for patients with mild to moderate renal impairment receiving citalopram.

■ Elderly

Little information is available on treating OCD in the elderly. Case reports and anecdotal information suggest that the antiobsessional drugs are likely to be equally effective in the elderly and in younger adults.⁶¹ Selection of medication for an elderly person with OCD, however, should be based on history of response and adverse side-effect profile. Treatment should be initiated with low doses in elderly patients, and doses should be increased slowly, with vigilance for emergence of side effects. Some elderly patients may ultimately require doses similar to those used in younger adults, but doses must be individualized according to response and tolerance of side effects.

In elderly patients refractory to SSRIs, an augmentation strategy with minimal risk is to add buspirone to SSRI therapy. The use of clonazepam should be avoided because of the potential for excess sedation, particularly in frail elderly patients and those with gait disturbances.⁶² Because of clomipramine's sedative and anticholinergic side effects, it is not usually chosen as first-line therapy for elderly OCD patients.⁶²

The multiple-dose elimination half-life of fluvoxamine was 17.4 and 25.9 hours in the elderly as compared to 13.6 and 15.6 hours in younger subjects at steady state for 50- and 100-mg doses, respectively.⁶³ The safety of fluvoxamine has not been adequately studied in the elderly and patients with cardiovascular disease. Dosage should be titrated slowly during initiation of fluvoxamine therapy in elderly patients.

Sertraline plasma clearance in elderly patients was approximately 40% lower than in a group of younger individuals. Clearance of desmethylsertraline was also decreased in elderly men but not in elderly women.²⁵

In a multiple-dose study in the elderly, the minimal concentrations of paroxetine were 70% to 80% greater than in nonelderly subjects. The manufacturer recommends that the initial dose be reduced in the elderly (10 mg/day), and total daily doses should not exceed 40 mg.²⁴

■ Pregnancy

In general, CBT alone should be used for pregnant patients except in cases in which the risks of untreated OCD outweigh the risks of drug use (e.g., a pregnant woman who will not eat because of contamination fears).⁵² Women with a history of OCD should be informed that OCD may worsen during pregnancy and during the postpartum period. OCD symptoms may exacerbate during the first trimester, especially if pharmacotherapy is discontinued just before conception or early in pregnancy. Symptoms often improve during the second trimester and worsen during the third trimester. The use of SSRIs in pregnancy and lactation is discussed in the chapter on depression (Chap. 67).

If drug therapy during pregnancy is required, fluoxetine appears to be the safest choice. However, the neurobehavioral effects of prenatal exposure on the neonate and the child have not been fully elucidated. Clomipramine should be avoided during pregnancy.⁶⁴ Clonazepam can be considered for OCD symptoms in pregnant women with disabling anxiety, but with higher doses (2 to 5 mg/day), hypotonia, apnea, and failure to feed have been observed in newborns.⁶⁴

■ ANTIDEPRESSANT THERAPY

■ Serotonergic Antidepressants

The only medications consistently demonstrating efficacy in controlled trials are the TCA clomipramine and the SSRIs fluoxetine, fluvoxamine, paroxetine, and sertraline. Sixty-five to seventy percent of patients with OCD respond to their first SSRI treatment, and up to 90% ultimately respond with additional drug trials. Improvement in symptoms is incomplete, and ranges from 25% to 60%. Most patients continue to have symptoms that limit their functioning.⁵⁶ Obsessive-compulsive symptoms improve over a 4- to 10-week treatment period.⁶⁵

Current evidence indicates that 5-HT is important for the antiobsessional effects of medication. The SSRIs and clomipramine inhibit

5-HT reuptake into the presynaptic neuron. Inhibiting reuptake of 5-HT makes more 5-HT available to postsynaptic receptors and reduces formation of the 5-HT metabolite 5-hydroxyindoleacetic acid. Although other antidepressants, such as imipramine and amitriptyline, inhibit 5-HT reuptake, they are less potent and selective than the SSRIs and clomipramine. Prolonged exposure to increased amounts of 5-HT after chronic antidepressant treatment (2 to 3 weeks) leads to altered responsiveness of postsynaptic 5-HT receptors or presynaptic autoregulatory receptors that govern 5-HT release in specific brain regions.⁶⁵

The most impressive and consistent evidence supporting a role for 5-HT in treating OCD is that only potent 5-HT reuptake inhibitors appear to be effective. Furthermore, an improvement in obsessional symptoms may correlate with plasma concentrations of clomipramine but not desmethylclomipramine, the metabolite of clomipramine with less selectivity for 5-HT reuptake inhibition. With clomipramine treatment, the decrease in obsessional symptoms correlates with a decrease in the concentration of 5-hydroxyindoleacetic acid in cerebrospinal fluid, and a decrease in platelet 5-HT content. The effectiveness of serotonergic agents in treating OCD lends support to the role of 5-HT in the etiology of OCD. However, because many patients fail to respond to these agents, the role of other neurotransmitter systems in the pathophysiology of OCD must continue to be explored.

■ PHARMACOKINETICS

Clomipramine is rapidly absorbed following oral administration. Maximum plasma concentrations occur within 2 hours. It is highly protein-bound (>90%) in the blood and has a half-life of 19 to 37 hours.⁶³ The drug is metabolized to desmethylclomipramine, which is pharmacologically active.⁶³ The pharmacokinetics of the SSRIs are discussed in Chapter 67.

■ EFFICACY

In a 10-week randomized study of 31 patients treated with fluvoxamine, paroxetine, or citalopram, there was no significant difference between treatments in antiobsessional effects.⁶⁶ Clomipramine was equivalent in efficacy when compared with fluoxetine or fluvoxamine.⁵⁹ A meta-analysis supported the superiority of clomipramine over fluoxetine, fluvoxamine, and sertraline.⁶⁷ Six of seven head-to-head comparisons of either fluoxetine, fluvoxamine, or paroxetine versus clomipramine found similar efficacy, but with a lower incidence of side effects with the SSRI.⁷³

Most experts agree that the SSRIs are better tolerated than clomipramine.⁵² The SSRIs are less likely to cause cardiovascular, sedative, anticholinergic, and weight gain side effects. Clomipramine is less likely than the SSRIs to cause insomnia, akathisia, nausea, and diarrhea. Side effects may be more severe when larger doses are used and with faster dose escalation. Tolerance to adverse effects often develops over 6 to 8 weeks of treatment, and tolerance is more likely to develop to nausea, diarrhea, sedation, diminished libido and/or orgasm, anxiety, restlessness, insomnia, and anticholinergic side effects than to akathisia.⁵²

■ Other Antidepressants

Venlafaxine, which acts as a serotonin and norepinephrine reuptake inhibitor, may be effective for OCD. In an open-label naturalistic trial, venlafaxine was studied in 39 patients with OCD (with 29 of the group

being treatment resistant). Sixty-nine percent responded as rated by the Clinical Global Impressions-Improvement scale.⁶⁹ In a double-blind switch study of paroxetine and venlafaxine using the YBOCS as a measurement of severity, 37 of 75 patients receiving venlafaxine were initial responders. However, in the switch phase open to nonresponders, only 3 patients out of 16 responded. In this study phase paroxetine was found to be more efficacious than venlafaxine.⁷⁰

■ ALTERNATIVE DRUG TREATMENTS

If there is no response or partial response to combined CBT and three antidepressant trials (one of which is clomipramine), augmentation with another drug and more intensive CBT can be tried. 5-HT enhancers and agents involving other neurotransmitter systems can be initiated, but controlled augmentation trials have been disappointing. Because of this disparity in results, it is suggested that attempts at augmentation be conducted with the use of rating scales or careful symptom severity assessment so that the benefit of the added drug therapy is clearly evident. Controlled studies of lithium or buspirone augmentation of clomipramine or fluvoxamine failed to demonstrate improvement in OCD symptoms.⁷¹ When buspirone is used as augmentation therapy, the initial dose is 5 mg three times daily, and the target dose should be 60 to 90 mg/day.⁵² In a randomized open-label trial, citalopram (40 mg/day) plus clomipramine (150 mg/day) was more effective in refractory patients than was citalopram alone.⁷² These are preliminary findings that await confirmation in a larger, double-blind trial.⁷²

DA receptor antagonists alone are not effective in the treatment of the core symptoms of OCD. In an open-case series of 17 fluvoxamine nonresponders, 88% of patients with comorbid tic disorder diagnoses responded after pimozide was added and 22% of patients without these comorbid diagnoses responded.⁷³ The recommended initial dose of pimozide is 0.5 mg, and the target dose is 1 to 6 mg/day. Pimozide can cause cardiovascular problems, and it should not be used concurrently with clomipramine.⁵² Haloperidol was significantly more effective than placebo in reducing obsessive-compulsive symptoms. Furthermore, those with a concurrent chronic tic disorder demonstrated a preferential response to the fluvoxamine-haloperidol combination.⁷³ The recommended initial dose of haloperidol is 0.5 mg, and the target dose is 0.25 to 6 mg/day.⁵² Patients should be nonresponsive to at least two antidepressant trials (including clomipramine) before haloperidol is tried because of the risk of tardive dyskinesia and other movement disorders with long-term use.⁷¹

Results of low-dose risperidone (0.5 to 2 mg/day) added to antidepressant therapy in refractory patients are encouraging. Treatment response over 6 weeks was rapid and consistent.⁷¹ An additional 8-week, open-label study reported that 50% of patients previously unresponsive to clomipramine responded after risperidone 3 mg/day was added. The recommended initial dose of risperidone is 0.25 mg, and the target dose is 0.5 to 5 mg/day.⁵² Thirty-six patients unresponsive to antidepressants were given risperidone, up to 6 mg/day or placebo in a double-blind trial. Risperidone treatment resulted in a significant reduction in YBOCS scores.⁷⁴ In an open-label trial of olanzapine augmentation of SSRIs for 8 weeks, most patients experienced complete or partial remission in doses of 1.25 to 20 mg/day.⁷⁵

■ Dosage and Administration

Table 70-4 summarizes dosing guidelines for the SSRIs and clomipramine. If there is inadequate response to an average dose, then

TABLE 70–4. Dosing of Selective Serotonin Reuptake Inhibitors in Treatment of OCD

| Generic Name | Usual Initial Daily Dose (mg) | Usual Daily Dosage Range (mg) | Average Target Daily Dose (mg) |
|-------------------------|-------------------------------|-------------------------------|--------------------------------|
| Citalopram ^a | 20 | 20–60 | 40 |
| Clomipramine | 10 | 100–250 | 150–200 |
| Fluoxetine | 20 | 20–80 | 40–60 |
| Fluvoxamine | 50 | 100–300 | 200 |
| Paroxetine | 20 | 20–60 | 40 |
| Sertraline | 50 | 75–200 | 150 |

^aNot FDA-approved for treatment of OCD. Optimal dosing guidelines are not well established.

Modified from Expert Consensus Panel for Obsessive-Compulsive Disorder.⁵²

it should be incrementally increased to the maximum dose within 4 to 9 weeks from the start of treatment. If there is an inadequate response after 4 to 6 weeks at the maximum dose, then another SSRI should be tried. Eight to thirteen weeks is considered an adequate trial before changing to another drug or augmenting with another agent.

After patients have responded to the acute phase of treatment, treatment gains are maintained with maintenance-phase **8** strategies. Monthly follow-up visits are recommended for at least 3 to 6 months, and a medication taper can be considered after 1 to 2 years of treatment. Medication should not be rapidly discontinued, and booster CBT sessions may reduce the risk of relapse when medication is withdrawn. The drug dosage can be decreased by 25%, and then 2 months should lapse before again decreasing the dose, **9** depending on response. Long-term or lifelong prophylaxis with pharmacotherapy is recommended after two to four severe relapses or three to four mild relapses.⁵² Although the appropriate maintenance dose of SSRIs is unknown, it is notable that one investigator was successful in reducing the dose of clomipramine from a mean of 270 mg/day to 165 mg/day in the maintenance phase. Mundo and colleagues studied patients successfully treated with clomipramine or fluvoxamine and reduced their doses by 33 to 66% for maintenance therapy. They found that the maintenance therapy was successful with reduced dosages of the antiobsessional drug, with clear advantages for tolerability and compliance. However, study duration was only 102 days.⁷⁶

CLINICAL CONTROVERSY

The role of atypical antipsychotics as adjunctive agents in managing treatment-resistant OCD is controversial, especially in view of the documentation that the addition of an atypical agent may also precipitate or worsen OCD symptoms. Most clinicians use the atypical antipsychotics cautiously as an add-on to antidepressant therapy in nonresponding or partially responding patients, especially those with concurrent tic disorder.

PHARMACOECONOMIC CONSIDERATIONS

The annual outpatient direct costs for patients seeking treatment for OCD in the United States in 1995 were \$5.1 billion. Aggregate inappropriate treatment costs were up to \$2.4 billion.⁷⁵ In 1990, the total cost to the economy was \$8 billion, which includes expenditures for direct (\$2.1 billion) and indirect costs. Direct costs include costs of hospitalization, outpatient professional services, and drugs. Indirect costs include costs associated with lost productivity, work loss, early retirement, and absenteeism. As OCD frequently has its onset in childhood or adolescence, loss of income over a lifetime is substantial.⁷⁷

EVALUATION OF THERAPEUTIC OUTCOMES

Target symptoms of OCD should be monitored closely. The degree of response may indicate a need to modify dosage, change drug, or augment therapy. Rating scales can be used to monitor symptom response to therapy for OCD. The clinician should inquire about and address problematic adverse effects (including the emergence of suicidal ideation) reported by the patient. Drug interactions should be monitored. Changes in social and occupational functioning should be assessed.

Patients older than 40 years of age should receive a pretreatment electrocardiogram before starting clomipramine. In patients with liver disease, baseline and periodic liver function tests are recommended when clomipramine is used. If clomipramine is given concurrently with sympatholytic antihypertensive agents, blood pressure should be regularly monitored. Patients receiving clomipramine who develop fever and sore throat should have leukocyte and differential white blood cell counts assessed to evaluate for agranulocytosis.

CONCLUSIONS

The past five years have brought a renewed interest in the recognition and management of PTSD. Health care workers are sensitized to the devastating effects that PTSD can have on patients' functioning, QOL, and use of health care resources. Adequately detecting and appropriately managing PTSD is important to improving the lives of patients who suffer from this chronic illness. Data on the efficacy of the SSRIs supports their use for both acute and long-term management of the symptoms of PTSD. The SSRIs are the first-line pharmacotherapy of PTSD and OCD. Research in OCD has resulted in new pharmacologic treatment strategies, especially with augmentation therapies.

ABBREVIATIONS

ASD: acute stress disorder
CBT: cognitive behavioral therapy

DA: dopamine
5-HT: serotonin
GABA: γ -aminobutyric acid
HPA: hypothalamic-pituitary-adrenal axis
MAOI: monoamine oxidase inhibitor
NE: norepinephrine
OCD: obsessive-compulsive disorder
PTSD: posttraumatic stress disorder
QOL: quality of life
SSRI: selective serotonin reuptake inhibitor
TCA: tricyclic antidepressant
VPFC: ventral prefrontal cortex
YBOCS: Yale-Brown Obsessive Compulsive Scale

SLEEP DISORDERS

Cherry W. Jackson and Judy L. Curtis

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Common causes of insomnia include jet lag, significant psychosocial stressors, excessive alcohol use, caffeine intake, and nicotine use.
- 2 Patients experiencing insomnia lasting longer than 3 weeks should be evaluated for symptoms of a medical or psychiatric disorder.
- 3 Monitoring mood symptoms of a patient experiencing a sleep disturbance after a significant loss or during a difficult time is important to prevent a long-term problem with insomnia and to provide appropriate therapy if a mood disorder occurs.
- 4 Sleep hygiene principles, such as relaxing before bedtime, exercising regularly, establishing a regular bedtime and wake-up time, and discontinuing alcohol, caffeine, and nicotine should be taught to individuals with insomnia.
- 6 Bedtime doses of antidepressants such as trazodone may be considered an alternative for patients experiencing insomnia.
- 6 Long-acting benzodiazepines should be avoided in the elderly.
- 7 Benzodiazepine tolerance and dependence are avoided by using low-dose therapy for the shortest possible duration.
- 8 Nonpharmacologic interventions such as weight loss, removing an obstruction in the airway, and or nasal continuous positive airway pressure are considered first-line therapies for obstructive sleep apnea.
- 9 Obstructive sleep apnea and central sleep apnea patients should avoid central nervous system depressants such as alcohol, benzodiazepines, and zolpidem.
- 10 Modafinil is the standard of treatment for daytime sleepiness associated with narcolepsy.

Approximately 70 million Americans suffer with a sleep-related problem, with as many as 60% experiencing a chronic disorder.¹ In a study by the National Institute of Aging, of 9000 patients age 65 and older, over 80% report a sleep-related disturbance.¹

SLEEP PHYSIOLOGY

SLEEP CYCLES

Sleep is divided into two phases: non-rapid eye movement (NREM) sleep and rapid eye movement (REM) sleep. Humans typically experience four to six cycles of NREM and REM sleep, with each cycle lasting between 70 and 120 minutes.²

There are four stages of NREM sleep. Healthy sleep will typically progress through the four stages of NREM sleep prior to the first REM period. From wakefulness, sleep typically progresses quickly through stages 1 and 2. During stages 3 and 4 NREM, both metabolic activity and brain waves slow. This slow-wave sleep occurs most frequently early in the sleep cycle. After stage 4, the first REM cycle occurs and typically lasts between 5 and 7 minutes. REM cycles tend to lengthen in the later stages of the sleep cycle.²

REM sleep involves a dramatic physiological change from stage 4 NREM slow-wave sleep, to a state in which the brain becomes electrically and metabolically activated.² REM occurs in bursts, and is accompanied by a 62% to 173% increase in cerebral blood flow,

generalized muscle atonia, poikilothermia, vivid dreaming, and fluctuations in respiratory and cardiac rate.²

CIRCADIAN RHYTHM

At birth human infants spend up to 20 hours a day sleeping, and it is not until between 3 and 6 months of age that differentiation between REM and NREM sleep occurs.² By age 3, the ultradian sleep-wake rhythm changes to a circadian pattern, with most sleep occurring at night. The suprachiasmatic nucleus of the brain serves as the biological clock and paces the circadian rhythm. Although the length of a day is 24 hours, in environments devoid of light cues, the sleep-wake cycle lasts 24.2 hours.³ Without environmental cues (*zeitgebers*) such as alarm clocks and lights, it would be difficult to set our internal clocks.^{3,4} In midlife, there is a gradual decline in sleep efficiency and sleep time.² In the elderly, sleep is lighter in depth and more fragmented, with intermittent arousals, shifts in the sleep stages, and a gradual disappearance of slow wave sleep.⁴

NEUROCHEMISTRY

The neurochemistry of sleep is complex since sleep cannot be localized to either a specific area of the brain or a specific neurotransmitter. NREM sleep appears to be controlled by the basal forebrain, the area surrounding the solitary tract in the medulla and the dorsal raphe

nucleus, which is primarily serotonergic.³ Sleep is reduced when there are decreases in serotonin or destruction of the dorsal raphe nucleus in the brain stem, which contains most of the brain's serotonergic bodies. REM sleep appears to be turned on by cholinergic cells in the mesencephalic, medullary, and pontine gigantocellular regions. REM sleep appears to be turned off by the dorsal raphe nucleus, the locus ceruleus, and the nucleus peribrachialis lateris, the latter two of which are primarily noradrenergic. The ascending reticular activating system and the posterior hypothalamus facilitate arousal and wakefulness.⁵ Dopamine has an alerting effect. Drugs that increase dopamine in the brain cause increased wakefulness, and those that decrease dopamine cause sleepiness.⁴ Neurochemicals involved in wakefulness include norepinephrine and acetylcholine in the cortex and histamine and neuropeptides such as substance P and corticotropin-releasing factor in the hypothalamus.^{4,6}

ELECTROPHYSIOLOGY

Sleep is typically measured and observed in sleep laboratories by electroencephalograms (EEGs), electro-oculograms (EOGs) of each eye, and electromyograms (EMGs) of the mentalis and submentalis muscles. This information in total is used to evaluate the character of sleep.

The EEG is characterized during wakefulness by low-voltage, rapid-frequency alpha (8 to 13 Hz) and beta rhythms (>13 Hz). Stage 1 of NREM sleep is the stage between wakefulness and sleep during which alpha waves evolve into slower theta waves (4 to 7 Hz). Individuals describe this experience as being awake, being drowsy, or as being asleep. Stage 2 is characterized by theta rhythms with sleep spindles (brief bursts of electrical activity at 12 to 14 Hz) and K complexes (an electronegative wave followed by an electropositive wave). Stage 3 and stage 4 sleep is called *delta sleep* since more than 20% to 50% of the sleep is characterized by high-amplitude slow activity known as delta waves (0.5 to 3 Hz). In this stage eye movements are absent and muscle tone is atonic.³

REM sleep is characterized by a low-amplitude, mixed-frequency EEG, absence of muscle tone, and bursts of bilateral rapid eye movements. Dreaming occurs during REM sleep, and if an individual is awakened during or at the end of one of these periods, 80% to 90% can report the content of their dream.^{5,6}

CLASSIFICATION OF SLEEP DISORDERS

The *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision classifies sleep disorders into four categories based on etiology (Table 71-1) and requires a minimum of 1 month before a sleep disorder can be diagnosed.^{7,8} Primary sleep disorders are those disorders in which there is no other etiology (mental disorder, substance-related disorder, or medical condition) responsible for the disorder. Primary sleep disorders appear to be based on an endogenous abnormality of the sleep-wake cycle, or circadian rhythm, and they are divided into dyssomnias or parasomnias. A *dyssomnia* is defined as an abnormality in the amount, quality, or timing of sleep, while a *parasomnia* is defined as abnormal behavioral or physiological events associated with sleep.

INSOMNIA

Insomnia is defined as a complaint of difficulty falling asleep, difficulty maintaining sleep, or experiencing nonrestorative sleep

TABLE 71-1. DSM-IV-TR Classification of Sleep Disorders

Primary sleep disorders

Dyssomnias

- Primary insomnia
- Primary hypersomnia
- Narcolepsy
- Breathing-related sleep disorder
- Circadian rhythm sleep disorder
 - Delayed sleep phase type
 - Jet lag type
 - Shift work type
 - Unspecified type
- Dyssomnia not otherwise specified

Parasomnias

- Nightmare disorder
- Sleep terror disorder
- Sleepwalking disorder
- Parasomnia not otherwise specified

Sleep disorders related to another mental disorder

- Insomnia related to another mental disorder
- Hypersomnia related to another mental disorder

Other sleep disorders

- Sleep disorder due to a general medical condition
- Substance-induced sleep disorder

(sleeping but not feeling rested) that lasts at least 1 month.⁸ This sleep disorder causes distress, frequently due to fear that they may not be able to fall asleep at bedtime, or impaired occupational functioning due to daytime fatigue or drowsiness. While young adults are more likely to complain that they have difficulty falling asleep, middle-aged and elderly adults are more likely to complain that they have middle-of-the-night awakening or early morning awakening.

It is important to evaluate insomnia based on its duration. A sleep complaint lasting two or three nights is considered to be transient insomnia. Short-term insomnia usually resolves in less than 3 weeks, and is typically due to illness, jet lag, or stress. According to the *Diagnostic and Statistical Manual*, insomnia lasting longer than 1 month is considered chronic.

EPIDEMIOLOGY

Insomnia is the most common complaint in general medical practice settings.⁹ Primary insomnia usually begins in young adulthood or middle age, and is rare in childhood or adolescence. More than 50% of the population complains of insomnia in their lifetime.¹ A 1-year prevalence study of insomnia in the United States reports that one-third of the individuals surveyed complained of insomnia, and 17% reported that the symptoms were serious.¹ Conservative estimates of chronic insomnia range from 9% to 12% in adulthood and up to 20% in the elderly.^{1,10} Women complain of insomnia twice as frequently as men. Individuals who are elderly, unemployed, separated or widowed, or those with a lower socioeconomic status reported a significantly higher incidence of insomnia. Forty percent with insomnia also had a concurrent psychiatric disorder (anxiety, depression, or substance abuse).⁹

Despite the prevalence of insomnia, only 5% of individuals seek medical attention for management of their insomnia. Approximately 10% to 20% use nonprescription drugs or alcohol to self-treat. Of

the 3% of the population who are prescribed sedative-hypnotics for insomnia, 11% report usage exceeding 1 year.¹¹

DIFFERENTIAL DIAGNOSIS

Primary insomnia is considered to be an endogenous disorder due to either a neurochemical or structural disorder affecting the sleep-wake cycle. Individuals with primary insomnia may be light sleepers who are easily aroused by noise, temperature, or anxiety. Some studies have suggested that primary insomnia is a “hyperarousal state,” in that insomnia patients have an increased metabolic rate compared with controls, and have longer-than-average sleep latencies in sleep studies.²

1 Evaluation of patients with a complaint of short-term or transient insomnia should focus on recent stressors, such as a separation, a death in the family, a job change, or college exams. Another common cause is jet lag. These individuals often develop situational anxiety based on fear of not being able to fall asleep. Environmental cues such as alarm clocks may also cause situational anxiety.²

2 Chronic insomnia is frequently associated with a psychiatric or medical condition, and individuals with such a complaint should receive a complete diagnostic examination. This evaluation should include routine laboratory tests and physical and mental status examinations, as well as ruling out any medication- or substance-related causes.¹² Common causes of insomnia are listed in Table 71–2.

► TREATMENT: Insomnia

The therapeutic management of insomnia is initially based on whether the individual has experienced a short-term, transient, or chronic sleep disturbance. Clinicians should assess the symptoms based on a description of the symptoms, onset, duration, frequency, effect on daytime function, sleep hygiene habits, and history of previous symptoms or treatment.¹³

3 General therapeutic management should be used for all patients with insomnia. Management includes identifying the cause of the insomnia, patient education on sleep hygiene, and stress management. Monitoring mood symptoms of a patient experiencing a sleep disturbance after a significant loss or during a difficult time is important to prevent a long-term problem with insomnia and to provide appropriate therapy if a mood disorder occurs. Any unnecessary pharmacotherapy should be eliminated.¹⁰ Transient insomnia, which occurs as a result of an acute stressor, is expected to resolve quickly, and should be treated with good sleep hygiene and careful use of sedative-hypnotics.¹⁴ Short-term insomnia, which lasts up to 3 weeks, is associated with situational, personal, or medical stress. Nonpharmacologic treatment is important in this type of insomnia, and if sedative-hypnotics are used, prevention of tolerance or dependence is an important consideration.¹³ Chronic insomnia requires careful assessment for the medical reason for the insomnia, as well as nonpharmacologic techniques and careful and less frequent use of sedative-hypnotics to prevent tolerance and dependence.¹²

■ NONPHARMACOLOGIC THERAPY

4 In many cases insomnia can be treated without sedative-hypnotics. Education about normal sleep and habits for good

TABLE 71–2. Common Etiologies of Insomnia

Situational

- Work or financial stress
- Interpersonal conflicts
- Major life events
- Jet lag or shift work

Medical

- Cardiovascular (angina, arrhythmias, heart failure)
- Respiratory (asthma, sleep apnea)
- Chronic pain
- Endocrine disorders (diabetes, hyperthyroidism)
- Gastrointestinal (gastroesophageal reflux disease, ulcers)
- Neurologic (delirium, epilepsy, Parkinson’s disease)
- Pregnancy

Psychiatric

- Mood disorders (depression, mania)
- Anxiety disorders (generalized anxiety disorder, obsessive-compulsive disorder, or panic disorder)
- Substance abuse (alcohol or sedative-hypnotic withdrawal)

Pharmacologically induced

- Anticonvulsants
- Central adrenergic blockers
- Diuretics
- Selective serotonin reuptake inhibitors
- Steroids
- Stimulants

sleep hygiene are often sufficient interventions.² Nonpharmacologic interventions for insomnia frequently consist of short-term cognitive behavioral therapies. The ones most studied include: stimulus control therapy, sleep restriction, relaxation therapy, cognitive therapy, paradoxical intention, and sleep hygiene (Table 71–3).^{10,15,16}

TABLE 71–3. Nonpharmacologic Recommendations for Insomnia

Stimulus control procedures

1. Establish regular times to wake up and to go to sleep (including weekends).
2. Sleep only as much as necessary to feel rested.
3. Go to bed only when sleepy. Avoid long periods of wakefulness in bed. Use the bed only for sleep or intimacy; do not read or watch television in bed.
4. Avoid trying to force sleep; if you do not fall asleep within 20–30 minutes, leave the bed and perform a relaxing activity (e.g., read, listen to music, or watch television) until drowsy. Repeat this as often as necessary.
5. Avoid daytime naps.
6. Schedule worry time during the day. Do not take your troubles to bed.

Sleep hygiene recommendations

1. Exercise routinely (three to four times weekly), but not close to bedtime because this may cause arousal.
2. Create a comfortable sleep environment by avoiding temperature extremes, loud noises, and illuminated clocks in the bedroom.
3. Discontinue or reduce the use of alcohol, caffeine, and nicotine.
4. Avoid drinking large quantities of liquids in the evening to prevent nighttime trips to the restroom.
5. Do something relaxing and enjoyable before bedtime.

CLINICAL CONTROVERSY

Some clinicians believe that sleep restriction is an effective form of treatment for chronic insomnia. Evidence from studies varies, and use of sleep restriction in many studies was part of combination therapy, and the specific contribution of sleep restriction toward sleep improvement was unclear.

PHARMACOLOGIC THERAPY

NONBENZODIAZEPINE HYPNOTIC AGENTS

Antihistamines exhibit sedating properties and are included in many over-the-counter sleep agents. They are effective in the treatment of mild insomnia and are generally safe.¹³ Diphenhydramine and doxylamine are more sedating than pyrilamine, and in addition, pyrilamine causes more gastrointestinal discomfort. In one study, patients reported that diphenhydramine causes sedation equivalent to that of pentobarbital 60 mg.¹³ Increasing the dose of antihistamines will not produce a linear increase in response. The safety and efficacy of antihistamines over placebo have been documented in several studies. In all studies, side effects were considered to be minimal.¹⁸ Antihistamines are considered to be less effective than benzodiazepines, and have the disadvantages of anticholinergic side effects, which are especially troublesome in the elderly.^{13,18}

The amino-acid L-tryptophan, a precursor of serotonin, was once popular as a natural sedative. Cases of eosinophilia-myalgia syndrome, which were most likely due to contamination of excipients, caused this product to be removed from the market.¹¹

Antidepressants are alternatives for patients with nonrestorative sleep who should not receive benzodiazepines, especially those who have depression, pain, or a risk of substance abuse. Using antidepressants for insomnia without depression is common but not well studied.¹⁸ Sedating antidepressants such as amitriptyline, doxepin, and nortriptyline are effective for inducing sleep continuity, although daytime sedation can be significant.¹⁸ Disadvantages include anticholinergic activity, adrenergic blockage, and cardiac conduction prolongations which are problematic in the elderly and in overdose situations.¹⁸

5 Trazodone is very sedating and improves sleep continuity.¹¹ Trazodone is popular for the treatment of insomnia in patients prone to substance abuse, since addiction and tolerance are not a problem. Trazodone is frequently used in patients with selective serotonin reuptake inhibitor (SSRI) and bupropion-induced insomnia in doses of 25 to 75 mg.¹¹ Adverse effects of trazodone include serotonin syndrome when used in combination with other antidepressants. Other side effects include oversedation and α -adrenergic blockade. Orthostasis may occur at any age, but it is more dangerous in the elderly. Priapism is a rare but serious side effect reported to occur in one in 6000 men. One in 23,000 will require surgical intervention, which can lead to permanent impotence.¹⁹

Some SSRIs are sleep promoting, while others may cause insomnia. Some of the new generation of antidepressants such as mirtazapine and nefazodone are also sedating. Sedating antidepressants may be effective in nondepressed patients, especially those who have insomnia and a dependency problem. Since many of these medications affect the cytochrome P450 system, it is important to evaluate for the potential of drug interactions with these agents.¹⁹

Melatonin is a hormone released by the pineal gland during the night. It is available as an over-the-counter agent and is promoted as a sleep aid. Although the dosage varies, the typical starting dose

is 3 mg. Most studies with melatonin have been in children with neurological impairment and in individuals with jet lag.¹¹ Since it is marketed as a dietary supplement, there may be inconsistencies in potency. This must be taken into consideration when recommending this agent.

Valerian is an herbal sleep remedy that has been studied for its sedative-hypnotic properties in patients with insomnia. The mechanism of action of this herb is still unknown, but it may involve inhibition of the enzyme that breaks down γ -aminobutyric acid (GABA). The recommended dose for insomnia ranges from 300 to 600 mg. An equivalent dose of dried herbal valerian root is 2 to 3 grams soaked in 1 cup of hot water for 20 to 25 minutes.²⁰ As with melatonin, and other herbal products not regulated by the Food and Drug Administration (FDA), valerian is not regulated for quality or consistency.

Zolpidem, an imidazopyridine chemically unrelated to benzodiazepines or barbiturates, has a short half-life of 6 to 8 hours.²¹ It acts selectively at the GABA benzodiazepine-1 receptor and has minimal anxiolytic and no muscle relaxant or anticonvulsant properties. It is comparable in efficacy to benzodiazepine hypnotics, reducing latency to sleep and increasing total sleep time and efficiency. Zolpidem is effective for reducing sleep latency and nocturnal awakenings and increasing total sleep time and does not appear to have significant effects on next-day psychomotor performance. Rebound effects on withdrawal and tolerance with prolonged use are minimal; however, theoretical concerns about abuse exist.²¹

The safety and efficacy of zolpidem for insomnia is similar to that of the benzodiazepines. As with other sedative medications, treatment optimally should not exceed 4 weeks to minimize tolerance and dependence. Zolpidem is less disruptive of sleep stages than benzodiazepines. The most common adverse effects include drowsiness, amnesia, dizziness, headache, and gastrointestinal complaints.²¹ Several cases of brief psychotic reactions have been reported in women.²¹

The recommended daily dose of zolpidem is 10 mg, but 5 mg is used in elderly patients and those with hepatic impairment. The dosage may be increased to 20 mg per night, but the incidence of adverse effects is dose related.²¹

Zaleplon is a pyrazolopyrimidine, and like zolpidem it binds selectively to the benzodiazepine-1 receptor. Zaleplon has a rapid onset of action, a half-life of 1 hour, and is metabolized to inactive metabolites.²² It is effective for decreasing time to sleep onset, but not for reducing nighttime awakening or for increasing the total sleep time. Zaleplon may be best used as a sleep aid for middle-of-the-night awakenings.

Zaleplon does not appear to cause rebound insomnia and has no effect on next-day psychomotor performance.²³ At doses of 5 to 20 mg, it has been shown to reduce sleep latency, and at 20 mg to increase sleep duration when compared with placebo. The recommended dose is 10 mg in adults and 5 mg in the elderly.²⁴

The most common adverse effects with zaleplon are dizziness, headache, and somnolence. There is some concern about the possible occurrence of dependence, but insufficient data exist to determine whether this will be an issue with this agent. Development of tolerance does not appear to be significant.²¹ There are two drug interactions of note: zaleplon plasma levels are increased when combined with cimetidine and decreased with rifampin.²¹

BENZODIAZEPINE HYPNOTICS

The most commonly used treatment for insomnia has been the benzodiazepines. All benzodiazepines are effective as sedative-hypnotics, although only five have been marketed for that purpose (Table 71-4).

TABLE 71–4. Pharmacokinetics of Benzodiazepine Hypnotic Agents

| Generic Name | t _{max} (h) ^a | Parent t _{1/2} (h) | Daily Dose Range (mg) | Metabolic Pathway | Clinically Significant Metabolites |
|--------------|-----------------------------------|-----------------------------|-----------------------|-------------------|---|
| Estazolam | 2 | 12–15 | 1–2 | Oxidation | — |
| Flurazepam | 1 | 8 | 15–30 | Oxidation | Hydroxyethylflurazepam Flurazepam aldehyde |
| Quazepam | 2 | 39 | 7.5–15 | N-dealkylation | N-DAF ^b |
| | | | | Oxidation | 2-Oxo-quazepam |
| Temazepam | 1.5 | 10–15 | 15–30 | Conjugation | — |
| Triazolam | 1 | 2 | 0.125–0.25 | Oxidation | — |

^a Time to peak plasma concentration.^b *N*-desalkylflurazepam, mean half-life 47 to 100 hours.

Benzodiazepines bind to GABA receptors in the brain resulting in stimulatory effects on GABAergic transmission and hyperpolarization of neuronal membranes. They have sedative, anxiolytic, muscle relaxant, and anticonvulsant properties. Benzodiazepines relieve insomnia by reducing sleep latency and increasing total sleep time. Benzodiazepines increase stage 2 sleep while decreasing REM, stage 3, and stage 4 sleep.¹¹ Benzodiazepines are very safe, and fatal overdoses are rare unless they are taken in combination with CNS depressants or alcohol.¹¹

■ Pharmacokinetics

The choice of a particular benzodiazepine is based on its pharmacokinetic profile. When used as a single dose, the extent of distribution and elimination half-life is important in predicting the duration of action. However, after multiple dosing, the elimination half-life and formation of active metabolites determine the extent of drug accumulation and resultant clinical effects.¹¹ The benzodiazepine pharmacokinetic profiles are summarized in Table 71–4. The onset of action depends on the rate of absorption. Flurazepam and triazolam are absorbed rapidly. Temazepam is less lipophilic and has a slower onset of effect. Sedation after flurazepam, estazolam, and quazepam occurs within 1 to 2 hours after ingestion.¹¹ Triazolam is redistributed quickly because of its high lipophilicity and thus has a short duration of effect.¹¹ Estazolam and temazepam are intermediate in their duration of action. The therapeutic effects of flurazepam and quazepam are long in comparison because of the active metabolites.

With the exception of temazepam, which is eliminated by conjugation, all benzodiazepine hypnotics are metabolized by hepatic microsomal oxidation and then undergo glucuronide conjugation. Oxidation may be inhibited in patients with impaired liver function, advanced age, or concurrent use of drugs that inhibit oxidation. Drugs that inhibit the cytochrome P450 3A4 enzyme (e.g., erythromycin, nefazodone, fluvoxamine, and ketoconazole) reduce the clearance of triazolam and increase its plasma concentrations.¹¹

Triazolam, which has a short elimination half-life, and estazolam and temazepam, which have intermediate elimination half-lives, lack clinically significant metabolites. Flurazepam and quazepam have long elimination half-lives. Flurazepam is metabolized rapidly to two short-acting metabolites, hydroxyethylflurazepam and flurazepam aldehyde. These metabolites contribute to sleep induction on the first night of therapy, but are eliminated within 13 hours.¹¹ *N*-desalkylflurazepam (*N*-DAF) is an active metabolite that has a very long half-life and accumulates extensively during multiple dosing.

N-DAF accounts for most flurazepam pharmacologic effects. Quazepam and one of its metabolites, 2-oxo-quazepam, have elimination half-lives of 39 hours.¹¹ Quazepam's oxo-quazepam metabolite is metabolized to *N*-DAF. If oxidation of *N*-DAF is impaired its half-life becomes prolonged, and complications of drug accumulation may result with repeated dosing; however, tolerance may develop to these effects. *N*-DAF may be useful when daytime anxiety or early morning awakening are complaints, but daytime sedation and impaired psychomotor performance may complicate therapy.¹¹

■ Adverse Effects

Side effects are dose dependent and vary according to the pharmacokinetics of the individual benzodiazepine. High doses with long or intermediate elimination half-lives have a greater potential for producing daytime sedation and performance impairment. These effects include excessive drowsiness, psychomotor incoordination, decreased concentration, and cognitive deficits. Tolerance may develop with time. Rapidly eliminated benzodiazepines have less potential for daytime sedation.¹¹

Tolerance to benzodiazepine hypnotic effects develops sooner with triazolam (after 2 weeks of continuous use) than with other benzodiazepine hypnotics.¹¹ The hypnotic efficacy of flurazepam, quazepam, and temazepam is maintained for 1 month of continuous nightly use.¹¹ Estazolam reportedly maintains the duration and quality of sleep at the maximum dosage (2 mg nightly) for up to 12 weeks.¹¹ Long-term use (greater than 6 months) of benzodiazepines was associated with a low risk of abuse, side effects, and tolerance in patients with severe, chronic sleep disorders; however, efficacy has not been established.¹¹

Anterograde amnesia, an impairment of memory and recall, occurs more frequently with triazolam than with temazepam; however, it has been reported with most benzodiazepines.¹¹ The lowest effective dosage should be used to avoid adverse effects on memory. When compared with temazepam, triazolam use was associated with a higher reported rate of confusion, bizarre behavior, agitation, and hallucination. These CNS effects occurred with higher doses and in older patients.¹¹ Because of the high incidence of CNS adverse effects, the United Kingdom suspended sales of triazolam in 1991.¹¹ Controversy surrounding triazolam led the FDA to review the agent in 1990 and 1992. Triazolam was considered safe and effective, but caution was noted regarding possible memory problems.

Rebound insomnia is characterized by increased wakefulness beyond baseline amounts that last for one to two nights after abrupt

discontinuation of benzodiazepine hypnotics with short or intermediate elimination half-lives. Rebound insomnia occurs more frequently after high doses of triazolam, even when ingested intermittently.¹¹ The occurrence of rebound insomnia can be minimized by using the lowest effective dose and tapering the dose on discontinuation.¹¹

6 The incidence of CNS side effects increases with age secondary to prolonged benzodiazepine half-lives, which may increase the potential for drug accumulation. Prolonged sedation and cognitive and psychomotor impairment are concerns in the elderly. Drugs with short and intermediate elimination half-lives are associated with fewer performance deficits; however, they may be associated with more daytime anxiety in elderly patients. There is an association between falls and hip fractures and the use of benzodiazepines with long elimination half-lives; thus flurazepam and quazepam should be avoided in elderly patients.²⁵

EVALUATION OF THERAPEUTIC OUTCOMES

Hypnotic therapy is indicated in individuals with transient or short-term insomnia.¹⁵ Patients should be counseled that sleep will return to normal when the precipitating stressor is eliminated, and they should also be educated on strategies for stimulus control and good sleep hygiene (see Table 71–3). If the stressor is expected to last more than 1 week, intermittent hypnotic use (three or four nights per week) should be prescribed for no more than 3 weeks.

For patients with chronic insomnia, medical, psychiatric, and pharmacologic causes should be identified and managed.¹¹ If treat-

ment of an underlying disorder fails to result in improvement, intermittent pharmacotherapy may be indicated. If the insomnia is psychophysiologic, several months of supervised hypnotic therapy may help alleviate anxiety and re-establish a regular sleep pattern on drug discontinuation; however, these patients require nonpharmacologic therapy as well.¹⁷

7 Tolerance and dependence can be avoided by using hypnotics at the lowest possible dose, intermittently, and for the shortest duration possible. From the outset of therapy, patients should receive instruction on frequency of drug use and the expected duration of therapy, to prevent development of dependence.

Withdrawal symptoms can be diminished by tapering the dosage gradually. Patients should be counseled on rebound insomnia when benzodiazepine therapy is terminated. Patients with difficulty initiating sleep and those who require daytime alertness should receive the short-acting benzodiazepine hypnotics or zaleplon. Those with difficulty maintaining sleep or those with early morning awakening may benefit from an agent with an intermediate elimination half-life if daytime performance is required. Benzodiazepines with long elimination half-lives should be considered if management of daytime anxiety is required. There is no rationale for the concurrent use of two benzodiazepines to treat anxiety and insomnia.

Benzodiazepine hypnotics should not be prescribed for individuals with sleep apnea, a history of substance abuse, or during pregnancy. Patients should be instructed to avoid alcohol; even taking alcohol on the day after ingestion of a benzodiazepine with a long elimination half-life can result in additive CNS impairment. Prescriptions for benzodiazepine hypnotics should be accompanied by printed information and verbal counseling on precautions.

SLEEP APNEA

Sleep apnea is defined as the cessation of airflow at the nose and mouth lasting at least 10 seconds. Sleep apnea is quantified using polysomnography (PSG) and is classified into two major categories: obstructive and central. Central sleep apnea involves impairment of the respiratory drive, while obstructive sleep apnea is caused by intermittent upper airway obstruction. Some patients will experience both central and obstructive sleep apnea. Patients with this sleep disorder have a high risk of morbidity and mortality.²⁶

Sleep apnea is very common. Approximately 9% of females and 24% of males experience sleep apnea. Sleep apnea is two to three times more common in men, and it is more common in middle-aged men than in younger men.²⁶ As many as 80% of middle-aged men snore, and 25% of heavy snorers have sleep apnea. Sleep apnea may be less prevalent in elderly patients, and it is theorized that this may be evidenced by sleep apnea's effect on mortality.²⁶

OBSTRUCTIVE SLEEP APNEA

Obstructive sleep apnea (OSA) is a potentially life-threatening condition characterized by snoring. At one end of the spectrum are those individuals who snore intermittently with little sleep disruption, and at the other end are patients who snore heavily and have severe gas exchange disturbances and respiratory failure, causing them to gasp for air. These episodes are repeated as often as 600 times per night.²⁶ As a result of these frequent arousals, hypoxia and sleep fragmentation occur. Hypoxia may lead to daytime sleepiness, impaired attention and

memory, and personality changes. Individuals with sleep apnea are usually not aware of the snoring or respiratory pauses, and symptoms are most frequently reported by their bed partner.²⁶

OSA is caused by occlusion of the upper airway due to factors such as obesity, and fixed upper airway lesions such as polyps, as well as enlarged tonsils or adenoids or the tongue. It can also be caused by acromegaly, amyloidosis, and hypothyroidism, as well as neurological conditions that impair upper airway muscle tone.²⁶ Medical complications include arrhythmias, hypertension, cor pulmonale, and sudden death.²⁶

Treatment of OSA must be individualized and depends on the severity of the disordered breathing and the amount of sleep disruption. Patients with severe apnea (>20 episodes per hour on PSG and excessive daytime somnolence) and those with moderate apneas (5 to 20 episodes per hour on PSG and excessive daytime somnolence or other daytime symptoms) have shown significant improvement and reduction in mortality with treatment.²⁷ Nonpharmacologic measures are the treatments of choice.

8 Weight loss may eliminate the apnea and reduce daytime hypersomnia; however, improvement is only limited. Treatment of underlying causes of obstruction (e.g., tonsillectomy, nasal septal repair, and nonsedating antihistamines for allergic rhinitis) may eliminate apneas during sleep. In patients with mild apnea and snoring with no daytime symptomatology, management may include avoidance of a supine sleep position.²⁷

Continuous positive airway pressure (CPAP) during sleep is the standard treatment for most patients with OSA. CPAP acts as a splint to maintain the patency of the oropharynx during respiration. Compliance is variable, ranging from 25% to 70%, and is the major limitation

of this treatment.²⁶ One night of noncompliance results in a complete reversal of the gains made in daytime alertness.²⁷

9 The most important pharmacologic intervention is the avoidance of all CNS depressants (e.g., alcohol, anxiolytics, hypnotics, narcotics, and zolpidem). Preliminary studies suggest that zaleplon does not interfere with respiratory function. CNS depressant use is potentially lethal since it inhibits the brain's reflex ability to cause a mini-arousal and resume breathing. Medication therapy should be reserved for patients with mild OSA and those who are treatment resistant. Protriptyline in doses of 10 to 30 mg daily reduces the frequency of apneas and increases oxygen saturation.^{26,28} The mechanism of action may be related to a decrease in REM sleep, the sleep stage in which most apneas occur. Imipramine was found to exert similar effects to protriptyline in two uncontrolled studies.²⁸ Fluoxetine and paroxetine have shown results similar to those of protriptyline, with fewer adverse effects. The SSRIs may be preferable to tricyclic antidepressants due to their similar efficacy but fewer adverse effects.²⁸ Medroxyprogesterone (MPG) has proved disappointing in OSA, showing no results in curing nighttime apnea. In contrast, MPG does appear to have a beneficial effect in daytime hypercapnia. At present the only role for MPG is in OSA patients with awake respiratory failure or noncompliance with CPAP. Theophylline is a respiratory stimulant that has been frequently used in patients with OSA. Studies with theophylline have shown questionable efficacy. Some studies have shown a reduction in obstructive events, but an increase in the number of arousals, increasing daytime sleepiness.²⁶ Mixed reviews have also been found for antihypertensive agents. Studies have evaluated the effects of angiotensin-converting enzyme inhibitors, calcium channel blockers, metoprolol, and clonidine, showing reduction in the frequency of apnea. Studies have also shown that antihypertensives can increase OSA.²⁶ Thus the efficacy of these agents is unclear.

CENTRAL SLEEP APNEA

Central sleep apnea (CSA) is a form of apnea in which breathing effort is not detected, in contrast to obstructive apnea, in which attempts at breathing are vigorous. CSA makes up only 10% of all apneas. Hypercapnic patients usually present with a morning headache and daytime somnolence, while nonhypercapnic patients complain of insomnia and nocturnal awakenings with shortness of breath or gasping. Although the majority of cases are idiopathic, identifiable causes are nasal obstruction, autonomic nervous system lesions (e.g., cervical cordotomy), neurological diseases (e.g., poliomyelitis, encephalitis, and myasthenia gravis), and congestive heart failure.²⁶

The primary treatment approach for CSA is supplemental oxygen and CPAP.²⁹ Pharmacologic treatments include acetazolamide, theophylline, and MPG. Acetazolamide induces a metabolic acidosis that stimulates respiratory drive. Long-term studies have shown a 70% reduction in CSA with acetazolamide, and no effect on obstructed breathing events. It has been suggested that acetazolamide induces a resetting of the CO₂ response threshold. Clinical use is limited because of adverse effects such as electrolyte changes, paresthesias, and precipitation of calcium phosphate salts in alkaline urine.^{26,29} Theophylline may have some efficacy in CSA related to congestive heart failure. In one trial there was a 60% reduction in central apneas per hour of sleep compared with 20% with placebo,²⁹ but further study is needed. In nonhypercapnic CSA patients, treatment may consist of benzodiazepines (triazolam or temazepam) to reduce arousals, and acetazolamide, CPAP, and oxygen to stabilize breathing patterns.²⁶

NARCOLEPSY

Narcolepsy is a severely debilitating neurologic disease that affects an estimated 140,000 Americans.³⁰ Despite the debilitating nature of the symptoms, the disease may go undiagnosed or misdiagnosed for many years. Prevalence estimates differ between studies, but narcolepsy is estimated to occur in 0.03% to 0.06% of the adult population.³⁰ The diagnosis appears to be equal in men and women, although there may be a higher diagnostic rate in men. Narcolepsy has been noted in children and adolescents, but it is typically recognized in the second decade of life and increases in severity through the third or fourth decade.³⁰

Four characteristic symptoms differentiate narcolepsy from other sleep disorders, and are known as the *narcolepsy tetrad*: sleep attacks, cataplexy, hypnagogic hallucinations, and sleep paralysis. Individuals with narcolepsy complain of excessive daytime sleepiness, with sleep attacks that last up to 30 minutes. Individuals complain of hypersomnia, fatigue, impaired performance, and disturbed nighttime sleep.

Cataplexy is an episode of sudden bilateral loss of muscle tone resulting in the individual collapsing and is often precipitated by situations characterized by high emotion (e.g., laughter, anger, or excitement). The individual remains conscious, and the episode is brief, lasting seconds to several minutes. Cataplexy occurs in 70% to 80% of people with narcolepsy.³⁰ Sleep paralysis occurs when the individual is falling asleep or when waking. It is an episodic loss of voluntary muscle tone. The individual is awake, but is unable to move or speak. Hypnagogic (meaning at the threshold of sleep) and hypnopompic (meaning upon awakening) hallucinations are brief, dream-like experiences that intrude into wakefulness. Nearly 70% of narcoleptics experience these hallucinations, and unfortunately these symptoms sometimes lead to an incorrect diagnosis of mental illness.³⁰ Disturbed nighttime sleep has been recognized as an essential feature in almost all patients with narcolepsy.

Narcolepsy may have multiple causes, including a genetic predisposition, since 3% of patients have a first-degree relative with the disorder.³¹ Molecular studies including human leukocyte antigen (HLA) typing have found a high incidence of HLA-DR2 haplotypes among narcoleptics, although this does not appear to be the only determinant. In spite of the high incidence of HLA-DR2 haplotypes in narcoleptics, there is also a high incidence in the non-narcoleptic population that could lead to misdiagnosis.³¹

It is now generally accepted that narcolepsy results from one or more defects in the functioning of the hypocretin-orexin neurotransmitter system. Neurons containing hypocretin-orexin are found in the lateral hypothalamus and project to various parts of the brain that are thought to regulate sleep. In 75% of narcoleptic patients, hypocretin-orexin is undetectable in cerebrospinal fluid.³⁴ On post-mortem examination, individuals with narcolepsy have deficiencies in hypocretin-orexin-producing neurons.³⁵ Despite the strong association between hypocretin-orexin deficiency and narcolepsy, the primary cause is unknown. Available data do suggest that the destruction of hypocretin-orexin-producing cells is part of an autoimmune process.^{36,37}

In the sleep laboratory, individuals with narcolepsy have impairment of both the onset and offset of REM and NREM sleep. Narcoleptics are unable to maintain either REM or NREM sleep, which results in multiple arousals during the night. It is thought that the REM sleep disturbance during the night causes the symptoms of cataplexy, sleep paralysis, and hypnagogic hallucinations.³¹

► **TREATMENT: Narcolepsy**

Nonpharmacologic management of narcolepsy includes counseling the patient and family concerning the illness to alleviate misconceptions around the individual’s behavior. Good sleep hygiene should be encouraged as well as two or more brief daytime naps. Daytime naps lasting 15 minutes each may help the individual with narcolepsy stay refreshed for several hours.

Doses of medications used to treat narcolepsy are summarized in Table 71–5. Pharmacologic management of narcolepsy is focused on two primary areas: treatment of excessive daytime sleepiness (EDS) and treatment of cataplexy.

◀10 Modafinil, a racemic compound unrelated to psychostimulants, is the current standard for the treatment of EDS.³⁸ Modafinil selectively targets neuronal pathways in the hypothalamus that regulate the normal sleep-wake cycle. The precise mechanism by which modafinil promotes wakefulness is unknown. Modafinil is readily absorbed, reaches peak plasma concentrations in 2 to 4 hours, and has a half-life of 15 hours. The dose is between 200 and 400 mg/day.³⁹ The efficacy of modafinil in treating EDS has been demonstrated in several randomized studies. EDS may also be treated with stimulants to improve alertness and to increase daytime performance. Cataplexy is not significantly treated with modafinil and must be treated with anticataplectic agents.⁴⁰

Modafinil is well tolerated, with the most commonly reported adverse effects being headache, nausea, nervousness, anxiety, and insomnia. Adverse effects are usually mild in severity. Preliminary evidence for modafinil suggests no signs of tolerance, withdrawal after abrupt discontinuation, or risk of abuse.⁴¹

Dextroamphetamine and methylphenidate also have FDA approval for the treatment of narcolepsy. Methamphetamine has also been used on an off-label basis. Methylphenidate and amphetamines have a fast onset of effect and durations of 6 to 10 and 3 to 4 hours, respectively. The dose may range from 5 to 60 mg daily and divided

doses are recommended, although more expensive sustained-release forms are available.

The stimulants improve alertness and increase daytime performance. In addition to increasing alertness, they may elevate mood and prevent sleep. Side effects may include insomnia, hypertension, palpitations, and irritability. Tolerance to long-term stimulant therapy may occur, necessitating dosage increases. Amphetamine use is associated with more likelihood of abuse and tolerance, especially when prescribed in high doses. Compliance with stimulants is generally poor, especially when high doses are required.⁴⁰

Pemoline, a mild CNS stimulant, has been used for the treatment of narcolepsy. It has a delayed onset of effect, but it has a duration of 8 to 10 hours. Pemoline’s dosage range is 18.75 to 112.5 mg/day. Although less potent than the amphetamines, adherence tends to be better. Unfortunately, rare but potentially lethal liver toxicity and the need for frequent liver function testing limit the acceptance of this agent for the treatment of narcolepsy.³⁸

Stimulants do not treat cataplexy effectively. The most effective treatment for cataplexy is tricyclic antidepressants or fluoxetine. The mechanism of antidepressants in relieving cataplexy, hypnagogic hallucinations, and sleep paralysis is unknown. Imipramine, protriptyline, clomipramine, fluoxetine, and nortriptyline are effective in approximately 80% of patients. Selegiline improves hypersomnolence and cataplexy through REM suppression and an increase in REM latency. The cost of the medication is high, and experience with the high doses needed for narcolepsy is limited.

Sodium oxybate (γ -hydroxybutyrate) shows the most promise of new agents for the treatment of narcolepsy. Early investigations demonstrated that the nightly administration of sodium oxybate changed sleep architecture to close to that of normal sleep. Sodium oxybate has been shown to increase slow-wave sleep, decrease nighttime awakenings, and increase REM efficiency. Not only does it

TABLE 71–5. Drugs Used to Treat Narcolepsy

| Generic Name | Trade Name (Manufacturer) | Daily Dosage Range (mg) |
|--|--|-------------------------|
| Excessive daytime somnolence | | |
| Dextroamphetamine | Dexadrine (GlaxoSmithKline) generics (various) | 5–60 |
| Dextroamphetamine/amphetamine salts ^a | Adderall (Shire US) | 5–60 |
| Methamphetamine ^b | Desoxyn (Abbott) | 5–15 |
| Methylphenidate | Ritalin (Novartis), generics (various) | 30–80 |
| Modafinil | Provigil (Cephalon) | 200–400 |
| Pemoline | Cylert (Abbott) | 37.5–112.5 |
| Adjunct agents for cataplexy | | |
| Fluoxetine | Prozac (Lilly), generics (various) | 20–80 |
| Gamma-hydroxybutyrate | Xyrem (Orphan Medical) | 60 mg/kg per night |
| Imipramine | Tofranil (Novartis), generics (various) | 50–250 |
| Nortriptyline | Aventyl (Lilly), Pamelor (Sandoz), generics (various) | 50–200 |
| Protriptyline | Vivactil (Merck), generics (various) | 5–30 |
| Selegiline | Eldepryl (Somerset) | 20–40 |

^a Dextroamphetamine sulfate, dextroamphetamine saccharate, amphetamine aspartate, and amphetamine sulfate.

^b Not available in some states.

Compiled from U.S. Modafinil in Narcolepsy Multicenter Study Group⁴¹ and Standard of Practice Committee of the American Sleep Disorders Association. Practice parameters for the use of stimulants in the treatment of narcolepsy. *Sleep* 1994;17:348–351.

improve the symptoms of EDS, it also decreases episodes of sleep paralysis, cataplexy, and hypnagogic hallucinations. The FDA approved sodium oxybate (Xyrem) in 2002.⁴²

EVALUATION OF THERAPEUTIC OUTCOMES

The primary objective of pharmacologic treatment of narcolepsy is to reduce symptoms that adversely impact the quality of life. This includes alleviating daytime sleepiness with modafinil or stimulants. The goal is to produce the fullest possible return of normal function for patients at work, school, home, and socially. Cataplexy, hypnagogic hallucinations, and sleep paralysis should be treated when they are present and troublesome. The health care provider should consider

the benefit:risk ratio for the individual patient, the cost of medication, the convenience of administration, and cost of laboratory tests when selecting a medicine for the treatment of narcolepsy.³⁸

CLINICAL CONTROVERSY

Some clinicians believe that combinations of long- and short-acting stimulants are effective for the treatment of narcolepsy. Some stimulants have a short effective period, while others have a longer duration of activity and slower onset of action. By combining stimulants with different activities it may be possible to achieve alertness more rapidly and for a longer period. In addition, although published evidence is limited, combinations of stimulants and antidepressants may be of benefit for treatment of sleepiness and cataplexy.

CIRCADIAN RHYTHM DISORDERS

The sleep-wake cycle is under the circadian control of oscillators and can be disrupted by misalignment between an individual's biological clock and external demands on the sleep cycle. Circadian rhythm sleep disorders usually present with either insomnia or hypersomnia, depending on the individual's performance requirements. Two commonly occurring circadian rhythm sleep disorders are jet lag and shift work sleep problems.

JET LAG

Jet lag occurs when individuals travel through multiple time zones and have dramatic changes in zeitgebers. Sleep disturbances typically last for 2 to 3 days, but may last as long as 7 to 10 days if the time zone changes are greater than 8 hours. Compared to westward travel, eastward travel is associated with a longer duration of jet lag. Jet lag also leads to decreased alertness, decreased performance, and an increased incidence of gastrointestinal disturbances.

Treatment of jet lag includes nonpharmacologic and pharmacologic management. Jet lag can be avoided in coast-to-coast travel in the U.S. if the duration is less than 7 days and the normal sleep-wake cycle is observed. For travel lasting longer than 7 days, adjustment to a westbound time zone can be made by staying up and arising one to two hours later several days prior to the trip. If traveling east, an earlier bedtime and wake time for several days prior to the trip will help. Pharmacologic treatment of jet lag includes the use of short-acting benzodiazepines. Melatonin has also been used to restore the circadian rhythm.

SHIFT WORK SLEEP PROBLEMS

Shift workers comprise approximately 20% of the work force.⁴³ Night shift work causes a misalignment in the sleep-wake cycle and circadian rhythm that is associated with a decrease in alertness, performance, and quality of daytime sleep. More than 65% of workers on rotating shifts complain of insomnia compared with only 20% who work one shift.⁴³ Shift workers have a higher injury rate, rate of divorce, occurrence of on-the-job sleepiness, and incidence of substance use. Night shift workers are usually in a state of permanent circadian misalignment due to the tendency to revert to conventional sleep schedules on their days off.⁴³ The treatment approach for shift work sleep problems is to promote good sleep hygiene, recommending a day shift job, extending daytime sleep by sleeping in the afternoon, or

scheduling a 2- to 3-hour nap on days off from work. Hypnotics may be useful. Scheduled exposure to bright lights at night and darkness in the daytime improves adaptation to night work and daytime sleep.⁴³ Melatonin has also been used successfully.

DYSSOMNIA NOT OTHERWISE SPECIFIED

A sleep disorder that is not endogenous or due to a medical condition or substance-related condition is categorized as "not otherwise specified." Restless leg syndrome and periodic limb movements are two sleep disturbances that do not meet criteria for any of the other sleep disorders.

RESTLESS LEG SYNDROME

Restless leg syndrome (RLS), or Ekbom's syndrome, is characterized by paresthesias that are felt deep in the calf muscles and cause the urge to keep the legs in motion. Sometimes it is verbalized as feeling like pins and needles or a crawling or cramping sensation. Although it usually occurs in the calves, it may also occur in the thighs or arms. RLS can be very distressing, and in some cases it has led to suicide.⁴⁴ RLS occurs in both males and females, and occurs more frequently in the elderly. It has been associated with uremia, anemia, and pregnancy; caffeine, stress, and fatigue all tend to worsen symptoms. The diagnosis is made on the clinical presentation. The sensation is bilateral and occurs only during rest and inactivity and is relieved by either walking or moving the legs. The discomfort returns when the person tries to sleep, resulting in insomnia.⁴⁴

Pharmacologic treatment of RLS includes dopaminergic agents, benzodiazepines, opioids, or anticonvulsants. In mild cases of RLS, benzodiazepines may be first-line agents. Clonazepam, lorazepam, triazolam, and temazepam have been effective. Clonazepam 0.5 to 2 mg is most frequently studied. Opiates such as methadone 5 to 20 mg, codeine 30 to 120 mg, and oxycodone 2.5 mg are very effective, but the development of tolerance is a concern. Abuse potential with opiates is also a concern due to the chronic nature of the condition.² Other agents that have been used include apomorphine, amantadine, tramadol, magnesium, oxycodone, propoxyphene, gabapentin, bromocriptine, clonidine, and carbamazepine.⁴⁵⁻⁵⁰ Tolerance may develop with any agent used. Patients should take the agent early enough to allow for drug absorption prior to bedtime. In severe cases, levodopa and the dopamine agonists cabergoline, pergolide, pramipexole, and ropinirole may be useful. The initial dose of levodopa

is 50 mg 30 minutes before bedtime. This dose may be titrated, with most patients achieving benefit from levodopa 200 mg/carbidopa 50 mg.⁴⁴ Rebound symptoms may occur; however, dosing during the day or using sustained-release products may alleviate rebound.

NOCTURNAL MYOCLONUS (PERIODIC LEG MOVEMENTS)

Most patients with RLS also have periodic leg movements (PLMs), and approximately one-third of patients with PLMs have RLS.⁴⁸ Unlike RLS, PLMs are diagnosed in the sleep laboratory. A burst of muscle activity lasting 0.5 to 5 seconds is noted in the anterior tibialis EMG recording. Confirmation of diagnosis is at least 40 bursts within 8 hours of sleep.⁴⁸

PLMs are stereotypic, repetitive, periodic movements of the legs that occur during sleep every 20 to 40 seconds and last 10 minutes to several hours.⁴⁸ The movements usually involve the big toe, but the ankle, knee, and hip may also flex. They may be terminated by a violent kick or other body movement. The person does not recognize the problem and only notes the daytime consequence of insufficient sleep and morning leg cramps. Often the bed partner describes the person as a restless sleeper and notes that the bedcovers are in disarray. Renal failure may predispose to PLMs.⁵¹ Benzodiazepine withdrawal and TCAs may precipitate the condition. The treatment approach for PLMs is similar to that of RLS. While mild cases may not require treatment, more severe cases may require clonazepam, baclofen, or opiates. TCAs usually worsen the problem, although in one case series, imipramine 25 mg improved symptoms in five patients. Lamotrigine 100 mg has improved symptoms.⁵² The most severe cases are treated with levodopa or dopamine agonists. Patients should take their medications early enough prior to bedtime to allow for drug absorption.

PARASOMNIAS

Parasomnias are adverse events that either occur during sleep or are exaggerated by sleep. Many of these disorders are considered to be disorders of partial arousal from various sleep stages. Examples of parasomnias are sleepwalking disorder, sleep terror disorder, and nightmare disorder.

Sleepwalking and sleep terrors are found normally in children between the ages of 4 and 12 and usually resolve in adolescence. These disorders are associated with psychopathology only if they persist into adulthood.⁵³ Sleep terrors may begin in adults between the ages of 20 and 30. Onset of sleepwalking in adults without a history of sleepwalking as children should prompt a search for a neurological or substance use condition.⁵³ Sleepwalking and sleep terror disorder involve intrusions of wakefulness into NREM sleep during the first third of the night. In sleepwalking, individuals become ambulatory, are difficult to awaken, and are amnesic for the event. Sleep terrors involve intense fear and autonomic arousal. Individuals are difficult to awaken, inconsolable, and amnesic for the event.⁵³

Treatment of sleepwalking involves protecting the individual from harm by putting safety latches on doors and windows, removing hazardous objects from bedrooms, and covering glass doors with heavy curtains. Benzodiazepines, SSRIs, or TCAs may be beneficial in adults. Benzodiazepines may also be helpful in curtailing sleep terrors in adults.⁵³

Nightmares are anxiety-provoking dreams characterized by vivid recall. Treatment is directed at reducing stress, anxiety, and sleep deprivation. In extreme cases, low-dose benzodiazepines may be

indicated. Cyproheptadine may be useful for adults with frequent, extremely disturbing nightmares.⁵³

PHARMACOECONOMIC CONSIDERATIONS

Despite the prevalence of sleep disorders, most cases go undiagnosed and untreated. The direct cost of insomnia alone adds an estimated \$13.9 billion to the national health care bill each year.^{1,54} The direct and indirect costs of sleep disorders including medications, treatment, absenteeism, decreased productivity, accidents, hospitalizations, and increased morbidity and mortality is estimated to be between \$92.5 and \$107.5 billion annually. Improvements in recognition and treatment may decrease the economic burden and prevent progression to both medical and psychiatric disorders.⁵⁴

Quality of life may be improved by appropriate treatment. For example, treatment of OSA with nasal CPAP improved the number of years of good health by 5.5 quality-adjusted life years. Hypnotic therapy has also been found to markedly improve both the disorder and quality of life in shift workers.⁵⁴

EVALUATION OF THERAPEUTIC OUTCOMES

A decision analysis for dyssomnias is shown in Figure 71-1. Patients with short-term or chronic insomnia should be evaluated after 1 week of therapy to assess for drug efficacy, adverse effects, and adherence to nonpharmacologic recommendations. Patients should be instructed to keep a sleep diary. The diary requires daily recording of bedtime, wake time, latency of sleep onset, number and duration of awakenings, medication ingestion, naps, and an index of sleep quality.

Individuals with sleep apnea treated with weight reduction and CPAP or drug therapy should be evaluated after 2 to 4 weeks of treatment for improvement in alertness and daytime symptoms (reduction in headache frequency and severity, improvement in memory, and decreased irritability) and weight reduction. The bed partner can be consulted regarding reduced snoring and gasping episodes. A repeat PSG is indicated if the patient has not shown clinical improvement. Overall, the goals of therapy are to reduce the number of apneic episodes and improve oxygen saturation.

In individuals with narcolepsy, reduction in daytime sleepiness, cataplexy, hypnagogic and hypnopompic hallucinations, and sleep paralysis are monitored. Patients should be evaluated monthly until an optimal dose is achieved, and then every 6 to 12 months to assess for the development of adverse drug effects (e.g., mood changes, sleep disturbances, and cardiovascular abnormalities). If symptoms increase during therapy, PSG should be performed.

Patients with RLS or PLMs should be evaluated monthly to monitor for excessive daytime somnolence, tolerance, efficacy, and adverse effects of the medication. Because the conditions are chronic, assessment should occur every 6 to 12 months and should include monitoring for depression because it is a frequent complication that should be treated.

CONCLUSION

Disturbances of sleep affect approximately one-third of the population. Effective management of sleep disturbances requires an accurate diagnosis. Treatment of sleep disorders involves both nonpharmacologic and pharmacologic management. Identifiable causes of insomnia should be managed if possible before instituting pharmacologic

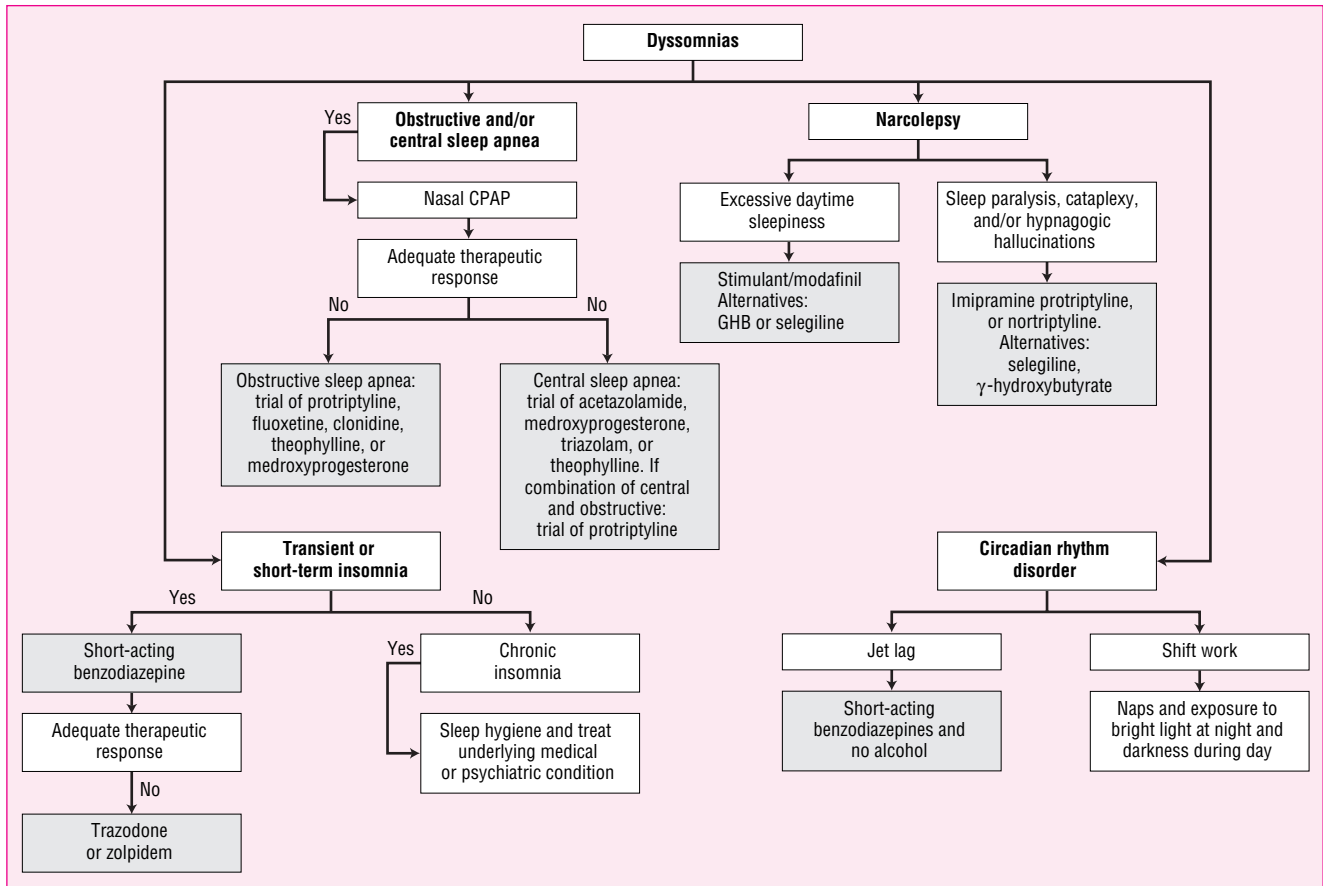

FIGURE 71-1. Algorithm for treatment of dyssomnias. (Adapted and reprinted with permission from Jermain DM. Sleep disorders. In: Jann M (ed): *Pharmacotherapy Self-Assessment Program*, 2nd ed. Kansas City, MO, American College of Clinical Pharmacy, 1995:139–154.)

therapy. Benzodiazepines are preferable for the treatment of short-term insomnia; however, their use is contraindicated in sleep apnea. Antidepressants are an alternative treatment for insomnia, and they effectively treat sleep apnea and some of the symptoms of narcolepsy. Modafinil, psychostimulants, TCAs, and fluoxetine are effective treatments for narcolepsy. Parasomnias and circadian rhythm disorders are usually managed nonpharmacologically. Mild cases of RLS and PLMs may be managed nonpharmacologically; more severe cases are treated with clonazepam, levodopa-carbidopa, or opiates.

PLM: periodic leg movement
 PSG: polysomnography
 REM: rapid eye movement (sleep)
 SSRI: selective serotonin reuptake inhibitor

DIABETES MELLITUS

Curtis L. Triplitt, Charles A. Reasner, and William L. Isley

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Diabetes mellitus is a group of metabolic disorders of fat, carbohydrate, and protein metabolism that results from defects in insulin secretion, insulin action (sensitivity), or both.
- 2 The incidence of type 2 diabetes mellitus (DM) is increasing. This has been attributed in part to increasing obesity, sedentary lifestyle, and an increasing minority population.
- 3 The two major classifications of diabetes mellitus are type 1 (insulin deficient) and type 2 (combined insulin resistance and relative deficiency in insulin secretion). They differ in clinical presentation, onset, etiology, and progression of disease. Both are associated with microvascular and macrovascular disease complications.
- 4 Diagnosis of diabetes is made by three criteria: fasting plasma glucose ≥ 126 mg/dL, a 2-hour value from a 75-g oral glucose tolerance test ≥ 200 mg/dL, or a casual plasma glucose level of ≥ 200 mg/dL with symptoms of diabetes; with results confirmed by any of the three criteria on a separate day.
- 5 Goals of therapy in diabetes mellitus are directed at reducing symptoms of hyperglycemia, reducing the onset and progression of retinopathy, nephropathy, and neuropathy complications, intensive therapy for associated cardiovascular risk factors, and improving quality and quantity of life.
- 6 Metformin should be included in the therapy for all type 2 DM patients, if tolerated and not contraindicated, as it is the only oral antihyperglycemic medication proven to reduce the risk of total mortality and cardiovascular death, according to the United Kingdom Prospective Diabetes Study.
- 7 Intensive glycemic control is paramount for reduction of microvascular complications (neuropathy, retinopathy, and nephropathy) as evidenced by the Diabetes Control and Complications Trial in type 1 DM and the United Kingdom Prospective Diabetes Study (UKPDS) in type 2 DM. The UKPDS also reported that control of hypertension in patients with diabetes will not only reduce the risk of retinopathy and nephropathy, but also reduce cardiovascular risk.
- 8 Knowledge of the patient's quantitative and qualitative meal patterns, activity levels, pharmacokinetics of insulin preparations, and pharmacology of oral antihyperglycemic agents are essential to individualize the treatment plan and optimize blood glucose control while minimizing risks for hypoglycemia and other adverse effects of pharmacologic therapies.
- 9 Type 1 treatment necessitates insulin therapy. Currently, the basal-bolus insulin therapy or pump therapy in motivated individuals often leads to successful glycemic outcomes. Basal-bolus therapy often includes a basal insulin for fasting and postabsorptive control, and rapid acting bolus insulin for mealtime coverage. Therapeutically, use of basal-bolus therapy in type 2 DM is increasing.
- 10 Treatment of type 2 DM often necessitates use of multiple therapeutic agents (combination therapy), including oral antihyperglycemics and insulin to obtain glycemic goals.
- 11 Aggressive management of cardiovascular disease risk factors in type 2 DM is necessary to reduce the risk for adverse cardiovascular events or death. Smoking cessation, use of antiplatelet therapy as a primary prevention strategy, aggressive management of dyslipidemia minimally to goal low-density lipoprotein-cholesterol (LDL-C) (< 100 mg/dL) and secondarily to raise high-density lipoprotein-cholesterol (HDL-C) to ≥ 40 mg/dL, and treatment of hypertension (again often requiring multiple drugs) minimally to $< 130/80$ mm Hg are vital.
- 12 Prevention strategies for type 1 DM have been unsuccessful. Prevention strategies for type 2 DM are established. Lifestyle changes, dietary restriction of fat, aerobic exercise for 30 minutes 5 times a week, and weight loss, form the backbone of successful prevention. To date, medications have been less effective than lifestyle changes to prevent progression to type 2 DM.
- 13 Patient education and ability to demonstrate self-care and adherence to therapeutic lifestyle and pharmacologic interventions are crucial to successful outcomes. Multidisciplinary teams of health care professionals including physicians (primary care, endocrinologists, ophthalmologists, and vascular surgeons), podiatrists, dietitians, nurses, pharmacists, social workers, behavioral health specialists, and certified diabetes educators are needed to optimize these outcomes in persons with diabetes mellitus.

1 Diabetes mellitus (DM) is a group of metabolic disorders characterized by hyperglycemia; is associated with abnormalities in carbohydrate, fat and protein metabolism; and results in chronic complications including microvascular, macrovascular, and neuropathic disorders. Nearly 18.2 million Americans have DM, yet only about two-thirds of them have been diagnosed.¹ The economic burden of DM approximated 132 billion dollars in 2002, including direct medical and treatment costs as well as indirect costs attributed to disability and mortality.¹ DM is the leading cause of blindness in adults aged 20 to 74 years, and the leading contributor to development of end-stage renal disease. It also accounts for approximately 82,000 lower extremity amputations annually.¹ Finally, a cardiovascular event is responsible for 75% of deaths in individuals with type 2 DM.¹

Although efforts to control hyperglycemia and associated symptoms are important, the major challenges in optimally managing the patient with DM are targeted at reducing or preventing complications, and improving life expectancy and quality of life. Research and drug development efforts over the past several decades have provided valuable information that applies directly to improving outcomes in patients with DM and have expanded the therapeutic armamentarium. Additionally, interventions in an attempt to prevent disease in high-risk populations have been reported for type 1 and 2 DM.

EPIDEMIOLOGY

Typical type 1 DM is an autoimmune disorder developing in childhood or early adulthood, although some latent forms do occur. Type 1 DM accounts for up to 10% of all cases of DM and is likely initiated by the exposure of a genetically susceptible individual to an environmental agent.² Candidate genes and environmental factors are reportedly prevalent in the general population, but development of β -cell autoimmunity occurs in less than 10% of the population and progresses to diabetes mellitus in less than 1% of the population.³

The prevalence of β -cell autoimmunity appears proportional to the incidence of type 1 DM in various populations. For instance, the countries of Sweden, Sardinia, and Finland have the highest prevalence of islet cell antibody (3% to 4.5%) and are associated with the highest incidence of type 1 DM, 22 to 35 per 100,000.⁴

Markers of autoimmunity have been detected in 14% to 33% of persons with type 2 DM in some populations and manifest with early failure of oral agents and insulin dependence. This type of DM has also been referred to as latent autoimmune diabetes in adults (LADA).⁴

Type 1 DM idiopathic is a nonimmune form of diabetes frequently seen in minorities with intermittent insulin requirements.⁵ The prevalence of type 1 DM has been increasing over the last one hundred years.⁶ Maturity onset diabetes of youth (MODY), which has an identifiable genetic defect in the glucokinase gene, and endocrine disorders such as acromegaly and Cushing’s syndrome, can be secondary causes of DM.⁷ These unusual etiologies, however, only account for 1% to 2% of the total cases of type 2 DM. See the section on other forms of diabetes mellitus later in this chapter for further discussion.

2 The prevalence of type 2 DM is increasing. Type 2 DM accounts for as much as 90% of all cases of DM, and overall the prevalence of type 2 DM in the United States is about 8.7% in persons age 20 or older. However, there is likely one person undiagnosed for every two persons currently diagnosed with the disease.¹ Multiple

FIGURE 72-1. Percentage of the population with diagnosed diabetes by age for the period 1991–1993. (Adapted from National Institutes of Health. Diabetes in America, 2nd ed. 1995.)

risk factors for the development of type 2 DM have been identified, including family history (i.e., parents or siblings with diabetes); obesity (i.e., $\geq 20\%$ over ideal body weight, or body mass index [BMI] ≥ 25 kg/m²); habitual physical inactivity; race or ethnicity (see list below); previously identified impaired glucose tolerance or impaired fasting glucose; hypertension ($\geq 140/90$ mm Hg in adults); high-density lipoprotein (HDL) cholesterol ≤ 35 mg/dL and/or a triglyceride level ≥ 250 mg/dL; history of gestational diabetes mellitus or delivery of a baby weighing >9 pounds; history of vascular disease; and polycystic ovary disease.⁸ The prevalence of type 2 DM increases with age, it is more common in women than in men in the United States, and varies widely among various racial and ethnic populations, being especially increased in some groups of Native Americans, Hispanic-American, Asian-American, African-American, and Pacific Island people⁴ (Figs. 72–1 and 72–2). While the prevalence of type 2 DM increases with age, the disorder is increasingly being recognized in adolescence. Much of the rise in adolescent type 2 DM is related to an increase in adiposity and sedentary lifestyle, in addition to an inheritable predisposition.⁹ Most cases of type 2 DM do not have a well-known cause; therefore it is uncertain whether it represents a few or many independent disorders manifesting as hyperglycemia.¹⁰ With increasing worldwide obesity, the prevalence of type 2 DM is increasing, though this has been recently disputed, suggesting that we are primarily just finding more cases through more aggressive screening.¹¹

Gestational diabetes mellitus (GDM) complicates roughly 7% of all pregnancies in the United States.¹² Most women will return to normoglycemia postpartum, but 30% to 50% will develop type 2 DM or glucose intolerance later in life.

FIGURE 72-2. Prevalence of diabetes mellitus (ages 45–74 years) in U.S. whites, blacks (1976–1980), and Latinos (1982–1984). (Adapted from National Institutes of Health. Diabetes in America, 2nd ed. 1995.)

PATHOGENESIS, DIAGNOSIS, AND CLASSIFICATION

CLASSIFICATION OF DIABETES

Diabetes is a metabolic disorder characterized by resistance to the action of insulin, insufficient insulin secretion, or both.¹³ The clinical manifestation of these disorders is hyperglycemia. The vast majority of diabetic patients are classified into one of two broad categories: type 1 diabetes caused by an absolute deficiency of insulin, or type 2 diabetes defined by the presence of insulin resistance with an inadequate compensatory increase in insulin secretion. Women who develop diabetes due to the stress of pregnancy are classified as having gestational diabetes. Finally, uncommon types of diabetes caused by infections, drugs, endocrinopathies, pancreatic destruction, and known genetic defects are classified separately (Table 72–1).

TYPE 1 DIABETES

3 This form of diabetes results from autoimmune destruction of the β cells of the pancreas. Markers of immune destruction of the β cell are present at the time of diagnosis in 90% of individuals and include islet cell antibodies, antibodies to glutamic acid decarboxylase, and antibodies to insulin. While this form of diabetes usually occurs in children and adolescents, it can occur at any age. Younger individuals typically have a rapid rate of β -cell destruction and present with ketoacidosis, while adults often maintain sufficient insulin secretion to prevent ketoacidosis for many years, which is often referred to as latent autoimmune diabetes in adults (LADA).⁴

TYPE 2 DIABETES

3 This form of diabetes is characterized by insulin resistance and at least initially, a relative lack of insulin secretion. Most individuals with type 2 diabetes exhibit abdominal obesity which itself causes insulin resistance. In addition, hypertension, dyslipidemia (high triglyceride levels and low HDL-cholesterol levels), and elevated inhibitor plasminogen activator-1 (PAI-1) levels are often present in these individuals. This clustering of abnormalities is referred to as the “insulin resistance syndrome” or the “metabolic syndrome.” Because of these abnormalities, patients with type 2 diabetes are at increased risk of developing macrovascular complications. Type 2 diabetes has a strong genetic predisposition and is more common in all ethnic groups other than those of European ancestry. At this point the genetic cause of most cases of type 2 diabetes is not well defined.¹⁴

GESTATIONAL DIABETES MELLITUS

Gestational diabetes mellitus (GDM) is defined as glucose intolerance which is first recognized during pregnancy. Gestational diabetes complicates about 7% of all pregnancies. Clinical detection is important, as therapy will reduce perinatal morbidity and mortality.

OTHER SPECIFIC TYPES OF DIABETES

Genetic Defects

Maturity onset diabetes of youth (MODY) is characterized by impaired insulin secretion with minimal or no insulin resistance. Patients typically exhibit mild hyperglycemia at an early age. The disease is inherited in an autosomal dominant pattern with at least three different

loci identified to date. Genetic inability to convert proinsulin to insulin results in mild hyperglycemia and is inherited in an autosomal dominant pattern. Similarly, the production of mutant insulin molecules has been identified in a few families and results in mild glucose intolerance.

Several genetic mutations have been described in the insulin receptor and are associated with insulin resistance. Type A insulin resistance refers to the clinical syndrome of acanthosis nigricans, virilization in women, polycystic ovaries, and hyperinsulinemia. Leprechaunism is a pediatric syndrome with specific facial features and severe insulin resistance due to a defect in the insulin receptor gene. Lipoatrophic diabetes probably results from postreceptor defects in insulin signaling.

SCREENING

TYPE 1 DIABETES MELLITUS

There is still a low prevalence of type 1 DM in the general population and due to the acuteness of symptoms, screening for type 1 DM is not recommended.¹⁵

TYPE 2 DIABETES MELLITUS

Based on expert opinion, the American Diabetes Association (ADA) recommends screening for type 2 DM every 3 years in all adults beginning at age 45 years.¹⁶ Testing should be considered at an earlier age and more frequently in individuals with risk factors. The recommended screening test is the fasting plasma glucose. An oral glucose tolerance test (OGTT) (more costly, less convenient) can be performed alternatively or in addition to fasting plasma glucose when a high index of suspicion for the disease is present.⁵

CHILDREN AND ADOLESCENTS

Despite a lack of clinical evidence to support widespread testing of children for type 2 DM, it is clear that more children and adolescents are developing type 2 DM. The ADA recommends that overweight (defined as BMI >85th percentile for age and sex, weight for height >85th percentile, or weight >120% of ideal [50th percentile] for height) youths with at least two of the following risk factors: a family history of type 2 diabetes in first- and second-degree relatives; Native Americans, African-Americans, Hispanic-Americans, and Asians/South Pacific Islanders; and those with signs of insulin resistance or conditions associated with insulin resistance (acanthosis nigricans, hypertension, dyslipidemia, or polycystic ovary syndrome) be screened. Testing should be done every 2 years starting at 10 years of age or at the onset of puberty if it occurs at a younger age.¹⁶

GESTATIONAL DIABETES

Risk assessment for GDM should occur at the first prenatal visit. Women at high risk (positive family history, history of GDM, marked obesity, or member of a high-risk ethnic group) should be screened as soon as feasible. If the initial screening is negative they should undergo retesting at 24 to 28 weeks' gestation. Evaluation for GDM can be done in one of two ways. The one-step approach involves an OGTT only and may be cost-effective in high-risk patient populations. The two-step approach uses a screening test to measure plasma or serum glucose concentration 1-hour after a 50-g oral glucose load

TABLE 72-1. Etiologic Classification of Diabetes Mellitus

1. **Type 1 diabetes^a** (β -cell destruction, usually leading to absolute insulin deficiency)
 - Immune mediated
 - Idiopathic
2. **Type 2 diabetes^a** (may range from predominantly insulin resistance with relative insulin deficiency to a predominantly insulin secretory defect with insulin resistance)
3. **Other specific types**
 - Genetic defects of β -cell function (42)
 - Chromosome 20q, HNF-4 α (MODY1)
 - Chromosome 7p, glucokinase (MODY2)
 - Chromosome 12q, HNF-1 β (MODY3)
 - Chromosome 13q, insulin promoter factor (MODY4)
 - Chromosome 17q, HNF-1 β (MODY5)
 - Chromosome 2q, neurogenic differentiation 1/ β -cell e-box transactivator 2 (MODY 6)
 - Mitochondrial DNA
 - Others
 - Genetic defects in insulin action
 - Type 1 insulin resistance
 - Leprechaunism
 - Rabson-Mendenhall syndrome
 - Lipoatrophic diabetes
 - Others
 - Diseases of the exocrine pancreas
 - Pancreatitis
 - Trauma/pancreatectomy
 - Neoplasia
 - Cystic fibrosis
 - Hemochromatosis
 - Fibrocalculous pancreatopathy
 - Others
 - Endocrinopathies
 - Acromegaly
 - Cushing's syndrome
 - Glucagonoma
 - Pheochromocytoma
 - Hyperthyroidism
 - Somatostatinoma
 - Aldosteronoma
 - Others
 - Drug- or chemical-induced
 - Vacor (pyriminil)
 - Pentamidine
 - Nicotinic acid
 - Glucocorticoids
 - Thyroid hormone
 - Diazoxide
 - β -Adrenergic agonists
 - Thiazides
 - Phenytoin
 - α -Interferon
 - Others
 - Infections
 - Congenital rubella
 - Cytomegalovirus
 - Others
 - Uncommon forms of immune-mediated diabetes
 - "Stiff-man" syndrome
 - Anti-insulin receptor antibodies
 - Others
 - Other genetic syndromes sometimes associated with diabetes
 - Down's syndrome
 - Klinefelter's syndrome
 - Turner's syndrome
 - Wolfram's syndrome
 - Friedreich's ataxia
 - Huntington's chorea
 - Laurence-Moon-Biidel syndrome
 - Myotonic dystrophy
 - Porphyria
 - Prader-Willi syndrome
 - Others
4. **Gestational diabetes mellitus (GDM)**

^a Patients with any form of diabetes may require insulin treatment at some stage of their disease. Such use of insulin does not in itself classify the patient.

Adapted with permission from Report of the Expert Committee.¹³

TABLE 72–2. Diagnosis of Gestational Diabetes Mellitus with a 100-g or 75-g Glucose Load

| 100-g Glucose load | |
|--------------------|--------------------------|
| Time | Plasma Glucose |
| Fasting | ≥95 mg/dL (5.3 mmol/L) |
| 1 hour | ≥180 mg/dL (10.0 mmol/L) |
| 2 hours | ≥155 mg/dL (8.6 mmol/L) |
| 3 hours | ≥140 mg/dL (7.8 mmol/L) |
| 75-g Glucose load | |
| Fasting | ≥95 mg/dL (5.3 mmol/L) |
| 1 hour | ≥180 mg/dL (10.0 mmol/L) |
| 2 hours | ≥155 mg/dL (8.6 mmol/L) |

Two or more values must be met or exceeded for a diagnosis of diabetes to be made. The test should be done in the morning after an 8- to 14-hour fast.

(glucose challenge test [GCT]), followed by a diagnostic OGTT on the subset of women exceeding a glucose threshold of either >140 mg/dL (80% sensitive) or >130 mg/dL (90% sensitive). The diagnosis of GDM is based on a 75-g (not as well validated) or 100-g OGTT. Criteria for diagnosis of GDM based on the OGTT are summarized in Table 72–2.

DIAGNOSIS OF DIABETES

4 The diagnosis of diabetes requires the identification of a glycemic cut point, which discriminates normals from diabetics (Table 72–3). The present cut points reflect the level of glucose above which microvascular complications have been shown to increase. Cross-sectional studies from Egypt, in Pima Indians, and in a representative sample from the United States have shown a consistent increase in the risk of developing retinopathy at a fasting glucose level above 99 to 116 mg/dL (5.5 to 6.4 mmol/L), at a 2-hour postprandial level above 125 to 185 mg/dL (6.9 to 10.3 mmol/L), and a hemoglobin A_{1c} (HbA_{1c}) above 5.9 to 6.0% (Fig. 72–3).^{13,17,18}

The ADA recommends using the fasting glucose as the principal tool for the diagnosis of diabetes mellitus in nonpregnant adults. In addition, as shown in Table 72–4, they defined a new category of glycemia, impaired fasting glucose (IFG). IFG is a plasma glucose of at least 100 mg/dL (5.6 mmol/L) but less than 126 mg/dL (7.0 mmol/L). This category corresponds to the category of impaired glucose tolerance (IGT), defined as a 2-hour glucose value ≥140 mg/dL (7.8 mmol/L), but less than 200 mg/dL (11.0 mmol/L) during an OGTT. Patients with either IFG or IGT are now commonly referred to as having “prediabetes” due to a higher risk of developing diabetes in the future.

TABLE 72–3. Criteria for the Diagnosis of Diabetes Mellitus^a

| |
|---|
| Symptoms of diabetes plus casual ^b plasma glucose concentration ≥200 mg/dL (11.1 mmol/L) |
| or |
| Fasting ^c plasma glucose ≥126 mg/dL (7.0 mmol/L) |
| or |
| 2-hour postload glucose ≥200 mg/dL (11.1 mmol/L) during an OGTT ^d |

^aIn the absence of unequivocal hyperglycemia, these criteria should be confirmed by repeat testing on a different day. The third measure (oral glucose tolerance test; OGTT) is not recommended for routine clinical use.

^bCasual is defined as any time of day without regard to time since last meal. The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.

^cFasting is defined as no caloric intake for at least 8 hours.

^dThe test should be performed as described by the World Health Organization, using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.

TABLE 72–4. Categorization of Glucose Status

| |
|---|
| <i>Fasting plasma glucose (FPG)</i> |
| Normal |
| • FPG <100 mg/dL (5.6 mmol/L) |
| Impaired fasting glucose (IFG) |
| • 100–125 mg/dL (5.6–6.9 mmol/L) |
| Diabetes mellitus ^a |
| • FPG ≥126 mg/dL (7.0 mmol/L) |
| <i>2-Hour postload plasma glucose (oral glucose tolerance test)</i> |
| Normal |
| • Postload glucose <140 mg/dL (7.8 mmol/L) |
| Impaired glucose tolerance (IGT) |
| • 2-hour postload glucose 140–199 mg/dL (7.8–11.1 mmol/L) |
| Diabetes mellitus ^a |
| • 2-hour postload glucose ≥200 mg/dL (11.1 mmol/L) |

^aProvisional diagnosis of diabetes (diagnosis to be confirmed; see Table 72–3).

The fasting and postprandial glucose levels do not measure the same physiologic processes and do not identify the same individuals as having diabetes. The fasting glucose reflects hepatic glucose production, which depends on insulin secretory capacity of the pancreas. The postprandial glucose reflects uptake of glucose in peripheral tissues (muscle and fat) and depends on insulin sensitivity of these tissues.

The ADA recommends use of hemoglobin A_{1c} (HbA_{1c}) determinations to monitor glycemic control in known diabetic patients. Because there is no gold standard assay and several countries do not have ready access to the test, an HbA_{1c} determination is not recommended to diagnose diabetes at the present time.

PATHOGENESIS

TYPE 1 DIABETES MELLITUS

Type 1 DM is characterized by an absolute deficiency of insulin. Most often this is the result of an immune-mediated destruction of pancreatic β cells, but rare unknown or idiopathic processes may contribute. What is evident are four main features: (1) a long preclinical period marked by the presence of immune markers when β -cell destruction is thought to occur; (2) hyperglycemia when 80% to 90% of β cells are destroyed; (3) transient remission (the so-called, “honeymoon” phase); and (4) established disease with associated risks for complications and death. Unknown is whether there is one or more inciting factors (e.g., cow’s milk, or viral, dietary, or other environmental exposure) that initiate the autoimmune process² (Fig. 72–4).

The autoimmune process is mediated by macrophages and T lymphocytes with circulating autoantibodies to various β -cell

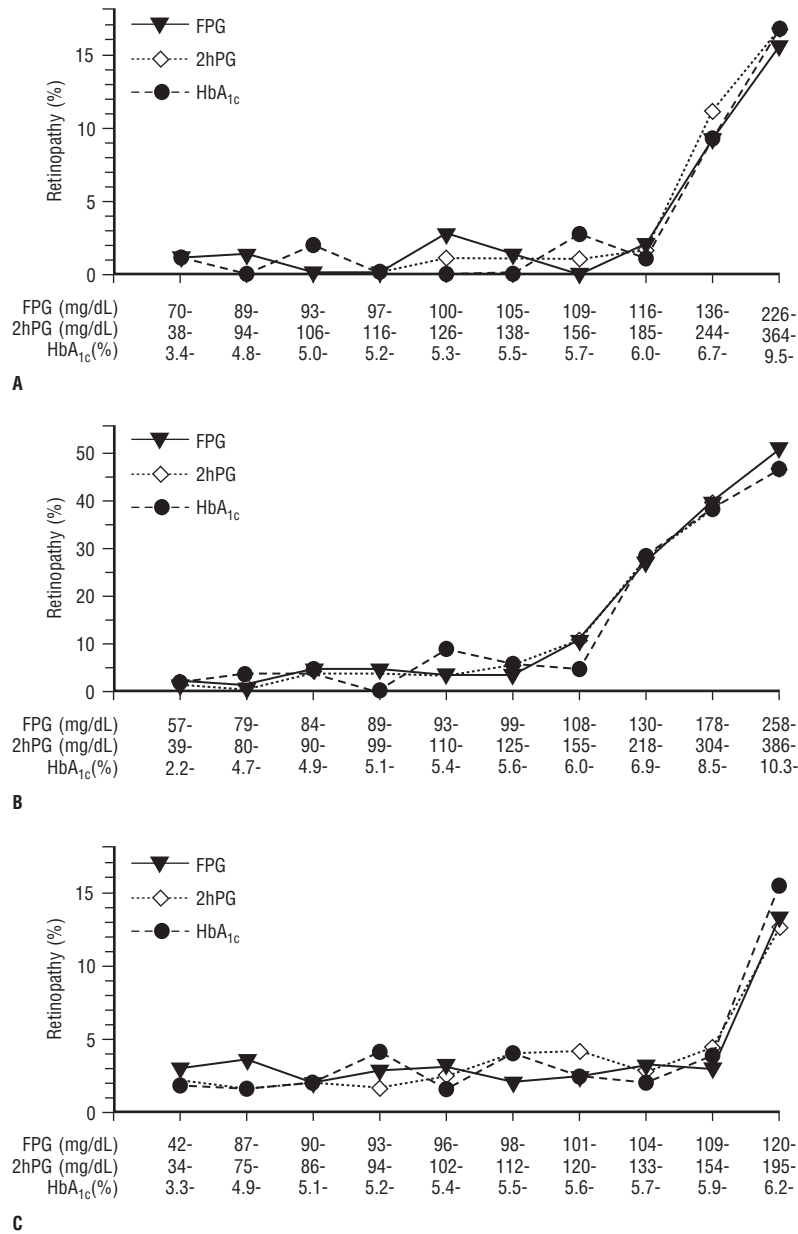

FIGURE 72-3. Prevalence of retinopathy by deciles of the distribution of fasting plasma glucose (FPG), 2-hour postprandial glucose (2-h PG), and hemoglobin A_{1c} (HbA_{1c}) in (A) Pima Indians,¹² (B) Egyptians,¹¹ and (C) in 40- to 74-year old participants in National Health and Nutrition Examination Survey (NHANES) III.¹³ The x-axis labels indicate the lower limit of each decile group. Note that these deciles and the prevalence rates of retinopathy differ considerably among the studies, especially the Egyptian study, in which diabetic subjects were oversampled. Retinopathy was ascertained by different methods in each study; therefore the absolute prevalence rates are not comparable between studies, but their relationships with FPG, 2-h PG, and HbA_{1c} are very similar within each population.

antigens. The most commonly detected antibody associated with type 1 DM is the islet cell antibody. The test for islet cell antibody, however, is difficult to standardize across laboratories. Other more readily measured circulating antibodies include insulin autoantibodies, antibodies directed against glutamic acid decarboxylase, insulin antibodies against islet tyrosine phosphatase, and several others. More than 90% of newly diagnosed persons with type 1 DM have one or another of these antibodies, as will 3.5% to 4% of unaffected first-degree relatives. Preclinical β -cell autoimmunity precedes the diagnosis of type 1 DM by up to 9 to 13 years. Autoimmunity may remit in some perhaps less-susceptible persons, or can progress to β -cell failure in

others. These antibodies are generally considered markers of disease rather than mediators of β -cell destruction. They have been used to identify individuals at risk for type 1 diabetes mellitus in evaluating disease prevention strategies. Other nonpancreatic autoimmune disorders are associated with type 1 DM, most commonly Hashimoto's thyroiditis, but the extent of organ involvement can range from no other organs to polyglandular failure.¹⁹

There are strong genetic linkages to the DQA and B genes and certain human leukocyte antigens (HLAs) may be predisposing (DR3 and DR4) or protective (DRB1*04008-DQB1*0302 and DRB1*0411-DQB1*0302) on chromosome 6.¹⁹ Other candidate gene

FIGURE 72-4. Scheme of the natural history of the β -cell defect in type 1 diabetes mellitus. (From ADA Medical Management of Type of 1 Diabetes, 3rd ed. 1998.)

regions have been identified on several other chromosomes as well. Because twin studies do not show 100% concordance, environmental factors such as infectious agents, chemical agents, and dietary agents are likely contributing factors in the expression of the disease.

TYPE 2 DIABETES MELLITUS

Normal Insulin Action

In the fasting state 75% of total body glucose disposal takes place in non-insulin dependent tissues: the brain and splanchnic tissues (liver and gastrointestinal tissues).²⁰ In fact, brain glucose uptake occurs at the same rate during fed and fasting periods and is not altered in type 2 diabetes.

The remaining 25% of glucose metabolism takes place in muscle, which is dependent on insulin.²¹ In the fasting state approximately 85% of glucose production is derived from the liver, and the remaining amount is produced by the kidney.^{20–22} In the fed state, carbohydrate ingestion increases the plasma glucose concentration and stimulates insulin release from the pancreatic β cells. The resultant hyperinsulinemia (1) suppresses hepatic glucose production and (2) stimulates glucose uptake by peripheral tissues.^{20,23} The majority (~80% to 85%) of glucose that is taken up by peripheral tissues is disposed of in muscle,^{20,23} with only a small amount (~4% to 5%) being metabolized by adipocytes.

Although fat tissue is responsible for only a small amount of total body glucose disposal, it plays a very important role in the maintenance of total body glucose homeostasis. Small increments in the plasma insulin concentration exert a potent antilipolytic effect, leading to a marked reduction in the plasma free fatty acid (FFA) level. The decline in plasma FFA concentration results in increased glucose uptake in muscle²⁴ and reduces hepatic glucose production.²⁵ Thus a decrease in the plasma FFA concentration lowers plasma glucose by both decreasing its production and enhancing the uptake in muscle.^{26,27}

Type 2 diabetic individuals are characterized by: (1) defects in insulin secretion; and (2) insulin resistance involving muscle, liver, and the adipocyte. Insulin resistance is present even in *lean* type 2 diabetic individuals (Fig. 72-5).

Impaired Insulin Secretion

The pancreas in people with a normal-functioning β cell is able to adjust its secretion of insulin to maintain normal glucose tolerance.

FIGURE 72-5. Whole body glucose disposal, a measure of insulin resistance, is reduced 40% to 50% in obese nondiabetic and lean type 2 diabetic individuals. Obese diabetic individuals are slightly more resistant than lean diabetic patients. (From DeFronzo RA. Diabetes Reviews 1977;5:177–269.)

Thus in nondiabetic individuals, insulin is increased in proportion to the severity of the insulin resistance and glucose tolerance remains normal. Impaired insulin secretion is a uniform finding in type 2 diabetic patients and the evolution of β -cell dysfunction has been well characterized in diverse ethnic populations.

DeFronzo and colleagues²⁸ measured the fasting plasma insulin concentration and performed oral glucose tolerance tests in 77 normal-weight type 2 diabetic patients and over 100 lean subjects with normal or impaired glucose tolerance (Fig. 72-6). The relationship between the fasting plasma glucose concentration and the fasting plasma insulin concentration resembles an inverted U or horseshoe. As the fasting plasma glucose concentration rises from 80 to 140 mg/dL, the fasting plasma insulin concentration increases progressively, peaking at a value that is 2- to 2.5-fold greater than in normal weight nondiabetic controls. When the fasting plasma glucose concentration

FIGURE 72-6. The relationship between fasting plasma insulin and fasting plasma glucose in 177 normal weight individuals. Plasma insulin and glucose increase together up to a fasting glucose of 140 mg/dL. When the fasting glucose exceeds 140 mg/dL, the β cell makes progressively less insulin, which leads to an overproduction of glucose by the liver and results in a progressive increase in fasting glucose. (Adapted from DeFronzo,²⁸ with permission.)

exceeds 140 mg/dL, the β cell is unable to maintain its elevated rate of insulin secretion and the fasting insulin concentration declines precipitously. This decrease in fasting insulin leads to an increase in hepatic glucose production overnight, which results in an elevated fasting plasma glucose concentration.²⁸

SITE OF INSULIN RESISTANCE IN TYPE 2 DIABETES

Liver

In type 2 diabetic subjects with mild to moderate fasting hyperglycemia (140 to 200 mg/dL, 7.8 to 11.1 mmol/L), basal hepatic glucose production is increased by ~ 0.5 mg/kg per minute. Consequently, during the overnight sleeping hours the liver of an 80-kg diabetic individual with modest fasting hyperglycemia adds an additional 35 g of glucose to the systemic circulation. This increase in fasting hepatic glucose production is the cause of fasting hyperglycemia.²⁰

Following glucose ingestion, insulin is secreted into the portal vein and carried to the liver, where it suppresses hepatic glucose output. If the liver is resistant to insulin and continues to produce glucose, there will be two inputs of glucose into the body, one from the liver and another from the gastrointestinal tract, and marked hyperglycemia will ensue.

Peripheral (Muscle)

Muscle is the major site of glucose disposal in man, and approximately 80% of total body glucose uptake occurs in skeletal muscle.²⁰ In response to a physiologic increase in plasma insulin concentration, muscle glucose uptake increases linearly, reaching a plateau value of 10 mg/kg per minute. In contrast, in lean type 2 diabetic subjects, the onset of insulin action is delayed for ~ 40 minutes, and the ability of insulin to stimulate leg glucose uptake is reduced by 50%. Therefore the primary site of insulin resistance in type 2 diabetic subjects resides in muscle tissue.

Peripheral (Adipocyte)

In obese nondiabetic and diabetic humans, basal plasma FFA levels are increased and fail to suppress normally after glucose ingestion. FFAs are stored as triglycerides in adipocytes and serve as an important energy source during conditions of fasting. Insulin is a potent inhibitor of lipolysis, and restrains the release of FFAs from the adipocyte by inhibiting the hormone-sensitive lipase enzyme. It is now recognized that chronically elevated plasma FFA concentrations can lead to insulin resistance in muscle and liver,^{20,24,27,29} and impair insulin secretion.^{26,30,31} In addition to FFAs that circulate in plasma in increased amounts, type 2 diabetic and obese nondiabetic individuals have increased stores of triglycerides in muscle^{32,33} and liver,^{34,35} and the increased fat content correlates closely with the presence of insulin resistance in these tissues.

In summary, insulin resistance involving both muscle and liver are characteristic features of the glucose intolerance in type 2 diabetic individuals. In the basal state, the liver represents a major site of insulin resistance, and this is reflected by overproduction of glucose. This accelerated rate of hepatic glucose output is the primary determinant of the elevated fasting plasma glucose concentration in type 2 diabetic individuals. In the fed state, both decreased muscle glucose uptake and impaired suppression of hepatic glucose production contribute to the insulin resistance. In obese individuals and in the majority ($>80\%$) of type 2 diabetic subjects, there is an expanded fat cell mass and the adipocytes are resistant to the antilipolytic effects of insulin. Most obese and diabetic individuals are characterized by expanded visceral adiposity, discussed in detail later in the chapter,

which is especially refractory to insulin effects and results in a high lipolytic rate. Not surprisingly, both type 2 diabetes and obesity are characterized by an elevation in the mean 24-hour plasma FFA concentration. Elevated plasma FFA levels, as well as increased triglyceride/fatty acyl CoA content in muscle, liver, and β cells, lead to the development of muscle/hepatic insulin resistance and impaired insulin secretion.

CELLULAR MECHANISMS OF INSULIN RESISTANCE

Insulin resistance and the components of the insulin resistance syndrome are described below.

Obesity and Insulin Resistance

Weight gain leads to insulin resistance, and obese nondiabetic individuals have the same degree of insulin resistance as lean type 2 diabetic patients.³⁶ In 1,146 nondiabetic, normotensive individuals, Ferrannini and associates showed a progressive loss of insulin sensitivity when the BMI increased from 18 kg/m² to 38 kg/m².³⁷ The increase in insulin resistance with weight gain is directly related to the amount of visceral adipose tissue.^{38,39}

The term *visceral adipose tissue* (VAT) refers to fat cells located within the abdominal cavity and includes omental, mesenteric, retroperitoneal, and perinephric adipose tissue. VAT has been shown to correlate with insulin resistance and explain much of the variation in insulin resistance seen in a population of African-Americans.⁴⁰ Visceral adipose tissue represents 20% of fat in men and 6% of fat in women. This fat tissue has been shown to have a higher rate of lipolysis than subcutaneous fat, resulting in an increase in free fatty acid production. These fatty acids are released into the portal circulation and drain into the liver, where they stimulate the production of very-low-density lipoproteins and decrease insulin sensitivity in peripheral tissues.³⁸ VAT also produces a number of cytokines which cause insulin resistance. These factors drain into the portal circulation and reduce insulin sensitivity in peripheral tissues.⁴¹

The fat cell also has the capability of producing at least one hormone that improves insulin sensitivity: adiponectin. This factor is made in decreasing amounts as an individual becomes more obese.^{42,43} In animal models, adiponectin decreases hepatic glucose production and increases fatty acid oxidation in muscle.^{44,45}

The Metabolic Syndrome

The association of insulin resistance with a clustering of cardiovascular risk factors including hyperinsulinemia, hypertension, abdominal obesity, dyslipidemia, and coagulation abnormalities has been referred to by a variety of names including “the insulin resistance syndrome,” “the metabolic syndrome,” “the dysmetabolic syndrome,” and “the deadly quartet,” to name a few. Since the description of the “insulin resistance syndrome” by Reaven in 1988,⁴⁶ the number of associated factors has continued to grow.

The most widely used criteria to define this syndrome were published as part of The National Cholesterol Education Program Adult Treatment Panel (NCEP-ATP) III Guidelines for the treatment of hypercholesterolemia.⁴⁷ The NCEP components of the metabolic syndrome are outlined in Table 72–5. The ATP guidelines establish a diagnosis of the metabolic syndrome when at least three of the five criteria are present. The metabolic syndrome has been assigned the diagnostic code 277.7 by the International Classification of Diseases, Ninth Revision,⁴⁸ which enables reimbursement for treating patients with this condition. The standard for the individual risk factors vary between NCEP-ATP and other expert panels including the World Health Organization and The American College of Endocrinology.

TABLE 72–5. Five Components of the Metabolic Syndrome (Individuals Having at Least Three Components Meet the Criteria for Diagnosis)

| Risk Factor | Defining Level |
|----------------------------|---------------------|
| Abdominal obesity | Waist circumference |
| Men | >102 cm (>40 in) |
| Women | >88 cm (>35 in) |
| Triglycerides | ≥150 mg/dL |
| High-density-lipoprotein C | |
| Men | <40 mg/dL |
| Women | <50 mg/dL |
| Blood pressure | ≥130/≥85 mm Hg |
| Fasting glucose | ≥110 mg/dL |

Reproduced from Expert Panel on Detection.⁴⁷

For example, NCEP-ATP uses waist circumference to define obesity, while other expert committees use the body mass index (BMI). The ATP guidelines base glucose intolerance on a fasting glucose while others prefer the results of an oral glucose tolerance test (OGTT). As we are better able to quantify the relationship between these factors and the development of cardiovascular disease, the definition of the syndromes and the individual component values will no doubt continue to be refined.

Prevalence. The insulin resistance syndrome (IRS) is common in the United States. Ford and colleagues analyzed the data from the Third National Health and Nutrition Evaluation Survey (NHANES III) carried out in 1988–1994.⁴⁹ The sample included 20,050 persons age 17 years and over, with glucose tolerance testing performed in 3,302 persons aged 40 to 74 years. Twenty six percent of this population had three or more of the metabolic abnormalities defined by the NCEP-ATP. The prevalence of the IRS increases with age, with 33% affected at age 40, 40% at age 50, and 50% by 60 years of age. The prevalence of the IRS also differs in various ethnic groups, with 52% of Mexican-Americans affected, compared to 36% of African-Americans and 40% of Caucasians.

The impact of treating the clinical components of the metabolic syndrome was demonstrated in the Steno-2 Study.⁵⁰ In this prospective study, 63 patients with diabetes and microalbuminuria were randomized to the usual therapy group and 67 patients were treated intensively. Intensive therapy consisted of diet and exercise and pharmacologic intervention aimed at hyperglycemia, hypertension, dyslipidemia, microalbuminuria, and increased coagulopathy (aspirin therapy). Treatment goals for intensive therapy included a blood pressure <130/80 mm Hg, HbA_{1c} <6.5%, total cholesterol <175 mg/dL, and triglycerides <150 mg/dL. All patients in the intensive treatment group were given an aspirin and treated with an angiotensin-converting enzyme (ACE) inhibitor. Patients in the intensively treated group showed a 53% reduction in cardiovascular disease and a 61% reduction in nephropathy. The magnitude of this reduction is greater than has been demonstrated with individual interventions, stressing the importance of targeting all the components of the metabolic syndrome. The study design did not allow conclusions regarding which interventions had the most impact.

CLINICAL PRESENTATION

The clinical presentations of type 1 DM and type 2 DM are very different (Table 72–6). Autoimmune type 1 DM can occur at any age. Approximately 75% will develop the disorder before age 20 years, but the remaining 25%, including relatives of index patients, develop the disease as adults. Individuals with type 1 diabetes mellitus are often thin and are prone to develop diabetic ketoacidosis if insulin is withheld, or under conditions of severe stress with an excess of insulin counterregulatory hormones.² Twenty to forty percent of patients with type 1 DM present with diabetic ketoacidosis after several days of polyuria, polydipsia, polyphagia, and weight loss. Occasionally, patients are diagnosed as short of “metabolic bankruptcy” when they have blood tests drawn for other reasons or for early symptoms. Because newly diagnosed patients with type 1 DM often have a small amount of residual pancreatic β -cell function, they may enter a “honeymoon” phase, when their blood glucose concentrations are relatively easy to control and small amounts of insulin are needed.

TABLE 72–6. Clinical Presentation of Diabetes Mellitus^a

| Characteristic | Type 1 DM | Type 2 DM |
|--|--------------------------|----------------------------------|
| Age | <30 years ^b | >30 years ^b |
| Onset | Abrupt | Gradual |
| Body habitus | Lean | Obese or history of obesity |
| Insulin resistance | Absent | Present |
| Autoantibodies | Often present | Rarely present |
| Symptoms | Symptomatic ^c | Often asymptomatic |
| Ketones at diagnosis | Present | Absent ^d |
| Need for insulin therapy | Immediate | Years after diagnosis |
| Acute complications | Diabetic ketoacidosis | Hyperosmolar hyperglycemic state |
| Microvascular complications at diagnosis | No | Common |
| Macrovascular complications at or before diagnosis | Rare | Common |

^aClinical presentation can vary widely.

^bAge of onset for type 1 DM is generally <20 years of age, but can present at any age. The prevalence of type 2 DM in children, adolescents, and young adults is increasing. This is especially true in ethnic and minority children.

^cType 1 may present acutely with symptoms of polyuria, nocturia, polydipsia, polyphagia, and weight loss.

^dType 2 children and adolescents are more likely to present with ketones, but after the acute phase may be treated with oral agents. Prolonged fasting can also produce ketones in individuals.

Once this residual insulin secretion wanes, the patients are completely insulin deficient and have more labile glycemia.

Patients with type 2 DM often present without symptoms, even though complications tell us that they may have had type 2 DM for

several years.¹⁰ Often these patients are diagnosed secondary to unrelated blood testing. Lethargy, polyuria, nocturia, and polydipsia can be seen at diagnosis in type 2 diabetes, but significant weight loss at diagnosis is less common.

▶ TREATMENT: Diabetes Mellitus

■ DESIRED OUTCOME

5 The primary goals of DM management are to reduce the risk for microvascular and macrovascular disease complications, to ameliorate symptoms, to reduce mortality, and to improve quality of life.⁵¹ Near-normal glycemia will reduce the risk for development of microvascular disease complications, but current evidence targets aggressive management of traditional cardiovascular risk factors (i.e., smoking cessation, treatment of dyslipidemia, intensive blood pressure control, and antiplatelet therapy) to reduce the likelihood of development of macrovascular disease.

Hyperglycemia not only increases the risk for microvascular disease, but contributes to poor wound healing, compromises white blood cell function, and leads to classic symptoms of DM. Diabetic ketoacidosis and hyperosmolar hyperglycemic state are severe manifestations of poor diabetes control, invariably requiring hospitalization. Reducing the potential for microvascular complications is targeted at adherence to therapeutic lifestyle intervention (i.e., diet and exercise programs) and drug-therapy regimens, as well as at maintaining blood pressure as near normal as possible.

■ GENERAL APPROACH TO TREATMENT

Appropriate care requires goal setting for glycemia, blood pressure, and lipid levels, regular monitoring for complications, dietary and exercise modifications, medications, appropriate self-monitoring of blood glucose (SMBG), and laboratory assessment of the aforementioned parameters.⁵¹ Glucose control alone does not sufficiently reduce the risk of complications in persons with DM.

■ GLYCEMIC GOAL SETTING AND THE HEMOGLOBIN A_{1C}

Controlled clinical trials provide ample evidence that glycemic control is paramount in reducing microvascular complications in both

type 1 DM⁵² and type 2 DM.⁵³ HbA_{1c} measurements are the gold standard for following long-term glycemic control for the previous 3 months.⁵⁴ Hemoglobinopathies, anemia, and red cell membrane defects can affect HbA_{1c} measurements. Other strategies (e.g., measurement of fructosamine) may be necessary to assess diabetes control in these patients. Unless the risk outweighs the benefit (as in elderly patients, patients with advanced complications, and patients with other advanced disease), an HbA_{1c} target of <7% is appropriate (Table 72–7), and lower values may be targeted if significant hypoglycemia and/or weight gain can be avoided.⁵¹

■ MONITORING COMPLICATIONS

The ADA recommends initiation of complications monitoring at the time of diagnosis of diabetes mellitus.⁸ Current recommendations continue to advocate yearly dilated eye examinations in type 2 DM, and an initial eye exam in the first 3 to 5 years in type 1 DM, then yearly thereafter. Less frequent testing (every 2 to 3 years) can be implemented upon the advice of an eye care specialist. The feet should be examined and the blood pressure should be assessed at each visit. A urine test for microalbumin once yearly is appropriate. Yearly testing for lipid abnormalities, and more frequently if needed to achieve lipid goals, is recommended.

■ SELF-MONITORING OF BLOOD GLUCOSE

The advent of SMBG in the early 1980s revolutionized the treatment of DM, enabling patients to know their blood glucose concentration at any moment easily and relatively inexpensively. Frequent SMBG is necessary to achieve near-normal blood glucose concentrations and to assess for hypoglycemia, particularly in patients with type 1 DM.⁵⁴ The more intense the insulin regimen is, the more intense the SMBG needs to be (four or more times daily in patients on multiple insulin injections or pump therapy). The utility and optimal frequency of SMBG for patients with type 2 DM is unresolved. Frequency of monitoring in type 2 DM should be sufficient to facilitate reaching glucose

TABLE 72–7. Glycemic Goals of Therapy

| Biochemical Index | ADA | ACE and AACE |
|-----------------------------|---|--------------|
| Hemoglobin A _{1c} | <7% ^a | ≤6.5% |
| Preprandial plasma glucose | 90–130 mg/dL (5.0–7.2 mmol/L) | <110 mg/dL |
| Postprandial plasma glucose | <180 mg/dL ^b (<10 mmol/L) | <140 mg/dL |

^aReferenced to a nondiabetic range of 4.0–6.0% using a DCCT-based assay. More stringent glycemic goals (i.e., a normal HbA_{1c}, <6%) may further reduce complications at the cost of increased risk of hypoglycemia (particularly in those with type 1 diabetes).

^bPostprandial glucose measurements should be made 1–2 hours after the beginning of the meal, generally the time of peak levels in patients with diabetes.

ADA, American Diabetes Association; ACE, American College of Endocrinology; AACE, American Association of Clinical Endocrinologists; DCCT, Diabetes Control and Complications Trial.

goals. The role of SMBG in improving glycemic control in type 2 DM patients is unproven.⁵⁵ Patients must be empowered to change their therapeutic regimen (lifestyle and medications) in response to test results, or no meaningful change is likely to be effected.

CLINICAL CONTROVERSY

Though recommended by most diabetes clinicians, few well-conducted studies have shown positive correlations with home blood glucose testing for type 2 DM. Also, at least one study saw no effect with reduction in average testing, as the HbA_{1c} did not deteriorate. Patients must be empowered to change their therapeutic regimen (lifestyle and medications) in response to test results, or no meaningful change is likely to be effected, and thus the money spent on the strip is wasted.

■ NONPHARMACOLOGIC THERAPY

■ DIET

Medical nutrition therapy is recommended for all persons with DM.⁵⁶ Paramount for all medical nutrition therapy is the attainment of optimal metabolic outcomes and the prevention and treatment of complications. For individuals with type 1 DM, the focus is on regulating insulin administration with a balanced diet to achieve and maintain a healthy body weight. Although still debated, most people with diabetes require a meal plan that is moderate in carbohydrates and low in saturated fat, with a focus on balanced meals. It is imperative that patients understand the connection between carbohydrates and glucose control. In addition, patients with type 2 DM often require caloric restriction to promote weight loss. Rather than a set diabetic diet, advocate a diet using foods that are within the financial reach and cultural milieu of the patient. Bedtime and between-meal snacks are not usually needed if pharmacologic management is appropriate.

CLINICAL CONTROVERSY

The recommended daily carbohydrate intake for type 2 DM, and even type 1 DM, has become controversial since low-carbohydrate diets such as the Atkins, South Beach, and Carbohydrate Addict's Diets have become exceptionally popular. Currently, the ADA recommends that approximately 60% to 70% of daily caloric intake should come from carbohydrates and monounsaturated fat. Many clinicians are trying to increase the monounsaturated fat percentage and decrease the carbohydrate percentage in a patient's diet to accomplish improved glycemic control. Recent studies have also documented short-term success for weight loss on low-carbohydrate diets, without deleterious effects on the lipid panel. Weight loss can reduce cardiovascular risk factors in type 2 DM.

■ ACTIVITY

In general, most patients with DM can benefit from increased activity.⁵⁷ Aerobic exercise improves insulin resistance and glycemic control in the majority of individuals, and reduces cardiovascular risk factors, contributes to weight loss or maintenance, and improves well-being. The patient should choose an activity that she or he is likely

to continue. Start exercise slowly in previously sedentary patients. Older patients, patients with long-standing disease (age >35 years, or >25 years with DM ≥10 years), patients with multiple cardiovascular risk factors, presence of microvascular disease, and patients with previous evidence of atherosclerotic disease should have a cardiovascular evaluation, probably including a graded exercise test with imaging, prior to beginning a moderate to intense exercise regimen. In addition, several complications (autonomic neuropathy, insensate feet, and retinopathy) may require restrictions on the activities recommended.

■ PHARMACOLOGIC THERAPY

Until 1995, only two options for pharmacologic treatment were available for patients with diabetes; sulfonylureas (for type 2 DM only) and insulin (for type 1 or 2). After 1995, a number of new oral agents and insulins have been introduced in the United States.

Currently, five classes of oral agents are approved for the treatment of type 2 diabetes: α -glucosidase inhibitors, biguanides, meglitinides, peroxisome proliferator activated receptor γ agonists (which are also commonly identified as thiazolidinediones or glitazones), and sulfonylureas. Oral agents are indicated for use in type 2 DM patients who are unable to achieve glycemic control goals despite diet and exercise. Oral antidiabetic agents are often grouped according to their glucose-lowering mechanism of action. Biguanides and thiazolidinediones are often categorized as insulin sensitizers due to their ability to reduce insulin resistance. Sulfonylureas and meglitinides are often categorized as insulin secretagogues because they enhance endogenous insulin release.

New options for implementation of insulin therapy are now available. Rapid-acting insulins (lispro and aspart) are available in insulin mixtures (Humalog Mix 75/25 and NovoLog Mix 70/30), and the long-acting basal insulin glargine has increased the ease of implementation of intensive insulin therapy for many patients. Glulisine, another rapid-acting insulin analog, has received Food and Drug Administration (FDA) approval for treatment of type 1 and 2 DM, and is expected to be marketed in 2005. Research on alternative delivery of insulin through inhalation or oral routes is continuing, though the latest information targets 2005 or 2006 as a likely time frame for the earliest FDA approval of a product.

The subsequent sections describe the current antidiabetic medications that are available to treat type 1 and type 2 diabetes mellitus.

■ DRUG CLASS INFORMATION

■ Insulin

■ *Pharmacology.* Insulin is an anabolic and anticatabolic hormone. It plays major roles in protein, carbohydrate, and fat metabolism. For a complete review of insulin action, the reader is referred to a diabetes physiology text.⁵⁸ Endogenously produced insulin is cleaved from the larger proinsulin peptide in the β cell to the active peptide of insulin and C-peptide, which can be used as a marker for endogenous insulin production. All commercially available insulin preparations contain only the active insulin peptide.

■ *Characteristics.* Characteristics that are commonly used to categorize insulins include source, strength, onset, and duration of action.

TABLE 72–8. Available Insulin Preparations

| Generic Name | Manufacturer | Analog ^a | Administration Options | Room Temperature ^b Expiration |
|---|--------------|---------------------|--|--|
| <i>Rapid-acting insulins</i> | | | | |
| Humalog (insulin lispro) | Lilly | Yes | Insulin pen, vial, or 1.5-mL and 3-mL pen cartridge | 28 days |
| NovoLog (insulin aspart) | Novo-Nordisk | Yes | Insulin pen, vial, or 3-mL pen cartridge | 28 days |
| Apidra (insulin glulisine) ^c | Aventis | Yes | Vial | 28 days |
| <i>Short-acting insulins</i> | | | | |
| Humulin R (regular) | Lilly | No | U-100, 10-mL vial | 28 days |
| Available in: U-100 and U-500 | | | U-500, 20-mL vial | |
| Novolin R (regular) | Novo-Nordisk | No | Insulin pen, vial, or 3-mL pen cartridge, and InnoLet ^d | Vial: 30 days; others: 28 days |
| <i>Intermediate-acting insulins</i> | | | | |
| NPH | | | | |
| Humulin N | Lilly | No | Vial, prefilled pen | Vial: 28 days; pen: 14 days |
| Novolin N | Novo-Nordisk | No | Vial, prefilled pen, and InnoLet ^d | Vial: 30 days; others: 14 days |
| Lente | | | | |
| Humulin L | Lilly | No | Vial | 28 days |
| <i>Long-acting insulins</i> | | | | |
| Humulin U (ultralente) | Lilly | No | Vial | 28 days |
| Lantus (insulin glargine) | Aventis | Yes | Vial | 28 days |
| <i>Pre-mixed insulins</i> | | | | |
| Pre-mixed insulin analogs | | | | |
| Humalog Mix 75/25 (75% neutral protamine lispro, 25% lispro) | Lilly | Yes | Vial, prefilled pen | Vial: 28 days; pen: 10 days |
| Novolog Mix 70/30 (70% aspart protamine suspension, 30% aspart) | Novo-Nordisk | Yes | Vial, prefilled pen, 3-mL pen cartridge | Vial: 28 days; others: 14 days |
| NPH-regular combinations | | | | |
| Humulin 70/30 | Lilly | No | Vial, prefilled pen | Vial: 28 days; pen: 10 days |
| Novolin 70/30 | Novo-Nordisk | No | Vial, pen cartridge, InnoLet ^d | Vial: 30 days; others: 10 days |
| Humulin 50/50 | Lilly | No | Vial | 28 days |

^aAll insulins available in the U.S. are now made by human recombinant DNA technology. An insulin analog is a modified human insulin molecule that imparts particular pharmacokinetic advantages.

^bRoom temperature defined as 59–86°F.

^cFDA approved, possible launch in 2005.

^dInnoLet: A prefilled insulin pen with a “kitchen timer” type of dial for determining the number of insulin units. May be useful in patients with impaired eyesight or dexterity.

Additionally, insulins may be characterized as analogs, defined as insulins that have had amino acids within the insulin molecule modified to impart particular physiochemical and pharmacokinetic advantages. Table 72–8 summarizes available insulin preparations.

U-100 and U-500, 100 units/mL and 500 units/mL, respectively, are the strengths of insulin currently available in the United States. U-500 regular insulin is available for individuals that may require large doses of insulin to control their diabetes. In the United States, all other insulins are available only in U-100 strength. For some type 1 diabetes patients who require extremely low doses of insulin, dilution of U-100 insulin to obtain accurate insulin doses may be necessary. Diluents and empty bottles can be obtained from the manufacturers for dilution.

Historically, insulin came from either beef or pork sources. Beef insulin differs by three amino acids and pork by one amino acid when compared to human insulin. Manufacturers in the United States have discontinued production of beef and pork source insulins as of December 2003, and now exclusively use recombinant DNA technology to manufacture insulin. Eli Lilly and Aventis currently use

a non-disease producing strain of *Escherichia coli* for synthesis of human insulin, whereas Novo Nordisk uses *Saccharomyces cerevisiae*, or bakers’ yeast, for synthesis.

Purity of insulin refers to the amount of proinsulin and other impurities present in a given insulin product. Prior to 1980, most insulin contained enough impurities (300 to 10,000 ppm) to cause local reactions upon injection, as well as systemic adverse effects from antibody production. Modern technology has provided less expensive techniques to purify insulin. As a result, all insulin products contain ≤10 ppm of proinsulin, with purified preparations (all recombinant DNA human insulin and insulin analogs) containing <1 ppm of proinsulin.

Regular crystalline insulin naturally self-associates into a hexameric (six insulin molecules) structure when injected subcutaneously. Before absorption through a blood capillary can occur, the hexamer must dissociate first to dimers, and then to monomers. This principle is the premise for additives such as protamine and zinc described below, and modification of amino acids for insulin analogs. Lispro, aspart, and glulisine insulins dissociate rapidly to monomers, thus absorption

is rapid. Lispro (B-28 lysine and B-29 proline human insulin; monomeric) insulin with two amino acids transposed, aspart (B-28 aspartic acid human insulin; mono- and dimeric) insulin with replacement of one amino acid, and glulisine (B-3 lysine and B-29 glutamic acid) are rapidly absorbed, peak faster, and have shorter durations of action when compared to regular insulin. In comparison to human insulin, with an isoelectric point of 5.4, the analog glargine insulin (A-21 glycine, B-30a-arginine, B-30a L-arginine, and B-30b L-arginine human insulin) has an isoelectric point of 6.8. In the bottle, glargine is buffered to a pH of 4, a level at which it is completely soluble, resulting in a clear colorless solution. When injected into the neutral pH of the body, it rapidly forms microprecipitates that slowly dissolve into monomers and dimers which are then subsequently absorbed. The result is a long-acting, peakless, 24-hour duration insulin analog.

Insulin analogs are modified human insulin molecules, and safety is paramount for FDA approval. Key factors that should be considered in the approval process include local injection reactions, antigenicity, efficacy compared to human insulin, insulin receptor binding affinity, and insulin-like growth factor 1–receptor affinity (which is compared to that of human insulin to determine mitogenic potential).

■ **Pharmacokinetics.** Subcutaneous injection kinetics are dependent on onset, peak, and duration of action, and are summarized in Table 72–9. Absorption of insulin from a subcutaneous depot is dependent on several factors, including: source of insulin, concentration of insulin, additives to the insulin preparations (e.g., zinc, protamine, etc), blood flow to the area (rubbing of injection area, increased skin temperature, and exercise in muscles near the injection site may enhance absorption), and injection site. Insulin is commonly injected in (from most rapid to slowest absorption): abdominal fat, posterior upper arms, lateral thigh area, and superior buttocks area. Insulin analogs, unlike other preparations of insulin, appear to retain their kinetic profile at all sites of injection. U-500 regular insulin has a delayed onset and requires a lower dose when compared to U-100 insulin. Addition of protamine (NPH, NPL, and aspart protamine suspension) or excess zinc (lente or ultralente insulin) will delay onset, peak, and duration of the insulin’s effect. Variability in absorption, inconsistent suspension of the insulin by the patient or health care provider when drawing up a dose, and inherent insulin action based on the pharmacokinetics of the products may all contribute to a labile glucose response. All insulin suspensions should be inverted or rolled gently at least 10 times to fully resuspend the insulin.

The half-life of an intravenous (IV) injection of regular insulin is about 9 minutes. Thus the effective duration of action of a single

IV injection is short, and changes in IV insulin rates will reach steady state in approximately 45 minutes. Intravenous pharmacokinetics of other soluble insulins (lispro, aspart, glulisine, and even glargine) appear similar to IV regular insulin, but they have no advantages over IV regular insulin and are more expensive.

Insulin is degraded in the liver, muscle, and kidney. Liver deactivation is 20% to 50% in a single passage. Approximately 15% to 20% of insulin metabolism occurs in the kidney. This may partially explain the lower insulin dosage requirements in patients with end-stage renal disease.

The pharmacokinetics of the inhaled insulin products under development appear to be similar to those of rapid-acting insulin preparations, but inhaled insulin has not been released as of this writing.⁵⁹

■ **Efficacy.** The efficacy of traditional insulins (e.g., regular, NPH, and lente insulins) is unequivocal. Insulin analog efficacy is measured via the same ways as traditional insulins. Insulin analogs in most studies have not shown superior HbA_{1c} levels when compared to traditional insulins, but are often preferred by patients and practitioners. Lispro, aspart, and glulisine are advantageous due to the ability to inject within 10 minutes of a meal, as compared to the recommendation to inject regular insulin approximately 30 minutes prior. Rapid-acting analogs have shown superior postprandial lowering of glucose when compared to regular insulin. Glargine insulin injected at bedtime has shown significantly less nocturnal hypoglycemia when compared to NPH injected at bedtime.

An educated patient in conjunction with a skilled practitioner can achieve excellent glycemic control with insulin therapy. Efficacy with insulin therapy is related to achieving glycemic control while minimizing the risk of potential side effects, specifically hypoglycemia and weight gain. Insulin is recommended in patients with: extremely high fasting plasma glucose levels (>280 to 300 mg/dL), patients with ketonuria or ketonemia, symptomatic patients (weight loss with polyuria, polydipsia, and/or nocturia), gestational diabetes mellitus, and if deemed appropriate by the clinician and patient.^{60–63}

■ **Microvascular Complications.** Insulin has been shown to be as efficacious as any oral agent for treating DM. The United Kingdom Prospective Diabetes Study, which used sulfonylureas or insulin, showed equal efficacy in lowering the risk of microvascular events in newly diagnosed type 2 DM.⁵³ Similarly, in type 1 DM the Diabetes Control and Complications Trial (DCCT) showed efficacy in reducing microvascular complications.⁵²

TABLE 72–9. Pharmacokinetics of Various Insulins Administered Subcutaneously

| Type of Insulin | Onset (Hours) | Peak (Hours) | Duration (Hours) | Maximum Duration (Hours) | Appearance |
|----------------------------|---------------|--------------|------------------|--------------------------|------------|
| <i>Rapid-acting</i> | | | | | |
| Aspart | 15–30 min | 1–2 | 3–5 | 5–6 | Clear |
| Lispro | 15–30 min | 1–2 | 3–4 | 4–6 | Clear |
| Glulisine ^a | 15–30 min | 1–2 | 3–4 | 5–6 | Clear |

^aFDA approved, possible launch in 2005.

■ **Macrovascular Complications.** The connection between high insulin levels (hyperinsulinemia), insulin resistance, and cardiovascular events incorrectly leads some clinicians to believe that insulin therapy may cause macrovascular complications. The UKPDS and DCCT found no differences in macrovascular outcomes with intensive insulin therapy. One study, the Diabetes Mellitus, Insulin Glucose Infusion in Acute Myocardial Infarction study⁶⁴ reported reductions in mortality with insulin therapy. This group assessed the effect of an insulin-glucose infusion in type 2 DM patients who had experienced an acute myocardial infarction. Those randomized to insulin infusion followed by intensive insulin therapy lowered their absolute mortality risk by 11% over a mean follow-up period of approximately 3 years. This was most evident in subjects who were insulin-naïve or had a low cardiovascular risk prior to the acute myocardial infarction.⁶⁴

■ **Adverse Effects.** The most common adverse effects reported with insulin are hypoglycemia and weight gain. Hypoglycemia is more common in patients on intensive insulin therapy regimens versus those on less-intensive regimens. Also, patients with type 1 DM tend to have more hypoglycemic events compared to type 2 DM patients. In the UKPDS study, performed over 10 years, the percentage of diabetic patients that needed assistance (third-party or hospitalization) due to a hypoglycemic reaction was 2.3%. The UKPDS reported a rate of 36.5% for risk of any hypoglycemic event, including mild, self-treated events. In the DCCT, tighter control produced a risk three times higher for severe hypoglycemia compared to conventional therapy. Glycemic goals should incorporate hypoglycemic risk vs. the benefit of lowering the glucose, when HbA_{1c} levels are near normal, especially in type 1 DM.

Minimization of risk for patients on insulin should include education about the signs and symptoms of hypoglycemia, proper treatment of hypoglycemia, and blood glucose monitoring. Blood glucose monitoring is essential for those on insulin, and is particularly of value in patients with hypoglycemia unawareness. Patients with hypoglycemia unawareness do not experience the normal sympathetic symptoms of hypoglycemia (tachycardia, tremulousness, and sweating).

Initial symptoms are often neuroglycopenic in nature (confusion, agitation, loss of consciousness, and/or progression to coma). Patients with hypoglycemia unawareness should check their blood glucose level prior to any activities that may be dangerous with a low blood sugar (e.g., driving and certain sports, among others). Proper treatment of hypoglycemia dictates ingestion of carbohydrates, with glucose being preferred. Unconsciousness is an indication for either IV glucose, or glucagon injection, which increases glycogenolysis in the liver. Glucagon use would be appropriate in any situation in which the patient does not have or cannot have ready IV access for glucose administration. Education for reconstitution and injection of glucagon is recommended for close friends and family of a patient who has recurrent neuroglycopenic events. The patient and close contacts should be informed that it can take 10 to 15 minutes for the injection to start raising glucose levels, and patients often vomit during this time. Proper positioning to avoid aspiration should be emphasized.

Weight gain is predominantly from increased truncal fat, and tends to be related to daily dose and plasma insulin levels present. Weight gain is undesirable in most type 2 DM, but may be seen as beneficial in underweight type 1 DM. Weight gain appears to be related to intensive insulin therapy, and can be somewhat minimized by physiologic replacement of insulin.

The two forms of lipodystrophy, though less common today in people with diabetes, still occur. Lipohypertrophy is caused by many injections into the same injection site. Due to insulin’s anabolic actions, a raised fat mass is present at the injection site with resultant variable insulin absorption. Lipoatrophy, in contrast, is thought to be due to insulin antibodies, with destruction of fat at the site of injection. Injection away from the site with more purified insulin is recommended, though several reports of lipoatrophy with lispro have been reported.

■ **Drug-Drug Interactions.** There are no significant drug-drug interactions with insulin, though other medications that may affect glucose control can be considered. Table 72–10 lists common medications known to affect blood glucose levels.

TABLE 72–10. Medications That May Affect Glycemic Control^a

| Drug | Effect on Glucose | Mechanism/Comment |
|--|-------------------------|---|
| Angiotensin-converting enzyme inhibitors | Slight reduction | Improves insulin sensitivity |
| Alcohol | Reduction | Reduces hepatic glucose production |
| α-Interferon | Increase | Unclear |
| Diazoxide | Increase | Decreases insulin secretion, decreases peripheral glucose use |
| Diuretics | Increase | May increase insulin resistance |
| Glucocorticoids | Increase | Impairs insulin action |
| Nicotinic acid | Increase | Impairs insulin action, increases insulin resistance |
| Oral contraceptives | Increase | Unclear |
| Pentamidine | Decrease, then increase | Toxic to β cells; initial release of stored insulin, then depletion |
| Phenytoin | Increase | Decreases insulin secretion |
| β-Blockers | May increase | Decreases insulin secretion |
| Salicylates | Decrease | Inhibition of I-kappa-B kinase-beta (IKK-beta) (only high doses, e.g., 4–6 g/day) |
| Sympathomimetics | Slight increase | Increased glycogenolysis and gluconeogenesis |
| Clozapine and olanzapine | Increase | Unclear; weight gain |

^aThis list is not inclusive of all medications reported to cause glucose changes.

■ **Dosing and Administration.** The dose of insulin for any person with altered glucose metabolism must be individualized. In type 1 DM, the average daily requirement for insulin is 0.5 to 0.6 units/kg, with approximately 50% being delivered as basal insulin, and the remaining 50% dedicated to meal coverage. During the honeymoon phase it may fall to 0.1 to 0.4 units/kg. During acute illness or with ketosis or states of relative insulin resistance, higher dosages are warranted. In type 2 DM a higher dosage is required for those patients with significant insulin resistance. Dosages vary widely depending on underlying insulin resistance and concomitant oral insulin sensitizer use. Strategies on how to initiate and monitor insulin therapy will be described later in the therapeutics section.

■ **Storage.** It is recommended that unopened insulins be refrigerated (36° to 46°F) prior to use. The manufacturer's expiration date printed on the insulin is used for unopened, refrigerated insulin. Once the insulin is in use, the manufacturer-recommended expiration dates will vary based on the insulin and delivery device. Table 72–8 outlines manufacturer-recommended expiration dates for room temperature (59° to 86°F) insulin. For financial reasons, patients may attempt to use insulins longer than their expiration dates, but careful attention must be paid to monitoring glycemic control and signs of insulin decay (clumping, precipitates, discoloration, etc) if this is attempted.

■ Sulfonylureas

■ **Pharmacology.** The primary mechanism of action of sulfonylureas is enhancement of insulin secretion. Sulfonylureas bind to a specific sulfonylurea receptor (SUR) on pancreatic β cells. Binding closes an adenosine triphosphate–dependent K^+ channel, leading to decreased potassium influx and subsequent depolarization of the membrane. Voltage-dependent Ca^{+2} channels open and allow an inward flux of Ca^{+2} . Increases in intracellular Ca^{+2} cause translocation of secretory granules of insulin to the cell surface and resultant exocytosis of the granule of insulin. Elevated secretion of insulin from the pancreas travels via the portal vein and subsequently suppresses hepatic glucose production.

■ **Classification.** Sulfonylureas are classified as first-generation and second-generation agents. The classification scheme is largely derived from differences in relative potency, relative potential for selective side effects, and differences in binding to serum proteins (i.e., risk for protein-binding displacement drug interactions). First-generation agents consist of acetohexamide, chlorpropamide, tolazamide, and tolbutamide. Each of these agents is lower in potency relative to the second-generation drugs: glimepiride, glipizide, and glyburide (Table 72–11). It is important to recognize that all sulfonylureas are equally effective at lowering blood glucose when administered in equipotent doses.

■ **Pharmacokinetics.** All sulfonylureas are metabolized in the liver; some to active, others to inactive metabolites (see Table 72–11). Cytochrome P450 (CYP450) 2C9 is involved with the hepatic metabolism of the majority of sulfonylureas. Agents with active metabolites or parent drug that are renally excreted require dosage adjustment or use with caution in patients with compromised renal function. The half-life of the sulfonylurea also relates directly to the risk for hypoglycemia. The hypoglycemic potential is therefore higher with chlorpropamide and glyburide. The long duration of effect of chlorpropamide may be particularly problematic in elderly individuals,

whose renal function declines with age, and therefore it has great potential for accumulation, resulting in severe and protracted hypoglycemia. Individuals at high risk for hypoglycemia (e.g., elderly individuals and those with renal insufficiency or advanced liver disease) should be started at a very low dose of a sulfonylurea with a short half-life. Hypoglycemia on low-dose sulfonylureas may dictate a short-acting insulin secretagogue (nateglinide or repaglinide) in lieu of a sulfonylurea.

■ **Efficacy.** As mentioned earlier, when given in equipotent doses, all sulfonylureas are equally effective at lowering blood glucose. On average, HbA_{1c} will fall 1.5% to 2%, with fasting plasma glucose reductions of 60 to 70 mg/dL. A majority of patients will not reach glycemic goals with sulfonylurea monotherapy. Patients who fail sulfonylurea usually fall into two groups: Those with low C-peptide levels and high (>250 mg/dL) fasting plasma glucose (FPG) levels. These patients are often primary failures on sulfonylureas (<30 mg/dL drop of FPG) and have significant glucose toxicity or slow-developing type 1 DM. The other group is those with a good initial response (>30 mg/dL drop of FPG), but which is insufficient to reach their glycemic goals. Over 75% of patients fall into the second group. Factors that portend a positive response include newly diagnosed patients with no indicators of type 1 DM, high fasting C-peptide levels, and moderate fasting hyperglycemia (<250 mg/dL). If glycemic goals are met, a secondary failure rate of approximately 5% to 7% per year can be expected.

■ **Microvascular Complications.** Sulfonylureas showed a reduction of microvascular complications in type 2 DM patients in the UKPDS.⁵³ A more in-depth discussion follows later in the chapter.

■ **Macrovascular Complications.** In the largest study to date, the UKPDS, no significant benefit or harm was seen in newly diagnosed type 2 DM patients given sulfonylureas over 10 years. The University Group Diabetes Program study documented higher rates of coronary artery disease in type 2 patients given tolbutamide, when compared to patients given insulin or placebo, though this study has been widely criticized.^{65,66} Some sulfonylureas bind to the SUR-2A receptor that is found in cardiac tissue. Binding to the SUR-2A receptor has been implicated in blocking ischemic preconditioning via K^+ channel closure in the heart. Ischemic preconditioning is the premise that prior ischemia in cardiac tissue can provide greater tolerance of subsequent ischemia. Thus patients with heart disease potentially have one compensatory mechanism to protect the heart from ischemia blocked. Conclusions are controversial and readers are referred to the pertinent articles for further discussion.^{67–69}

■ **Adverse Effects.** The most common side effect of sulfonylureas is hypoglycemia. The pretreatment fasting plasma glucose is a strong predictor of hypoglycemic potential. The lower the FPG is upon initiation, the higher the potential for hypoglycemia. Also, in addition to the high-risk individuals outlined in the pharmacokinetics section, those who skip meals, exercise vigorously, or lose substantial amounts of weight are also more likely to experience hypoglycemia.

Hyponatremia (serum sodium <129 mEq/L) is reportedly associated with tolbutamide, but it is most common with chlorpropamide and occurs in as many as 5% of individuals treated. An increase in antidiuretic hormone secretion is the mechanism for hyponatremia. Risk factors include age >60 years, female gender, and concomitant use of thiazide diuretics.

Weight gain is common with sulfonylureas. In essence, patients who are no longer glycosuric and who do not reduce caloric intake

TABLE 72–11. Oral Agents for the Treatment of Type 2 Diabetes Mellitus

| Generic Name (generic version available?) Y = yes, N = no | Brand | Dose (mg) | Recommended Starting Dosage (mg/day) | | Equivalent Therapeutic Dose (mg) | Maximum Dose (mg/day) | Duration of Action | Metabolism or Therapeutic Notes |
|--|----------------------|---|--|--------------------------------|---|------------------------------|-----------------------|--|
| | | | Nonelderly | Elderly | | | | |
| <i>Sulfonylureas</i> | | | | | | | | |
| Acetohexamide (Y) | Dymelor | 250, 500 | 250 | 125–250 | 500 | 1500 | Up to 16 hours | Metabolized in liver; metabolite potency equal to parent compound; renally eliminated |
| Chlorpropamide (Y) | Diabinese | 100, 250 | 250 | 100 | 250 | 500 | Up to 72 hours | Metabolized in liver; also excreted unchanged renally |
| Tolazamide (Y) | Tolinase | 100, 250, 500 | 100–250 | 100 | 250 | 1000 | Up to 24 hours | Metabolized in liver; metabolite less active than parent compound; renally eliminated |
| Tolbutamide (Y) | Orinase | 250, 500 | 1000–2000 | 500–1000 | 1000 | 3000 | Up to 12 hours | Metabolized in liver to inactive metabolites that are renally excreted |
| Glipizide (Y) | Glucotrol | 5, 10 | 5 | 2.5–5 | 5 | 40 | Up to 20 hours | Metabolized in liver to inactive metabolites |
| Glipizide (N) | Glucotrol XL | 2.5, 5, 10, 20 | 5 | 2.5–5 | 5 | 20 | 24 hours | Slow-release form; do not cut tablet |
| Glyburide (Y) | DiaBeta Micronase | 1.25, 2.5, 5 | 5 | 1.25–2.5 | 5 | 20 | Up to 24 hours | Metabolized in liver; elimination 1/2 renal, 1/2 feces |
| Glyburide, micronized (Y) | Glynase | 1.5, 3, 6 | 3 | 1.5–3 | 3 | 12 | Up to 24 hours | Equal control, but better absorption from micronized preparation |
| Glimepiride (N) | Amaryl | 1, 2, 4 | 1–2 | 0.5–1 | 2 | 8 | 24 hours | Metabolized in liver to inactive metabolites |
| <i>Short-acting insulin secretagogues</i> | | | | | | | | |
| Nateglinide (N) | Starlix | 60, 120 | 120 with meals | 120 with meals | NA | 120 mg three times a day | Up to 4 hours | Metabolized by cytochrome P450 (CYP450) 2C9 and 3A4 to weakly active metabolites; renally eliminated |
| Repaglinide (N) | Prandin | 0.5, 1, 2 | 0.5–1 with meals | 0.5–1 with meals | NA | 16 | Up to 4 hours | Metabolized by CYP 3A4 to inactive metabolites; excreted in bile |
| <i>Biguanides</i> | | | | | | | | |
| Metformin (Y) | Glucophage | 500, 850, 1000 | 500 mg twice a day | Assess renal function | NA | 2550 | Up to 24 hours | No metabolism; Renally secreted and excreted |
| Metformin extended-release (N) | Glucophage XR | 500, 750 (generic available for 500 mg) | 500–1000 mg with evening meal | Assess renal function | NA | 2550 | Up to 24 hours | Take with evening meal or may split dose; may consider trial if intolerant to immediate-release |
| <i>Thiazolidinediones</i> | | | | | | | | |
| Pioglitazone (N) | Actos | 15, 30, 45 | 15 | 15 | NA | 45 | 24 hours | Metabolized by CYP 2C8 and 3A4; two metabolites have longer half-lives than parent compound |
| Rosiglitazone (N) | Avandia | 2, 4, 8 | 2–4 | 2 | NA | 8 mg/day or 4 mg twice a day | 24 hours | Metabolized by CYP2C8 and 2C9 to inactive metabolites that are renally excreted |
| <i>α-Glucosidase inhibitors</i> | | | | | | | | |
| Acarbose (N) | Precose | 25, 50, 100 | 25 mg one to three times a day | 25 mg one to three times a day | NA | 25–100 mg three times a day | 1–3 hours | Eliminated in bile |
| Miglitol (N) | Glyset | 25, 50, 100 | 25 mg one to three times a day | 25 mg one to three times a day | NA | 25–100 mg three times a day | 1–3 hours | Eliminated renally |

with improvement of blood glucose will store excess calories. Other notable, although much less common, adverse effects of sulfonylureas are skin rash, hemolytic anemia, gastrointestinal upset, and cholestasis. Disulfiram-type reactions and flushing have been reported with tolbutamide and chlorpropamide when alcohol is consumed.

■ **Drug Interactions.** Several drugs are thought to interact with sulfonylureas, and Table 72–12 summarizes them by proposed mechanisms of action.⁷⁰ Drug interactions from protein-binding changes should occur shortly after the interacting medication is given, as the concentration of free (thus active) sulfonylurea will acutely increase. First-generation sulfonylureas, which bind to proteins ionically, are more likely to cause drug-drug interactions than second-generation sulfonylureas, which bind nonionically.⁷¹ Of note, the clinical importance of protein-binding interactions has been questioned, as the majority of these drug interactions have been found to truly be due to hepatic metabolism. Drugs that are inducers or inhibitors of CYP450 2C9 should be monitored carefully when used with a sulfonylurea. Additionally, other drugs known to alter blood glucose should be considered (see Table 72–10).

■ **Dosing and Administration.** The usual starting dose and maximum dose of sulfonylureas are summarized in Table 72–11. Lower dosages are recommended for most agents in elderly patients and those with compromised renal or hepatic function. The dosage should be titrated every 1 to 2 weeks (use a longer interval with chlorpropamide) to achieve glycemic goals. This is possible due to the rapid increase of insulin secretion in response to the sulfonylurea. Of note, immediate-release glipizide's maximal dose is 40 mg/day, but its maximal effective

dose is about 10 to 15 mg/day. The maximal effective dose of sulfonylureas tends to be about 60% to 75% of their stated maximum dose.

■ Short-Acting Insulin Secretagogues

■ **Pharmacology.** Though the binding site is adjacent to the binding site of sulfonylureas, nateglinide and repaglinide stimulate insulin secretion from the β cells of the pancreas, similarly to sulfonylureas. Repaglinide, a benzoic acid derivative, and nateglinide, a phenylalanine amino acid derivative, both require the presence of glucose to stimulate insulin secretion. As glucose levels diminish to normal, stimulated insulin secretion diminishes.

■ **Pharmacokinetics.** Both nateglinide and repaglinide are rapid-acting insulin secretagogues that are rapidly absorbed (~0.5 to 1 hour) and have a short half-life (1 to 1.5 hours). Nateglinide is highly protein-bound, primarily to albumin, but also to α_1 -acid glycoprotein. Nateglinide is predominantly metabolized by CYP2C9 (70%) and CYP3A4 (30%) to less active metabolites. Glucuronide conjugation then allows rapid renal elimination. Repaglinide is mainly metabolized by the CYP3A4 system to inactive metabolites that are excreted in the bile.

■ **Efficacy.** In monotherapy, both significantly reduce postprandial glucose excursions and reduce HbA_{1c} levels. Repaglinide, dosed 4 mg three times a day, when compared to glyburide in diet-treated drug-naïve patients reduced HbA_{1c} levels less (1% vs. 2.4%, from baseline, respectively).⁷² Nateglinide, dosed 120 mg three times a day in a similar population reduced HbA_{1c} values by 0.8%.⁷³ The lower efficacy of these agents vs. sulfonylureas should be considered when patients are >1% above their HbA_{1c} goal. These agents can be used to provide increased insulin secretion during meals, when it is needed, in patients close to glycemic goals. Also, it should be noted that addition of either agent to a sulfonylurea will not result in any improvement in glycemic parameters.

■ **Adverse Effects.** Hypoglycemia is the main side effect noted with both agents. Hypoglycemic risk appears to be less vs. sulfonylureas. In part, this is due to the glucose-sensitive release of insulin. If the glucose concentration is normal, less glucose-stimulated release of

TABLE 72–12. Drug Interactions with Sulfonylureas

Reproduced from Gerich.⁷⁰

insulin will occur. In two separate studies, nateglinide rates of hypoglycemia were 3% and repaglinide 15% vs. glyburide and glipizide rates of 15% and 19%, respectively. Weight gain of 2 to 3 kg has been noted with repaglinide, whereas weight gain with nateglinide appears to be <1 kg.

■ **Drug Interactions.** Glycemic control and hypoglycemia should be closely monitored when inducers or inhibitors of CYP3A4 are given with repaglinide. Gemfibrozil, a common medication used to treat hypertriglyceridemia in DM, more than doubles the half-life of repaglinide and has resulted in prolonged hypoglycemic reactions. Nateglinide appears to be a weak inhibitor of CYP2C9 based on tolbutamide metabolism, though no significant drug-drug interactions have been reported.

■ **Dosing and Administration.** Nateglinide and repaglinide should be dosed prior to each meal (up to 30 minutes prior). The recommended starting dose for repaglinide is 0.5 mg in subjects with HbA_{1c} <8% or treatment-naïve patients, increased weekly to a total daily dose of 16 mg (see Table 72–11). The maximal effective dose of repaglinide is likely 2 mg with each meal, as a dose of 1 mg prior to each meal provides approximately 90% of the maximal glucose-lowering effect. Nateglinide should be dosed at 120 mg prior to meals, and does not require titration. A 60-mg dose is available, but the HbA_{1c} decrement is small (0.3% to 0.5%). If a meal is skipped, the medication can be skipped, and meals extremely low in carbohydrate content may not need a dose. Both agents may be used in patients with renal insufficiency, and offer an excellent alternative in patients experiencing hypoglycemia with low-dose sulfonylurea. Caution is advised for patients with moderate to severe hepatic impairment, as nateglinide has not been studied and the half-life is prolonged with use of repaglinide.

■ Biguanides

■ **Pharmacology.** Metformin is the only biguanide available in the United States. Metformin has been used clinically for 45 years, and has been approved in the U.S. since 1995. Metformin enhances insulin sensitivity of both hepatic and peripheral (muscle) tissues. This allows for an increased uptake of glucose into these insulin-sensitive tissues. The exact mechanisms of how metformin accomplishes insulin sensitization are still being investigated, though adenosine 5'-monophosphate-activated protein kinase activity, tyrosine kinase activity enhancement, and glucose transporter 4 all play a part. Metformin has no direct effect on the β cells, though insulin levels are reduced, reflecting increases in insulin sensitivity.

■ **Pharmacokinetics.** Metformin has approximately 50% to 60% oral bioavailability, low lipid solubility, and a volume of distribution that approximates body water. Metformin is not metabolized and does not bind to plasma proteins. Metformin is eliminated by renal tubular secretion and glomerular filtration. The average half-life of metformin is 6 hours, though pharmacodynamically, metformin's antihyperglycemic effects last >24 hours.

■ **Efficacy.** Metformin consistently reduces HbA_{1c} levels by 1.5% to 2.0%, fasting plasma glucose levels by 60 to 80 mg/dL, and retains the ability to reduce fasting plasma glucose levels when they are extremely high (>300 mg/dL). The sulfonylureas' ability to stimulate insulin release from β cells at extremely high glucose levels

is often impaired, a concept commonly referred to as *glucose toxicity*. Metformin also has positive effects on several components of the insulin resistance syndrome. Metformin decreases plasma triglycerides and LDL-C by approximately 8% to 15%, as well increasing HDL-C very modestly (2%). Metformin reduces levels of plasminogen activator inhibitor-1 and causes a modest reduction in weight (2 to 3 kg).

■ **Microvascular Complications.** Metformin (n = 342) was compared to intensive glucose control with insulin or sulfonylureas in the UKPDS. No significant differences were seen between therapies with regard to reducing microvascular complications.

6 ■ **Macrovascular Complications.** Metformin reduced macrovascular complications in obese subjects in the UKPDS.⁷⁴ Metformin significantly reduced all-cause mortality and risk of stroke vs. intensive treatment with sulfonylureas or insulin. Metformin also reduced diabetes-related death and myocardial infarctions vs. the conventional treatment arm of the UKPDS. Metformin should be included in the therapy for all type 2 DM patients, if tolerated and not contraindicated, as it is the only oral antihyperglycemic medication proven to reduce the risk of total mortality and cardiovascular death.

■ **Adverse Effects.** Metformin causes gastrointestinal side effects, including abdominal discomfort, stomach upset, and/or diarrhea in approximately 30% of patients. Anorexia and stomach fullness is likely part of the reason loss of weight is noted with metformin. These side effects are usually mild and can be minimized by slow titration. Gastrointestinal side effects also tend to be transient, lessening in severity over several weeks. If encountered, make sure patients are taking metformin with or right after meals, and reduce the dose to a point at which no gastrointestinal side effects are encountered. Increases in the dose may be tried again in several weeks. Anecdotally, extended-release metformin (Glucophage-XR) may lessen some of the GI side effects. Metallic taste, interference with vitamin B₁₂ absorption, and hypoglycemia during intense exercise has been documented, but are clinically uncommon.

Metformin therapy rarely (3 cases per 100,000 patient-years) causes lactic acidosis. Any disease state that may increase lactic acid production or decrease lactic acid removal may predispose to lactic acidosis. Tissue hypoperfusion, such as that due to congestive heart failure, hypoxic states, shock, or septicemia, via increased production of lactic acid; and severe liver disease or alcohol, via reduced removal of lactic acid in the liver, all increase the risk of lactic acidosis. The clinical presentation of lactic acidosis is often nonspecific flu-like symptoms, thus the diagnosis is usually made by laboratory confirmation. Metformin use in renal insufficiency, defined as a serum creatinine of 1.4 mg/dL in women and 1.5 mg/dL in men or greater, is contraindicated, as it is renally eliminated. Elderly patients, who often have reduced muscle mass, should have their glomerular filtration rate estimated by a 24 hour urine creatinine collection. If the calculated glomerular filtration rate is less than 70 to 80 mL/min, metformin should not be given. Due to the risk of acute renal failure during intravenous dye procedures, metformin therapy should be withheld starting the day of the procedure and resumed in 2 to 3 days, when normal renal function has been documented.

■ **Drug Interactions.** Cimetidine competes for renal tubular secretion of metformin and concomitant administration leads to higher metformin serum concentrations. At least one case report of lactic acidosis with metformin therapy implicates cimetidine. Other cationic

drugs may interact similarly such as procainamide, digoxin, quinidine, trimethoprim, and vancomycin.⁷⁵

■ **Dosing and Administration.** Metformin immediate-release is usually dosed 500 mg twice a day with the largest meals to minimize gastrointestinal side effects. Metformin may be increased by 500 mg weekly until glycemic goals or 2000 mg/day is achieved (see Table 72–11). Metformin 850 mg may be dosed daily, and then increased every 1 to 2 weeks to the maximum dose of 850 mg three times a day (2550 mg/day). Approximately 80% of the glycemic-lowering effect may be seen at 1500 mg, and 2000 mg/day is the maximal effective dose.

Extended-release metformin can be initiated at 500 mg a day with the evening meal and titrated weekly by 500 mg as tolerated to a single evening dose of 2000 mg/day. Twice daily to three times a day dosing of extended-release metformin may help to minimize gastrointestinal side effects and improve glycemic control. Metformin extended-release 750 mg tablets may be titrated weekly to the maximum dose of 2250 mg/day, though as stated above, 1500 mg/day provides the majority of the glycemic-lowering effect.

■ Thiazolidinediones

■ **Pharmacology.** Thiazolidinediones are also referred to as TZDs or glitazones. Pioglitazone and rosiglitazone are the two currently approved thiazolidinediones for the treatment of type 2 DM (see Table 72–11). Thiazolidinediones work by binding to the peroxisome proliferator activator receptor- γ (PPAR- γ), which are primarily located on fat cells and vascular cells. The concentration of these receptors in the muscle is very low; thus this is unlikely to be the main site of action. Thiazolidinediones enhance insulin sensitivity at muscle, liver, and fat tissues indirectly. Thiazolidinediones cause preadipocytes to differentiate into mature fat cells in subcutaneous fat stores. Small fat cells are more sensitive to insulin and more able to store free fatty acids. The result is a flux of free fatty acids out of the plasma, visceral fat, and liver into subcutaneous fat, a less insulin-resistant storage tissue. Muscle intracellular fat products, which contribute to insulin resistance, also decline.

■ **Pharmacokinetics.** Pioglitazone and rosiglitazone are well absorbed with or without food. Both are highly (>99%) protein bound to albumin. Pioglitazone is primarily metabolized by CYP2C8, and to a lesser extent by CYP3A4 (17%), with the majority being eliminated in the feces. Rosiglitazone is metabolized by CYP2C8, and to a lesser extent by CYP2C9, then conjugated with two-thirds found in urine and one-third in feces. The half-life of pioglitazone and rosiglitazone is 3 to 7 hours and 3 to 4 hours, respectively. Two active metabolites of pioglitazone with longer half-lives deliver the majority of activity at steady state. Both medications have a duration of antihyperglycemic action of over 24 hours.

■ **Efficacy.** Pioglitazone and rosiglitazone, given for about 6 months, reduce HbA_{1c} values ~1.5% and reduce FPG levels by approximately 60 to 70 mg/dL at maximal doses. Glycemic-lowering onset is slow, and maximal glycemic-lowering effects may not be seen until 3 to 4 months of therapy. It is important to inform patients of this fact and that they should not stop therapy even if minimal glucose lowering is initially encountered. The efficacy of both drugs is dependent on sufficient insulinemia. If there is insufficient endogenous insulin production (β -cell function) or exogenous insulin delivery via injections, neither will lower glucose concentrations efficiently. Interestingly,

patients who are more obese, or who gain weight on either medication tend to have a larger reduction in HbA_{1c} values. Pioglitazone consistently decreases plasma triglyceride levels by 10% to 20%, whereas rosiglitazone tends to have a neutral effect. LDL-C concentrations tend to increase with rosiglitazone 5% to 15%, but do not significantly increase with pioglitazone. Both appear to convert small, dense LDL particles, which have been shown to be highly atherogenic, to large, fluffy LDL particles, that are less dense. Large, fluffy LDL particles may be less atherogenic, but any increase in LDL must be of concern. Both drugs increase HDL similarly, up to 3 to 9 mg/dL. Thiazolidinediones also affect several components of the insulin resistance syndrome. Plasminogen-activator inhibitor-1 (PAI-1) levels are decreased, and many other adipocytokines are affected, endothelial function improves, and blood pressure may decrease slightly.

■ **Microvascular Complications.** Thiazolidinediones reduce HbA_{1c} levels, which have been shown to be related to the risk of microvascular complications.

■ **Macrovascular Complications.** Macrovascular outcome studies are in progress. Thiazolidinediones improve endothelial function, raise HDL levels, slightly lower blood pressure, and have been shown to reduce restenosis after percutaneous transluminal coronary artery stenting.

■ **Adverse Effects.** Troglitazone, the first thiazolidinedione approved, caused idiosyncratic hepatotoxicity and had 28 deaths from liver failure, which prompted removal from the U.S. market in March 2000. Approximately 1.9% of patients placed on troglitazone had alanine aminotransferase (ALT) levels more than three times the upper limit of normal. The incidence, using these criteria for elevated liver enzymes, with pioglitazone (0.25%) and rosiglitazone (0.2%) has been low. No evidence of hepatotoxicity was reported in an analysis of more than 5,000 patients given rosiglitazone or pioglitazone.^{76,77} Several case reports of hepatotoxicity with rosiglitazone or pioglitazone have been reported, but improvement in ALT was consistently noted when the drug was discontinued. Prior to therapy, it is recommended that an ALT be checked. ALT monitoring vigilance has been lowered, and it is now recommended that the ALT be checked periodically at the practitioner's discretion. Prior guidelines recommended every 2 months for the first year of therapy, then periodically. Patients with ALT levels >2.5 times the upper limit of normal should not start either medication, and if the ALT is >3 times the upper limit of normal the medication should be discontinued.

Retention of fluid leads to many different possible side effects with rosiglitazone and pioglitazone. The etiology of the fluid retention has not been fully elucidated, but appears to include peripheral vasodilation and/or improved insulin sensitization with a resultant increase in renal sodium and water retention. A reduction in plasma hemoglobin (2% to 4%), attributed to a 10% increase in plasma volume, may result in a dilutional anemia which does not require treatment. Edema is also commonly (4% to 5% in mono- or combination therapy) reported. When a thiazolidinedione is used in combination with insulin, the incidence of edema (~15%) is increased. Thiazolidinediones are contraindicated in patients with New York Heart Association Class III and IV heart failure, and great caution should be exercised when given to patients with Class I and II heart failure or other underlying cardiac disease, as pulmonary edema and heart failure have been reported. Edema tends to be dose related and if not severe, a reduction in the dose as well as use of diuretics will allow the continuation of therapy in the majority of patients.⁷⁸

Weight gain, which is also dose related, can be seen with both rosiglitazone and pioglitazone. Mechanistically, both fluid retention and fat accumulation play a part in explaining the weight gain. Thiazolidinediones, besides stimulating fat cell differentiation, also reduce leptin levels, which stimulate appetite and food intake. Average weight gain varies, but a 1.5- to 4-kg weight gain is not uncommon. Rarely, a patient will gain large amounts of weight in a short period of time, and this may necessitate discontinuation of therapy. Weight gain positively predicts a larger HbA_{1c} reduction, but must be balanced with the well documented effects of long term weight gain.

As a caution, anovulatory patients may resume ovulation on thiazolidinediones. Adequate pregnancy and contraception precautions should be explained to all women capable of becoming pregnant, as both agents are pregnancy category C.

■ **Drug Interactions.** No significant drug interactions have been noted with either medication. Neither pioglitazone nor rosiglitazone appear to be inhibitors or inducers of CYP3A4/2C8 or CYP2C8/CYP2C9, respectively, though drugs that are strong inhibitors or inducers of these pathways necessitate close monitoring.

■ **Dosing and Administration.** The recommended starting dosages of pioglitazone and of rosiglitazone are 15 mg once daily and 2 to 4 mg once daily, respectively. Dosages may be increased slowly based on therapeutic goals and side effects. The maximum dose and maximum effective dose of pioglitazone is 45 mg, and rosiglitazone is 8 mg once daily, though 4 mg twice a day may reduce HbA_{1c} by 0.2% to 0.3% more vs. 8 mg once daily.

■ **α-Glucosidase Inhibitors**

■ **Pharmacology.** Currently, there are two α-glucosidase inhibitors available in the United States (acarbose and miglitol). α-Glucosidase inhibitors competitively inhibit enzymes (maltase, isomaltase, sucrase, and glucoamylase) in the small intestine, delaying the breakdown of sucrose and complex carbohydrates.^{79,80} They do not cause any malabsorption of these nutrients. The net effect from this action is to reduce the postprandial blood glucose rise.

■ **Pharmacokinetics.** The mechanism of action of α-glucosidase inhibitors is limited to the luminal side of the intestine. Some metabolites of acarbose are systemically absorbed and renally excreted, whereas the majority of miglitol is absorbed and renally excreted unchanged.

■ **Efficacy.** Postprandial glucose concentrations are reduced (40 to 50 mg/dL), while fasting glucose levels are relatively unchanged (~10% reduction). Efficacy on glycemic control is modest (average reductions in HbA_{1c} of 0.3% to 1%), affecting primarily postprandial glycemic excursions. Thus patients near target HbA_{1c} levels with near normal fasting plasma glucose levels, but high postprandial levels, may be candidates for therapy.

■ **Microvascular Complications.** α-Glucosidase inhibitors modestly reduce HbA_{1c} levels, which have been shown to be related to the risk of microvascular complications.

■ **Macrovascular Complications.** The STOP-NIDDM study demonstrated that acarbose can decrease the conversion rate of impaired glucose tolerance to diabetes, as well as reduce the risk of

cardiovascular events.^{81,82} Currently, no medication is FDA approved for the prevention of type 2 DM.

■ **Adverse Effects.** The gastrointestinal side effects, such as flatulence, bloating, abdominal discomfort, and diarrhea, are very common and greatly limit the use of α-glucosidase inhibitors. Mechanistically, these side effects are caused by distal intestinal degradation of undigested carbohydrate by the microflora, which results in gas (CO₂ and methane) production. α-Glucosidase inhibitors should be initiated at a low dose and titrated slowly to reduce gastrointestinal intolerance. Beano, an α-glucosidase enzyme, may help to decrease gastrointestinal side effects, but may decrease efficacy slightly.⁸³

If a patient develops hypoglycemia within several hours of ingesting an α-glucosidase inhibitor, oral glucose is advised because the drug will inhibit the breakdown of more complex sugar molecules. Milk, with lactose sugar, may be used as an alternative when no glucose is available, as acarbose only slightly (10%) inhibits lactase.

Rarely, elevated serum aminotransferase levels have been reported with the highest doses of acarbose. It appeared to be dose and weight related, and is the premise for the weight-based maximum doses.

■ **Dosing and Administration.** Dosing for both miglitol and acarbose are similar. Initiate with a very low dose (25 mg with one meal a day); increase very gradually (over several months) to a maximum of 50 mg three times a day for patients ≤60 kg or 100 mg three times a day for patients >60 kg (see Table 72–11). Both α-glucosidase inhibitors should be taken with the first bite of the meal so that drug may be present to inhibit enzyme activity. Only patients consuming a diet high in complex carbohydrates will have significant reductions in glucose levels. α-Glucosidase inhibitors are contraindicated in patients with short-bowel syndrome or inflammatory bowel disease, and neither should be administered in patients with serum creatinine >2 mg/dL, as this population has not been studied.

■ PIVOTAL TRIALS

■ DIABETES CONTROL AND COMPLICATIONS TRIAL

➤ Much of the last century in diabetes care was dominated by the debate over whether glycemic control actually was causative in complications of DM. Animal studies and some human studies suggested that the worse the glycemia the greater the risk of complications. But “the glucose hypothesis” was not ultimately accepted as proven until the publication of the DCCT in 1993.⁵² One thousand four hundred forty-one patients with type 1 DM were divided into two groups: those without complications (726 subjects, primary prevention), and those with early microvascular complications (715 subjects, secondary prevention). These two groups were then again divided into two groups, one randomized to receive conventional therapy (one or two shots of insulin daily and infrequent SMBG with no attempt to change therapy based on home blood glucose readings), and the other to receive intensive therapy (3+ injections of insulin daily or insulin pump, with frequent SMBG and alteration of insulin therapy based on SMBG results, plus frequent contact with a health professional). After 6.5 years mean follow-up with a difference in HbA_{1c} between the two groups being ≈2% (≈9% vs. ≈7%), retinopathy was decreased by 76% in the primary prevention cohort, with retinopathy progression reduced 54% in the secondary prevention group. Neuropathy was decreased by 60% in both groups combined. Microalbuminuria

was decreased 39%, while macroproteinuria was reduced 54% with intensive therapy. Hypoglycemia was more common and weight gain greater with intensive therapy. A non–statistically significant reduction in coronary events was seen in the intensively treated group as compared to the conventional group. Follow-up studies 8 years after the DCCT ended continued to show an advantage of good glycemic control over what was previously considered conventional therapy.⁸⁴ The DCCT revolutionized therapy of DM, demanding that stricter glycemic control be the goal.

■ IMPLICATIONS OF THE UNITED KINGDOM PROSPECTIVE DIABETES STUDY

The UKPDS was a landmark study for the care of patients with type 2 DM, confirming the importance of glycemic control for reducing the risk of microvascular complications.⁵³ More than 5000 patients with newly diagnosed type 2 DM were entered into the study. Patients were followed for an average of 10 years. The major portion of the study assessed “conventional therapy” (no drug therapy unless the patient was symptomatic or had fasting plasma glucose >270 mg/dL), versus intensive therapy starting with either sulfonylureas or insulin, aimed at keeping the fasting plasma glucose <108 mg/dL. A subset of obese patients was studied using metformin as the primary therapeutic agent.

CLINICAL CONTROVERSY

Preservation of β -cell function, and thus arresting the progression of type 2 diabetes, appears to be the future goal of treatment. The UKPDS clearly showed that sulfonylureas, metformin, and insulin are ineffective in stopping the progressive β -cell failure. In animal models thiazolidinediones (TZDs) have been able to arrest β -cell failure, and in humans short-term indirect β -cell function measures have shown improvements. This could mean that TZDs arrest the progressive β -cell decline in type 2 DM. Based on these data and the large amount of indirect evidence showing that TZDs may be cardioprotective, some clinicians have started using TZDs as first-line therapy. Glucagon-like peptide-1 derived therapies have also shown promise in this area, though no agents are FDA approved at the face of this writing. Long-term studies are underway.

Significant findings from the study include:

- Microvascular complications (predominantly the need for laser photocoagulation on retinal lesions) are reduced by 25% when median HbA_{1c} is 7% as compared to 7.9%.⁵³
- A continuous relationship exists between glycemia and microvascular complications, with a 35% reduction in risk for each 1% decrement in HbA_{1c}. No glycemic threshold for microvascular disease exists.⁸⁵
- Glycemic control has minimal effect on macrovascular disease risk.⁵³ Excess macrovascular risk appears to be related to conventional risk factors such as dyslipidemia and hypertension.⁸⁶
- Sulfonylureas and insulin therapy do not increase macrovascular disease risk.⁵³
- Metformin reduces macrovascular risk in obese patients.⁷⁴
- Vigorous blood pressure control reduces microvascular and macrovascular events.⁸⁶ There was no evidence for a threshold systolic blood pressure above 130 mm Hg for protection

against complications. β -Blockers and angiotensin-converting enzyme (ACE) inhibitors appear to be equally efficacious.⁸⁷

■ THERAPEUTICS

8 Knowledge of the patient’s quantitative and qualitative meal patterns, activity levels, pharmacokinetics of insulin preparations, and pharmacology of oral antidiabetic agents for type 2 DM are essential to individualize the treatment plan and optimize blood glucose control while minimizing risks for hypoglycemia and other adverse effects of pharmacologic therapies.

■ TYPE 1 DIABETES MELLITUS

The choice of therapy for type 1 DM is simple: all patients need insulin. However, how that insulin is delivered to the patient is a matter of considerable practice difference among patients and clinicians. Historically, after the discovery of insulin by Banting and Best in 1921, frequent injections of regular insulin (initially the only insulin available) were given. Modifications of insulin led to longer-acting insulin suspensions and the use by many patients of one or two shots of longer-acting insulin each day. Because SMBG and HbA_{1c} testing were not available at that time, patients and practitioners had no idea how well their patients’ blood glucose concentrations were controlled, other than a vague sense from an indirect method, measurement of glucose in the urine. While the renal threshold for glucose is relatively predictable in young healthy subjects, it is highly variable in older patients and patients with renal disease. The advent of SMBG and HbA_{1c} testing in the 1980s revolutionized the care of diabetes, enabling patients and practitioners to directly access blood glucose for assessment, and enabling the patient to make instantaneous changes in the insulin regimen if need be. Modern diabetes management would be impossible without these two tools.

Contemporary management of type 1 DM attempts to match carbohydrate intake with glucose-lowering processes, most commonly insulin, as well as with exercise. Diet is still the cornerstone of diabetes therapy, but unlike in previous years, attempts are made to allow the patient to live as normal a life as possible. Understanding the principles of glucose input and glucose egress from the blood will allow the practitioner and the patient great latitude in the management of patients with type 1 DM.

Simplistically speaking, one can break down normal insulin secretion into a relatively constant background level of insulin (“basal”) for the fasting and postabsorptive period, and prandial spikes of insulin after eating (“bolus”) (Fig. 72–7).⁸⁸ Insulin sensitivity and insulin secretion are not constant throughout the day, rendering the basal concept inaccurate. However, in most clinical situations, this approach provides a useful paradigm for understanding and applying insulin treatment for type 1 DM. The other basic principle to consider is that the timing of insulin onset, peak, and duration of effect must match meal patterns and exercise schedules to achieve near-normal blood glucose values throughout the day.

Historically, complexity of insulin regimens has usually been related to the number of injections of insulin administered per day. This is a reasonable classification. Clearly one injection of any insulin preparation daily will in no way mimic normal physiology, and therefore is unacceptable. Similarly, two injections of any insulin daily will fail to replicate normal insulin release patterns. Injection regimens that begin to approximate physiologic insulin release start with

Intensive insulin therapy regimens

FIGURE 72-7. Relationship between insulin and glucose over the course of a day and how various insulin regimens could be given. A, aspart; CS-II, continuous subcutaneous insulin infusion; G, glargine; L, lente; Lis, lispro; N, NPH; R, regular; UL, ultralente.

“split-mixed” injections of a morning dose of neutral protamine Hagedorn (NPH) and regular insulin before breakfast, and again before the evening meal. The presumption is made that the morning NPH insulin gives basal insulin for the day and covers the midday meal, the morning regular insulin covers breakfast, the evening NPH insulin gives basal insulin for the rest of the day, and the evening regular covers the evening meal. If patients are very compulsive about consistency of timing of their injections and meals and intake of carbohydrate, such a strategy may be successful. However, most patients are not sufficiently predictable in their schedule and food intake to allow “tight” glucose control with such an approach.

The first modification that is frequently made to such a regimen is the movement of the evening NPH to bedtime (now three total injections per day) because the fasting glucose in the morning is too high. This approach improves glycemic control and reduces hypoglycemia, sufficiently intensifying the insulin therapy for some patients.⁸⁹ However, many patients need a more intense approach that also allows greater flexibility in their lifestyle.

9 The basal-bolus concept is an attempt to replicate normal insulin physiology with a combination of intermediate- or long-acting insulin to give the basal component, and short-acting insulin to give the bolus component. Various strategies have been used for the former, including once- or twice-daily NPH, lente, or ultralente insulin, or once-daily insulin glargine. Most patients require two shots of all of the above insulins except insulin glargine. Also, all of the above

insulins, with the exception of insulin glargine, have some degree of peak effect that must be considered in planning meals and activity. Insulin glargine is a feasible basal insulin supplement for most patients with type 1 DM. The bolus insulin component is given before meals with regular insulin, lispro insulin, or insulin aspart. The rapid onset of action and short time course of lispro insulin and insulin aspart more closely replicate normal physiology. This approach allows the patient to vary the amount of insulin injected, depending on the preprandial SMBG level, the anticipated activity (upcoming exercise may reduce insulin requirement), and anticipated carbohydrate intake. Most patients will have a prescribed dose of insulin preprandially that they vary by use of a “sliding scale.” This type of adjusted scale insulin is intended to optimize the insulin regimen. In light of the negative connotation of the term “sliding scale” (usually referring to giving insulin only after the blood glucose increases, rather than treating the underlying disorder), a better descriptor for the adjusted-dose insulin is *variable-dose prandial insulin* or insulin algorithm. Carbohydrate counting is a very effective tool for determining the amount of insulin to be injected preprandially. Although general algorithms give rough guidelines, each patient will have to adjust the prescribed preprandial insulin dosage to achieve optimal glucose control.

As a rough estimate, patients may be begun on ≈ 0.6 units/kg per day with basal insulin 50% of total dose and prandial insulin 20% of total dose prebreakfast, 15% prelunch, and 15% presupper. Type 1 DM patients generally require between 0.5 and 1 unit/kg per day. The need for significantly higher amounts of insulin suggests the presence of insulin antibodies or insulin resistance (coexistent endocrinopathy or type 2 DM).

Obviously, insulin pump therapy (continuous subcutaneous insulin infusion [CSII], generally using lispro or aspart insulin to diminish aggregation) is the most sophisticated form of basal bolus insulin delivery system. CSII may be slightly more efficacious in achieving good glycemic control than multiple-dose insulin injections.^{90,91} Extensive discussion of this mode of therapy is beyond the scope of this text.⁹² Nevertheless, the basic principles for implementation are the same. The one advantage of pump therapy is that the basal insulin dose may be varied, consistent with changes in insulin requirements throughout the day. In selected patients, this feature will allow greater glycemic control with CSII. However, insulin pumps require even greater attention to detail and frequency of SMBG than four injections daily.⁹³ In appropriately selected patients willing to pay sufficient attention to detail of SMBG and insulin administration, CSII can be a very useful form of therapy.

Intensive therapy (basal bolus) to all adult patients with type 1 DM at the time of diagnosis is recommended to reinforce the importance of glycemic control from the outset rather than change strategies over time after lack of control. Occasional patients with an extended honeymoon period may need less intense therapy initially, but should be converted to basal bolus therapy at the onset of glycemic lability. For patients insisting on two injections daily, NPH and regular insulin (starting at 0.6 units/kg with two-thirds in the morning, two-thirds of morning dose as NPH, and one-half of evening dose as NPH) may be sufficient. Regardless of the regimen chosen, gross adjustments in the total insulin dose can be made based on HbA_{1c} measurements and symptoms such as polyuria, polydipsia, and weight gain or loss. Finer insulin adjustments can be determined on the basis of the results of frequent SMBG.

All patients receiving insulin should have extensive education in the recognition and treatment of hypoglycemia. Yearly (or more often) questioning about the recognition of hypoglycemia is warranted. Documentation of frequency of hypoglycemia, particularly that requiring assistance of another person, visit to an emergent or

urgent care facility, or hospitalization, should be recorded. In type 1 DM, the development of hypoglycemia unawareness is common. It may result from progression of disease with autonomic neuropathy. Loss of adrenergic warning signs in such a situation is a relative contraindication to intensive insulin therapy. More commonly, type 1 DM patients have loss of warning signs because of a presumed lower set-point for release of counterregulatory hormones as a result of frequent episodes of hypoglycemia (“hypoglycemia begets hypoglycemia”).⁹⁴ In such situations, more normal hypoglycemia awareness may be restored by reduction or redistribution of the insulin dose to eliminate significant hypoglycemic episodes. A recent publication has found that short-term treatment with theophylline will improve hypoglycemia awareness.⁹⁵ Whether this therapy should routinely be employed is still unknown.

Children and pubescent adolescents are relatively protected from microvascular complications and must be managed with consideration of what is practical. Therefore it is not unreasonable to use less-intense management (two shots per day, premixed insulins) until the patient is postpubertal.⁹⁶

Occasional patients have antibodies to injected insulin, but the significance of the antibodies is minimal.⁹⁷ Human insulin therapy has not totally eliminated insulin allergies, although most patients have a local reaction that will dissipate over time. If the allergic reaction does not improve or is systemic, insulin desensitization can be carried out.⁹⁸ Protocols for desensitization are available from major insulin manufacturers. While more common in the animal insulin era, lipohypertrophy is still seen in some patients with longstanding type 1 DM. Such patients give their insulin injections in the same site to minimize discomfort. Because insulin absorption from an area of lipohypertrophy is unpredictable, avoidance of injections into these areas is mandatory.

Several common errors can occur in the therapy of patients with type 1 DM, causing erratic glucose fluctuations:

- Failure to take into account peaks of insulin action when using a peaking insulin and planning meals and/or activity. Eating should be planned around the peaks of the insulin.
- Random rotation of insulin injection sites. There is sufficient variability of insulin absorption from site to site that this practice alone may cause wide glucose swings. The most consistent absorption of insulin is from the abdominal wall. We try to get our patients to take all their injections in the abdomen. If the patient is unable or unwilling to follow this advice, then systematic site rotation is the next preferable option. The patient always gives the insulin injection in the same region of the body the same time of the day each day. For instance, the arms are always used every morning. Needless to say, the patient would not inject in a limb and then go out and exercise that limb, increasing blood flow and insulin absorption.
- Overinsulinization is a very common problem. The answer to all high blood glucose is not necessarily more insulin, as the patient may be insulinopenic, or may be “rebounding” from a previous low glucose and treating it with excessive amounts of carbohydrate. Fastidious SMBG, particularly during the night (or selected use of continuous glucose monitoring) will help sort this out. Also, practitioners sometimes do not adequately differentiate type 1 DM from type 2 DM when using insulin. Patients with type 1 DM are insulinopenic but have normal insulin sensitivity. Patients with type 2 DM have varying degrees of insulin resistance. Therefore one unit change in the dose of insulin for a patient with type 1 DM may have a dramatic effect on glucose concentrations, whereas in some

patients with type 2 DM 10 to 20 times that amount of insulin may have little effect on glucose. Large changes in insulin dose in patients with type 1 DM are not usually indicated unless the patient’s blood glucose control is very poor. Widely erratic SMBG results and/or weight gain often suggest overinsulinization.

- When in doubt, always double check the patient’s technique for insulin dosing, insulin injection, and SMBG. Sometimes the simplest of errors results in miserable glycemic control.

Islet cell and whole pancreas transplantation are occasionally used in patients, usually renal transplants, who require immunosuppressive therapy for other reasons.⁹⁹ There has been considerable interest in islet cell transplantation since investigators in Edmonton reported success without using glucocorticoids as immunosuppressive agents.¹⁰⁰ Some of these patients are able to come off insulin altogether.

TYPE 2 DIABETES MELLITUS

Pharmacotherapy for type 2 DM has changed dramatically in the last few years with the addition of several new drug classes and recommendations to achieve more stringent glycemic control. Symptomatic patients may initially require treatment with insulin or combination oral therapy to reduce glucose toxicity (which may reduce β -cell insulin secretion and worsen insulin resistance). Patients with HbA_{1c} \approx 7% or less are usually treated with therapeutic lifestyle measures with or without an insulin sensitizer. Those with HbA_{1c} $>$ 7% but $<$ 8% are initially treated with single oral agents. Patients with higher initial HbA_{1c} may benefit from initial therapy with two oral agents.

Depending on patient motivation and adherence to therapeutic lifestyle changes, most patients with HbA_{1c} greater than 9% to 10% will likely require therapy with two or more agents to reach glycemic goals. Treatment of type 2 DM often necessitates use of multiple therapeutic agents (combination therapy), including oral antihyperglycemics and insulin to obtain glycemic goals.

The best initial oral therapy for patients with type 2 DM is widely debated. Based on the results of the UKPDS and safety record, obese patients ($>$ 120% ideal body weight) without contraindications should be started on metformin titrated to \approx 2,000 mg/d.¹⁰¹ Near-normal weight patients may be treated with insulin secretagogues. Failure of initial therapy should result in addition rather than substitution (reserve substitution for intolerance to a drug due to side effects) of another class of drug. For cost and efficacy reasons, metformin and an insulin secretagogue are often first- and second-line therapy. Initial oral combination therapy for patients with HbA_{1c} $>$ 9% to 10% should be considered, and several oral combination products (Glucovance and Metaglip) have been approved as a first-line treatment. Figure 72–8 is an algorithm developed by the Texas Diabetes Council for glycemic control. Thiazolidinediones may be substituted in situations in which a patient is intolerant of, or has a contraindication to, metformin as an insulin sensitizer. In the UKPDS, insulin, metformin, or sulfonylureas did not halt β -cell failure. Thiazolidinediones, in a Zucker diabetic fatty rat model, preserved β -cell function.¹⁰² Short-term human studies have reinforced these results through indirect measures of β -cell function, and if similar results are found long-term, thiazolidinediones could become first-line therapy. For dual therapy, HbA_{1c} reductions vary according to the medication added to the current therapy (Table 72–13). After a patient has inadequate control on two drugs, adding a third class of oral agents (usually a thiazolidinedione) can be considered, though triple therapy is not presently FDA approved. (Triple

combination therapy with a sulfonylurea, metformin, and troglitazone was approved,¹⁰³ but troglitazone is no longer available for use.) An alternative is to add an intermediate-acting or long-acting insulin at bedtime, to the initial oral agent used or two-drug combination. Sulfonylureas are often stopped when insulin is added, but continuing the sulfonylurea is permissible until multiple daily injections are started, at which time it should definitely be discontinued.

Virtually all patients with type 2 DM ultimately become relatively insulinopenic and will require insulin therapy. Insulin therapy for type 2 DM has changed dramatically in the last few years. Specifically, patients are often “transitioned” to insulin by using a bedtime injection of an intermediate- or long-acting insulin, using oral agents primarily for control during the day.^{104,105} This strategy leads to less hyperinsulinemia during the day and is associated with less weight gain than the more traditional insulin strategies. Because most patients are insulin resistant, insulin sensitizers are commonly used with insulin therapy. Patients with type 2 DM are usually well buffered against hypoglycemia. Patients should be monitored for hypoglycemia by asking about nocturnal sweating, nightmares (both indicative of nocturnal hypoglycemia), palpitations, tremulousness, and neuroglycopenic symptoms, as well as SMBG. When bedtime insulin plus daytime oral medications fails, a conventional multiple daily dose insulin regimen while continuing the insulin sensitizers should be tried. Concerns and problems with insulin administration as addressed in the section on type 1 DM generally relate to the therapy of type 2 DM. However, patients with type 2 DM rarely have hypoglycemia unawareness. Also, the variability of insulin resistance means that insulin doses may range from 0.7 to 2.5 units/kg or more. Figure 72–9 is an algorithm for insulin therapy options in type 2 diabetes developed by the Texas Diabetes Council.

The availability of short-acting insulin secretagogues, very short-acting insulin, and α -glucosidase inhibitors, all of which target postprandial glycemia, has reminded practitioners that glycemic control is a function of fasting and preprandial glycemia and postprandial glycemic excursions.¹⁰⁶ Therefore postprandial glucose measurements may need more emphasis if the HbA_{1c} is near the glycemic goal. Currently, it remains to be seen whether targeting after-meal glucose excursions will have more of an effect on complications risk than more conventional strategies. Importantly, postprandial excursions proportionally contribute more than the fasting plasma glucose to the HbA_{1c} percentage obtained as the HbA_{1c} nears goals, and thus will need to be targeted for optimal glycemic control in many patients. In epidemiologic studies post–glucose challenge glucose measurements are a better predictor of macrovascular disease risk and form the basis for American College of Endocrinology/American Association of Clinical Endocrinologists postprandial glycemic goals (see Table 72–7).¹⁰⁷

■ SPECIAL POPULATIONS

■ CHILDREN AND ADOLESCENTS WITH TYPE 2 DM

Type 2 DM is increasing in adolescence.¹⁰ Obesity and physical inactivity seem to be particular culprits in the pathogenesis of this disease. Given the many years that the patient will have to live with diabetes, and recent evidence that the timeline for complications may mimic that of older adults, extraordinary efforts should be expended on lifestyle modification measures in an attempt to normalize glucose levels. Failing that strategy, the only labeled oral agent for use in children (10 to 16 years) is metformin, though sulfonylureas are also commonly used in therapy. Thiazolidinediones have not been studied

in children, but studies to ascertain safety and efficacy are currently underway. In adolescent females, the possibility of future pregnancy should be considered in the prescription of any drug regimen.

■ ELDERLY PATIENTS WITH DM

Elderly patients with newly diagnosed DM (almost always type 2 DM) present a different therapeutic challenge. Consideration of the risks of hypoglycemia in this population and the probable life span should help determine if less-stringent glycemic goals should be set. Thinner, older patients may primarily be treated with shorter-acting insulin secretagogues, low-dose sulfonylureas (preferably not long-acting ones), or α -glucosidase inhibitors. Risk for lactic acidosis, which increases with older age and the age-related decline in renal function, makes metformin therapy more problematic. Thiazolidinediones may offer another alternative in patients in whom some weight gain is not unwelcome. Simple insulin regimens may be another easy approach to glycemic control in elderly patients with newly diagnosed DM.

■ GESTATIONAL DM

Gestational DM is diagnosed as previously described. Dietary therapy to minimize wide fluctuations in blood glucose is of paramount importance.⁵ Intensive educational efforts are usually necessary. Pregnant women without DM maintain plasma glucose concentrations between 50 and 130 mg/dL. Frequent SMBG is needed to tell whether dietary interventions are successful. If fasting plasma glucose is >105 mg/dL, or 1-hour postprandial plasma glucose levels are >155 mg/dL, or if 2-hour postprandial plasma glucose levels are >130 mg/dL, insulin therapy is usually begun. One shot of NPH or a mixture of NPH and regular insulin in a 2:1 ratio given before breakfast may be adequate to reach glucose targets. Titration of insulin and switching to more complicated regimens is guided by SMBG results. In spite of the long-standing labeling of sulfonylureas as contraindicated in pregnancy, one randomized, open-label, controlled trial evaluated the efficacy of glyburide as compared to insulin initiated after 11 weeks' gestation.¹⁰⁸ Adequate control of blood glucose was achieved as compared to traditional insulin therapy, with less hypoglycemia in the glyburide group. No evidence of any difference in complications, specifically cord-serum insulin concentrations, incidence of macrosomia, cesarean delivery, or neonatal hypoglycemia between regimens were noted. Glyburide was not detected in the cord serum of any infant. As the study limited enrollment beyond 11 weeks' gestation, no conclusions regarding teratogenicity can be made from this study. The ADA cites this study in a position paper and mentions its utility, but also warns that it is not a labeled use of the drug and suggests further studies are needed to establish its safety.¹² Patients with gestational DM should be evaluated 6 weeks after delivery to ensure that normal glucose tolerance has returned. Because these patients' long-term risk for the development of DM is considerable, periodic assessment after that is warranted.

■ SPECIAL SITUATIONS

■ SICK DAYS

Acute self-limited illness rarely presents a major problem for patients with type 2 DM, but can be a significant challenge for insulinopenic type 1 DM patients.¹⁰⁹ While caloric intake generally declines, insulin

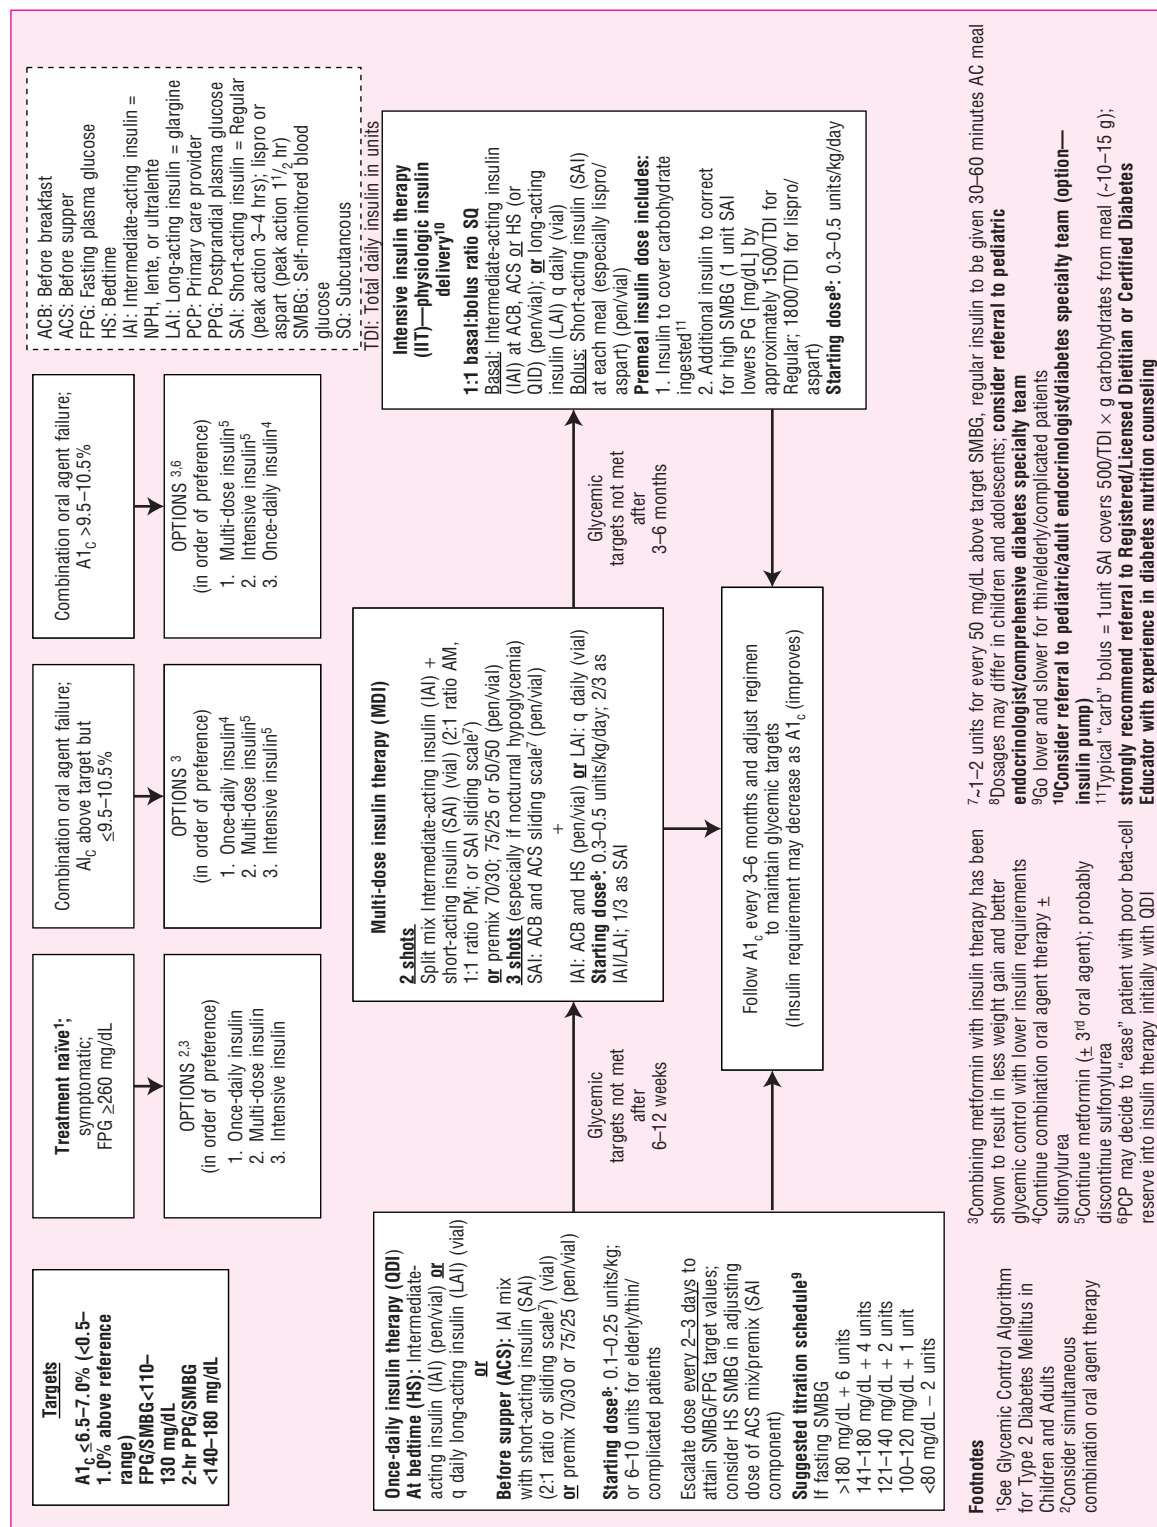

FIGURE 72-9. Insulin algorithm for type 2 DM in children and adults. See www.texasdiabetescouncil.org for current algorithms. (Reprinted with permission from the Texas Diabetes Council.)

sensitivity also decreases, meaning that it may take greater amounts of insulin to control blood glucose concentrations. Patients need to be adept at frequent SMBG, checking urine ketones, use of short-acting insulin, and understanding that sugar intake in this situation is not “bad” but may be necessary to “cover” the insulin therapy given to keep the patient out of diabetic ketoacidosis. We encourage patients to continue their usual insulin regimen and to use supplemental rapid-acting insulin based on SMBG results, with further additional insulin given if ketonuria develops. Sugar and electrolyte solutions, such as sports drinks, can be used to maintain hydration, to provide needed electrolytes if there are significant gastrointestinal or urinary losses, and to provide sugar to keep the patient from developing hypoglycemia because of the extra insulin that is usually needed. In contrast, type 2 patients may need to switch to sugar-free drinks if blood glucose levels are continually elevated. Most patients can be taught how to sufficiently manage sick days and avoid hospitalization.

■ DIABETIC KETOACIDOSIS AND HYPEROSMOLAR HYPERGLYCEMIC STATE

Diabetic ketoacidosis and hyperosmolar hyperglycemic state are true diabetic emergencies.^{110,111} A comprehensive discussion of their treatment is beyond the scope of this book. In patients with known diabetes, diabetic ketoacidosis is usually precipitated by insulin omission in type 1 DM, and intercurrent illness, particularly infection, in both type 1 and type 2 DM. However, patients with type 1 or type 2 DM (the latter being usually non-whites or Hispanics) may present at initial presentation.¹¹² It is possible that some of the patients deemed to have type 2 DM actually have type 1 idiopathic DM. Patients with diabetic ketoacidosis may be alert, stuporous, or comatose at presentation. The hallmark diagnostic laboratory values include hyperglycemia, anion gap acidosis, and large ketonuria. Afflicted patients have fluid deficits of several liters and sodium and potassium deficits of several hundred milliequivalents. Restoration of intravascular volume acutely with normal saline, followed by hypotonic saline to replace free water, potassium supplements, and constant infusion insulin restore the patient’s metabolic status relatively quickly. A flow sheet is often helpful in tracking the fluid and insulin therapies and laboratory parameters in these patients. Bicarbonate administration is generally not needed and may be harmful, especially in children.¹¹³ Treatment of the inciting medical condition is also vital. Hourly bedside monitoring of glucose and frequent monitoring (every 2 to 4 hours) of potassium is essential. Metabolic improvement is manifested by an increase in the serum bicarbonate or pH. Serum phosphorus usually starts high and plummets to lower-than-normal levels, though replacing phosphorus, while not unreasonable, is of questionable benefit in most patients. Fluid administration alone will reduce the glucose concentration, so a decrement in glucose values does not necessarily mean that the patient’s metabolic status is improving. Rare patients will require larger amounts of insulin than those usually given (5 to 10 units/h). We double the patient’s insulin dose if the serum bicarbonate has not improved after the first 4 hours of insulin therapy. Constant infusion of a fixed dose of insulin and the administration of intravenous glucose when the blood glucose level decreases to <250 mg/dL is preferable to titration of the insulin infusion based on the glucose level. The latter strategy may delay clearance of the ketosis and prolong treatment. The insulin infusion should be continued until the urine ketones clear and the anion gap closes. Long-acting insulin should be given 1 to 3 hours prior to discontinuing the insulin infusion. Intramuscular regular insulin or subcutaneous insulin lispro or aspart given every 1 to

2 hours can be utilized rather than an insulin infusion in patients without hypoperfusion. Patients may develop hyperchloremic metabolic acidosis with treatment if they have been given large volumes of normal saline in the course of their treatment. Such a situation does not require any specific treatment.

Hyperosmolar hyperglycemic state usually occurs in older patients with type 2 DM, at times undiagnosed, or in younger patients with prolonged hyperglycemia and dehydration or significant renal insufficiency. A large ketonemia is usually not seen, as residual insulin secretion suppresses the production of ketones. Infection or another medical illness is the usual precipitant. Fluid deficits are usually greater and blood glucose concentrations higher (at times >1000 mg/dL) in these patients than in patients with diabetic ketoacidosis. Blood glucose levels should be lowered very gradually with hypotonic fluids and low-dose insulin infusions (1 to 2 units/h). Rapid correction of the glucose levels, a drop greater than 75 to 100 mg/dL per hour, is not recommended, as it can result in cerebral edema. This is especially true for children with diabetic ketoacidosis. Mortality is high with the hyperosmolar hyperglycemic state.

■ HOSPITALIZATION FOR INTERCURRENT MEDICAL ILLNESS

Patients on oral agents may need transient therapy with insulin to achieve adequate glycemic control. In patients requiring insulin, patients should receive scheduled doses of insulin with additional short-acting insulin. “Sliding-scale” insulin is to be discouraged, as it is notorious for not controlling glucose and for sometimes resulting in therapeutic misadventures, with wide swings in the blood glucose as the patient “bounces” from hypoglycemia to hyperglycemia.¹¹⁴ In-hospital mortality is increased in many hyperglycemic conditions. Recent work documented a reduction in mortality in type 2 diabetes patients with acute myocardial infarctions¹¹⁵ who receive constant intravenous insulin during the acute phase of the event to maintain near-normal glucose concentrations. In the case of cardiac ischemia, the beneficial effects may be a result of reducing free fatty acids or inflammation with insulin therapy. Similar mortality results have been documented in several intensive care unit settings using intravenous insulin and tight glucose control.^{116,117} Recently, the American College of Endocrinology released a position statement on inpatient glycemic control which recommended preprandial levels <110 mg/dL, and postprandial levels <180 mg/dL.¹¹⁸ It is prudent to stop metformin in all patients who arrive in acute care settings until full elucidation of the reason for presentation can be ascertained, as contraindications to metformin are prevalent in hospitalized patients.¹¹⁹

■ PERIOPERATIVE MANAGEMENT

Surgical patients may experience worsening of glycemia for reasons similar to those listed above for intercurrent medical illness.¹²⁰ Patients on oral agents may need transient therapy with insulin to control blood glucose. In patients requiring insulin, scheduled doses of insulin or continuous insulin infusions are preferred. For patients who can eat soon after surgery, the time-honored approach of giving one-half of the usual morning NPH insulin dose with dextrose 5% in water intravenously is acceptable, with resumption of scheduled insulin, perhaps at reduced doses, within the first day. For patients requiring more prolonged periods without oral nutrition and for major surgery, such as coronary artery bypass grafting and major abdominal surgery,

constant infusion intravenous insulin is preferred. Metformin should be discontinued temporarily after any major surgery until it is clear that the patient is hemodynamically stable and normal renal function is documented.

REPRODUCTIVE-AGE WOMEN AND PRECONCEPTION CARE FOR WOMEN

An increasing prevalence of DM has been noted in reproductive-age women.^{121,122} Prepregnancy planning is absolutely mandatory, as organogenesis is largely completed within 8 weeks, so good glycemic control should be obtained prior to conception. Unfortunately, major congenital malformations due to poor glucose control remain the leading cause of mortality and serious morbidity in infants of mothers with type 1 or type 2 diabetes. For women with diabetes mellitus controlled by lifestyle measures alone, conversion to insulin as soon as the pregnancy is confirmed is appropriate. For women with polycystic ovary disease who ovulate and become pregnant with insulin sensitizer therapy, conversion to insulin is mandatory as soon as pregnancy is confirmed. Insulin is the only acceptable pharmacologic therapy during pregnancy for women with diabetes mellitus in the United States. In Europe, metformin is sometimes used in pregnancy for type 2 DM, but its use is eschewed in the United States. Patients previously treated with insulin may need intensification of their regimen to achieve therapeutic goals. Normal pregnancy is associated with a decrease in the blood glucose concentration as fuel is diverted to the fetus. Pregnant patients will be ingesting both meals and snacks daily. SMBG is generally intensified to try to reach glycemic targets and reduce fetal and maternal morbidity. Whether preprandial or postprandial glucose concentrations should be the target of therapy is hotly debated. Ketosis should be avoided, requiring urine monitoring for ketones in the morning and if the blood sugar is >200 mg/dL.

There has been some concern about the safety of insulin analogs in pregnancy, both for fetal development and advancement of microvascular complications. One study has shown no increase in retinopathy or progression of same with the use of insulin lispro in pregnancy.¹²³

SPECIAL TOPICS

PREVENTION OF DIABETES MELLITUS

Efforts to prevent type 1 DM with immunosuppressives¹²⁴ or injected¹²⁵ or oral insulin therapy¹²⁶ have been unsuccessful. The Diabetes Prevention Program¹²⁷ confirmed that modest weight loss in association with exercise can have a dramatic impact on insulin sensitivity and the conversion from impaired glucose tolerance to type 2 diabetes. In this study approximately 2,000 individuals with impaired glucose tolerance were randomized to lifestyle changes (diet, exercise, and weight loss) vs. usual care. The study, which was originally planned to be ongoing for 5 years, was stopped after 2.8 years because the results were so conclusive. The usual care group developed diabetes at the rate of 11% each year. The lifestyle arm developed diabetes at a rate of 5% per year, a 58% reduction in the risk of developing diabetes.¹²⁷ Surprisingly, a modest amount of diet and exercise yielded impressive results. The exercise program in the lifestyle group was walking 30 minutes 5 days each week. The mean weight loss over the 2.8 year study period was only 8 pounds. Similar results were seen in the Finnish Diabetes Study.¹²⁸ In the Diabetes Prevention

Program¹²⁷ discussed above, approximately 1,000 of the study patients were randomized to metformin therapy. The metformin-treated patients showed a 4-pound weight loss on average, and a reduction in the risk of developing diabetes of 31% compared to placebo.¹²⁷ Interestingly, young and overweight individuals on metformin had a greater reduction in the risk of developing diabetes than normal weight and older study patients.¹²⁷

The TRIPOD study¹²⁹ evaluated the ability of troglitazone to prevent the development of diabetes in women with a history of gestational diabetes. The rate of development of diabetes in the placebo arm of the study was approximately 12% per year, compared to about 5% in the treatment group. Total preservation of β -cell function was demonstrated over a 5-year period in women who had near normal β -cell function at baseline and who initially responded to the drug.¹²⁹ The preservation of β -cell function was observed 8 months after the drug had been discontinued. It should be noted that no pharmacologic agents are currently FDA approved or recommended for prevention of type 2 diabetes, though prevention studies are underway using rosiglitazone, pioglitazone, nateglinide, ramipril, and valsartan.¹³⁰

CLINICAL CONTROVERSY

Diabetes mellitus is associated with a substantially higher risk of morbidity and mortality. Pharmacologic prevention or delay of type 2 DM has been widely discussed since the release of the Diabetes Prevention Program results. Though lifestyle changes were more effective, with a 58% lower relative risk of progression to diabetes, metformin 850 mg twice a day reduced the risk by 31%. Acarbose, troglitazone, and orlistat all have been able to prevent or delay the onset of type 2 DM. Despite these data, there are no FDA-approved or ADA-recommended medications for the delay or prevention of type 2 DM. Medications require monitoring, can have serious side effects, and have been documented to be less effective than lifestyle changes. Despite this, many clinicians are giving high-risk patients medication for the delay or prevention of diabetes, in combination with lifestyle changes.

PATIENT EDUCATION

It is not satisfactory to give patients with DM brief instructions with a few pamphlets and expect them to manage their disease adequately. Thinking that diabetes education is limited to one or two encounters is misguided; education is a lifetime exercise. Successful treatment of DM involves lifestyle changes for the patient (e.g., medical nutrition therapy, physical activity, self-monitoring of blood glucose and possibly of urine for ketones, and taking prescribed medications). The patient must be involved in the decision-making process and must learn as much about the disease and associated complications as possible. Emphasis should be placed on the evidence that indicates that complications can be prevented or minimized with glycemic control and management of risk factors for cardiovascular disease. Recognition of the need for proper patient education to empower them into self-care has generated programs for certification in diabetes education. Certified diabetes educators (CDEs) must document their patient education hours and sit for a certification examination that assesses the knowledge, tasks, and skills of an educator in order to become certified. An increasing number of nurses, pharmacists, dietitians, and

physicians are becoming CDEs to document to the public that they meet a minimum standard for diabetes education, and to fulfill quality initiatives in meeting guidelines for education recognition.¹³¹

■ TREATMENT OF CONCOMITANT CONDITIONS AND COMPLICATIONS

■ RETINOPATHY

Patients with established retinopathy should see an ophthalmologist or optometrist trained in diabetic eye disease.¹³² A dilated eye exam is required to fully evaluate diabetic eye disease. Early background retinopathy may reverse with improved glycemic control. More advanced retinopathy will not regress with improved glycemia, and may actually worsen with short-term improvements in glycemia. Studies are underway to determine whether medical therapy independent of glucose control will prevent the development of advanced retinopathy. Laser photocoagulation has markedly improved sight preservation in diabetic patients.

■ NEUROPATHY

Peripheral neuropathy is the most common complication seen in type 2 DM patients in outpatient clinics.¹³³ Paresthesias, numbness, or pain may be the predominant symptom. The feet are involved far more often than the hands. Improved glycemic control may alleviate some of the symptoms. If neuropathy is painful, symptomatic therapy is empiric, including low-dose tricyclic antidepressants, anticonvulsants (gabapentin, carbamazepine, and maybe phenytoin), duloxetine, venlafaxine, topical capsaicin, and various pain medications, including tramadol and nonsteroidal anti-inflammatory drugs. Recently, another anticonvulsant, topiramate, has shown promise in the reduction of symptoms, with the positive side effect of weight loss in type 2 diabetes patients. The numb variant of peripheral neuropathy is not treated with medication. Clinical manifestations of diabetic autonomic neuropathy include resting tachycardia, exercise intolerance, orthostatic hypotension, constipation, gastroparesis, erectile dysfunction, sudomotor dysfunction (anhidrosis, heat intolerance, gustatory sweating, and/or dry skin), impaired neurovascular function, and hypoglycemic autonomic failure. Gastroparesis can be a severe and debilitating complication of DM. Improved glycemic control, discontinuation of medications that slow gastric motility, and the use of metoclopramide (preferably for only a few days at a time) or erythromycin may be helpful. Gastric pacemakers as therapeutic hardware are rarely used, though available. Orthostatic hypotension may require pharmacologic management with mineralocorticoids or adrenergic agonist agents. In severe cases, supine hypertension is extreme, mandating that the patient sleep in a sitting or semirecumbent position. Patients with cardiac autonomic neuropathy are at a higher risk for silent myocardial infarction and mortality. The hallmark of diabetic diarrhea is its nocturnal occurrence. Diabetic diarrhea frequently responds to a 10- to 14-day course of an antibiotic such as doxycycline or metronidazole. In more unresponsive cases, octreotide may be useful. Erectile dysfunction is common in diabetes, and initial treatment should include a trial of one of the oral medications currently available to treat erectile dysfunction. People with diabetes often require the highest doses of these medications to have an adequate response. Sudomotor dysfunction, as earlier defined, results in loss of sweating and resultant dry, cracked skin. Use of hydrating creams and ointments is needed.

■ MICROALBUMINURIA AND NEPHROPATHY

Diabetes mellitus, and particularly type 2 DM, is the biggest contributor statistically to the development of end-stage renal disease in the United States.¹³⁴ The American Diabetes Association recommends a screening urinary analysis for albumin at diagnosis in persons with type 2 DM. Precise onset of type 2 DM can rarely be ascertained, and patients will often present at diagnosis with microvascular complications. In type 1 DM, microalbuminuria rarely occurs with short duration of disease or before puberty. Screening individuals with type 1 DM should begin with puberty and after 5 years' disease duration. There are three methods for assessing microalbuminuria: (1) measurement of the urine albumin:creatinine ratio in a random spot collection (preferably the first morning void); (2) 24-hour timed collection; and (3) timed (e.g., 4-hour or 10-hour overnight) collection. Microalbuminuria on a spot urine specimen is defined as a ratio of 30 to 300 mg/g albumin:creatinine. On timed collections, microalbuminuria is defined as 30 to 300 mg/24 hours or an albumin excretion rate of 20 to 200 mcg/min. Because of day-to-day variability, microalbuminuria should be confirmed on at least two of three samples over 3 to 6 months. Additionally, when assessing urine protein or albumin, conditions that may cause transient elevations in urinary albumin excretion should be excluded. These conditions include: intense exercise, recent urinary tract infections, hypertension, short-term hyperglycemia, heart failure, and acute febrile illness.¹³⁴

In type 2 DM, the presence of microalbuminuria is a strong risk factor for macrovascular disease and is frequently present at the time of diagnosis. Microalbuminuria may be a weaker predictor for future kidney disease in type 2 vs. type 1 DM.

Glucose and blood pressure control are most important for the prevention of nephropathy, and blood pressure control is the most important for retarding the progression of established nephropathy. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers, considered first-line recommended treatment modalities, have shown efficacy in preventing the clinical progression of renal disease in patients with type 2 diabetes mellitus.^{135–137} Diuretics frequently are necessary due to the volume-expanded state of the patient and are recommended second-line therapy. The American Diabetes Association and the National Kidney Foundation blood pressure goal of <130/80 mm Hg can be difficult to achieve. Three or more antihypertensives are often needed to treat to goal blood pressures.

■ PERIPHERAL VASCULAR DISEASE AND FOOT ULCERS

Claudication and nonhealing foot ulcers are common in type 2 DM patients.¹³⁸ Smoking cessation, correction of lipid abnormalities, and antiplatelet therapy are important strategies in treating claudicants. Pentoxifylline or cilostazol may be useful in selected patients. Revascularization is successful in selected patients. Local débridement and appropriate footwear and foot care are vitally important in the early treatment of foot lesions. In more advanced lesions, topical treatments may be of benefit. Diabetic foot care is an excellent example of the adage, "an ounce of prevention is worth a pound of cure."

■ CORONARY HEART DISEASE

◀ The risk for coronary heart disease (CHD) is two to four times greater in diabetic patients than in nondiabetic individuals. CHD

TABLE 72–14. Classification of Lipid and Lipoprotein Levels in Adults

| Parameter | Goal | Treatment (In Order of Preference) |
|-----------------|----------------------------------|--|
| LDL cholesterol | <100 mg/dL | Lifestyle; HMG-CoA reductase inhibitors; cholesterol absorption inhibitor; niacin or fenofibrate |
| HDL cholesterol | Men >40 mg/dL Women >50 mg/dL | Lifestyle; nicotinic acid; fibric acid derivatives |
| Triglycerides | <150 mg/dL | Lifestyle; glycemic control; fibric acid derivatives; high-dose statins (in those with high LDL) |

HDL, high-density lipoprotein; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; LDL, low-density lipoprotein.

is the major source of mortality in patients with DM. Recent studies suggest that multiple risk-factor intervention (lipids, hypertension, smoking cessation,¹³⁹ and antiplatelet therapy)¹⁴⁰ will reduce the burden of excess macrovascular events. Epidemiologic data suggest that CHD prevention guidelines for type 2 DM apply equally to patients with type 1 DM.¹⁴¹ β -Blocker therapy supplies an even greater protection from recurrent CHD events in diabetic patients than in non-diabetic subjects. Masking of hypoglycemic symptoms is a greater problem in type 1 DM patients than in patients with type 2 DM.

■ Lipids

The Scandinavian Simvastatin Survival Study showed 42% reduction in CHD events in diabetic patients with known CHD and very high LDL-C levels with simvastatin therapy (mean dose, 27 mg/day with LDL-C reduction of approximately 35%).¹⁴² Lesser degrees of risk reduction have been shown in other secondary prevention studies in patients treated with pravastatin with mild-to-moderate LDL-C elevation at baseline.¹⁴³ The Heart Protection Study randomized 5,963 patients age >40 years with diabetes and total cholesterol >135 mg/dL. A significant 22% reduction (95% confidence interval [CI] 13 to 30) in the event rate for major cardiovascular events was seen with simvastatin 40 mg per day. This was evident even at lower LDL levels (<116 mg/dL), and suggests that ~30% reduction in LDL levels regardless of starting LDL levels may be appropriate.¹⁴⁴ The diabetic subgroup in the Veterans Administration HDL Intervention Trial of CHD patients with low HDL-C and low LDL-C showed approximately 22% reduction in CHD events in diabetic patients with known CHD when HDL-C was increased by approximately 6% by gemfibrozil.¹⁴⁵

The new National Cholesterol Education Program Adult Treatment Panel III (NCEP-ATP)⁴⁷ guidelines classify the presence of DM as a CHD risk equivalent, and therefore recommend that LDL-C be lowered to <100 mg/dL. Unlike previous guidelines, more consideration is now given to HDL-C and triglycerides. The primary target is the treatment of LDL-C. After the LDL-C goal is reached (usually with a statin), triglycerides are considered for pharmacologic management, assuming unresponsiveness to glycemic control efforts, weight management, and exercise. In such situations, a non-HDL-C goal is established (a surrogate for all apolipoprotein B-containing particles). The non-HDL-C goal for patients with DM is <130 mg/dL. Niacin or a fibrate can be added to reach that goal if triglycerides are 201 to 499 mg/dL. Niacin or a fibrate can also be added if the LDL-C goal is reached, but the patient has low HDL-C (<40 mg/dL). Patients with marked hypertriglyceridemia (≥ 500 mg/dL) are at risk for pancreatitis. Efforts to reduce triglycerides with glycemic control, elimination

of other secondary causes (including medications), and drug therapy (fibrate and/or niacin) are effective treatment strategies. The American Diabetes Association also recommends similar LDL goals, but places raising HDL as the second priority (Table 72–14).

■ HYPERTENSION

The role of hypertension in increasing microvascular and macrovascular risk in patients with DM has been confirmed in the UKPDS⁸⁶ and Hypertension Optimization Treatment¹⁴⁶ trials. The American Diabetes Association recommends aggressive goals for blood pressure (<130/80 mm Hg) in patients with DM.⁵¹ ACE inhibitors and angiotensin receptor blockers are generally recommended for initial therapy. The National Kidney Foundation also suggests that the blood pressure goal be less than 130/80 mm Hg, as well as recommending diuretics as second-line therapy in patients with diabetic kidney disease.¹⁴⁷ Many patients require multiple agents, on average three agents, to obtain goals, so diuretics, calcium channel blockers, and β -blockers frequently are useful as second and third agents. Blood pressure goals are generally more difficult to achieve than glycemic goals or lipid goals in most diabetic patients.¹⁴⁸

CLINICAL CONTROVERSY

Initial therapy choices for hypertension in diabetes mellitus usually include angiotensin-converting enzyme inhibitors or an angiotensin receptor blocker due to their well documented renoprotective effects. Currently, angiotensin receptor blockers have less robust data to support cardiovascular reduction compared to other therapeutic choices, yet the data that exists appears to be positive in patients with type 2 DM. Also, diuretics have shown superior results to an ACE inhibitor in the ALLHAT trial. The ADA currently recommends the use of any class (ACE inhibitors, angiotensin receptor blockers, β -blockers, diuretics, or calcium channel blockers) of antihypertensive medication that has shown benefit in prevention of poor cardiovascular outcomes. Choice of monotherapy may not be important, as an average of two to three antihypertensive medications are needed to reach blood pressure goals.

■ TRANSPLANTATION

Whole pancreas and islet cell transplantation are still relatively experimental procedures in patients with type 1 DM; those with end-stage renal disease also receive kidney transplantation.¹⁴⁹

PHARMACOECONOMIC CONSIDERATIONS

As described in the introduction, the direct and indirect costs of DM are substantial. Much of the indirect costs are related to loss of productivity due to the significant morbidity (hospitalizations, loss of vision, lower extremity amputations, kidney failure, and cardiovascular events) associated with the disease. For a disease that affects only 5% to 6% of the population, it is responsible for 11% to 12% of health expenditures. With evidence from the DCCT and UKPDS to support intensive blood glucose control to reduce the risk of complications, the question of cost effectiveness comes into play.

An economic model based on the DCCT approximates that 120,000 persons in the U.S. would meet criteria for intensive intervention. The cost of implementing intensive therapy over the lifetime of the population is estimated at \$4 billion dollars. The benefits of this strategy are net gains of 920,000 years of sight, 691,000 years free from end-stage renal disease, and 678,000 years free from lower extremity amputations. The incremental cost per year of life gained is \$28,661. This is well within the limits of a cost-effective strategy and compares favorably to treatment of high blood pressure or hypercholesterolemia.

Economic analysis of intensive therapy for type 2 DM is more complex. Outcomes must also factor in the burden of cardiovascular disease as the major cause of mortality. One model analyzed the health benefits and economics of treating type 2 DM with the goal of achieving normoglycemia, but using outcomes based on the DCCT trial results. Accounting for the prevalence of cardiovascular disease in type 2 DM, an estimate of \$16,002 incremental cost per quality-adjusted life year gained was obtained. The limitation of this analysis is that while the UKPDS did demonstrate an improvement in diabetes-related outcomes, the overall efficacy on microvascular disease complications was not mirrored by the DCCT.

Two economic analyses were performed on data generated from the UKPDS, one assessing cost effectiveness of an intensive blood glucose control policy in type 2 DM, and the other assessing improved blood pressure control in hypertensive patients with type 2 DM. In the first analysis, outcome was measured as the incremental cost per event-free year gained within the trial. Based on trial outcomes and assumptions, the incremental cost in the intensive treatment group per event-free year gained is \$1,366. While intensive treatment costs were higher, the cost per event-free year gained appears cost-effective. The second analysis showed the incremental cost per extra year free from microvascular and macrovascular end points from intensive blood pressure control in a standard clinical practice model to be \$1498. The incremental cost per life year gained was estimated at \$619, again demonstrating the cost-effectiveness of intensive intervention.^{151,152}

EVALUATION OF THERAPEUTIC OUTCOMES

MONITORING OF THE PHARMACEUTICAL CARE PLAN

A comprehensive pharmaceutical care plan for the patient with DM will integrate considerations of goals to optimize blood glucose control and protocols to screen for, prevent, or manage microvascular and macrovascular complications. In terms of standards of care for persons with DM, one can review the document published by the American Diabetes Association that outlines initial and ongoing assessments for patients with DM.⁵¹ For quality-of-care measures, one can refer to the National Diabetes Quality Improvement Alliance web site at
