6) Although acetogens have been classically regarded as obligate anaerobes, they can tolerate and reduce small quantities of O_2 and exist in habitats subject to transient fluxes of O_2.

7) Acetogens utilize substrate-level phosphorylation, membranous electron transport systems, and ATPases to conserve energy.

8) Although the acetyl-CoA pathway is the hallmark of acetogens, they can also utilize other terminal electron-accepting, energy-conserving processes, including the dissimilation of aromatic acrylates and nitrate. Thus, acetogens are not strictly dependent upon acetogenesis.

9) The acetyl-CoA pathway can be repressed when alternative terminal electron acceptors are utilized. Thus, acetogens do not always produce acetate.

10) Acetogens form different types of trophic interactions for other microorganisms, including syntrophic relationships with other anaerobes and commensal relationships with fermentative microaerophiles.

11) Numerous theoretical commercial applications for acetogens have been evaluated; however, to date, no commercial-scale application has been reported.

Numerous unresolved questions might be considered worthy of further investigation: What is the biochemical nature of the diverse catabolic processes of acetogens? How are these processes regulated at the gene level? Are acetogens more capable of degrading cellulose and other large biopolymers than previously thought? Can acetogens oxidize inorganic compounds, or is their catabolism restricted to the oxidation of carbonaceous substrates? What is the in situ impact of acetogens in complex habitats, such as the endorhizosphere of plants, gastrointestinal ecosystems, and the terrestrial subsurface? Can the metabolic capabilities of acetogens be successfully harnessed and put to commercial use?

The body of published information on acetogens has reached enormous proportions, and it has not been possible to provide adequate coverage to all of these works in this chapter. The authors invite individuals working in this area to send their latest results to the corresponding author (H. L. Drake) so that this information can be included when this chapter is updated at a future date.

Dedication and Acknowledgment

This tapestry is dedicated to Harland G. Wood and Lars G. Ljungdahl, the two individuals who carried the ball when no one else could. The authors express their appreciation to Anita Gößer for her many years of excellence in culturing and analyzing acetogens, to Marcus Horn for assistance with the phylogenetic analyses, to Georg Acker for electron microscopy of isolates, to Millie Wood for permission to publish the photo of Harland Wood, to Volker Müller for helpful discussions on bioenergetics, and to John Breznak, Paul Lindahl, Terry Miller, Steve Ragsdale, and Meyer Wolin for providing

unpublished information and helpful suggestions. Current support for the authors' laboratory is derived in part from funds from the German Research Society (DFG) and the German Ministry of Education, Research, and Technology (BMBF), and is gratefully acknowledged.

CHAPTER 1.14

Virulence Strategies of Plant Pathogenic Bacteria

BARBARA N. KUNKEL AND ZHONGYING CHEN

Introduction

Plant pathogenic bacteria, like bacterial pathogens that infect animals, must be able to evade or suppress general antimicrobial defenses and acquire nutrients and water from their hosts to successfully colonize and grow within host tissue. Plant pathogenic bacteria have adapted well to their hosts, which are structurally and physiologically quite different from animals. Since successful infection relies to a great extent on the ability of a pathogen to modulate the physiology of its host, plant pathogenic bacteria have evolved several unique virulence strategies in addition to virulence mechanisms also utilized by bacterial pathogens of animals.

One current area of intense research in the field of plant-pathogen interactions is the identification and characterization of pathogen virulence factors and the elucidation of their mode of action within the host. This chapter summarizes recent progress in this area of research, focusing on four Gram-negative bacterial pathogens that grow on living tissue and cause primarily leaf spotting or wilt diseases of plants: *Pseudomonas syringae*, *Xanthomonas campestris*, *Ralstonia solanacearum* and *Erwinia amylovora*, the causal agents of leaf spots, leaf blights, vascular wilts, and fire blights, respectively (Schroth, 1981; Chan and Goodwin, 1999; Eastgate, 2000; Genin and Boucher, 2002). The focus is on these pathogens because in recent years significant progress has been made towards elucidating the molecular mechanisms underlying their virulence (Staskawicz et al., 2001; da Silva et al., 2002; Salanoubat et al., 2002; Buell et al., 2003; Buttner and Bonas, 2003). The recent genome sequence data made available for representative strains of several of these pathogens (*P. syringae*, *X. campestris* and *R. solanacearum*) have also begun to provide additional insight into their virulence strategies (da Silva et al., 2002; Salanoubat et al., 2002; Buell et al., 2003). Further, since several of these pathogens can infect *Arabidopsis thaliana*, a widely studied model plant, use of molecular and genetic approaches to investigate the mode of action of pathogen virulence factors within this host has begun to contribute to our understanding of the virulence strategies of these plant pathogenic bacteria (Kunkel, 1996; Glazebrook, 2001; Quirino and Bent, 2003). For reviews on several other fascinating groups of plant-associated microbes, the tumor-inducing *Agrobacterium* spp., the soft rot *Erwinia* species, and the root-nodulating Rhizobia, refer to several recent articles (Broughton et al., 2000; Gelvin, 2003; Toth et al., 2003) and the relevant chapters in this volume (The Genus Agrobacterium in Volume 5; Erwinia and Related Genera in Volume 6; and Root and Stem Nodule Bacteria of Legumes in this Volume).

The Biology of Bacterial Plant Pathogens and Their Hosts

The Plant Apoplast as a Unique Niche for Bacterial Pathogens

Phytopathogenic bacteria are extracellular pathogens. Depending on the specific pathogen, they can grow epiphytically on plant surfaces, in between plant cells within host tissues, in what is referred to as the "apoplast," or within the vasculatory system (Beattie and Lindow, 1994; Alfano and Collmer, 1996; Agrios, 1997). The apoplast is considered to be an unfavorable environment for most microorganisms, as it contains several antimicrobial compounds (Dangl and Jones, 2001; Dixon, 2001; Glazebrook, 2001; Pignocchi and Foyer, 2003) and is believed to be relatively nutrient-poor. Additionally, plant defenses that are induced upon microbial attack are often targeted to the extracellular space (Hammond-Kosack and Jones, 1996). Therefore, to successfully colonize plant tissue, pathogens must both tolerate existing antimicrobial defenses and modulate the apoplastic environment to render it suitable for pathogen growth. This includes evading or suppressing antimicrobial host defenses and eliciting the release of nutrients and water from plant cells (Fig. 1).

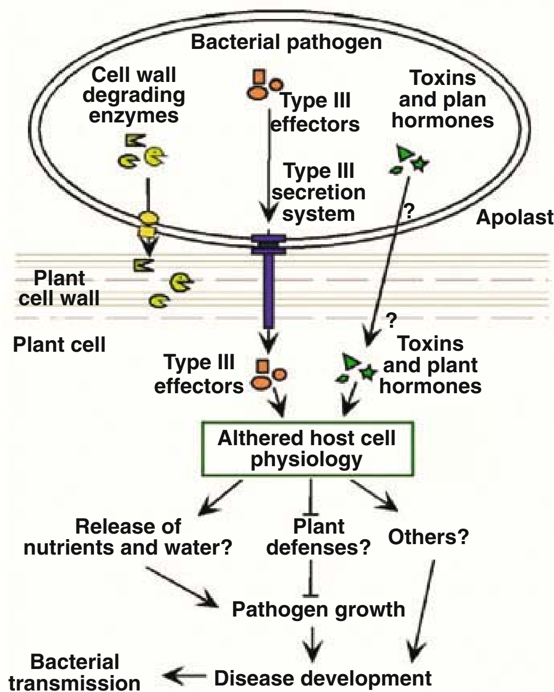

Fig. 1. Secreted virulence factors deployed by bacterial plant pathogens. Bacterial plant pathogens colonize the apoplastic space between plant cells. As extracellular pathogens, these organisms deploy an arsenal of secreted virulence factors to modulate host cell processes from outside plant cells. These factors include: 1) low molecular weight phytotoxins, plant hormones, and hormone analogs that are secreted into the apoplast, many of which presumably enter or are taken up by plant cells; 2) protein virulence factors (or "effectors") that are delivered directly into the plant cell cytosol via a specialized type III secretion system (TTSS), and 3) plant cell wall degrading enzymes that are secreted through a sec-dependent type II secretion system (Alfano and Collmer, 1996; Sandkvist, 2001) and function to degrade or remodel the plant cell wall. Type III-delivered effector molecules are proposed to function inside plant cells to modulate host cell physiology, thus rendering host tissue suitable for pathogen growth and disease development. The activities of these molecules may include: suppression of plant defense responses, stimulating the release of nutrients and water into the apoplast, promoting disease symptom development, and facilitating pathogen release from infected tissue, and hence pathogen transmission.

Plant cell walls also play an important role in plant-pathogen interactions. Unlike animal cells, plant cells are surrounded by a semi-rigid cell wall that provides structural support, maintains cell shape, cements adjacent plant cells together, and serves as a barrier to pathogen invasion and spread within infected tissue. Plant cell walls are composed of several complex carbohydrate polymers, the most abundant of which are cellulose and pectin (Carpita and McCann, 2000). Several of these carbohydrates may also serve as carbon sources for bacteria that can degrade cell wall polymers and take up and metabolize the resulting polysaccharide fragments.

Plant Defense Against Microbial Attack

Plants have evolved multiple basal defense mechanisms to protect themselves against microbial attack (Heath, 2000; Thordal-Christensen, 2003). For example, plants constitutively produce an array of nonspecific, antimicrobial compounds that serve as biochemical barriers to microbial colonization (Hammond-Kosack and Jones, 2000; Dixon, 2001). Additionally, in response to microbial attack, plants activate a complex series of general defense responses that are believed to inhibit colonization by microbial organisms. These inducible defenses include a rapid oxidative burst, accumulation of elevated levels of one or more endogenous signaling molecules, such as salicylic acid (SA), jasmonic acid (JA) and ethylene, induction of several defense-related genes (e.g., pathogenesis related or *PR* genes), the production of antimicrobial phytoalexins and lytic enzymes, and the reinforcement of plant cell walls surrounding the site of infection (Hammond-Kosack and Jones, 1996; Glazebrook et al., 1997; Felix et al., 1999; Gomez-Gomez and Boller, 2002).

Many of these defenses are also induced in response to infection by successful pathogens. However, in susceptible interactions (i.e., those resulting in disease) induction is weaker and occurs at a relatively late stage of infection and does not prevent disease development (Jakobek and Lindgren, 1993; Glazebrook et al., 1997; Tao et al., 2003). Rather, the expression of these defenses appears to limit spread of the pathogen and the severity of disease. Thus, it is widely believed that successful plant pathogens must be able to evade or actively inhibit induction of these general antimicrobial defenses to facilitate colonization of plant tissues (Fig. 1). Presumably, the ability to tolerate host defenses or to avoid and suppress activation of defenses normally induced upon microbial attack are traits that distinguish successful plant pathogens from non-pathogenic organisms (Alfano and Collmer, 1996; Felix et al., 1999; Jin et al., 2003). Recently, much interest has been focused on identifying the pathogen virulence factors involved in these processes and elucidating how they function to modify host defense mechanisms.

In addition to the basal defense mechanisms described above, plants have evolved a unique mechanism allowing them to detect and fend off invading pathogens (Dangl and Jones, 2001; Staskawicz et al., 2001). In many instances, even though a pathogen is able to colonize and initiate growth within host tissue, further multiplication and spread of the pathogen is curtailed by the

rapid and strong activation of host defense responses (Dangl and Jones, 2001; Glazebrook, 2001). The end result is disease resistance and little-to-no visible sign of infection.

In such resistant interactions, the rapid activation of host defenses is triggered by specific recognition of one or more elicitor molecules produced by the invading pathogen and is dependent on the expression of specific plant disease resistance (*R*) genes within the host (Dangl and Jones, 2001; Staskawicz et al., 2001; Bonas and Lahaye, 2002). Thus, pathogen recognition is controlled at the genetic level and is governed by plant *R* genes that confer on the plant the ability to recognize pathogen strains expressing specific elicitors, which are often referred to as "avirulence factors" (Dangl and Jones, 2001; Nimchuk et al., 2001; Staskawicz et al., 2001; Bonas and Lahaye, 2002). In many cases the pathogen avirulence (*avr*) genes directing production of these elicitors have been identified. Many pathogen *avr* genes and the corresponding plant *R* genes have been cloned, and much research has been focused on elucidating the mechanisms by which they mediate pathogen recognition and disease resistance (reviewed in Dangl and Jones [2001] and Martin et al. [2003]).

The existence of *avr* factors seems paradoxical, as it is unclear how elicitation of host defense responses would be of benefit to the pathogen. However, the prevalence of *avr* genes among pathogenic strains indicates that they must provide some selective advantage for the pathogen. Thus it has been proposed that the primary function of bacterial Avr proteins is to promote pathogen growth and disease development on susceptible host plants (Alfano and Collmer, 1996; Nimchuk et al., 2001; Staskawicz et al., 2001; Ponciano et al., 2003). Accordingly, several bacterial *avr* genes have been shown to contribute to virulence on susceptible plant lines lacking the corresponding resistance gene (Nimchuk et al., 2001; Ponciano et al., 2003; and see the section Type III Secretion in this Chapter). However, the function of Avr proteins and the mechanisms by which they promote parasitism and disease are not well understood. Given that most Avr proteins appear to be secreted directly into the plant cell (see the section Type III Secretion in this Chapter), perhaps it is not surprising that plants have evolved the ability to recognize these molecules as signs of pathogen attack (Dangl and Jones, 2001).

Virulence Strategies of Extracellular Pathogens

Given the physiology of plants and the nature of the antimicrobial defense responses they deploy, plant pathogens have evolved a variety of specialized virulence strategies to facilitate colonization of plant tissue. These include: tolerating pre-existing antimicrobial compounds; evading, overcoming or suppressing antimicrobial host defenses; eliciting the release of nutrients and water from plant cells; and in many cases, interfering with the integrity of plant cell walls surrounding the initial site of infection.

The achievement of these goals relies to a great extent on the ability of plant pathogens to modulate host physiology. As these pathogens are extracellular, they deploy an arsenal of secreted virulence factors to modulate host cell processes from outside plant cells (Fig. 1). These virulence factors include: 1) low molecular weight phytotoxins that are secreted into the apoplast (Bender et al., 1999), 2) protein virulence factors (or "effectors") that are delivered directly into the plant cell cytosol via a specialized, type III secretion system (TTSS; Galan and Collmer, 1999; Jin et al., 2003), 3) degradative enzymes that target the plant cell wall, and 4) extracellular polysaccharides (EPS). Additionally, in some interactions plant pathogens may directly modulate hormone physiology within their hosts through the production of plant hormones or hormone analogs (Alfano and Collmer, 1996).

Plant pathogens also express genes believed to help them adapt to the stressful conditions that are constitutively present or that are generated by the host in response to microbial attack. These include the production of proteins and enzymes to counter oxidative stress (e.g., glutathione S-transferase, superoxide dismutase, and catalase), as well as enzymes that may detoxify antimicrobial compounds (Boch et al., 2002; Salanoubat et al., 2002; Buell et al., 2003).

In the majority of pathogenic interactions, disease ensues only after the pathogen has colonized and grown to high levels in the infected tissue. In many cases, disease symptom production is believed to facilitate pathogen release from infected tissue and spread to uninfected tissues and neighboring plants (Agrios, 1997). Therefore, the elicitation of disease symptoms is also often considered an important virulence strategy.

Low Molecular Weight Phytotoxins

Many plant pathogens produce low molecular weight, non-host specific phytotoxins that contribute to virulence, either by directly damaging plant cells or by modulating host cellular metabolism or physiology to promote symptom development (Alfano and Collmer, 1996; Bender et al., 1999; Birch, 2001). The most well character-

ized of these phytotoxins are those produced by *P. syringae* species, and include lipodepsipeptide toxins (e.g., syringomycins and syringopeptins), modified peptides (e.g., tabtoxin and phaseolotoxin), and polyketides (e.g., coronatine).

Lipodepsipeptide Toxins

Syringomycins and syringopeptins are examples of the two classes of lipodepsipeptide toxins produced by *P. syringae* pv. *syringae* during infection. The syringomycins are cyclic lipodepsinonapeptide phytotoxins that consist of a polar cyclic peptide head containing nine amino acids attached to a hydrophobic 3-hydroxy carboxylic acid tail (Bender and Scholz-Schroeder, 2004). Several structurally similar syringomycins are produced by different *P. syringae* pv. *syringae* strains that contain different amino acid residues in the nine peptide ring. Syringopeptins are somewhat larger than the syringomycins and contain a peptide moiety of 22 or 25 amino acids attached to either a 3-hydroxydecanoic or a 3-hydroxydodecdanoic acid (Bender and Scholz-Schroeder, 2004). As in syringomycins, the amino acid chain is cyclized to form a nine-peptide ring. Many of the amino acids present in the syringopeptins are hydrophobic, and thus contribute to the amphipathic nature of these toxins.

The syringomycins and syringopeptins induce necrosis in plant tissues by inserting into plant cell plasma membranes, causing increased transmembrane flux of ions, the disruption of electrical potential across the cell membrane, and eventual plant cell death (Hutchison and Gross, 1997). The amphipathic nature of these toxins is likely to facilitate their insertion into plant cell membranes. Both classes of toxins have been shown to form channels in lipid membranes through a mechanism believed to involve initial insertion of toxin monomers into the membrane, followed by aggregation of multiple monomers to form a pore (Bender and Scholz-Schroeder, 2004).

Lipodepsipeptide phytotoxins are likely to play an important role in interactions between *P. syringae* pv. *syringae* and its hosts, as all strains of *P. syringae* pv. *syringae* analyzed to date produce both syringomycins and syringopeptins. However, these toxins appear to contribute quantitatively to *P. syringae* pv. *syringae* virulence, and the relative importance of these toxins appears to vary among different pathogen-host interactions (Bender et al., 1999; Scholz-Schroeder et al., 2001).

Although much progress has been made toward understanding the biosynthesis and pore-forming activities of the lipodepsipeptide phytotoxins (Bender and Scholz-Schroeder, 2004), their actual role in pathogenesis is not understood. They may contribute to pathogen virulence by stimulating plant cell necrosis and disease lesion development, or by modulating host cell physiology or signaling by altering the flux of ions across plant cell membranes. Additionally, as both syringomycins and syringopeptins exhibit biosurfactant activities, they could potentially contribute to virulence by reducing the surface tension of water and thus facilitate the spread of bacteria across plant surfaces (Bender et al., 1999), thereby promoting tissue colonization and spread of the pathogen within infected plant tissue.

Interestingly, the recent completion of the genomic sequence of *R. solanacearum* has revealed two large open reading frames predicted to encode proteins with high similarity to syringomycin synthase (Salanoubat et al., 2002), suggesting that this pathogen may also produce syringomycin.

Modified Peptide Toxins

The structure and mode of action of two modified peptide toxins, tabtoxin and phaseolotoxin, produced by *P. syringae* pathovars *tabaci* and *phaseolicola*, respectively, are especially well understood. Tabtoxin is a dipeptide toxin that contains tabtoxinine-β-lactam (TβL), linked by a peptide bond to threonine (Bender et al., 1999). TβL is the toxic moiety of tabtoxin and is released from the intact toxin upon hydrolysis of the peptide bond by the action of aminopeptidases within the plant (Levi and Durbin, 1986). TβL, which induces the degradation of chlorophyll in plant cells (thus causing yellowing or "chlorosis" of normally green plant tissue), irreversibly inhibits the enzyme glutamine synthetase (Thomas et al., 1983). As glutamine synthetase is required for efficient detoxification of ammonia in plant cells, inactivation of this enzyme results in accumulation of high levels of ammonia and the disruption of thylakoid membranes within the chloroplast.

Phaseolotoxin is a tripeptide consisting of ornithine, alanine and a homoarginine linked to a sulfo-diaminophosphinyl moiety (Moore et al., 1984). When taken up by plant cells, phaseolotoxin is hydrolyzed to produce octicidine, an irreversible inhibitor of ornithine carbamoyl transferase (OCTase; Mitchell and Bieleski, 1977). OCTase is a key enzyme in the urea cycle that converts ornithine and carbamoyl phosphate to citrulline. Inhibition of OCTase by phaseolotoxin results in accumulation of ornithine and reduction in arginine levels, and leads to the production of severe chlorosis within plant tissue (Bender et al., 1999). Both tabtoxin and phaseolotoxin contribute significantly to

pathogen virulence, presumably by inhibiting photosynthesis, and thus limiting available resources within the plant for mounting a successful defense response and by contributing to the severe yellowing of plant tissues associated with disease (Agrios, 1997).

Coronatine

The polyketide phytotoxin coronatine is produced by many different *P. syringae* strains (Bender et al., 1999). Coronatine is of interest to both plant biologists and plant pathologists, as it appears to function as a molecular mimic of two different endogenous plant hormones, JA and ethylene, both of which are known to play important roles in plant defense (Bender et al., 1999; Kunkel and Brooks, 2002). Coronatine is comprised of two distinct chemical moieties, coronafacic acid (CFA; a polyketide) and coronamic acid (CMA; an ethylcyclopropyl amino acid) that are joined by an amide linkage (Bender et al., 1999). The CFA moiety shares structural and functional relatedness with several jasmonates (e.g., MeJA), a group of plant growth regulators and defense signaling molecules that are produced under conditions of biological stress (Wasternack and Parthier, 1997; Weber, 2002). The CMA moiety also has biological activity and resembles aminocyclopropyl carboxylic acid (ACC), the immediate precursor of ethylene (Toshima et al., 1993). Ethylene is involved in many aspects of plant biology, including fruit ripening, senescence and defense (Bleecker and Kende, 2000; and see the section Ethylene in this Chapter).

Coronatine contributes to the virulence of *P. syringae* by promoting both pathogen growth and lesion formation in several host plants (Bender et al., 1999; Brooks et al., 2004). The biological effects of coronatine closely resemble those induced by jasmonates and include induction of chlorosis (i.e., yellowing of green tissue due to degradation of chlorophyll), production of the protective pigment anthocyanin, inhibition of root growth, promotion of plant cell growth and enlargement, and the induction of several JA-responsive genes (Feys et al., 1994; Bender et al., 1999; Zhao et al., 2003).

The mechanisms underlying the virulence activity of coronatine are not well understood. Results from genetic studies utilizing both *P. syringae* mutants impaired in coronatine biosynthesis and *A. thaliana* and tomato mutants that are impaired in JA signaling, suggest that coronatine promotes pathogen virulence by stimulating JA signaling within the plant (Feys, 1994; Kloek, 2001; Zhao, 2003; D. Brooks et al., manuscript submitted). However, how this leads to increased susceptibility to *P. syringae* is unclear. One hypothesis, based on mounting evidence that the SA and JA-dependent defense signaling pathways are mutually antagonistic, is that coronatine-induced activation of JA signaling results in inhibition of SA-dependent defense responses, which are effective in limiting *P. syringae* infection and disease (Kunkel and Brooks, 2002). The finding that reduced susceptibility to *P. syringae* in *A. thaliana* coronatine insensitive (*coi1*) mutant plants is associated with increased signaling through the SA-dependent defense pathway (Kloek et al., 2001), and the recent observation that coronatine suppresses induction of several SA-dependent defense-related genes in tomato (Zhao et al., 2003) are consistent with this hypothesis. Thus, production of coronatine appears to result in suppression of host defenses, thereby providing *P. syringae* with a window of opportunity during which it can colonize and grow within host tissue.

Coronatine may also be directly involved in disease symptom development (Kloek et al., 2001). The in planta growth defect of *P. syringae* coronatine biosynthetic mutants is restored in *A. thaliana* plant mutants in which SA-dependent defenses are compromised. However, although the coronatine mutants grow to wildtype levels in these plants, disease symptom development is not fully restored (D. Brooks et al., manuscript submitted). The mechanism by which coronatine contributes to lesion formation is not understood.

Type III Secretion

Like most Gram-negative bacterial pathogens of animals studied to date, the bacterial plant pathogens discussed in this chapter require a functional type III secretion system (TTSS) for pathogenesis (Galan and Collmer, 1999; Cornelis and Van Gijsegem, 2000; Staskawicz et al., 2001; Buttner and Bonas, 2003; Jin et al., 2003). Type III secretion systems mediate the transfer of bacterial proteins (also referred to as "effectors") directly into the cytosol of the host cell, where they interfere with or modulate normal host cell processes to facilitate bacterial invasion, growth and disease production (Fig. 1). In animal systems, many of these effectors induce changes in the host cell cytoskeleton, while others modify eukaryotic signal transduction pathways (Galan and Collmer, 1999; Cornelis and Van Gijsegem, 2000; Cornelis, 2002; Buttner and Bonas, 2003).

In the case of plant pathogenic bacteria, mutants defective in TTSS are usually unable to grow or cause disease on normally susceptible hosts, indicating that the integrity of the TTSS is essential for pathogenesis (Lindgren et al., 1986). Much progress has been made towards

elucidating the structure and components of the TTSS, and in identifying the effector proteins secreted through this apparatus. Insights into the function of several type III effectors and how they contribute to the virulence of plant pathogens have also been recently obtained.

Structure and Components of TTSS of Bacterial Plant Pathogens

The structural components of the TTSS of Gram-negative bacterial pathogens of animal and plants are highly conserved. As these systems have been extensively described elsewhere (Galan and Collmer, 1999; Collmer et al., 2000; Cornelis and Van Gijsegem, 2000; Buttner and Bonas, 2002; Jin et al., 2003), the TTSS apparatus will not be discussed in detail. However, note that structurally the TTSSs of plant pathogenic bacteria are slightly different from those described for the animal pathogens. For example, the TTSS of several mammalian pathogens, including *Salmonella typhimurium* and *Shigella flexneri*, are associated with protruding, needle-like surface structures that are approximately 80 nm in length (Kubori et al., 1998; Blocker et al., 1999). The TTSS of several plant pathogenic bacteria are associated with relatively longer, pilus-like structures (referred to as "Hrp pili"; He and Jin, 2003). The Hrp pilus of *P. syringae* pv *tomato* strain DC3000 is approximately 8 nm in diameter and has been observed to be up to 200 nm in length, which is presumably long enough to span the plant cell wall (Brown et al., 2001; Jin and He, 2001). Several studies suggest (but do not directly demonstrate) that the Hrp pilus serves as the conduit through which bacterial proteins are secreted (Brown et al., 2001; Jin and He, 2001).

Identification of Type III Effectors

The importance of TTSS for pathogenesis has prompted many research groups to direct a significant amount of effort towards identifying and characterizing proteins that are secreted through the TTSS. An inventory of effector proteins secreted by plant pathogenic bacteria has been recently compiled in several excellent reviews (Collmer et al., 2002; Buttner and Bonas, 2003; Buttner et al., 2003; Greenberg and Vinatzer, 2003; Jin et al., 2003).

A variety of approaches have been used to identify these effectors. The first type III-secreted proteins studied were those identified on the basis of their ability to elicit TTSS-dependent host defense responses on resistant plant genotypes (Staskawicz, 2001). This may not be surprising, given the eagerness of plant pathologists to elucidate the mechanisms underlying pathogen recognition and disease resistance. Further, given that type III effectors are secreted directly into host cells, and thus may serve as "easy targets" for recognition during the evolution of host surveillance systems, it may not be surprising that many effector molecules serve as elicitors of plant defense.

Recently, more comprehensive approaches for identifying genes encoding type III effectors have been employed. These approaches include: 1) utilizing information regarding gene location and gene regulation, 2) direct functional assays to screen for secreted proteins, and 3) taking advantage of common structural features of known TTSS-secreted proteins to carry out "genomic mining" experiments. For instance, in *P. syringae* and *X. campestris*, several genes encoding effector proteins are located within or adjacent to the gene clusters encoding the structural components of the TTSS (Alfano et al., 2000; Noel et al., 2002; Charity et al., 2003). Further, the expression of many *P. syringae* genes encoding either structural TTSS components or TTSS effector proteins depends on HrpL, an alternative RNA polymerase σ factor required for pathogenesis (Xiao et al., 1994b). The HrpL σ factor directs transcription of TTSS-associated genes by recognizing a consensus "*hrp* box" in the promoter regions of these genes (Innes et al., 1993; Xiao and Hutcheson, 1994a). This information has been used as the basis of genetic screens to identify genes potentially encoding TTSS effector proteins (Fouts et al., 2002; Zwiesler-Vollick et al., 2002; Bretz et al., 2003). Likewise, a molecular genetic strategy has been used to identify *X. campestris* genes whose expression is dependent on HrpX, an AraC-like transcriptional activator that is essential for induction of TTSS-related genes in this organism (Noel et al., 2001).

Although type III effectors do not have an obvious signal sequence targeting them for secretion, the proteins appear to be modular in structure, with the amino terminal region carrying information required for secretion (Guttman et al., 2002). Analyses of the primary amino acid sequences of several known *P. syringae* type III effectors has revealed a strikingly well-conserved pattern of amino acid biases within the first 50 residues that appear to be essential for secretion (Guttman et al., 2002; Petnicki-Ocwieja et al., 2002). As the genomes of several plant pathogenic bacteria have been sequenced, the above features have facilitated genomic mining experiments to identify the entire repertoire of type III effectors secreted by these pathogens (Collmer et al., 2002; Greenberg and Vinatzer, 2003).

Interestingly, plant pathogenic bacteria appear to have larger inventories of type III effectors than do animal pathogenic bacteria. For instance,

at last count, *P. syringae* pv. *tomato* strain DC3000 has 38 predicted effector proteins (Buell et al., 2003), whereas only six effector proteins have been characterized for *Yersinia* spp. and 10 effector proteins (secreted from two different TTSS apparatuses) have been identified for *Salmonella* (Cornelis and Van Gijsegem, 2000). The fact that plant pathogenic bacteria appear to secrete more type III effectors may be an adaptive feature of plant pathogens. This also suggests that more functional redundancy may exist among the effectors deployed by plant pathogens (Buttner and Bonas, 2003). Consistent with this hypothesis, although the collective importance of type III effectors in pathogenesis is obvious, mutations in single effector genes usually do not dramatically alter bacterial virulence, at least when assayed under laboratory conditions (Ponciano et al., 2003).

In contrast to TTSS structural components, which are highly conserved between various plant and animal pathogens (Cornelis and Van Gijsegem, 2000; Buttner and Bonas, 2003; Jin et al., 2003), the sequences and inventories of type III effectors vary considerably among different plant pathogens (and even among different strains of the same species; Collmer et al., 2002; Greenberg and Vinatzer, 2003). This variation suggests that different strains have evolved different repertoires of virulence factors to infect and cause disease on specific host plants. Thus, characterizing type III effectors and elucidating the mechanisms through which they contribute to pathogenesis is of great interest and may eventually provide insight into the molecular basis of host-specificity.

Elucidating the Function of Type III Effectors

The majority of TTSS effectors secreted by bacterial plant pathogens are predicted to function inside plant cells, and secretion into the host cell has been demonstrated for several effector proteins (Casper-Lindley et al., 2002; Szurek et al., 2002; Hotson et al., 2003). Additionally, several type III effectors, including AvrB, AvrRpt2 and AvrPto from *P. syringae* and AvrBs3 from *X. campestris*, have been shown to function inside plant cells in experiments monitoring their elicitor and virulence activities when expressed in plant cells (Leister et al., 1996; Chen et al., 2000; Marois, 2002; Hauck et al., 2003; Jamir, 2004).

Consistent with their proposed site of activity within plant cells, despite their prokaryotic-origin, many type III effectors have features typical of eukaryotic proteins. For example, the *P. syringae* effector proteins AvrRpm1, AvrB, AvrPto, and AvrPphB, have consensus N-terminal myristoylation sites. Several of these proteins have been shown to be myristoylated inside host cells (Nimchuk et al., 2000), and this modification appears to be required for the proper localization of these type III effectors to the host plasma membrane (Nimchuk et al., 2000; Shan et al., 2000). All members of the AvrBs3/PthA family of effectors found in the genus *Xanthomonas* carry functional nuclear localization signals (NLSs). An NLS at the carboxy-terminus of AvrBs3 from *X. campestris* has been shown to be required for interaction with importin α, which is part of the host nuclear import machinery (Szurek et al., 2001). Thus, type III effectors of prokaryotic origin appear to take advantage of eukaryote-specific post-translational modification and targeting mechanisms to access specific subcellular compartments within the host cell.

Given that type III effector proteins are translocated into the host during infection, these molecules (including those that elicit host defenses) are believed to modulate various aspects of host cell biology and physiology to promote disease. The proposed mode of action of these proteins include suppressing plant defenses, eliciting release of water and nutrients from host cells into the apoplast, promoting disease symptom development, and facilitating bacterial transmission (Alfano and Collmer, 1996; Greenberg and Vinatzer, 2003; Jin et al., 2003; Ponciano et al., 2003; Fig. 1). However, in the majority of cases, neither the mode of action nor the targets of these effector proteins within the plant are known.

Various strategies to elucidate the activities of these effectors have been employed. These strategies include protein sequence and structural analyses, biochemical approaches to identify interacting proteins, and the analysis of transgenic plants expressing effector proteins. Such studies have revealed several different potential roles for TTSS effectors, including facilitating type III secretion, proteolysis of host proteins, suppressing plant defense, and modulating endogenous host signaling processes.

FACILITATORS OF TYPE III SECRETION. Several type III effectors, including HrpZ and HrpW from *P. syringae*, and HrpF from *X. campestris* pv. *vesicatoria*, are believed to be secreted into the apoplastic space and are proposed to function as "helper proteins" to facilitate type III secretion during pathogenesis. The predicted structural properties of the *P. syringae* HrpZ protein resemble those of other bacterial proteins believed to interact with host cell membranes, such as YopB from *Y. enterocolitica* (Lee et al., 2001). Likewise, HrpF from *X. campestris* has been found to contain two putative transmembrane regions, suggesting its association with membranes (Buttner et al., 2002). Consistent with these hypotheses, both proteins have

been shown to have lipid-binding activity and to form ion-conducting pores in vitro when associated with lipid bilayers (Lee et al., 2001; Buttner et al., 2002). The pore forming activity of these proteins suggests that they function either in assisting delivery of virulence factors into the plant cell cytoplasm or by mediating nutrient and water release from host cells. Since HrpF is dispensable for protein secretion in vitro but is required in vivo for the recognition of an effector with elicitor activity by resistant plants, it has been proposed that HrpF may facilitate translocation of one or more effector proteins into the host cell (Rossier et al., 2000).

PROTEOLYSIS OF HOST PROTEINS. Amino acid sequence alignment and structural analyses have suggested that several type III effectors have proteolytic activity. AvrPphB from *P. syringae* pv. *phaseolicola* has similarity to *Yersinia* YopT, a cysteine proteinase (Shao et al., 2002). Consistent with the hypothesis that AvrPphB is a protease, AvrPphB has been shown to proteolytically cleave both itself and PBS1, an *A. thaliana* protein kinase required for AvrPphB avirulence activity (Shao et al., 2003).

AvrRpt2 from *P. syringae* pv. *tomato* is also predicted to encode a cysteine protease. Although AvrRpt2 protease activity has not been demonstrated biochemically, the amino acid residues predicted to make up the catalytic core of this protease are required for the defense-inducing activity of AvrRpt2 (Axtell et al., 2003). Two possible substrates for AvrRpt2 have been identified: AvrRpt2 itself (Axtell et al., 2003) and the *A. thaliana* RIN4 protein, which is required for *RPM1*-mediated resistance (Axtell and Staskawicz, 2003; Mackey et al., 2003; and see the section Suppression of Host Defenses in this Chapter).

The C-terminal portion of the XopD protein from *X. campestris* pv. *vesicatoria* has a high degree of similarity with the C-terminal catalytic domain of the Ulp1 ubiquitin-like protease protein family and has been shown to have cysteine protease activity specific for small ubiquitin-like modifier (SUMO)-lated substrates found specifically in plants (Hotson et al., 2003). On the basis of amino acid sequence similarity, three additional effectors from *X. campestris* pv. *vesicatoria*, AvrRxv, AvrBsT and AvrXv4, as well as PopP1 from *R. solanacearum* appear to belong to the YopJ family of ubiquitin-like protein proteases. Interestingly, like XopD, YopJ exhibits specificity for SUMO-lated proteins (Orth et al., 2000; Lavie et al., 2002).

Although the importance of the above demonstrated or predicted proteolytic activities in pathogen virulence has not yet been explored, these findings suggest that the use of type III effectors to cleave specific host signaling molecules is a common strategy of bacterial pathogens.

MODULATION OF HOST SIGNALING. Primary amino acid sequence analysis has also revealed a potential role for HopPtoD2 from *P. syringae.* The carboxyl-terminal domain of HopPtoD2 appears to encode a protein tyrosine phosphatase. Consistent with this finding, HopPtoD2 has protein tyrosine phosphatase activity and appears to contribute to virulence by modulating host defense responses (Petnicki-Ocwieja et al., 2002; Bretz et al., 2003; and see the section Suppression of Host Defenses in this Chapter).

SUPPRESSION OF HOST DEFENSES. Many type III effectors have been shown to modulate host defense responses. For example, several effectors, including AvrRpt2, AvrPphC and VirPphA, can inhibit host recognition of bacterial strains expressing specific avirulence factors (Ritter and Dangl, 1996; Jackson et al., 1999; Chen et al., 2000; Tsiamis et al., 2000). One of the best-studied cases of this type of defense suppression involves the *P. syringae* effector AvrRpt2. AvrRpt2 can interfere with the recognition of *P. syringae* strains carrying *avrRpm1* or *avrB* by plants carrying the corresponding resistance gene, *RPM1* (Ritter and Dangl, 1996; Chen et al., 2000). The mechanism underlying this interference activity of AvrRpt2 has been recently revealed by studies demonstrating that the TTSS-mediated delivery of AvrRpt2 leads to the disappearance of RIN4, a plant protein required for the stability of RPM1 (Mackey et al., 2002; Mackey et al., 2003; Axtell and Staskawicz, 2003). This finding is consistent with the hypothesis that AvrRpt2 is a sequence-divergent cysteine protease whose activity is required for elimination of RIN4 during infection (Axtell et al., 2003).

The suppression of host defenses by type III effector proteins can also occur downstream of pathogen recognition. For instance, the type III effectors AvrPtoB and HopPtoD2 suppress programmed cell death (e.g., the Hypersensitive Response or HR). HopPtoD2 also suppresses production of reactive oxygen species, and AvrPto suppresses cell wall-based extracellular defenses that are normally induced following pathogen recognition (Abramovitch et al., 2003; Bretz et al., 2003; Espinosa et al., 2003; Hauck et al., 2003; Jamir et al., 2004). These observations indicate that plant pathogenic bacteria can use type III effectors to suppress plant defenses at multiple steps in the plant defense signaling pathway.

ALTERATION OF OTHER ASPECTS OF HOST PHYSIOLOGY. Several type III effectors may promote pathogen virulence by affecting other aspects of host biology, for example by

modulating plant hormone physiology. The expression of the *P. syringae* effector protein AvrRpt2 in susceptible transgenic *A. thaliana* plants (i.e., lacking the corresponding resistance gene *RPS2*) promotes pathogen growth and disease development (Chen et al., 2000). Interestingly, three independent transgenic lines expressing *avrRpt2* exhibited seedling phenotypes reminiscent of signaling mutants defective in responding to the plant hormone auxin. These transgenic seedlings also exhibited increased sensitivity to exogenous application of auxin (Kunkel et al., 2004; Z. Chen et al., manuscript in preparation). These findings suggest that AvrRpt2 modulates host auxin physiology . Consistent with this hypothesis, AvrRpt2 appears to modulate free auxin levels, both in uninfected transgenic seedlings and during infection with *P. syringae* (Kunkel et al., 2004; Z. Chen et al., manuscript in preparation). The mechanism by which AvrRpt2 modulates auxin physiology within the host is presently not understood, nor is it clear whether this activity is related to the virulence activity of AvrRpt2. However, as is discussed in more detail in the section Auxin, it is reasonable to speculate that *P. syringae* may utilize virulence factors such as AvrRpt2 to modulate endogenous free auxin levels within the plant as a strategy to promote pathogen growth and disease formation.

AvrBs3 from *X. campestris* may also modulate host auxin biology. AvrBs3 stimulates host cell enlargement, a process associated with auxin, and induces expression of a group of auxin-regulated genes (Marois et al., 2002). However, whether these physiological changes induced by AvrBs3 contribute to pathogen virulence has not been demonstrated. Additional examples of modulation of hormone physiology by pathogens are discussed in the section Modulation of Plant Hormone Physiology in this Chapter.

Type III effectors can also function to promote several other aspects of pathogenesis, including formation of bacterial colonies in plant tissue, production of necrotic disease lesions, and facilitating pathogen transmission (Guttman and Greenberg, 2001; Badel et al., 2002; Badel et al., 2003; Wichmann and Bergelson, 2004).

ANALYSIS OF TYPE III EFFECTOR FUNCTION. One of the major challenges in understanding TTSS effector function is to identify the targets of these virulence factors within the host and to elucidate the roles of these molecules in pathogenesis. Thus the possibility that individual host molecules may be targeted by multiple type III effectors is important to keep in mind. For instance, in addition to being targeted for elimination by AvrRpt2, the *A. thaliana* RIN4 protein is phosphorylated by two other *P. syringae* effectors, AvrRpm1 and AvrB (Mackey et al., 2002). The fact that RIN4 is modified by multiple type III effectors suggests that this host protein may play an important role in *P. syringae/A. thaliana* pathogenesis.

Note also that individual type III effectors may target more than one host molecule or process. For instance, the *P. syringae* effector AvrRpt2 interferes with *RPM1*-mediated pathogen recognition, a process that is tightly correlated with the ability of AvrRpt2 to trigger the disappearance of RIN4 (Mackey et al., 2002; Mackey et al., 2003; Axtell and Staskawicz, 2003). In addition, AvrRpt2 promotes bacterial virulence during susceptible interactions (Chen et al., 2000; Guttman and Greenberg, 2001), and modulates host auxin physiology (Kunkel, 2004; Z. Chen et al., manuscript in preparation). Importantly, since the virulence activity of AvrRpt2 is maintained on *A. thaliana* plants lacking a functional *RIN4* gene, AvrRpt2 virulence activity is not dependent on RIN4 (Lim and Kunkel, 2004; Belkhadir et al., 2004). Thus, AvrRpt2 must have virulence targets other than RIN4.

Although a tremendous amount of progress towards identifying and characterizing plant pathogenic type III effectors has been recently made, the mode of action of most of these effectors is still unknown. The finding that the primary amino acid sequences of most effector proteins do not provide much insight regarding function, and that in most cases mutation of the effector genes does not result in pronounced virulence phenotypes have not helped to hasten our understanding of these proteins. Future studies involving host gene expression profiling and proteomic approaches to reveal the potential effects of these pathogen molecules on plant defense and other aspects of host physiology may help elucidate the function of some of these effectors. Likewise, localization of effector proteins within host cells, as well as identification of plant proteins that interact with the effectors, will also contribute to our understanding of effector function within plant cells.

Plant Cell Wall Degrading Enzymes

Plant cell walls play an important role in plant-pathogen interactions. As extracellular pathogens, phytopathogenic bacteria encounter plant cell walls as barriers preventing access to the cytoplasmic contents of host cells, as deterrents to pathogen spread within infected tissue, as physical substrates on which to grow, and as a potentially rich source of carbon (Agrios, 1997). Thus, not surprisingly, many plant pathogens include a battery of cell wall degrading enzymes in their repertoire of virulence factors.

Plant cell walls are composed primarily of complex carbohydrate polymers, the most

abundant of which are pectins, hemicelluloses and celluloses (Carpita and McCann, 2000). These polymers are arranged into a highly organized structure consisting of a meshwork of cellulose microfibrils imbedded in a gel-like matrix of pectins and hemicelluloses. Plant pathogens synthesize and secrete a variety of cell wall-degrading enzymes, including pectinases (e.g., polygalacturonases, pectate lyases, and pectin methyl esterases), cellulases and proteases. These enzymes work collectively to soften or break down plant cell walls, thereby facilitating pathogen entry and the release of nutrients for pathogen growth (Barras et al., 1994). The secretion of these exoenzymes may also result in the loosening of the middle lamellae that hold together adjacent plant cell walls, thus promoting the spread of pathogens between host cells and beyond the initial infection site.

The soft-rot pathogens, such as *Erwinia chrysanthemi* and *E. carotovora*, which make their living by macerating the plants' tissue, secrete multiple cell wall degrading enzymes. The importance of these enzymes in the virulence of these pathogens is well established (reviewed in Toth [2003] and Erwinia and Related Genera in Volume 6). *Xanthomonas campestris* pv. *campestris* also has an extensive collection of genes encoding putative cell wall degrading enzymes, including several pectic enzymes and cellulases (da Silva et al., 2002). Presumably, these enzymes contribute to the massive degeneration of plant tissue that occurs during development of black rot disease in plants infected with *X. campestris* pv. *campestris* (Agrios, 1997). However, as *Erwinia* and *X. campestris* pathogens secrete complex mixtures of degradative enzymes and possess multiple genes encoding functionally redundant isoenzymes, the precise role of any one of these enzymes in pathogenesis has been difficult to determine (Chan and Goodwin, 1999; Toth et al., 2003).

The roles of plant cell wall degrading enzymes during pathogenesis of vascular wilt and leaf spotting pathogens such as *R. solanacearun* and *P. syringae* are less clear. *Ralstonia solanacearum* encodes multiple known or predicted pectolytic enzymes, including endoglucanases, polygalacturonases, and a pectin methyl esterase (Genin and Boucher, 2002; Salanoubat et al., 2002). Genetic studies have revealed that several of these pectolytic enzymes contribute quantitatively to bacterial wilt disease development by facilitating invasion, colonization, and systemic spread of the pathogen within host tissue (Schell et al., 1988; Huang and Allen, 1997; Huang and Allen, 2000).

Recent sequence analysis has revealed that *P. syringae* pv. *tomato* strain DC3000 also encodes several potential cell wall degrading enzymes, including a polygalacturonase, a pectin lyase, and three enzymes predicted to have cellulytic activity (Buell et al., 2003). The role of these enzymes in DC3000 virulence is not known, and no cell wall degrading activity has been reported for this strain. However, pectolytic enzymes have been reported to contribute to symptom development during infection by *P. syringae* pv. *lachrymans* (Bauer and Collmer, 1997). Interestingly, three TTSS effector proteins (HopPmaH$_{Pto}$, HrpW and HopPtoP) classified as "helper proteins" that may assist in delivery of TTSS secreted proteins, possess carboxy-terminal domains with similarity to pectolytic enzymes (Charkowski et al., 1998; Boch et al., 2002; Collmer et al., 2002). The secretion of these potential pectolytic enzymes (either through sec-dependent or TTSS-dependent processes) could possibly facilitate the assembly of functional type III secretion complexes at the bacteria-plant cell wall interface.

Extracellular Polysaccharides

Many plant pathogens produce large amounts of exopolysaccharides (EPS). EPSs are carbohydrate polymers that are secreted by bacteria and form either a closely attached capsule layer surrounding the bacterial cell, or a loosely associated extracellular slime (Denny, 1995). The virulence of several phytopathogenic bacteria, including *R. solanacearum*, *E. amylovora*, *X. campestris* and *P. syringae* is associated with their ability to produce various EPS polymers during growth in plant tissue (Denny, 1995). EPSs are believed to provide a selective advantage to phytopathogenic bacteria through multiple functions including: 1) facilitating absorption of water, minerals and nutrients; 2) providing protection from abiotic stresses encountered during epiphytic or saprophytic growth, as well as from toxic molecules encountered during growth in plant tissue; 3) promoting colonization and spread within host tissue; and 4) contributing to the production of disease symptoms such as water-soaking and wilting (Denny, 1995).

One of the most important virulence-associated characteristics of the wilt pathogen *R. solanacearum* is the ability to produce large amounts of a viscous, high molecular mass, acidic EPS (EPS1) in planta. Production of large amounts of EPS1 by bacteria colonizing vascular tissue appears to interfere with transduction of water and nutrients within infected plants, resulting in wilting and, in some cases, the ultimate death of aerial portions of the plant (Denny and Baek, 1991; Kao et al., 1992). Consistent with these observations, infection with *R. solanacearum* strains bearing mutations in the EPS1 biosynthetic loci resulted in reduced wilting

(Denny and Baek, 1991). A study involving detailed microscopic analysis of the infection process revealed that EPS1-deficient mutants of *R. solanacearum* are less invasive than wildtype strains, suggesting that EPS1 may also be required for efficient colonization and movement within plant roots (Saile et al., 1997; Araud-Razou et al., 1998). Further, the accumulation of electron-dense material in plant tissue infected with *eps1* mutants raises the possibility that these mutants elicit nonspecific defenses within the host. Thus, EPS1 may also contribute to pathogen virulence by evading or suppressing host defenses (Araud-Razou et al., 1998).

Erwinia amylovora, well-known as the causal agent of fire blight of pear, produces two major EPSs, levan and amylovoran, that may contribute to this pathogen's ability to also cause wilting diseases on young plants (Denny, 1995). However, only amylovoran, a viscous, acidic heteropolysaccharide containing primarily galactose and glucuronic acid (Eastgate, 2000), has been clearly demonstrated to contribute to virulence of *E. amylovora*, and amylovoran-negative mutants exhibit reduced in planta bacterial growth and symptom development (Bellemann and Geider, 1992; Bernhard et al., 1993). Amylovoran is proposed to promote virulence by suppressing pathogen recognition by the host (Metzger et al., 1994), promoting tissue invasion and causing water-soaking and tissue collapse (Eastgate, 2000).

Xanthomonas campestris strains produce large amounts of the EPS known as xanthan gum that can accumulate to very high levels in infected plant tissues (Denny, 1995). Xanthan gum is a high molecular weight EPS composed of a cellulose backbone to which trisaccharide side chains are attached. Xanthan exhibits several unique properties in solution that have rendered it useful in industrial applications (Becker et al., 1998). However, despite being one of the most well-studied polysaccharides produced by phytopathogenic bacteria, the role of xanthan in pathogenesis is not understood. Xanthan clearly contributes to pathogen aggressiveness, as *X. campestris* strains carrying mutations that specifically disrupt EPS production exhibit reduced virulence (Katzen et al., 1998). It has been proposed that xanthan contributes to *X. campestris* fitness by providing protection against desiccation and hydrophobic molecules, and through facilitating tissue colonization by promoting adhesion of bacteria to biological surfaces (Chan and Goodwin, 1999). The recent discovery that xanthan is involved in formation of aggregates of *X. campestris* pv. *campestris* in culture suggests that this EPS may be involved in biofilm formation (Dow et al., 2003). Biofilm formation may be important during early stages of tissue colonization, for example, by promoting epiphytic survival or by providing protection against antimicrobial compounds encountered within plant tissues. Interestingly, dispersal of bacteria from such a biofilm at later stages of infection may be required to facilitate colonization of the vascular system (Dow et al., 2003).

The major EPS produced by *P. syringae* growing in planta is alginate, a copolymer of *O*-acetylated β-1,4-linked D-mannuronic acid and its C-5 epimer, L-glucuronic acid (Osman et al., 1986). Studies have associated *P. syringae* virulence with the amount of alginate produced in culture (Osman et al., 1986; Denny, 1995). Although the role of alginate in promoting virulence of *P. syringae* is not fully understood, alginate contributes to the virulence of the human pathogen *P. aeruginosa* by providing protection from host defenses and antibiotic treatment (Boyd and Chakrabarty, 1995). In studies designed to assess the role of alginate in *P. syringae* pv. *syringae* virulence, a *P. syringae* pv. *syringae* alginate lyase (*algL*) mutant impaired in alginate production exhibited reduced epiphytic fitness, grew to lower levels in plant tissue and elicited less severe disease symptoms on bean leaves (Yu et al., 1999). These findings indicate that production of alginate by this *P. syringae* strain is associated with increased epiphytic fitness on leaf surfaces and may also contribute to pathogen virulence by facilitating colonization or dissemination of the bacterium in planta.

Modulation of Plant Hormone Physiology

Several plant pathogens have evolved the ability to modulate signaling processes mediated by plant hormones as a strategy for manipulating host physiology (Agrios, 1997). Plant hormones, which are also often referred to as "plant growth regulators," are endogenous signaling molecules important for many aspects of plant growth and development. The most well-known growth regulators are auxin, ethylene, cytokinins, abscisic acid, gibberellins, jasmonates (JA) and salicylic acid (SA; Davies, 1995). Three of these hormones in particular, SA, JA and ethylene, are important in mediating plant defenses in response to pathogen or herbivore attack (Hammond-Kosack and Jones, 2000; Kunkel and Brooks, 2002). Not surprisingly, there is mounting evidence that the SA, JA and ethylene defense signaling pathways are modulated by plant pathogens. However, the specific hormone signaling pathway targeted by a given pathogen seems to depend on the virulence strategy employed by the pathogen (e.g., whether it is a necrotroph that rapidly kills plant cells to obtain nutrients, or a biotroph that colonizes living

plant tissue; Reymond and Farmer, 1998; Thomma et al., 2001).

SALICYLIC ACID SA plays a central role in defense against pathogen attack. During infection, plants often accumulate SA, and exogenous application of SA or SA analogs results in enhanced resistance to a wide variety of pathogens (Ryals et al., 1996). Plant mutants that are impaired in their ability to accumulate SA exhibit enhanced susceptibility to many pathogens (Nawrath and Metraux, 1999; Wildermuth et al., 2001). Thus, to successfully colonize host tissue, virulent bacterial pathogens presumably have evolved mechanisms for interfering with SA-mediated defense responses, for instance by delaying or preventing the accumulation of high levels of SA within host tissue or by suppressing SA-dependent signaling downstream of SA accumulation.

For example, the deployment of several *P. syringae* type III effectors, including AvrRpt2, AvrPphC, VirPphA and AvrPphF, delays the accumulation of SA within the infected plant by inhibiting host recognition of bacteria expressing specific avirulence factors (Ritter and Dangl, 1996; Jackson et al., 1999; Chen et al., 2000; Tsiamis et al., 2000; and the section Suppression of Host Defenses in this Chapter). Another potential strategy for interfering with induction of SA-dependent defenses is degradation of SA. This mechanism may be deployed by *R. solanacearum*, whose genome includes several genes encoding putative SA-degrading enzymes (Salanoubat et al., 2002).

Pseudomonas syringae, and presumably other pathogens as well, may also facilitate colonization of host tissue by suppressing SA-dependent signaling. As discussed in the section on the phytotoxin Coronatine, coronatine may be utilized by *P. syringae* to downregulate SA-dependent defense responses (Kunkel and Brooks, 2002). Likewise, the *P. syringae* type III effectors AvrRpt2 and HopPtoD2 suppress the expression of SA-regulated defense-related genes during infection on susceptible plants (Bretz et al., 2003; Chen et al., 2004). In the case of AvrRpt2, this appears to occur without altering SA levels (Chen et al., 2004). Therefore, plant pathogenic bacteria appear to deploy several different strategies to interfere with various aspects of SA-dependent defenses within the host.

JASMONATES A group of biochemically related plant growth regulators collectively referred to as "jasmonates" ("JAs") are involved in defense against both herbivorous insect pests and necrotrophic bacterial and fungal pathogens that colonize dead plant tissues. Thus, intact JA signaling processes are required for resistance to attack by these organisms (Kunkel and Brooks, 2002; Farmer et al., 2003). In contrast, JA signaling is required for disease susceptibility of *A. thaliana* and tomato plants to the biotrophic bacterial pathogen *P. syringae* (Feys et al., 1994; Kloek et al., 2001; Zhao et al., 2003; Laurie-Berry et al., manuscript in preparation). This may not be surprising, given that coronatine, an important virulence factor for *P. syringae*, is a molecular mimic of JAs (Feys et al., 1994; Weiler et al., 1994; Bender et al., 1999). Molecular and genetic studies suggest that coronatine modulates JA signaling within the plant to promote pathogenesis and disease development (Feys et al., 1994; Weiler et al., 1994; Kloek et al., 2001; Zhao et al., 2003). However, the mechanism(s) underlying this process is not well understood, nor is it clear why stimulation of JA signaling promotes *P. syringae* pathogenesis. One hypothesis is that stimulation of JA signaling results in antagonism of SA-dependent defenses (Kloek, 2001; Zhao, 2003; Brooks et al., manuscript submitted; and the section Coronatine). Alternatively (or additionally), stimulation of JA signaling within the plant could result in enhanced disease production, for example, by stimulating an increase in free auxin levels within the plant (Kunkel et al., 2004; see Auxin).

ETHYLENE The role of the gaseous plant hormone ethylene in plant-microbe interactions is complex, as it is required for resistance against some pathogens and for disease susceptibility in others (Kunkel and Brooks, 2002). *Ralstonia solanacearum* and *P. syringae*, two pathogens for which normal ethylene responsiveness in the host is important for disease development (Bent et al., 1992; Lund et al., 1998; Hoffman et al., 1999; Weingart et al., 2001; Hirsch et al., 2002), have been reported to produce ethylene, both in culture and in planta (Freebairn and Buddenhagen, 1964; Weingart and Volksch, 1997). These findings suggest that ethylene production by *R. solanacearum* and *P. syringae* plays an important role in disease development. Consistent with this hypothesis, it was found that ethylene synthesis mutants of some strains of *P. syringae* pv. *glycinea* grew to significantly reduced levels in bean and soybean plants (Weingart et al., 2001). Interestingly, in addition to encoding the ethylene biosynthetic gene ACC oxidase, the *R. solanacearum* genome contains a gene encoding ACC deaminase (Salanoubat et al., 2002), an enzyme involved in ethylene degradation. This finding suggests that *R. solanacearum* may carefully modulate ethylene levels within the plant for a maximal virulence effect.

AUXIN Although the roles of auxin in promoting plant cell division and growth in diseases caused by tumorigenic plant pathogens such as *A. tumefaciens* and *P. savastanoi* is well established (Yamada, 1993; Gelvin, 2003; and see The Genus Agrobacterium in Volume 5), the involvement of this plant growth regulator in disease caused by the nontumorigenic bacterial pathogens discussed in this chapter has not been carefully investigated.

Interestingly, a number of non gall-forming plant pathogens, including *R. solanacearum*, *X. oryzae* pv. *oryzae* and several *P. syringae* strains from different pathovar groups, have been reported to produce indole acetic acid (IAA), the predominant naturally occurring active form of auxin, when grown in culture (Phelps and Sequeira, 1968; Fett et al., 1987; Glickmann et al., 1998; Ansari and Sridhar, 2000). Further, recent sequence analysis has revealed that *R. solanacearum* strain GM1000 and *P. syringae* strain DC3000 possess genes predicted to be involved in auxin biosynthesis (Salanoubat et al., 2002; Buell et al., 2003). Thus, auxin production appears to be a common feature of many bacterial plant pathogens that are not reported to cause tumorigenic growth of plant tissues. Several *P. syringae* strains also harbor an *iaaL* gene that encodes an enzyme believed to catalyze the conversion of IAA to IAA-lysine, a conjugated form of IAA that is considered to be biologically less active than free IAA (Glickmann et al., 1998). Thus, presumably these bacteria are not only able to produce auxin, but are also able to adjust free IAA levels within the plant.

Pathogen infection can result in stimulation of auxin production by the host, and many biochemical studies to investigate the biosynthetic pathways responsible for this increase in IAA have been carried out (Phelps and Sequeira, 1968). However, the role that auxin plays in these interactions is not well understood. More recently IAA levels have been reported to increase in *A. thaliana* plants infected with virulent *X. campestris* or *P. syringae* strains (O'Donnell et al., 2003; Kunkel et al., 2004). The source of this increase in free IAA has not been established. However, the observation that several *A. thaliana* genes encoding enzymes involved either in IAA biosynthesis or in hydrolysis of IAA-amino-acid conjugates are upregulated upon infection with *P. syringae* (Niyogi et al., 1993; Bartel and Fink, 1994; Zhao and Last, 1996; Hull et al., 2000; Tao et al., 2003; Kunkel et al., 2004) suggests that the increase in free IAA in infected plants is generated, at least in part, by the plant.

It is presently unclear whether the increase in free IAA levels observed in infected plants is defense-related and is induced as a protective mechanism in response to pathogen attack, or alternatively, whether it is stimulated by the pathogen to render the plant more susceptible to infection. However, given that several pathogens are able to produce IAA in culture (and presumably in plant tissue as well), it is reasonable to speculate that auxin contributes to disease development and the virulence of these pathogens. Several pieces of evidence support this hypothesis. The observation that auxin downregulates expression of defense-related genes in cultured tobacco cells and plant tissues suggests that auxin may inhibit host defenses (Shinshi et al., 1987; Rezzonico et al., 1998). Additionally, injection of auxin-producing *A. tumefaciens* or *P. savastanoi* bacteria into tobacco leaves prior to injection of an avirulent *P. syrinage* strain inhibited the development of visible tissue collapse (e.g., the hypersensitive response or HR) associated with the host defenses response. The ability of the *A. tumefaciens* or *P. savastanoi* strains to suppress the *P. syringae*-induced HR was dependent on the presence of functional auxin biosynthetic genes, suggesting that auxin is directly involved in suppressing the HR (Robinette and Matthysse, 1990). Therefore, auxin may contribute to pathogen virulence by suppressing plant defenses. Our recent observation that exogenous application of the auxin analog 1-naphthalene-acetic acid (NAA) to *A. thaliana* plants resulted in increased disease susceptibility to *P. syringae* further supports the hypothesis that auxin promotes disease development during pathogenesis of *P. syringae* (Kunkel, 2004; Z. Chen et al., manuscript in preparation).

Taken together, the above observations suggest that some plant pathogens may modulate endogenous free auxin levels within the plant as a strategy to promote pathogen growth and disease formation. Three virulence factors that appear to contribute to this process have been recently identified: the *P. syringae* phytotoxin coronatine and two TTSS effector proteins, AvrRpt2 from *P. syringae* and AvrBs3 from *X. campestris*. Coronatine may play an important role in modulating host auxin physiology during infection by *P. syringae*. The expression of several genes involved in either producing IAA (e.g., *CYP79B2*) or releasing free IAA from conjugated pools within the plant (e.g., *IAR3*) are induced by JA treatment (Sasaki et al., 2001). Thus, induction of these genes upon infection by *P. syringae* may be stimulated by the production of coronatine, which is a molecular mimic of JA. The observation that normal induction of IAA-producing genes was not observed upon infection with coronatine biosynthetic mutants of *P. syringae* strain DC3000 indicates that coronatine is required for the induction of these genes

and suggests that *P. syringae* utilizes coronatine to actively modulate free IAA levels within the plant during infection (Kunkel et al., 2004).

Transgenic *A. thaliana* plants constitutively expressing the *P. syringae* type III effector AvrRpt2 (and lacking the corresponding resistance gene, *RPS2*) exhibit several phenotypes associated with altered auxin physiology. These include an increased number of lateral roots, altered gravitropic responses, and increased sensitivity to the auxin analogs 2,4-dichlorophenoxyacetic acid (2,4-D) and NAA. Further, transgenic seedlings expressing AvrRpt2 accumulate slightly elevated levels of free IAA (Kunkel, 2004; Z. Chen et al., manuscript in preparation). The fact that these transgenic plants also exhibit enhanced susceptibility to *P. syringae* (Chen et al., 2000) suggests that AvrRpt2 may promote pathogen virulence by modulating host auxin physiology.

AvrBs3 of *X. campestris* pv. *vesicatoria* is another example of a type III effector that may modulate host auxin physiology. AvrBs3 contains nuclear localization signals and an acidic transcription activation domain, suggesting that it modulates host gene expression (Szurek et al., 2001). In susceptible pepper plants delivery of AvrBs3 specifically induces the expression of a group of auxin-induced *SAUR* genes (Marois et al., 2002). However, unlike AvrRpt2, the presence of AvrBs3 does not appear to affect free IAA levels of infected plants (Marois et al., 2002). Thus, AvrBs3 may alter host auxin physiology by altering IAA responses downstream of free IAA production and release from internal pools.

The Complexities of Hormone Signaling Networks in Plant-microbe Interactions

Note that the amount of crosstalk between the hormone signaling pathways discussed above is significant (Gazzarrini and McCourt, 2003). For instance, after reading this chapter it should be clear that a large amount of interplay exists between the SA and JA signaling pathways (see the sections Salicylic Acid and Jasmonates in this Chapter), and that pathogens such as *P. syringae* may take advantage of the mutually antagonistic crosstalk between these pathways to manipulate signaling within the plant (Reymond and Farmer, 1998; Kunkel and Brooks, 2002; and see the section Coronatine in this Chapter). Likewise, auxin appears to upregulate the expression of ACC synthase 4 (ACS4; Abel et al., 1995), an enzyme that catalyzes a rate-limiting step in ethylene biosynthesis. Thus auxin may also induce ethylene biosynthesis. Moreover, as described in the sections on Auxin and Jasmonates, increasing evidence suggests that auxin and JA signaling pathways are interconnected. Therefore, the involvement of one plant hormone in a plant-pathogen interaction could be mediated, at least in part, through the action of one or more other plant hormones. Future studies aimed at untangling these complicated signaling networks will undoubtedly provide valuable insight into the virulence mechanisms used by bacterial plant pathogens.

Challenges

The recent use of a combination of genetic, molecular, and genomic approaches has led to major advances in the identification of numerous potential new virulence factors. The challenge that lies ahead is to develop experimental strategies that will facilitate the investigation of the mode of action of these factors and how they function collectively within the plant to promote pathogen virulence and disease. Given the potential functional redundancy of these factors, and the fact that their mode of action may not always be accurately predicted (so little is known about the plant processes that contribute to pathogenesis), it would be wise to utilize a variety of approaches in these future studies. Studies involving plant genetic, genomic and biochemical approaches, as well as physiological and gene expression analyses of transgenic plants expressing specific pathogen virulence factors (e.g., type III effector proteins) are already ongoing. In certain situations, advantage can also be taken of the observations that certain bacterial virulence factors are active in yeast (for examples, see Abramovitch et al. [2003] and Jamir et al. [2004]). Thus the power of yeast genetics is likely to facilitate the identification of host components that are important in mediating the activity of these virulence factors.

Collectively, these studies are likely to provide valuable information regarding both the molecular mechanisms underlying pathogen virulence and the host processes that are modulated during pathogenesis. The insight gained from these experiments may also lead to the development of new approaches for controlling virulence and disease development in agronomically important plant-pathogen interactions.

CHAPTER 1.15

The Chemolithotrophic Prokaryotes

DONOVAN P. KELLY AND ANN P. WOOD

Introduction

Ihre Lebensprozesse spielen sich nach einem viel einfacheren Schema ab; durch einen rein anorganischen chemischen Prozess . . . werden alle ihre Lebensbewegungen im Gange erhalten.

["Their life processes are played out in a very simple fashion; all their life activities are driven by a purely inorganic chemical process."]

—Winogradsky, 1887

Such was Winogradsky's (1887) description of the ability of certain bacteria to use energy from inorganic chemicals. Winogradsky's (1887) name for such organisms was "Anorgoxydanten" (literally "inorganic oxidizers"). Today the term chemolithotrophy is used to describe the energy metabolism of bacteria that use the oxidation of inorganic substances, in the absence of light, as a source of energy for cell biosynthesis and maintenance (Rittenberg, 1969; Brock and Schlegel, 1989; Kelly, 1990a). Chemolithotrophs exhibit extraordinary diversity of substrates, modes of carbon nutrition, morphology, and habitat. Grouping chemolithotrophs into some kind of homogeneous taxonomic unit is thus at least as artificial as grouping by most taxonomic devices in that virtually every possible morphology and physiology among bacteria (including the archaebacteria) are represented. Such taxonomic "lumping" does have value because some fundamental aspects of carbon and energy metabolism unify many of the chemolithotrophs into groups that are useful for physiological comparison.

The fundamental process in energy-conserving metabolism and in all respiratory processes is the transfer of hydrogen from a state more electronegative than that of the H^+/H_2O couple to that of water. Classically, "heterotrophs" or "chemoorganotrophs" obtain reducing potential from the dehydrogenation of organic compounds. Although a great variety of organic substrates is available and many are oxidized by heterotrophs, only a few principal metabolic processes exist whereby the hydrogen equivalents are fed into energy-conserving electron transport. Chief among these are processes that use the dehydrogenases of sugar phosphates and of organic acids, especially those of the tricarboxylic acid cycle. Diversity among substrates is thus merely a peripheral aspect of organism function; the central energy-generating and -conserving processes are fundamentally the same and involve the same kinds of components. This observation applies equally to the chemolithotrophs. Their electron-transporting and energy-trapping mechanisms are essentially the same as those of chemoorganotrophs (Kelly, 1978, 1982, 1989, 1990a).

From the time of its inception the concept of chemolithotrophy was linked with the autotrophic assimilation of carbon dioxide. Thus, Pfeffer (1897) coined "chemosynthesis," the term that was used for many years to describe the metabolism of bacteria that use inorganic oxidations to support autotrophic carbon dioxide assimilation (Kiesow, 1963; Jannasch and Wirsen, 1979; Brock and Schlegel, 1989). And Winogradsky's definition of the "Anorgoxydant" uncompromisingly coupled energy generation from inorganic oxidation with not only cell synthesis exclusively from carbon dioxide but also the concept of the general toxicity of organic nutrients (Winogradsky, 1922; Rittenberg, 1969, 1972; Schlegel, 1975; Whittenbury and Kelly, 1977). This concept is now known to be too restrictive because organisms (subsequently isolated) proved to be facultatively chemolithoautotrophs (growing on organic media as heterotrophs), mixotrophic (obtaining energy or carbon from both inorganic and organic sources), or chemolithotrophic heterotrophs (using inorganic energy substrates to effect assimilation of organic growth substrates).

The concepts of autotrophy (the assimilation of carbon dioxide as the major or sole source of biosynthetic carbon) and chemolithotrophy (growth with inorganic energy sources) thus were accepted as separate processes obligatorily linked in some specialized types of organisms. Paradoxically, this both clarified and blurred the boundaries between the "autotrophic" and "heterotrophic" bacteria (Rittenberg, 1972; Whittenbury and Kelly, 1977; Kelly, 1990a).

Clarification resulted from the fact that energy generated from an inorganic source does not have to be coupled exclusively to autotrophy (equally, the "organic oxidation" of formate or methanol can be coupled to autotrophic growth on carbon dioxide). Thus, physiological classification was in terms of either energy or carbon nutrition (Kelly, 1971). "Blurring" came from the possibility of extending the concept of autotrophy from a restricted definition. Thus, autotrophy could be defined in ever broader terms as metabolic processes that obtain (i) most carbon for biosynthesis from carbon dioxide by the action of ribulose bisphosphate carboxylase enzyme and derive energy chemolithotrophically; (ii) carbon from carbon dioxide by the Calvin-Bassham-Benson cycle (which we shall call the "Calvin cycle"); (iii) most carbon from carbon dioxide by any biochemical means; or (iv) one-carbon compounds for all biosynthesis by processes fundamentally akin to those involved in the autotrophic fixation of carbon dioxide (Smith and Hoare, 1977; Whittenbury and Kelly, 1977). It is clearly preferable to distinguish carbon and energy metabolism, especially among chemolithoautotrophs, but there is no merit in restricting the definition of autotrophy to those organisms using the Calvin cycle. Studies in recent years have established that distinct pathways, in addition to the Calvin cycle pathways from which they differ, operate in some groups of autotrophs. The term autotrophy should be applied without question to all organisms capable of basing biosynthesis on one-carbon compounds. In our view it is useful to separate "methylotrophy" from "autotrophy" when considering the pathways by which organisms growing on one-carbon compounds as sole source of energy convert those one-carbon units into biomass. This enables a clear distinction between methylotrophically-based energy- and carbon-metabolism to be made. There can be methylotrophic autotrophs, which use methanol or methylamine oxidation to drive carbon dioxide fixation by the Calvin cycle and non-autotrophic methylotrophs, which use from C1-compound oxidation to drive the serine pathway or the Quayle (ribulose monophosphate) cycle to assimilate formaldehyde.

Inorganic Oxidations as Sources of Energy

In principle, any inorganic exergonic oxidation reaction might be expected to be the basis of the energy-conserving metabolism of a chemolithotroph if (i) the reaction creates sufficient energy to support ATP synthesis and electron transport, enabling proton translocation and phosphorylation, (ii) conditions during geological time favor evolution and selection of suitable enzyme systems and organisms. The latter criterion was not always met, inasmuch as chemolithotrophs have not been shown to exploit some potentially energy-yielding processes. This absence probably reflects low concentrations or unavailability of the reaction components in the natural environment and no selective pressure or advantage leading to the survival of any organisms evolving such oxidation capacities.

The reactions unequivocally established as sources of chemolithotrophic energy are the oxidation of hydrogen, ammonia, nitrite, sulfur and its reduced compounds, ferrous iron, and possibly cuprous copper, antimony, and uranium (IV). Detailed consideration of the organisms involved, the mechanisms and types of reactions catalyzed, and the mechanisms of energy trapping are given in the specialist chapters in *The Prokaryotes* and in specialist reviews. This chapter attempts to present views of the chemolithotrophs from the perspective of energy yields of known chemolithotrophic oxidations, possible origins of chemolithotrophic processes, factors limiting the distribution and diversity of chemolithotrophs, and the potential for chemolithotrophy among known bacteria and those which still may remain to be discovered.

Energy Yields from Inorganic Oxidations

Estimates of the efficiency of energy production from inorganic oxidations in chemolithotrophs have been made from thermodynamic calculations and the measurement of growth and carbon dioxide assimilation (e.g., Baas Becking and Parks, 1927; Fromageot and Senez, 1960; Kelly, 1978, 1982, 1990a, 1999). Estimates of ATP production for oxidative phosphorylation in nitrifying bacteria and for sulfur, hydrogen, and iron oxidation are available and generally reflect P/O ratios of about 1.0, except for hydrogen where a normal complete electron transport chain, possibly allowing P/O = 3.0, is present. Some studies using chemostat culture with chemolithotrophs have been reported, and in some cases, maximum theoretical growth yields for the oxidation of different inorganic substrates can be compared and related to probable oxidation pathways and the theoretically available free energy. Chemostat culture methods with thiobacilli growing on sulfur compounds or iron have proved useful to the interpretation of oxidation and energy-coupling mechanisms (Hempfling and Vishniac, 1967; Timmer-ten-Hoor, 1976; Kelly et al., 1977;

Eccleston and Kelly, 1978; Justin and Kelly, 1978; Kelly, 1982, 1990; Jones and Kelly, 1983). Overall oxidation reactions exploited by the different groups of known chemolithotrophs are given in Table 1, and our current knowledge of the energy calculated to be available from these reactions and the observed growth or energy yields achieved by some chemolithotrophic bacteria are given in Table 2. Kelly (1990a, 1999) has reviewed this topic in more detail.

Except in the case of hydrogen oxidation, where the electrode potential is more negative than the NAD+/NADH couple, all these oxidations couple electron transport to the cytochrome system of the bacteria, and NAD+ reduction requires energy-dependent electron flow from cytochromes (Kelly, 1978, 1990a). This dependence is a biochemical hindrance to the growth of such chemolithotrophs because their energy metabolism is often largely concerned with the generation of NADH. Less of the energy available from an oxidation can be coupled more directly to biosynthesis than would occur, for example, during growth on hydrogen or pyruvate as an energy substrate. In addition, many of the most-studied chemolithotrophs use the Calvin cycle to fix carbon dioxide as a main source of carbon, and more than 80% of the total

Table 1. Known chemolithotrophic oxidation reactions.

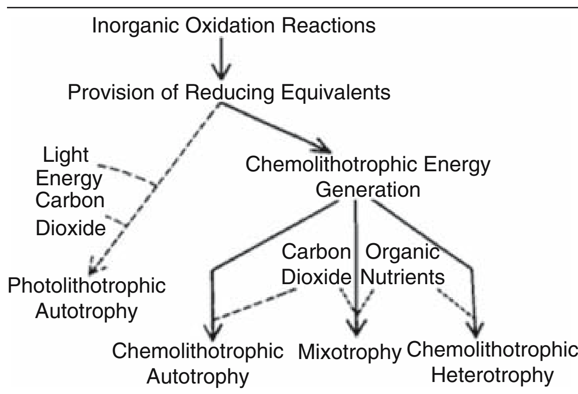

Table 2. Energetics and growth yields from the chemolithotrophic oxidations of Table 1.

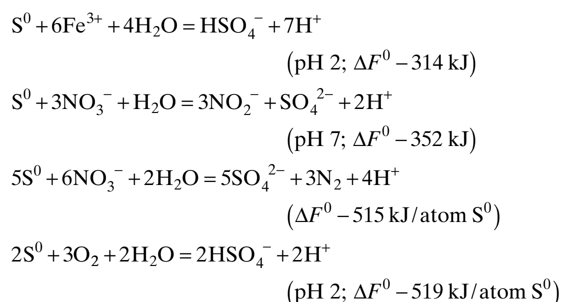

$S^0 + 6Fe^{3+} + 4H_2O = HSO_4^- + 7H^+$ $(pH\ 2;\ \Delta F^0 - 314\ kJ)$

$S^0 + 3NO_3^- + H_2O = 3NO_2^- + SO_4^{2-} + 2H^+$ $(pH\ 7;\ \Delta F^0 - 352\ kJ)$

$5S^0 + 6NO_3^- + 2H_2O = 5SO_4^{2-} + 3N_2 + 4H^+$ $(\Delta F^0 - 515\ kJ/atom\ S^0)$

$2S^0 + 3O_2 + 2H_2O = 2HSO_4^- + 2H^+$ $(pH\ 2;\ \Delta F^0 - 519\ kJ/atom\ S^0)$

energy budget of non-hydrogen-oxidizing chemolithotrophs is indicated for use in converting carbon dioxide to an amount of carbohydrate, equivalent to that found in the growth nutrient of most heterotrophs. This combination of energy requirements explains why the growth yields of chemolithotrophs (already limited by the relatively low molar energy yield of their substrates) are generally apparently rather meager. In fact, they convert energy with reasonable efficiency, in spite of the biochemical problems to be surmounted (Justin and Kelly, 1978; Kelly, 1990a, 1999).

Chemolithotrophy and Autotrophy among Heterotrophs

A consequence of the historical development of the concepts of chemolithotrophy and "chemoautotrophy" was that any capacity for heterotrophic growth in an organism isolated originally as an autotroph tended to be regarded as an additional property of an organism that was primarily an "autotroph." Thus, the first isolates of the facultatively autotrophic thiobacilli were classified as *Thiobacillus novellus* rather than as a *Pseudomonas* that could grow chemolithoautotrophically. This procedure of slotting such organisms into "filing boxes" on the basis of their autotrophy, essentially devaluing their heterotrophic potential as a secondary character, was introduced by Winogradsky and used for most of the following hundred years. The practice has had both good and bad consequences for our understanding of the chemolithotrophs and their place in the natural environment. It has been good because it focused attention on the "obligate chemolithotroph" as an accepted physiological phenomenon, exemplified by clearly definable genera (*Thiobacillus*, some strains of *Beggiatoa*, *Hydrogenobacter*, *Hydrogenovibrio*, *Aquifex*, and the nitrifying bacteria being good examples; Kelly and Harrison, 1989; Nishihara et al., 1990, 1991, 1998; Huber et al., 1992; Shima and Suzuki, 1993; Nelson and Hagen, 1996), and it has enabled and motivated numerous investigators to probe the biochemistry of chemolithotrophic processes. It has been a hindrance to the broader understanding of chemolithotrophy in the natural environment because for many years minds were closed to the idea that chemolithotrophy could be a property of heterotrophs.

The period of microbiologists' reluctance to seek "new" chemolithotrophs (Schlegel, 1975), ended with a new understanding that mixed physiology and metabolic flexibility involving chemolithotrophy and autotrophy is the basis of

successful growth and survival in more organisms than was dreamed previously. Even *Beggiatoa*, so central in the formulation of the concept of the Anorgoxydant is proving a bizarre physiological kaleidoscope.

One of the first cracks in the defense of the concept that chemolithotrophy is a unique and essential taxonomic character was the reclassification of the hydrogen bacteria. For years, autotrophic growth with hydrogen oxidation as a source of energy justified the grouping of these bacteria (all known examples of them were also heterotrophic) into an artificial taxon known as "hydrogen bacteria." In 1969, these were scattered by new thinking and reclassified into diverse standard genera of heterotrophs, on the basis of their morphology and heterotrophic physiology, with their hydrogen-based chemolithotrophy and autotrophy being regarded simply as additional physiological properties (Davis et al., 1969).

The other genus of questionable validity is *Thiobacillus*, whose members obtain energy from oxidizing inorganic sulfur. As currently constituted, this genus contains diverse obligate chemolithotrophs, which differ from each other so widely that they should be reclassified into new genera (Kelly, 1989; Kelly and Harrison, 1989; Kelly and Wood, 1999), as well as facultatively heterotrophic species, which should be reassigned to existing genera of chemoorganotrophs or to new genera, created for them using heterotrophic metabolism and molecular biological criteria. For example some species, such as those described in the previous edition (Kelly, 1991) as *T. novellus* and *T. versutus*, are extremely versatile heterotrophs that can exhibit mixotrophy (in which heterotrophic and chemolithoautotrophic mechanisms operate simultaneously) and are taxonomically remote from obligately chemolithotrophic species. Since the previous edition of *The Prokaryotes*, *T. versutus* has been recognized as a species of *Paracoccus* (Katayama et al., 1995), and 16S rRNA gene sequence analysis has placed *T. novellus* in the α-Proteobacteria, whereas the type species, *T. thioparus*, is a member of the β-Proteobacteria (Lane et al., 1992). Other species, including the obligate chemolithotrophs *T. tepidarius*, *T. neapolitanus*, *T. halophilus*, *T. hydrothermalis* and *T. thiooxidans* have been found to be members of the γ-Proteobacteria, and unlikely to be related even at the genus level to the type species of *Thiobacillus* (McDonald et al., 1997; Kelly and Wood, 1999).

Among the early isolates of autotrophic organisms that had become regarded as probable heterotrophs, or at best mixotrophs, were *Gallionella* and *Beggiatoa*, but their ability to grow respectively as iron- or sulfide-oxidizing chemolithotrophs is now well established (Keil, 1912; Hanert, 1981; Nelson and Jannasch, 1983; Nelson et al., 1986a, 1986b, 1989a; Kelly, 1988). There have been unequivocal demonstrations of an obligately autotrophic, sulfide-oxidizing marine strain of *Beggiatoa* that used a biosynthetic citric acid cycle, lacked 2-oxoglutarate dehydrogenase, and showed virtually no regulatory effect by organic substrates on its constitutive ribulose bisphosphate carboxylase (Hagen and Nelson, 1996). An intriguing observation was that growth of *Beggiatoa alba* on acetate was greatly stimulated by the availability of sulfide, which was apparently used as an energy source enabling surplus assimilation of acetate over that obtainable heterotrophically (Güde et al., 1981). Similarly intriguing is the presence of the autotrophic enzyme, ribulose bisphosphate carboxylase in non-autotrophic strains of *Beggiatoa*, the enzyme seemingly being under repression control by acetate (Nelson et al., 1989b). *B. leptomitiformis* grows mixotrophically on succinate medium with thiosulfate or tetrathionate, which are oxidized to generate ATP by oxidative phosphorylation (Grabovich et al., 1998), further extending the range of strains of filamentous sulfur bacteria exhibiting this kind of mixed energy generation. Another filamentous genus believed to be capable only of mixotrophic growth with inorganic sulfur compounds was *Thiothrix*, but then *T. ramosa* was shown to be able to grow autotrophically using thiosulfate oxidation as sole energy source (Odintsova et al., 1993). Interestingly, while *Thiothrix* and *Beggiatoa* are both members of the γ-Proteobacteria, *Thiothrix* was not part of the novel monophyletic lineage comprising *Beggiatoa* and *Thioploca* (Teske et al., 1996).

Among the unicellular sulfur bacteria, recent work has shown just how blurred is the physiological distinction between the classical definition of *Thiobacillus* and heterotrophs capable of chemolithotrophy. Thus, obligately heterotrophic marine pseudomonads showing thiosulfate-stimulated growth (and carbon dioxide fixation) have been isolated and shown to produce sulfate, as would thiobacilli (Ruby et al., 1981). Even *Pseudomonas aeruginosa* shows increased growth yields in chemostat culture on glucose, when oxidizing thiosulfate to tetrathionate (Mason and Kelly, 1988). Chemolithoautotrophy on thiosulfate is also known in new and old genera of heterotrophs, including *Thiosphaera* (Robertson and Kuenen, 1983; now reclassified as *Paracoccus pantotrophus*, Ludwig et al., 1993; Kelly et al., 1999), *Paracoccus denitrificans*, and other hydrogen-oxidizing heterotrophs (Friedrich and Mitrenga, 1981; Kelly, 1988, 1989). An organism, called *Thiobacillus* Q, isolated as the predominant organism from

ditch water, using a chemostat limited by acetate plus thiosulfate, proved to be incapable of autotrophic growth, and thus to be another example of a heterotroph capable also of chemolithoheterotrophy (Gommers and Kuenen, 1988). It thus bears some similarity to *Thiobacillus intermedius* (London, 1963; now reclassified as *Thiomonas* intermedia; Moreira and Amils, 1997) and the original description of *Thiobacillus perometabolis* (now *Thiomonas perometabolis*), which grew best as chemolithotrophic heterotrophs (London and Rittenberg, 1967; Katayama-Fujimura and Kuraishi, 1983). Mixotrophy and chemolithotrophic heterotrophy have been shown also in the extreme thermoacidophile, *Sulfolobus* and in iron-oxidizing mesophiles and thermophiles (Wood and Kelly, 1983; Barros et al., 1984; Wood et al., 1987). Metabolic flexibility exhibited by such bacteria and the facultatively heterotrophic thiobacilli is of great survival significance to such organisms (Whittenbury and Kelly, 1977; Robertson and Kuenen, 1991) during competition in the natural environment. Thus, mixotrophy can enable these bacteria to dominate in mixed populations when both chemolithotrophic and chemoorganotrophic nutrients are present (Gottschal et al., 1979; Kelly and Kuenen, 1984). The observation of such flexibility should stimulate us to ask just how adaptable the physiology of the lithotrophs may be: whether, for example, the photolithotrophs function significantly as sulfur-oxidizing chemolithotrophs in darkness when given access to low concentrations of oxygen. Thus, *Thiocapsa* can grow in darkness using aerobic oxidation of thiosulfate or sulfide to support carbon dioxide fixation (Kondratieva et al., 1976; Kondratieva, 1989). Pigmentation is lost under such conditions, but ribulose bisphosphate carboxylase specific activity is similar under all photo- or chemolithotrophic conditions. The bacteria thus have the adaptive ability to behave physiologically like thiobacilli. Phenomena of this kind could prove to have considerable ecological and biogeochemical significance in the natural environment. Their widespread demonstration would further prove the undesirability of establishing dogmatic definitions of physiological types of organisms without the possibility of overlap areas. Thus, organisms of seemingly very different fundamental physiology could, under appropriate conditions, behave similarly. Indeed the converse question should be addressed: are any missing links of physiological types of obligate or facultative autotrophs possible? What of obligate hydrogen oxidizers and facultatively heterotrophic nitrifying bacteria, neither of which was proved to exist when one of us wrote the equivalent chapter in the first edition of *The Prokaryotes* (Kelly, 1981). There is now also no doubt that numerous organisms exist that have no autotrophic potential but use energy from lithotrophic oxidations to support growth on organic carbon sources. A remarkably versatile example is *Sulfurospirillum deleyianum*, which can use hydrogen as an electron donor, with its oxidation coupled to the reduction of inorganic or organic acceptors (oxygen, nitrate, nitrite or reduced sulfur compounds, or dimethylsulfoxide or C4-organic acids). This organism also uses sulfide as an electron donor (with acetate as carbon source), reducing nitrate and nitrite to ammonia to generate metabolic energy (Eisenmann et al., 1995). Some of these concepts are summarized in Fig. 1.

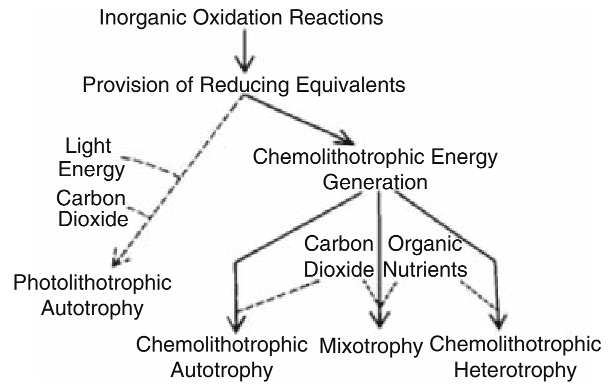

Fig. 1. Scheme illustrating the relation of inorganic oxidations to chemolithotrophic and photolithotrophic metabolism.

For many decades, the species of the nitrifying bacteria were uniformly believed to be obligate chemolithoautotrophs, in accordance with Winogradsky's original description of them and use of their properties to define the Anorgoxydant. Subsequently, facultative heterotrophy was proved in nitrite-oxidizing species, in which acetate or pyruvate was used to support aerobic and anaerobic growth (Smith and Hoare, 1968; Bock, 1976; Freitag et al., 1987; Bock et al., 1988). Also, one of the most abundant of the nitrite-oxidizing bacteria in the natural environment, *Nitrobacter vulgaris*, has been shown to grow faster heterotrophically than autotrophically, and can reduce nitrate (to nitrite, ammonia, NO and N_2O) during anaerobic growth on acetate or pyruvate (Bock et al., 1990). The complexity of habitat niches and complexity of the involvement of nitrite-oxidizing bacteria in soil ecosystems, is thus greater than was long believed. As yet, nitrite- (or ammonia-) dependent chemolithotrophic heterotrophy has not been shown, but mixotrophic growth of *N. vulgaris* can be faster than during heterotrophy (Bock et al., 1990).

The Overlap of Autotrophy, Methylotrophy and Chemolithotrophy

The methane-oxidizing bacteria, such as *Methylococcus*, are dependent on methane oxidation (or in some cases also methanol) for energy and carbon, but even in these the autotrophic enzyme ribulose bisphosphate carboxylase has been found (Taylor, 1977), and could contribute to the synthesis of phosphoglycerate during growth on methane (Stanley and Dalton, 1982). Interestingly, the amount of the carboxylase in *M. capsulatus* in chemostat culture decreased with oxygen-limitation (Khmelenina et al., 1992), possibly suggesting its function as an oxygenase has a greater importance. The carbon monoxide-oxidizing bacteria also fix carbon dioxide by means of the Calvin cycle, as do *Thiobacillus novellus* and *Paracoccus* versutus during growth on methylamine, methanol or formate as substrates (Kelly et al., 1979; Kelly and Wood, 1982, 1984; Meyer, 1989). Thus, autotrophy can occur in organisms growing on methylotrophic or other one-carbon energy substrates and does not have to be linked to chemolithotrophic energy sources. Growth of some thiobacilli and hyphomicrobia has been shown using one-carbon sulfur compounds as sole substrates (for review, see Kelly and Smith, 1990b). These substrates, including dimethyl sulfoxide, dimethyl sulfide, dimethyl disulfide and methanethiol, provide a somewhat remarkable meeting place or common feeding ground for sulfur-dependent chemolithoautotrophs and truly methylotrophic organisms. Thus some strains of *Thiobacillus thioparus* oxidize both the methyl and the sulfur groups and obtain energy from their oxidation. The thiobacilli cannot grow on one-carbon compounds, such as methylamine, which is used by the hyphomicrobia, and the latter cannot grow on sulfide or thiosulfate unless a compound such as methylamine is also supplied. Remarkably, the hyphomicrobia can grow mixotrophically on methylamine and thiosulfate, when they derive energy from oxidizing the latter, and use this to increase the proportion of methylamine-carbon incorporated by the serine pathway. They are thus chemolithotrophic methylotrophs that show no capacity for autotrophy, and serve to illustrate further that chemolithotrophic energy-generating processes can underpin or enhance the metabolism and growth not only of diverse autotrophs, but also of methylotrophs and heterotrophs. It also illustrates that substrates such as inorganic sulfide, methylated sulfides, methylamines, and other intermediates of sulfur or one-carbon metabolism may be competed for in the natural environment by organisms of diverse basic physiology, including specialist thiobacilli and hyphomicrobia, as well as some chemolithotrophic heterotrophs.

Chemoorganotrophic Potential among Obligate Chemolithotrophs

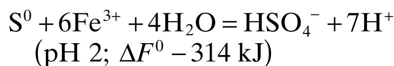
So far we have dwelt on the diversity of organisms, both autotrophs and heterotrophs in which the potential for chemolithotrophic energy conservation from inorganic oxidations resides. In writing such an introduction twenty or fifty years ago, the emphasis would have been placed on the uniqueness of the chemolithotrophic mode of growth and the puzzle of why in some organisms the chemolithoautotrophic mode of growth is obligatory (van Niel, 1943; Umbreit, 1947; Kelly, 1967, 1971). The reason why some bacteria exhibit this obligate chemolithotrophy is still inadequately explained (Kelly, 1971; Zavarzin, 1989), and it is probable that there is no single, simple, and universal explanation. Certainly, impermeability to organic nutrients is not the reason, as many obligate thiobacilli and nitrifying bacteria incorporate organic compounds at the expense of chemolithotrophically-generated energy. Also it has long been realized that the hypothesis that fundamental differences exist between the central metabolic processes of chemolithotrophs and heterotrophs was not tenable. Indeed the problem is made more intriguing by the evidence for storage polymers in obligate strains of thiobacilli and *Nitrobacter* (van Gool et al., 1971). *Thiobacillus neapolitanus* has been shown not only to accumulate polyglucose to levels exceeding 20% of the cellular protein content (Beudeker et al., 1981a), but also to consume this under conditions of (aerobic) carbon dioxide starvation, and to degrade it under anaerobic conditions by a heterolactic fermentation pathway (Beudeker et al., 1981b). A wide range of organic-nitrogen compounds, such as purines and urea, can be used to provide nitrogen for the chemolithoautotrophic growth of *Thiobacillus thiooxidans* (Brierley and Brierley, 1968; Metzdorf and Kaltwasser, 1988), and some obligate strains exhibit requirements for trace compounds such as vitamins. Thus the explanation for obligate chemolithotrophy must lie in the nature of the central regulatory processes that control carbon flow to biosynthesis in such bacteria, and this also must determine their seeming inability to oxidize exogenously supplied organic nutrients as sources of energy. The significant chemolithotrophic-energy-dependent incorporation of some compounds (such as amino acids) indicates that in the natural envi-

ronment the obligate chemolithotroph, while likely to be mainly autotrophic, must exhibit a degree of chemolithotrophic heterotrophy. They are thus at one end of a continuum of physiological behaviour, as discussed by Kelly and Kuenen (1984).

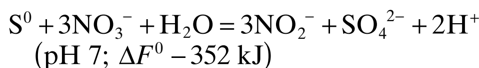
It has become clear that chemolithotrophy is not a restricted property of a few quaint but ecophysiologically-specialized bacteria, but it is a metabolic mode shared among many heterotrophs and may enable them to prevail over less versatile species in the competition for resources in nutrient-restricted natural environments.

Some Novel Chemolithotrophic Reactions and Some "New" Chemolithotrophs

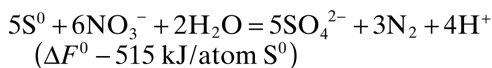
Potentially energy-yielding novel reactions have been found in sulfur-oxidizing thiobacilli and *Sulfolobus*, and in iron-oxidizing thermophiles. *Thiobacillus ferrooxidans* and *T. thiooxidans* can oxidize sulfur at the expense of ferric iron reduction as the respiratory oxidant (Brock and Gustafson, 1976). *T. ferrooxidans* does this anaerobically and thus may be capable of anaerobic growth using this system. It is noteworthy that previous reports of ferric iron reduction by heterotrophs have attributed the process to nitrate reductase (Thauer et al., 1977), but the probable inability of these bacteria to denitrify may suggest the existence of a specialist enzyme system, possibly a relict of a metabolic process that evolved before the appearance of nitrate respiration in early microorganisms. The amount of energy available from sulfur oxidation coupled to iron reduction is comparable with that from nitrate reduction or from aerobic sulfur or iron oxidation:



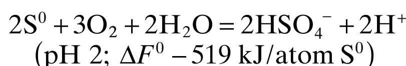
$$S^0 + 6Fe^{3+} + 4H_2O = HSO_4^- + 7H^+ \quad (\text{pH } 2;\ \Delta F^0 - 314 \text{ kJ})$$



$$S^0 + 3NO_3^- + H_2O = 3NO_2^- + SO_4^{2-} + 2H^+ \quad (\text{pH } 7;\ \Delta F^0 - 352 \text{ kJ})$$



$$5S^0 + 6NO_3^- + 2H_2O = 5SO_4^{2-} + 3N_2 + 4H^+ \quad (\Delta F^0 - 515 \text{ kJ/atom } S^0)$$



$$2S^0 + 3O_2 + 2H_2O = 2HSO_4^- + 2H^+ \quad (\text{pH } 2;\ \Delta F^0 - 519 \text{ kJ/atom } S^0)$$

Iron-oxidizing, moderately thermophilic, chemolithotrophic heterotrophs were described by Brierley et al. (1978, 1980; Clark and Norris, 1996), growing on ferrous iron or pyrite as a substrate, but incapable of sustained growth on sulfur. Those isolates did, however, grow on copper sulfide (CuS), but only if small amounts (e.g., 1 mM) of iron (Fe^{2+} or Fe^{3+}) were present. Such organisms might simply be exhibiting an unusually high requirement for assimilable iron to grow on sulfur compounds. It is also possible that their main source of energy could be the oxidation of ferrous iron, with its constant regeneration by either biological oxidation of the CuS with Fe^{3+} or purely chemical reaction of CuS with ferric sulfate, according to the following processes:

1. Biological, energy-yielding aerobic ferrous iron oxidation:

$$4FeSO_4 + O_2 + 2H_2SO_4 = 2Fe_2(SO_4)_3 + 2H_2O$$

2. Sulfide oxidation at the expense of ferric iron reduction:

$$CuS + Fe_2(SO_4)_3 = CuSO_4 + 2FeSO_4 + S^0$$

3. Chemical reduction of ferric iron:

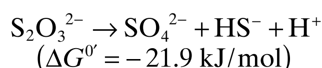
$$S^{2-} + 8Fe^{3+} + 4H_2O = SO_4^{2-} + 8Fe^{2+} + 8H^+$$

Measurement of growth yields or carbon dioxide fixation in such an organism should elucidate the main energy-yielding processes because considerably greater yields should result if both sulfide and iron oxidation were energy coupled, rather than solely the latter.

Earlier, we noted that all then known hydrogen-oxidizing autotrophs could be classified as heterotrophs (Davis et al., 1969). The vacant metabolic niche of the obligately chemolithoautotrophic hydrogen-oxidizer was filled in 1980 with the demonstration that such bacteria exist in some hot springs (Kawasumi et al., 1988). Several species of the thermophilic (and one case of a halophilic) *Hydrogenobacter* genus have been described (Kristjansson et al., 1985; Nishihara et al., 1990) and found growing on hydrogen optimally at 70°C, fixing carbon dioxide by a reductive tricarboxylic acid cycle, but shown to be incapable of growth on a wide range of simple and complex organic materials. Nishihara et al. (1989) isolated another obligately chemolithoautotrophic, halophilic hydrogen bacterium that grew best at 37°C (with no growth at 45°C) and used the Calvin cycle to fix carbon dioxide. This bacterium represented a further metabolic signature on the bewildering palimpsest of microbial physiology. Interestingly, it also grows on inorganic sulfur compounds and if originally it had been isolated from enrichment culture (for example on thiosulfate), it would have been classifiable as "*Thiobacillus*," but only if its ability to use hydrogen had not been tested. It is interesting to note the degree of overlap among the obligate and facultative hydrogen-oxidizers in their ability also to use inorganic sulfur oxidation for energy.

This metabolic overlap, and presence of versatile physiology is perhaps nowhere more remarkably emphasized than in *Acidianus* (Segerer et al., 1986; Zillig et al., 1986; Fuchs et al., 1996). *Acidianus* species are extremely thermophilic (85–90°C) and acidophilic (pH 2.0–2.5) archaebacteria. They are capable of aerobic autotrophic growth on elemental sulfur, which they oxidize to sulfate, while fixing carbon dioxide by a not yet fully resolved mechanism that resembles the 3-hydroxypropionate pathway postulated in *Chloroflexus* (Holo, 1989; Ishii et al., 1996). These bacteria are also capable of strictly anaerobic autotrophic growth during which they reduce elemental sulfur to hydrogen sulfide at the expense of hydrogen oxidation (Kelly, 1985, 1988; Segerer et al., 1985, 1986; Zillig et al., 1985, 1986). Thus, chemolithotrophy can exist in the same organisms using aerobic sulfur oxidation or anaerobic hydrogen oxidation, while simultaneously dissolving the previous distinction of sulfur oxidation and reduction as properties of quite distinct physiological groups of organisms.

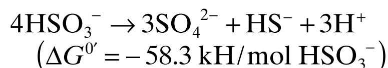
This distinction has been weakened further by the work of Cypionka (e.g., Bak and Cypionka, 1987) on sulfate-reducing bacteria that can grow using "sulfur fermentation" as a means of generating chemolithotrophic energy (Kelly, 1987, 1988, 1990a). Thus, *Desulfovibrio sulfodismutans* and *Desulfobacter curvatus* are among organisms able to conserve energy from the anaerobic disproportionation of thiosulfate or sulfite to produce mixtures of sulfate and sulfide as end products; thus, both sulfur (or sulfite) reduction to sulfide and anaerobic oxidation to sulfate occur in their energy-generating mechanism. The overall process is a fermentation, in that the combined oxidation state of the end products equals that of the substrate (Bak and Cypionka, 1987; Bak and Pfennig, 1987; Kelly, 1987, 1988):



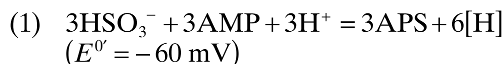
$$S_2O_3^{2-} \rightarrow SO_4^{2-} + HS^- + H^+ \quad (\Delta G^{0\prime} = -21.9\ \text{kJ/mol})$$

Recent studies have shown that there is differential fractionation of the sulfur isotopes (^{32}S and ^{34}S) within thiosulfate, when this is the sulfur compound being disproportionated by *Desulfovibrio desulfuricans*. Disproportionation of thiosulfate yielded sulfate that was isotopically heavier than the inner- sulfur (sulfonate- , $-SO_3-$) of thiosulfate, and sulfide which was isotopically lighter than the outer- (sulfane-, -S-) of thiosulfate (Cypionka et al., 1998; Smock et al., 1998). This means that the disproportionation of thiosulfate does not result in its direct conversion to sulfate and sulfide, but that intermediate reactions occur during which there is fractionation of ^{32}S and ^{34}S (Cypionka et al., 1998).

Enzymological studies have partially resolved the probable mechanism of these processes and how the free energy is conserved (Krämer and Cypionka, 1989). The overall reaction, and three component steps leading to sulfate and sulfide formation from sulfite, with ATP formation, may be:

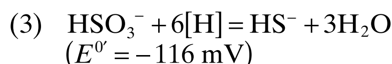


$$4HSO_3^- \rightarrow 3SO_4^{2-} + HS^- + 3H^+ \quad (\Delta G^{0\prime} = -58.3\ \text{kH/mol}\ HSO_3^-)$$



$$(1)\quad 3HSO_3^- + 3AMP + 3H^+ = 3APS + 6[H] \quad (E^{0\prime} = -60\ \text{mV})$$

$$(2)\quad 3APS + 3PPi = 3ATP + 3SO_4^{2-}$$



$$(3)\quad HSO_3^- + 6[H] = HS^- + 3H_2O \quad (E^{0\prime} = -116\ \text{mV})$$

(where APS is adenylyl sulfate and PPi is pyrophosphate).

The problem implicit in this scheme is that the reductant-donating reaction [1] is less electronegative than that producing sulfide (3). This led Krämer and Cypionka (1989) to postulate energy-dependent reversed electron transport as part of the overall process. This would be needed if an alternative means of oxidizing sulfite to sulfate were not found in these anaerobes. Such an oxidation could well involve energized membrane functions that lead to further ATP synthesis (in a coupled sulfite oxidation and sulfite reduction) and possibly to $NAD(P)^+$ reduction. These sulfite or thiosulfate-fermenting chemolithotrophs are in fact chemolithotrophically heterotrophic in that they have been grown on sulfur compounds as sole energy source and on acetate as carbon source. The sulfur fermentation continued also when hydrogen was provided as an oxidizable substrate (Krämer and Cypionka, 1989).

Hydrogen oxidation is of course a source of energy not only to many aerobes and the sulfur-reducing archaebacteria (already discussed), but also to the sulfate-reducing bacteria and the methanogens (Table 3, equation 1). The chemolithotrophy and autotrophy of the sulfate-reducing bacteria have a long and somewhat bizarre history. For some time, *Desulfovibrio* was regarded as a facultative autotroph, oxidizing hydrogen to reduce sulfate and fixing carbon dioxide as a source of carbon. The autotrophic status of *Desulfovibrio* species (Butlin and Adams, 1947) was demoted to that of "not to be true autotrophs" (Mechalas and Rittenberg, 1960; Postgate, 1979), and then the genus was reinstated as having strains truly capable of chemolithotrophy on hydrogen and sulfate (Badziong et al., 1978; Thauer, 1989). Now some sulfate-reducers also are known to be capable of chemolithotrophic autotrophy, such as

Desulfobacterium autotrophicum, which uses the reductive acetyl CoA pathway to fix carbon dioxide, and *Desulfobacter hydrogenophilus*, which uses the reductive tricarboxylic acid cycle (Fuchs, 1989).

Clearly the physiological types of chemolithotrophs, and metabolic combinations involving chemolithotrophy, are many and various, and many more novelties can be expected as *The Prokaryotes* is progressively updated.

Evolutionary Aspects of the Origin of Chemolithotrophy

For perhaps two billion years, since the origin of life on earth, metabolic evolution occurred in a globally anaerobic environment. Before the appearance of the oxygen atmosphere, the widely accepted view of life processes was that of a fermentative metabolism acting at the expense of organic materials (the "prebiotic soup") accumulated during an era of prebiotic chemical evolution (Oparin, 1957; Maden, 1995). Thus, the first living entity was regarded as a completely heterotrophic unit using abiotically preformed organic molecules (Horowitz, 1945). Metabolism during this period might have included the development of some steps of the tricarboxylic acid cycle as an anaerobic process, and of bacterial photosynthesis at the expense of organic compounds, with hydrogen and sulfide as reductants. During this time, the earliest chemolithotrophs were postulated to have appeared: these were proposed to be methanogens, which reduced carbon dioxide with hydrogen, and the sulfate-reducing bacteria, which used hydrogen as well as other reductants.

There is, however, no longer a universal acceptance of the view that the earliest organisms were heterotrophs (Maden, 1995; Edwards, 1998). One view gaining strong support is that the earliest self-sustaining metabolism was rooted in chemolithoautotrophy (Wächterhäuser, 1988, 1990a, 1990b, 1992). All of the most deeply rooted lines of Bacteria and Archaea are hyperthermophiles, and many of these are autotrophs (Woese, 1987; Burggraf et al., 1992; Stetter, 1992). Indeed, Stetter (1992) has proposed that the deepest branches of the phylogenetic tree comprise chemolithotrophic autotrophs, thus indicating autotrophy as a primordial metabolic process. It is also possible that chemolithotrophy predated autotrophy, and that the first chemolithotrophs were chemolithotrophic heterotrophs, using inorganic energy sources as well as prebiotic organic molecules.

There is a widely accepted view that the first autotrophic processes were akin to those now seen in the sulfur- and sulfate-reducing bacteria and Archaea (i.e., cyclic processes involving organic acids). The process once regarded as typifying autotrophy, namely the Calvin reductive pentose phosphate cycle, is regarded as being of much later origin and as having evolved from earlier sugar-metabolizing pathways (Maden, 1995). The Calvin cycle is apparently not functional in carbon dioxide fixation by Archaea and hydrogen- or sulfur-oxidizing hyperthermophiles (Fuchs and Stupperich, 1985; Maden, 1995; Schönheit and Schäfer, 1995), and this is used as evidence that it cannot have been a primordial pathway. It is noteworthy, however, that genes apparently coding for a novel (or even primordial) form of ribulose bisphosphate carboxylase occur in *Pyrococcus* and other Archaea (Ezaki et al., 1998), but their origin and whether they are the result of later lateral gene transfer, is not known. If these genes are relict rather than a result of lateral transfer, the Calvin cycle could be of much more ancient origin, arising in chemolithotrophic heterotrophs in which biosynthesis using simple exogenous sugars had already evolved. An argument for a later origin also has been applied to the carbon monoxide dehydrogenase pathway (acetyl coenzyme A pathway), which requires additional carbon dioxide fixing processes to support biosynthesis beyond the level of two-carbon units (Maden, 1995). Wächterhäuser (1990a, 1990b, 1992) postulates that the first pathway of autotrophic carbon fixation was an archaic precursor of the reductive citric acid cycle, whose descendent is found in examples of modern eubacteria, green sulfur bacteria, hyperthermophilic hydrogen bacteria, and Archaea (Evans et al., 1966; Schauder et al., 1987; Wächterhäuser, 1990a, 1990b; Shima and Suzuki, 1993; Beh et al., 1993; Maden, 1995).

Studies of anciently duplicated genes encoding components of the protein-targeting machinery have been suggested to help identify the root of the universal tree of life (Gribaldo and Cammarano, 1998). The key protein of the signal recognition particle (SRP54 in Eukarya and Fm in Bacteria) and the protein involved in the recognition and binding of the ribosome SRP nascent polypeptide complex (SR alpha in Eukarya and Ftsy in Bacteria) are products of ancient gene duplication that appears to predate the divergence of all extant taxa (Gribaldo and Cammarano, 1998). This leads to the reasoning that the first bifurcation in the tree of life separated the lineage leading to Bacteria from a common ancestor to Archaea and Eukarya (Gogarten and Taiz, 1992; Gogarten, 1995; Gribaldo and Cammarano, 1998). Phylogenetic studies on dissimilatory sulfite reductases and adenylyl sulfate (APS) reductase (Hipp et al., 1997; Wagner et al., 1998), using organisms as diverse as *Chromatium*, *Archaeoglobus* and *Desulfovibrio*, showed gene homology for these

reductase enzymes. The degree of similarity of the DNA sequences for the bacterial and Archaeal genes was such that the most likely explanation was a common origin from ancestral reductase genes. This suggests that the genes for the ancestral reductases were present before the split between the domains of Bacteria, Archaea and Eukarya took place. This kind of evidence lends considerable weight to a view of primordial organisms that were chemolithotrophs capable of the dissimilatory processing of inorganic sulfur compounds, including the earliest sulfur- and sulfate-reducing organisms.

While the dating of early evolutionary processes is exceedingly conjectural, the consensus view at present is that chemolithotrophic and autotrophic processes existed early in the development of living systems. Currently, however, there is debate about (1) the validity of the concept of the divergence of the Bacteria and the Archaea (Gupta, 1998a, 1998b), and (2) the nature and dating of the progenitor organisms that led to modern life forms (Gogarten-Boeckels et al., 1995; Gogarten et al., 1996). The first argument does not greatly affect our view of a very ancient origin of chemolithoautotrophy, but the theory advanced by the latter authors may push back the origin of these processes to a time in Earth's history even prior to the cessation of heavy meteoritic bombardment (Chyba, 1992; Gogarten-Boeckels et al., 1995). Their hypothesis is that prokaryotic forms evolved and could have reached a sophisticated state of development by about 3.7 billion years (3.7 Gyr) ago. These primordial prokaryotes would have colonized extremely hot environments but did not arise necessarily in such environments. The deep phylogenetic separation of modern Archaea and Bacteria, and their fundamental differences in cell biology, could be evidence of their descent from distinct primordial ancestors, each extant at 3.7 Gyr, rather than a common cenancestor. If a mass-extinction-scale extra-terrestrial impact event occurred at 3.7 Gyr, resulting in near-boiling of oceans, then only isolated examples of ancient primordial, hyperthermophilic prokaryotic types might have survived, and two of these might have led by subsequent separate evolution to the Bacteria and Archaea (and presumably the Eukarya). This scenario would make the common ancestor of all current life forms a chemolithotrophic autotroph, which originated little more than 0.5 Gyr after the formation of the Earth.

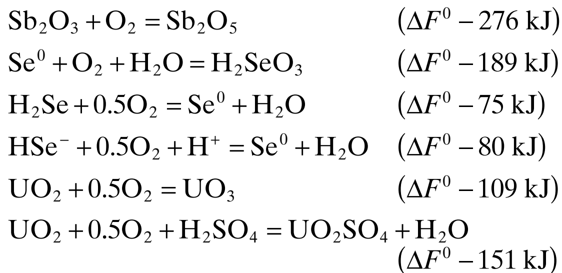
If one accepts the view that elemental oxygen and nitrate are both relatively very recent additions to the natural environment (Broda, 1977a; Gautier, 1992), the latter only appearing when the biosphere became less reducing, then the modern chemolithotrophs, dependent on oxygen or nitrate respiration, must be regarded as relatively recent evolutionary products. Their origins, however, are clearly traced from the types of inorganic oxidative metabolism (e.g., of hydrogen by sulfate-reducers, and of both hydrogen and sulfide by photolithotrophs) that evolved in the anaerobic phase of evolution. The basic patterns for chemolithotrophic and autotrophic biochemistry could well have been laid in this period; thus, the principle for sulfur-compound oxidation now seen in thiobacilli could have developed in ancient phototrophs. Interestingly, in relation to the idea of primordial organisms being anaerobic hyperthermophiles, there are several examples of modern thermophiles or hyperthermophiles capable of hydrogen oxidation either aerobically or by nitrate reduction to dinitrogen. Examples are *Hydrogenobacter acidophilus* (optimum temperature 65°C and pH 3–4; Shima and Suzuki, 1993) and the Archeon *Pyrobaculum aerophilum* (optimum growth at 100°C; Volkl et al., 1993). Better known are the examples of *Sulfolobus* and *Acidianus* (some with temperature optima approaching 100°C), capable of aerobic sulfur oxidation or anaerobic hydrogen oxidation coupled to sulfur reduction (Fuchs et al., 1996); however, such organisms and *Pyrobaculum* are clearly unlike any primordial Archeon in being facultative aerobes, but their unusual combination of chemolithotrophic potentials could be relict indicators of the earliest chemolithotrophic biochemical processes.

The mechanisms for ammonia (and possibly nitrite) oxidation could stem from more ancient methane-oxidizing organisms: methane oxidation by ammonia-oxidizers supports this view, and the similarities of the DNA sequences for genes encoding ammonia and methane monooxygenases (Holmes et al., 1995) are consistent with evolution from common ancestral enzyme forms. The major changes were, of course, the development of enzyme systems enabling the reaction with oxygen and in some cases the coupling of energy conservation to the oxidation of inorganic substances.

The questions remain: are other lithotrophs to be discovered in nature, or are such theoretically possible chemolithotrophs missing from nature? If so, did they once exist?

As already stated, any exergonic oxidation reaction with a reasonably electronegative potential might support metabolism and growth. The oxidation of ferrous iron is a good example of a process of rather low energy yield and unfavorable electrode potential (relative to NAD^+ reduction) that has been very successfully exploited in the evolution of organisms like *Thiobacillus ferrooxidans*. Among some

possible reactions would be the oxidation of metals that show several valence states. Thus, manganese oxidation (possibly a source of energy for ill-defined organisms like *Metallogenium*) could well prove to be the basis of a chemolithotrophic process, and the demonstration of ribulose 1,5-bisphosphate carboxylase genes in a marine manganese-oxidizing bacterium suggests that autotrophy driven by manganese oxidation may be possible (Caspi et al., 1996). There is also reasonable evidence that cytochrome-mediated oxidation of cuprous copper and stannous tin occurs in *T. ferrooxidans* (Lewis and Miller, 1977), which appears anyway to obtain energy from the former. Other metal oxidations mentioned in the literature are of antimony (for which there is evidence of an organism; Lyalikova, 1972), selenium and uranium, for which possible reactions are:



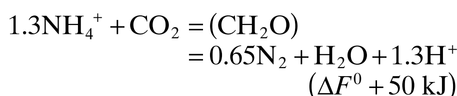
$$Sb_2O_3 + O_2 = Sb_2O_5 \quad (\Delta F^0 - 276\ \text{kJ})$$
$$Se^0 + O_2 + H_2O = H_2SeO_3 \quad (\Delta F^0 - 189\ \text{kJ})$$
$$H_2Se + 0.5O_2 = Se^0 + H_2O \quad (\Delta F^0 - 75\ \text{kJ})$$
$$HSe^- + 0.5O_2 + H^+ = Se^0 + H_2O \quad (\Delta F^0 - 80\ \text{kJ})$$
$$UO_2 + 0.5O_2 = UO_3 \quad (\Delta F^0 - 109\ \text{kJ})$$
$$UO_2 + 0.5O_2 + H_2SO_4 = UO_2SO_4 + H_2O \quad (\Delta F^0 - 151\ \text{kJ})$$

All of these oxidations yield at least as much energy as iron oxidation, presuming the ΔF0 values to reflect free energy changes that could be trapped metabolically.

Oxidation of anions also could be energy yielding: the organisms using sulfur oxyanions and nitrite are well known. Other energy substrates could be compounds of tellurium, molybdenum, vanadium, or any salt of a multivalent element capable of further oxidation. Another possible substrate might be phosphine (PH_3), which could be oxidized through several intermediates to orthophosphate, with an overall large change in free energy:

$$PH_3 + 2O_2 = H_3PO_4 \quad (\Delta F^0 - 1166\ \text{kJ})$$

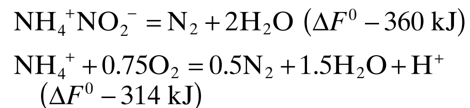
Broda (1977b) discussed the apparently unfulfilled expectation that two further types of ammonia-oxidizing bacteria might exist. The first of these was anaerobic, photosynthetic ammonia bacteria, which use NH_4^+ in a way analogous to sulfide, use light-dependent CO_2-fixation, and generate dinitrogen from ammonia:



$$1.3NH_4^+ + CO_2 = (CH_2O) = 0.65N_2 + H_2O + 1.3H^+ \quad (\Delta F^0 + 50\ \text{kJ})$$

Such phototrophic organisms, if they ever existed, could have been the precursors of the modern aerobic nitrifying bacteria.

Anaerobic ammonia oxidation had not been shown in known species of modern nitrifying bacteria, and this was attributed to the presumed need for an oxygenation of ammonia to hydroxylamine which was obligatorily dependent on elemental oxygen. Broda (1977b) speculated that anaerobic ammonia oxidation using nitrite as oxidant is feasible, with dinitrogen as the end product. Similarly, aerobic ammonia oxidation to N_2 is theoretically possible as a chemolithotrophic process (Broda, 1977b):



$$NH_4^+NO_2^- = N_2 + 2H_2O \quad (\Delta F^0 - 360\ \text{kJ})$$
$$NH_4^+ + 0.75O_2 = 0.5N_2 + 1.5H_2O + H^+ \quad (\Delta F^0 - 314\ \text{kJ})$$

Both these reactions are more exergonic overall than aerobic ammonia oxidation to nitrite. That comparable processes may indeed be catalysed by anaerobic ammonia-oxidizing bacteria is indicated by the observation in a commercial denitrification plant that the overall nitrogen balance of the system could be explained only if ammonia oxidation with nitrate as oxidant was occurring (Mulder, 1989). Novel anaerobic, ammonium-oxidizing (“Anammox”), bacteria were shown to be highly enriched in this plant, apparently growing autotrophically by obtaining energy from the conversion of ammonia and nitrite (via nitrite, hydroxylamine and hydrazine) to nitrogen gas (van der Graaf et al., 1996, 1997). The well-known aerobic nitrifier, *Nitrosomonas*, has been shown to couple anaerobic ammonia oxidation to the reduction of nitrogen dioxide, with the formation of NO and nitrite (Schmidt and Bock, 1997).

The sulfur-oxidation-dependent reduction of ferric iron referred to earlier also could be a relict of a primordial, energy-yielding, proto-chemolithotrophic process. In the pre-oxic biosphere, most iron was probably in the ferrous state, but because of the absence of autooxidation, ferrous iron may have been a substrate for a form of photosynthesis. In any case, it was oxidized to ferric iron over possibly 10^9 years following the appearance of O_2-photosynthesis, but before free oxygen began to accumulate in the atmosphere. Abundant sulfide and iron could thus have made a selective “niche” for such chemolithotrophy.

Probably many of the theoretically feasible reactions for energy generation will not be found in any organisms, past or present, because the substrates of the reactions were never sufficiently abundant on earth for any chance evolution of an enzyme system that

used the reaction to have survived. The modern chemolithotrophs seem to be so successful by one of two physiological specializations. Either they are specialist organisms, like the obligately chemolithotrophic sulfur oxidizers, which do not compete with heterotrophs because they use an inorganic substrate not available to most of the latter and are not dependent on organic carbon; or they are versatile facultative organisms, capable in organic, nutrient-rich environments of "switching off" their chemolithotrophic autotrophic metabolism and competing as successful heterotrophs. The place of mixotrophy and chemolithotrophic heterotrophy in the natural environment is less certain but probably confers advantage on such organisms, as they can compete simultaneously for distinct and unrelated sources of energy and carbon. In rather selective environments (such as acid, hot, or metal-rich habitats) where the chemolithotroph is best adapted to survive (e.g., the sulfur-oxidizing thermophiles of hot springs or the metal-tolerant, acidophilic, iron-oxidizing organisms of mineral leaching systems), mixotrophy could be a great selective advantage, where there is perhaps minimal competition with pure heterotrophs. Mixotrophy, in particular, potentially enables an organism to exploit as many nutritional facets of its environment as possible.

Our growing understanding of the complexity of the metabolic possibilities among chemolithotrophs and heterotrophs with chemolithotrophic potential, as well as the realization of the extreme antiquity of chemolithoautotrophic processes, not only helps explain why so many organisms can live together in seeming contradiction of the competitive exclusion principle, but also means that even greater metabolic variety can be expected to be discovered.

CHAPTER 1.16

Oxidation of Inorganic Nitrogen Compounds as an Energy Source

EBERHARD BOCK AND MICHAEL WAGNER

Introduction

Life depends on the element nitrogen. In nature, nitrogen exists mainly in the oxidation states -III (NH_3), O (N_2), +I (N_2O), +II (NO), +III (NO_2^-), +IV (NO_2), and +V (NO_3^-). Owing to nitrogen transformations by the activity of living organisms and to chemical instability, any form of oxidation state has only a transient existence. Dinitrogen (N_2) is the most inert and frequent constituent of the atmosphere.

Taking into account also abiotic transformations, three cycles of nitrogen can be distinguished:

1. The cycle of the atmosphere
2. The interaction between the atmosphere and the biosphere
3. The cycle of the biosphere

The nitrogen cycle mediated by the biosphere (Fig. 1) can also be characterized by mobilization and immobilization of nitrogen compounds. Most of the reactions are catalyzed exclusively by prokaryotes. By microbial nitrogen fixation, dinitrogen is reduced to ammonia and subsequently transferred to amino acids and assimilated into cell material. On the other hand, ammonia is released from organic nitrogen compounds by microbial activity called "ammonification" or "mineralization." Ammonia (NH_3)/ammonium (NH_4^+) is the most frequently found form of nitrogen in the biosphere and is transferred efficiently over long distances via volatilization. In contrast, nitrite is usually found in trace amounts in aerobic habitats and only accumulates at low oxygen partial pressure, e.g., in soil with high water potential. Because of the toxicity of nitrite for living organisms, the maintenance of low nitrite concentration in aerobic habitats is essential. Under oxic conditions, ammonia and nitrite are not stable and are converted to nitrate by nitrifying bacteria. Nitrification, the biological oxidation of reduced forms of inorganic nitrogen to nitrite and nitrate, is catalyzed by two physiological groups of bacteria. Ammonia-oxidizing bacteria, which use ammonia and not ammonium as substrate (Suzuki et al., 1974), gain energy from oxidation of ammonia to nitrite, and nitrite-oxidizing bacteria thrive by oxidizing nitrite to nitrate. In sea- and freshwater as well as in soil, nitrite produced by the ammonia oxidizers is immediately consumed by nitrite oxidizers and thus the nitrite concentration is extremely low in these environments (El-Demerdash and Ottow, 1983; Schmidt, 1982). Nitrate can be assimilated by plants and microorganisms. Under anoxic or oxygen-limited conditions, nitrate is used as electron acceptor for anaerobic respiration (if organic matter is available) and thereby converted to ammonia (respiratory ammonification) or dinitrogen (denitrification).

This chapter focuses on nitrifying bacteria, which use the oxidation of inorganic nitrogen compounds as their major energy source. Lithotrophic nitrifiers are Gram-negative bacteria and conventionally have been placed in the family Nitrobacter iaceae (Buchanan, 1917; Watson, 1971a; Watson et al., 1989). However, phylogenetically the lithoautotrophic ammonia oxidizer s, characterized by the prefix *Nitroso*-, and nitrite oxidizer s, characterized by the prefix *Nitro*-, are not closely related (Teske et al., 1996; Purkhold et al., 2000). Comparative 16S rRNA sequence analysis demonstrated that all recognized ammonia oxidizer s are either members of the β- or γ-subclass of Proteobacteria (Fig. 2). The genera *Nitrosomonas* (including *Nitrosococcus mobilis*), *Nitrosospira*, *Nitrosolobus* and *Nitrosovibrio* form a closely related monophyletic assemblage within the β-subclass of Proteobacteria (Head et al., 1993; Woese et al., 1984; Teske et al., 1994; Utåker et al., 1995; Pommerening-Röser et al., 1996; Purkhold et al., 2000), whereas the genus *Nitrosococcus* constitutes a separate branch within the γ-subclass of Proteobacteria (Woese et al. 1985; Purkhold et al., 2000). Among the nitrite oxidizer s, the genera *Nitrobacter*, *Nitrococcus* and *Nitrospina* were assigned to the α-, γ-, and γ-subclass of Proteobacteria, respectively (Orso et al., 1994; Teske et al., 1994). Nitrite oxidizer s of the genus *Nitrospira* are affiliated with the

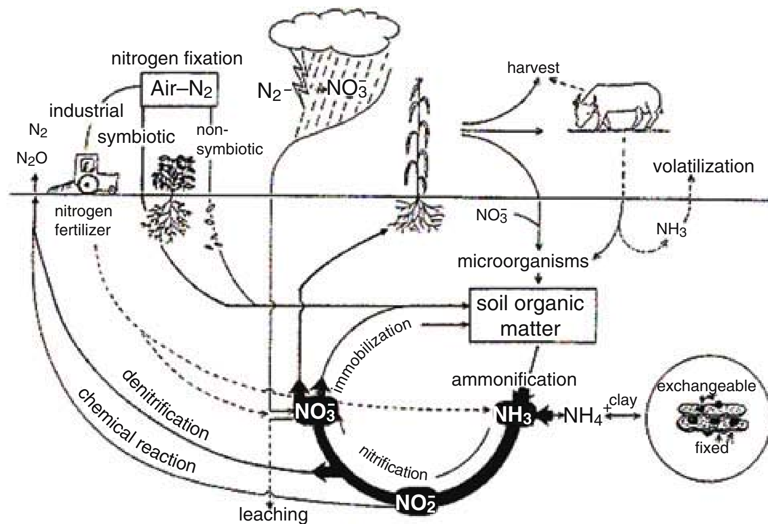

Fig. 1. Nitrogen cycle mediated by the biosphere.

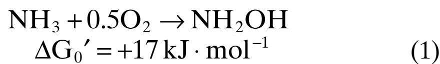
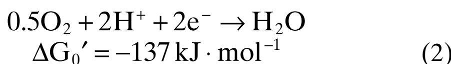
recently described *Nitrospira*-phylum, which represents an independent line of descent within the domain Bacteria (Ehrich et al., 1995).

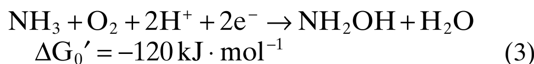
The most important character of lithotrophic nitrifying bacteria is energy generation via ammonia oxidation to nitrite (3. Biochemistry of ammonia oxidizing bacteria) and nitrite oxidation to nitrate (5. Biochemistry of nitrite oxidizing bacteria), respectively, according to the following equations:



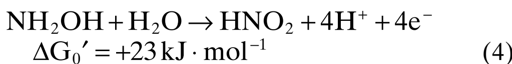
$$NH_3 + 0.5O_2 \rightarrow NH_2OH \quad \Delta G_0' = +17\,kJ \cdot mol^{-1} \qquad (1)$$



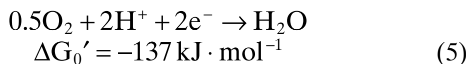
$$0.5O_2 + 2H^+ + 2e^- \rightarrow H_2O \quad \Delta G_0' = -137\,kJ \cdot mol^{-1} \qquad (2)$$



$$NH_3 + O_2 + 2H^+ + 2e^- \rightarrow NH_2OH + H_2O \quad \Delta G_0' = -120\,kJ \cdot mol^{-1} \qquad (3)$$

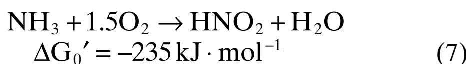


$$NH_2OH + H_2O \rightarrow HNO_2 + 4H^+ + 4e^- \quad \Delta G_0' = +23\,kJ \cdot mol^{-1} \qquad (4)$$

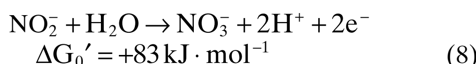


$$0.5O_2 + 2H^+ + 2e^- \rightarrow H_2O \quad \Delta G_0' = -137\,kJ \cdot mol^{-1} \qquad (5)$$

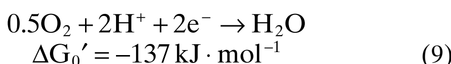
$$NH_2OH + 1.5O_2 \rightarrow HNO_2 + 2e^- + 2H^+ \quad \Delta G_0' = -114\,kJ \cdot mol^{-1} \qquad (6)$$



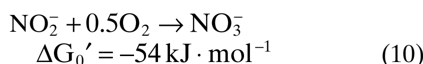
$$NH_3 + 1.5O_2 \rightarrow HNO_2 + H_2O \quad \Delta G_0' = -235\,kJ \cdot mol^{-1} \qquad (7)$$



$$NO_2^- + H_2O \rightarrow NO_3^- + 2H^+ + 2e^- \quad \Delta G_0' = +83\,kJ \cdot mol^{-1} \qquad (8)$$



$$0.5O_2 + 2H^+ + 2e^- \rightarrow H_2O \quad \Delta G_0' = -137\,kJ \cdot mol^{-1} \qquad (9)$$



$$NO_2^- + 0.5O_2 \rightarrow NO_3^- \quad \Delta G_0' = -54\,kJ \cdot mol^{-1} \qquad (10)$$

Equations 1 and 2 describe the two half-reactions of ammonia oxidation to the intermediate hydroxylamine (NH_2OH). The total reaction is given in equation 3. For hydroxylamine oxidation, no oxygen is consumed (equation 4). Subsequently two electrons are transferred back to reaction 2, and the remaining two electrons pass to the respiratory chain (equation 5). The second step of ammonia oxidation, the hydroxylamine oxidation, is depicted in equation 6. The overall reaction (equation 7) shows that biogenic ammonia oxidation causes nitric acid production. The $\delta G_0'$ value of reaction 7 is significantly higher than that of nitrite oxidation (equation 10). Nitrite oxidation starts with equation 8. Electrons are released and penetrate the respiratory chain at the cytochrome *c* level (equation 9). There is no acid production when nitrite is oxidized to nitrate (equation 10).

Ammonia oxidation is initiated by the enzyme ammonia monooxygenase (AMO; 3.2 Enzymes involved in ammonia oxidation; Ammonia monooxygenase), which oxidizes ammonia to hydroxylamine. Substrates for AMO are ammonia (Wood, 1986), dioxygen, and two electrons. One atom of molecular oxygen is reduced to water, while the second oxygen atom is incorporated to form hydroxylamine. The intermediate hydroxylamine is further oxidized to nitrite by hydroxylamine oxidoreductase (HAO; 3.2 Enzymes involved in ammonia oxidation; hydroxylamine oxidoreductase). Two of the four electrons derived are required for AMO activity, and the other two are used for energy generation (3.3 Rlectron Flow and Energy Transduction). The AmoA protein is assumed to contain the active site of AMO (Hyman and Arp, 1992). A second AMO subunit named "AmoB" has been identified (Bergmann and Hooper, 1994a). The

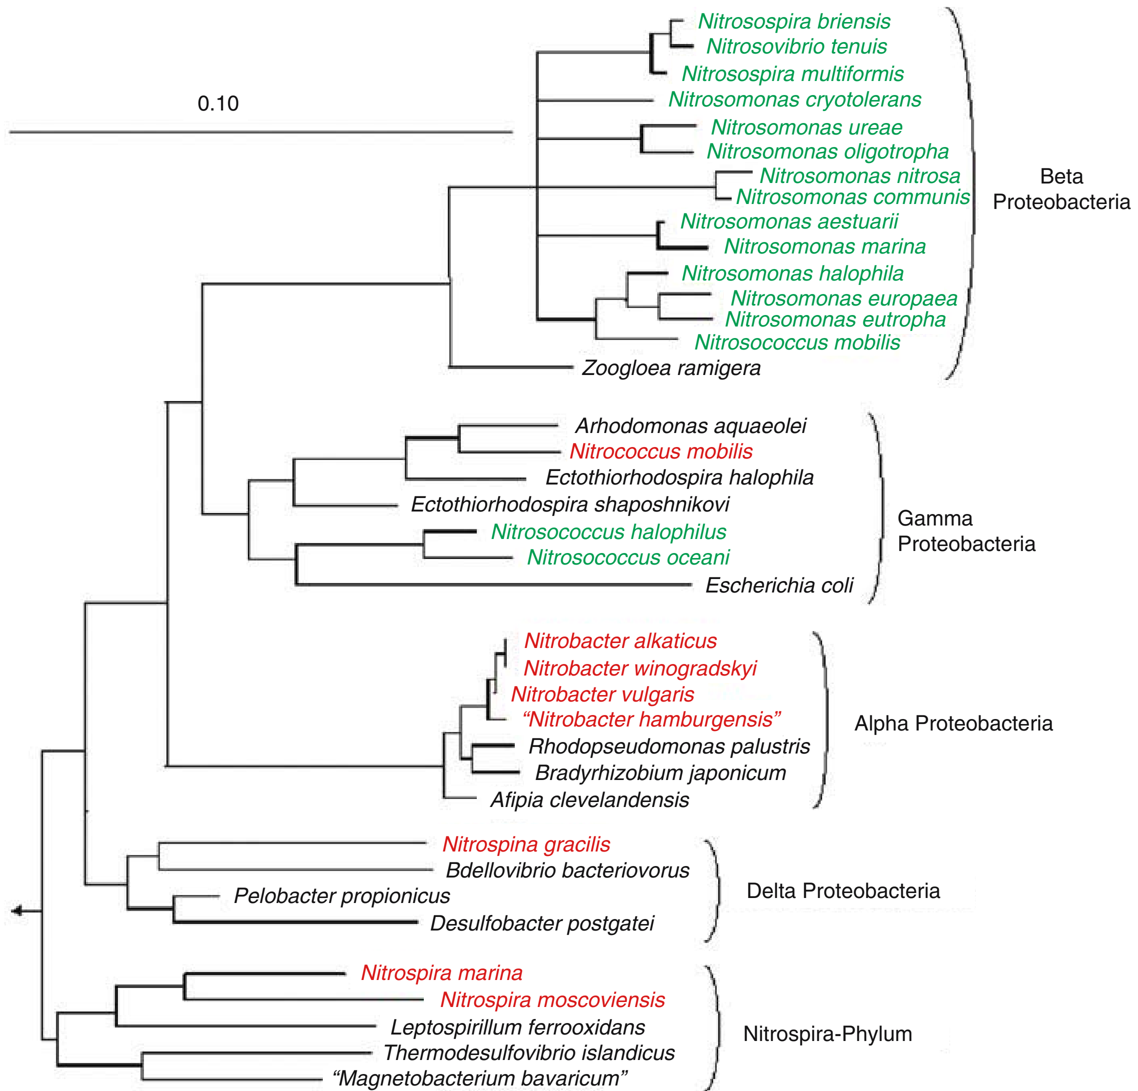


Fig. 2. 16S rRNA-based tree reflecting the phylogenetic relationship of ammonia- and nitrite-oxidizing bacteria. The consensus tree is based on the results of a maximum likelihood analysis of the 16S rRNA primary structure data from the nitrifying bacteria shown in the tree and a selection of reference sequences. Only homologous positions that share identical residues in at least 50% of all available almost complete bacterial 16S rRNA sequences were included for tree reconstruction. In the tree, ammonia oxidizer s are labeled green, and nitrite oxidizer s are depicted in red. It should be noted that the assignment of the genus *Nitrospina* to the δ-Proteobacteria is tentative and might change if additional reference sequences become available. Multifurcations connect lineages for which no unambiguous branching order could be retrieved using different treeing methods. Bar represents 10% estimated sequence divergence.

gene cluster encoding AMO contains a third open reading frame termed "*amoC*," which is located upstream of the genes *amoA* and *amoB* (Klotz et al., 1997; 4. Genetics of ammonia oxidizer s). Neither AmoA nor AmoB have been purified in the active state as yet. The enzyme HAO is a trimer of 63-kDa subunits, including seven c-type hemes and a novel heme (P-460) per monomer (Arciero and Hooper, 1993; Hoppert et al., 1995; Igarashi et al., 1997). The enzyme is located in the periplasmic space, but anchored in the cytoplasmic membrane.

Nitrite oxidation is initiated by the enzyme nitrite-oxidoreductase (NO_2-OR; 5.2. Enzymes involved in nitrite oxidation) which occurs as characteristic membrane-associated two-dimensional crystals in all nitrite oxidizer s. These regularly arranged particles are located on the surface of the cytoplasmic—and if present—intracytoplasmic membranes of nitrite-oxidizing bacteria. In all *Nitrobacter* species and in *Nitrococcus*, particles are arranged in rows, whereas in Nitrospina and both Nitrospira species, hexagonal patterns were observed. The NO_2-OR con-

sists of two subunits (Meincke et al., 1992). For *Nitrobacter hamburgensis*, the molecular weight of one particle was found to be 186 kDa representing an αβ-heterodimer (Spieck et al., 1996). The full sequence of the β-subunit as well as a partial sequence of the α-subunit of the NO_2-OR of *Nitrobacter hamburgensis* shows similarities to nitrate reductases of several chemoorganotrophic bacteria (6. Genetics of nitrite oxidizer s). During oxidation of nitrite to nitrate, the additional oxygen atom of nitrate is derived from water (Aleem et al., 1965b) and two electrons are released for energy generation.

In addition to lithotrophic nitrifiers, various heterotrophic bacteria, fungi and algae (Focht and Verstraete, 1977; Killham, 1986; Papen et al., 1989) are capable of oxidizing ammonia to nitrate. However, in contrast to lithotrophic nitrification, heterotrophic nitrification is not coupled to energy generation (7. Heterotrophic nitrification). Consequently, heterotrophic nitrifiers are dependent on the oxidation of organic substrates (Focht and Verstraete, 1977; Kuenen and Robertson, 1987). During heterotrophic nitrification, ammonia or reduced nitrogen from organic compounds (e.g., the amino group of amino acids) is co-oxidized to hydroxylamine, gaseous nitrogen oxides, nitrite or nitrate. For example, methane-oxidizing bacteria were shown to co-oxidize ammonia to nitrite by a biochemically well-characterized particulate (membrane-bound) methane monooxygenase and a unique hydroxylaminoxidoreductase (Anthony, 1982; Yoshinari, 1985; O'Neil and Wilkinson, 1977; Zahn et al., 1994; Bergmann et al., 2000). The methane monooxygenase is assumed to be biochemically related to the AMO of ammonia-oxidizing bacteria, and methane-oxidizing bacteria are potential contributors to nitrification in the rhizosphere of rice plants (Bodelier and Frenzel, 1999). Conversely, ammonia oxidizer s are able to oxidize methane to methanol (Hyman and Wood, 1983; Ward, 1987; Jones and Morita, 1983; Steudler et al., 1996), but up to now, there is no evidence that ammonia oxidizer s significantly contribute to the oxidation of atmospheric methane (CH_4) in natural systems (Jlang and Bakken, 1999; Bodelier and Frenzel, 1999). In general, heterotrophic nitrification is considered to contribute only marginally to the global nitrogen cycle (Brady, 1984; Brown, 1988) but nevertheless might be of local importance especially in heath and conifer forest soils (for example, see van de Dijk et al., 1980; Schimel et al., 1984).

Lithotrophic nitrifiers are autotroph ic bacteria that fix carbon dioxide (CO_2) via the Calvin-Benson cycle (Harms et al., 1981), and to a lesser extent, via phosphoenolpyruvate carboxylase (Takahashi et al., 1993). In the past, they were thus described as obligate lithoautotrophs and were thought to find organic compounds toxic. However, this assumption is not correct for several nitrifier species. Clark and Schmidt (1967) demonstrated that ammonia oxidizer s of the genus *Nitrosomonas* and nitrite oxidizer s of the genus *Nitrobacter* are capable of growing mixotrophically with ammonia or nitrite as electron donors and with a combination of carbon dioxide and organic compounds as carbon source. Compared to purely autotroph ic growth, the addition of organic compounds stimulated cell growth and increased cell yield (Steinmüller and Bock, 1976; Matin, 1978; Krümmel and Harms, 1982; Watson et al., 1986). Furthermore, the nitrite oxidizer s *Nitrobacter winogradskyi*, *N. hamburgensis* and *N. vulgaris* can grow chemoorganotrophically with acetate or pyruvate as electron donor and dioxygen or nitrate (in absence of dioxygen) as electron acceptor (Bock, 1976; Freitag et al., 1987). However, for these organisms, heterotrophic growth was always slower than lithotrophic growth. Recently, Daims and coworkers (Daims et al., 2000; H. Daims et al., 2001) showed that in nitrifying activated sludge, not yet cultured *Nitrospira*-related nitrite oxidizer s fix CO_2 and simultaneously take up pyruvate but not acetate, butyrate and propionate. In addition, some strains of *Nitrosomonas* can utilize organic substances like urea or glutamine as source of their substrate ammonia for lithotrophic growth (Koops et al., 1991).

The transformation of ammonia to nitrate via nitrite by the nitrifying bacteria has various direct and indirect implications for natural and man-made systems. For example, nitrifying bacteria contribute directly or indirectly to loss of nitrogen compounds from various environments due to:

1. Leaching of mobile nitrogen compounds produced by nitrifiers. Leaching is the mobilization and transfer of nitrate to rivers, lakes, seawater and groundwater. Nitrification is not desirable in agricultural soil because it induces loss of soil nitrogen. Fertilizer ammonium, which is required for plant growth, adsorbs well to clay particles of soil owing to its positive charge (Fig. 1). When converted to nitrate, the inorganic soil nitrogen becomes mobile and thus susceptible to denitrification and leaching. In some countries, nitrification inhibitors like nitrapyrin (N-Serve) are used in agriculture to minimize nitrogen loss (Huber et al., 1977; Keeny, 1986; Slangen and Kerkhoff, 1984; Lipschultz et al., 1981; Poth and Focht, 1985).
2. Denitrification. Denitrification is the microbial reduction of nitrate via nitrite, nitric oxide (NO) and nitrous oxide (N_2O) to dinitrogen (N_2). This type of anaerobic respiration can be per-

formed by a variety of phylogenetically different heterotrophic microorganisms. By aerobic oxidation of ammonia to nitrate, nitrifying bacteria produce the electron acceptor for subsequent denitrification in many natural and engineered systems. During the last years, nitrifiers also have been shown to be able to denitrify (3.5 denitrification catalyzed by ammonia oxidizer s).

3. Chemodenitrification of nitrite (produced by the ammonia oxidizer s) in acidic environments. Chemodenitrification is defined as nonenzymatically catalyzed loss of nitrogen due to dismutation of nitric acid at pH values <4.5 leading to the formation of nitrate and gaseous nitric oxide. In the atmosphere, nitric oxide is unstable and reacts with oxygen or ozone to form gaseous nitrogen dioxide, which chemically dismutates to nitrous and nitric acid in the presence of water.

In addition to the well-recognized metabolic activity, nitrifiers react to and produce gaseous nitrogen oxides like N_2O, NO and nitrogen dioxide (NO_2). For example, the presence of NO is required for ammonia oxidation of *Nitrosomonas eutropha* (Zart et al., 2000). Furthermore, cell growth and the ammonia-oxidizing activity of this species is enhanced by NO_2 (Zart and Bock, 1998). On the other hand, NO is always produced during ammonia oxidation (Stüven and Bock, 2001; Schmidt et al., 2001b). In the absence of oxygen, *Nitrosomonas eutropha* (and to a certain extent *Nitrobacter* sp.) are able to denitrify concomitant with the production of nitric oxide, nitrous oxide and dinitrogen (in the case of *N. eutropha*; Poth and Focht, 1985; Freitag et al., 1987; Zart and Bock, 1998; Bock et al., 1995). Furthermore, NO_2 has recently been reported to be produced by *Nitrosomonas europaea* if grown in coculture with *Paracoccus denitrificans* (Stüven and Bock, 2001). Owing to the above-mentioned activities, ammonia-oxidizing bacteria are considered to contribute to the increasing nitrous oxide level in the atmosphere (Bouwman, 1993). While flux mechanisms for nitric oxide exchange are frequently studied (e.g., Conrad, 1996), the processes of nitrogen dioxide production and release from soil have rarely been investigated (Williams et al., 1992; Baumgärtner et al., 1991). Nitric oxide, nitrogen dioxide and nitrous oxide circles between soil and atmosphere are of great importance because N_2O is a greenhouse gas and NO and NO_2 act as effectors for metabolic activity of microorganisms. The latter effect is of particular importance considering the increasing amounts of the nitrogen oxides NO and NO_2 in the anthropogenically polluted atmosphere originating from methane-, oil- and coal-combustion. Compared to these sources, the contribution of microbiologically produced NO and NO_2 however is marginal.

The production of nitric and nitrous acid by nitrifiers also contributes to biodeterioration and can cause harmful effects for plants. With an outdoor exposure experiment lasting for 7 years, Mansch and Bock (1998) could demonstrate that the ammonia concentration of the atmosphere in the city of Duisburg (Germany) was high enough to support cell growth of lithotrophic ammonia oxidizer s in natural sandstone. The formation of nitrous and nitric acid by such endolithic nitrifiers causes biodeterioration of carbonaceous masonry (Bock and Sand, 1993). Furthermore, in unbuffered environments (e.g., forest soils), the oxidation of ammonia to nitric and nitrous acid leads to acidification followed by the formation of aluminum ions (Al^{3+}) from insoluble aluminates, which are toxic to the roots of trees (Mulder et al., 1989; Stams et al., 1991). However, it should be kept in mind that plants can also benefit from nitrifying activity. Especially, many tree species prefer nitrate instead of ammonia as nitrogen source.

Nitrification is also important in biotechnology for efficient removal of ammonium from sewage (Painter, 1988; Eighmy and Bishop, 1989). Nitrifiers oxidize ammonium, which together with urea is the most frequently found nitrogen compound in sewage, to nitrate which can subsequently be removed from the sewage by denitrifying bacteria via anaerobic respiration. This treatment, which is an integral part of modern nutrient removal at wastewater treatment plants, prevents environments from increasing amounts of ammonia (causing eutrophication and oxygen depletion) and reduces the toxic effects of ammonium to aquatic life. However, the slow growth rate of nitrifiers and their susceptibility to changes in pH and temperature as well as to toxic sewage compounds causes frequent failure of nitrification in municipal and industrial wastewater treatment plants. In the future, wastewater treatment plants also might exploit the unique physiology of recently identified but not yet cultured novel planctomycetes that can catalyze anaerobic oxidation of ammonium to dinitrogen with nitrite as electron acceptor (Strous et al., 1999; Schmid et al., 2000; see Anaerobic Ammonium Oxidation Catalyzed By Deep Branching Planctomycetes in this Chapter).

Nitrifying bacteria are slow-growing organisms because their cell growth is inefficient. For example, nitrite oxidizer s oxidize 85–115 mol of nitrate to generate the energy required for assimilation of 1 mol of carbon dioxide (Bömeke, 1954). Thus, it is not surprising that the shortest generation times measured in laboratory experiments did not exceed 7 h for *Nitrosomonas* and 10 h for *Nitrobacter* (Bock et al., 1990). For cell division in natural environ-

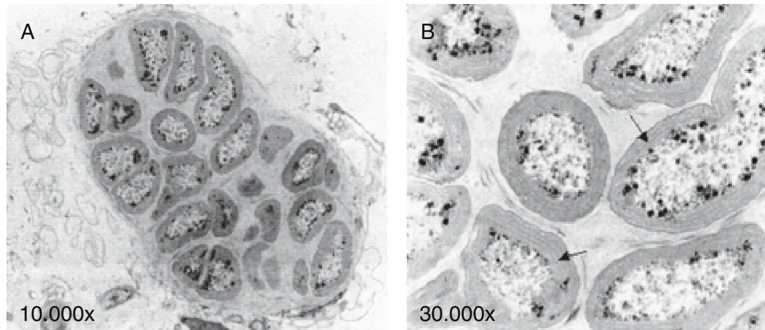

Fig. 3. Transmission electron micrographs of ultrathin sections of an ammonia oxidizer microcolony in activated sludge (A). Arrows indicate intracytoplasmic membranes (B). Modified from Wagner et al. (1995).

ments, most nitrifier species even need several days to weeks depending on substrate, oxygen availability, the temperature and pH values. The slow growth rates of nitrifiers have severely hampered cultivation-dependent approaches to investigate the number, community composition and dynamics of nitrifiers in different environments. The number of nitrifiers in complex systems has been traditionally determined by the most-probable-number (MPN) technique (Matulewich et al., 1975). However, this method is time-consuming and the nitrifier cell counts determined usually do not correlate well with nitrifying potential estimated for the same environmental sample under optimized laboratory conditions (Belser and Mays, 1982; Belser, 1979; Groffmann, 1987; Mansch and Bock, 1998). These discrepancies illustrate that not all nitrifiers can be cultivated using standard methods (Stephen et al., 1998; Juretschko et al., 1998; Purkhold et al., 2000). Furthermore, in many environments nitrifiers form dense microcolonies of ten to several thousand cells embedded in extracellular polymeric substances (EPS; Fig. 3). Since these microcolonies are resistant to the dispersal techniques implemented in standard cultivation protocols, the use of these protocols dramatically underestimates the number of nitrifiers occurring in microcolonies (Watson et al., 1989; Stehr et al., 1995; Wagner et al., 1995).

For direct microscopic enumeration of nitrifiers in complex samples, the fluorescent antibody (FA) technique can be applied (Belser, 1979; Fliermanns et al., 1974), but for antibody production, the target cells have to be isolated first as pure culture and the produced antibodies often recognize only a few strains of a species (Belser and Schmidt, 1978). Recently monoclonal antibodies targeting the nitrite oxidoreductase were developed that allow group-specific detection of nitrite-oxidizing bacteria (Bartosch et al., 1999). In addition, polyclonal antibodies specifically recognizing the AmoB protein of β-subclass ammonia oxidizer s are available (Pinck et al., 2001). Alternatively, nitrifiers can be detected in environmental samples independent from their

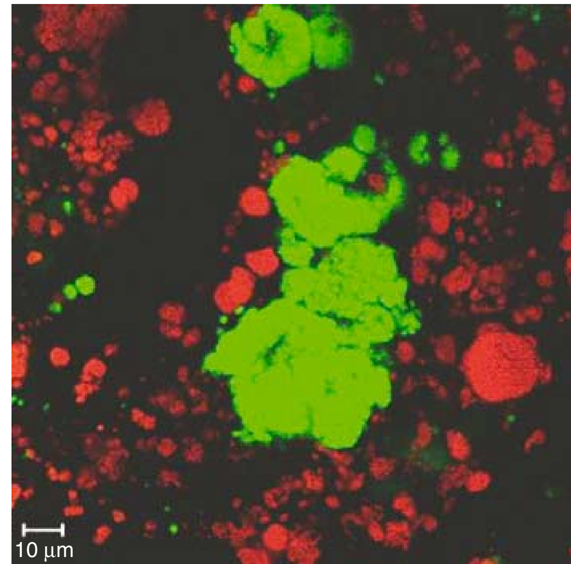

Fig. 4. In situ detection (with fluorescently labeled 16S rRNA-targeted oligonucleotide probes) of ammonia-oxidizing and nitrite-oxidizing bacteria in a nitrifying biofilm from a municipal wastewater treatment plant. Ammonia oxidizer s are stained red, whereas nitrite-oxidizing bacteria of the genus *Nitrospira* appear green. Bar = 10 μm.

culturability by using a variety of different polymerase chain reaction (PCR)-techniques for specific amplification of 16S rRNA gene fragments (e.g., Degrange and Bardin, 1995; Hiorns et al., 1995; Voytek and Ward, 1995; McCaig et al., 1994; Kowalchuk et al., 1997; Utåker and Nes, 1998) or a fragment of the *amoA* gene (e.g., Rotthauwe et al., 1997; Purkhold et al., 2000). Quantitative population structure analysis of nitrifying bacteria within their natural habitat can most precisely be obtained by applying the recently developed set of rRNA-targeted oligonucleotide probes for fluorescence in situ hybridization (FISH; Wagner et al., 1995; Wagner et al., 1996; Mobarry et al., 1996; Juretschko et al., 1998; Daims et al., 2000; Fig. 4).

Nitrifying bacteria are present in oxic and even anoxic environments. They are widely distributed in fresh water, seawater, soils, on/in

rocks, in masonry, and in wastewater treatment systems. Nitrifiers also could be enriched or isolated from extreme habitats like heating systems with temperatures of up to 47°C (Ehrich et al., 1995; E. Lebedeva, personal communication) and permafrost soils up to a depth of 60 m at a temperature of down to –12°C. Although the pH optimum for cell growth is 7.6–7.8, nitrifiers were frequently detected in environments with suboptimal pH (e.g., acid tea soils and forest soils at pH values below 4) but also in highly alkaliphilic soda lakes at a pH of 9.7–10.5 (Sorokin et al., 2001). Growth under suboptimal acidic conditions might be possible by ureolytic activity, by aggregate formation (De Boer et al., 1991), or as biofilms (e.g., on clay particles; Allison and Prosser, 1993). In many environments, nitrifier sensitivity to sunlight is of ecological importance. The light sensitivity of ammonia- and nitrite oxidizer s increases from blue light to long wave UV (Hooper and Terry, 1974; Hyman and Wood, 1984a; Shears and Wood, 1985). Based on spectroscopic similarities, Shears and Wood (1985) postulated a model of the ammonia monooxygenase light inhibition similar to the three-stage catalytic cycle of the tyrosinase reaction. In *Nitrobacter*, which is more sensitive to visible light than *Nitrosomonas* (Bock, 1965), the photooxidation of *c*-type cytochrome s is assumed to cause light-induced cell death (Bock, 1970).

Although *Nitrosomonas euopaea* and *Nitrobacter* sp. are the most commonly investigated ammonia- and nitrite oxidizer s in laboratory studies, molecular analysis revealed that other nitrifiers are of higher importance in many natural and engineered systems. For example, stone material of historical buildings and many soil systems seem to be dominated by members of the genera *Nitrosovibrio* and *Nitrosospira*, respectively (Spieck et al., 1992; Hiorns et al., 1995; Stephen et al., 1996; Meincke et al. 1989), whereas different *Nitrosomonas* species and *Nitrosococcus mobilis* are the most abundant ammonia oxidizer s in wastewater treatment plants (Juretschko et al., 1998; Purkhold et al., 2000). Interestingly, not yet cultured members of the genus *Nitrospira* and not *Nitrobacter* are the most abundant nitrite oxidizer s in sewage treatment plants and aquaria filters (Burrell et al., 1998; Juretschko et al., 1998; Wagner et al., 1996; Daims et al., 2000).

Phylogeny of Lithotrophic Nitrifying Bacteria

Traditionally, nitrifying bacteria have been lumped together into one coherent group, the family Nitrobacter iaceae (Watson, 1971a; Watson et al., 1989). Based on their ability to lithotrophically oxidize either ammonia to nitrite or nitrite to nitrate, nitrifying bacteria were separated into two groups, the ammonia- and the nitrite oxidizer s. The assignment of ammonia- and nitrite-oxidizing bacteria into genera was dependent primarily upon their morphological features like cell size, shape, and the arrangement of the intracytoplasmic membranes (Watson et al., 1989). The physiological and morphological grouping of the nitrifying bacteria is in contradiction to data obtained from molecular phylogenetic studies which show at least subdivision level diversity within and between the ammonia- and nitrite oxidizer s (Head et al., 1993; Orso et al., 1994; Teske et al., 1994; Purkhold et al. 2000; Ehrich et al., 1995). Significant differences between ammonia- and nitrite-oxidizing bacteria are also indicated by the fact that both physiological groups possess very different key enzyme systems for the energy-gaining oxidation of ammonia and nitrite, respectively (Enzymes involved in ammonia oxidation; Enzymes involved in nitrite oxidation). With the exception of the nitrite oxidizer s of the genera *Nitrospina* and *Nitrospira*, all known nitrifiers are closely related to phototrophs and thus presumably originated in several independent events by conversion of photosynthetic ancestors to chemolithotroph s (Teske et al., 1994). Consistent with this conversion hypothesis, all nitrifying bacteria related to phototrophs retain the general structural features of the putative ancestor's photosynthetic membrane complex, while nitrite oxidizer s of the genera *Nitrospina* and *Nitrospira* lack intracytoplasmic membranes (ICMs). However, it should be noted that the ammonia oxidizer s of the genera *Nitrosospira* and *Nitrosovibrio* lack an extensive intracytoplasmic membrane system (Koops and Möller, 1992).

Phylogeny of Ammonia Oxidizer s

Chemolithotroph ic ammonia oxidizer s were isolated for the first time at the end of the nineteenth century (Winogradsky, 1892). Since then, 16 species of ammonia oxidizer s have been described (Jones et al., 1988; Koops et al., 1976; Koops et al., 1990; Koops et al., 1991; Watson, 1965), and according to DNA-DNA hybridization experiments, at least 15 additional genospecies are "hidden" in existing culture collections (Koops et al., 1991; Koops and Harms, 1985; Stehr et al., 1995). Our current perception of evolutionary relationships of ammonia-oxidizing bacteria is mainly based on comparative sequence analysis of their genes encoding the 16S rRNA and the active site polypeptide of the ammonia monooxygenase (AmoA). During

the last decade, the genes for both biopolymers were sequenced for all recognized ammonia oxidizer species (Alzerreca et al., 1999; Head et al., 1993; Pommerening-Röser et al., 1996; Teske et al., 1994; Purkhold et al., 2000; Rotthauwe et al., 1995; Rotthauwe et al., 1997; McTavish et al., 1993; Horz et al., 2000) and the deduced phylogeny now provides an encompassing and relatively robust framework for assignment of 16S rDNA and *amoA* sequences of 1) ammonia oxidizer isolates (Stehr et al., 1995; Suwa et al., 1997; Utåker et al., 1995; Juretschko et al., 1998) and 2) cloned sequence fragments directly retrieved from the environment (e.g., Stephen et al., 1996; Rotthauwe et al., 1995; Purkhold et al., 2000).

According to comparative 16S rRNA sequence analysis, all recognized ammonia oxidizer s are members of two monophyletic lineages within the β- and γ-subclass of Proteobacteria (Fig. 5). The marine species *Nitrosococcus halophilus* and *Nitrosococcus oceani*, which are distantly related to methane-oxidizing bacteria, cluster together in the γ-subclass of Proteobacteria. All other ammonia oxidizer s form a monophyletic assemblage within the β-subclass of Proteobacteria, most closely related to the iron-oxidizer *Gallionella ferruginea*. This lineage encompasses the genera *Nitrosomonas* (including *Nitrosococcus mobilis*, which is actually a member of the genus *Nitrosomonas*), *Nitrosovibrio*, *Nitrosolobus* and *Nitrosospira*. It has been suggested (Head et al., 1993) and subsequently questioned (Teske et al., 1994) that the latter three genera should be reclassified into the single genus *Nitrosospira*. The nitrosomonads can be further subdivided into the *N. europaea/Nc. mobilis* cluster, the *N. marina* cluster, the *N. oligotropha* cluster, and the *N. communis* cluster (Purkhold et al., 2000). *Nitrosomonas cryotolerans* forms a separate lineage within the β-Proteobacteria. The genera *Nitrosospira*, *Nitrosolobus* and *Nitrosovibrio* are closely related and form a cluster to the exclusion of the nitrosomonads. Similar but not identical evolutionary relationships were obtained if comparative analysis of AmoA sequences were performed (Purkhold et al., 2000). In the AmoA tree, the *N. europaea/Nc. mobilis* cluster, the *N. marina* cluster, and the *Nitrosospira*-cluster are retained, whereas the members of the *N. oligotropha* cluster and the *N. communis* cluster form no monophyletic assemblages.

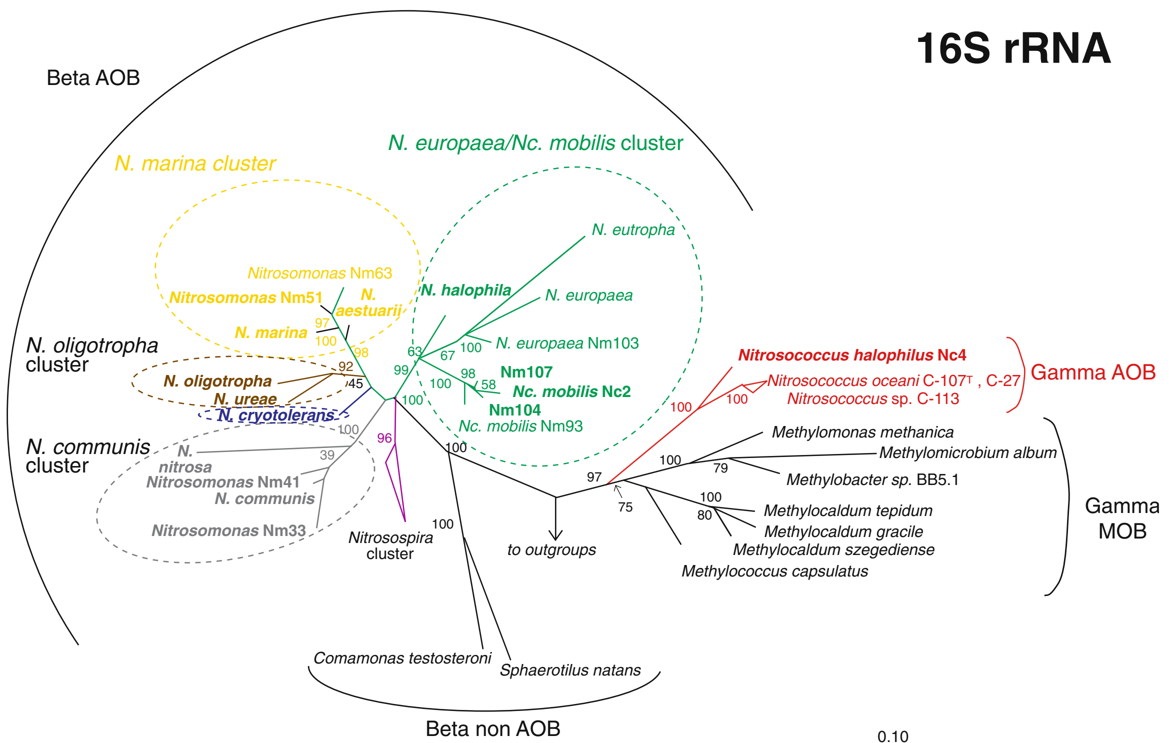

Fig. 5. Phylogenetic neighbor-joining 16S rRNA tree reflecting the relationships of ammonia-oxidizing bacteria and several reference organisms. The multifurcation connects branches for which a relative order could not be unambiguously determined by applying different treeing methods. Parsimony bootstrap values for branches are reported. Missing bootstrap values indicate that the branch in question was not recovered in the majority of bootstrap replicates by the parsimony method. AOB = ammonia-oxidizing bacteria; MOB = methane-oxidizing bacteria. The bar indicates 10% estimated sequence divergence. Modified from Purkhold et al. (2000).

Phylogeny of Nitrite Oxidizer s

Four different genera, *Nitrobacter*, *Nitrococcus*, *Nitrospina* and *Nitrospira*, of lithotrophic nitrite-oxidizing bacteria have been described. From 16S rRNA sequence analysis, the first three genera were assigned to different subclasses of the Proteobacteria, whereas *Nitrospira* is the name-giving genus of an independent bacterial phylum (Fig. 5). The genus *Nitrobacter* contains the four closely related species (*N. hamburgensis*, *N. vulgaris*, *N. winogradskii* and *N. alkalicus*) within the α-subclass of Proteobacteria. Nitrite oxidizer s of the genus *Nitrobacter* are phylogenetically related to *Bradyrhizobium japonicum*, *Blastobacter denitrificans*, *Afipia felis*, *Afipia clevelandensis* and the phototroph *Rhodobacter palustris* (Seewaldt et al., 1982; Orso et al., 1994; Teske et al., 1994) with which *Nitobacter* shares a nearly identical arrangement of ICMs.

The genus *Nitrococcus* represented by the single marine species *Nitrococcus mobilis* is, like the marine ammonia oxidizer s of the genus *Nitrosococcus*, a member of the ectothiorhodospira branch of the γ-subclass of Proteobacteria, consistent with an assumed photosynthetic ancestry of these nitrifiers. *Nitrococcus* and *Nitrosococcus* are the only nitrite- and ammonia oxidizer s that are relatively closely related, but the closest relatives of *Nitrococcus mobilis* are the phototrophic bacteria *Arhodomonas aquaeoli*, *Ectthiorhodospira halochloris* and *Ectthiorhodospira halophila* (Teske et al., 1994).

The genus *Nitrospina* with the marine *Nitrospina gracilis* as the only species (represented by two isolates, one from the Atlantic and the other from the Pacific) has been provisionally assigned to the δ-subclass of Proteobacteria and is the only member of a deep branch within this subclass (Teske et al., 1994). *Nitrospina gracilis* shows no ICMs.

The genus *Nitrospira* encompasses the marine species *Nitrospira marina* and *Nitrospira moscoviensis*, isolated from a municipal water heating system. The genus *Nitrospira* forms a monophyletic grouping with the genera *Thermodesulfovibrio*, *Leptospirillum* and with "*Magnetobacterium bavaricum*." This phylogenetic assemblage has recently been identified as a novel phylum within the domain Bacteria and was named "*Nitrospira phylum*" (Ehrich et al., 1995). There is accumulating molecular evidence that *Nitrospira*-related nitrite oxidizer s are of major importance for nitrite-oxidation in wastewater treatment plants and aquarium filters (Burrell et al., 1998; Juretschko et al., 1998; Hovanec et al., 1998; Daims et al., 2000), and also occur in many natural environments including the rhizosphere (Fig. 6). Like *Nitrospina gracilis*, members of the genus *Nitrospira* do not possess ICMs and are apparently not closely related to phototrophic bacteria.

Biochemistry of Ammonia-Oxidizing Bacteria

Ammonia oxidizer s are lithoautotrophic organisms using carbon dioxide as the main carbon source (Bock et al., 1991). Their only way to gain energy is the two-step oxidation of ammonia to nitrite (Hooper, 1969). Investigations of the K_m values and pH optima indicate that ammonia (NH_3) rather than ammonium (NH_4^+) is the substrate of ammonia oxidizer s (Suzuki et al., 1974; Drozd, 1976). This is in accordance with results showing that the ammonia-oxidizing enzyme might be located in the cytoplasmic membrane (Suzuki and Kwok, 1981a; Tsang and Suzuki, 1982), since membranes are highly permeable to ammonia but not to ammonium (Kleiner, 1985). First, ammonia is oxidized to hydroxylamine (Kluyver and Donker, 1926) by the ammonia monooxygenase (AMO; Hollocher et al., 1981). This enzyme does not possess high substrate specificity and also oxidizes several apolar compounds such as methane, carbon monoxide or some aliphatic and aromatic hydrocarbons (Hooper et al., 1997). These compounds can act as competitive inhibitors of ammonia oxidation (Hyman et al., 1988; Keener and Arp, 1993). The second step is performed by the hydroxylamine oxidoreductase (HAO). This enzyme oxidizes hydroxylamine to nitrite (Wood, 1986). Two of the four electrons released (Andersson and Hooper, 1983) are required for the AMO-reaction (Tsang and Suzuki, 1982), whereas the remaining ones are used for the generation of proton motive force (Hollocher et al., 1982) to regenerate ATP and NADH (Wheelis, 1984; Wood, 1986). Most of the investigations on energy metabolism of ammonia-oxidizing bacteria have been carried out with *Nitrosomonas europaea*. Keeping in mind that the ammonia oxidizer s encompass five different genera affiliated to two proteobacterial subclasses (Phylogeny of ammonia oxidizer s), additional species should be investigated to obtain a more encompassing picture of the biochemistry of the ammonia-oxidizing system (Giannakis et al., 1985).

Ammonia and Hydroxylamine as Substrates

The overall process of ammonia oxidation to nitrite may be characterized as a two-stage process:

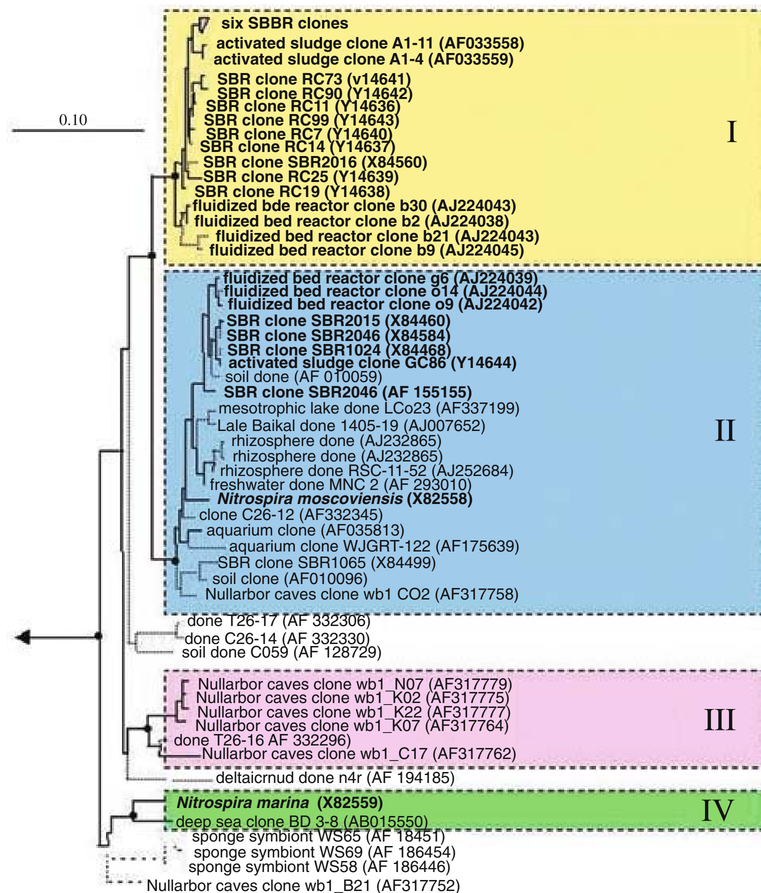

Fig. 6. Phylogenetic tree of the genus *Nitrospira* based on comparative analysis of 16S rRNA sequences. The basic tree topology was determined by maximum likelihood analysis of all sequences longer than 1,300 nucleotides. Shorter sequences were successively added without changing the overall tree topology. Branches leading to sequences shorter than 1,315 nucleotides are dotted to point out that the exact affiliation of these sequences cannot be determined. Black spots on tree nodes symbolize high parsimony bootstrap support above 90% based on 100 iterations. The scale bar indicates 0.1 estimated changes per nucleotide. The four sublineages of the genus *Nitrospira* are delimited by horizontal dashed lines and marked by the numbers I to IV. Two of the four sublineages entirely consist of 16S rDNA sequences amplified from environmental samples. Modified from H. Daims et al., 2001.

$$NH_3 + 0.5O_2 \rightarrow NH_2OH \qquad (11)$$

$$NH_2OH + H_2O \rightarrow HNO_2 + 4H^+ + 4e^- \qquad (12)$$

However, this two-stage scenario is a simplification. For lithotrophic ammonia oxidizer s, ammonia is essential as the primary substrate. The intermediate hydroxylamine (NH_2OH) is the real energy source. The coupling between ammonia- and hydroxylamine oxidation, a complex mechanism not yet established in detail, is suggested by several observations. The addition of hydroxylamine to ammonia-oxidizing cells shortened the lag-phase of ammonia oxidation (Hooper, 1969), probably by providing reductants to the monooxygenase. It is generally assumed that partial reduction of *c*-type cytochrome s is necessary to start ammonia oxidation. Cytochrome reduction was attained by addition of hydroxylamine to cell-free preparations of *Nitrosomonas europaea* (Suzuki et al., 1981b). If both ammonia and hydroxylamine are used, the molar growth yield of hydroxylamine was found to be twice the amount of ammonia (Böttcher and Koops, 1994; De Bruijn et al., 1995). On the other hand, increasing amounts of hydroxylamine are inhibitory to ammonia oxidation (Hyman and Wood, 1984b; Poth and Focht, 1985; Abeliovich and Vonshak, 1993), probably due to imbalancing the redox state of AMO and HAO (Wood, 1986). Another result is more difficult to understand. All attempts to grow ammonia oxidizer s on hydroxylamine as the only substrate have failed, although hydroxylamine is oxidized to nitrite (Lees, 1952; Hoffman and Lees, 1953; Engel and Alexander, 1958; Nicholas and Jones, 1960). This failure is most likely not caused by the toxicity of hydroxylamine, because addition of hydroxylamine in the presence of ammonia promotes substrate oxidation and cell growth. As demonstrated recently, *Nitrosomonas eutropha* cells are capable of growing on hydroxylamine as the only substrate when AMO is simultaneously inhibited by acetylene (S. Oesterreicher, personal communication; Fig. 7). Without addition of acetylene, *N. eutropha* cells lyse within 3 days when hydroxylamine is oxidized to nitrite, although within the first day NADH and ATP are still formed (C. Look, personal communication). It is important to note that during these experiments ammonia was present as nitrogen source because hydroxylamine could not be assimilated. The observation that reduc-

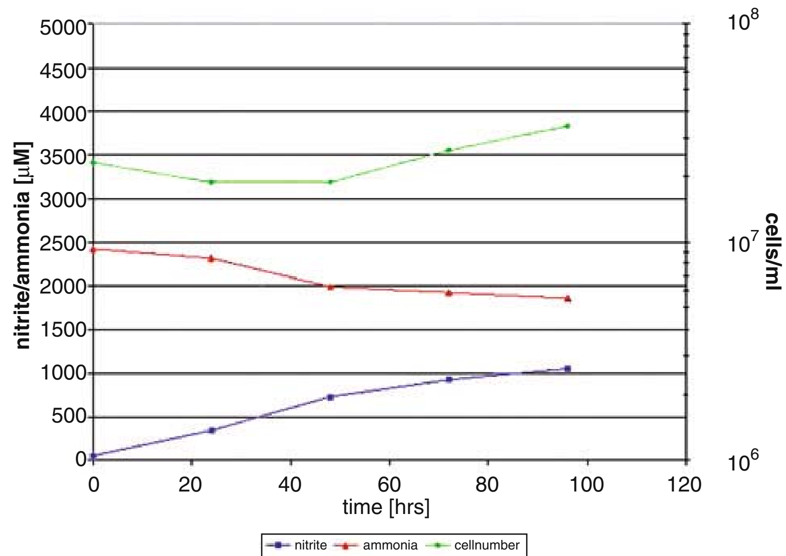

Fig. 7. Growth of *Nitrosomonas eutropha* in the presence of ammonia, 2,315 parts per million (ppm) acetylene, and hydroxylamine (4 mmol) as substrate (48–96h). The AMO was inhibited by acetylene, while cell growth was detectable after a lag phase of 2 days. Most of the hydroxylamine undergoes deterioration in contact with atmospheric oxygen. As calculated from additional nitrite formation, 400 µmol of hydroxylamine were oxidized to nitrite resulting in an increase of cell number.

tion of a functionally active AMO in the absence of ammonia leads to cell death could be explained by the formation of toxic oxygen radicals by this enzyme under these conditions. This suicidal activity of ammonia oxidizer s also might cause nitrification breakdown in wastewater treatment plants, if 1) plenty of organic substrate is available as additional alternative electron donor and 2) ammonia is present in very low concentrations.

Enzymes Involved in Ammonia Oxidation

Ammonia Monooxygenase The first intermediate of ammonia oxidation is assumed to be hydroxylamine (Genes encoding AMO, HAO, and related Enzymes). In the presence of hydrazine (an irreversible inhibitor of hydroxylamine oxidation; Nicholas and Jones, 1960; Hynes and Knowles, 1978), the production of small quantities of hydroxylamine from ammonia was observed (Hoffman and Lees, 1953; Yoshida and Alexander, 1964). Using $^{18}O_2$, it could be demonstrated that more than 92% of the oxygen in hydroxylamine originates from dioxygen (Dua et al., 1979). The enzyme AMO, catalyzing the conversion of ammonia to hydroxylamine, has not yet been purified as active protein, but Hyman and Wood (1985a) were able to identify a membrane-associated ^{14}C-labeled protein, putatively representing a component of AMO, when whole cells of *Nitrosomonas europaea* were incubated with [^{14}C]acetylene. The N-terminal amino acid sequence of the [^{14}C]acetylene-labeled protein (AmoA) was determined. Based on this sequence, an oligonucleotide was derived and was used to identify and clone the gene *amoA*. The AmoA protein is a 31.8 kDa (McTavish et al., 1993), probably containing the active site of AMO (Hyman and Arp, 1992), and consists of five transmembrane sequences and one periplasmic loop. In the same operon, a second gene *amoB* is located adjacent to *amoA*. From the deduced amino acid sequence, the protein has a molecular weight of 43 kDa (Bergmann and Hooper, 1994a), and is characterized by two transmembrane domains and two periplasmic loops (Vanelli et al., 1996). Upstream of the genes *amoA* and *amoB*, a third open reading frame *amoC* is located which might encode a chaperone helping the AmoA and AmoB protein subunits to integrate into the membrane properly (Klotz et al., 1997).

Indirect evidence indicates that AMO is a copper-containing monooxygenase (Rees and Nason, 1966; Tomlinson et al., 1966; Loveless and Painter, 1968; Dua et al., 1979; Hollocher et al., 1981; Wood, 1988a; Hooper and Terry, 1973). Quantitative immunoblot analysis using polyclonal antibodies revealed that total cell protein of *Nitrosomonas eutropha* consisted of approximately 6% AmoA and AmoB, when cells were grown using standard conditions (Pinck et al., 2001). The specific cellular amount of AMO in cells of *Nitrosomonas eutropha* was regulated by ammonium concentration. At high ammonium concentrations, less AMO was found than under ammonium-limiting conditions. Furthermore, AMO seems to be strongly protected from degradation. Cells starving one year for ammonia still contained high amounts of AMO, although they showed far less ammonia oxidation activity than growing cells. Hence, the amount of AMO does not directly correlate with the activity of ammonia oxidation.

Most information about the reactions catalyzed by AMO originates from studies with intact cells. In addition to oxidizing ammonia, AMO can hydroxylate non-growth-supporting substrates such as hydrocarbons and alcohols (Hooper and Terry, 1973; Suzuki et al., 1976; Tsang and Suzuki, 1982; Hyman and Wood, 1983; Hyman and Wood, 1984a; Hyman and Wood, 1984b; Hyman et al., 1985b; Voysey and Wood, 1987). This is not only of theoretical interest but also could be of importance for microbial ecology (Hall, 1986). For example, pure cultures of ammonia oxidizer s are able to oxidize methane, but could not grow on this alternative electron donor (O'Neil and Wilkinson, 1977; Hyman and Wood, 1983; Jones and Morita, 1983). Recent data, however, suggest that at least in the rice rhizosphere, ammonia oxidizer s do not significantly contribute to the methane oxidation (Bodelier and Frenzel, 1999; Co-oxidation and Inhibition of AMO). This capability reflects structural and functional homologies between the ammonia- and the methane monooxygenase of ammonia oxidizer s and methanotrophs, respectively (Bedard and Knowles, 1989). Since substrates or competetive inhibitors of AMO are apolar, it seems reasonable to assume that its active site is hydrophobic. As suggested by Hooper et al. (1997), the reaction is started by the activation of oxygen rather than the substrate. Oxygen might be activated by reduction with a reduced metal-containing center of the enzyme followed by the release of water to form a reactive oxygen species. This compound may extract an electron from the substrate (hydroxylation of the substrate) or interact with nitric oxide to form the real oxidant nitrogen dioxide /dinitrogen tetroxide (see also Fig. 17).

HYDROXYLAMINE OXIDOREDUCTASE The key enzyme of hydroxylamine oxidation, HAO, is a multiheme enzyme, located in the periplasmic space (Olson and Hooper, 1983; Hooper et al., 1984b; Hooper and DiSpirito, 1985; Genes encoding AMO, HAO, and related Enzymes) The enzyme complex has a relative molecular weight of 180,315–190,315 and consists of an α3 oligomer closely associated with three heme centers including seven *c*-type hemes and a novel heme, P-460, per monomer (Arciero and Hooper, 1993; Hoppert et al., 1995; Igarashi et al., 1997; Bergmann and Hooper, 1994b). The P-460 was found to be a CO-binding heme (Hooper et al., 1978; Lipscomb et al., 1982b). According to spectroscopic and chemical investigations, the P-460 iron resides in a heme-like macrocycle, but the presumed porphyrin must have some unusual features (Andersson et al., 1984). In total, HAO constitutes about 40% of the *c*-type heme of *Nitrosomonas europaea* (Hooper et al., 1978). The *c*-type hemes of HAO can be placed into two classes with different oxidation-reduction midpoint potentials and protein environments, respectively (Lipscomb and Hooper, 1982a; Prince et al., 1983; Hooper, 1984a; Collins et al., 1993; Arciero et al., 1991). A detailed discussion of possible interactions of the described redox centers of the HAO can be found in Hooper (1989).

Hydroxylamine is supposed to bind at the HAO near the P-460 center. Electrons are released and transferred to *c*-hemes (Hooper and Terry, 1977; Hooper and Balny, 1982; Olson and Hooper, 1983). Initially, Hooper and Balny (1982) postulated that HAO catalyzes a two-electron dehydrogenation of hydroxylamine and a subsequent net addition of one oxygen atom from dioxygen. Later, they favored a mechanism in which water was the source of the second oxygen atom of the metabolic final product nitrite (Andersson and Hooper, 1983; Hooper, 1984a).

The oxidation of hydroxylamine to nitrite was postulated to be a two-step reaction with enzyme-bound nitroxyl (HNO) as an intermediate (Andersson and Hooper, 1983):

$$NH_2OH \rightarrow [HNO] + 2H^+ + 2e^- \quad (13)$$

$$[HNO] + H_2O \rightarrow HNO_2 + 2H^+ + 2e^- \quad (14)$$

However, in cell-free extracts of *Nitrosomonas europaea*, nitric oxide was suggested as another possible intermediate of hydroxylamine oxidation (Hooper and Terry, 1979). Experiments with ^{15}N-label showed that nitric oxide was produced by hydroxylamine oxidation and not by nitrite reduction. The authors discussed a mixed-function hydroxylation of nitric oxide to be involved in the oxidation from (HNO) to nitrite, with all intermediates being enzyme-bound. Miller and Wood (1983) analyzed CO-binding cytochrome s of the *b* type in *Nitrosomonas europaea* and discussed their possible function in binding nitric oxide resulting from hydroxylamine oxidation.

Electron Flow and Energy Transduction

ELECTRON FLOW The first step of ammonia oxidation to nitrite, the conversion to hydroxylamine, is endergonic. Thus, hydroxylamine is the real energy-generating substrate. If all subsequent steps of the hydroxylamine oxidation to nitrite are coupled to electron transport chains, a maximum yield of four electrons can result. The number of electrons passing to the terminal oxidase(s), however, is uncertain because four systems (ammonia monooxygenase, nitrite reductase, cytochrome oxidase and NADH production) are fed with electrons from the oxidation of hydroxylamine to nitrite (Wood, 1986).

Electrons from HAO reduce cytochrome c_{554}, a 25-kDa tetraheme protein (Andersson et al., 1986b). Because both ammonia and hydroxylamine oxidation seem to be balanced at a steady state, cytochrome c_{554} is thought to be the first electron transfer branch point. Two of the four electrons released from the hydroxylamine oxidation must pass to the monooxygenase reaction, the latter two flow to a second branch point, e.g., cytochrome c_{552} and then to one of the terminal oxidases cytochrome aa_3 (DiSpirito et al., 1986) or nitrite reductase. Once per 5.7 cycles, two electrons are assumed to enter a reverse electron transfer pathway for NADH production (Wood, 1986). Cytochrome c_{554} is a probable candidate for the proposed central role because it is a two-electron carrier (Arciero et al., 1991; Bergmann et al., 1994c). The electron carriers downstream have not been investigated in detail. However, the production of nitric and nitrous oxide by *Nitrosomonas europaea* and *N. eutropha* suggested that nitric oxide reductase as well as nitrous oxide reductase might be present (Hooper et al., 1997). Yamanaka and Shinra (1974) postulated the path of electrons from HAO to the terminal oxidase to be:

HAO → cytochrome c_{554} → cytochrome c_{552} → terminal oxidase. However, several other membrane-bound redox carriers have been identified in Nitrosomonas europaea. The function of a tetraheme *c*-type cytochrome (Cyt *c* B) is unknown (Bergmann et al., 1994c). The periplasmic diheme cytochrome *c* peroxidase (Arciero and Hooper, 1994) of Nitrosomonas europaea might protect enzymes like HAO, which are easily inactivated by hydrogen peroxide (H_2O_2; Hooper and Terry, 1977). Wood (1986) suggested a more conventional construction of the electron transport chain, involving ubiquinone and membrane-bound *b*- and *c*-type cytochrome s. Wood (1986) discussed a possible proton motive Q-cycle as described by Mitchell (1975). Ubiquinone (Q8 species) and membrane-bound cytochrome s of types *b* and *c* were identified in Nitrosomonas europaea (Hooper et al., 1972; Tronson et al., 1973; Miller and Wood, 1983). In Fig. 8, a model of the electron flow in ammonia oxidizer s is depicted.

Fig. 8. Model of the electron flow in ammonia-oxidizing bacteria. The part of the figure dealing with nitric oxide, nitrogen dioxide and dinitrogen tetroxide is hypothetical (Novel aspects). CM = cytoplasmic membrane, i = inside the cell/cytoplasmic space, and o = outside of the cell/periplasmic space, and TCA = the tricarboxylic acid cycle. Figure was kindly provided by I. Schmidt.

Energy Transduction ATP synthesis driven by proton motive force occurs in *Nitrosomonas* (Drozd, 1976; Drozd, 1980; Hollocher et al., 1982; Kumar and Nicholas, 1982). This energy transduction is assumed to proceed at the level of hydroxylamine oxidation, but the process is not as yet well understood.

A simplified scheme would be a two-proton release per electron pair translocated from hydroxylamine to the electron transport chain via the periplasmic located HAO outside the membrane. In addition, the consumption of two protons in the cytochrome oxidase reaction is probably located on the cytoplasmic site of the membrane. However, the exact amount of ATP gained by oxidation of hydroxylamine is not known, since the total number of electrons fed into the energy-generating respiration chain per mol hydroxylamine oxidized varies, depending upon growth stage and environmental conditions. This variation reflects the fact that the production of NADH by reverse electron flow is not constant and coupled to hydroxylamine oxidation by an unknown mechanism.

According to Hollocher et al. (1982), the H^+/O ratio depends on the substrate concentration. From their measurements, they extrapolated the maximum values to be 3.4 and 4.4 for ammonia and hydroxylamine oxidation, respectively. In addition, Drozd (Drozd, 1976; Drozd, 1980) stated the maximum P/O ratio from hydroxylamine oxidation to be only one. Measurements of respiration-driven proton translocation indicated the association of only one proton translocation loop, with the transport of

two electrons channeled from hydroxylamine to the terminal oxidase.

NADH Production Aleem (1966) showed that cell-free extracts of *Nitrosomonas europaea* catalyzed an ATP-dependent $NAD(P)^+$ reduction with hydroxylamine as substrate. The reaction was interpreted as ATP-driven reverse electron flow. This hypothesis is in accordance with the postulate that the transmembrane oxidation-reduction loops of respiration chains are reversible, with the exception of the cytochrome -*c* oxidase loop. However, in vivo, the proton motive force resulting from the hydroxylamine oxidation might perhaps drive the reverse direction of the electron flow directly, without support of ATP as previously demonstrated for the nitrite oxidizer s *Nitrobacter winogradskyi* and *Nitrobacter vulgaris* (Freitag and Bock, 1990).

Co-Oxidation and Inhibition of AMO

The ammonia monooxygenase (AMO) is a nonspecific enzyme. Ammonia oxidizer s are capable of co-oxidizing a range of hydrocarbons (including methane and even xenobiotics), which raised interest in exploiting these microorganisms for bioremediation (Vanelli et al., 1990). The broad substrate range of AMO also is responsible for inhibition of ammonia oxidizer s by a variety of substances (Table 1). During oxidation of acetylene via AMO, reactive intermediates that bind irreversibly to AMO are formed in the presence of oxygen. The same mechanism causes the inhibition of AMO by trichlorethylene. The acetylene inhibition can be ameliorated by high ammonia concentrations via an unknown mechanism (Hyman and Wood, 1985a). Competitive inhibitors of AMO are methylfluorides, dimethylether (Voysey and Wood, 1987; Miller et al., 1993; Hyman et al., 1994) alkanes, alkenes (Hyman et al., 1988), and aromatic compounds (e.g., aniline; Keener and Arp, 1994; Voysey and Wood, 1987; Hyman and Wood, 1983; Jones and Morita, 1983). Carbon monoxide (CO) not only binds irreversibly to cytochrome s but also competitively inhibits AMO, the enzyme that oxidizes it to carbon dioxide (Tsang and Suzuki, 1982; Erickson et al., 1972). Since copper is a cofactor of AMO (Loveless and Painter, 1968; Hooper and Terry, 1973), metal chelators such as allylthiourea and diethyldithiocarbamate are noncompetitive, reversible inhibitors (Lees, 1952).

In addition to some of the above-mentioned inhibitors, Table 1 lists other inhibitors of ammonia oxidation that do not directly interact with AMO. Ammonia oxidation is much more strongly inhibited by all listed physical parameters and chemical compounds than is hydroxylamine oxidation.

Denitrification Catalyzed by Ammonia Oxidizers

Ammonia-oxidizing bacteria not only catalyze aerobic ammonia oxidation but also show denitrifying activity with nitrite as electron acceptor. For example, small amounts of nitric oxide and nitrous oxide are produced during denitrification with ammonia as electron donor at reduced oxygen concentrations (Hooper, 1968; Goreau et al., 1980; Remde and Conrad, 1990; Stüven et al., 1992). When using $^{14}NH_4^+$ and $^{15}NO_2^-$, Poth and Focht (1985) demonstrated that nitrous oxide

Modified from Hooper and Terry (1973).

was produced at low oxygen tension by nitrite reduction and not by hydroxylamine oxidation. The reaction is thought to be catalyzed by a periplasmic soluble cytochrome oxidase/nitrite reductase induced at low oxygen partial pressure (Miller and Wood, 1982; Miller and Nicholas, 1985; DiSpirito et al., 1985). Additionally, the formation of dinitrogen was observed (Poth, 1986; Bock et al., 1995), indicating that at least some strains of *Nitrosomonas* possess a nitrous oxide reductase. However, this enzyme has not been isolated as yet from denitrifying ammonia oxidizer s.

Ammonia oxidizer s show relatively high denitrification activities when they are cultivated under oxygen-limited conditions in the presence of organic matter (mixotrophic growth conditions; Bock et al., 1995). However, under these conditions, ammonia oxidation rates are low (Zart et al., 1996). For this reason, the denitrifying potentials of ammonia oxidizer s cannot be efficiently exploited for one-step nitrogen removal in wastewater treatment plants.

In the absence of dissolved oxygen, *Nitrosomonas eutropha* and *Nitrosomonas europaea* are capable of anoxic denitrification using molecular hydrogen, or simple organic compounds such as acetate, pyruvate, or formate as electron donors and nitrite as electron acceptor (Bock et al., 1995; Abeliovich and Vonshak, 1992; Stüven et al., 1992).

Genetics of Ammonia Oxidizer s

Relatively little information regarding the genetic makeup of ammonia oxidizer s is available. Most studies focussed on *Nitrosomonas europaea* (genome of ca. 2.2 Mb) whose genomic sequence is currently being determined (spider.jgi-psf.org). For the other ammonia oxidizer s of the β- and λ-subclasses of Proteobacteria (Phylogeny of ammonia oxidizer s), sequence information is restricted to the genes coding for the 16S rRNA (for a review, see Purkhold et al., 2000), the 16S-23S rDNA intergenic spacer region (Aakra et al., 1999), as well as the ammonia monooxygenase operon (Rotthauwe et al., 1995; Purkhold et al., 2000; Alzerreca et al., 1999). Recently, a gene for a copper-containing dissimilatory nitrite reductase (*nirK*) has been detected by PCR and was sequenced for several β-subclass ammonia-oxidizing bacteria is underway (Casciotti and Ward, 2001). Ammonia oxidizer s can also harbor plasmids, as demonstrated by the isolation and characterization of two cryptic plasmids in a *Nitrosomonas* strain retrieved from activated sludge (Yamagata et al., 1999).

Genes Encoding AMO, HAO and Related Enzymes

Genes coding for enzymes involved in the oxidation of ammonia, particularly the ammonia monooxygenase (AMO), the hydroxylamine oxidoreductase (HAO), and the accompanying cytochrome s have been most intensively studied in *N. europaea*, which has multiple copies of these primary nitrification genes (Enzymes involved in ammonia oxidation). *Nitrosomonas europaea* has a duplicated *amo* operon containing a continuous arrangement of the genes *amoC*, *amoA* and *amoB*, which are cotranscribed as a 3.5-kb mRNA and encode the three subunits of AMO, AmoC, AmoB and AmoA (McTavish et al., 1993; Klotz et al., 1997; Sayavedra-Soto et al., 1998). A third copy of *amoC*, which is not associated with the genes for the other subunits of this enzyme, has recently been identified (Sayavedra-Soto et al., 1998). Multiple *amo* operons also have been found in several other ammonia oxidizer s (Table 2). Furthermore, *N. europaea* has at least three copies of each of the genes coding for the hydroxylamine oxidoreductase (*hao*) and cytochrome c_{554} (*cycA* or *hcy*; McTavish et al., 1993; Hommes et al., 1994). Each copy of the *hao* gene is located 950 bp upstream of a copy of the *hcy* gene, but both genes are always found to be within different operons (Bergmann et al., 1994c; Sayavedra-Soto et al., 1994). Downstream of two of the *hcy* genes, an ORF (*cycB*) predicted to encode another tetraheme cytochrome *c* was detected (Bergmann et al., 1994c). The nucleic acid sequences of the multiple copies of all abovementioned genes (except for the unlinked *amoC* genes) are either identical or highly similar within a single ammonia oxidizer species, whereas much lower similarities occur between the respective genes of different species. Thus, it is likely that the multiple gene copies originated from relatively recent gene duplication events and were not caused by lateral gene transfer (Klotz and Norton, 1998). It has been speculated that the presence of multiple genes might 1) allow more-rapid generation of the respective mRNA during ammonia flushes within the local environment of the ammonia oxidizer s (Hommes et al., 1998) or 2) be responsible for maintaining a certain ratio of the gene products (Bergmann et al., 1994c).

In addition to those genes with products directly involved in ammonia oxidation, genes of *N. europaea* encoding the enolase (*eno*) and CTP synthase (*pyrG*) were sequenced (Mahony and Miller, 1998). The enolase catalyzes the conversion of 2-phosphoglycerate to phosphoenolpyruvate, and its gene was found to be linked on the chromosome with the *pyrG* gene, albeit both

Table 2. Number of *amo* operons and *amoC* copy numbers in different ammonia oxidizer s.

Organism	*amo* operon number	*amoC* copy number[a]

[a]Several ammonia oxidizers contain in their genomes an additional *amoC* copy not linked to other *amo* genes. In *N. europaea*, the additional *amoC* copy has 60% nucleic acid sequence similarity to each of the other two *amoC* copies.
From Norton et al. (1996); Alzerreca et al. (1999), and data from GenBank.

genes are not cotranscribed. A similar arrangement of both genes is present in the *Escherichia coli* genome (where they are cotranscribed), though these genes are not linked in other investigated bacterial genomes.

Unfortunately, no sequence information regarding the genes involved in CO_2 fixation/carboxysome formation of the autotroph ic ammonia oxidizer s is currently available.

Regulation of AMO and HAO

One unusual feature of *N. europaea* is that it possesses multiple copies of those genes directly involved in ammonia oxidation. This is remarkable, since, with the exception of rRNA and tRNA genes, only relatively few cases of gene duplications have been described for bacteria (e.g., Hass et al., 1992; Sela et al., 1989; Tubulekas and Hughes, 1993; Kusian et al., 1995). The significance of the *N. europaea* ammonia oxidation genes being present in multiple copies has been investigated using techniques for transformation and insertional mutagenesis (Hommes et al., 1996; Hommes et al., 1998). Disruption of each of the two *amoA* copies showed that each copy was functional in *N. europaea* and that neither copy is essential in the cell. However, knockout of one of the *amoA* copies, but not of the other has a significant influence on the growth rates of the cells (Hommes et al., 1998), suggesting different regulation of each copy. Surprisingly, however, the putative σ^{70}-type promotors of both *amoA* genes were found to be identical (Hommes et al., 2001), indicating that the differential transcription of both genes (Hommes et al., 1998) involves regions upstream of the promotor where the DNA sequences of both copies diverge (Hommes et al., 2001). Similar results were obtained with cells carrying single mutations in each of the *amoB* genes (Stein et al., 2000). Insertional mutagenesis of each of the three *hao* gene copies, all of which possess σ^{70}-type promotors (Hommes et al., 2001), showed that none of them was essential and that their inactivation could be compensated fully by the two remaining *hao* genes (Hommes et al., 1996). However, owing to the presence of three *hao* gene copies, differences in their regulation might only become apparent after simultaneous inactivation of two of the copies.

Ammonia-oxidizing bacteria thrive in environments where ammonia is often present in very low concentrations. In these habitats, the capability to efficiently make use of temporal flushes of ammonia might represent an important selective advantage for an ammonia oxidizer. Therefore, the genetic and physiological responses of ammonia oxidizer s under conditions of ammonium limitation (ammonium present in amounts that can be metabolized to completion), of starvation (absence of ammonium), and in the presence of excess ammonium were intensively investigated. *Nitrosomonas cryotolerans* and *N. eutropha* survive ammonia starvation for at least 25 weeks (Jones and Morita, 1985) and one year, respectively (Pinck et al., 2001). In contrast to energy-starved heterotrophic bacteria, *N. cryotolerans* cells after 10 weeks of starvation 1) do not miniaturize, 2) maintain stable levels of intracellular ATP, and 3) show no changes in the total protein, DNA or RNA levels (Johnstone and Jones, 1988). Furthermore, quantitative FISH demonstrated that ammonia oxidizer s in activated sludge maintain relatively stable cellular rRNA concentrations during starvation for one month or inhibition with allylthiourea for several days (Wagner et al., 1995; Morgenroth et al., 2000). During prolonged starvation for several months or years ammonia oxidizer s lose ammonia-oxidizing activity but still contain significant amounts of AMO inasmuch as this enzyme is degraded more slowly in comparison to the mean cellular protein (Pinck et al., 2001). Under conditions of ammonia starvation, the mRNA of the *amo* gene disappears within 8 hours, though the ammonia and hydroxylamine oxidation activities do not change over a period of 24 h (Stein and Arp, 1998a). Limiting ammonium concentrations results in a large loss of ammonia-oxidizing activity (85%) after 24 h, but it neither affects the steady-state levels of *amoA* mRNA nor the result in degradation of the AmoA subunit (Stein and Arp, 1998a). Interestingly, short-chain alkanes and other substrates having a high binding affinity for AMO ameliorate the inactivating effects of ammonia limitation by protecting the

energy-generating activity of *N. europaea* from potentially toxic by-products of its metabolism (Stein and Arp, 1998a, b; Ammonia and hydroxylamine as Substrates). Interestingly, *N. europaea* cells grown in biofilms recover much faster after ammonium starvation than their planktonic counterparts. Preliminary data suggest that this phenomenon might be caused by cell-to-cell communication via *N*-(3-oxohexanoyl)-L-homoserine lactone (Batchelor et al., 1997). As expected, ammonium/ammonia induces the transcription of the ammonia monooxygenase and hydroxylamine oxidoreductase genes as well as the transcription of several additional genes that were not further characterized in *Nitrosomonas europaea* (Sayavedra-Soto et al., 1996). Furthermore, the activity of AMO is regulated by the presence of ammonia at translational (Hyman and Arp, 1995; Stein et al., 1997) and posttranslational (Stein et al., 1997) levels.

Biochemistry of Nitrite-Oxidizing Bacteria

The second step of nitrification, the oxidation of nitrite to nitrate, is performed by nitrite-oxidizing bacteria. Although at least four different genera of nitrite oxidizer s exist in nature (Phylogeny of nitrite oxidizer s), most of our knowledge on the physiology and biochemistry of these organisms stems from research on *Nitrobacter* species and thus cannot be generalized for all nitrite oxidizer s.

The key enzyme of nitrite-oxidizing bacteria is the membrane-bound nitrite oxidoreductase (Tanaka et al., 1983), which oxidizes nitrite with water as the source of oxygen to form nitrate (Aleem et al., 1965b). The electrons released from this reaction are transferred via *a*- and *c*-type cytochrome s to a cytochrome oxidase of the aa_3-type. However, the mechanism of energy conservation in nitrite oxidizer s is still unclear. Neither Hollocher et al. (1982) nor Sone et al. (1983) were able to find an electron transport chain linked to proton translocation in nitrite-oxidizing cells of *Nitrobacter winogradskyi*. The first product of energy conservation was shown to be NADH and not ATP (Sundermeyer and Bock, 1981).

Except for *Nitrobacter*, all other isolated nitrite oxidizer s are obligate lithotrophs with nitrite serving as the only energy source. Although many strains of Nitrobacter are able to grow heterotrophically, growth is very inefficient and slow (Smith and Hoare, 1968; Bock, 1976). Additionally, inorganic substrates other than nitrite, namely nitric oxide, can be used for lithotrophic growth, indicating metabolic diversity among *Nitrobacter* species (Freitag et al., 1987).

In anoxic environments, *Nitrobacter* cells are able to grow by denitrification (Freitag et al., 1987; Bock et al., 1988). Nitrate can be used as acceptor for electrons derived from organic compounds to promote anaerobic growth. Since the oxidation of nitrite is a reversible process, the nitrite oxidoreductase can reduce nitrate to nitrite in the absence of oxygen (Sundermeyer-Klinger et al., 1984). Furthermore, the nitrite oxidoreductase copurifies with a nitrite reductase that reduces nitrite to nitric oxide (Ahlers et al., 1990).

Nitrite as a Substrate

The utilization of nitrite as an energy source has been the subject of several reviews (Wood, 1986; Hooper, 1989; Bock et al., 1991; Yamanaka et al., 1981; Tanaka et al., 1983; Sundermeyer-Klinger et al., 1984; Fukuoka et al., 1987). Nitrite is oxidized to nitrate and the oxygen atom in the nitrate molecule is derived from water (Aleem, 1965a; Kumar et al., 1983; Hollocher, 1984) according to equation (8).

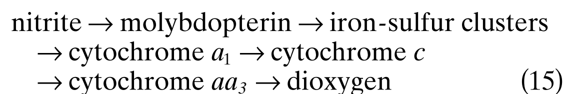
$$NO_2^- + H_2O \rightarrow NO_3^- + 2H^+ + 2e^- \quad (8)$$

The two electrons released are transported to oxygen, as described in equation (9).

$$2H^+ + 2e^- + 0.5O_2 \rightarrow H_2O \quad (9)$$

The produced nitrate is inhibitory for *Nitrobacter* species at concentrations between 30 and 65 mM, probably owing to feedback inhibition.

The electron flux from nitrite to oxygen could pass the following electron carriers (Bock et al., 1992):



$$\text{nitrite} \rightarrow \text{molybdopterin} \rightarrow \text{iron-sulfur clusters} \rightarrow \text{cytochrome } a_1 \rightarrow \text{cytochrome } c \rightarrow \text{cytochrome } aa_3 \rightarrow \text{dioxygen} \quad (15)$$

Enzymes Involved in Nitrite Oxidation

NITRITE OXIDOREDUCTASE Nitrite oxidation is a reversible process. The enzyme nitrite oxidoreductase (NO_2-OR) catalyzes the oxidation of nitrite to nitrate and the reduction of nitrate to nitrite (Genetics of nitrite oxidizer s). The NO_2-OR is an inducible membrane protein present in Nitrobacter cells, which are either grown lithotrophically with nitrite or heterotrophically in the presence of nitrate. Depending upon the enzyme isolation technique, the molecular features of NO_2-OR vary considerably. Cytochrome s of the *a*- and *c*-type were present when the enzyme of *Nitrobacter wino-*

gradskyi was solubilized with Triton X-100 and purified by ion exchange and size exclusion chromatography (Tanaka et al., 1983). The purified protein was composed of three subunits of 55, 29 and 19 kDa. Cytochrome a_1 and c were also found when *n*-octylglycoside was chosen as detergent. However, using sodium deoxycholate and subsequent isolation by sucrose gradient centrifugation, only cytochrome c could be detected (Sundermeyer-Klinger et al., 1984). In this preparation, the holoenzyme of *Nitrobacter hamburgensis* consisted of three subunits with relative weights of 116–130, 65 and 32 kDa. No cytochrome s were found when the NO_2-OR was isolated from membranes by heat treatment. In this case, only two subunits of 115–130 and 65 kDa were present for *Nitrobacter winogradskyi*, *Nitrobacter vulgaris* and for *Nitrobacter hamburgensis* (Bock et al., 1990).

All preparations of the NO_2-OR contain molybdenum (Mo) and iron-sulfur clusters. In membranes of *Nitrobacter winogradskyi*, signals attributed to molybdenum were detected by electron proton resonance spectroscopy (Ingledew and Halling, 1976). In isolated NO_2-OR, molybdenum occurred in the form of molybdopterin (Krüger et al., 1987). The molybdenum content varied between 0.13 (Sundermeyer-Klinger et al., 1984) and 1.4 γ-atoms per molecule (Fukuoka et al., 1987). This difference can probably be explained by the fact that molybdenum often is lost during the enzyme isolation procedure. Molybdenum is essential for nitrite oxidation, and when it is replaced by tungsten, lithoautotrophically growing cells of *Nitrobacter hamburgensis* are inhibited, whereas heterotrophically growing cells are not. Flavoproteins are absent in NO_2-OR preparations. When isolated with Triton X-100, manganese was found to be associated with the NO_2-OR (Tanaka et al., 1983). The pH optimum of the NO_2-OR for nitrite oxidation differs from that for nitrate reduction. Optimal pH for nitrite oxidation with ferricytochrome c_{550}, ferricyanide, or chlorate as oxidants is about 8.0. With reduced methyl or benzyl viologen as reductants, the optimal pH for nitrate reduction ranges from 6.0 to 7.0. The apparent K_m value for nitrite oxidized by the NO_2-OR with the aid of different electron acceptor s varied with the test conditions between 0.5 and 2.6 mM (Tanaka et al., 1983) or 0.5 and 3.6 mM (Sundermeyer-Klinger et al., 1984), whereas the K_m value for nitrate amounted to about 0.9 mM.

It is important to note that the specific activities of NO_2-OR are influenced by the purification steps of the isolation procedure. As shown in Table 3, the nitrite oxidation activity and the nitrate reduction activity are highest in the membrane fraction. Both activities decrease to about 80% when NO_2-OR is isolated from membranes without detergent. If Triton X-100 or sodium deoxycholate is used for isolation, this effect is even more pronounced (Yamanaka and Fukumori, 1988; Sundermeyer-Klinger et al., 1984).

Table 3. Activity variations of the nitrite oxidoreductase isolated from mixotrophically grown cells of *Nitrobacter hamburgensis* depending on the isolation procedure.

	Specific activity (units)	
Fraction	NO_2^--oxidizing activity[a]	NO_3^--reducing activity[b]
Crude extract, 8,000 × g	1.728	2.101
Supernatant	2.338	1.839
Membranes	6.047	3.270
Membranes after heat treatment	2.582	4.882
Purified enzyme	2.506	1.740

[a]The unit of activity for NO_2^- oxidizing was determined with ClO_3^- as electron acceptor. One unit is defined as the oxidation of 1 μM nitrite per minute and per milligram of protein.
[b]The nitrate reductase activity was measured with reduced methyl viologen (MVH) as electron donor. One unit is defined as the reduction of 1 μM nitrate and per minute and per milligram of protein.

CYTOCHROME *c* OXIDASE In *Nitrobacter* species, absorption peaks at 605 nm in difference spectra indicate a cytochrome c oxidase of the aa_3-type. This membrane-bound enzyme was purified to an electrophoretically homogeneous state (Yamanaka et al., 1981; Sewell et al., 1972), and the function of cytochrome aa_3 was determined as a terminal oxidase by photoactivation of CO-inhibited oxygen consumption. In contrast to mitochondrial terminal oxidases, cytochrome aa_3 of *Nitrobacter winogradskyi* is composed of two subunits with 40 and 27 kDa in a molar ratio of l:l (Yamanaka et al., 1979). One molecule of the enzyme contains two molecules of heme a, two atoms of copper, one atom of magnesium but no zinc (Yamanaka and Fukumori, 1988). The K_m values were estimated to be 110 and 24 μM for horse heart cytochrome c and ferricytochrome c (both of which can serve as electron donors) of *Nitrobacter winogradskyi*, respectively. Phospholipids isolated from *Nitrobacter winogradskyi* did not stimulate the oxidation rate of native ferrocytochrome c or horse heart cytochrome c (Yamanaka and Fukumori, 1988). If cytochrome aa_3 was incorporated in phospholipid vesicles or membrane vesicles, respiratory control was observed, but proton-pumping activity was not (Sone et al., 1983; Sone, 1986).

NITRITE REDUCTASE In *Nitrobacter vulgaris*, a membrane-bound nitrate reductase (NiR) was copurified with the nitrite oxidoreductase (Ahlers et al., 1990). The NiR reduces nitrite to

nitric oxide, which is released under reduced oxygen partial pressure from the cells to the environment. Therefore, this enzyme seems to be a dissimilatory nitrite reductase of the denitrification type.

In the sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) of NO_2-OR and NiR, three bands are visible. In addition to the two proteins with M_r 115,000 and 65,000, which are constituents of the NO_2-OR, a third protein with M_r 63,000, possibly representing the NiR, is detectable. The pH optimum of the NiR was shown to be 6.1 and the K_m value for nitrite was 0.263 mM. The isoelectric point (IEP) was calculated to be at pH 5.5–6.0. Reduced horse heart cytochrome *c* can serve as an electron donor for nitrite reduction in *Nitrobacter winogradskyi* and *Nitrobacter vulgaris*. The biological function of NiR is difficult to understand, since ATP generation has not been detected during nitrite reduction (Freitag and Bock, 1990).

Electron Flow and Energy Transduction

As shown in Fig. 9, the first step, the electron transfer from nitrite to cytochrome a1 is catalyzed by the enzyme nitrite oxidoreductase. Cytochrome a_1 was shown to be necessary to channel electrons from nitrite to cytochrome *c* (Yamanaka and Fukumori, 1988). Cytochrome a_1 of *Nitrobacter winogradskyi* is not autoxidizable (Tanaka et al., 1983) and shows a typical absorption maximum at 589 nm. It is always found in nitrite-oxidizing and nitrate-reducing cells of all *Nitrobacter* species. On the other hand, *Nitrospira marina* does not possess any cytochrome of the *a*-type (Watson et al., 1986).

The electrons enter the underlying respiratory chain at the level of cytochrome *c* (Aleem, 1968; Cobley, 1976b; Aleem and Sewell, 1981; Sundermeyer and Bock, 1981; Tanaka et al., 1983). The reduction of cytochrome *c* is a thermodynamically unfavorable step, which is slow in cell-free extracts. Electrons derived from the nitrite/nitrate couple have a redox potential of $E_{m,7}$ = +420 mV, whereas those of ferrocytochrome *c*/ferricytochrome *c* have a potential of $E_{m,7}$ = +260 mV. A relatively high nitrite concentration would cause a lowering of the redox potential, but in natural habitats, high nitrite concentrations are rarely found (Schmidt, 1982). Actually, a highly active cytochrome aa_3 pushes nitrite oxidation by the removal of electrons from cytochrome *c*. In addition, the concentration of cytochrome aa_3 also varies dependent upon the oxygen concentration. SDS-PAGE experiments demonstrated that cells of Nitrobacter vulgaris grown under high oxygen partial pressure possess high nitrite-oxidizing activity and a high cytochrome aa_3 content, whereas those cells

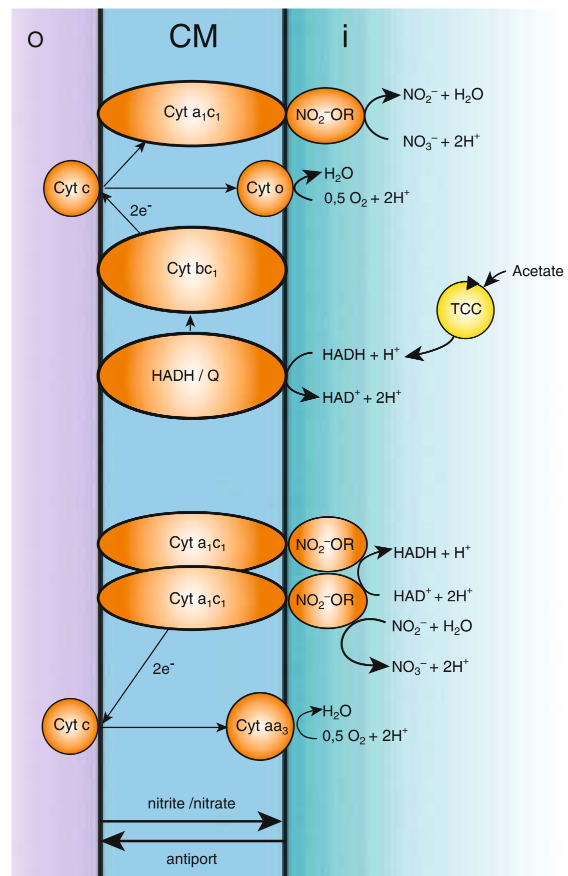


Fig. 9. Model of the electron flow in *Nitrobacter*. Depicted are the pathways of denitrification and heterotrophic growth (upper part) and the nitrification pathway (lower part). CM = cytoplasmic membrane, i = inside the cell/cytoplasmic space, o = outside of the cell/periplasmic space, NO_2-OR = nitrite oxidoreductase, and TCA = the tricarboxylic acid cycle. Figure was kindly provided by I. Schmidt.

grown under low oxygen tension have a low activity and a low cytochrome aa_3 content (E. Bock, unpublished observation).

The nitrite-oxidizing system of *Nitrobacter vulgaris* can be remodeled by reassociation of n-octylglycoside-isolated NO_2-OR with cytochrome aa_3. The activity of the nitrite-oxidizing system increased with increasing amounts of cytochrome *c* oxidase (Fig. 10). Present alone, NO_2-OR or cytochrome aa_3 was unable to oxidize nitrite to nitrate. The in vitro modeling of the nitrite-oxidizing system of *Nitrobacter vulgaris* shows clearly that both enzymes are essential for the oxidation of nitrite to nitrate, with oxygen as the terminal electron acceptor. At a fixed NO_2-OR content, the enzyme activity is regulated by the concentration of cytochrome aa_3.

In addition to oxygen, CO_2 can serve as electron sink in *Nitrobacter*. Cytochrome *c* oxidation

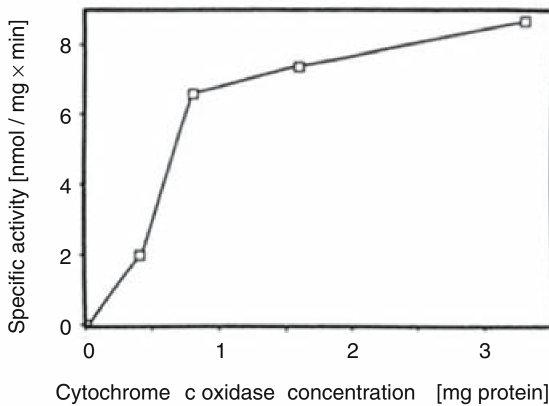

Fig. 10. Increase of the specific nitrite-oxidizing activity in cell-free enzyme preparations of *Nitrobacter vulgaris*. Isolated nitrite oxidoreductase was complemented with increasing amounts of cytochrome oxidase (aa_3) for 20 h at 28°C. The specific activity was measured as nitrite oxidized to nitrate with oxygen as the electron acceptor.

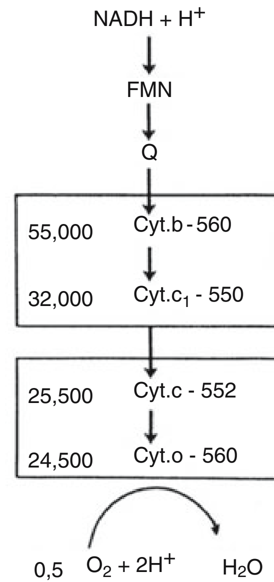

Fig. 11. Components of the conventional respiratory chain of *Nitrobacter*. The blocks symbolize proteins and their subunits in M_r.

generates energy that is necessary for autotroph ic carbon dioxide fixation. Since lithoautotrophic growth is inefficient, 85–115 mol of nitrite have to be oxidized to assimilate 1 mol of carbon dioxide (Bömecke, 1954).

Electron Flow of the Conventional Respiratory Chain The electrons from nitrite meet the underlying respiratory chain at the level of cytochrome *c* (not shown in Fig. 9). This chain functions in lithotrophically, mixotrophically, and heterotrophically growing cells as well as in endogenous respiring cells of *Nitrobacter* in the absence or presence of oxygen (Fig. 11). Electrons from NADH + H^+ (NADH) pass via flavin mononucleotide (FMN) and ubiquinone to a cytochrome bc_1-complex and finally to the terminal oxidase.

The responsible NADH oxidase has not yet been isolated. However, FMN was found to be present in heterotrophically grown *Nitrobacter* cells (Kirstein et al., 1986). Ubiquinone Q_{10} was the isoprenoid in the respiratory chain (Aleem and Sewell, 1984).

The cytochrome bc_1 is supposed to consist of a cytochrome b_{560} (55 kDa) and cytochrome *c*1-550 (32 kDa; M. Rudert, unpublished observations). The terminal oxidase (presented in Fig. 11) is a protein complex isolated from *Nitrobacter vulgaris* cells (M. Rudert, unpublished observations) consisting of a 25-kDa cytochrome c_{552} and a 24.5-kDa cytochrome *o*. This oxidase is assumed to be active at high oxygen partial pressure and is also present in lithotrophically grown cells of *Nitrobacter winogradskyi* (Aleem and Sewell, 1984) as well as in heterotrophically grown cells of *Nitrobacter hamburgensis* (Kirstein et al., 1986). At low oxygen tension, cytochrome aa_3 might perform this function (Fig. 9).

Additional electron carriers have been described by different authors. Kurokawa et al. (1987) isolated a flavin adenine dinucleotide-containing flavoenzyme from lithotrophically grown cells of *Nitrobacter winogradskyi* with NAD(P)H cytochrome *c* reductase and transhydrogenase activities. Two cytochrome s of the *b*-type, b_{560} and b_{564}, were found in *Nitrobacter hamburgensis*. Cytochrome b_{560} is typical for heterotrophically grown cells and might belong to the bc_1 complex (Kirstein et al., 1986). The function of cytochrome b_{564} is unknown. Several additional membrane-bound and soluble cytochrome s of the *c*-type have been described (Chaudhry et al., 1981; Miller and Wood, 1982). As reported by Tanaka et al. (1982) and Yamanaka et al. (1982), the amino acid composition of a soluble cytochrome *c* of *Nitrobacter winogradskyi* is similar to the mitochondrial cytochrome *c*.

ATP Production A generally accepted concept for the mechanism of energy generation derived from the described electron flow system is not available. Cobley (1976a) reported proton release into the cytoplasm, whereas Wetzstein and Ferguson (1985) detected proton extrusion into the periplasmic space coupled to oxidation of nitrite with artificial electron donors. However, proton pumping activity able to drive a membrane-bound ATPase could neither be mea-

sured for nitrite-oxidizing cells nor for nitrite-oxidizing vesicles (Hollocher et al., 1982).

Apart from the oxidation of exogenous organic substrates, *Nitrobacter* cells can oxidize endogenous material, e.g., poly-β-hydroxybutyrate; this metabolic activity is called "endogenous respiration." It has been shown that both the oxidation of exogenic and endogenic matter cause electron flow via a "normal" respiratory chain. Thus, nitrite-oxidizing *Nitrobacter* can be considered as a regulatory specialist because nitrite oxidation interferes with normal respiration, e.g., nitrite oxidation might inhibit endogenous respiration (Eigener and Bock, 1975). Changing from endogenous respiration to nitrite oxidation, active cells increased their ATP pool to a maximum of 1 mol of ATP by the oxidation of 1 of mol nitrite (Aleem, 1968). All attempts to reproduce this result have failed, but in whole cells and in membrane vesicles, ATP was formed at the expense of NADH oxidation with nitrate (Kiesow, 1964; Freitag and Bock, 1990) and/or oxygen as electron acceptor (Sewell and Aleem, 1979).

In *Nitrobacter*, phosphorylation of ADP is carried out by a membrane-bound ATP synthase. Isolated *Nitrobacter* ATPase is similar to the F1-ATPase from a thermophilic bacterium (Yamanaka and Fukumori, 1988). With respect to ATP production, *Nitrobacter* might be best described as a "normal" respiring organism, but this does not explain why heterotrophic growth is so slow.

NADH PRODUCTION AND CELL GROWTH Lithotrophically grown cells of *Nitrobacter winogradskyi* and *Nitrobacter vulgaris* possess an average poly-β-hydroxybutyrate (PHB) content of 10–30% of the cell dry weight (E. Bock, unpublished observations). This relatively high content indirectly indicates overproduction of NADH. Kiesow (1964) demonstrated in vivo NADH synthesis in nitrite-oxidizing cells by measuring the increase in extinction at 340 nm. Repeating these experiments, we also found NADH formation but only at low oxygen partial pressure. The reaction was sensitive to the uncoupler 2,4-dinitrophenol and insensitive to the ATPase inhibitor *N,N′*-dicyclohexyl carbodiimide (DCCD; Freitag and Bock, 1990).

In Fig. 12, the classical scheme of reverse electron flow for generation of NADH is shown. The functional models proposed by Wood (1986) and Hooper (1989) leave many questions unanswered. For example, the authors cannot explain why nitrite-oxidizing cells or spheroplasts of *Nitrobacter winogradskyi* do not produce a proton gradient, which is necessary to understand reverse electron flow (Hollocher et al., 1982). As stated above, nitrite-oxidizing bacteria are able

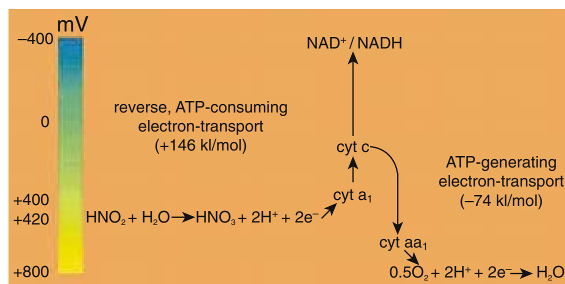

Fig. 12. Classical scheme of ATP-dependent NADH synthesis in nitrite-oxidizing cells of *Nitrobacter*.

to grow with nitrite, although the electron transfer from nitrite to cytochrome *c* is more electronegative than the nitrite/nitrate couple (Aleem, 1968; Ferguson, 1982). In spite of the existing unfavorable redox potential of cytochrome *c*, the electrons released from nitrite are promptly removed by cytochrome aa_3, so that nitrite oxidation can proceed without energy consumption (O'Kelley et al., 1970). As shown by Cobley (Cobley, 1976a; Cobley, 1976b), the membrane potential has a stimulatory effect on the rate of nitrite oxidation. In experiments with whole cells and membrane vesicles, the nitrite-oxidizing activity decreased in the presence of uncouplers, which collapsed the membrane potential. Thus, even the loss of activity of the isolated NO_2-OR might be caused by the loss of the transmembrane electric field, which mediates a conformation transition between an "inactive" and an "active" form of the enzyme (Tsong and Astumian, 1987).

Sundermeyer and Bock (1981) were the first to present evidence that NADH synthesis is the primary energy-conserving process in nitrite-oxidizing cells. In addition to nitrite, nitric oxide was shown to be a suitable electron donor for NADH synthesis (Freitag and Bock, 1990). Figures 13 and 14 show the formation of NADH (increase in absorption at 340 nm) in whole cells of *Nitrobacter winogradskyi*. When nitrite was added to aerobic cell suspensions, the dissolved oxygen tension dropped within 5 min to less than 4% of saturation. As shown in Fig. 13, the NADH pool of the cells first decreased for 5 min and then increased at a constant rate. When nitrite was added to anaerobic cell suspensions, the NADH content increased without any lag phase (Fig. 14). As shown in the figures, the rates of NADH formation with nitric oxide as substrate were faster than those with nitrite. Compared to $E_{m,7}$ = +420 mV for the nitrite/nitrate couple, the redox potential of the nitric oxide/nitrite couple is $E_{m,7}$ = +374 mV (Wood, 1978), if water is the reactant. Thermodynamically, there is no great difference between the two reactions;

nevertheless, nitric oxide was the better substrate than nitrite when *Nitrobacter winogradskyi* was grown lithoautotrophically.

It is generally accepted that NADH generation in *Nitrobacter* cells is an ATP-independent reaction as shown for *Thiobacillus ferrooxidans* (Lu and Kelly, 1988). But it is still unclear how NADH is synthesized.

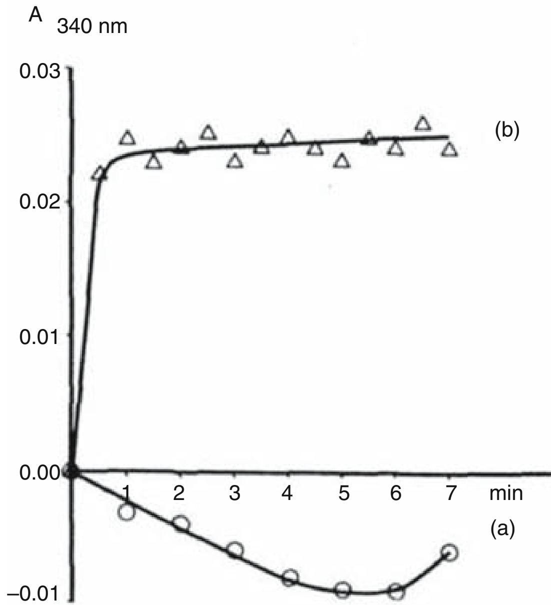

Fig. 13. NADH formation in whole cells of *Nitrobacter winogradskyi* in the presence of nitrite (a) and nitric oxide (b) under oxic conditions. NADH production was measured as the increase in absorption at 340 nm.

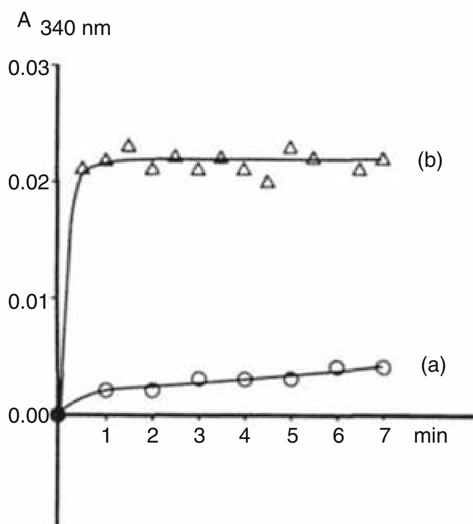

Fig. 14. NADH formation in whole cells of *Nitrobacter winogradskyi* in the presence of nitrite (a) and nitric oxide (b) under anoxic conditions. NADH production was measured as the increase in absorption at 340 nm.

Genetics of Nitrite Oxidizer s

With exception of the 16S rRNA genes (Sorokin et al., 1998; Orso et al., 1994; Teske et al., 1994; Ehrich et al., 1995), no genetic data are available for nitrite-oxidizing bacteria other than *Nitrobacter* (Phylogeny of nitrite oxidizers). For *Nitrobacter* species, sequence of the 16S-23S rRNA intergenic spacer and partial sequences of the 23S rRNA genes have been determined (Grundmann et al., 2000). Furthermore, the genes encoding the two catalytic core subunits of cytochrome *c* oxidase of *Nitrobacter winogradskyi* occur in the same operon. Similar to many ammonia-oxidizing bacteria, *N. winogradskyi* possess at least two copies of these genes in its genome (Berben, 1996). In addition, the sequences of the Calvin cycle genes were determined for *Nitrobacter vulgaris* (Strecker et al., 1994) and *Nitrobacter winogradskyi* (GenBank accession numbers {AF109915} and {AF10 9914}). In *Nitrobacter vulgaris*, the genes for the large and small subunits of ribulose-1,5-bisphosphate carboxylase/oxygenase, the glyceraldehyde-3-phosphate dehydrogenase and a regulatory protein of the LysR family are located together within one cluster. Another cluster contains the genes for fructose-1,6- and sedoheptulose-1,7-biphosphatase, phosphoribulokinase, and fructose-1,6- and sedoheptulose-1,7-bisphosphatealdolase. Furthermore, the genes for both subunits (*norA* and *norB*) of the membrane-bound nitrite oxidoreductase (NO_2-OR) from *Nitrobacter hamburgensis* were sequenced. These genes cluster together with an additional ORF (*norX*) in the order *norA*, *norX* and *norB*. The deduced amino acid sequence of protein NorB contains four cysteine clusters with striking homology to those of iron-sulfur centers of bacterial ferredoxins. The β-subunit and the sequenced part of the α-subunit of NO_2-OR exhibit significant sequence similarities with the β- and α-subunits of the two dissimilatory nitrate reductases of several chemo-organotrophic bacteria including *E. coli* (Kirstein and Bock, 1993). This is consistent with biochemical data that suggest a close functional similarity between both enzyme complexes (Sundermeyer-Klinger et al., 1984; Hochstein and Tomlinson, 1988).

Heterotrophic Nitrification

The oxidation of ammonia (van Niel et al., 1993), hydroxylamine (Ralt et al., 1981) or organic nitrogen compounds, e.g., oximes (Castignetti and Hollocher, 1984), to nitrite and nitrate by various chemo-organotrophic microorganisms is called "heterotrophic nitrification." Heterotrophic nitrification is a cometabolism that is

not coupled to energy conservation (Wood, 1988b). Thus, growth of all heterotrophic nitrifiers is completely dependent on the oxidation of organic substrates (Focht and Verstraete, 1977; Kuenen and Robertson, 1987). The final product of heterotrophic nitrification often is nitrite (Castignetti and Gunner, 1980), so that heterotrophic nitrification may supply the substrate for lithotrophic nitrite oxidizer s and heterotrophic denitrifiers. This additional nitrite production (together with the ability of nitrite oxidizer s to grow chemo-organotrophically) might explain why in many environments the number of lithoautotrophic nitrite oxidizer s is much higher than that of lithoautotrophic ammonia oxidizer s (Kuenen and Robertson, 1987).

Recently, attention has been driven to heterotrophic nitrifiers because many of them are capable of aerobic denitrification in the presence of organic matter, leading to the complete elimination of dissolved nitrogen compounds with the formation of gaseous nitrogen oxides and/or dinitrogen gas (Castignetti and Hollocher, 1984; Robertson et al., 1989; Andersson and Levine, 1986a; van Niel et al., 1987). Owing to the simultaneous nitrifying and denitrifying activity, nitrification rates of heterotrophic nitrifiers are often underestimated (Castignetti and Hollocher, 1984; Kuenen and Robertson, 1987). For example, *Paracoccus denitrificans* (formerly called *Thiosphaera pantotropha*) produces nitrite from urea, ammonia and hydroxylamine and is also able to reduce nitrite even under aerobic conditions (Robertson and Kuenen, 1983; Robertson and Kuenen, 1984; Robertson and Kuenen, 1988). Therefore, in cultures of this organism, nitrite only accumulates when the nitrite reductase activity is repressed.

Biochemically, the ammonia-oxidizing enzyme of *Paracoccus denitrificans* shows some similarities to the AMO of lithotrophic ammonia oxidizer s, e.g., the ability to oxidize alkanes, the apparent requirement for copper, and inhibition by light, diethyldithiocarbamate and allylthiourea (Moir et al., 1996a; Crossmann et al., 1997). The purified ammonia-oxidizing enzyme of *P. denitrificans* contains two polypeptides of 38 and 46 kDa, respectively (Moir et al., 1996a). However, the genes encoding for these polypeptides are not closely related to the *amo*-genes of lithotrophic ammonia oxidizer s (Crossmann et al., 1997). The hydroxylamine oxidoreductase from *P. denitrificans* is a monomeric protein of approximately 18.5 kDa containing nonheme-iron (Wehrfritz et al., 1993; Moir et al., 1996b).

The environmental importance of heterotrophic nitrifiers is controversial in the literature. Generally it is assumed that in most environments, the biological conversion of reduced forms of nitrogen to nitrite and nitrate is catalyzed mainly by the lithoautotrophic ammonia- and nitrite-oxidizing bacteria and not by heterotrophic nitrifiers. This reflects that the nitrification rates of heterotrophic nitrifiers are small compared to those of autotroph ic nitrifiers (Robertson and Kuenen, 1988). Therefore, heterotrophic nitrification was thought to occur preferentially under conditions unfavorable for autotroph ic nitrification, e.g., in acidic environments (Killham, 1986). In such environments, heterotrophic bacteria, fungi and even some algae might contribute considerably to nitrification (Schimel et al., 1984; Killham, 1986; Killham, 1987; Robertson and Kuenen, 1990; Spiller et al., 1976). But according to recent reports, even in acidic soils, heterotrophic nitrification contributes to overall nitrate production only to a minor extent (Stams et al., 1990; Barraclough and Puri, 1995).

Novel Aspects

Nitrogenous Oxides Are Essential for Aerobic Ammonia Oxidation

Nitrifying as well as denitrifying bacteria contribute to the net production of nitrogenous oxides from soil (Kester et al., 1996; Kester et al., 1997a, b) and from aquatic environments (Xu et al., 1995). This is noteworthy since the gaseous compounds nitric oxide (NO), nitrogen dioxide (NO_2) and nitrous oxide (N_2O) are of significance for the chemistry of the atmosphere (Johnston, 1972; Crutzen, 1979; Galbally and Roy, 1983). Additionally, nitrous oxide acts as a greenhouse gas (Wang et al., 1976; Andersson and Levine, 1986a). Furthermore, nitric oxide and to a more moderate extent nitrogen dioxide (Mancinelli and McKay, 1983) have strong inhibitory effects on bacteria (Mancinelli and McKay, 1983; Shank et al., 1962). Toxicity of nitric oxide is based on its capability to form metal nitrosyl complexes (mainly with heme proteins, iron-sulfur proteins, and copper-containing proteins; Henry et al., 1991), resulting, for example, in the inhibition of cytochrome oxidases (Carr and Ferguson, 1990). Furthermore, nitric oxide was shown to form S-nitrosothiols from sulfhydryl-groups (Stammler et al., 1992; Hausladen et al., 1996) and to cause $C \rightarrow T$ transitions in the DNA (Wink et al., 1991).

To protect themselves from toxic effects of nitric oxide many bacteria possess detoxifying enzymes. Denitrifying organisms produce nitric oxide by the activity of the nitrite reductase but are able to keep the internal nitric oxide concentration low by reducing it to nitrous oxide via the NO-reductase. Thus, these organisms are

strongly dependent on a close functional coupling between both enzymes (Zumft, 1993). Consistent with this finding, loss of NO-reductase is lethal for denitrifying cells of *Pseudomonas stutzeri* (Braun and Zumft, 1991). Other organisms, for example *Pseudomonas* strain PS88, which do not possess the ability to denitrify, are able to detoxify nitric oxide by means of oxidative processes that convert it to nitrate (Baumgärtner et al., 1996; Hausladen et al., 1996; Koschorreck et al., 1996).

For ammonia-oxidizing bacteria under oxic conditions, NO is also toxic but only in the absence of ammonia (E. Bock, unpublished observation). If ammonia is present, NO and/or NO_2 are even essential for aerobic ammonia oxidation. Therefore, the removal of nitric oxide (NO) from cultures of *Nitrosomonas eutropha* by intensive aeration leads to inhibition of ammonia oxidation. This phenomenon has implications on batch-cultivation of ammonia oxidizer s in the laboratory (Zart and Bock, 1998). Usually, it is necessary to avoid intensive aeration or stirring during the first days of incubation, otherwise, the cells will grow very slowly or even not at all. It was possible to achieve recovery of ammonia oxidation by adding nitric oxide to the air supply. The grade of recovery was dependent on the concentration of nitric oxide supplied (Zart et al., 2000). Inhibition of ammonia oxidation was also observed, when nitric oxide was removed from nitrifying cells of *N. eutropha* by means of DMPS (2,3-dimercapto-1-propane-sulfonic acid) in the presence of Fe^{3+} ions. The addition of nitric oxide lowered inhibition by DMPS. In another assay, ammonia oxidation of *Nitrosomonas eutropha* was inhibited by activity of the NO-detoxifying bacterium *Pseudomonas* PS88 (Baumgärtner et al., 1996; Koschorreck et al., 1996) and could be recovered by addition of NO or lowering the activity of the pseudomonad (Zart et al., 2000). The enhancing effect of nitric oxide and nitrogen dioxide on aerobic nitrification and cell growth of *Nitrosomonas eutropha* could also be demonstrated using fermenter cultures (Zart and Bock, 1998). As shown in Fig. 15, the specific activity of ammonia oxidation increased drastically in the presence of nitric oxide and even more if nitrogen dioxide was added instead of nitric oxide. *Nitrosomonas eutropha* was able to tolerate long exposure (up to 30 days) to nitrogen dioxide or nitric oxide at a concentration as high as 50 ppm when ammonia was oxidized. This is unusual since already 1 ppm nitric oxide is inhibitory for various chemo-organotrophic bacteria (Mancinelli and McKay, 1983). This experiment also shows that nitrite is not a potent inhibitor for *N. eutropha* because nitrite accumulated in this experiment to 100 mM. Thus, ammonia oxidation in

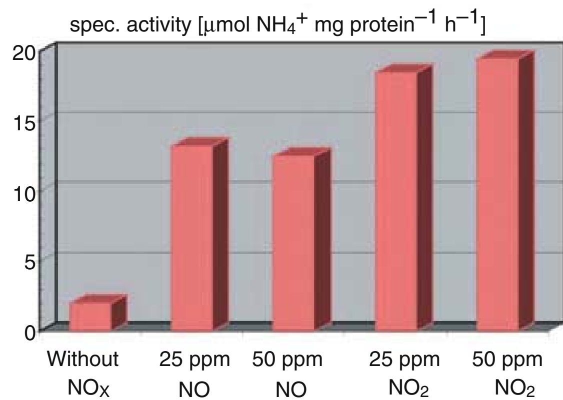

Fig. 15. Increase in specific activity of ammonia oxidation in fermenter cultures of *Nitrosomonas eutropha* upon addition of nitric oxide or nitrogen dioxide to the air supply.

N. eutropha was obviously not inhibited by nitrite accumulation as described for *N. europaea* (Anthonisen et al., 1976; Wullenweber et al., 1978; Drozd, 1980).

The increase of nitrification rates upon nitrogen dioxide or nitric oxide addition was partly due to a significant increase of cell density. In the presence of 50 ppm of nitrogen dioxide, it was possible to obtain up to 2×10^{10} cells ml^{-1} of *N. eutropha* (Zart and Bock, 1998), a cell density of ammonia oxidizer s, which to our knowledge has never been reported before. Generally, in batch cultures of different Nitrosomonas strains, a cell density of about 2×10^8 cells ml^{-1} is rarely exceeded (Engel and Alexander, 1958; Prosser, 1989). In continuous cultures of *N. europaea* with complete biomass retention, Tappe et al. (1996) obtained about 5×10^9 cells ml^{-1}. But it is not clear so far, how nitric oxide and nitrogen dioxide affect the maximum cell density of these organisms.

Beyond this, nitric oxide and nitrogen dioxide had an enhancing effect on the increase of cell number of *Nitrosomonas eutropha* (Zart and Bock, 1998). The specific growth rate (measured as increase in protein) slightly increased upon addition of nitrogen dioxide, but the fission rate increased in a much stronger way. Thus, it is obvious that cell growth was uncoupled from protein increase. Consequently, the cells were depleted of protein when growing in the presence of nitrogen dioxide. This is shown in Fig. 16 where the alteration of cell morphology of *Nitrosomonas eutropha* grown in presence of 50 ppm of nitrogen dioxide is depicted for a period of four weeks. Most striking is the reduction of cell material and the increase of electron dense inclusion bodies. These inclusion bodies were storage material and resembled glycogen-like particles of *Nitrospina gracilis* (Watson and Waterbury,

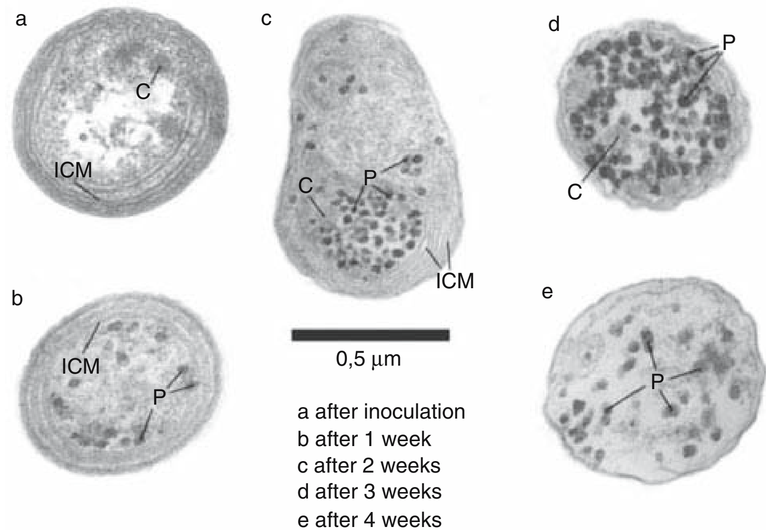

Fig. 16. Electron micrograph of ultrathin sections of cells of *Nitrosomonas eutropha* showing the morphological alteration of cells grown in a fermenter aerated with 50 ppm NO_2. The cells were harvested from the reactor after inoculation (a) and for one (b), two (c), three (d), and four weeks (e) of incubation. ICM = intracytoplasmic membranes, C = carboxysome, and P = unknown particles/ electron dense inclusion bodies.

1971b) and *Nitrosolobus multiformis* (Watson et al., 1971c). Surprisingly, reduction of the protein content per cell was accompanied by increased specific activity of ammonia oxidation.

Although nitrification and cell growth of ammonia oxidizer s were enhanced by adding nitric oxide or nitrogen dioxide to the air supply of the cultures, the cell yield (cell protein produced per mol of ammonia oxidized) and the energy efficiency slightly decreased. This finding might be due to the aerobic production of N_2 induced by the addition of NO_2 (Zart and Bock, 1998). More than 50% of the ammonia was oxidized to dinitrogen (N_2) and traces of nitrous oxide (N_2O) by *Nitrosomonas eutropha*. Increasing amounts of supplementary nitrogen dioxide resulted in increasing nitrogen losses (Zart and Bock, 1998). Previously, significant nitrogen losses were only obtained with extremely oxygen-limited cultures of ammonia-oxidizing bacteria (Bock et al., 1995; Zart et al., 1996).

Recently, it could be demonstrated that the addition of NO_2 to cells of *Nitrosomonas eutropha* grown first under anoxic conditions with hydrogen as electron donor and nitrite as electron acceptor (Schmidt and Bock, 1997) and then shifted to oxic conditions significantly reduced the lag for the initiation of ammonia oxidation (Schmidt et al., 2001b).

Formation of nitric oxide was up to now interpreted as formation of a by-product of ammonia oxidation without significance for the metabolism of ammonia oxidizer s. Inhibition of ammonia oxidation of *Nitrosomonas eutropha* upon withdrawal of nitric oxide from the culture medium indicates that the production of nitric oxide by ammonia oxidizer s seems to be not the formation of a “waste compound” but rather the provision of an important agent for the oxidation of ammonia (Zart et al., 1999). However, nitrogen dioxide rather than nitric oxide could represent the decisive agent, where the latter is acting as precursor for nitrogen dioxide. This hypothesis is based on reports of Schmidt and Bock (Schmidt and Bock, 1997; Schmidt and Bock, 1998) who described anaerobic oxidation of ammonia by *Nitrosomonas eutropha* using nitrogen dioxide as an oxygen donor in the AMO reaction. It seems not unlikely that nitrogen dioxide might be involved in the conversion of ammonia to hydroxylamine under oxic conditions as well. In such a case, nitrogen dioxide might act as cosubstrate for the AMO reaction. But since atmospheric nitrogen dioxide concentration hardly exceeds 800 ppb (Galbally and Roy, 1983; Baumgärtner, 1991), the cells would not be able to cover their requirements by consuming it just from the atmosphere. They might rather produce nitric oxide, which can be oxidized chemically to nitrogen dioxide with dioxygen (Bodenstein, 1918). Although the latter reaction proceeds predominantly in the gas phase (Ford et al., 1993; Wink et al., 1993), nitrogen dioxide-consuming reactions (Lewis and Deen, 1994) and low concentrations of nitric oxide in the liquid (Pires et al., 1994) can alter the development of the aqueous reaction, so that nitrogen dioxide might be produced in biological systems by oxidation of nitric oxide as it is in the gas phase (Huie, 1994).

Considering the finding of Dua et al. (1979) that up to 97% of the oxygen of hydroxylamine originates from molecular oxygen, it is important to note that oxidation of ammonia with nitrogen

dioxide leads to the formation of hydroxylamine and nitric oxide (Schmidt and Bock, 1997). Under oxic conditions, the latter might be reoxidized with dioxygen to form nitrogen dioxide, which would again be available for the oxidation of ammonia by the AMO. Thus, molecular oxygen would not react directly with ammonia but is hypothetically mediated by nitric oxide / nitrogen dioxide. Consequently, it is not necessary to provide nitric oxide or nitrogen dioxide and ammonia in the same ratio since the nitrogenous oxides are permanently recycled. In Fig. 17, a hypothetical model of this NO_x-cycle is depicted which refers to the three-stage catalytic cycle of the tyrosinase reaction (Shears and Wood, 1985). The AMO can have three oxidation states (Shears and Wood, 1985; Bedard and Knowles, 1989; Keener and Arp, 1993). As already mentioned, copper is a constituent of the enzyme and NO/N_2O_4 is involved in ammonia oxidation. Therefore it can be speculated that NO is a cofactor of the AMO. In accordance with Zart and Bock (1998), enzyme-bound N_2O_4 is the final cosubstrate for oxidizing ammonia to hydroxylamine. Dinitrogen tetroxide (N_2O_4) is formed from NO by oxidation with molecular oxygen. The AMO consists of 3 stages: 1) the deoxy-form (reduced), 2) the oxy-form (oxidized), and 3) the metoxy-form (oxidized). The first stage is oxygen-sensitive, the second and the third one are oxygen-stable. The oxygen sensitivity of the deoxy-form is caused by an excess of electrons that might lead to the formation of oxygen radicals, which directly or indirectly react with NO, forming peroxy nitrite (OONO). This compound is toxic and destroys the AMO. This working

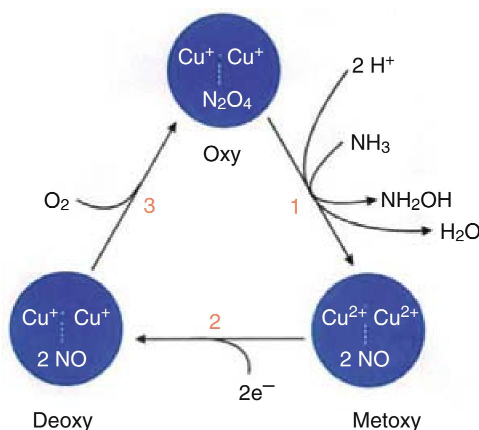

Fig. 17. Hypothetical model of an NO_x-mediated three-stage cycle driving the oxidation of ammonia to hydroxylamine in ammonia-oxidizing bacteria. This cycle does not contribute to the release of NO during aerobic ammonia oxidation (Stüven and Bock, 2001), which is probably caused by chemodenitrification of nitrite at the hydroxylamine oxidoreductase (HAO).

model is in accordance with the observation that purified AMO can oxidize ammonia to hydroxylamine with NADH (H^+) as electron donor under anoxic conditions with N_2O_4 as oxidant. Oxygen was shown to be inhibitory (E. Bock and C. Pinck, unpublished data). Copper in the active center might be responsible for noncovalently binding the nitrogen oxides in form of nitrosyl-complexes. As described, oxygen is reacting with NO of the deoxy-form (Fig. 17/3), transforming NO to N_2O_4 (oxy-form). The copper ions are oxidized from Cu^+ to Cu^{2+}. The N_2O_4-molecule of the oxy-form is the final oxygen-donor for ammonia oxidation to hydroxylamine. By this reaction, the enzyme is transferred to the metoxy-form (Fig. 17/1), which is subsequently converted by reduction to the deoxy-form, thereby completing the cycle (Fig. 17/2). This model also provides an explanation for the inhibition of ammonia oxidation after withdrawal of nitric oxide. As demonstrated recently acetylen inhibits the aerobic and not the anaerobic ammonia oxidation. Therefore acetylene is assumed to bind to the deoxyform of the AMO (Schmidt et al., 2001a). Additionally, the oxidation of ammonia with nitrogen dioxide /dinitrogen tetroxide ($DG0' = -140$ kJ $\cdot$ mol $^{-1}$) is thermodynamically more favorable than the "classical" oxidation of ammonia with dioxygen ($DG0' = -120$ kJ $\cdot$mol $^{-1}$).

Anaerobic Ammonia Oxidation Catalyzed by *Nitrosomonas eutropha*

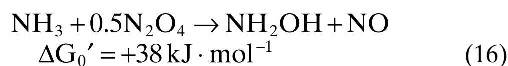
Anaerobic Ammonia Oxidation with Nitrogen dioxide In the absence of dissolved oxygen, ammonia oxidation and cell growth has been observed recently in cultures of *Nitrosomonas eutropha* (Schmidt and Bock, 1997). Those cells were able to replace molecular oxygen by nitrogen dioxide or dinitrogen tetroxide, respectively. Hydroxylamine and nitric oxide were formed in this reaction. While nitric oxide was not further metabolized, hydroxylamine was oxidized to nitrite. However, anoxic ammonia oxidation with nitrogen dioxide was more than tenfold slower than ammonia oxidation with oxygen as electron acceptor.

The activity of ammonia oxidizer s decreases when the oxygen concentration in the medium decreases too. This can be put down to the fact that the oxidant for ammonia oxidation was limited. Therefore, the organisms need another oxidant for anaerobic ammonia oxidation. For a long time, nitrite was discussed as a suitable oxidant (Broda, 1977), but as shown in numerous experiments, it could not serve as electron acceptor for anaerobic ammonia oxidation and cell growth in *Nitrosomonas* (Bock et al., 1995; Zart et al., 1996).

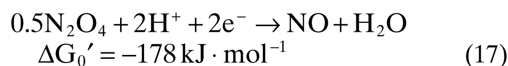
ANAEROBIC AMMONIA OXIDATION IN CELL-FREE EXTRACTS To reveal the stoichiometry of anaerobic ammonia oxidation, consumption and production of ammonia, nitrogen dioxide, nitric oxide, nitrite, nitrous oxide, and dinitrogen were analyzed in cell-free extracts of *N. eutropha*. Many attempts were performed to prepare active cell-free extracts of *Nitrosomonas europaea* under oxic conditions (Suzuki et al., 1970; Suzuki et al., 1981b). One of the most serious problems associated with the characterization of the AMO in extracts has been the instability of the enzyme activity (Suzuki et al., 1974; Suzuki et al., 1981b; Ensign et al., 1993) caused by the sensitivity of reduced AMO to oxygen (C. Pinck and E. Bock, unpublished observation). In contrast, the ammonia-oxidizing enzyme system is stable and active in cell-free extracts under anoxic conditions and thus allowed to characterize the anaerobic ammonia oxidation (Schmidt and Bock, 1998). In a helium atmosphere supplied with 25 ppm of nitrogen dioxide, ammonia and nitrogen dioxide were consumed in a ratio of approximately 1:2 by cell-free extracts of Nitrosomonas eutropha. The production of nitric oxide was closely related to the consumption of nitrogen dioxide. Nitric oxide was released in amounts nearly equimolar to the consumption of nitrogen dioxide. The production rate of nitrite was significantly lower than the oxidation rate of ammonia. It is assumed that nitrogen dioxide and nitrite served as acceptors for electrons derived from ammonia oxidation. Approximately 22% of the nitrite was converted into gaseous nitrogen compounds (nitrogen-loss). The main products of denitrification were dinitrogen and traces of nitrous oxide. During the anaerobic ammonia oxidation, hydroxylamine concentrations between 30 and 40 μM were measured. In control experiments with cell-free extracts of *Ralstonia eutropha* (formerly *Alcaligenes eutrophus*), *Enterobacter aerogenes* and *Pseudonocardia nitrificans*, neither ammonia oxidation nor nitrogen dioxide consumption could be detected. In sterile control experiments, there was again no ammonia consumption. In addition, no formation of nitric oxide, dinitrogen or nitrous oxide was measurable.

At 25°C and atmospheric pressure, the ratio of nitrogen dioxide (NO_2) to its dimer dinitrogen tetroxide (N_2O_4) is 30:70. To decide whether nitrogen dioxide or dinitrogen tetroxide is the electron acceptor for anaerobic ammonia oxidation, experiments were performed at a temperature of 4°C, conditions under which the dinitrogen tetroxide concentration is almost 100%. Experiments were performed with crude cell-free extracts in the presence of hydrazine as specific inhibitor for HAO. Although the specific activity of the cell-free extracts decreased significantly at 4°C, anaerobic ammonia oxidation could be detected with a stoichiometry of the converted nitrogen-compounds comparable to those observed at 25°C. These results indicate that dinitrogen tetroxide can be used as electron acceptor for anaerobic ammonia oxidation.

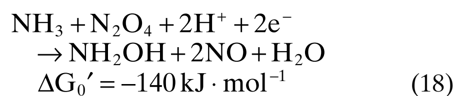
Based on the observed correlations between ammonia and nitrogen dioxide/dinitrogen tetroxide consumption and nitric oxide and hydroxylamine production, the following equations are proposed. Equations 16 and 17 describe the two half-reactions of the anaerobic ammonia oxidation. The total AMO reaction is presented in equation 18:



$$NH_3 + 0.5N_2O_4 \rightarrow NH_2OH + NO \quad \Delta G_0{}' = +38\,kJ \cdot mol^{-1} \tag{16}$$

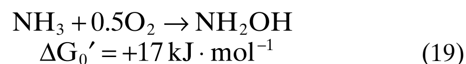


$$0.5N_2O_4 + 2H^+ + 2e^- \rightarrow NO + H_2O \quad \Delta G_0{}' = -178\,kJ \cdot mol^{-1} \tag{17}$$

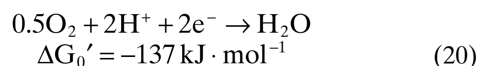


$$NH_3 + N_2O_4 + 2H^+ + 2e^- \rightarrow NH_2OH + 2NO + H_2O \quad \Delta G_0{}' = -140\,kJ \cdot mol^{-1} \tag{18}$$

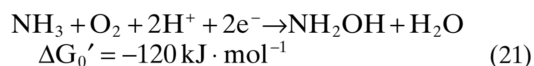
For comparison, the aerobic ammonia oxidation to hydroxylamine is given in equations 19 to 21.



$$NH_3 + 0.5O_2 \rightarrow NH_2OH \quad \Delta G_0{}' = +17\,kJ \cdot mol^{-1} \tag{19}$$



$$0.5O_2 + 2H^+ + 2e^- \rightarrow H_2O \quad \Delta G_0{}' = -137\,kJ \cdot mol^{-1} \tag{20}$$



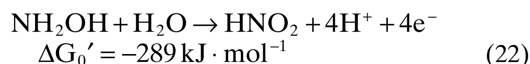
$$NH_3 + O_2 + 2H^+ + 2e^- \rightarrow NH_2OH + H_2O \quad \Delta G_0{}' = -120\,kJ \cdot mol^{-1} \tag{21}$$

The $\delta G_0{}'$ values of the reactions (17 and 20) were calculated under the assumption that the reducing equivalents for the AMO are energetically near the ubiquinone level (+110 mV). Equations (16) to (21) indicate that there are only a few differences between the anaerobic and the aerobic ammonia oxidation of *Nitrosomonas eutropha*. Instead of molecular oxygen in the course of aerobic ammonia oxidation, dinitrogen tetroxide was used as electron acceptor and nitric oxide, an additional product, was released.

It appears likely that the same enzyme is responsible for both the aerobic and the anaerobic ammonia oxidation, since 1) hydroxylamine is an intermediate of both reactions, 2) acetylene inhibits the aerobic as well as the anaerobic ammonia oxidation, and 3) anaerobic ammonia oxidation starts immediately after transferring cell-free extracts to anoxic conditions.

For the oxidation of hydroxylamine under oxic conditions, no oxygen is needed. Therefore, it can be assumed that under anoxic conditions,

hydroxylamine was oxidized according to reaction 22 as well.



$$NH_2OH + H_2O \rightarrow HNO_2 + 4H^+ + 4e^- \quad \Delta G_0{}' = -289\,kJ \cdot mol^{-1} \qquad (22)$$

Increasing pool sizes of intracellular ATP and NADH indicated energy conservation in the absence of oxygen but presence of nitrogen dioxide (Schmidt and Bock, 1998). Under these conditions, reducing equivalents were also used for the reduction of carbon dioxide, resulting in cell growth and excretion of extracellular organic compounds like glycerol into the medium.

The relevance of the anaerobic ammonia oxidation with NO_2/N_2O_4 as oxidant for microbial ecology cannot be assessed at present. The nitrogen dioxide concentration of maximal 400–800 ppb in the atmosphere (Crutzen, 1979) should be too low to support anaerobic ammonia oxidation. However, this metabolism might occur in oxygen-limited zones, where locally restricted higher nitrogen dioxide concentrations might exist because of the reaction of molecular oxygen and nitric oxide (Nielsen, 1992).

Anaerobic Ammonium Oxidation Catalyzed by Deep Branching Planctomycetes

Recently, a novel organism was discovered which is capable of catalyzing the anaerobic oxidation of ammonium, with nitrite as electron acceptor (Strous et al., 1999). This organism, which up to now cannot be obtained in pure culture, was enriched from a denitrifying plant reactor where the anaerobic ammonium oxidation process was observed for the first time (Mulder et al., 1995; van de Graaf et al., 1995). By comparative 16S rDNA sequence analysis, the organism was identified as a novel, deep-branching member of the order Planctomycetales and the name "*Candidatus* Brocadia annamoxidans" was proposed (Jetten et al., 2001). The 16S rDNA-based molecular diversity surveys and subsequent fluorescence in situ hybridization analyses of several reactors and wastewater treatment plants with anaerobic ammonia-oxidizing activity demonstrated that at least two different genera that form a monophyletic lineage within the Planctomycetales (Fig. 18) can catalyze this process (Schmid et al., 2000; Schmid et al., 2001). In most plants analyzed so far, "*Candidatus* Kuenenia stuttgartiensis" and not "*Candidatus* Brocadia annamoxidans" is the most abundant anaerobic ammonium oxidizer (Schmid et al., 2000; Jetten et al., 2001).

"*Candidatus* Brocadia annamoxidans" is a chemolithoautotrophic organism with a very low growth rate ($0.003\ h^{-1}$) and a conspicuous ultrastructure. It contains inside the cytoplasm so-called "anammoxosomes," membrane-bounded compartments that make up 30–60% of the cell volume and harbor an unusual hydroxylamine oxidoreductase (Jetten et al., 2001). The metabolic pathway of the so-called "ANAMMOX" process proposed for "*Candidatus* Brocadia annamoxidans" differs significantly from the known pathway of aerobic, lithotrophic ammonia oxidizer s, since ammonium is supposed to be oxidized with hydroxylamine to form hydrazine (N_2H_4), which is subsequently oxidized to dinitrogen, the main end product of the ANAMMOX process. The four reducing equivalents generated in this oxidation step are used for the initial reduction of nitrite to hydroxylamine (van de Graaf et al., 1997). Preliminary data suggest that the unusual hydroxylamine oxidoreductase of "*Candidatus* Brocadia annamoxidans" (Jetten et al., 2001), which has a smaller molecular mass than the respective enzyme of *Nitrosomonas* and contains several *c*-type cytochrome s, catalyzes the oxidation of hydrazine to dinitrogen. Anaerobic ammonia oxidation occurs only if the cell density of "*Candidatus* Brocadia annamoxidans" is higher than 10^{10} to 10^{11} cells ml^{-1}. The reason for this cell density dependent activity is not clear so far. The following equations (23–26) summarize the proposed pathway. The overall reaction resembles a process already proposed in 1977 based on theoretical considerations (Broda, 1977).

$$HNO_2 + 4[H] \rightarrow NH_2OH + H_2O \qquad (23)$$

$$NH_2OH + NH_3 \rightarrow N_2H_4 + H_2O \qquad (24)$$

$$N_2H_4 \rightarrow N_2 + 4[H] \qquad (25)$$

$$HNO_2 + NH_3 \rightarrow N_2 + 2H_2O \qquad (26)$$

From equation 26, it is obvious that the overall reaction is balanced. No reducing power is gained which is essential for the fixation of carbon dioxide by autotroph ic organisms. To gain these reducing equivalents, the cells are required to oxidize nitrite to nitrate. Therefore, the amount of nitrite consumed is about 20% higher than one could expect from equation 26, and nitrate is additionally formed (van de Graaf et al., 1996):

$$HNO_2 + H_2O + NAD \rightarrow HNO_3 + NADH_2 \qquad (27)$$

The metabolic activity of "*Candidatus* Brocadia annamoxidans" is strongly inhibited by oxygen, phosphate, acetylene or shock loading. In addition, organic electron donors or high concentrations of nitrite are inhibitory (van de Graaf et al., 1996).

"*Candidatus* Brocadia annamoxidans" oxidizes ammonium anaerobically about 50-fold faster than *Nitrosomonas eutropha* with 25 ppm

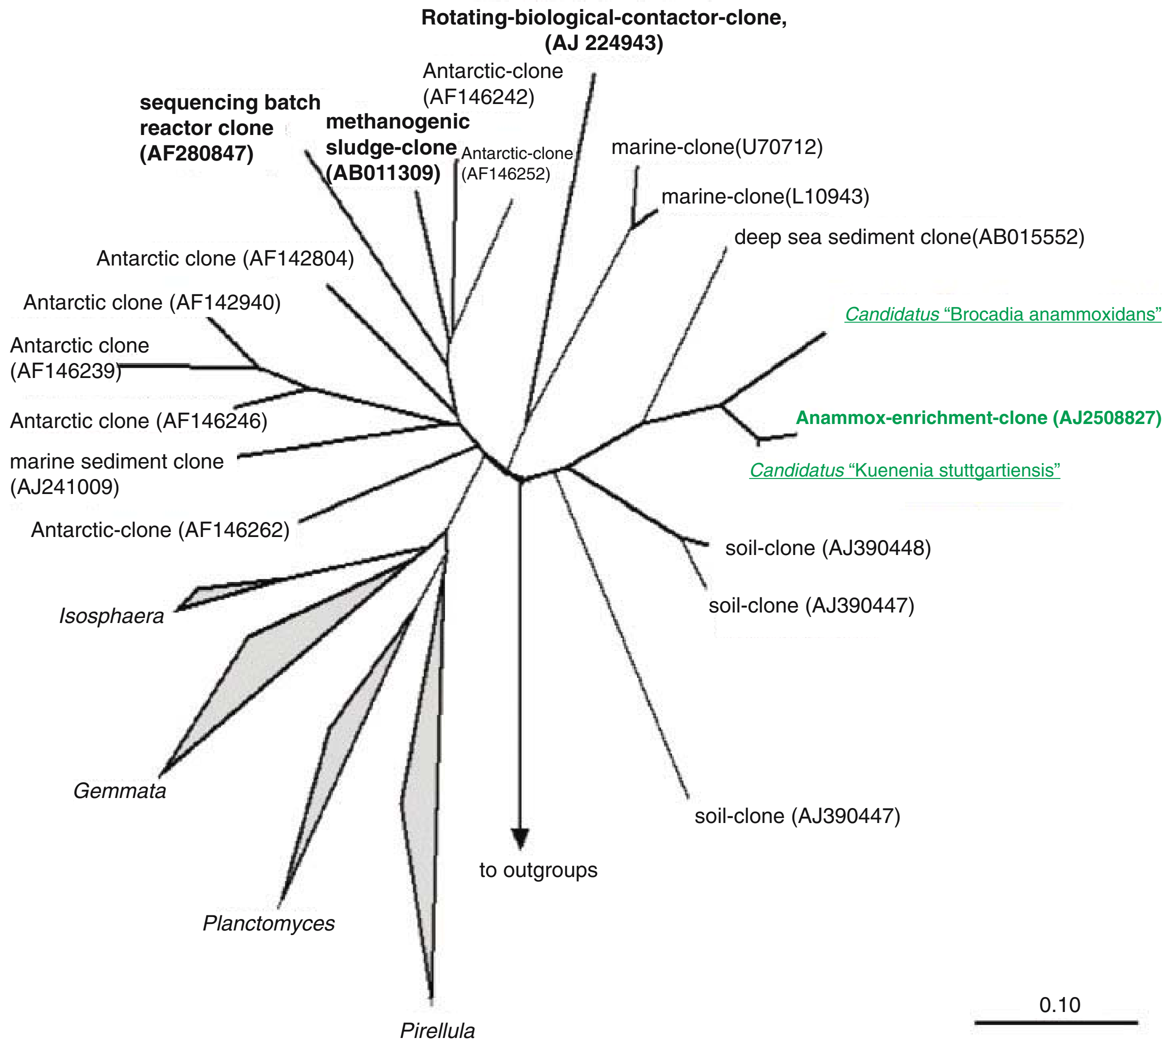


Fig. 18. 16S rDNA tree of the Planctomycetales. Anaerobic ammonium oxidizers are labeled green. The scale bar represents 10% estimated sequence divergence. Modified from Schmid et al. (2001).

of nitrogen dioxide in the absence of oxygen (Anaerobic ammonia oxidation catalyzed by Nitrosomonas eutropha). Since ANAMMOX was shown to exhibit rather efficient ammonium elimination rates of up to 3 kg of NH_4^+ m^{-3} day^{-1} (van de Graaf et al., 1996), it is suitable for the treatment of wastewater containing much ammonium and little organic chemical oxygen demand (COD). For such wastewater, it has been calculated that the replacement of the conventional nitrogen elimination steps by ANAMMOX would result in a reduction of the operational costs of up to 90% (Jetten et al., 2001). However, the presence of anaerobic ammonium oxidizers in addition to ammonium nitrite is required in the wastewater. Therefore, partial conventional nitrification, converting approximately half of the ammonium to nitrite, and ANAMMOX have been combined for efficient nitrogen removal from high-strength organic wastewater (summarized in Jetten et al., 2001). It should however be noted that very long lag-phases are required for obtaining ANAMMOX activity in such plants (Mulder et al., 1995; Jetten et al., 1997), which might be a disadvantage for applications.

CHAPTER 1.17

The H_2-Metabolizing Prokaryotes

EDWARD SCHWARTZ AND BÄRBEL FRIEDRICH

Introduction

During the era of prebiotic evolution, which culminated in the appearance of cellular life forms, the earth had a reducing atmosphere. Fueled by volcanic activity and by magmatic outgassing, levels of atmospheric molecular hydrogen (H_2) may have been as high as 1% (Walker, 1977; Kasting, 1993). Various evolutionary scenarios envisage primeval life forms with H_2-based metabolism, e.g., ur-methanogens or ur-sulfate reducers (Stetter, 1992; Wächtershäuser, 1992; Edwards, 1998). With the advent of oxygenic photosynthesis (a process which may have originated as early as 3.5 billion years ago), oxygen began accumulating in the atmosphere and hydrogen levels decreased (Walker, 1977; Hayes, 1983; Blankenship, 1992; Kasting et al., 1992; Nisbet and Fowler, 1999). Concomitantly, strictly H_2-dependent organisms retreated to restricted habitats. Nevertheless, H_2 continues to be an important and widespread metabolite in both the archaeal and bacterial realms of the microbial world, in oxic as well as in anoxic habitats. The physiological role of H_2 in microbes is dual: Firstly, H_2 is a growth substrate, i.e., a source of energy and reductant. Prokaryotes of different metabolic types, such as methanogens, anoxygenic phototrophs, and aerobic knallgas bacteria, exploit H_2. Secondly, H_2 production is a means of dispersing excess reductant from fermentative metabolism. Hydrogen is among the fermentation products of both facultative fermenters, such as *Escherichia coli*, and obligate fermenters such as *Clostridium pasteurianum*.

This chapter surveys the H_2-metabolizing prokaryotes. It covers both H_2 evolution and H_2 consumption in archaea and bacteria. A glance at the list of H_2-metabolizing prokaryotes (Tables 1 and 2) will convince the reader that H_2 metabolism is not limited to specialized microbes grouped in a few taxonomic units. The comprehensive approach chosen here cuts across the boundaries of the physiological groups described in classical microbiology textbooks. This is necessary since the physiology of many H_2 metabolizers can only be explained in the context of syntrophic associations.

The common denominator of the disparate taxonomic and physiological groups treated here is hydrogenase, the enzyme responsible for reversibly catalyzing the reaction:

$$H_2 \rightleftharpoons 2H^+ + 2e^- \quad (1)$$

It is now agreed that presently known hydrogenases belong to three groups of independent phylogenetic origin. These groups are defined on the basis of their metal content: [FeFe] hydrogenases, [NiFe] hydrogenases (including [NiFe(Se)] hydrogenases), and [Fe] hydrogenases (formerly referred to as “metal-free hydrogenases”). Thus, hydrogenases constitute an example of convergent evolution. The [FeFe] and [NiFe] hydrogenases are particularly interesting in this context. Although the representatives of these two groups are not related, both the architectures of their active sites and the mechanisms of the chemical reaction catalyzed by them reveal striking similarities.

The past decade has seen rapid advances in our knowledge of the genetic basis of H_2 metabolism on the one hand and of the structure and catalytic mechanism of hydrogenases on the other. Accordingly, the major part of this chapter is devoted to an overview of these genetic, biochemical and spectroscopic studies. Hydrogen evolution and consumption is not catalyzed by hydrogenases alone. Nitrogenase, the enzyme which catalyzes the production of NH_3 from atmospheric dinitrogen, produces H_2 as a byproduct of N_2 fixation. Nitrogen-fixing prokaryotes are mentioned here because of their important contribution to the global H_2 flux and because N_2 reduction is an important physiological context of hydrogenase. An in-depth treatment of this subject is, however, beyond the scope of this article.

Hydrogenases are also found in eukaryotes. The hydrogenases of the chloroplasts of green algae, for instance, have attracted much attention in recent years (Happe et al., 1994; Florin et al., 2001). Furthermore, some eukaryotic microbes possess organelles called

"hydrogenosomes" which contain hydrogenases and engage in H_2 metabolism (Müller, 1993). Since organelles are descendents of prokaryotic cells, these organisms will be mentioned briefly but not treated in depth.

A number of review articles have been published on various aspects of H_2 metabolism and hydrogenases (Adams, 1990; Wu and Mandrand, 1993; Sasikala et al., 1993; Albracht, 1994; Vignais and Toussaint, 1994; Fontecilla-Camps, 1996; Maier and Böck, 1996; Frey, 1998; Nandi and Sengupta, 1998; Peters, 1999; Casalot and Rousset, 2001; Vignais et al., 2001; Horner et al., 2002). The reader is also referred to reviews on various groups of H_2-metabolizing prokaryotes including sulfate reducers (Fauque et al., 1988; Voordouw, 1995), aerobic, H_2-oxidizing bacteria (Aragno and Schlegel, 1992; Friedrich and Schwartz, 1993), methanogens (Sorgenfrei et al., 1997; Thauer, 1998), homoacetogens (Drake, 1994) and cyanobacteria (Tamagnini et al., 2002).

Ecology

The term "H_2-metabolizing prokaryotes" lumps together many taxonomically and physiologically unrelated organisms. Accordingly, the representatives of this group are found in a range of very different habitats. This section does not

attempt to describe exhaustively the biotopes of H_2-metabolizing prokaryotes. The emphasis, rather, is on the interactions between H_2-producers and H_2-consumers, which are important for global geochemical cycles.

The Global H_2 Budget

Before considering the ecophysiology of the various groups of H_2-metabolizing prokaryotes and the microbial communities they belong to, it is appropriate to briefly discuss the global budget of atmospheric H_2. Three types of processes impact the pool of atmospheric H_2: anthropogenic, biogenic and geochemical. As will be discussed later, substantial amounts of H_2 are turned over within microbial ecosystems without, however, affecting the atmospheric H_2 budget. Conrad has summarized the numerous studies on atmospheric H_2 (Conrad, 1988). Anthropogenic activities are a major source of atmospheric H_2. Equally important is the production of H_2 by the oxidation of atmospheric methane (CH_4) and nonmethane hydrocarbons. This entails chemical reactions with photochemically produced hydroxyl radical. Photochemical evolution of H_2 accounts for 30–40% of the total production. In contrast, the total biospheric emission, i.e., the contribution of all ocean, lake and soil biota to the global H_2 pool is only 7–11%. Several studies have addressed the sources of biogenic H_2 emission breaking it down into its marine, lacustrine and terrestrial components. The major part of the euphotic surface layer of the world's oceans are supersaturated for H_2. Thus, a net emission of H_2 from the surface water to the atmosphere must take place. While experimental data are still lacking, the main source of this H_2 is probably the N_2-fixing cyanobacteria and prochlorophytes. The same probably holds true for H_2 production in the oxic layers of freshwater lakes. The H_2 concentration of the epilimnion reaches levels of 0.5–50 nM (Schropp et al., 1987). Studies have shown that the H_2 concentration of lake water correlates with cell counts of cyanobacteria on the one hand and with N_2 fixation rates on the other (Conrad et al., 1983a; Schmidt and Conrad, 1993; Schütz et al., 1988). The results refute the older notion that H_2 arises by fermentation in the anoxic sediment and diffuses up into the oxic zone. Almost all of the H_2 evolved in anoxic sediments is also consumed there.

The contribution of soil to the atmospheric H_2 pool is more complex. Most soils do not emit H_2 but, on the contrary, consume it (Seiler, 1978; Conrad and Seiler, 1981; Conrad and Seiler, 1985). An exception to this are soils in areas where leguminous plants grow. Symbiotic rhizobia in root nodules produce H_2 in conjunction with N_2 fixation. An estimated 1 million tons of H_2 is produced by nodule bacteria annually (Evans et al., 1987). During the vegetation period, the rates of H_2 production by root nodules are high enough to lead to a net increase in the H_2 concentration in the soil. A portion of this H_2 escapes to the atmosphere. Thus, in all three major environmental zones, release of H_2 into the atmosphere is a result of N_2 fixation. The production of H_2 by microbial fermentation processes in the gut of termites may be an exception to this generalization. It has been estimated that as much as 10^{14} g of H_2 could be released into the atmosphere annually by these microbes (Zimmerman et al., 1982). Experimental data on this question are inconclusive. Laboratory experiments with termites pointed to a significant release (Zimmerman et al., 1982). On the other hand, measurements made in the field on actual termite mounds showed that there was no measurable release of H_2 at all (cited by Conrad [1988] as W. Seiler and R. Conrad, unpublished observation). On the consumption side of the balance sheet, chemical processes in the atmosphere are responsible for only a small fraction of H_2 decomposition. By far the most important global sink for H_2 is the soil, which accounts for over 90% of the total global consumption. Remarkably, consumption of atmospheric H_2 in soils may not be directly attributable to the activity of microorganisms. Rather, it appears that H_2-oxidizing activity associated with soil particles is the basis of H_2 consumption by soil (reviewed by Conrad, 1996). Various lines of evidence support this conclusion: 1) For an organism to utilize atmospheric H_2, it must have a K_m for H_2 in the range of 5–80 nM (Conrad, 1984). Several characterized strains of chemolithotrophic bacteria have K_m values for H_2 above 0.5 μM. 2) Suspensions of H_2-oxidizing chemolithotrophs provided with a mixture of H_2 and air as growth substrate consume H_2 down to a certain concentration. After this point, no more H_2 is utilized and growth ceases. The critical concentration for H_2 uptake is known as the threshold value. The threshold for H_2 utilization for various H_2-oxidizing laboratory strains is significantly higher than the concentration of H_2 in the atmosphere (Conrad and Seiler, 1979; Conrad et al., 1983b; Schuler and Conrad, 1990). 3) The H_2-oxidizing activity of the soil is destroyed by boiling and autoclaving and has an optimum of 25–40°C (Seiler, 1978; Fallon, 1982; Schuler and Conrad, 1991a). 4) The H_2-oxidizing activity associated with size-fractioned soil particles is not correlated with parameters indicative of microbial biomass (ATP content and microscopic cell counts; Häring et al., 1994). Taken together, these results suggest that hydrogenase enzymes released from lysed bacteria and immobilized on

soil particles or persisting in dead cells are responsible for oxidation of atmospheric H_2 in the soil.

The above findings are paradoxical, since H_2-oxidizing chemolithoautotrophs are readily isolated from a variety of soil biotopes. Why are chemolithoautotrophs widespread in soils if they are not able to metabolize atmospheric H_2? The following aspects are important in this context and may be at least part of the explanation. 1) Most of the classical, mesophilic H_2-oxidizers (knallgas bacteria) isolated from soils are facultative chemolithoautotrophs that also thrive organotrophically (Aragno and Schlegel, 1992). Such organisms are predestined to utilize H_2 that is transiently available in biologically relevant concentrations. It is well known that soils rapidly become anoxic when they are waterlogged. This can lead to a transient production of H_2 when soil microbes shift to fermentation. 2) Various soil microenvironments, e.g., the vicinity of root nodules, may provide high local concentrations of H_2 which could at least transiently support the growth of H_2-oxidizing chemolithotrophs. 3) Syntrophic associations between H_2 producers and H_2 consumers may be a widespread phenomenon. Juxtaposition of individual cells would, in effect, provide the consumer with a high local concentration of H_2. This will be discussed in more detail below.

Habitats of H_2-Evolving Prokaryotes

Anaerobic food chains which degrade organic material via the various fermentation processes outlined above are a major source of H_2 in the biosphere (Fig. 1). Fermenting organisms are limited to anoxic zones rich in organic substance. Marine and lacustrine sediments are the most important biotopes of this sort. These sediments are fed by a constant influx of organic material derived from photosynthetic primary producers and from the ensuing food chains. The upper, oxic layer of the sediment varies in depth both in marine and freshwater sediments. Below this layer is the zone of anoxic decomposition. In this stratum, H_2 is evolved as a product of fermentation. The H_2 produced neither accumulates nor does it escape in significant quantities to the oxic zone. If H_2 were to accumulate, the fermentative metabolic processes would soon come to a halt, since these are inhibited by relatively low concentrations of H_2 in the environment. The inhibitory concentrations vary for the different fermentative reactions, depending on their energetics. Fermentation of fatty acids to acetate, H_2 and CO_2, for instance, is more endergonic than the fermentation of ethanol to acetate and H_2 and the former process ceases at a much lower concentration of external H_2 than the latter (See

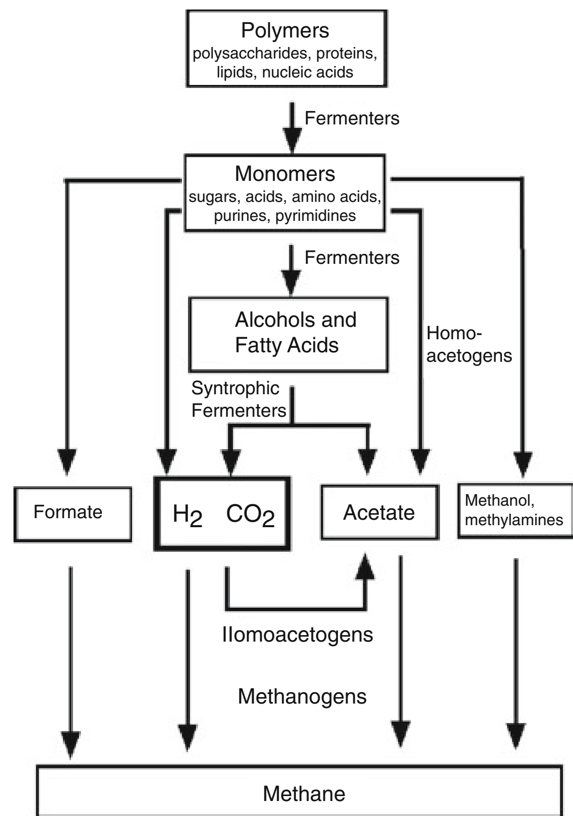

Fig. 1. Schematic overview of the flux of matter in the anaerobic zone of freshwater sediments. The major pathways in the mineralization of organic substance and the microbial groups responsible for them are given (after The Anaerobic Way of Life in this Volume).

Syntrophism among Prokaryotes in this Volume). Studies on the sediment of a eutrophic lake showed that fermentation of butyrate and propionate were inhibited by H_2 concentrations of 100 nM and 20 nM, respectively (Conrad et al., 1986). The concentration of H_2 is kept at a low level, i.e., 5–30 nM in marine sediments and 1–150 nM in lacustrine sediments, due to constant depletion by H_2-consuming organisms (reviewed by Jørgensen, 1989; see also Strayer and Tiedje, 1978; Lovley and Klug, 1982a; Robinson and Tiedje, 1982; Phelps and Zeikus, 1984; Conrad et al., 1985). High turnover rates for H_2 have been measured. In a study on a lake sediment, the turnover time of the pool of free H_2 was estimated to be 2 min (Conrad et al., 1985).

Two minor habitats of fermenting bacteria deserve mention. The stomach of ruminants and the gut of xylophagous arthropods including termites (Breznak, 1982; Zimmerman et al., 1982; Leschine, 1995; Ricke et al., 1996; Flint, 1997). The rumen harbors a rich microbial flora. Among these microorganisms are bacteria such as *Ruminococcus albus* and *Butyrovibrio fibrisol-*

vens which ferment cellulose to organic acids, H_2 and CO_2.

Hydrogen is generated as a byproduct of N_2 fixation in both oxic and anoxic environments. Cyanobacteria and prochlorophytes are probably the most widespread diazotrophs on earth. These organisms inhabit the upper, oxic zones of oceans and lakes. The anoxygenic photosynthetic bacteria, which occupy deeper zones depleted for O_2, also engage in N_2 fixation. These and other diazotrophs contain uptake hydrogenases and, hence, are capable of exploiting at least a part of the H_2 generated by nitrogenase. However, hydrogenase-free strains abound in nature resulting in the liberation of large quantities of H_2. The third important group of diazotrophs are the endosymbiotic rhizobia. The role of these organisms in rhizospheric H_2 production has been mentioned above. A special cyanobacterial habitat is the extensive mats found in coastal areas. The mats consist of a gelatinous mass produced by the microbes. The generation of H_2 leads to the formation of bubbles in this viscous matrix. The mats formed by different microbial communities differ in their consistency. This, in turn, determines whether the H_2 is retained or released into the atmosphere (Hoehler et al., 2001).

Habitats of H_2-Consuming Prokaryotes

Both biogenic and abiogenic H_2 production can support growth of H_2-utilizing prokaryotes. Many H_2-utilizing species profit from fermentative H_2 production in anoxic sediments. The two most important groups of H_2-consumers in such biotopes are the methanogenic archaea and the sulfate-reducing bacteria. It has been known for some time that methanogens and sulfate reducers compete for H_2 (Winfrey and Zeikus, 1977; Winfrey et al., 1977; Abram and Nedwell, 1978; Oremland and Polcin, 1982; Lovley et al., 1982; Lovley and Klug, 1983). Sulfate reducers outcompete the methanogens in the presence of sulfate, because the former have a higher affinity for H_2 and a higher growth yield (Kristjansson et al., 1982; Schönheit et al., 1982). In studies using pure cultures, K_m and Y_{H2} values of 5.0 ± 0.5 μM and 0.2 g protein/mol H_2, respectively, were determined for *Methanospirillum hungatei* JF-1 versus 1.1 ± 0.1 μM and 0.85 g protein/mol H_2, respectively, for *Desulfovibrio* strain G11 (Robinson and Tiedje, 1984). The key factor determining which of the two terminal degradation processes—sulfidogenesis or methanogenesis—prevails in a given habitat is SO_4^{2-} concentration. In anoxic marine sediments, where there is an abundant supply of SO_4^{2-}, sulfate reduction is the dominant process, consuming most of the available H_2 and acetate.

The sulfate level in lakes varies depending on their trophic state, but in general is lower than in seawater. The thickness of the zone of sulfate reduction varies accordingly. In eutrophic lakes the sulfate concentration in the sediment drops of sharply. Here the zone of sulfate reduction is only a few centimeters thick. In lakes with lower nutrient contents the zone of sulfate reduction extends deeper into the sediment (Lovley and Klug, 1983). Competition for H_2 does not mean that sulfate reduction and methanogenesis are mutually exclusive processes. Various methanogens can exploit substrates, e.g. methylamine, that are not utilized by sulfate reducers (Oremland and Polcin, 1982; Winfrey and Ward, 1983). Therefore, the two groups of organisms can coexist in the same biotope, as has been shown for instance for estuarine sediments. According to one estimate based on sediment from an oligotrophic lake, the fraction of the total flux of electrons and carbon routed through sulfate reduction is between 30 and 81% of the total terminal metabolism (Lovley and Klug, 1983).

Sulfate reduction is also an important process in extreme environments, such as the anaerobic sediments of soda lakes. Among the specialized, H_2-utilizing, sulfate-reducing bacteria found in such sediments are the alkaliphilic lithoheterotroph *Desulfonatronovibrio hydrogenovorans* and the alkaliphilic lithoautotroph *Desulfonatronum lacustre* (Zhilina et al., 1997; Pikuta et al., 1998).

The role of soils as habitats for facultative H_2-oxidizing chemolithotrophs has been discussed above. Two niches are especially important in this context: the rhizosphere in the vicinity of nodulated plants, and the interface of anoxic enclaves where H_2 is evolved and can diffuse into the surrounding oxic zone.

A few obligately chemolithoautotrophic bacteria, which oxidize either H_2 or sulfur, have been described. These include both mesophilic and thermophilic forms. The latter are mostly confined to special niches such as hot springs and hydrothermal vents. *Hydrogenobacter thermophilus* and *Hydrogenobacter halophilus* inhabit freshwater and saline hot springs, respectively (Kawasumi et al., 1984; Nishihara et al., 1989; Nishihara et al., 1990). The hyperthermophilic H_2-oxidizing bacterium *Aquifex pyrophilus* grows in hot marine sediments (Huber et al., 1992). Several obligately chemolithotrophic archaea have been identified. *Thermodiscus maritimus* and *Pyrodictium occultum* inhabit submarine solfataric springs (Fischer et al., 1983). Two obligate H_2-oxidizing, sulfate-reducing archaea, *Ignicoccus islandicus* and *Ignicoccus pacificus*, were enriched from hot marine sediments and from the orifice of a deepsea vent, respectively (Huber et al., 2000). These organ-

isms utilize the H_2, CO_2 and sulfate dissolved in the hydrothermal fluid for growth. Thus, they are chemolithoautotrophic primary producers and form the basis of food chains in their respective habitats (Jannasch and Mottl, 1985). The hyperthermophile *Archaeoglobus profundus* is another example of obligate H_2-based lithotrophy (Burggraf et al., 1990b). However, this organism requires organic carbon sources.

Syntrophy and Interspecies H_2 Transfer

Syntrophy is the mutual metabolic dependence of two different types of prokaryotes (Syntrophism among Prokaryotes in this Volume). The first obligately syntrophic relationship involving an exchange of H_2 between the partner organisms was recognized by Bryant. He discovered that the ethanol-degrading "bacterium" *Methanobacillus omelianskii* was in fact a coculture of a so-called "S-organism," which was the actual ethanol-degrader, and a methanogen. The ethanol-degrader was strictly dependent on the methanogen, because the latter consumed H_2, thereby "pulling" the otherwise thermodynamically unfavorable oxidation of ethanol. Wolin reported new examples of microbial H_2 exchange and introduced the phrase "interspecies hydrogen transfer" to describe this general phenomenon (Scheifinger et al., 1975; Wolin, 1976, 1982). Based on quantitative studies on freshwater sediments, Conrad proposed the juxtaposition of H_2-producers and H_2-consumers (Conrad et al., 1985). He suggested that the two types of cells are in close, physical contact in particles or flocs. As a result of juxtaposition, a major fraction of the H_2 produced would never enter the pool of dissolved H_2 but rather be transferred directly from cell to cell. This would explain the discrepancy between turnover rates in the extracellular H_2 pool and growth yield of the population of methanogens.

The interspecies transfer of H_2 between juxtaposed cells of H_2-producers and H_2-consumers is especially important for organisms which ferment fatty acids, such as butyrate and propionate, since for thermodynamic reasons these processes are inhibited by low levels of H_2 (Boone and Bryant, 1980). Numerous syntrophic H_2-producing strains have been identified as partners in interspecies H_2 transfer. These include strains such as *Desulfovibrio vulgaris*, *Thermoanaerobacter brockii* and *Pelobacter venetianus* which ferment primary alcohols (Bryant et al., 1977; Ben-Bassat et al., 1981; Schink and Stieb, 1983), the butyrate and propionate fermenters *Syntrophomonas wolfei*, *Syntrophomonas bryantii*, *Syntrophobacter wolinii*, *Syntrophobacter pfennigii* and *Smithella propionica* (McInerney et al., 1979; Boone and Bryant, 1980; Stieb and Schink, 1985; Wallrabenstein et al., 1995; Liu et al., 1999), the acetate oxidizer *Thermoacetogenium phaeum* (Hattori et al., 2000), and the oligosaccharide-fermenting strain Thermicanus aegypticus (Gössner et al., 1999). Interestingly, the propionate fermenters isolated so far are all capable of reducing sulfate (Harmsen et al., 1995; Conrad, 1999). On the other hand, there is important indirect evidence that a significant portion of the syntrophic population of some sediments is made up of sulfate reducers. Addition of sulfate to freshwater methanogenic sediments caused an immediate cessation of methane production (Lovley et al., 1982b; Conrad et al., 1987). The most likely explanation for this observation is that sulfate reducers, which at low-sulfate concentrations obtain energy mainly via fermentation and therefore release H_2 to rid themselves of excess reductant, immediately switch to respiration when sulfate is available as the terminal electron acceptor. In doing so, they cut off the supply of H_2 to the methanogens. A similar effect has been observed in methanogenic soils of rice paddies (Achtnich et al., 1995a; Achtnich et al., 1995b; Krylova et al., 1997). Sulfate reducers are probably predestined to participate in syntrophic associations because of the ambivalent nature of their H_2-metabolism: They can take on the role of H_2-consumer or H_2-producer, depending on the sulfate concentration in the environment (Boone and Bryant, 1980; McInerney et al., 1981b; Traore et al., 1981).

Physiology—Varieties of H_2 Metabolism

This section is a brief summary of the major metabolic activities involving H_2 in prokaryotes. In light of the diversity of the metabolic types, it is obvious that this discussion is intended as an overview emphasizing the various physiological roles assumed by hydrogenases.

H_2-Evolving Processes

Fermentation The decomposition of organic matter via fermentation is one of the major biotic energy-yielding processes in anaerobic habitats (reviewed by The Anaerobic Way of Life in this Volume). Various types of fermentation result in the formation of H_2 as a terminal product and hence constitute a substantial contribution to the global H_2 balance. Both obligate and facultative fermenters produce H_2. One of the best-studied representatives of the former group is *Clostridium pasteurianum*. This bacterium ferments glucose and other substrates and evolves H_2 as a means of dispersing excess reductant. Hydrogen

production is catalyzed by two monomeric [FeFe] hydrogenases (Mortenson and Chen, 1974; Adams et al., 1989; Adams, 1990). A classical example of fermentative H_2 production in a facultative fermenter is mixed-acid fermentation in *E. coli*. This organism produces H_2 via the formate hydrogenlyase reaction (reviewed by Sawers [1994]). The hydrogenase 3, one of four [NiFe] hydrogenase isoenzymes in *E. coli*, is part of a membrane-bound complex containing the enzyme formate dehydrogenase (Sawers et al., 1985; Sawers and Boxer, 1986a; Böhm et al., 1990; Sauter et al., 1992). The formate hydrogenlyase complex converts formate, an intermediary fermentation product, to the gaseous products CO_2 and H_2 (Fig. 2).

Fermentative bacteria constitute a major group of rumen flora, and as such, they are instrumental in the breakdown of cellulose and other biopolymers (reviewed by Hungate [1966] and Flint [1997]). Representatives of this group such as *Butyrivibrio fibrisolvens*, *Ruminococcus albus*, *Megasphaera elsdenii* and *Eubacterium limosum* ferment various substrates to organic acids, CO_2 and H_2 (Miller and Wolin, 1973; Joyner et al., 1977; Miller and Wolin, 1979). Hydrogen does not accumulate in the digestive tract, however, since it is immediately consumed by methanogens and/or homoacetogens (Sharak-Genthner and Bryant, 1987). *Megasphaera elsdeni* is with respect to H_2 metabolism the best-studied organism of this group. It produces a monomeric, [FeFe] hydrogenase which is one of the smallest of all (Van Dijk et al., 1979; Filipiak et al., 1989; Atta and Meyer, 2000).

The thermophilic archaea *Pyrococcus furiosus* and *Thermococcus litoralis* obtain energy via a strictly fermentative metabolism and dispose of surplus reducing equivalents in the form of H_2 or H_2S (Bryant and Adams, 1989; Schäfer and Schönheit, 1991; Pedroni et al., 1995; Rákhely et al., 1999). These organisms contain specialized cytoplasmic, tetrameric [NiFe] hydrogenases called "sulfhydrogenases." The role of this type of hydrogenase could be to transfer electrons from a donor (reduced nicotinamide adenine dinucleotide phosphate [$NADPH_2$] in the case of *P. furiosus* or reduced ferredoxin in the case of *T. litoralis*) to protons or, in the presence of S^0, to sulfur, thereby catalyzing the formation of H_2 or H_2S, respectively (Malik et al., 1989; Blumentals et al., 1990; Ma et al., 1993; Ma and Adams, 1994; Rákhely et al., 1999). *Pyrococcus furiosus* synthesizes two sulfhydrogenase isoenzymes encoded by duplicated genes (Bryant and Adams, 1989; Ma et al., 1993; Ma et al., 2000) and a third hydrogenase that is clearly related to the multisubunit [NiFe] hydrogenase 3 of *E. coli* (Sapra et al., 2000). The physiological role of the latter enzyme is supposedly comparable to that of the sulfhydrogenases: evolution of H_2 to dispose of reducing equivalents during fermentation. A complex isolated from *P. furiosus* membranes under mild conditions was shown to possess H_2-evolving activity using reduced *P. furiosus* ferredoxin as electron donor (Silva et al., 2000). The fact that this activity is sensitive to inhibition by a complex I inhibitor suggests that the complex engages in proton pumping.

Another example of fermentative H_2 production is in *Thermotoga maritima*, a thermophilic, strictly anaerobic bacterium found in warm marine sediments (Huber et al., 1986). Fermentative H_2 evolution in *T. maritima* is catalyzed by a heterotrimeric cytoplasmic [FeFe] hydrogenase (Verhagen et al., 1999). The physiological redox carrier of *T. maritima* hydrogenase is not known. Neither reduced ferredoxin nor $NADPH_2$ func-

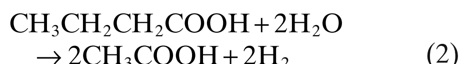
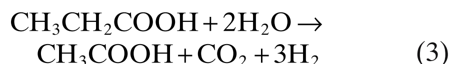
tioned as electron donors in vitro (Blamey et al., 1994; Verhagen et al., 1999).

Another group of specialized fermenters are the syntrophic, fatty-acid oxidizers which inhabit anaerobic sediments (reviewed by Syntrophism among Prokaryotes in this Volume). These bacteria ferment butyrate and propionate via reactions that are endergonic under standard conditions (Thauer et al., 1977):



$$CH_3CH_2CH_2COOH + 2H_2O \rightarrow 2CH_3COOH + 2H_2 \quad (2)$$



$$CH_3CH_2COOH + 2H_2O \rightarrow CH_3COOH + CO_2 + 3H_2 \quad (3)$$

To solve the thermodynamic problem inherent in these reactions, the syntrophic fermenters live in aggregates with H_2-utilizing organisms such as methanogens. Hydrogen is consumed as rapidly as it is produced, preventing its accumulation in the milieu. Thus, the reactions are "pulled" in the direction of the oxidized products (cf., the discussion of syntrophic associations in the section Syntrophy and Interspecies H_2 Transfer in this Chapter).

The cyanobacteria are phototrophic organisms. However, many cyanobacterial strains switch to a fermentative metabolism during periods of darkness when O_2 of the milieu is exhausted by respiration (reviewed in Stal and Moezelaar, 1997). In this metabolic state, they usually consume endogenous reserves (such as glycogen) that accrue during photosynthetic growth. In *Microcystis* PCC7806 and *Cyanothece* PCC7822, for instance, endogenous glycogen is fermented to ethanol, acetate, lactate, CO_2 and H_2 via a mixed acid pathway using ferredoxin as oxidant (van der Oost et al., 1989; Moezelaar and Stal, 1994). Hydrogenase couples H_2 production to ferredoxin reoxidation. *Microcoleus chthonoplastes* employs a similar mixed acid-type fermentation to generate energy under anoxic conditions (Moezelaar et al., 1996). However, this organism produces hydrogen from formate via a formate hydrogenlyase reaction.

Many anoxygenic phototrophs ferment endogenous reserves in the dark and thereby produce H_2 as one of the fermentation products. *Rhodospirillum rubrum* grows anaerobically in the dark on fructose or pyruvate (Schön, 1968; Uffen and Wolfe, 1970; Schön and Biedermann, 1973; Uffen, 1973a; Uffen, 1973b; Jungermann and Schön, 1974). The key enzyme for the fermentation of pyruvate is pyruvate-formate lyase (Gorrell and Uffen, 1977; Gorrell and Uffen, 1978). Formate hydrogenlyase catalyzes the evolution of CO_2 and H_2 from formate (Kohlmiller and Gest, 1951). *Rhodobacter capsulatus* ferments fructose to succinate, lactate, acetate, CO_2 and H_2 (Yen and Marrs, 1977; Madigan and Gest, 1978; Schultz and Weaver, 1982). Also capable of fermentation are *Rhodopseudomonas palustris*, *Rhodopseudomonas viridis* and *Rhodobacter sphaeroides* (Uffen and Wolfe, 1970).

Anaerobic CO Oxidation The anoxygenic photosynthetic bacterium *Rhodospirillum rubrum* can grow anaerobically in the dark on CO as the sole source of energy (Uffen, 1976). Under these conditions, it forms a membrane-bound enzyme complex consisting of carbon monoxide dehydrogenase (CODH) and a CO-insensitive [NiFe] hydrogenase (Fox et al., 1996a; Fox et al., 1996b). Together these enzymes catalyze the following net reaction:

$$CO + H_2O \rightarrow CO_2 + H_2 \quad (4)$$

Like the hydrogenase 3 of *E. coli*, this multienzyme complex includes other proteins related to reduced nicotinamide adenine dinucleotide (NADH):quinone dehydrogenase (complex I; Fox et al., 1996a). The fact that CO supports growth of *R. rubrum* in the dark argues for an energy conserving function of the CO dehydrogenase-hydrogenase complex. Another well-studied example of carboxydotrophy is the Gram-positive bacterium *Carboxydothermus hydrogenoformans* (Svetlichny et al., 1991; Soboh et al., 2002).

Production of H_2 as a Byproduct of N_2 Fixation Nitrogen fixation is one of the main processes of biogenic H_2 production but is unique for the reason that it does not involve a specialized H_2-forming enzyme, i.e., a hydrogenase, but rather nitrogenase. Although beyond the scope of a review dedicated to hydrogenases, nitrogenase-mediated H_2 production deserves mention on account of its global dimension. About 30–50% of the total reducing power consumed by nitrogenase is side-tracked into the formation of H_2 (Schubert and Evans, 1976; Brewin, 1984; Evans et al., 1987). This phenomenon, a paradox considering the efficiency of other enzyme systems, raises the question of a biological role for this "side effect." However this may be, N_2-fixing microbes often possess uptake hydrogenases which permit them to recover at least a part of the energy flowing into nitrogenase-mediated H_2 production. Surprisingly, however, this is by no means a universal feature of diazotrophs. In many soil habitats, both H_2-oxidizing and H_2-nonoxidizing strains of the same diazotrophic species can be isolated. Therefore, significant quantities of H_2 must escape into the environment (reviewed by Evans et al., 1987). This could be a major source of nutrient for H_2-utilizing microbes such as the aerobic H_2-oxidizing bacteria (La Favre and Focht, 1983; Schuler and Conrad, 1991b).

The capacity to reduce atmospheric dinitrogen is found both in archaea and bacteria, in aerobic as well as in anaerobic organisms (see Dinitrogen-Fixing Prokaryotes in this Volume for a list). Among the best-studied diazotrophs are the rhizobia including *Bradyrhizobium japonicum*, *Sinorhizobium meliloti* and *Rhizobium leguminosarum* (reviewed in Hennecke [1990], Agron et al. [1994], Stacey et al. [1995], van Rhijn and Vanderleyden [1995], Ovtsyna et al. [2000], and Spaink [2000]), strains of *Azotobacter* (reviewed by Peters et al., 1995) and various cyanobacteria (Fay, 1992; Haselkorn and Buikema, 1992). Many oxygenic and anoxygenic phototrophs fix dinitrogen and produce H_2 concomitantly. Gest and Kamen discovered that cultures of *R. rubrum* grown in the light under nitrogenase-inducing conditions evolved significant amounts of H_2 (Gest and Kamen, 1949a; Gest and Kamen, 1949b). This process was referred to as "photoproduction" of H_2. Subsequently, H_2 photoproduction was observed in other phototrophic bacteria including *R. capsultus*, *R. gelatinosus* and *R. palustris*. Later investigations revealed that nitrogenase-catalyzed reduction of protons is the basis of H_2 photoproduction (Bulen et al., 1965a; Bulen et al., 1965b). Recently, a different kind of photoproduction has been postulated. A hypothesis has been put forward that hydrogenases may act as redox buffers for the photosynthetic apparatus during transition from darkness to light (Appel and Schulz, 1998; Appel et al., 2000). During such a transition, electrons from the photosynthetic apparatus could be channeled to H_2 via a hydrogenase. Indeed, in *Synechocystis*, a darkness-to-light transition triggers a transient production of H_2 (Abdel-Basset and Bader, 1998). This hypothesis awaits confirmation by additional experimental studies.

Production of H_2 as a Byproduct of Phosphite Oxidation Recently, a novel pathway for phosphite oxidation was discovered in *E. coli* (Yang and Metcalf, 2004). The well known periplasmic enzyme alkaline phosphatase (BAP) turned out to be the sole enzyme of this pathway, which catalyzes the following reaction:

$$H_3PO_3 + H_2O \rightarrow H_3PO_4 + H_2 \quad (5)$$

Thus, BAP is an H_2-evolving hydrogenase. To date, BAP is the only microbial phosphatase show to have this activity.

H_2-Consuming Processes

Aerobic H_2 Oxidation The aerobic hydrogen-oxidizing (knallgas) bacteria attracted the attention of microbiologists early on (Kaserer, 1906; Niklewski, 1910). These organisms utilize H_2 as a source of energy via the oxyhydrogen reaction:

$$2H_2 + O_2 \rightarrow 2H_2O \quad (6)$$

The first part of the above net reaction, a heterolytic cleavage of H_2, is catalyzed by various types of [NiFe] hydrogenases. It turned out that the first knallgas bacteria to be isolated and systematically studied were facultative H_2 chemolithoautotrophs, which in the presence of sugars or organic acids grew organoheterotrophically. Furthermore, many of these organisms utilized H_2 and organic substances mixotrophically (reviewed by Aragno and Schlegel [1992]). The first obligate H_2 chemolithotrophs were discovered relatively recently. The aerobic thermophile *Hydrogenobacter thermophilus* is an obligate chemolithoautotroph (Kawasumi et al., 1984). The bacterium can, however, use H_2 or elemental sulfur alternatively as electron donors. The marine bacterium *Hydrogenovibrio marinus* is an obligate H_2 oxidizer (Nishihara et al., 1991; Nishihara et al., 1997). Mixotrophic H_2 utilization probably plays an important role in pathogens of the human gastrointestinal tract. In the stomach pathogen *Helicobacter pylori*, for instance, hydrogenase significantly effects the efficiency of colonization of the gastric mucosa in the mouse experimental system (Olson and Maier, 2002).

Ralstonia eutropha (formerly *Alcaligenes eutrophus*) is one of the classical knallgas bacteria (Wilde, 1962) and is now one of the best-studied H_2 oxidizers. *Ralstonia eutropha* thrives on mixtures of H_2 and CO_2 but can, alternatively, utilize a broad spectrum of organic compounds. Moreover, it can also utilize H_2 and organic substrates simultaneously. The bacterium contains two energy-generating [NiFe] hydrogenases: A membrane-bound type and a tetrameric, cytoplasmically localized species (Schneider and Schlegel, 1976; Schink and Schlegel, 1979). The membrane-bound enzyme is anchored to the periplasmic face of the cytoplasmic membrane and feeds electrons into a respiratory chain via a *b*-type cytochrome (Fig. 2). This type of hydrogenase is very widespread and is the basis of H_2 oxidation in most of the aerobic H_2 oxidizers examined so far. The soluble, tetrameric hydrogenase of *R. eutropha* was the first of its kind to be characterized genetically (Tran-Betcke et al., 1990). It consists of a hydrogenase moiety complexed with a NADH oxidoreductase module (Fig. 2). The enzyme couples the oxidation of H_2 to the reduction of NAD^+. A similar tetrameric [NiFe] hydrogenase is found in the Gram-positive, facultative H_2-oxidizer *Rhodococcus opacus* (formerly *Nocardia opaca*; Schneider et al., 1984a, 1984b; Grzeszik et al., 1997b).

Some diazotrophs are facultative chemolithoautotrophs. This dual strategy makes sense for inhabitants of the rhizosphere, since they

often form hydrogenase to recycle H_2 produced during N_2 fixation and hence have the enzymatic tools to exploit H_2 produced externally by other diazotrophs. The endosymbiotic N_2-fixer *Bradyrhizobium japonicum* is an example for this group (Hanus et al., 1979). Outside the root nodule, *B. japonicum* is able to grow on H_2 and CO_2 as sole sources of energy and carbon. *Azotobacter vinelandii* is a free living, strictly aerobic diazotroph. It is not an autotroph, but thrives mixotrophically on H_2 in the presence of organic substrates (Wong and Maier, 1985).

In the aerobic carboxydotrophs, CO can serve as the sole source of energy and carbon (reviewed in Meyer, 1989). Many of these bacteria also thrive on H_2 and CO_2, and mixotrophic growth on H_2 or CO in the presence of organic acids has also been reported (Kiessling and Meyer, 1982). In *Oligotropha carboxydovorans*, oxidation of H_2 is catalyzed by a membrane-bound hydrogenase (Santiago and Meyer, 1997; Fig. 2).

Some phototrophs are facultative H_2 chemolithotrophs (Bogorov, 1974; Madigan and Gest, 1979; Siefert and Pfennig, 1979; Kämpf and Pfennig, 1980; Kämpf and Pfennig, 1986). This has been shown for *Rhodobacter capsulatus*, *Rhodobacter sulfidophilus* and *Rhodopseudomonas acidophila*, which grow in the dark on H_2 as sole source of energy and reducing power.

METHANOGENESIS Methanogenesis is one of the major H_2-consuming processes in the biosphere. The global, annual rate of natural CH_4 production has been estimated to be 190 ± 70 Tg (Lelieveld et al., 1998). Hydrogenotrophic methanogens are true lithotrophs that convert H_2 and CO_2 to CH_4 according to the following net reaction:

$$4H_2 + CO_2 \rightarrow CH_4 + 2H_2O \quad (7)$$

Other methanogens can utilize partially reduced forms of carbon such as methanol:

$$CH_3OH + H_2 \rightarrow CH_4 + H_2O \quad (8)$$

Whatever carbon compound is used as substrate, H_2 is the source of reductant in most methanogens and, hence, hydrogenases participate at different stages of methanogenesis. The enzymatic pathway varies depending on the carbon substrate and organism (reviewed in Thauer [1998] and Keltjens and Vogels [1993]). The production of CH_4 from CO_2 proceeds via an initial reaction in which *N*-formylmethanofuran is formed. In *Methanosarcina barkeri*, this reaction is dependent on reducing equivalents generated by the *Escherichia coli* hydrogenase3-like hydrogenase (Ech) (Meuer et al., 2002; Fig. 3). Similar membrane-bound complexes are thought to fulfill the same function in species of *Methanothermobacter* (Tersteegen and Hedderich, 1999). Following the formation of *N*-formylmethanofuran, the C_1 unit is transferred to another carrier, tetrahydromethanopterin (H_4MPT), and reduced in a stepwise fashion: N^5, N^{10}-methenyl-H_4MPT is first converted to N^5, N^{10}-methylene-H_4MPT. Subsequently N^5, N^{10}-methylene-H_4MPT is reduced to N^5-methyl-H_4MPT. A cytoplasmic [NiFe] hydrogenase, the trimeric F_{420}-reactive hydrogenase present in two isoenzymes, contributes reducing equivalents in the form of reduced cofactor F_{420} which drive these reactions (Fig. 3). When deprived of nickel, *M. thermoautotrophicus* and some other methanogens produce high levels [Fe] hydrogenase, the so-called "H_2-forming H_4MPT dehydrogenase." Hydrogen-forming H_4MPT dehydrogenase, also called "Hmd hydrogenase," is a cytoplasmic homodimer. This enzyme apparently substitutes for the nickel-containing F_{420}-reactive hydrogenase, catalyzing the reduction of coenzyme F_{420}. In the final stage of methanogenesis, CH_3-S-CoM and HS-CoB are oxidized to the heterodisulfide CoM-S-S-CoB liberating CH_4 (Fig. 3). The enzyme heterodisulfide reductase then regenerates the reduced forms of coenzyme M and coenzyme B via the reduction of CoM-S-S-CoB using reducing equivalents generated by hydrogenase. The heterodisulfide reductase differs from species to species. In strains of *Methanosarcina*, the enzyme is membrane-bound. It receives its reducing power from a hydrogenase attached to the outer surface of the cytoplasmic membrane via the electron carrier methanophenazine (Fig. 3). The reduction of CoM-S-S-CoB results in the formation of scalar protons and, hence, a gradient across the membrane which couples H_2 oxidation to phosphorylation of ADP. In other species (e.g., strains of *Methanothermobacter*, *Methanococcus* and *Methanopyrus*), the heterodisulfide reductase and an F_{420}-nonreducing hydrogenase form a soluble complex located in the cytoplasm (Setzke et al., 1994).

Methanosarcina barkeri, *M. mazei* and other methylotrophic methanogens can grow on substances such as methanol, methylamines and acetate in addition to H_2 and CO_2 (Keltjens and Vogels, 1993; Deppenmeier et al., 1999). Regardless of what substrate is utilized, CH_4 production leads to the formation of the heterodisulfide CoM-S-S-CoB and the pools of coenzymes HS-CoM and HS-CoB are replenished by the action of the heterodisulfide reductase. If adequate amounts of H_2 are available, the reducing power for this reaction is supplied by membrane-bound methanophenazine-reducing hydrogenases. In the absence of H_2, reducing power comes from a membrane-bound $F_{420}H_2$-dehydrogenase, which oxidizes coenzyme F_{420} in an energy-conserving manner. Both hydrogenase and

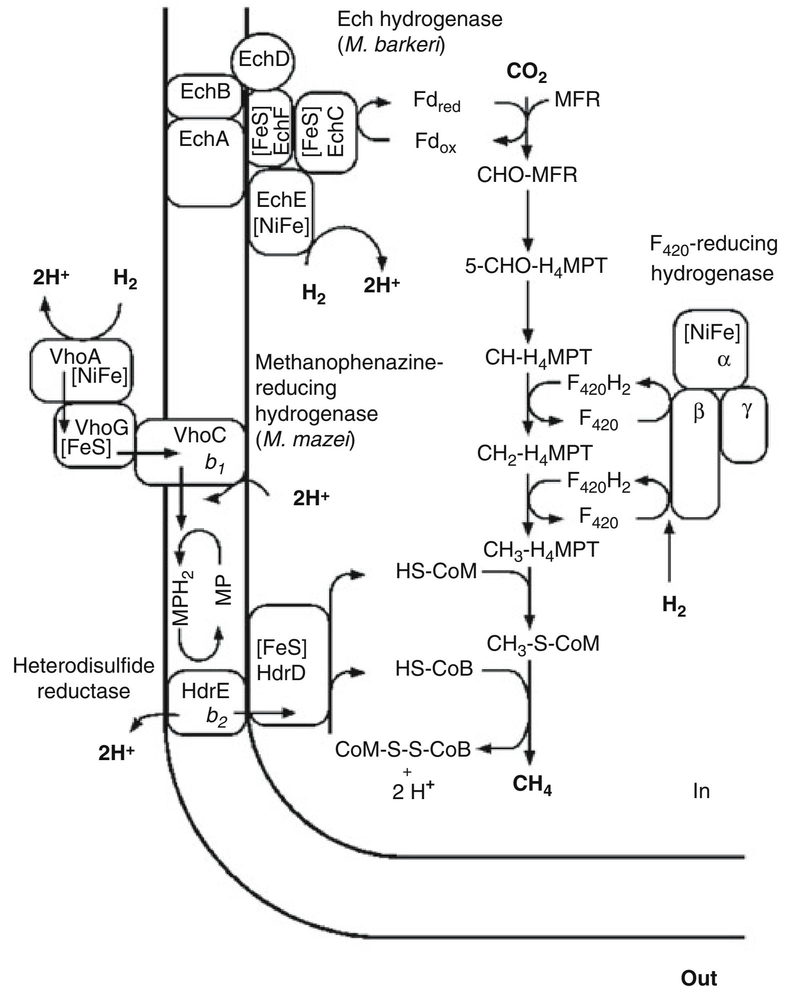


Fig. 3. Archaeal hydrogenases of *Methanosarcina* strains: subunit composition, catalytic activity and cellular location. MP, Methanophenazine; MFR, methanofuran; CHO-MFR, formyl-methanofuran; HS-CoB. Coenzyme B; HS-CoM, coenzyme M; Fd_{red}/Fd_{ox}, reduced/oxidized ferredoxin; b_1, and b_2, cytochromes b_1, and b_2, respectively. See text for additional details.

$F_{420}H_2$-dehydrogenase are coupled to the heterodisulfide reductase via the redox intermediate methanophenazine (Deppenmeier, 1995a).

The Ech hydrogenase of *Methanosarcina barkeri* is part of a multisubunit membrane-bound complex related to hydrogenase 3 of *E. coli* (Künkel et al., 1998). Recent studies point to multiple metabolic roles for the Ech hydrogenase (Meuer et al., 2002). During growth on H_2 and CO_2, Ech oxidizes H_2, transferring the electrons to ferredoxin. Reduced ferredoxin provides the reducing power for the first step of methanogenesis, the reduction of CO_2 to formylmethanofuran. In acetoclastic methanogenesis, Ech couples the oxidation of reduced ferredoxin (arising from the oxidation of the carbonyl group of acetate) to the production of H_2. Finally, during growth on methanol, H_2 and CO_2, Ech seems to have a biosynthetic role.

Acetogenesis When organisms such as *Acetobacterium woodii*, *Moorella thermoacetica*, *Moorella thermoautotrophica* and *Clostridium aceticum* grow on CO_2 and H_2, CO_2 is converted to acetate via the Ljungdahl-Wood pathway (see Acetogenic Prokaryotes in this volume). This reaction proceeds via the following stoichiometry:

$$2CO_2 + 4H_2 \rightarrow CH_3COOH + 2H_2O \quad (9)$$

The reducing power for this reaction is ultimately derived from H_2 by the action of hydrogenases (Drake, 1982; Pezacka and Wood, 1984). *Acetobacterium woodi* contains a soluble hydrogenase of the [FeFe] type (Ragsdale and Ljungdahl, 1984). *Sporomusa sphaeroides* oxidizes H_2 with the help of a dimeric, membrane-bound, [NiFe] hydrogenase (Dobrindt and Blaut, 1996).

Sulfate and Sulfur Reduction The different strains of sulfate-reducing bacteria and archaea use a spectrum of electron donors including alcohols, H_2 and organic acids such as acetate, lactate, malate and pyruvate (reviewed by Dissimilatory Sulfate- and Sulfur-Reducing Prokaryotes in this Volume). The electron accep-

tor, sulfate, sulfite, thiosulfate or elemental sulfur, is reduced to sulfide. via the following net reactions:

$$4H_2 + H_2SO_4 \rightarrow H_2S + 4H_2O \quad (10)$$

$$3H_2 + H_2SO_3 \rightarrow H_2S + 3H_2O \quad (11)$$

$$4H_2 + H_2S_2O_3 \rightarrow 2H_2S + 3H_2O \quad (12)$$

$$H_2 + S \rightarrow H_2S \quad (13)$$

Thus, the oxidation of an organic compound or H_2 is coupled to the reduction of a sulfur compound. This process entails the generation of a proton gradient across the cytoplasmic membrane. Energy is conserved via a chemiosmotic mechanism, for which reason the process is loosely called "anaerobic respiration" (Brandis and Thauer, 1981). Many sulfate reducers thrive on H_2 as the sole source of energy and reductant. This group includes strains of *Desulfovibrio*, *Desulfomicrobium*, *Desulfobacter*, *Desulfobacterium*, *Desulfonema*, *Desulfobulbus*, *Desulfosarcina*, *Thermodesulfovibrio* and *Thermodesulfobacterium* (see Dissimilatory Sulfate- and Sulfur-Reducing Prokaryotes in this Volume). Several of these strains can grow lithoautotrophically on H_2 and CO_2 (Jansen et al., 1984; Schauder et al., 1987; Schauder et al., 1989). Autotrophic growth on H_2 and CO_2 has been documented for *Desulfovirio fructosovorans*, *Desulfomicrobium apsheronum* (Rozanova et al., 1988), *Desulfobacterium autotrophicum* (Brysch et al., 1987), *Desulfotomaculum geothermicum* (Daumas et al., 1988), *Desulfotomaculum kuznetsovii* (Rozanova et al., 1988), *Desulfobacter hydrogenophilus*, *Desulfomonas limicola* and *Desulfosarcina variabilis* (Widdel, 1988a). Perhaps the most remarkable property of sulfate reducers is their mixotrophic metabolism, i.e., their ability to utilize H_2 and organic compounds simultaneously. In this case, energy is generated by two different modes operating at the same time: 1) electron-transport phosphorylation driven by the hydrogenase-dependent respiratory chain and 2) substrate-level phosphorylation coupled to the oxidation of an organic substrate. Hydrogen is one of the products of the latter process. If sufficient sulfate is present, net production of H_2 seldom occurs. Hydrogen produced via fermentation is reoxidized via the hydrogenase-dependent respiratory chain (Tsuji and Yagi, 1980). Under low-sulfate conditions, H_2 is produced and released into the environment (Postgate, 1952; Vosjan, 1975; Hatchikian et al., 1976; Traore et al., 1981).

Extensive studies on sulfate-reducing bacteria have revealed the existence of multiple hydrogenases in one and the same organism (see Voordouw [1992] for a list). Various strains of *Desulfovibrio vulgaris* and *Desulfovibrio desulfuricans*, for instance, form three different hydrogenases, one representative each of the [FeFe], [NiFe] and [NiFe(Se)] types. The assignment of physiological functions to the hydrogenases is difficult in such cases. One approach to the problem is the analysis of mutants with defined genetic lesions. *Desulfovibrio fructosovorans* forms three different hydrogenases: Two of these, an [FeFe] and a [NiFe] enzyme, are periplasmic. The third hydrogenase is a tetrameric, cytoplasmic, NADP-dependent [FeFe] enzyme (Rousset et al., 1990; Malki et al., 1995; Malki et al., 1997). The former enzymes are probably part of an H_2-dependent respiratory chain. The latter could couple H_2 oxidation directly to the generation of reducing equivalents. Mutants defective for the [NiFe] hydrogenase or the cytoplasmic hydrogenase or both still grew well on H_2 and sulfate. During growth on fructose, lactate and pyruvate, the mutants behaved differently: The strain defective for the [NiFe] enzyme grew as well as the wildtype. Growth of the strains lacking a functional cytoplasmic hydrogenase was significantly curtailed (Malki et al., 1997). Thus, the bioenergetic contributions of the three hydrogenases are not sharply defined and seem to allow for a certain degree of mutual compensation. However, the cytoplasmic [FeFe] hydrogenase is evidently more important during growth involving fermentative utilization of organic substrates. *Desulfovibrio vulgaris* Hildenborough harbors a soluble periplasmic [FeFe] hydrogenase and two membrane-bound enzymes: a [NiFe] hydrogenase and a [NiFe(Se)] hydrogenase. The genome sequence of this organism indicates the presence of a fourth hydrogenase akin to hydrogenase 3 of *E. coli* (Pohorelic et al., 2002). A *Desulfovibrio vulgaris* mutant defective for the [FeFe] hydrogenase showed reduced growth both on H_2 and on lactate (Pohorelic et al., 2002). Under the latter conditions, the mutant also liberated much more H_2 than the wildtype. Thus, the [FeFe] hydrogenase is involved in the utilization both of external H_2 and of internally generated H_2 arising from the fermentation of organic substrates. The respiration of sulfate with H_2 as electron donor has been reported for other groups of bacteria aside from the classical sulfate reducers. One example of this is *Allochromatium minutissimum* (Nakamura, 1939; Nakamura, 1941), which grows anaerobically in the dark on H_2 and sulfate.

In some anaerobic H_2-oxidizers, sulfur takes the place of sulfate as electron acceptor in the oxidation of H_2 (see Hedderich et al. [1999] for a list). These organisms are typically found in hot, marine solfataras. The marine thermophilic archaeon *Thermoproteus neutrophilus* is an obli-

gate chemolithoautotroph, growing on H_2 and elemental sulfur with CO_2 as sole carbon source (Fischer et al., 1983). Its relatives, *Thermoproteus tenax* and *Pyrobaculum islandicum*, are H_2-utilizing chemolithotrophs that can grow in a facultative chemoorganotrophic mode, respiring sulfur (Fischer et al., 1983). *Pyrodictium occultum* and *Pyrodictium brockii* are both hyperthermophilic archaea that obtain energy via H_2/S chemolithotrophy (Fischer et al., 1983; Stetter and Gaag, 1983a). In the latter organism, H_2 oxidation is catalyzed by a dimeric, membrane-bound [NiFe] hydrogenase (Pihl et al., 1989; Pihl and Maier, 1991). The moderately thermophilic, strictly anaerobic bacterium *Desulfurella multipotens* is a facultative chemolithotroph growing on H_2 and elemental sulfur (Miroshnichenko et al., 1994).

Mixotrophic growth has been reported for another member of the genus *Pyrodictium*: The marine hyperthermophile *Pyrodictium abyssi* (Pley et al., 1991). Unlike the other two species, it is a heterotroph, growing by fermentation of organic compounds. The addition of elemental sulfur to heterotrophic cultures has little effect on growth. However, when H_2 and S are provided in addition to organic substrates, growth is markedly stimulated and sulfur is reduced to H_2S. Perhaps the most impressive examples of the metabolic versatility of the sulfur-reducers are the archaeon *Acidianus infernus* and its relatives (Segerer et al., 1986). Under anaerobic conditions these organisms grow by H_2/S chemolithotrophy. They are, however, facultative aerobes: In the presence of O_2 they oxidize sulfur to sulfuric acid. The exploitation of a variety of electron acceptors for the oxidation of H_2 is not limited to archaea. The bacterium *Sulfurospirillum deleyianum* (Schumacher et al., 1992; Eisenmann et al., 1995) can grow on H_2 or elemental sulfur as sole source of energy and reducing power. It utilizes a palette of electron acceptors including oxygen, nitrate, nitrite, sulfur compounds, and organic acids. The hyperthermophile *Aquifex pyrophilus* (Huber et al., 1992) grows on H_2 in the presence of O_2 just like a conventional knallgas bacterium. Alternatively, both S^0 and $S_2O_3^{-2}$ can serve as electron donors in place of H_2. Under anoxic conditions, *A. pyrophilus* can grow on H_2, S^0 or $S_2O_3^{-2}$ using nitrate as the terminal electron acceptor. Furthermore, in the late stage of exponential growth on H_2 under oxic conditions, *A. pyrophilus* switches from O_2 to S^0 as the terminal electron acceptor and begins producing H_2S.

The model organism for biochemical and molecular studies on anaerobic respiration is *Wolinella succinogenes* (Hedderich et al., 1999; Lancaster, 2001). This anaerobic, rumen organism oxidizes H_2 using sulfur in the form of polysulfide as the terminal electron acceptor (Jacobs and Wolin, 1963; Kröger and Innerhofer, 1976; Bronder et al., 1982; Jankielewicz et al., 1995). The membrane-bound [NiFe] hydrogenase is coupled to the membrane-bound polysulfide reductase via the redox carrier menaquinone (Dross et al., 1992).

Fe(III) Reduction Many strains of Fe(III) reducing bacteria are capable of using H_2 as an electron donor. The coupling of H_2 oxidation to the reduction of Fe(III) is an important energy-yielding process in subsurface microbial communities. Members of the family Geobacteriaceae are also capable of reducing other metals such as Mn(IV) and U(VI). Both *Geobacter hydrogenophilus* and *Geobacter sulfurreducens* grow on H_2 (Coates et al., 1991; Caccavo et al., 1994). In *Geobacter sulfurreducens*, H_2 oxidation is catalyzed by a membrane-bound hydrogenase (Coppi et al., 2004).

Dehalorespiration Certain bacteria exploit specialized respiratory chains, in which the oxidation of H_2 or organic acids is coupled to the dehalogenation of haloaliphatic or haloaromatic compounds. This type of energy metabolism is known as dehalorespiration and has been found in both gram-negative and gram-positive bacteria. Hydrogenases and reductive dehalogenases are key components of these pathways. Among the representatives of this group are both strict H_2 oxidizers, such as *Dehalobacter restrictus* (Holliger et al., 1998), and organisms, such as *Halospirillum multivorans* (Scholz-Muramatsu et al., 1995), which can utilize a variety of electron donors. Both of these strains contain membrane-bound hydrogenases.

Anoxygenic Photosynthesis In the versatile metabolism of the anoxygenic phototrophic bacteria, H_2 has different roles depending on the growth conditions (Vignais et al., 1985). Two of the metabolic functions of H_2 have been discussed above: H_2 is consumed as a source of energy and reductant during aerobic, chemolithoautotrophic growth and is produced as a fermentation product during anaerobic, heterotrophic growth. A third role of H_2 is linked to anaerobic growth in the light: Many anoxygenic phototrophs can utilize H_2 as an electron donor for photoautotrophic growth. This was first shown for the purple sulfur bacterium *Allochromatium minutissimum* (Roelofsen, 1934; Gaffron, 1935). Photosynthetic H_2 oxidation is dependent on uptake hydrogenases (Gest, 1951). Both purple nonsulfur and purple sulfur bacteria are capable of photosynthetic growth on H_2 (see

Drews and Imhoff [1991] for a list). Included in this group are *Rhodospirillum rubrum* (Ormerod and Gest, 1962; Anderson and Fuller, 1967), *Rhodopseudomonas palustris* (Qadri and Hoare, 1968), *Rubrivivax gelatinosus* (Wertlieb and Vishniac, 1967), *Rhodobacter capsulatus* (Klemme and Schlegel, 1967), *Allochromatium vinosum* (Gitlitz and Krasna, 1975) and *Thiocapsa roseopersicina* (Gogotov, 1968). In some if not all of the above-named organisms, oxidation of H_2 for photosynthetic growth is catalyzed by membrane-bound [NiFe] hydrogenases (Gitlitz and Krasna, 1975; Adams and Hall, 1977; Bagyinka et al., 1982; Kondratieva and Gogotov, 1983; Kovacs et al., 1983; Gogotov, 1984; Zorin et al., 1996; Fig. 2).

The purple sulfur bacterium *Thiocapsa roseopersicina* contains at least three hydrogenases (Colbeau et al., 1994; Rákhely et al., 1998; Kovács et al., 2002; Rákhely et al., 2004). Two of these hydrogenases are dimeric, membrane-bound enzymes; the third is a cytoplasmic, pentameric hydrogenase. While the precise physiological roles of the three species remain to be delineated, one of the membrane-bound enzymes (HupSL) seems to be involved in the recycling of H_2 produced by nitrogenase (Kovács and Bagyinka, 1990). The soluble, NAD-reducing hydrogenase catalyzes the evolution of H_2 in vivo. The physiological significance of the later reaction is unclear.

Ancillary Processes This category comprises H_2-consuming metabolic activities that are allied to and dependent upon H_2-evolving processes in one and the same cell. Here we are dealing with hydrogenases whose primary purpose is to consume internally produced H_2. Hydrogenase-free strains of the organisms in question are readily isolated from natural habitats and thrive despite the lack of H_2-activating enzymes. The foremost activity of this kind is the so-called “hydrogen recycling” observed in many diazotrophs. This is the role of the dimeric, membrane-bound, [NiFe] hydrogenases in the endosymbiotic N_2-fixers such as *Rhizobium leguminosarum* (Brewin, 1984). A similar function can be ascribed to free-living N_2-fixers such as *Azotobacter chroococcum* (Ford et al., 1990), *Bradyrhizobium japonicum* (Harker et al., 1984; Sayavedra-Soto et al., 1988), *Rhodobacter capsulatus* (Willison et al., 1983; Leclerc et al., 1988) and *Rhodocyclus gelatinosus* (Uffen et al., 1990). In the latter three cases hydrogenases can also catalyze the oxidation of externally available H_2 and hence support facultative chemolithotrophic growth. Another example which falls into this category is the hydrogenase-mediated consumption of H_2 which is evolved as a terminal product of fermentation. This is probably the role of one or both of the hydrogenase isoenzymes 1 and 2 of *E. coli* (overview in Sawers, 1994). These two membrane-bound uptake hydrogenases are formed under anoxic conditions, and may act to conserve energy by oxidizing H_2 generated by the formate hydrogen lyase complex. *Desulfovibrio vulgaris* and other sulfate reducers evolve H_2 both during growth on SO_4^{-2} and during fermentation. A portion of this H_2 is reoxidized by hydrogenase in an energy-conserving mechanism called “hydrogen cycling” (Odom and Peck, 1981; Lupton et al., 1984). The methanogen *M. barkeri* deserves mention in this context. During growth on acetate, H_2 is produced by the Ech hydrogenase (Meuer et al., 2002). The internally produced H_2 is consumed by the methanophenazine-reducing hydrogenases.

Classification of Hydrogenases

The first hydrogenases to be isolated and characterized biochemically were the iron-containing enzymes of sulfur-reducing bacteria. Later on, it was discovered that some hydrogenases contain nickel in addition to iron (Friedrich et al., 1981b; Graf and Thauer, 1981). The preponderance of hydrogenases that have been characterized to date are of this type. Some of these enzymes contain selenium in the form of the unusual amino acid selenocysteine (Rieder et al., 1984; He et al., 1989). Finally, [Fe] hydrogenases found in methanogens are a relatively recent discovery (Thauer et al., 1996). These enzymes, called “H_2-evolving N^5,N^{10}-methylenetetrahydromethanopterin dehydrogenases” or “Hmd hydrogenases,” are neither mechanistically nor structurally related to other hydrogenases. Originally classified as “metal-free hydrogenases,” the Hmd’s were subsequently shown to contain iron. Unlike the classical iron hydrogenases, however, the Hmd’s harbor cofactor-bound, redox-inactive iron, but no iron-sulfur centers (Lyon et al., 2004).

Early classification schemes, which had mainly biochemical data to go on, grouped hydrogenases on the basis of metal content or redox cofactors (Fauque et al., 1988; Przybyla et al., 1992). A rapidly growing base of nucleotide sequence data prompted Voordouw to attempt a classification on the basis of comparisons of deduced amino-acid sequences (Voordouw, 1992). In a similar study, Wu and Mandrand (1993) went a step further. These authors generated multiple alignments for full-length amino acid sequences and performed cluster analysis on the pairwise alignment scores. On the basis of the resulting dendrograms, 30 hydrogenases were grouped in six classes. Recently, Vignais and coworkers have refined and extended this classification system,

including a greatly expanded database (Vignais et al., 2001). They carried out thorough cluster analyses using both complete amino acid sequences and segments corresponding to functional domains. The results of this important study support the notion that hydrogenases belong to three phylogenetically distinct groups: [FeFe] hydrogenases, [NiFe] hydrogenases (including [NiFe(Se)] hydrogenases), and [Fe] hydrogenases. Thus, the original, pragmatic classification now has a foundation in molecular phylogenetics.

[NiFe] Hydrogenases

The revised system of Vignais and coworkers subdivides the [NiFe] hydrogenases into four groups (see Vignais et al. [2001] for dendrograms):

Group 1. Energy-transducing hydrogenases Enzymes which couple the oxidation of H_2 to electron-transport phosphorylation. This group includes both membrane-bound hydrogenases attached to the periplasmic side of the cytoplasmic membrane and nonmembrane-bound, periplasmic hydrogenases. The group breaks down into two subclusters. One contains the membrane-bound hydrogenases of the proteobacteria, and the other, archaeal membrane-bound hydrogenases.

Group 2. Sensory hydrogenases These soluble proteins are components of signal-transmitting circuits governing the expression of hydrogenase genes. Specialized hydrogenases of this type have to date been identified in *Bradyrhizobium japonicum*, and strains of *Ralstonia* and *Rhodobacter*. The group includes a second subcluster containing cyanobacterial uptake hydrogenases.

Group 3. Multimeric cytoplasmic hydrogenases These are enzymes of complex subunit composition, which interact with soluble cofactors. The four subclusters contain F_{420}-reducing hydrogenases of methanogenic archaea, F_{420}-nonreducing hydrogenases of *Methanothermobacter* and *Methanococcus* strains, sulfhydrogenases of thermophilic archaea, and cytoplasmic NAD-reducing hydrogenases of *R. eutropha*, *R. opacus* and cyanobacteria.

Group 4. *Escherichia coli* hydrogenase 3 and relatives *Escherichia coli* hydrogenase 3 is an H_2-evolving enzyme, which is part of the multisubunit formate-hydrogen lyase complex. Similar enzymes have been identified in various bacteria and archaea including *R. rubrum*, *C. hydrogenoformans*, *M. barkeri*, *M. thermoautotrophicus* and *P. furiosus*.

[FeFe] Hydrogenases

The [FeFe] hydrogenases are quite heterogeneous in quaternary structure and domain organization (Vignais et al., 2001). Monomeric, dimeric, trimeric and tetrameric enzymes have been described. Moreover, the basic hydrogenase domain is coupled to various other functional modules in one and the same subunit. Even analyses confined to partial sequences correponding to the conserved hydrogenase catalytic site (H-cluster) fail to show well-separated subgroups (Vignais et al., 2001). Thus, a subdivision of the [FeFe] hydrogenases is not feasable at present.

[Fe] Hydrogenases

A third class of hydrogen-activating enzymes consists of the Hmd's. Originaly discovered in *Methanothermobacter marburgensis*, Hmd enzymes have been found in other methanogenic archaea including *Methanococcus voltae* and *Methanopyrus kandleri* (Thauer et al., 1996). The extensive sequence identity in this class of enzymes shows that they are highly conserved.

Biochemistry

The old observation that knallgas bacteria require Ni for growth on H_2, O_2 and CO_2 (Bartha and Ordal, 1965; Tabillion et al., 1980) took on new significance when it was discovered that Ni is essential for the biosynthesis of active hydrogenase in *Ralstonia eutropha* (Friedrich et al., 1981b) and that hydrogenase purified from *Methanothermobacter marburgensis* contains the transition metal Ni (Graf and Thauer, 1981). Since then, extensive biochemical, genetic and spectroscopic analyses have shed light on the molecular structure and catalytic mechanism of the three classes of hydrogenase: [NiFe], [FeFe], and [Fe] hydrogenases.

Three-dimensional structures are now available for both the [NiFe] and [FeFe] hydrogenases. This section focuses on the structure and function of the dinuclear metal site and its interaction with various prosthetic groups either embedded in the same polypeptide or located on other subunits.

[NiFe] Hydrogenases

The Basic Module The basic module of a catalytically active [NiFe] hydrogenase consists of two heterologous subunits of approx. 60 and 30 kDa (reviewed by Albracht [2001] and Fontecilla-Camps et al. [2001]). Three-dimensional structures of [NiFe] hydrogenases

from anaerobic sulfate-reducing bacteria, including *Desulfovibrio gigas* (Volbeda et al., 1995; Volbeda et al., 1996), *Desulfovibrio vulgaris* (strain Miyazaki F; Higuchi et al., 1997), *Desulfovibrio fructosovorans* (Montet et al., 1997), *Desulfovibrio desulfuricans* (Matias et al., 2001) and of the [NiFe(Se)] hydrogenase from *Desulfomicrobium baculatum* (formerly *Desulfovibrio baculatus*; Garcin et al., 1999) have been solved. In the following, the structure of the prototypic [NiFe] hydrogenase of *D. gigas* is described in detail and compared with other representatives of this group of enzymes.

The *D. gigas* hydrogenase contains one nickel and twelve iron atoms. Eleven of the Fe atoms are assigned to three iron-sulfur clusters in the small subunit. The twelfth Fe atom and the Ni atom are located in the large subunit (Hatchikian et al., 1978; Cammack et al., 1982; Huynh et al., 1987). The [NiFe] active site is coordinated by an N-terminal and a C-terminal pair of cysteines (Fig. 4). Two of the thiolate groups (provided by Cys68 and Cys533) form a bridge between the two metals (Volbeda et al., 1995). In the case of the [NiFe(Se)] hydrogenase of *Desulfomicrobium baculatum*, the nickel ligating cysteine residue (Cys530) is occupied by a selenocysteine (Garcin et al., 1999). Electron density maps of the oxidized catalytically inactive [NiFe] hydrogenase of the sulfate-reducing bacteria show μ-oxo or hydroxo (*D. gigas*) and sulfur species (*D. vulgaris*) as bridging ligands between the Ni and the Fe atom. This bridging ligand disappears upon reduction, a process which correlates with the onset of the catalytic cycle (Volbeda et al., 1995; Higuchi et al., 1997).

Characteristic electron density peaks were observed near the Fe atom. Fourier-Transform Infrared (FTIR) spectroscopy, conducted with the [NiFe] hydrogenase of *Allochromatium vinosum* (formerly *Chromatium vinosum*), uncovered three distinct infrared bands in the high stretching frequency region (Bagley et al., 1994; Bagley et al., 1995). These bands were subsequently ascribed to three intrinsic diatomic nonprotein ligands, one CO and two CN^- ligands, bound to the Fe at the heterodinuclear site (Happe et al., 1997; Pierik et al., 1999). FTIR studies on the *D. gigas* [NiFe] hydrogenase confirmed the assignment of one CO and two CN^- ligands (Fig. 4). Modelling predicts that the two CN^- ligands accept hydrogen bonds from the two protein-borne amino acids Arg463 and Ser486 and that the CO is completely surrounded by hydrophobic residues (Volbeda et al., 1995; Volbeda et al., 1996). In the *D. vulgaris* enzyme, one of the three nonprotein ligands was modeled as SO (Higuchi et al., 1997). This assignment was confirmed by pyrolysis spectrometry (Higuchi et al., 2000) pointing to a mixed population of the diatomic ligands SO/ CN^- and CO.

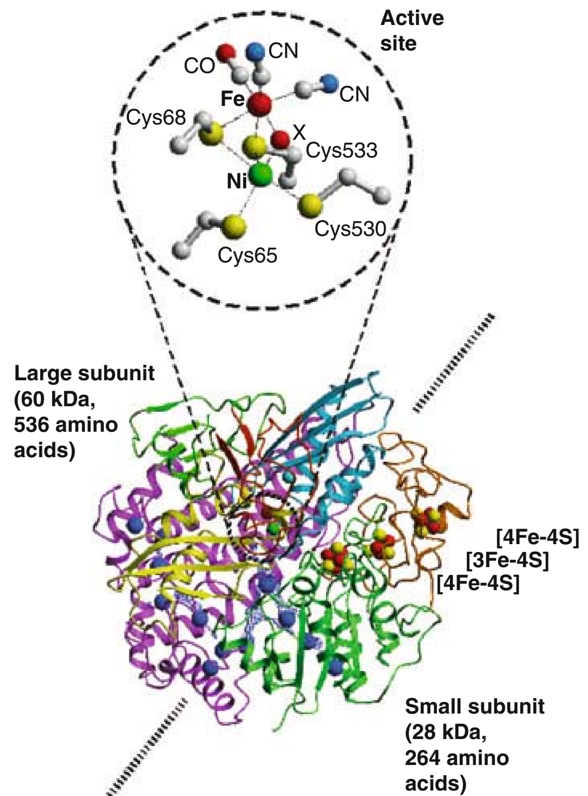

Fig. 4. Three-dimensional structure of the *Desulfovibrio gigas* [NiFe] hydrogenase. The structure of the active site is shown as a blow-up. The plane of the interface between the two subunits is indicated by a thick, dashed line. The large subunit (to the left and above the dashed line) harbors the active site. The small subunit coordinates three iron-sulfur clusters (red: iron; yellow: sulfur). Cysteine residues which participate in coordinating the active-site metals are labeled. The xenon atoms used to probe for tunnels in the protein are colored blue. A blue grid indicates the inferred gas channel (Montet et al., 1997). The blow-up shows the three diatomic ligands and the bridging ligand (X) present in the oxidized form of the enzyme. (Based on Frey et al. [2000] and Fontecilla-Camps et al. [2001]. Reproduced with permission.)

The heterodinuclear site might also differ in the number of diatomic ligands. FTIR data combined with chemical analysis suggest that the structure of the active site in the cytoplasmic NAD-reducing [NiFe] hydrogenase of the aerobically H_2-oxidizing *Ralstonia eutropha* is somewhat different. The data point to the existence of two extra CN^- ions, one bound to the Fe and one bound to the Ni atom (Happe et al., 2000). This special architecture, which may account for the O_2 and CO insensitivity of this particular hydrogenase, has yet to be confirmed by X-ray crystallography.

On the basis of the biochemical and structural data, it can be concluded that the standard type

of [NiFe] hydrogenase forms a globular heterodimer with a radius of 3 nm. The two subunits make contact over a large planar surface (Fig. 4) and are held together by intersubunit ion pairs, which are important for enzyme stability (Szilágyi et al., 2002). The catalytic site and the proximal [4Fe-4S] cluster of the small subunit are buried deep in the protein (Volbeda et al., 1995). Spectroscopic data and the spatial arrangement of the proximal [4Fe-4S], the medial [3Fe-4S], and the distal [4Fe-4S] cluster, all of which are separated from each other by 1.0–1.5 nm, suggest that the iron-sulfur clusters function as an "electrical wire." The proximal [4Fe-4S] cluster could directly exchange electrons with the catalytic site (Fig. 5). The N-terminal part of the small subunit is composed of a highly conserved flavodoxin domain and the binding site for the proximal [4Fe-4S]. These two elements are obviously essential features of all [NiFe] hydrogenases. The involvement of the medial [3Fe-4S] in the redox reaction with H_2 is still a matter of debate since its redox potential is too high relative to that of the H_2 reactive site (Albracht, 2001; Fontecilla-Camps et al., 2001). The distal [4Fe-4S] cluster of the *D. gigas* small subunit is coordinated by three cysteines and one histidine residue. The solvent-exposed histidine appears to be essential for the electronic exchange between the hydrogenase and its corresponding redox partner, e.g., a multiheme cytochrome c_3 (Rousset et al., 1998b).

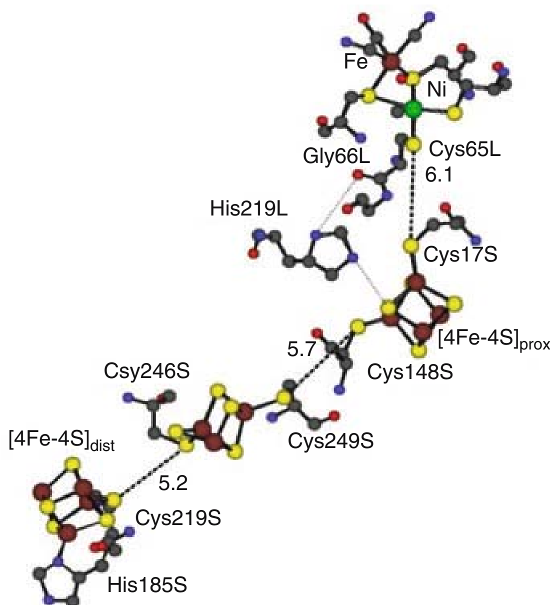

Fig. 5. A hypothetical electron transfer pathway in the [NiFe] hydrogenase of *D. gigas*. The active site is shown along with the Fe-S centers and relevant amino acids. Key distances between atoms (thick dashed lines) are given in Å. Hydrogen bonds are indicated by thin dashed lines. Residues are labeled according to their location in the large (L) and small (S) subunit (based on Volbeda et al. [1995]).

The [NiFe] hydrogenase small subunits are less conserved. In the H_2-sensing proteins, the set of amino acids responsible for coordinating the medial iron-sulfur cluster contains a cysteine at the position of the conserved proline residue, suggesting the existence of a medial [4Fe-4S] cluster in this group of proteins (Kleihues et al., 2000). A similar iron-sulfur cluster composition has been reported for the F_{420}-reducing [NiFe(Se)] hydrogenase of *Methanococcus voltae*. Reconstitution of a medial [3Fe-4S] cluster by site-directed mutagenesis yielded a protein displaying near wildtype activity with benzyl viologen but drastically decreased activity with the physiological acceptor coenzyme F_{420} (Bingemann and Klein, 2000). The conversion of the native [3Fe-4S] to a [4Fe-4S] cluster in the [NiFe] hydrogenase of *D. fructosovorans* had little effect on the enzymatic activity irrespective of whether redox dyes or cytochrome c_3 were used as electron acceptors. On the other hand, the mutation conferred pronounced oxygen sensitivity to the protein (Rousset et al., 1998b). This observation supports the notion that in some organisms, the [3Fe-4S] cluster protects the enzyme from inactivation by oxygen (Albracht, 1994).

A few [NiFe] hydrogenases, including the NAD-reducing multimeric hydrogenases and the *E. coli* type 3 hydrogenases, contain a minimal version of a functional hydrogenase module consisting of a [NiFe] active site in the large subunit and one proximal [4Fe-4S] cluster in the small subunit. It was demonstrated with *R. eutropha* mutants that this subform meets the minimal requirements for being catalytically active (Massanz et al., 1998).

THE NIFE ACTIVE SITE Comparison of over 100 deduced amino-acid sequences clearly show that [NiFe] hydrogenases share a number of common motifs. The large hydrogenase subunit contains a set of at least five related signatures in the N-terminal and C-terminal regions that are located close to the active site (Voordouw et al., 1989; Wu and Mandrand, 1993). A systematic site-directed mutagenesis was initiated with the multimeric NAD-reducing hydrogenase of *R. eutropha* and shed some light on the possible role of some of these conserved residues in catalysis (Massanz and Friedrich, 1999; Burgdorf et al., 2002). The pattern, inferred from multiple sequence alignments of two specific motifs, the so-called signatures "L1" and "L2," including the Ni-liganding cysteines, provided the basis for the recent classification of [NiFe] hydrogenases (Vignais et al., 2001). In most cases, the L2 signature ends at a histidine residue (His536 in *D.*

gigas), which marks the C-terminal endopeptidase cleavage site. In group 4 [NiFe] hydrogenases, represented by hydrogenase 3 of *E. coli*, and the related enzymes of *Rhodospirillum rubrum*, *Methanosarcina barkeri*, *Methanobacterium thermoautotrophicum* and *Pyrococcus furiosus*, this specific histidine is replaced by an arginine residue (reviewed by Tersteegen and Hedderich [1999]). A large peak of electron density in the vicinity of the large subunit terminal histidine was identified as an extra metal, a magnesium ion in the *D. gigas* (Volbeda et al., 1995) and the *D. vulgaris* enzymes and an iron ion in the *Dm. baculatum* hydrogenase (Garcin et al., 1999).

Hydrogen and protons have to bridge a distance of 3 nm to reach the active site or to return to the surface of the protein. Several proton pathways involving histidines, glutamates, carboxylate groups, and internal water molecules have been discussed. A possible proton pathway, proposed more recently for the *D. gigas* hydrogenase (Fig. 6), implicates two conserved glutamic acid residues (Glu 18 and Glu 46) in the large subunit and water molecules located between the [NiFe] and the Mg site (Fontecilla-Camps et al., 2001).

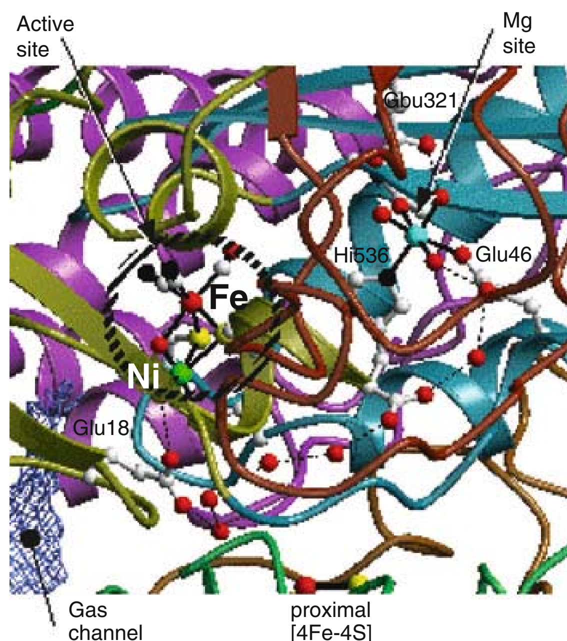

Fig. 6. Close-up view of the active site of the *Desulfovibrio gigas* [NiFe] hydrogenase. The three diatomic ligands and the bridging ligand (red) present in the oxidized form of the enzyme are shown. A putative proton pathway is indicated by the small red spheres connected by a dotted line. A blue grid (lower left) marks the inferred gas channel (Montet et al., 1997). A Mg atom is shown as blue ball. Based on Frey et al. (2000) and Fontecilla-Camps et al. (2001). Reproduced with permission.

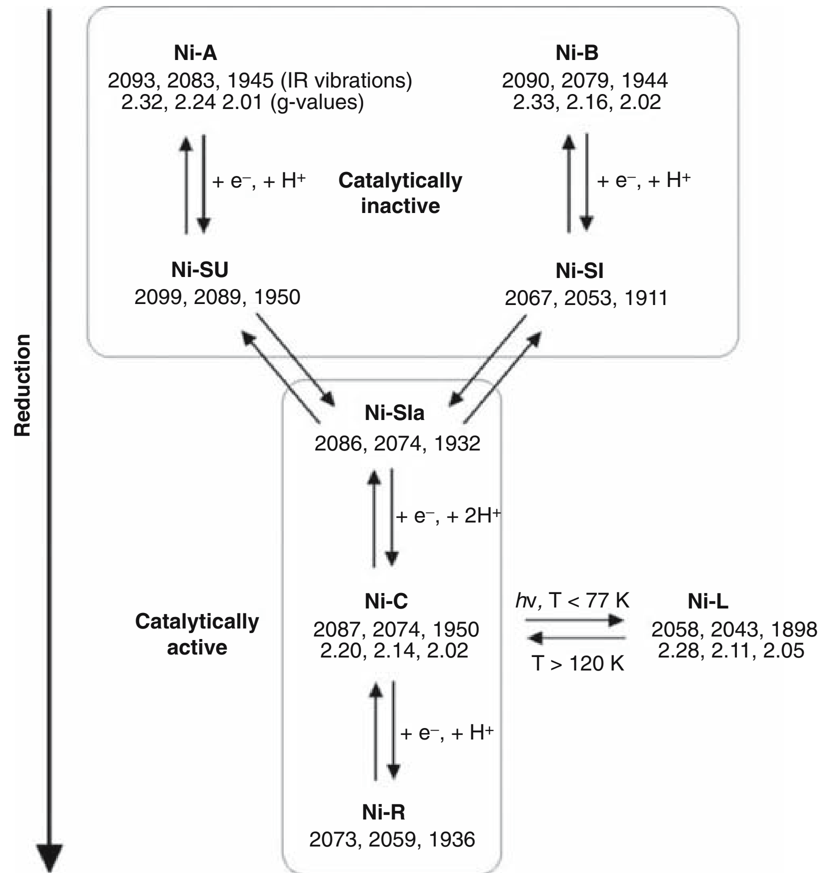
The diffusion of molecular hydrogen, the smallest molecule in nature, through a protein matrix was for a long time considered to occur randomly. A cavity map, calculated from the electron density data for the *D. gigas* hydrogenase, showed a network of hydrophobic channels connecting the active site with the protein surface. Experiments on the diffusion of xenon in crystals of the [NiFe] hydrogenase from *D. fructosovorans* indicated that there are a few discrete hydrophobic channels for H_2 in the protein. Molecular dynamics simulations confirmed this result (Montet et al., 1997). Thus, the movement of H_2 through hydrogenase is probably not random but proceeds rather via discrete pathways.

THE CATALYTIC CYCLE Cleavage of H_2 by hydrogenases is a heterolytic process yielding H^- and H^+ as demonstrated by isotope exchange experiments a long time ago (Krasna, 1979). Although the precise reaction is still not solved, enzymatic and X-ray structure analyses in concert with primary electron paramagnetic resonance (EPR), electron nuclear double resonance (ENDOR), electron spin echo envelope modulation (ESEM), Fourier transform infrared(FTIR) spectroscopy, X-ray absorption spectroscopy (XAS), and quantum chemical calculations have shed light on the chemical mechanism of the catalytic cycle (reviewed by Albracht [1994], Fontecilla-Camps [1996], Cammack [2001], Maroney and Bryngelson [2001], and Stein and Lubitz [2002]).

Spectroscopy has shown that the unpaired electron, or the EPR-detectable unpaired spin, is located in standard [NiFe] hydrogenases close to nickel and possibly in the vicinity of one of its sulfur ligands, but not to iron. From this observation, it was inferred that the iron is retained as a low-spin Fe^{2+} during the entire catalytic cycle and that the diatomic ligands on the iron contribute to the maintainance of this redox state (Happe et al., 1997). The nickel at the active site undergoes several redox changes. Three paramagnetic, EPR-detectable Ni-states, Ni-A, Ni-B and Ni-C have been identified (Fig. 7) which differ in the infrared stretching frequencies and the position of the g_y lines of the rhombic signals. Following isolation, the hydrogenase from *D. gigas* contains a mixture of the Ni-A and Ni-B forms which display different activation kinetics. The Ni-A form, characterized as "unready" showing a Ni(III) signal with a g-tensor of 2.24 in the EPR spectrum, could be fully activated only after incubation with H_2 for several hours, whereas the Ni-B form, the "ready" state, in a Ni(III) coordination with a g-tensor of 2.16, was activated by H_2 within a few minutes (Fernandez et al., 1985). These oxidized enzyme species bear O^{-2} or OH^- molecules bridging the two metals,

Fig. 7. Redox states of nickel in standard [NiFe] hydrogenase. See text for details.



as shown by X-ray structure analysis (Volbeda et al., 1995). They are catalytically inactive and do not participate in the catalytic cycle. Sequential one-electron reductions by external reducing agents, involving several diamagnetic intermediates, finally result in the formation of the EPR-detectable catalytically active Ni-C form of the hydrogenase (van der Zwaan et al., 1990; Fig. 7). Ni-C is photosensitive and becomes converted to Ni-L upon illumination, leading to the reduction of the Ni(III) to Ni(I). Binding of CO in the Ni-C state also yields a specific paramagnetic Ni-CO form.

During reductive activation, the oxygen species dissociate from the [NiFe] active site, and the catalytic cycle is initiated. The idea that H_2 is bound to the [NiFe] center, and a hydride is formed and occupies the position of the bridging ligands, seems to be generally accepted. This process is accompanied by the release of a proton, possibly assisted by one of the terminal cysteines which might act transiently as a base, and the transfer of one electron to the oxidized proximal [4Fe-4S] cluster. To keep the cycle running, the fully reduced hydrogenase in the the diamagnetic Ni-R state (Fig. 7) has to be reconverted to the more oxidized H_2-accepting forms. This is achieved by the release of protons and the transfer of two additional electrons from the [NiFe] center via the iron-sulfur cluster(s) to an external redox partner. Once this reaction is completed, the enzyme is ready to enter a second catalytic cycle (Albracht, 1994; Cammack, 2001; Stein and Lubitz, 2002).

INTERACTIONS OF DIMERIC [NIFE] HYDROGENASES WITH REDOX PARTNERS The type of interaction with a specific redox partner can often be deduced from the structural features of the hydrogenase small subunit. In the periplasmic hydrogenases of sulfate reducers, the residues which coordinate the distal [4Fe-4S] cluster are located close to the C-terminal end of the small subunit (Fig. 8). Several species of *Desulfovibrio* contain periplasmic low-potential *c*-type cytochromes. One of these, the tetraheme cytochrome c_3, is probably one of the primary redox partners of periplasmic hydrogenases (Aubert et al., 2000; Morelli et al., 2000; Matias et al., 2001). The shuttling of electrons from the hydrogenase to membrane complexes of polyheme cytochromes of the Hmc family by *c*-type cytochromes may be a general mechanism in *Desulfovibrio* species (Rossi et al., 1993).

Membrane-bound, periplasmically oriented [NiFe] hydrogenases as found in many proteo-

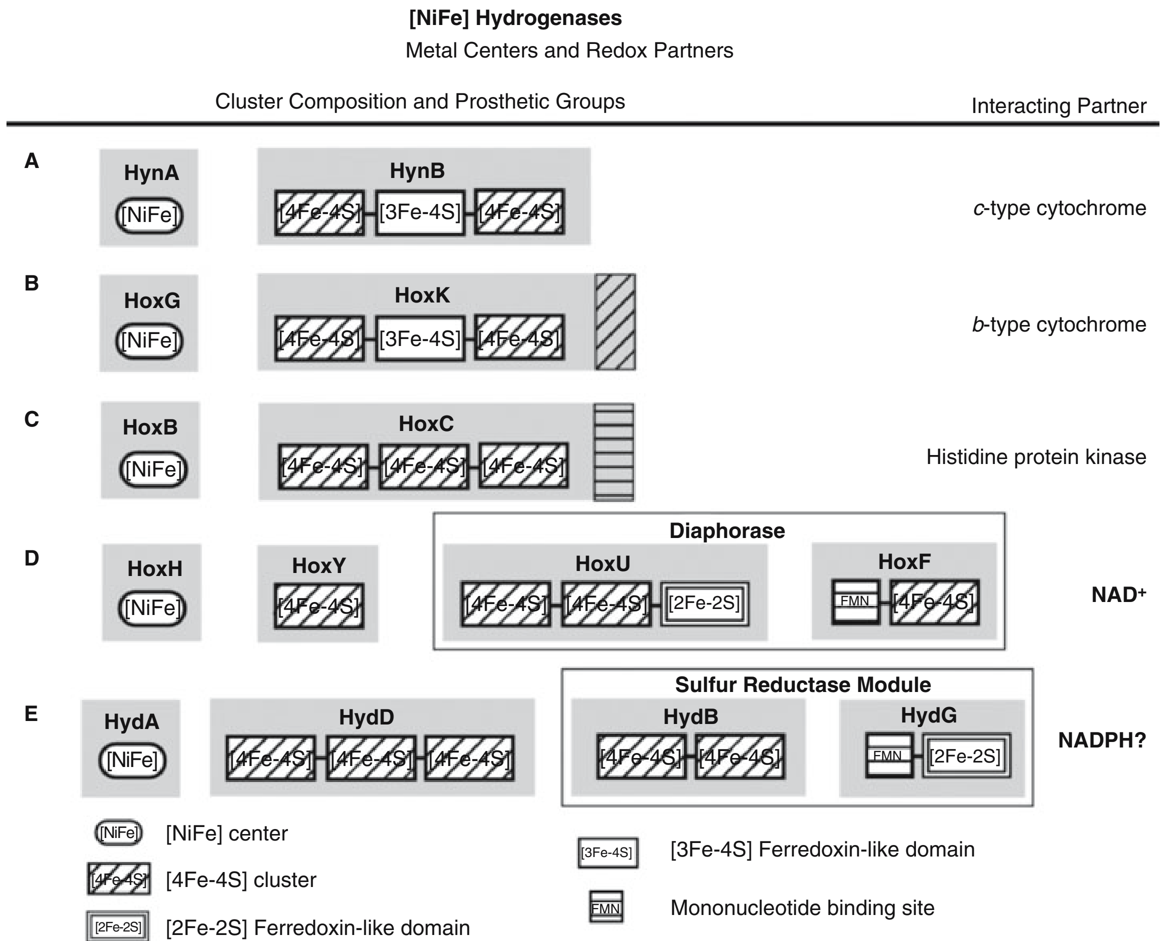


Fig. 8. Domain organization of selected [NiFe] hydrogenases. Gray boxes represent hydrogenase subunits (not to scale). Redox partners are listed at the right. A key to the symbols is given in the lower part of the figure. (A) *D. gigas* [NiFe] hydrogenase. (B) *R. eutropha* membrane-bound hydrogenase (MBH). Hatched area symbolizes the characteristic C-terminal region of the small subunit. (C) *R. eutropha* regulatory hydrogenase (RH). Hatched area symbolizes the characteristic C-terminal region of the small subunit. (D) *R. eutropha* soluble hydrogenase (SH). The diaphorase moiety is boxed. (E) *Thermococcus litoralis* sulfhydrogenase. The putative sulfur reductase module is boxed.

bacteria are characterized by a highly conserved (approx. 50 amino acid) segment at the C-terminus of the small subunit (Fig. 8). This hydrophobic region is essential for binding the hydrogenase to the membrane and coupling the electron flow to the quinone pool of the respiratory chain. A membrane-integral cytochrome *b* has been isolated as a complex with the heterodimeric [NiFe] hydrogenase from *Wolinella succinogenes* (Dross et al., 1992; Dross et al., 1993). This cytochrome, designated "HydC," binds two heme groups. Analysis of site-directed mutants revealed that substitution in HydC of three histidine residues (His25, His67 and His186), which are predicted to be heme B ligands, abolished quinone reactivity of the *W. succinogenes* hydrogenase, while benzylviologen reduction was retained. A similar phenotype was observed by mutating two conserved histidine residues in the small hydrogenase subunit HydA. One of the residues is located in the membrane-integrated C-terminal helix of HydA (His 305) and the other is supposed to be involved in the ligation of the distal [4Fe-4S] cluster. The data convincingly show that these components are necessary for electron transport from H_2 to either fumarate or polysulfide, and for quinone reactivity (Gross et al., 1998). Moreover, with cytochrome *b* deficient mutants of *R. eutropha*, it was demonstrated that the *b*-type cytochrome is bifunctional. In addition to its electron-tranferring function, it anchors the hydrogenase to the membrane (Bernhard et al., 1997). An energy-conserving system analogous to the respiration-linked proteobacterial H_2 oxidation is instrumental also in the archaeon *Methanosarcina mazei* Gö 1. The outside-oriented membrane-bound [NiFe] hydrogenase of this

strain transfers electrons from H_2 via a *b*-type cytochrome and methanophenazine to the heterodisulfide oxidoreductase. This reaction is coupled to the generation of a proton motive force (Ide et al., 1999). Thus it appears that the cytochrome *b* serves as a common primary electron acceptor for a large group of hydrogenases.

The H_2-sensing regulatory [NiFe] hydrogenases of *Bradyrhizobium japonicum* (Black et al., 1994), *Rhodobacter capsulatus* (Elsen et al., 1996), and *Ralstonia eutropha* (Lenz et al., 1997) also contain a C-terminal region of approx. 50 amino acids in the small subunit. Although the sequence of this peptide is highly conserved within this group of proteins, it is completely distinct from the C-terminal small subunit region of membrane-bound [NiFe] hydrogenases (Fig. 8). This observation points to a specific role of the C-terminal extension in partner recognition and hence signal transduction. In fact, the formation of a tight complex between the H_2-sensing hydrogenase of *R. eutropha* and its cognate signal-transmitting histidine protein kinase has been demonstrated in vitro using purified components (Bernhard et al., 2001). Unlike the standard energy-converting [NiFe] hydrogenases, which are isolated as simple heterodimers ($\alpha\beta$), the H_2-sensing hydrogenase of *R. eutropha* forms a tetramer consisting of two dimeric species ($\alpha_2\beta_2$) which accomodates an additional redox sensitive nonmetal cofactor (Bernhard et al., 2001).

Multimeric Hydrogenase Complexes Less information is available on the interaction of the hydrogenase module within multisubunit [NiFe] hydrogenase complexes. Such modules are often characterized by a truncated form of the small subunit which differs remarkably in its amino acid composition and cofactor content from the small subunit of the prototypic *D. gigas* hydrogenase (Fig. 4). Heteromultimeric [NiFe] hydrogenases generally reside in the cytoplasm or are bound to the inner surface of the cytoplasmic membrane. A typical feature of one group of multimeric hydrogenases is a tight association of the hydrogenase module with a second redox-active moiety that binds coenzymes such as F_{420} (8-hydroxy-5-deazaflavin), NAD or NADP which are reversibly reduced by H_2.

The F_{420}-reducing hydrogenases of methanogens are heterotrimeric FAD-containing enzymes which tend to form aggregates. A well-characterized example is the F_{420}-reducing hydrogenase from *Methanobacterium formicicum* (Baron and Ferry, 1989a; Baron and Ferry, 1989b), which consists of the subunits FrhA, FrhB and FrhG. The FrhA subunit contains the [NiFe] center and the FrhB subunit harbors the binding site for the cofactor F_{420}. Variants of this hydrogenase exist which contain selenium in addition to nickel and iron. Methylotrophic methanogens such as *Methanosarcina* strains possess membrane-bound hydrogenases (Fig. 3). In *Methanosarcina mazei*, a cytochrome *b* serves as the primary electron acceptor (Ide et al., 1999). The redox carrier methanophenazine shuttles electrons from the hydrogenase to heterodisulfide oxidoreductase. In hydrogenotrophic methanogens, which are devoid of cytochromes, the physiological electron acceptor of the F_{420}-nonreducing hydrogenase is not yet known.

Methanococcus voltae harbors two enzymes each of a [NiFe] and and of a [NiFe(Se)] hydrogenase. One enzyme of each pair is of the F_{420}-reducing type, the other represents the F_{420}-nonreducing type. The F_{420}-nonreducing [NiFe(Se)] hydrogenase has a peculiar structure. The large subunit lacks the C-terminal cysteinyl or selenocysteinyl ligands to Ni. This domain is contained on a separate peptide of 25 amino acids.

The soluble cytoplasmic NAD-reactive [NiFe] hydrogenases of bacterial species consist of four heterologous subunits (Fig. 2). The hydrogenase module contains a truncated form of the small electron-transferring subunit with only one Fe-S cluster as prosthetic group (Fig. 8). This moiety is associated with a heterodimeric iron flavoprotein, the so-called "diaphorase module" (Schneider and Schlegel, 1976; Schneider et al., 1984a; Tran-Betcke et al., 1990). The diaphorase consists of a large (approx. 65-kDa) polypeptide, HoxF, and a small (approx. 25-kDa) subunit, HoxU. The diaphorase moiety accomodates three to four iron-sulfur clusters and one flavin mononucleotide (Fig. 8). Sequence alignments revealed a close relationship between the diaphorase part of the NAD-linked hydrogenases and three peripheral subunits of bacterial and mitochondrial NADH ubiquinone oxidoreductases (Tran-Betcke et al., 1990; Pilkington et al., 1991; Friedrich et al., 2000). The HoxF polypeptide appears to be a fusion product of the 24- and the 52-kDa subunits of bovine complex I, and HoxU is homologous to the N-terminal part of the 75-kDa subunit. Further similarities between hydrogenases and complex I will be discussed below.

The NAD-reactive hydrogenases are found in aerobic H_2-oxidizing bacteria including the well studied *Rhodococcus opacus* (formerly *Nocardia opaca*) and *Ralstonia eutropha* (formerly *Alcaligenes eutrophus*; Schneider and Schlegel, 1976; Schneider et al., 1984a; Tran-Betcke et al., 1990; Grzeszik et al., 1997b). A cytoplasmic, NAD-reducing hydrogenase was identified in the methanotroph *Methylococcus capsulatus* (Hanczár et al., 2002). Similar enzymes, designated "bidirectional hydrogenases" have more recently also

been found in cyanobacteria (reviewed by Tamagnini et al. [2002]). An NAD-reactive cyanobacterial hydrogenase was first characterized and sequenced from the filamentous *Anabaena variabilis* ATCC 29413 (Schmitz et al., 1995; Serebryakova et al., 1996). Subsequently this type of hydrogenase was also identified in unicellular cyanobacteria and appears to be loosely associated with cytoplasmic and thylacoid membranes (Kentemich et al., 1989; Serebryakova et al., 1994). A cytoplasmic, NAD-reducing hydrogenase was also found in the methanotroph *Methylococcus capsulatus* (Hanczár et al., 2002). Recently, a bidirectional hydrogenase was discovered in *Thiocapsa roseopersicina* (Rákhely et al., 2004). The biological function of the bidirectional hydrogenases is still obscure. A group of closely related tetrameric NADP-reactive [NiFe] hydrogenases has been found in the hyperthermophilic archaeal species of *Pyrococcus* (Ma et al., 1993; Pedroni et al., 1995; Ma et al., 2000) and *Thermococcus* (Rákhely et al., 1999). The HydA and HydD subunits of this type of enzyme constitute the hydrogenase module, whereas the HydB and HydG subunits form the flavin-containing NADP-reactive moiety of the protein (Fig. 8). It is remarkable that this group of [NiFe] hydrogenases has both H_2-oxidizing and S^0-reducing activities. During fermentation, the enzyme accepts both polysulfides or protons as electron acceptors and is therefore designated a "sulfhydrogenase" (Ma et al., 1993).

The H_2-evolving [NiFe] hydrogenases expressed under strictly anoxic conditions are constituents of multicomponent membrane-bound enzyme complexes which share the ability to couple the oxidation of carbonyl groups, derived from formate, acetate or carbon monoxide, to the reduction of protons, yielding H_2. The most extensively studied example is the formate-hydrogenlyase complex in *E. coli* comprising eight *hyc* gene products. The hydrogenase module of hydrogenase 3 consists of the active-site-containing subunit HycE and the small subunit HycG, which harbors only the proximal [4Fe-4S] cluster (Fig. 2). Both the formate dehydrogenase moiety of the complex and the two hydrogenase subunits are attached to the inner side of the cytoplasmic membrane via intrinsic membrane proteins, which serve as membrane anchors and electron mediators between the two redox proteins (Böhm et al., 1990; Sauter et al., 1992). It has so far not been possible to isolate the entire hydrogenase 3 complex.

The CO-induced [NiFe] hydrogenase of *Rhodospirillum rubrum* is a constituent of the CO-oxidizing enzyme system which permits the organism to grow in the dark with carbon monoxide as the sole energy source (Uffen, 1976). Like *E. coli* hydrogenase 3, the CooLH hydrogenase complex of *R. rubrum* is rather labile, and hence biochemical data are limited (Fox et al., 1996a; Fox et al., 1996b). Multisubunit [NiFe] hydrogenase complexes of the *E. coli* type 3 are also present in archaea such as *Methanothermobacter* species (Tersteegen and Hedderich, 1999), in *Methanosarcina barkeri* strain Fusaro (Künkel et al., 1998), and in *Carboxidothermus hydrogenoformans* (Soboh et al., 2002; Fig. 3). The intact Ech hydrogenase complex has been purified to homogeneity from cells of *M. barkeri* (Meuer et al., 1999). It consists of two membrane-spanning subunits and four hydrophilic subunits, all of which show a particularly strong resemblance to subunits of complex I (Albracht and Hedderich, 2000; Vignais et al., 2001). Ech hydrogenase catalyzes the reversible reduction of a 2[4Fe-4S] ferredoxin by H_2 (Meuer et al., 1999). With the aid of a mutant, it was elegantly shown recently that the Ech hydrogenase of *M. barkeri* has a key function in methanogenesis (Meuer et al., 2002). During acetate-dependent growth, this enzyme mediates H_2 evolution from reduced ferredoxin by the oxidation of the acetate-borne carbonyl group to CO_2. Under H_2/CO_2 growth conditions, the Ech hydrogenase catalyzes the energetically unfavorable reduction of ferredoxin, which in turn is used as a low potential electron donor for the anabolic synthesis of pyruvate. Simultanously the reduced ferredoxin serves as reducing equivalents for the first step of methanogenesis, the reduction of CO_2 to formylmethanofuran. Because of the low mid-point potential of the CO_2 + methanofuran/CHO-methanofuran couple ($E^{0\prime} = -500$ mV), the reaction is endergonic, with H_2 as electron donor ($E^{0\prime} = -414$ mV; Bertram and Thauer, 1994). It has been proposed that Ech hydrogenases function as proton or sodium pumps providing low potential reducing equivalents (Meuer et al., 1999), and on the basis of sequence comparisons, it is hypothesized that a specific ferredoxin-like subunit is the electrical driving unit of the proton pump in complex I and proton-pumping hydrogenases (Albracht and Hedderich, 2000). This subunit is absent in the dimeric [NiFe] hydrogenases and in the tetrameric NAD-reducing hydrogenases.

[FeFe] Hydrogenases

MOLECULAR CHARACTERISTICS The [FeFe] hydrogenases are found in anaerobic, primarily H_2-evolving organisms, including fermentative bacteria, sulfate-reducers, and some lower eukaryotes. They are characterized by an extremely high oxygen sensitivity, a high turnover rate, and a low affinity for the substrate

hydrogen (reviewed by Adams [1990], Peters [1999], Nicolet et al. [2000], Vignais et al. [2001], and Horner et al. [2002]). In addition to monomeric [FeFe] hydrogenases, there are dimeric, trimeric and tetrameric enzymes.

Two well characterized examples are the monomeric 61-kDa cytoplasmic [FeFe] hydrogenase of *Clostridium pasteurianum* (Adams and Stiefel, 1998) and the dimeric periplasmic enzyme of *Desulfovibrio desulfuricans* consisting of a large (43-kDa) and a small (10-kDa) subunit (Nicolet et al., 1999). The [FeFe] hydrogenase of *C. pasteurianum* uses protons as electron acceptors to rid the cell of excess reducing equivalents, thereby regenerating oxidized ferredoxin and leading to the production of H_2. The [FeFe] hydrogenase of *D. desulfuricans* plays a role in H_2 uptake. The active site consists of a unique metal-containing prosthetic group, the so-called "H-cluster" (Fig. 9). The H-cluster is composed of a single [4Fe-4S] subcluster bridged through a thioether linkage (provided by a cysteine residue) to a specific iron binuclear subcluster (Peters et al., 1998; Nicolet et al., 1999). A multiple amino acid sequence alignment revealed considerable similarity within the H-cluster-coordinating region, indicating a fairly conserved architecture of the active site. Additional domains, however, which differ remarkably in size and cofactor content, are often present in this class of hydrogenases.

Recently, the three-dimensional structure of hydrogenase isoenzyme I from *C. pasteurianum* (Peters et al., 1998) and the [FeFe] hydrogenase from *D. desulfuricans* (Nicolet et al., 1999) has been determined at a resolution of 1.8 and 1.6 Å, respectively. A comparison revealed a highly related multidomain structure divided into an active site domain, bearing the H-cluster, and accessory cluster domains (Fig. 10). Both hydrogenases share in addition to the H-cluster the so-called "F-domain," containing two [4Fe-4S] clusters in a ferredoxin-like domain (Peters, 1999; Nicolet et al., 2000). It is interesting to note that the H-cluster of the *D. desulfuricans* hydrogenase occupies a region spanning the small subunit and the N-terminal part of the large subunit.

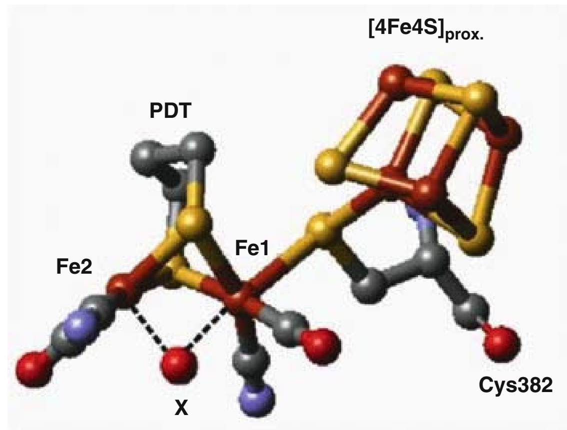

Fig. 9. The H cluster of the *D. desulfuricans* [FeFe] hydrogenase. The iron atoms are labeled "Fe1" and "Fe2." The larger bridging ligand is modeled as 1,3-propanedithiol (PDT). The smaller ligand is marked "X." Based on Nicolet et al. (1999).

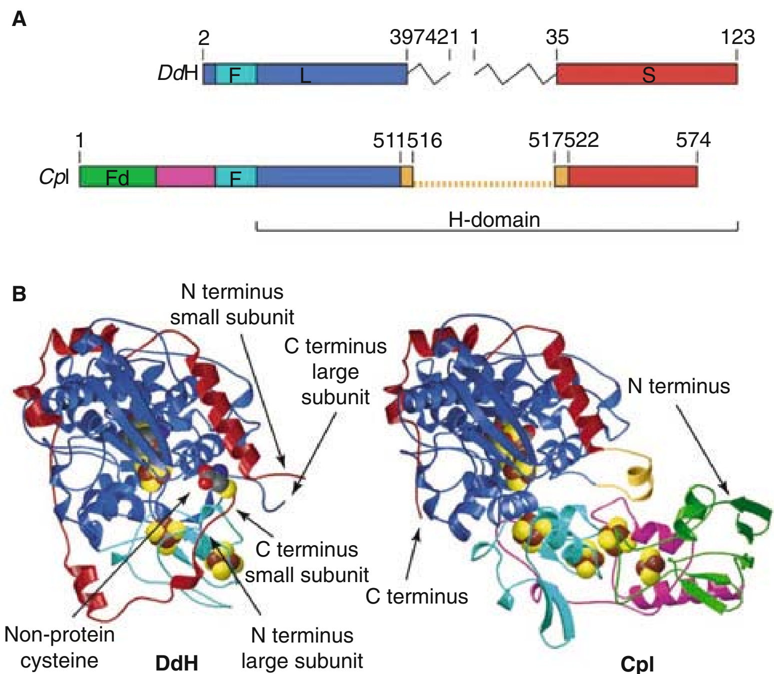

Fig. 10. Structural comparison of two [FeFe] hydrogenases. (A) Schematic representation of the *Desulfovibrio desulfuricans* [FeFe] hydrogenase (DdH) and of the *Clostridium pasteurianum* [FeFe] hydrogenase I (CpI). Structurally related domains are rendered in the same color. The small and large subunits of DdH are labeled S and L, respectively. The first 34 amino acids of the DdH small subunit and the last 24 residues of the large subunit are missing in the mature proteins. The plant-ferredoxin-like domain (Fd) is shown in green, and the F-domain, which harbors 2 [4Fe-4S] centers, in turquoise. An additional [4Fe-4S] center is colored pink. (B) The three-dimensional structures of DdH (left) and CpI (right). The color-coding is based on the diagram in (A). From Nicolet et al. (2000), with permission from Elsevier Science.

The latter provides also the binding site for the F-cluster. Thus the small subunit of the *D. desulfuricans* enzyme does not represent a single domain but rather a stretched polypeptide chain which is wrapped around the large subunit (Fig. 10). The *C. pasteurianum* hydrogenase contains two additional iron-sulfur centers not present in the *D. desulfuricans* enzyme. Both prosthetic groups are located in the N-terminal part of the protein. This implies a [2Fe-2S] cluster with structural similarity to plant-type ferredoxins and a [4Fe-4S] cluster coordinated through three cysteine ligands and a single histidine ligand (Peters et al., 1998). This coordination is equivalent to the distal [4Fe-4S] cluster coordination in the *D. gigas* [NiFe] hydrogenase (Volbeda et al., 1995).

Catalytic Reaction One of the outstanding features of the iron binuclear subcluster discovered in both the *C. pasteurianum* and the *D. desulfuricans* [Fe] hydrogenases is the existence of two terminal nonprotein ligands at each Fe atom (Fe1 and Fe2; Fig. 9). FTIR studies suggest the presence of both CN^- and CO ligands (Pierik et al., 1998) that provide a similar coordination environment as found in [NiFe] hydrogenases. Unlike the [NiFe] center, which is bound to the protein by two cysteine ligands, the Fe1-Fe2 atoms lack a direct linkage to the protein (Fig. 9). In both crystallized enzymes, the two Fe atoms are bridged through sulfur atoms, which are covalently linked to each other through a bridging molecule. In the case of *D. desulfuricans*, this bridging molecule was tentatively identified as propan dithiol (Nicolet et al., 1999). The two subgroups of [FeFe] hydrogenases obviously differ in the nature of the third bridging ligand between Fe1 and Fe2. In the enzyme from *C. pasteurianum*, this ligand was identified as a CO, and in *D. desulfuricans*, this site was modeled as an asymmetrically coordinated water molecule (Nicolet et al., 2000). A terminal water molecule was demonstrated as a fifth ligand at the bimetallic site in the *C. pasteurianum* structure (Peters et al., 1998).

The coordination environment of the two metals in [FeFe] hydrogenases favors Fe2 as a candidate for displacement and formation of a bound hydride intermediate. This assumption is consistent with the result that the competitive inhibitor CO binds to Fe2 in the enzyme from *C. pasteurianum* (Lemon and Peters, 1999). Further support comes from the observation that a hydrophobic continous channel leads from the protein surface and ends at the Fe2 coordination site of the *D. desulfuricans* structure (Hatchikian et al., 1999). This region is highly conserved in the *C. pasteurianum* enzyme and points to a specific access of H_2 to the active site as has been discussed for the [NiFe] hydrogenases (Montet et al., 1997). Finally a potential pathway for the transfer of protons was proposed involving charged and polar amino acid side chains, water molecules, and two conserved residues in the vicinity of Fe2. The latter imply a lysine residue (K358 in Cp and K237 in Dd) hydrogen bonded to a diatomic ligand of Fe2, and a cysteine residue (C299 in Cp and C178 in Dd) located in hydrogen-bonding distance to the terminally coordinated water molecule in the *C. pasteurianum* enzyme (Peters, 1999).

Diversity of [FeFe] Hydrogenases and Hydrogenase-Related Proteins The smallest [FeFe] hydrogenase unit (45–48 kDa) bearing an H-cluster subdomain only (Fig. 11) has been discovered in green algae (Happe and Naber, 1993; Happe et al., 1994). This type of enzyme, first reported for *Chlamydomonas reinhardtii*, appears to be present also in *Scenedesmus obliquus* (Florin et al., 2001; Wünschiers et al., 2001) and *Chlorella fusca* (Winkler et al., 2002). The hydrogenase is linked to the photosynthetic electron transport chain and receives its electrons for H_2 evolution from reduced [2Fe-2S] ferredoxin, which is generated during the fermentative metabolic cycle of these organisms (Florin et al., 2001). Another simple [FeFe] hydrogenase, which contains in addition to the H-cluster a clostridial F-subdomain (Fig. 9), is represented in prokaryotic species such as *Megasphera elsdenii* (Atta and Meyer, 2000; Fig. 11) as well as in lower eukaryotes such as *Trichomonas vaginalis* (Bui and Johnson, 1996; Horner et al., 2000). In spite of the absence of additional prosthetic groups, the *M. elsdenii* hydrogenase uses electron donors of the type found in clostridia including a 2[4Fe-4S] ferredoxin and a flavodoxin (Atta and Meyer, 2000). In the anaerobic eukaryotic organisms, the [FeFe] hydrogenases are localized to intracellular organelles of endosymbiotic origin (Müller, 1993; Martin and Müller, 1998; Moreira and Lopez-Garcia, 1998). In the case of chytrid fungi, anaerobic ciliates and trichomonads, these organelles are denoted as hydrogenosomes and considered as modified mitochondria which have lost the capacity for oxidative phosphorylation while gaining the ability for ferredoxin-coupled H_2 production from pyruvate.

Multisubunit [FeFe] hydrogenase complexes are present in some prokaryotic species. The large (73-kDa) subunit HydA harbors the active site of the heterotrimeric [FeFe] hydrogenase from the hyperthermophilic *Thermotoga maritima* (Fig. 11). Sequence analysis predicts that the enzyme is a multiple iron-sulfur cluster-containing flavoprotein which uses NADH as the electron donor. The latter two features still need

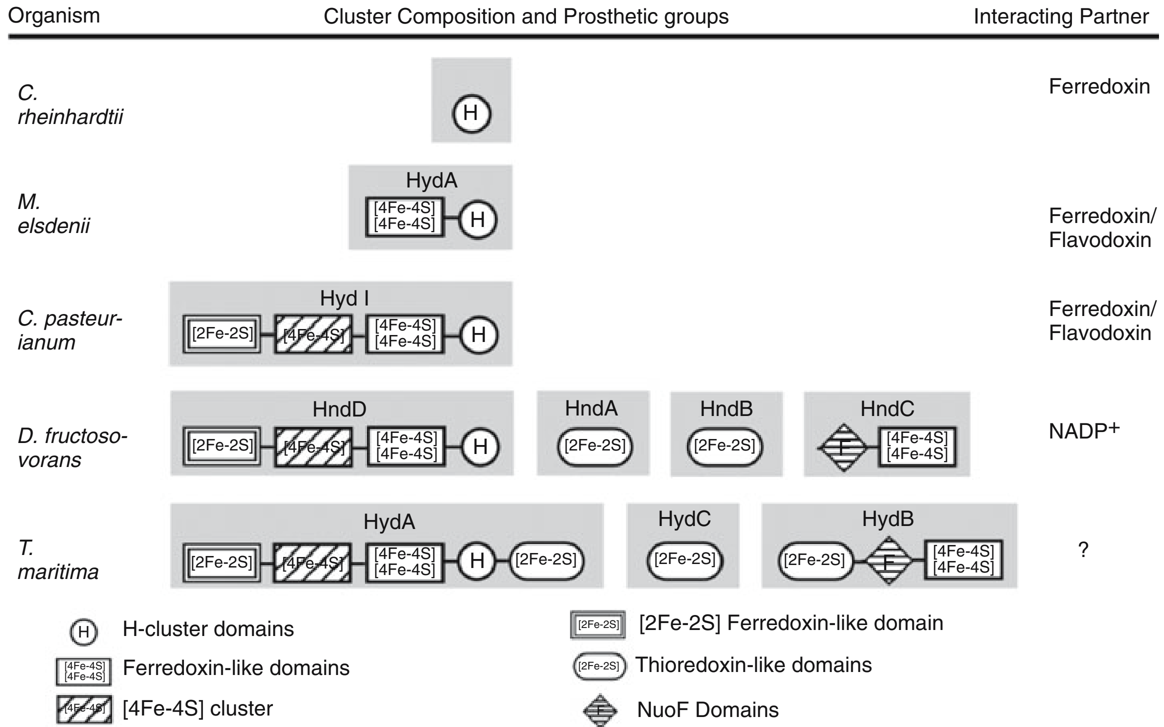

Fig. 11. Domain organization of selected [FeFe] hydrogenases. Gray boxes represent hydrogenase subunits (not to scale). Redox partners are listed at the right. A key to the symbols is given in the lower part of the figure.

to be confirmed experimentally with purified holoenzyme (Verhagen et al., 1999). Each of the three [FeFe] hydrogenase subunits contains a domain which is similar to the bacterial thioredoxin-like [2Fe-2S] ferredoxins and the NuoE polypeptide of NADH-ubiquinone oxidoreductase. An additional domain, homologous to the NuoF subunit of complex I, was uncovered in the HydB polypeptide (Fig. 11). These observations again emphasize the evolutionary relationship between complex I and hydrogenases.

The catalytic subunit of the heterotetrameric cytoplasmic NADP-reducing [FeFe] hydrogenase of *D. fructosovorans* has a similar accessory domain composition as the clostridial hydrogenases (Malki et al., 1995). Its overall structure resembles that of the *T. maritima* enzyme showing the typical complex I-related domains assigned to three separate subunits (Fig. 11). Indeed it was suggested that the HynB and HynC subunits of *D. fructosovarans* are fused to a single polypeptide (HydB) in *T. maritima* (Vignais et al., 2001).

Sequences related to [FeFe] hydrogenase genes have been identified in genomes of aerobic eukaryotes, including the human genome. Members of this novel class of nuclear proteins are termed "nuclear prelamin A recognition factors" (NARFs; Barton and Worman, 1999). A general cellular function of NARFs, such as a role in the regulation of the cell cycle, is the subject of ongoing discussion. Since H_2-converting processes have so far not been observed in higher eukaryotes, it is unlikely that NARF proteins are implicated in energy metabolism.

[Fe] Hydrogenases

The H_2-forming methylentetrahydromethanopterin dehydrogenases (Hmd's) of methanogenic archaea represent a third, phylogenetically distinct class of hydrogenases (Zirngibl et al., 1990; Thauer et al., 1996; Berkessel, 2001). These homodimeric enzymes, characterized as H_2-forming methylenetetrahydromethanopterin dehydrogenase (Hmd), are present in methanogenic archaea where they catalyzes a step in met hanogenesis, namely, the reversible reduction of N^5,N^{10}-methenyltetrahydromethanopterin with H_2 to N^5,N^{10}-methylenetetrahydromethanopterin (Thauer, 1998). The product is used by the F_{420}-specific N^5,N^{10}-methylenetetrahydromethanopterin dehydrogenase for the reduction of F_{420} (Fig. 3). Both enzymes are coordinately expressed at a high level under nickel depletion (Afting et al., 1998). With the aid of the hydrogen

isotope assays and two-dimensional nuclear magnetic resonance (2D NMR), it was possible to explore the H_2-forming reaction in further detail and to demonstrate a stereoselective hydride transfer (Thauer et al., 1996). Unlike other hydrogenases, which are iron-sulfur proteins, the Hmd's contain only redox-active iron bound to a thermolabile cofactor. Exposure of the Hmd's to UV-A or blue light results in inactivation of the enzyme and release of iron (Buurman et al., 2000; Lyon et al., 2004).

Maturation of Hydrogenases

The complex architecture of the active site in [NiFe] and [FeFe] hydrogenases raises the question of how such metal centers are synthesized and assembled into the polypeptides. Auxiliary proteins which control metal insertion and coordinated folding of the protein are often involved in the biosynthesis of metalloenzymes. Inspection of the nucleotide sequences of [NiFe] hydrogenase gene complexes revealed numerous highly conserved accessory genes, which are usually closely linked to the corresponding structural genes. Mutant analysis delivered the first evidence for a complex co- or post-translational metal insertion pathway. This chapter focuses on the maturation of [NiFe] hydrogenases (Böhm et al., 1990; Friedrich and Schwartz, 1993; Maier and Böck, 1996; Casalot and Rousset, 2001; Robson, 2001; Blokesch et al., 2002). At present, scarcely anything is known about the insertion of the H-cluster into [FeFe] hydrogenases. This article does not address the acquisition of metals, the synthesis of iron-sulfur clusters, and other prosthetic groups which are shared with other metalloproteins. Depending on the cellular location and specific functional properties, [NiFe] hydrogenases undergo various levels of maturation. The maturation process will be discussed below step by step.

[NiFe] Center Insertion

At least six *hyp* gene products (HypA, HypB, HypC, HypD, HypE and HypF), present in bacterial as well as archaeal [NiFe] hydrogenase-containing species, are involved in the insertion of the heterodinuclear metal center (Table 3). The designation *hyp* stands for "genes affecting *hy*drogenases *p*leiotropically." This means that mutations in the individual *hyp* genes either reduce or abolish the activity of multiple [NiFe] hydrogenase isoenzymes, as demonstrated for *Escherichia coli* (Lutz et al., 1991) and *Ralstonia eutropha* (Dernedde et al., 1996; Wolf et al., 1998).

The sequence of events that lead to the formation of active [NiFe] hydrogenases is now emerging. A current model of the reaction cycle is predominantly based on studies on hydrogenase 3 of *E. coli*. Its [NiFe] center-containing subunit HycE is part of a protein complex attached to the inner face of the cytoplasmic membrane (Rossmann et al., 1994; Fig. 2). The working model (Fig. 12) postulates a sequential insertion of the two metals into the precursor. First, iron and its diatomic ligands are assembled. A HypC-HypD complex seems to act as a platform for this process. The insertion of at least one CN- is mediated by HypF (Paschos et al., 2001) in concert with HypE (Blokesch et al., 2002). According to the model, carbamoyl phosphate is the source of at least one of the CN- ligands. HypF, which contains several conserved functional domains (Table 3), converts carbamoyl phosphate to carbamoyl adenylate in an ATP-dependent reaction. In a transient HypE-HypF

Table 3. Characteristics of Hyp proteins.

Protein	Size[a] (kDa)	Sequence motif(s)	Putative function[b]
HypA	13.2	Cysteine cluster $CX_2CX_{12}CX_2C$	Ni insertion
HypB[c]	31.6	Cysteine cluster CX_2CGC, GTP-binding domain, His-rich region	Ni insertion and in some cases also Ni storage
HypC	9.7	Conserved N-terminal Cys residue	Chaperone which forms a complex with HypD and the large subunit
HypD	41.4	[Fe-S] cluster	Fe-dependent complex formation with HypC
HypE	33.7	ATP-binding site	Complex formation with HypF, ATPase
HypF	82.0	*o*-Carbamoyl transferase domain, two zinc finger motifs, acylphosphatase domain, and glycine-rich motif	Conversion of carbamoyl phosphate to the CN^- ligand, carbamoyl phosphate-dependent ATP cleavage
HypX[c]	65.7	N_{10}-formyltetrahydrofolate binding site, and enoyl-CoA hydratase/isomerase signature	Insertion of extra CN^-

Abbreviations: *hyp*, genes affecting *hy*drogenases *p*leiotropically; Cys, cysteine; and CN^-, cyanide ion.
[a]Sizes of *E. coli* K12 Hyp proteins are given (Lutz et al., 1991; Maier et al., 1996).
[b]References are given in the text.
[c]HypB of *E. coli* is devoid of a stretch of His residues. HypX is not present in *E. coli*.

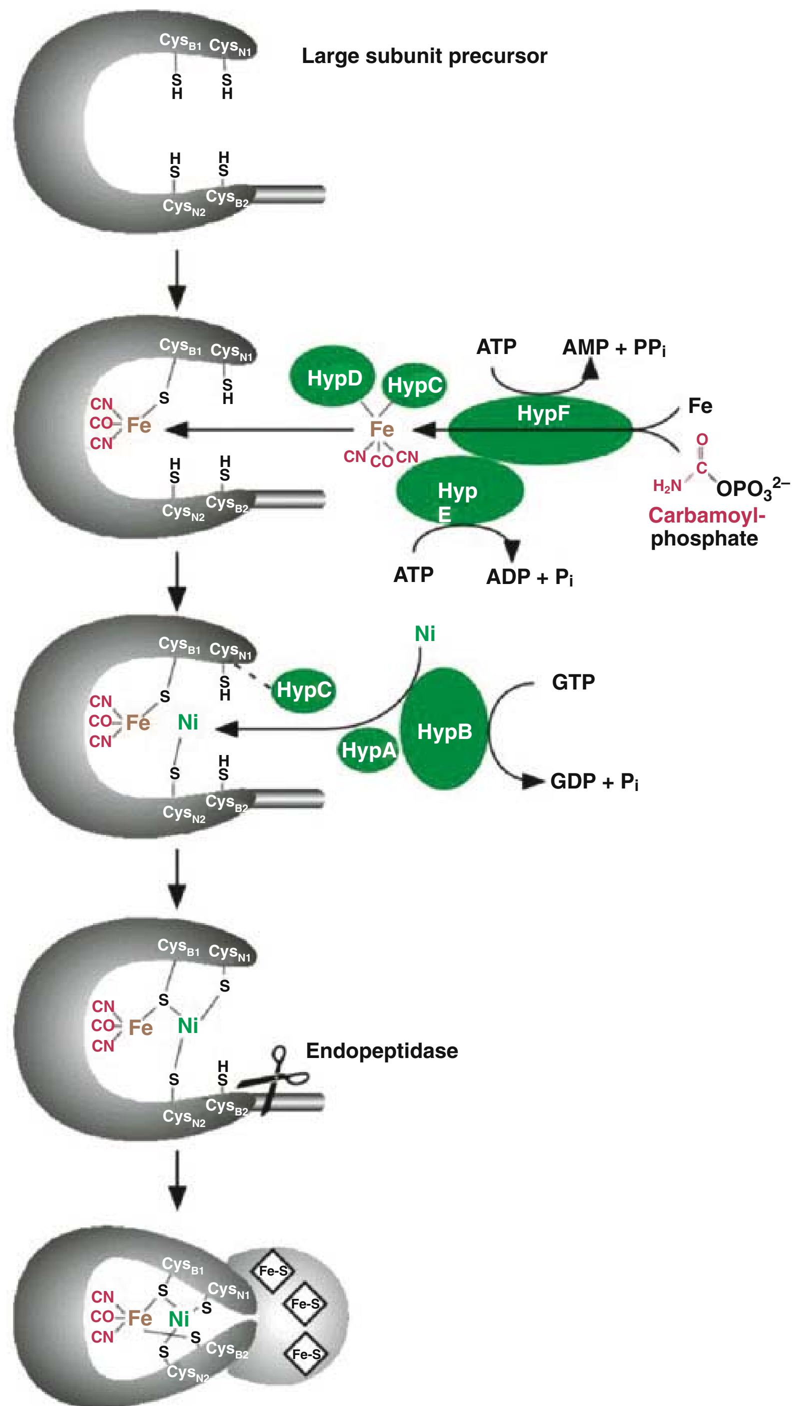

Fig. 12. Molecular model for the maturation of [NiFe] hydrogenases based mainly on studies on *E. coli* hydrogenase 3. The large and small subunits of the hydrogenase are shown in dark and light gray, respectively. The Hyp proteins are depicted in green. Iron-sulfur clusters are indicated as diamonds (Fe-S). See text for details.

complex, HypF mediates the carbamoylation of HypE at the C-terminal cysteine. Finally, HypE catalyzes the dehydration of the carbamoylate moiety to thiocyanate and then transfers this group to the iron waiting on HypC-HypD. (Paschos et al., 2001; Blokesch et al., 2002; 2004).

The steps leading to the formation of the other two ligands are as yet unknown. It is postulated that the Fe(CN-)2CO group is completed on the HypC-HypD complex and then transferred to the large subunit (Blokesch et al., 2002). A HypC-HycE complex is an intermediate in the latter step. One of the nickel-coordinating cysteine residues (CysN1; Fig. 12) is required for the formation of the complex. Although the mechanism of HycE-HypC complex formation is not yet known, disulfide bridge formation between HycE and HypC can be excluded (Magalon and

Böck, 2000). Because of the lack of data from other organisms, it would be premature to generalize the above mechanistic scheme. A global two-hybrid study an *Helicobacter pylori* indicates a HypE/HypF interaction (Rain et al., 2001). In *Thiocapsa roseopersicina* there are two distinct HypC species. Both are required for the assembly of the hydrogenases in this organism (Maróti et al., 2003). Various complexes including HypC-HypD, HypE-HypF1, HypC-HypD-HypE and HypC-HoxH have been detected in *R. eutropha* (Jones et al., 2005).

Metal center assembly proceeds by nickel incorporation catalyzed by the HypB protein in conjunction with HypA (Olson et al., 2001; Hube et al., 2002; Fig. 12). HypB proteins share a GTP-binding site (Table 3) and GTP hydrolysis is essential for HypB-mediated nickel insertion in *E. coli* (Maier et al., 1995). Some of the hydrogenase activity, however, can be rescued in a *hypB* mutant by supplying high concentrations of Ni^{+2} to the medium (Waugh and Boxer, 1986). Unlike *E. coli* HypB, the majority of HypB proteins contain stretches of His residues with potential Ni-chelating function. In fact, binding of Ni^{+2} ions has been demonstrated for the HypB proteins of *Sinorhizobium leguminosarum* (Rey et al., 1994) and *Bradyrhizobium japonicum* (Fu et al., 1995). This observation suggests that in some organisms HypB has a dual function: It not only delivers Ni^{+2} ions to the hydrogenase but acts also as a nickel storage protein.

An additional Hyp protein, HypX (formerly designated "HoxX"), has so far been found only in aerobically H_2-oxidizing bacteria, including *B. japonicum* (Van Soom et al., 1993), *R. eutropha* (Lenz et al., 1994) and *S. leguminosarum* (Rey et al., 1996). Mutations in *hypX* decreased the activity of hydrogenase under certain growth conditions in two nitrogen-fixing organisms (Rey et al., 1996; Durmowicz and Maier, 1997) as well as in a chemolithotroph (Buhrke and Friedrich, 1998). The HypX protein reveals two interesting sequence motifs: an N-terminal N_{10}-formyltetrahydrofolate binding site and a C-terminal signature that is typical for enoyl-CoA hydratases and isomerases. It was postulated that HypX plays a role in the recruitment of diatomic ligands in a tetrahydrofolate (THF)-coupled reaction (Rey et al., 1996). Recent studies with the NAD-reducing hydrogenase from *R. eutropha*, isolated from a *hypX* mutant, suggest that HypX is indeed involved in the delivery of an extra CN^- to the Ni atom (Bleijlevens, 2002; Buhrke, 2002).

Genomic sequencing has now uncovered *hypX* isologs in other prokaryotes including *Aquifex aeolicus* (Deckert et al., 1998) and *Streptomyces avermitilis* (Omura et al., 2001). The *hyp* genes are lacking in *Thermotoga maritima*, an organism which harbors [FeFe] hydrogenase only (Nelson et al., 1999). Thus Hyp proteins are obviously not involved in the synthesis of [FeFe] hydrogenases. If there is a protein-mediated metal center assembly process for this class of hydrogenases, different and as yet unknown components must be involved.

The Final Step Involves Proteolysis

Once the [NiFe] center is incorporated into the active site (Fig. 12), the chaperone HypC dissociates from the hydrogenase precursor HycE and a specific endopeptidase, HycI in the case of *E. coli* hydrogenase 3, completes the reaction cycle by cleaving 32 amino acids from the C-terminus of the active site subunit (Rossmann et al., 1994). During this process, the endopeptidase is proposed to inspect correct metal insertion and to trigger a conformational change by proteolysis, henceforth allowing the hydrogenase to enter a folded, oligomeric state. Crystal structure analysis of HybD, the endopeptidase specific for hydrogenase 2 of *E. coli*, has uncovered a metal binding site (Glu16, Asp62, His93) which is obviously implicated in nickel recognition during the proofreading process (Fritsche et al., 1999; Theodoratou et al., 2000a).

C-terminal proteolysis in multiple [NiFe] hydrogenase-containing organisms is mediated by individual endopeptidases which are functionally not interchangeable. The length of the cleaved peptides varies considerably (between 13 and 32 amino acids), whereas the cleavage sites seem to be rather conserved. A basic amino acid is separated by three amino acids from the terminal Ni-coordinating cysteine (Cys_{B2}; Fig. 12). The exact position of endoproteolytic cleavage was experimentally determined to be an arginine residue in HycE of the *E. coli* hydrogenase 3 (Rossmann et al., 1994; Theodoratou et al., 2000b) and a histidine residue in HoxH of the *R. eutropha* NAD-reducing hydrogenase (Thiemermann et al., 1996). Crystal structure analysis of the [NiFe] hydrogenases from the sulfate reducers revealed a similar situation: All primary sequences terminate at a histidine residue (Volbeda et al., 1995; Higuchi et al., 1997; Montet et al., 1997; Matias et al., 2001).

Not all hydrogenases, however, undergo C-terminal proteolysis during maturation. The H_2-sensing proteins (reviewed by Vignais et al., 2001), the CO-induced hydrogenase of *Rhodospirillum rubrum* (Fox et al., 1996a; Fox et al., 1996b) and the Ech hydrogenase of *Methanosarcina barkeri* (Künkel et al., 1998) are examples. Although experimental results have shown that metal center insertion into the H_2-sensing proteins of *B. japonicum* (Olson et al., 1997), *R. capsulatus* (Colbeau et al., 1998) and *R. eutropha*

(Buhrke et al., 2001) relies on *hyp* gene products, a C-terminal extension at the active site subunit is dispensible for metal center assembly. This contradicts data obtained with most hydrogenases, e.g., hydrogenase 3 of *E. coli* (Binder et al., 1996) and the NAD-reducing hydrogenase of *R. eutropha* (Massanz et al., 1997). In the latter cases, it was unambiguously shown that genetically designed extension-free HycE and HoxH mutants failed to express active hydrogenase and to incorporate nickel. At present, the discrepancy between the two systems cannot be resolved.

Membrane Translocation of Hydrogenases

Periplasmic and periplasmically oriented membrane-bound [NiFe] and [FeFe] hydrogenases belong to a group of redox proteins that are exported across the cytoplasmic membrane through a special translocation pathway which functions independently of the general secretion (Sec) machinery of the cell (reviewed by Berks [1996], Voordouw [2000], and Wu et al. [2000]). All proteins that undergo this mode of translocation share a signal sequence bearing a common conserved motif (S/T)-R-R-X-F-L-K referred to as the "twin arginine leader." This type of leader occurs in bimetallic hydrogenases in addition to periplasmic redox proteins containing iron-sulfur clusters, flavine adenine dinucleotide, polynuclear copper sites or molybdopterin cofactors. It directs the various redox proteins to the recently identified Mtt (membrane targeting and translocation) or synonymously termed Tat (twin arginine translocation) pathway. The salient feature of this system is that it transports proteins in partially or completely folded form (Bogsch et al., 1998; Hynds et al., 1998; Santini et al., 1998; Sargent et al., 1998; Weiner et al., 1998). The Mtt/Tat pathway resembles the DpH-driven import of proteins into the thylacoid lumen of chloroplasts (Settles et al., 1997).

In Tat deficient mutants of *Azotobacter chroococcum* (Yates et al., 1997), *E. coli* (Rodrigue et al., 1999) and *R. eutropha* (Bernhard et al., 2000), membrane targeting of [NiFe] hydrogenases is arrested and they accumulate in the cytoplasm. Although the mislocated enzymes are physiologically inactive, they nevertheless have catalytic activity, as evidenced in assays of soluble extracts using redox dyes as electron mediators. This clearly shows that metal center assembly by the Hyp proteins occurs in the cytoplasm prior to translocation of the hydrogenase.

Only the small subunit of [NiFe] hydrogenases has an unusually long N-terminal twin-arginine leader peptide of 30–50 amino acid residues, whereas the large subunit lacks an export signal. Early observations on the [FeFe] hydrogenase of *Desulfovibrio vulgaris* (Hildenborough) led to the proposal that the large subunit is translocated with the small subunit (Voordouw and Brenner, 1985; van Dongen et al., 1988). Since then, experimental evidence has accumulated which clearly points to a tandem export of the two subunits. Genetic studies conducted with [NiFe] hydrogenases from *E. coli* (Menon et al., 1991; Menon and Robson, 1994a; Rodrigue et al., 1999), *Desulfovibrio vulgaris* (Nivière et al., 1992), *R. eutropha* (Bernhard et al., 1996), *Desulfovibrio gigas* (Rousset et al., 1998a) and *Wolinella succinogenes* (Gross et al., 1999) are all in line with a cotranslocation model. Several requirements have to be met to achieve proper export of the oligomeric hydrogenases. Membrane targeting depends on an intact twin-arginine leader peptide at the C-terminus of the small subunit, on the presence of the large subunit, its nickel acquisition, and its C-terminal processing. Thus, periplasmic and periplasmically oriented membrane-bound [NiFe] hydrogenases undergo the most complex maturation process as depicted in a schematic model (Fig. 13).

It seems likely that additional proteins participate in the maturation of this group of hydrogenases. The role of chaperonins (GroES and GroEL) on the activity of the three hydrogenase isoenzymes in *E. coli* has been investigated and evidence presented for an involvement of these chaperonins in the biosynthesis of hydrogenase 3 (Rodrigue et al., 1996). Preliminary data suggest that additional hydrogenase-specific auxiliary proteins control translocation of oligomeric hydrogenass (Fig. 13). It is remarkable that membrane-bound hydrogenase operons contain sets of tightly linked accessory genes whose precise function is not understood. Inactivation of *hyaE* and *hyaF* in the hydrogenase 1 operon of *E. coli* (Menon et al., 1991) and the homologous gene sequences *hoxO* and *hoxQ* in the MBH operon of *R. eutropha* (Bernhard et al., 1996) lead to the formation of catalytically inactive hydrogenase, which accumulates in the cytosol.

Crystal structure analysis of the [FeFe] hydrogenase from *Desulfovibrio desulfuricans* (Nicolet et al., 1999) has confirmed earlier predictions concerning export of hydrogenases in sulfate reducers (Voordouw and Brenner, 1985). In the mature functional molecule, the 34-amino-acid twin arginine signal peptide, predicted from the DNA sequence of the small subunit, is missing (Hatchikian et al., 1999; Nicolet et al., 1999). This result clearly indicates that periplasmic [FeFe] hydrogenases are subject to a similar translocation process as [NiFe] hydrogenases. A second peptide of 24 amino acids, assigned to the C-terminus of the large *D. desulfuricans* subunit, is also absent in the mature protein, but whether this processing is related to translocation or

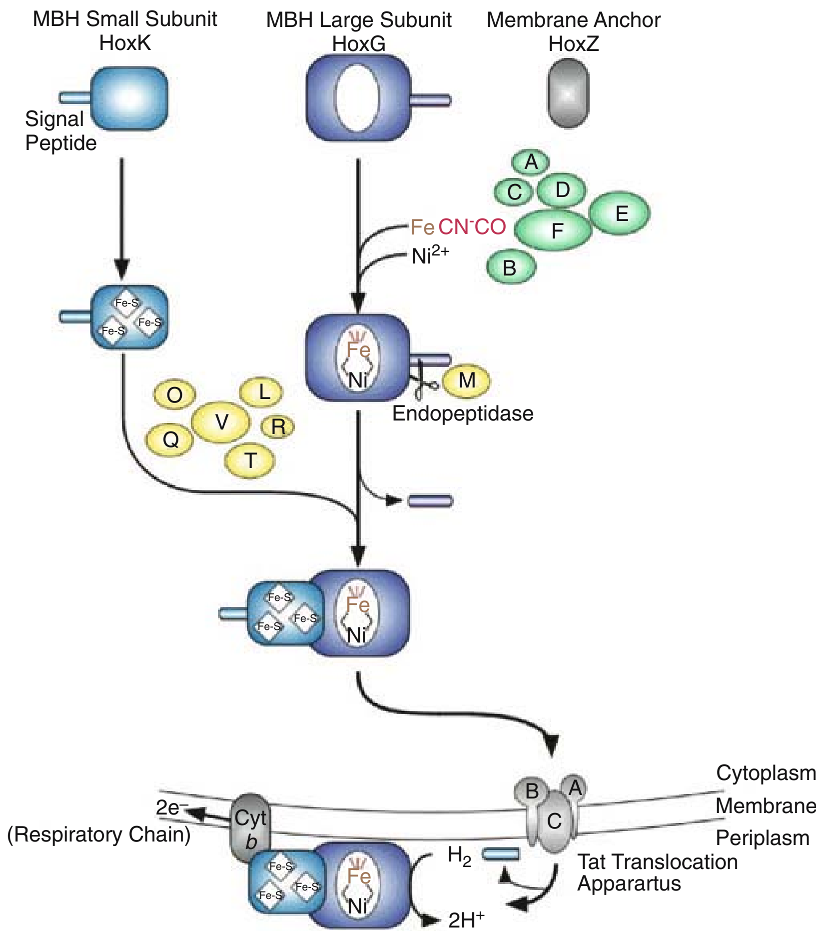

Fig. 13. Molecular model for the maturation of the *R. eutropha* membrane-bound hydrogenase. Hyp proteins (A, B, C, D, E and F) and specialized Hox accessory proteins (M, L, O, Q, R, T and V) are labeled. See text for details.

other maturation functions is still a matter of debate.

Hydrogenase Genes and Their Regulation

Genetic and molecular studies have led to the identification and characterization of the genetic determinants of numerous hydrogenase enzymes in bacteria, archaea and lower eukaryotes. More recently, genomic sequencing projects have contributed to the base of genetic data on hydrogenases. It is now possible to sketch the genetic organization of the hydrogenase genes of representatives of several important taxonomic groups. In some cases, the transcriptional units have been defined by Northern analysis. Detailed information on hydrogenase expression and the underlying regulatory mechanisms is only available for a few systems (see Friedrich et al. [2001] for a list).

It has long been known that various prokaryotes contain multiple hydrogenase isoenzymes. This raised the question regarding the total number of hydrogenases in a given organism. Genome sequence data is obviously an important source of information here and can provide a tentative answer which is, of course, subject to biochemical confirmation. The *E. coli* genome sequencing project confirmed the presence of the four previously identified hydrogenase operons (Blattner et al., 1997). The genome sequence of *Methanothermobacter thermoautotrophicus* predicts the existence of five distinct hydrogenases in this organism (Smith et al., 1997). Three of these have been characterized biochemically. Three sets of hydrogenase genes have been identified in the genome of *A. aeolicus* (Deckert et al., 1998). No hydrogenase genes were identified in the genomes of *H. influenzae* and *M. tuberculosis*.

In many prokaryotes, hydrogenase genes are carried on autochthonous plasmids, some of which are transmissible via conjugation (reviewed by Friedrich and Schwartz [1993]). Plasmid-linked hydrogenase genes are often found in organisms in which H_2 metabolism is part of a facultative lifestyle. Plasmid-borne hydrogenase genes provide a simple explanation for the combinations of hydrogenases of various biochemical types found in some prokaryotes.

Nucleotide sequences are now available for well over 100 hydrogenases. A compilation of these data presents, at first glance, a complex and confusing picture. This is, in part, due to the fact that, depending on the type of hydrogenase and its metabolic context, a more or less complex set of gene products is required. As outlined above, the three types of hydrogenases differ with respect to maturation. Furthermore, the requirement for regulatory proteins is different; conditionally expressed hydrogenases are governed by cognate regulators, which are superfluous in organisms in which the enzyme is synthesized constitutively. In general, five different classes of hydrogenase-related genes can be differentiated on the basis of function: 1) structural genes, i.e., the genes encoding peptides directly involved in the reversible activation of H_2; 2) genes coding for the additional subunits of multisubunit hydrogenases, e. g., the *b*-type cytochromes of bacterial membrane-bound hydrogenases; 3) accessory genes coding for proteins involved in hydrogenase maturation; 4) genes for redox couplers which are not components of a multisubunit hydrogenase enzyme, such as the polyferredoxins encoded by archaeal hydrogenase operons; and 5) regulatory genes. Adding to the complexity, different combinations of the above genes are grouped in transcriptional units which can be either adjacent or scattered over a replicon. Finally, the relationship of evolutionarily conserved genes is obscured by a hodgepodge of inconsistent nomenclature. The following survey summarizes data pertaining to genetic organization for a selection of representatives of the various groups of hydrogenases, pointing out some basic patterns underlying the diversity. In keeping with the premise that the three classes of hydrogenases ([NiFe], [FeFe] and [Fe]) originated independently, the discussion is divided into three parts.

Genetic Organization

[NiFe] Hydrogenases The bulk of the presently available nucleotide sequence data relates to the [NiFe] hydrogenases. Sorting these sequences solely on the basis of operon structure reveals seven groups, each of which defines a conserved gene pattern. On the one hand, these groups correlate well with the subclusters defined by clustering analysis of the deduced amino acid sequences of the hydrogenase subunits (Vignais et al., 2001). On the other hand, they reflect common biochemical and physiological properties of the respective enzymes. The seven groups are as follows: 1) the *vho* and *vht* operons encoding the methanophenazine-reducing hydrogenases of the methanogenic archaeon *Methanosarcina mazei*; 2) the operons encoding the bacterial membrane-bound hydrogenases; 3) the *mvh* operon of *Methanothermobacter* and the operons for F_{420}-nonreactive hydrogenases of *Methanococcus* strains; 4) the *fru*, *frc* and *frh* operons for the F_{420}-reactive hydrogenases of *Methanococcus voltae*, *Methanothermobacter thermoautotrophicus* and *Methanosarcina* species; 5) the operons for the cytoplasmic sulfhydrogenases of fermentative archaea, such as *Pyrococcus furiosus* and *Thermococcus litoralis*; 6) the genes for the cytoplasmic, NAD-reducing enzymes of *R. eutropha* and cyanobacteria; and 7) the operons for the multimeric, membrane-bound hydrogenases of the *E. coli* hydrogenase 3 family.

Archaeal Membrane-Bound Hydrogenases In *M. mazei*, two operons (*vhoGAC* and *vhtGACD*) encoding F_{420}-nonreactive hydrogenases have been identified and sequenced (Deppenmeier, 1995a; Deppenmeier et al., 1995b). Each operon contains genes for the hydrogenase small (*vhoG* and *vhtG*) and large subunits (*vhoA* and *vhtA*) followed by a gene for a *b*-type cytochrome (*vhoC* and *vhtC*). The *vht* operon contains a fourth gene, *vhtD*, which predicts a protein with similarity to the maturation proteases associated with bacterial membrane-bound hydrogenases, suggesting that at least one of the two *M. mazei* F_{420}-nonreactive hydrogenases undergoes a similar maturation process. The genomic sequence of *M. mazei* provides additional evidence for this assumption (Deppenmeier et al., 2002): A set of *hyp* genes (*hypC*, *hypD*, *hypA* and *hypE*) is located adjacent to the *vho* operon in the opposite orientation. Furthermore, tandem copies of *hypB* and *hypC* are found a few kilobases away from the *vhtGACD* operon and solitary copies of *hypF* and *hypE* are present at remote sites. Northern analysis confirmed that the *vho* and *vht* operons are both expressed as single transcripts approx. 4,500 nucleotides (nt) in size (Fig. 14).

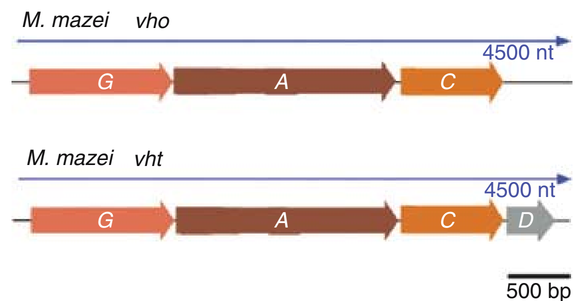

Fig. 14. Organization of the *vho* and *vht* operons of *Methanosarcina mazei*. Light brown arrows represent genes for the hydrogenase small subunits, dark brown arrows, genes for the large subunits, and orange arrows, genes for *b*-type cytochromes. A gene for a putative maturation protease, *vhtD*, is shown in gray. Thin blue arrows symbolize experimentally determined transcripts (sizes given in nucleotides).

Bacterial Membrane-Bound Hydrogenases The closest relatives of the Vho and Vht hydrogenases of *M. mazei* are the bacterial membrane-bound hydrogenases. Examples of this type of hydrogenase are found in both Gram-negative and Gram-positive bacteria. The most thoroughly studied representatives are the membrane-bound hydrogenases of various proteobacteria (Friedrich and Schwartz, 1993; Vignais and Toussaint, 1994). In contrast to the *vho* and *vht* operons, the proteobacterial genes form large, polycistronic transcriptional units. In the following, four examples of this group are discussed: The MBH locus of *R. eutropha*, the *hup*/*hyp* regions of *R. capsulatus* and *R. leguminosarum* and the *E. coli hya* operon.

The MBH locus of *R. eutropha* is a contiguous series of hydrogenase genes occupying approx. 23 kb on the megaplasmid pHG1 (Kortlüke et al., 1992; Dernedde et al., 1993; Dernedde et al., 1996; Fig. 15). The first two genes, *hoxK* and *hoxG*, which code for the small and large subunit of the hydrogenase, respectively, are followed by a gene (*hoxZ*) encoding a *b*-type cytochrome. This is the primary electron acceptor of the membrane-bound hydrogenase and also mediates attachment of the enzyme to the outer surface of the cytoplasmic membrane (Bernhard et al., 1997). The *hoxZ* gene is followed by a series of genes designated *M*, *L*, *O*, *Q*, *R*, *T* and *V*. The *hoxM* gene encodes a specific protease required for the C-terminal processing of the large subunit. The function of the other gene products is unclear. Immediately downstream of *hoxV* lies a second group of accessory genes called "*hyp* genes." The *hyp* genes are involved in the assembly of the [NiFe] center of the hydrogenase active site (see the section Maturation of Hydrogenases in this Chapter). Immediately downstream of the *R. eutropha* hyp region is a set of regulatory genes designated "*hoxA*," "*hoxB*," "*hoxC*" and "*hoxJ*" (Lenz et al., 1997). Their function will be discussed below in detail.

The same basic pattern of genes with minor variations is found in several other representatives of the proteobacteria. In *R. capsulatus*, a *hypF* gene is absent from the *hyp* operon. In its place is the regulatory gene *hupR1*. A set of regulatory genes (*hupTUV*), which corresponds to *hoxJ*/*hoxB*/*hoxC*, is encoded together with a *hypF* gene in a transcriptional unit immediately upstream of the main hydrogenase operon (Elsen et al., 1996; Fig. 15). In *R. leguminosarum*, an additional gene (*hupE*) of unknown function is located downstream of the protease gene, *hupD*. In *Methylococcus capsulatus* (Bath) hupE is adjacent to the structural genes hupSL (Csáki et al., 2001). The *E. coli hya* operon, which encodes a membrane-bound hydrogenase isoenzyme designated "hydrogenase 1," is simpler than the three examples discussed above (Menon et al., 1990; Fig. 15). This is partly due to the fact that maturation of this enzyme is mediated by the Hyp proteins encoded in an operon adjacent to the *hyc* operon. In addition to a gene for a maturation protease, *hyaD*, two other accessory genes, *hyaE* and *hyaF*, are present. It is not clear whether, aside from the Hyp proteins, accessory proteins encoded in the other hydrogenase operons are required for the function of hydrogenase 1.

An interesting variant is the *hynSL* operon of *Thiocapsa roseopersicina*. The genes *hynS* and *hynL*, which encode the small and large subunits, respectively, of a membrane-bound hydrogenase, are separated by two reading frames desig-

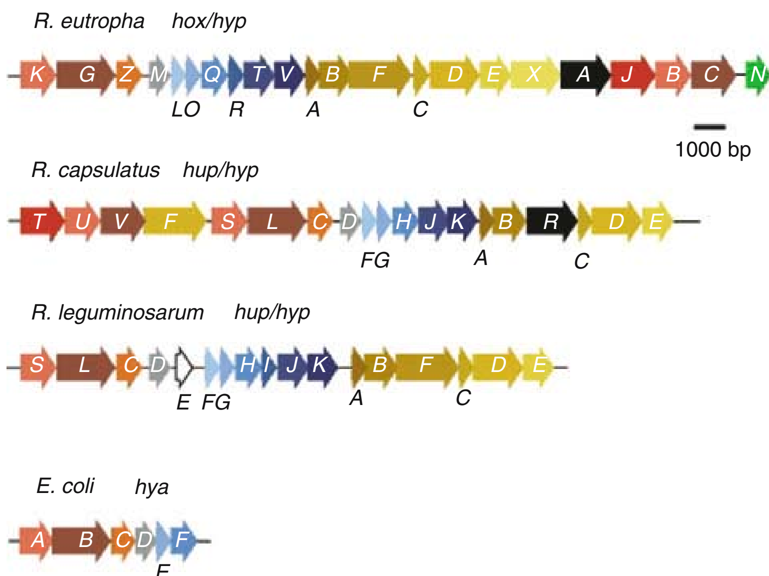

Fig. 15. Organization of hydrogenase operons of *R. eutropha*, *R. capsulatus*, *R. leguminosarum* and *E. coli*. Color-coding emphasizes similarity at the level of deduced amino-acid sequences. Light brown arrows represent genes for the small subunits, dark brown arrows, genes for the large subunits, and orange arrows, genes for *b*-type cytochromes. Genes for maturation proteases are shown in gray. The *hyp* genes are shown in shades of yellow and gold, and other accessory genes, in shades of blue. NtrC-type response regulators are black, and histidine protein kinases are red. The nickel transporter *hoxN* is colored green. Singular genes of unknown function are left uncolored.

nated *isp1* and *isp2*. These reading frames are not related to any known hydrogenase accessory genes (Rákhely et al., 1998).

The Cytoplasmic F_{420}-Nonreactive Hydrogenases The operons encoding the F_{420}-nonreactive hydrogenases of *M. thermoautotrophicus* (*mvhDGAB*) and *M. voltae* (*vhcDGAB* and *vhuDGAB*; Reeve et al., 1989; Halboth and Klein, 1992) are representatives of another conserved family (Fig. 16). The first open reading frame (ORF) of each operon predicts a protein of unknown function. This is followed by genes for the small (*mvhG*, *vhcG* and *vhuG*) and large subunits (*mvhA*, *vhcA* and *vhuA*) of the hydrogenase. A fourth gene encodes a polyferredoxin, which may be the primary electron acceptor interacting with the hydrogenase in vivo. The *vhuDGAUB* operon is an interesting variant (Halboth and Klein, 1992). In place of a gene for the large subunit, as is found in the other operons, there are two ORFs. The second, short ORF, designated *vhuU*, predicts a polypeptide related to the C-terminus of typical large subunits. This is particularly intriguing, since this part of the protein participates in coordination of the [NiFe] center.

The F_{420}-Reactive Hydrogenases Genes for F_{420}-reactive hydrogenases have also been cloned and sequenced. *Methanococcus voltae* and *M. barkeri* each contains two such operons (Halboth and Klein, 1992; Vaupel and Thauer, 1998; Fig. 17). The four operons share the same pattern: The hydrogenase large and small subunits are encoded by the first and third genes, respectively. The final gene of the set encodes the third subunit of the trimeric enzyme, which may carry the site of interaction with the cofactor F_{420}. In all four operons, the genes for the large and small subunits are separated by an additional ORF which probably encodes a specific protease responsible for the C-terminal proteolytic processing of the large subunit.

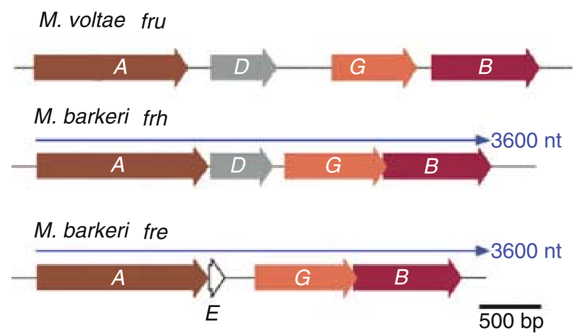

Fig. 17. Organization of the *M. voltae fru* operon and of the *M. barkeri frh* and *fre* operons. The genes for the subunit with the F_{420}-binding site are dark red. For additional details, see the legends to Figs. 14 and 15.

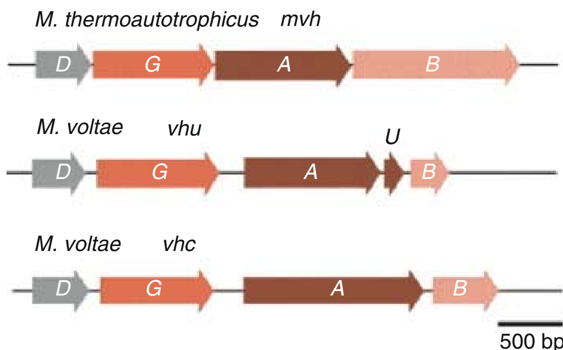

Fig. 16. Organization of the *M. thermoautotrophicus mvh* operon and of the *M. voltae vhc* and *vhu* operons. The genes for polyferredoxins are shown in pink. For additional details see the legends to Figs. 14 and 15.

Sulfhydrogenases The tetrameric, H_2-producing sulfhydrogenases of archaea are encoded by four-gene transcriptional units (Pedroni et al., 1995; Rákhely et al., 1999). In *P. furiosus* and *T. litoralis*, the small and large subunits are encoded by the third and fourth genes of each operon. The first and second genes encode proteins related to subunits of sulfite reductases. The latter gene products probably form the dimeric sulfur-reducing module of the tetrameric enzyme (Fig. 18).

The Cytoplasmic, NAD-Reducing Hydrogenases The cytoplasmic, NAD-reducing hydrogenase of *R. eutropha* is the prototype of a family of multimeric enzymes related both structurally and physiologically. The hydrogenases of this family are often called "bidirectional." The *R. eutropha* enzyme is encoded by a complex operon consisting of four structural genes and five accessory genes (Tran-Betcke et al., 1990; Thiemermann et al., 1996; Wolf et al., 1998; Fig. 19). The operon is expressed as a 7,600-nt primary transcript, which is apparently cleaved into smaller secondary mRNAs (Oelmüller et al., 1990). The first two genes of the operon (*hoxF* and *hoxU*) code for the NADH-oxidoreductase (diaphorase) moiety of the enzyme. The two genes immedi-

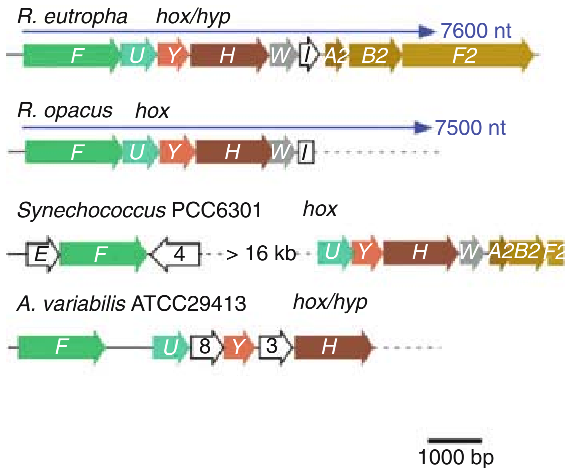

Fig. 19. Organization of the *R. eutropha* and *R. opacus* SH loci and of the *Synecchococcus* PCC6301 (*A. nidulans*) and *A. variabilis hox* regions. The genes encoding subunits of the NADH oxidoreductase module are shown in shades of green, and the *hyp* genes, in shades of yellow and gold. For additional details see the legends to Figs. 14 and 15.

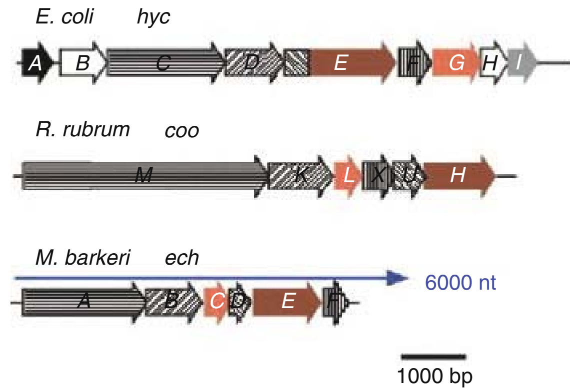

Fig. 20. Organization of the *E. coli hyc* operon, the *R. rubrum coo* operon, and the *M. barkeri ech* operon. Genes encoding proteins related to components of NADH:ubiquinone oxidoreductase I of *E. coli* are hatched. The gene products of *E. coli hycC*, *hycD*, *hycE* (partial) and *hycF* (and of the related genes) are isologous to *E. coli* proteins NuoL/NuoM/NuoN, NuoH and NuoI, respectively. For additional details see the legends to Figs. 14 and 15.

ately downstream (*hoxY* and *hoxH*) encode the small and large subunits, respectively, of the hydrogenase module. The product of *hoxW* is a specific protease which mediates C-terminal processing of the large subunit (Thiemermann et al., 1996). The product of *hoxI* is identical to the so-called "B protein," which is coexpressed with the SH (Kärst et al., 1987). Downstream of *hoxI* is a duplicated set of *hyp* genes: *hypA2*, *-B2* and *-F2* (Wolf et al., 1998). The operon encoding the soluble, tetrameric hydrogenase of the Gram-positive bacterium *Rhodococcus opacus* seems to be a carbon copy of the *R. eutropha* operon. The sequenced segment of the *R. opacus* operon revealed the genes *hoxF*, *-U*, *-Y*, *H*, *-W* and part of *hoxI* (Grzeszik et al., 1997a). A 7,500-nt transcript has been reported, suggesting that here, too, *hyp* genes are included in the hydrogenase mRNA. A similar set of genes directs the expression of a so-called "bidirectional hydrogenase" in the unicellular cyanobacterium *Synecchococcus* PCC6301 *Anacystis nidulans*; Boison et al., 1996). As in the case of *R. eutropha*, a set of structural genes (*hoxUYH*) is followed by a contiguous set of accessory genes (*hoxWhypABF*). A *hoxI*-like gene is missing in this series of genes. A *hoxF* homologon accompanied by a gene designated "*hoxE*" is encoded in a separate transcriptional unit located at a distance of 16 kb. HoxE is related to the protein NuoE of complex I and is a component of the mature hydrogenase (Schmitz et al., 2002). Another variant of the same genetic pattern is found in the filamentous cyanobacterium *Anabaena variabilis*. The bidirectional hydrogenase of this organism is encoded by an operon containing the genes *hoxF*, *-U*, *-Y* and *-H* (Schmitz et al., 1995). ORF8 and ORF3, which flank *hoxY*, code for proteins of unknown function (Fig. 19).

Multimeric H_2-Evolving Hydrogenases Both archaea and bacteria contain multimeric H_2-evolving hydrogenases encoded in complex operons (Fig. 20). The prototype of this class of enzymes is the *E. coli* hydrogenase 3, which uses electrons from formate to reduce protons, thereby generating H_2 gas. Hydrogenase 3 is encoded in a complex locus together with a set of Hyp proteins. The corresponding operons (*hycBCDEFGHI* and *hypABCDE*) are adjacent to each other and are transcribed from divergent promoters (Böhm et al., 1990; Figs. 20 and 23). The gene for the positive regulator FhlA is located downstream of the *hyp* operon and is transcribed from its own promoter. Two additional genes form a separate transcriptional unit located in the same gene cluster: *hypF*, which encodes a maturation protein, and *hydN*, whose function is unknown. The hydrogenase large and small subunits are encoded by the genes *hycE* and *hycG*, respectively. The *hycI* gene encodes a maturation endopeptidase. The function of the other gene products is largely unknown. The product of *hycF* is probably an FeS-containing protein. The *hycC* and *hycD* genes encode membrane-spanning proteins. The latter three proteins, as well as HycE and HycG, are related to components of the NADH:ubiquinone oxidoreductase complex (complex I) of *E. coli* and other organisms. Similar sets of genes have been identified in the anoxygenic phototroph *R. rubrum* (Fox et al., 1996a), the chemolithoau-

totroph *C. hydrogenoformans* (Soboh et al., 2002), and the methanogen *M. barkeri* (Künkel et al., 1998). The genomes of *P. furiosus*, *M. marburgensis*, *M. thermoautotrophicus*, *M. kandleri* and *M. janaschii* encode related hydrogenases with a more complex subunit composition (Tersteegen and Hedderich, 1999). *Escherichia coli* contains a second operon of the same type designated "*hyf*" (Andrews et al., 1997; Skibinski et al., 2002), the function of which is unknown. The operons of this family differ in gene number and order. Nevertheless, they all encode multisubunit hydrogenases containing proteins related to various components of complex I.

The above summary leads to the conclusion that typical patterns of gene organization are correlated with the major structural types of hydrogenases. Thus, conserved metabolic and structural specialization are reflected in conserved operonic structures. Basic blueprints of genetic organization persist across taxonomic boundaries.

[FeFe] Hydrogenases The genetic information for [FeFe] hydrogenases is contained, judging by the available sequence data, in simple transcriptional units consisting of 1–3 genes. The [FeFe] hydrogenase of *Desulfovibrio vulgaris* (Hildenborough), the first hydrogenase ever to be cloned and sequenced, is encoded by a pair of genes for the large and small subunits (Voordouw and Brenner, 1985). The structure of the *hydAB* operon of the closely related strain *Desulfomicrobium norvegicum* (formerly *Desulfovibrio desulfuricans* strain Norway) is the same (Hatchikian et al., 1999). Owing to the lack of transcript data on the one hand and to the paucity of sequence data on the other, it cannot be ruled out that additional genes belong to the same transcriptional unit or that hydrogenase accessory genes are present at other sites. The monomeric hydrogenase (CpI) of *Clostridium pasteurianum* is encoded by a solitary gene which appears to be a fusion of the paired genes which normally code for the two hydrogenase subunits (Meyer and Gagnon, 1991; Fig. 10). The same applies to the monomeric hydrogenase of *M. elsdenii* (Atta and Meyer, 2000). The set of genes encoding the [FeFe] hydrogenase of the hyperthermophile *Thermotoga maritima* is a singular case. Three genes, designated "*hydC*," "*-B*" and "*-A*," determine the γ, β, and α subunits of the trimeric enzyme (Verhagen et al., 1999). The *hydA* gene encodes the basic hydrogenase moiety and resembles the "fused" gene of *C. pasteurianum* (Fig. 10). The sequence of *hydB* predicts an FeS-containing flavoprotein related to HndC of *D. fructosovorans*. The deduced sequence of HydC reveals that this protein is related to NuoE of complex I.

At present the cytoplasmic, NADP-reducing hydrogenase of *D. fructosovorans* is both biochemically and genetically in a class of its own (Malki et al., 1995). The first gene of the *hndABCD* operon, *hndA*, predicts a protein similar to the large diaphorase subunit of the NAD-reducing hydrogenase of *R. eutropha*. The deduced product of *hndC* also shows marked similarity to the diaphorase moiety of the *R. eutropha* enzyme. The N-terminal part of HndC resembles HoxF, whereas the C-terminal part is similar to HoxU. Remarkably, HndD is not related to *R. eutropha* HoxH but rather contains sequence motifs typical of [FeFe] hydrogenases.

[Fe] Hydrogenases The [Fe] hydrogenases of *M. marburgensis* and other methanogenic archaea are N^5,N^{10}-methylene-H_2MPT dehydrogenases (Afting et al., 1998). The monocistronic gene for the homodimeric enzyme of *M. thermoautotrophicus* has been identified in the genomic sequence (Smith et al., 1997).

Regulation of Hydrogenase Genes

[NiFe] Hydrogenases The *R. eutropha hox* regulon is composed of two operons located on the 450-kb pHG1 megaplasmid and separated by ca. 70 kb (Eberz et al., 1986; Figs. 15 and 21). The MBH operon encodes the dimeric, membrane-bound hydrogenase and is transcribed as a >17-kb mRNA (Schwartz et al., 1999). The genes for the cytoplasmic, NAD-reducing hydrogenase belong to the SH operon. A 7,600-nt transcript has been mapped to this locus (Oelmüller et al., 1990). Expression of the two operons is coordinate and responds to two environmental conditions (Fig. 21): 1) the availability of H_2 and 2) the quality of the carbon and energy sources present in addition to H_2 (Friedrich et al., 1981a; Friedrich, 1982). The expression of the hydrogenase regulon is controlled at the level of transcription. The -24 and -12 promoters have been mapped upstream of the two operons and their activity is strictly dependent on the minor transcription factor σ^N (Schwartz et al., 1998). The activity of P_{MBH} and P_{SH} is governed by the NtrC-type activator protein HoxA (Eberz and Friedrich, 1991; Schwartz et al., 1998). This positive transcriptional regulator is encoded by the gene *hoxA* located downstream of the *hyp* genes in the MBH operon (Eberz and Friedrich, 1991). A moderate, σ^D-dependent promoter (P_{hoxA}) drives low-level, constitutive transcription of *hoxA* and perhaps of the downstream genes *hoxB*, *hoxC* and *hoxJ* as well. Constitutive transcription of *hoxA* guarantees that at least a basal level of HoxA is present in the cell at all times, making sure that the organism is poised to respond to the environmental cue for hydroge-

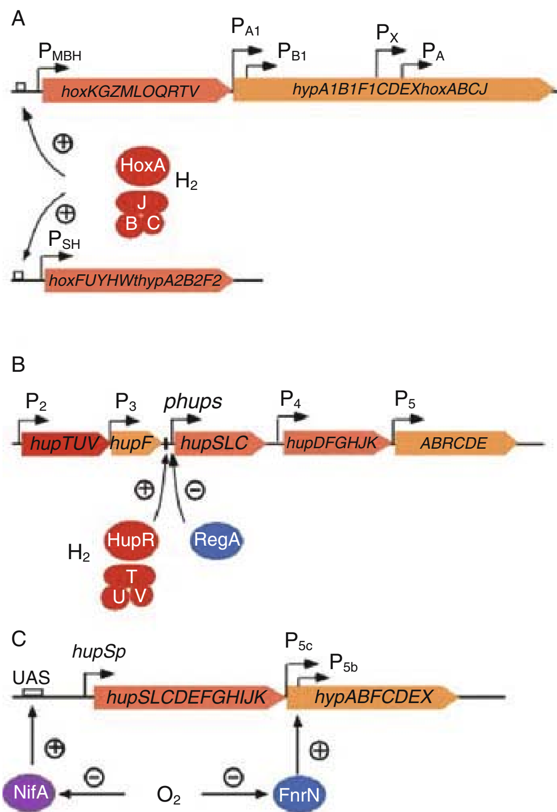

Fig. 21. Molecular models for the regulation of hydrogenase expression in *Ralstonia eutropha* (A), *Rhodobacter capsulatus* (B) and *Rhizobium leguminosarum* (C). Colored arrows represent genes or operons. Colored ovals symbolize regulatory proteins. Binding sites of regulatory proteins are indicated by open boxes.

nase expression, i.e., H_2 (Schwartz et al., 1999). At least some of the transcripts initiated at P_{MBH} extend a full 17,000 nt, encompassing *hoxA*. As a result, P_{MBH} and *hoxA* form a positive feedback system. Induction of the hydrogenase regulon results in the amplification of both MBH and HoxA. The amplified levels of HoxA also drive up the production of SH. HoxA is, like other members of the NtrC family, a DNA-binding protein (Zimmer et al., 1995). Deletion analysis of the SH upstream region pointed out a tandem palindrome 5′ of the -24 and -12 promoters. A similar motif is also present in the MBH upstream region. The distance between the palindromic element and promoter in the two upstream regions is compatible with the standard model for -24/-12 promoter activation, involving binding of the activator protein and protein-protein contact between activator and σ^N -RNA polymerase (RNAP) holoenzyme. In vitro studies using HoxA-containing extracts indicate that HoxA binds to DNA-fragments from the SH upstream region harboring the tandem palindrome, suggesting an NtrC-like mechanism of transciptional activation (Zimmer et al., 1995).

Detailed investigation of H_2-dependent hydrogenase expression led to the identification of an H_2-responsive signalling pathway (Friedrich et al., 1996; Lenz and Friedrich, 1998). This pathway is mediated by three components: 1) the response regulator HoxA, 2) a histidine protein kinase designated "HoxJ" and 3) a cytoplasmic hydrogenase-like protein, called a "regulatory hydrogenase" (RH), encoded by the genes *hoxB* and *hoxC*. HoxA and HoxJ constitute a two-component system. As in other two-component systems, HoxJ phosphorylates itself in an autocatalytic reaction. Subsequently, transfer of the phosphate group to the cognate response regulator HoxA can take place. Unlike most other two-component systems, however, phosphorylation of the response regulator has a negative effect on transcription of the subordinate genes. This conclusion is based on various experimental findings. First, deletion of gene *hoxJ* results in a deregulation of the system manifest as a drastic increase in hydrogenase gene expression in the absence of H_2. Furthermore, replacement of the conserved Asp-55 residue, the putative phosphorylation target in HoxA, has a similar effect, as does alteration of the Gly-422 in the kinase module of HoxJ (Lenz and Friedrich, 1998). The phosphotransfer reaction from HoxJ to HoxA has been demonstrated in vitro (M. Forgber, O. Lenz and B. Friedrich, unpublished observation). HoxB and HoxC comprise a nickel-containing tetramer with the structure $\alpha_2\beta_2$ (Kleihues et al., 2000; Bernhard et al., 2001). Comparisons of deduced amino-acid sequences revealed that HoxBC is a relative of the dimeric [NiFe] hydrogenases. The protein does, indeed, catalyze low but significant rates of H_2-dependent methylene blue reduction in vitro (Bernhard et al., 2001). The RH forms a complex with HoxJ (Bernhard et al., 2001). This complex can be reconstituted in vitro by mixing purified components. A stretch of amino acids at the C-terminus of HoxB is essential for both the formation of the $\alpha_2\beta_2$ tetramer and the complex formed between this tetramer and HoxJ (Buhrke, 2002). Notably, this C-terminal peptide is different from the C-termini of the energy-generating membrane-bound hydrogenases. In RH null mutants, hydrogenase gene expression is totally abolished, indicating that the RH is a positive regulator (Lenz and Friedrich, 1998). The available data support the following molecular model for H_2 sensing (Lenz et al., 2002; Fig. 22): A cytoplasmic H_2-sensing complex, consisting of RH and HoxJ, governs the phosphorylation status of HoxA. In the absence of H_2, HoxJ mediates phosphotransfer to HoxA, rendering it inactive. When molecules of H_2 enter the cell, they engage

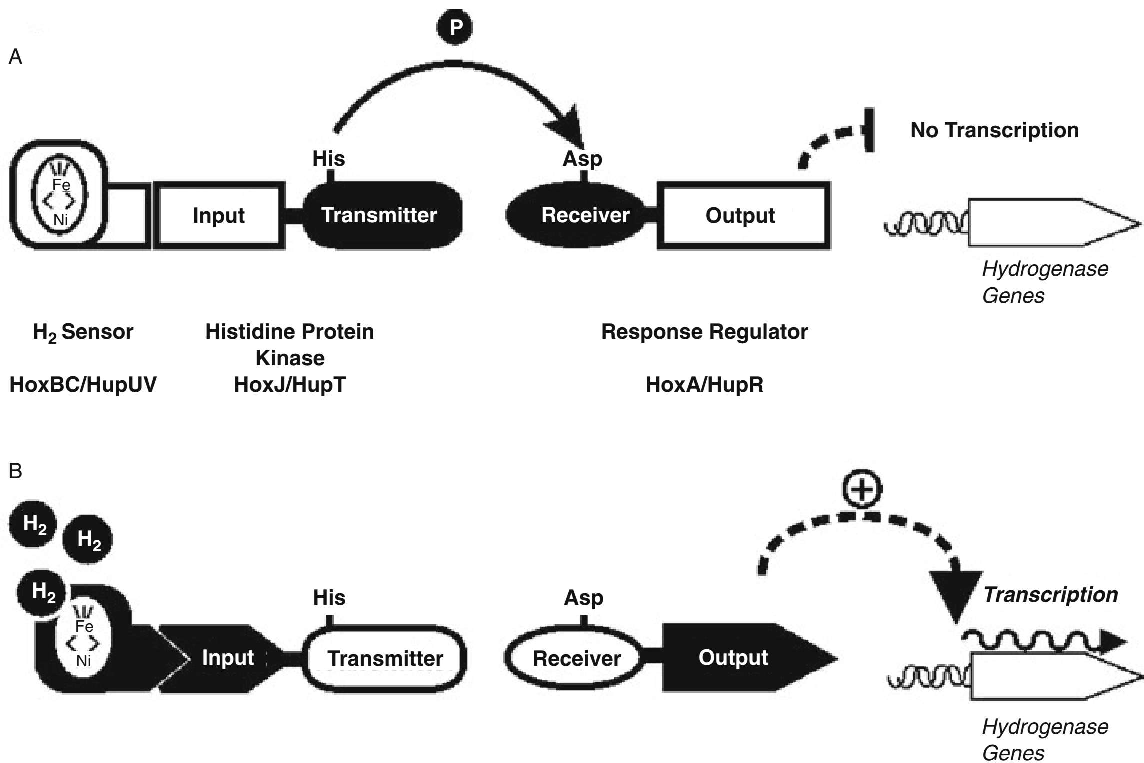

Fig. 22. Molecular model for H_2 sensing in *R. eutropha* and *R. capsulatus*. The upper part of the diagram (A) illustrates the interactions between the components of the H_2-sensing apparatus in the absence of H_2. The lower part (B) represents the protein-protein interactions in the presence of H_2. Transmitter and receiver domains of the histidine kinases and response regulators, respectively, are shown in red. The solid arrow symbolizes the phosphotransfer reaction. Dashed arrows indicate positive (+) or negative (–) control.

the RH, unleashing a specific interaction between it and HoxJ. The latter interaction may involve the transfer of electrons between the additional cofactor in the RH and the PAS domain in the input module of HoxJ. Thus, the RH blocks the net phosphoryl transfer from HoxJ to HoxA and ultimately is a positive control on H_2-dependent transcription.

Interestingly, the signal transduction pathway is cryptic in some natural isolates of *R. eutropha* (Lenz et al., 1997). In *R. eutropha* H16, a single-nucleotide exchange in the region of *hoxJ* corresponding to the transmitter domain reactivates signal transduction.

A second layer of regulation is superimposed on H_2-responsive signalling. This involves control of hydrogenase expression exerted by additional carbon and energy sources. Catabolite control is probably very important for *R. eutropha*, since in the natural habitat, it will very likely be confronted with both H_2 and organic substrates at the same time. Monitoring hydrogenase gene expression in the presence of both H_2 and organic substrates reveals a clear correlation between substrate quality and expression levels: Expression is high when poor substrates are available in addition to H_2 and vice versa (O. Lenz and B. Friedrich, unpublished results). In this context, substrate quality is judged on the basis of the corresponding growth rate. The underlying regulatory mechanisms are not yet known.

Despite major differences in the organization of the hydrogenase determinants in the phototroph *R. capsulatus* and the chemolithotroph *R. eutropha*, the H_2-oxidizing systems of these two organisms share a common regulatory mechanism. The dimeric [NiFe] hydrogenase of *R. capsulatus* is encoded in the *hupSLC* operon under the control of the p*hupS* promoter (Toussaint et al., 1997; Fig. 21). The *hupDFGHJK*, *hypAB-hupR-hypCDE* and *hupTUVF* operons are transcribed from separate promoters. An additional promoter is located upstream of *hypF*. Promoter p*hupS* is under the control of an NtrC-like regulator, HupR, but is σ^D-dependent as evidenced by mutagenesis of promoter sequences (Dischert et al., 1999) and by experiments with *rpoN* mutants (Colbeau and Vignais, 1992). HupR binds to the palindromic sequence TTG-N_5-CAA upstream of p*hupS* (Toussaint et al., 1997; Dischert et al., 1999). An integration host

factor (IHF)-binding motif located between the upstream activation sequence (UAS) and p*hupS* is another feature typical of promoters controlled by NtrC-like regulators. As in other systems, the architectural protein IHF is not essential for hydrogenase expression but has a pronounced stimulatory effect (Toussaint et al., 1991). The presence of H_2 triggers a 10-fold induction of hydrogenase activity (Toussaint et al., 1997). This effect depends on an H_2-sensing system similar to that found in *R. eutropha*. A histidine protein kinase, HupT, and an H_2-sensing hydrogenase, HupUV, cooperate with HupR in mediating signal transduction. HupT is a negative regulator (Elsen et al., 1993; Dischert et al., 1999). According to the model, HupT mediates phosphorylation of HupR in the absence of H_2 (Fig. 22). As in the case of *R. eutropha* HoxA, the phosphorylated form of HupR is inactive, preventing transcription of the hydrogenase genes under noninducing conditions (Dischert et al., 1999). HupUV is a cytoplasmically localized dimeric [NiFe] hydrogenase with a low but significant level of hydrogenase activity (Vignais et al., 1997; Vignais et al., 2000). HupUV presumably interacts with HupT governing the HupT/HupR phosphotransfer reaction. This interaction is, however, diametrically different from that of its *R. eutropha* counterpart. Since HupUV$^-$ mutants express hydrogenase constitutively (Elsen et al., 1996), HupUV must have a stimulatory effect on the net phosphoryl transfer to HupR. Apart from the specific, H_2-dependent control, hydrogenase expression is also regulated by the global, redox-responsive regulator pair RegA/RegB (Elsen et al., 2000). RegA exerts a negative effect on p*hupS* by binding to a site located between the promoter and the HupR UAS.

In contrast to *R. eutropha* and *R. capsulatus*, hydrogenase expression in the symbiotic N_2-fixer *R. leguminosarum* is not controlled by H_2 availability. In the latter organism, hydrogenase is expressed in bacteroids but not in vegetative cells (Palacios et al., 1990). The hydrogenase genes, which belong to three transcriptional units, are under the control of O_2-sensitive global regulators (Fig. 21). The first operon, containing the hydrogenase structural genes, is regulated by NifA (Brito et al., 1997). Transcription is driven by the -24/-12-type promoter *hupS*$_P$ upstream of *hupS* (Hidalgo et al., 1992). Deletion analysis of the region 5′ of *hupS*$_P$ indicated the existence of sequence elements essential for *hup* gene transcription. Experiments in a heterologous system indicated that transcription from *hupS*$_P$ is dependent on σ^N and is under the control of NifA (Brito et al., 1997). Similar experiments also indicated the involvement of IHF in the activation of *hupS*$_P$. Thus, the *R. leguminosarum hup* genes belong to the *nif* regulon. The coexpression of hydrogenase and nitrogenase in *R. leguminosarum* is not surprising, since the physiological role of hydrogenase in this organism is the utilization of H_2 generated as a byproduct of N_2 fixation. A second operon contains *hyp* genes: *hypBFCDEX*. Expression of this operon is induced under microaerobic conditions both in bacteroids and in vegetative cells (Palacios et al., 1990). Two transcriptional start sites have been mapped upstream of *hypB*, suggesting the existence of two promoters designated "P_{5a}" and "P_{5b}" (Hernando et al., 1995). While the significance of P_{5a} is unclear, P_{5b} appears to be a typical Fnr-dependent promoter with a characteristic anaerobox. *Rhizobium leguminosarum* contains two copies of the gene *fnrN* (Gutierrez et al., 1997). The expression of the *hypBFCDEX* operon is reduced in single *fnrN* mutants and abolished in the double mutant. A third transcriptional unit consists of the gene *hypA* (Hernando et al., 1998). Unlike the other *hyp* genes, *hypA* is expressed only under symbiotic conditions. The regulation of the *hypA* promoter, P_{5c}, is not yet understood. An intriguing finding is the discovery of a defective copy of a gene for a response regulator in the *Rhizobium leguminosarum* hydrogenase gene cluster (Brito et al., 1997). This remnant could be a relic of a defunct H_2-dependent regulatory system.

A very different regulatory mechanism controls expression of the *hyc* genes which encode the hydrogenase isoenzyme 3 of *E. coli*. The divergently transcribed *hycBCDEFGHI* and *hypABCDE* operons belong to the formate regulon (Böhm et al., 1990; Lutz et al., 1990; Lutz et al., 1991). A third transcriptional unit, separated from the *hycBCDEFGHI* operon by the functionally unrelated genes *ascB*, *-F* and *-G*, consists of the genes *hydN* and *hypF* (Maier et al., 1996). These operons are transcribed from three σ^N-dependent promoters designated "P_C," "P_P" and "P," respectively (Fig. 23). The activator protein FhlA governs the expression of the regulon in response to intracellular formate accumulation (Schlensog and Böck, 1990; Schlensog et al., 1994). The FhlA protein forms a complex with formate, binds to sites upstream of the subordinate promoters, and is, itself, transcribed by the weak constitutive, σ^D-dependent promoter P_{fhlA}. However, transcripts originating at P_P encompass *fhlA*, leading to an amplification of intracellular FhlA levels under inducing conditions. A second regulator, HycA, counteracts FhlA and thus mediates negative control of the regulon.

Hydrogenases 1 and 2 of *E. coli* are encoded by the operons *hyaABCDEF* and *hybOABCDEFG*, respectively (Menon et al., 1990; Menon et al., 1994b). Both biochemical and genetic studies have led to a coherent picture of the regula-

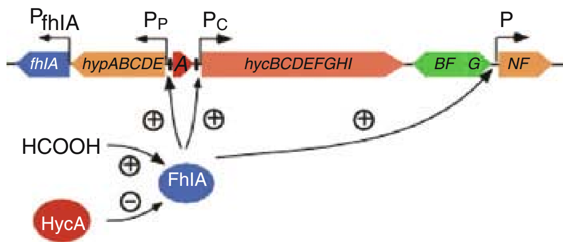

Fig. 23. Molecular model for the regulation of the *E. coli hyc* and *hyp* operons. See Fig. 21 for details.

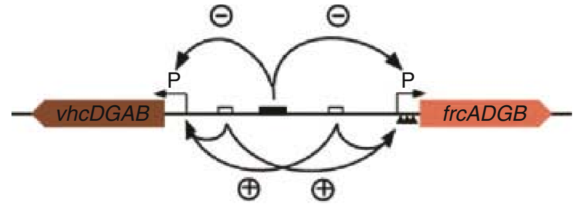

Fig. 24. Molecular model for the regulation of the selenocysteine-containing hydrogenases in *Methanococcus voltae*. The colored arrows represent the *vhc* and *frc* operons. Promoters are symbolized by arrows marked "P." A solid box denotes a negatively acting sequence element. Two positively acting sequence elements are represented by open boxes. Solid triangles denote a repetitive sequence motif.

tion of these operons (Ballantine and Boxer, 1985; Ballantine and Boxer, 1986; Sawers et al., 1985; Sawers and Boxer, 1986a; Brøndsted and Atlung, 1994; Brøndsted and Atlung, 1996; Wu et al., 1989; Richard et al., 1999). Like the *hyc* operon, both the *hya* and *hyb* operons are induced under anaerobic conditions. The ArcA/ArcB system is involved in the regulation of both operons albeit differently. Under anaerobic conditions ArcA suppresses *hyb* expression and activates *hya* expression (Richard et al., 1999). The fumarate and nitrate reduction regulator (FNR) is also involved in the expression of the active holoenzymes but the effect is evidently indirect. Nitrate, acting via the NarX/NarL and NarQ/NarP systems, represses the synthesis of both hydrogenases. Another two-component system, DpiA/DpiB stimulates expression of the *hya* operon. The latter effect is mediated by the positive regulator AppY.

An unusual regulatory mechanism has been reported for the *Anabaena* sp. strain PCC 7120 *hup* operon (Carrasco et al., 1995). This filamentous cyanobacterium is capable both of oxygenic photosynthesis and nitrogen fixation. Since nitrogenase is an O_2-labile enzyme, the processes of nitrogen fixation and photosynthesis demand a spatial separation. In *Anabaena* PCC7120, nitrogen fixation takes place only in heterocysts. In the vegetative cells, which do not require uptake hydrogenase, the *hupL* gene is inactive owing to the presence of a 10.5-kb intervening sequence element. In the course of differentiation to a heterocyst, the intervening element is excised resulting in a continuous *hupL* reading frame. Another recent discovery is the observation that expression of hydrogenase genes in *Rhodospirillum rubrum* and *Synechococcus* sp. PCC7942 oscillates in a circadian rhythm (Van Praag et al., 2000; Schmitz et al., 2001). In the case of *Synechococcus*, both the *hoxEF* and *hoxUYHWhypAB* operons are controlled at the level of transcription by a circadian clock. A photoreceptor in the form of bacteriophytochrome is probably responsible for entrainment of the oscillation (Schmitz et al., 2000).

Experimental data on the regulation of hydrogenase genes in archaea are scant. The best studied system is the methanogen *Methanococcus voltae* (Sorgenfrei et al., 1997). In *M. voltae*, four operons encode two selenium-containing and two selenium-free hydrogenase isoenzymes (Halboth and Klein, 1992). It is, therefore, not surprising that selenium is a key factor governing expression of the hydrogenase genes (Berghöfer et al., 1994).

The *fruADGB* and *vhuDGAUB* operons, which code for the selenium-containing enzymes, are expressed both in the presence and absence of selenium. In contrast, transcripts of the corresponding operons for the selenium-free enzymes are detectable only under selenium limitation. The latter operons, *frcADGB* and *vhcDGAB*, are arranged in a head-to-head orientation and are transcribed from divergent promoters located in the common 453-bp upstream region (Fig. 24). Transcription from the *frc* and *vhc* promoters is coordinately regulated (Noll et al., 1999). Deletion analysis of the upstream region suggests the presence of both positively and negatively acting sequence elements. One of the negatively acting sequence elements is located between the *frc* promoter and the start codon of *frcA*, and consists of a tandem repetition of a heptamer (Noll et al., 1999). An undecamer (5′-TCTATATAAAC-3′) located upstream of each of the promoters was shown to mediate positive control. Interestingly, mutations in either sequence element affect both promoters. A 55-kDa protein which binds specifically to this sequence element has been purified by DNA-affinity chromatography (Müller and Klein, 2001).

A study on the expression of the *M. barkeri ech* operon revealed that *ech* transcript was present under all growth conditions tested, suggesting that *ech* transcription is constitutive (Künkel et al., 1998). In *M. mazei*, the *vho* and *vht* operons are differentially expressed

(Deppenmeier, 1995a): *vht* is expressed during growth on H_2 and CO_2 but not on acetate. The *vho* operon, on the contrary, seems to be expressed constitutively. This points to a degree of physiological specialization of the two isoenzymes.

The examples discussed above reveal that hydrogenase enzymes are integrated into specific physiological functions by diverse regulatory mechanisms. It is evident that the regulatory scheme is dictated more by the physiological context than by the phylogenetic origin of the given hydrogenase.

[FeFe] Hydrogenases Not much is known about the regulation of genes for [FeFe] hydrogenases. *Clostridium acetobutylicum* produces high levels of hydrogenase activity during acidogenic fermentation and very low levels after switching to solventogenesis (Gorwa et al., 1996). The monocistronic *hydA* operon, which encodes a [FeFe] hydrogenase, is expressed as a 1900-nt transcript (Gorwa et al., 1996). The intracellular levels of *hydA* mRNA show the same pattern of substrate dependence as the enzyme activity levels, suggesting that *hydA* is regulated at the level of transcription.

[Fe] Hydrogenases *Methanothermobacter marburgensis* forms an [Fe] hydogenase called "H_2-forming methylenetetrahydromethanopterin" or "Hmd." This enzyme is synthesized regardless of the availability of nickel. However, under nickel-limited conditions the cytoplasmic level of the enzyme is raised sixfold. Under the latter conditions, Hmd substitutes for the F_{420}-reducing hydrogenase, a [NiFe] hydrogenase, in a reducing step of methanogenesis (Fig. 3). The expression of Hmd is regulated at the transcriptional level and responds to Ni concentration but not to the availability of H_2 (Afting et al., 2000).

Evolutionary Aspects

Since the pioneering work of Miller (1953) showing that the synthesis of the simpler organic building blocks of living organisms could occur spontaneously under conditions assumed to be similar to those on the primeval earth, biologists have envisaged an evolution of prebiotic systems in an ocean rich in organic compounds (Miller and Orgel, 1974). Hence, it was widely assumed that the first organisms were heterotrophs which fed on the organic compounds in the primeval broth. More recently, discrepancies in this hypothesis have prompted a reconsideration (Maden, 1995). One of the incongruities confronting the assumption of a heterotrophic origin of life is the fact that many of the deepest branching lineages of the phylogenetic tree contain autotrophic organisms. This indicates that autotrophy is not of recent origin but rather very ancient. Taking this into account, various hypotheses postulating an autotrophic origin of life have been put forward. The most comprehensive and rigorous of these was proposed by Wächtershäuser (Wächtershäuser, 1988; Wächtershäuser, 1990; Wächtershäuser, 1992). According to his theory of "pyrite-pulled surface metabolism," the primordial, energy-yielding process for prebiotic evolution is the reaction of ferrous sulfide and H_2S yielding pyrite and H_2:

$$FeS + H_2S \rightarrow FeS_2 + H_2 \quad (14)$$

The free energy for this reaction under standard conditions is -38 kJ/mol. This is sufficient to drive an archaic CO_2-fixing cycle similar to the reductive citric-acid cycle of contemporary organisms. Wächtershäuser suggests that pyrite formed in this process could serve as a matrix for the growing pool of organic reactants. Anabolic metabolites bind tightly enough to the surface of pyrite to prevent their loss to the solution but are still capable of two-dimensional diffusion.

The theory outlined above is valuable because of its explanatory power in reconstructing events of prebiotic evolution. Is also attractive because it offers a perspective for later evolutionary phases. Once the formation of phospholipid micelles permitted the liberation of cells from the pyrite surface, the above reaction may have been harnessed by early phosphorylation-based energy metabolism. One scenario envisages a primitive system consisting of three enzymes: a sulfur reductase, a hydrogenase, and an ATPase (the latter two being integral membrane proteins). The H_2S produced inside the cell by reduction of sulfur could diffuse out and react with FeS yielding pyrite and H_2. Thereupon the H_2 could be oxidized by the hydrogenase, providing reductant for the cytoplasmic sulfur reductase. The ensuing H^+ gradient could drive ATP synthesis.

A milestone in the evolution of living systems was the appearance of compartmental organization characteristic of contemporary eukaryotic cells. Most biologists are convinced that the organelles of eukaryotic cells developed out of an endosymbiosis of a bacterium within an archaeal host (Margulis, 1970). One of the weak points of this theory is its vagueness regarding the selective pressure responsible for the original endosymbiotic association. Moreover, the classical theory does not explain the origin of hydrogenosomes, the specialized, H_2-producing organelles found in many anaerobic lower eukaryotes. Recently, a novel hypothesis has

been put forward by Martin and Müller (1998) to remedy these deficits. Their "hydrogen hypothesis" proposes that H_2 metabolism was the basis of the archaic, endosymbiotic association according to the following scenario: A strictly autotrophic, strictly H_2-dependent archaeon such as a primitive methanogen is assumed to be the host cell, and a bacterium with respiratory and fermentative (i.e., H_2-producing) capabilities is assumed to be the symbiont. The initial liason between the two must have originated in an anoxic environment with sufficient H_2 and CO_2 for growth of the host. The association of symbiont and host would render the host cell independent of environmental sources of H_2. On the other hand, in the absence of environmental H_2 the host cell would be totally dependent on the symbiont and be subject to selective pressure to optimize gas exchange between the symbiont and itself. This could lead to progressive engulfment of the symbiont. This would, in turn, necessitate that the host cell acquire transport systems (e.g., via gene transfer from the symbiont) to supply the symbiont with organic substrates for its heterotrophic metabolism. At this stage, the heterotrophic metabolism of the symbiont and the autotrophic metabolism of the host coexist. In the final stage, a progressive transfer of genetic determinants from symbiont to host could eventually replace its autotrophic metabolism by heterotrophic pathways of the symbiont. This would turn the symbiont into a mitochondrion or a hydrogenosome, depending on the remaining set of enzymes. One of the strengths of the hydrogen hypothesis is the fact that associations like the one postulated as the starting point of the archaeal/bacterial partnership are widespread in present-day microbial communities. The syntrophic associations of H_2-producers and H_2-consumers in anaerobic habitats are well-known. Another advantage of the hydrogen hypothesis compared with the original endosymbiotic hypothesis is that the former accounts for both mitochondriate and amitochondriate cells.

Another aspect of H_2 metabolism with a profound impact on the course of evolution is the production of H_2 by cyanobacterial mats. With the advent of photosynthesis, the concentration of O_2 in the atmosphere began increasing. The gradual transition to an oxidizing atmosphere over a period of about 0.5 billion years set the stage for the evolution of respiratory aerobes. Prerequisite for this development was the production of O_2 on a global scale and the concomitant removal of reduced chemical compounds. It was long believed that burial of reduced carbon species was the only process of sufficient magnitude to account for the global change in the atmospheric redox status. Recent studies on subtidal and intertidal mats suggest that H_2 production in these mats could have had a major geochemical impact (Hoehler et al., 2001; Jørgensen, 2001). The mats, which harbor varied microbial populations dominated by the cyanobacterial species *Microcoleus chthonoplastes* and *Lyngbia* spp., were the predominant terrestrial life form for 2 billion years. Measurements of gas production in the modern cyanobacterial mats revealed a dual cycle of H_2 production due in part to the activity of nitrogenase. In contrast to other microbial communities, a major fraction of this H_2 is not recycled but liberated into the atmosphere and, hence, eventually escapes into space. Extrapolation of the H_2 production by modern mats suggests that, on a geological time scale, they could have contributed significantly to the removal of reductant from the earth's biogeochemical cycles.

CHAPTER 1.18

Hydrocarbon-Oxidizing Bacteria

EUGENE ROSENBERG

Introduction

Periodic ecological disasters caused by large oil spills call attention, in a dramatic manner, to the toxicity of petroleum. The fact that hydrocarbons persist for months and even years following major oil spills indicates that hydrocarbon biodegradation is slow in most natural environments. To the microbiologist, the fundamental questions are: What are the biochemical mechanisms of hydrocarbon degradation? Which microorganisms are involved? What are their special properties? What limits the rate of hydrocarbon degradation in the environment? And from an applied point of view, what (if anything) can be done to accelerate this rate? Several decades of research on hydrocarbon-oxidizing bacteria have provided considerable data relevant to these questions. This chapter will discuss the distribution, nutritional requirements, enumeration, isolation identification, special physiologic characteristics, and potential applications of hydrocarbon-degrading bacteria. The specific class of methane oxidizers will be presented in separate chapters.

Habitats

Hydrocarbons are a ubiquitous class of natural compounds. Not only are they found in petroleum-polluted areas, but chemical analyses have revealed the presence of significant quantities of aliphatic and aromatic hydrocarbons in most soils and sediments (Giger and Blumer, 1974; Stevenson, 1966). The most probable origin of the low concentrations of widely distributed hydrocarbons is ongoing biosynthesis by certain plants and microorganism (Fehler and Light, 1970; Hardwood and Russel, 1984; Hunt et al., 1980; Juttner, 1976; Kolattukudy et al., 1972; Mikkelsen and Von Wettstein-Knowles, 1978; Winters et al., 1969). Hydrocarbons are produced by reduction of fatty acyl-CoA by enzymes which utilize NADH or NADPH. Other sources of hydrocarbons are natural seeps on the ocean floor and unburned fuel from oil-burning engines (Floodgate, 1984). Since hydrocarbons are natural products as well as pollutants, it is not surprising that hydrocarbon-oxidizing bacteria are widely distributed in nature. A sample of ecological studies on hydrocarbon-degrading bacteria is shown in Table 1.

It can be seen that hydrocarbon oxidizers are located in virtually all natural areas, although with large variations in cell concentration. As would be expected, the ratio of hydrocarbon-oxidizing bacteria to the total population of heterotrophic bacteria, as well as the variety of hydrocarbon-degrading microorganisms found in a particular ecosystem, may change according to the time of sampling or the extent of oil pollution (Geiselbrecht et al., 1996). Atlas (1981) has discussed many of the factors that limit the growth of hydrocarbon-oxidizing bacteria in nature. These include physical constraints, such as temperature, availability of oxygen, salinity, pH, and the extent to which the particular habitat is an open or closed ecosystem. Nutritional factors are also important and include the availability of utilizable sources of nitrogen, phosphorus and other elements, the nature of the hydrocarbon substrate and its effective concentration, and the possible presence of toxic substances either in the petroleum product or in the environment itself.

Effect of Oil Pollution

The localization of hydrocarbon-oxidizing bacteria in natural environments has received considerable attention because of the possibility of utilizing their biodegradation potential in the treatment of oil spills. Because of the enormous quantities of crude and refined oils that are transported over long distances and consumed in large amounts, the hydrocarbons have now become a very important class of potential substrates for microbial oxidation. It is not surprising, therefore, that hydrocarbon-oxidizing microorganisms have recently been isolated in large numbers from a wide variety of natural aquatic and terrestrial environments. Several

Table 1. Sample habitats and characteristics of hydrocarbon-utilizing microorganisms.

Location	Source	Carbon source	Cell concentration	Reference
Prince William Sound	Surface	Hexadecane	$2–12 \times 10^3$ per g	Lindstrom et al. (1991)
Alaska, beach gravel	Subsurface	Hexadecane	$1–12 \times 10^3$ per g	
Tyrolean Alps	Subsoil	Diesel	$0.2–3 \times 10^4$ per g	Margesin and Schinner (1997)
Bayway Refinery, New Jersey	Surface	Jet fuel	$1–4 \times 10^3$ per g*	Song and Bartha (1990)
	Surface	Jet fuel	$1–6 \times 10^3$ per g*	
Prince William Sound	Surface	Fuel oil	$10^3–10^4$ per g	Haines et al. (1996)
Alaska, Duck Island	Sand	—		
Pudget Sound, Washington	Contaminated sediment	Phenanthrene	$10^4–10^3$ per g	Geiselbrecht et al. (1996)
	Uncontaminated sediment	Phenanthrene	$10^3–10^4$ per g	
Barataria Bay (Louisiana Coast)	Over 200 stations along the coast	Lightweight paraffin oil	$10^3–10^4$ per g mud	ZoBell and Prokop (1966)
Chesapeake Bay	Eastern Bay (water)	Nondetergent motor oil	$0.5–6 \times 10^3$ per ml	Walker and Colwell (1976b)
	Eastern Bay (sediment)	Nondetergent motor oil	$8–99 \times 10^3$ per g	Walker and Colwell (1976b)
	Colgate Creek (water)	Nondetergent motor oil	$90–4.4 \times 10^3$ per ml	Walker and Colwell (1976b)
	Colgate Creek (sediment)	Nondetergent motor oil	$10–9.0 \times 10^3$ per g	Walker and Colwell (1976b)
Atlantic Ocean sediment off North Carolina coast	250 meters off shore (depth 9 meter)	Model petroleum substrate	$1.5–1.2 \times 10^2$ per ml	Walker and Colwell (1976)
	50 km from shore, Continental Shelf (depth, 62 meters)	Model petroleum substrate	$3 \times 10^2–3 \times 10^3$	Walker et al. (1976)
	375 km from shore (depth, 5,000 meters)	Model petroleum substrate	4×10^4 per ml	Walker et al. (1976)
Alaskan waters	Chuchi Sea	Crude oil	$10^3–10^4$ per ml	Horowitz and Atlas (1977)
	Port Valdez	Crude oil	3×10^2 per liter	Robertson et al. (1973)
	Prudhoe Bay	Crude oil	7×10^2 per liter	Atlas and Schofield (1975)
	Cape Simpson oil	Crude oil	3×10^6 per g soil	Atlas and Schofield (1975)
Southern Louisiana marsh sediments	Airplane Lake	Crude oil	$10^3–10^2$ per g sediment	Crow et al. (1975)
	Martigan Point	Crude oil	$10^3–10^2$ per g sediment	Crow et al. (1975)
Field plots	Marcus Hook, PA	Hexadecane	$4.4–11 \times 10^4$ per g	Raymond et al. (1976)
	Tulsa, OK	Hexadecane	$1–5 \times 10^2$ per g	Raymond et al. (1976)
	Corpus Christi, TX	Hexadecane	$3–66 \times 10^4$ per g	Raymond et al. (1976)
Lake Mendota, WI	Surface water	Hexadecane	$10^2–8 \times 10^3$ per ml	Ward and Brock (1976)

		Naphthalene	1×10^3 per ml	

*Determined by FDA (fluorescein diacetate) epifluorescence.

investigators have demonstrated an increase in the number of hydrocarbon-oxidizing bacteria in areas that suffer from oil pollution (Table 1). Walker and Colwell (1976a, b) observed a positive correlation between the percentage of petroleum-degrading bacteria in the total population of heterotrophic microorganisms and the amount of heptane-extractable material in sediments of Colgate Creek, a polluted area of Chesapeake Bay. In contrast, no correlation was found when total numbers of hydrocarbon oxidizers (rather than percentages) were compared to hydrocarbon levels. Horowitz and Atlas (1977b) observed shifts in microbial populations in an Arctic freshwater lake after the accidental spillage of 55,000 gallons of leaded gasoline. The ratio of hydrocarbon-utilizing to total heterotrophic bacteria was reported to be an indicator of the gasoline contamination. These investigators also studied shifts in microbial populations in Arctic coastal water using a continuous flow-through system, following the introduction of an artificial oil slick (Horowitz and Atlas, 1977a). The addition of the oil

appeared to cause a shift to a greater percentage of petroleum-degrading bacteria. Atlas and Bartha (1973b) found similar results in an oil-polluted area in Raritan Bay off the coast of New Jersey. Hood et al. (1975) compared microbial populations in sediments of a pristine salt marsh with those of an oil-rich marsh in southeastern Louisiana. These investigators also found a high correlation between the percentage of hydrocarbon oxidizers and the level of hydrocarbons in the sediments. Significant increases in the number of hydrocarbon-utilizing microorganisms were found in field soils following the addition of several different oil samples (Raymond et al., 1976). No estimate of the ratio of hydrocarbon oxidizers to the total heterotrophic population was presented.

From the studies discussed above, it is clear that the presence of hydrocarbons in the environment frequently brings about a selective enrichment in situ for hydrocarbon-utilizing microorganisms. Evidence also has been presented suggesting that the supplementation of certain ecosystems, particularly oil-polluted marine environments with nitrogen and phosphorus may increase the relative number of hydrocarbon oxidizers (Atlas and Bartha, 1973a; Gutnick and Rosenberg, 1977; Reisfeld et al., 1972; Song and Bartha, 1990).

Isolation and Enumeration

The use of hydrocarbons as substrates for bacterial growth presents special problems to both the microorganism using them as a source of carbon and energy and to the investigators in the field of hydrocarbon microbiology. Depending on the solubility of the particular hydrocarbon in water, its physical state (solid, liquid, or gas), and toxicity, different isolation methods must be employed. In all cases, the heterogeneity of the system complicates sampling, enumeration, and growth measurement procedures. After a discussion of general nutritional requirements for hydrocarbon-degrading bacteria, several specific procedures for the selective enrichment and isolation of the different hydrocarbon degraders will be presented.

General Nutritional Requirements

In addition to the requirements for suitable cell-hydrocarbon interactions and the specific genetic potential of the organism for hydrocarbon oxidation, a number of general nutritional conditions must be fulfilled for bacteria to utilize hydrocarbons. These nutritional requirements depend on the fact that hydrocarbons, as the name denotes, are compounds composed solely of carbon and hydrogen atoms. Thus, all other elements essential for cell growth must be available in the growth medium. These include molecular oxygen, utilizable forms of nitrogen, phosphorus, sulfur, metals, and trace components. The requirement for molecular oxygen has been given much attention, particularly with respect to maximum production of single-cell protein by hydrocarbon-degrading microorganisms (Mimura et al., 1973; Schocken and Gibson, 1984). The limitation for oxygen is easily overcome in small-scale laboratory studies, or in open aqueous systems where the oil-water interface is in direct contact with air at all times. The possibility of anaerobic decomposition of hydrocarbons has received considerable attention (Hollinger and Zehnder, 1996). Although hydrocarbon utilization by strictly anaerobic sulfate-reducing bacteria (e.g., Rosenfeld, 1947) has been reported, evidence that pure cultures of sulfate-reducing bacteria can attack hydrocarbon in the absence of additional sources of organic carbon is not definite. However, a few microbial species appear to be able to grow on pure alkane in the absence of molecular oxygen, if provided with nitrate as an electron acceptor (Senez and Azoulay, 1961; Mihelcic and Luthy, 1988) or sulfate (Rueter et al., 1994; Rabus et al., 1996).

The nitrogen and phosphorus requirements for maximum growth of hydrocarbon oxidizers can generally be satisfied by ammonium phosphate. Alternatively, these requirements can be met with a mixture of other salts, such as ammonium sulfate, ammonium nitrate, ammonium chloride, potassium phosphate, sodium phosphate, and calcium phosphate. When ammonium salts of strong acids are used, the pH of the medium generally decreases with growth. This problem can often be overcome by using urea as the nitrogen source. In theory, approximately 150 mg of nitrogen and 30 mg of phosphorus are consumed in the conversion of 1 g of hydrocarbon to cell material. In open systems, the high water solubility of most utilizable sources of nitrogen and phosphorus reduces their effectiveness because of rapid dilution. In principle, this problem can be solved by using oleophilic nitrogen and phosphorus compounds with low C:N and C:P ratios. It was found that a combination of paraffinized urea and octyl phosphate was able to replace nitrate and inorganic phosphate, respectively (Atlas and Bartha, 1973a). A more economical way may be to add water insoluble controlled-release nitrogen and phosphorus fertilizers. This technology has been successfully demonstrated in laboratory and field experiments (Rosenberg et al., 1996). One intriguing possibility to obviate the need for addition of nitrogen compounds to the medium is to use a

bacterium that is capable of both hydrocarbon degradation and nitrogen fixation. Such microorganisms were reported following enrichment on hydrocarbon media lacking nitrogen salts (Coty, 1967).

In addition to utilizable sources of nitrogen and phosphorus, the mineral requirements of hydrocarbon-degrading bacteria can be met by the addition of K^+, Mg^{2+}, Fe^{2+}, and SO_4^{2-} to purified media. All other inorganic ions required by bacteria to obtain optimum growth are commonly present in sufficient concentration as contaminants in these salts. For most marine hydrocarbon degraders, artificial sea water (or filtered sea water), supplemented simply with phosphate, a nitrogen source, and the hydrocarbon serves as an adequate medium for enrichment culture studies. In certain aquatic environments under conditions in which the water was supplemented with nitrogen and phosphorus, a high concentration of iron may limit oil biodegradation (Dibble and Bartha, 1976). Under these conditions, an encapsulated oleophilic iron compound, ferric octoate, was found to be as effective in stimulating biodegradation as various water-soluble iron derivatives, such as ferric ammonium citrate.

Enumeration of Hydrocarbon-Degrading Bacteria

The determination of the concentration of hydrocarbon-degrading bacteria is one of the methods commonly used for monitoring oil pollution in the environment. Theoretical difficulties associated with the interpretation of these data have been discussed elsewhere (Floodgate, 1973). The enumeration of hydrocarbon-degrading bacteria presents two special technical problems, sampling and choice of carbon source. Petroleum-degrading bacteria tend to adhere to hydrophobic materials (Fig. 1). Thus, unless the bacteria are removed from the material and dispersed prior to enumeration, only minimum cell numbers can be obtained. The choice of a carbon source is an even more serious problem. Petroleum is an extremely complex-mixture of hydrocarbons. Because certain bacteria may grow only on minor components in the oil, it would be necessary to incorporate large quantities of petroleum into the growth medium to ensure sufficient substrate for these bacteria to grow well. However, high concentrations of petroleum and mixtures of hydrocarbons cannot be used, because they are toxic to bacteria (Vestal et al., 1984). Thus, the enumeration of hydrocarbon-degrading bacteria using petroleum as the carbon source selects primarily for bacteria that can degrade major components of the oil mixture. Often, pure hydrocarbons and mixtures of pure hydrocarbons and fractions of crude oil can be used to advantage in replacing petroleum as the carbon source in the isolation medium. The following four methods have been used to enumerate hydrocarbon-degrading bacteria in the marine, estuarine, and freshwater environments:

Fig. 1. Phrase contrast photomicrograph of bacterial strain UP-2 (Horowitz et al., 1975) growing on supplemented 0.1% hexadecance-seawater medium. During expontial growth most of the cells appear to be in the form of microcolonies tightly bound to oil droplets. Diameter of oil droplets approximately 150 μm.

Enumeration of Hydrocarbon-Degrading Bacteria in Marine Material Not Miscible with Water (Gunkel and Trekel, 1967)

1. Approximately 2 g of the material to be examined is placed in a sterile bottle containing 100 ml sterile sea water or salts medium.
2. After 1 ml of a sterile. nontoxic, nonionic emulsifier and 1 drop of an antifoam agent are added to the sample, the mixture is homogenized to disperse and break up the bacterial aggregates (e.g., an Ultra Turrax homogenizer run at 24,000 rpm for 30 s).
3. The homogenized sample is then diluted serially in steps of 1 : 10 in sterile sea water or salts medium.
4. One-ml samples of the appropriate dilutions are then inoculated into bottles or tubes containing the following sterile medium:

Aged sea water	750 g
Distilled water	250 ml
NH_4Cl	0.5 g
K_2HPO_4	0.5 g
NaH_2PO_4	1.0 g

5. After addition of 1 drop of sterile hydrocarbon. the samples are incubated for 2–6 weeks, depending on the temperature of incubation.
6. Bottles remaining turbid after addition of 1 ml HCl to dissolve inorganic salts are scored, and the most-probable-number calculated from tables published in Standard Methods (American Public Health Association, 1995).

Enumeration of Hydrocarbon-Utilizing Bacteria by Direct Plating of Estuarine Water and Sediment Samples (Colwell et al., 1973)

Estuarine salts solution:

Distilled water	l liter
NaCl	10 g
$MgCl_2$	2.3 g
KCl	0.3 g

Oil powder: 10 g of hydrocarbon dissolved in 30 ml of diethyl ether is mixed with 10 g of silica gel, allowed to evaporate, and then added to the following basal medium prior to autoclaving.

Oil agar medium:

Distilled water	1 liter
NaCl	10 g
$MgSO_4$	0.5 g
NH_4NO_3	1.0 g
$FeCl_3$ (25 g ·ml $^{-1}$)	1 drop
Purified agar (Difco)	20 g
Oil powder	10 g
KH_2PO_4 (10 g ·100 ml $^{-1}$)*	3.0 ml
K_2HPO_4 (10 g ·100 ml $^{-1}$)*	7.0 ml
Fungizone*	10 mg

*added after autoclaving

Enumeration of Hydrocarbon-Degrading Bacteria in Fresh Water (Ward and Brock, 1976)

Basal medium:

Distilled water	1 liter
NaCl	0.4 g
NH_4Cl	0.5 g
$MgSO_4 \cdot 7H_2O$	0.5 g
$NaHPO_4 \cdot 7H_2O$*	0.05 g
KH_2PO_4*	0.05 g

* Added after autoclaving

Serial dilutions are made in the basal medium. One drop of sterile hydrocarbon is added to 10 ml of basal medium. After incubation at the appropriate temperature, growth is detected by pellicle formation at the surface of the oil droplet. Most-probable-number is determined from the tables published in Standard Methods (American Public Health Association, 1995).

Enumeration of Hydrocarbon-degrading Bacteria by a 96-well Plate Procedure (Haines et al., 1996)

The 96-well plates were processed with a Beckman Biomek 1000 laboratory robot (Beckman Instruments, Fullerton, CA, USA) which filled the wells with medium, performed ten-fold serial dilutions of the sample, and added oil to the inoculated wells. The robot added 180 ml of BH (Bushnell-Haas medium, Difco) to each well in 11 of the 12 rows, leaving the first row empty. It transferred 200 ml of undiluted sample to the wells in the first row, mixed their contents, and then transferred 20 ml to each well in the second row. The contents of the second row were mixed, and 20 ml was transferred to each well in the third row. This procedure of mixing and transfer was carried out for all except the last row, which served as a sterile control. Sterile pipet tips were used for each transfer. After the dilutions were completed, 2 ml of oil was added to each well as the growth substrate. The plates were sealed in plastic bags and incubated for 14 days at 20°C. Positive wells were scored in one of two ways. When F2 (number 2 fuel oil) was the carbon source, 50 ml of a sterile solution (3 g ·liter $^{-1}$) of INT (iodonitrotetrozolium violet; Research Organics, Cleveland, OH, USA) was added to each well. INT competes with O_2 for electrons from the respiratory electron transport chain, and it is reduced to an insoluble formazan that deposits as a red precipitate in the presence of active respiring microorganisms. Red or pink wells were scored as positive. When a crude oil was used as the carbon source, a smooth oil slick developed in each well. Positive wells were scored by emulsification or dispersion of this oil slick. INT cannot be used effectively with crude-oil substrates, because their dark color interferes with detection of formazan deposition.

Enrichment Culture for Hydrocarbon-Degrading Bacteria

Since hydrocarbons are natural products that are widely distributed in nature, it is not surprising that bacteria able to degrade hydrocarbons can easily be isolated by standard enrichment culture procedures. By varying parameters, such as temperature, pH, hydrocarbon concentration, and basal medium, a wide variety of different hydrocarbon-degrading and emulsifying bacteria can be obtained from either aquatic or terrestrial environments. In most studies, crude oi1 or a petroleum distillate was used as the sole carbon and energy source in the enrichment culture procedure. Under those conditions, bacteria that specialize in the oxidation of low-molecular-weight n-alkanes are generally obtained. Bacteria that grow more slowly or oxidize minor components of crude oil never increase much in batch enrichments, although the activity of these microorganism may be of special significance in natural environments. To overcome this difficulty, enrichment culture procedures have to be employed using different carbon sources. The following examples represent only a few of the possible variations.

Enrichment of Crude Oil-Degrading Bacteria in Supplemented Sea Water (Reisfeld et al., 1972)

To 20 ml of unsterilized sea water in a 125-ml flask were added: 155 mg unsterilized crude oil, 0.056 mM KH_2PO_4, and 7.6 mM $(NH_4)_2SO_4$. After inoculation with about 1 g beach tar or oily sand, the flask was incubated at 30°C with shaking. After about 1 week, the oil became evenly dispersed throughout the liquid. One ml of this culture was then transferred to 20 ml sterile sea water supplemented with 0.056 mM KH_2PO_4, 7.6 mM $(NH_4)_2SO_4$, and 1 drop of sterile crude oil. (The crude oil was sterilized by filtration through a Millipore 0.45 mm membrane filter.) After one passage, the oil became emulsified in 2–4 days. Such mixed cultures were maintained by serial transfers to fresh media at 3 to 4-day intervals. Pure cultures were obtained by streaking the enrichment culture either onto the above medium solidified with 1.5% agar (Difco) or nutrient agar (Difco) prepared with filtered sea water. Isolated colony types were found to grow both on nutrient and oil-containing media.

Enrichment culture procedures used to isolate crude oil-degrading bacteria, such as that described in the preceding paragraph, yield a mixture of several different strains even after several transfers. One reason for this is the heterogeneity of the carbon source. Low-molecular-weight paraffin oxidizers (C_{10} to C_{25}) generally dominate the cultures because of their more rapid growth rate. To isolate bacteria that could utilize other fractions of crude oil, the following sequential enrichment culture can be employed:

Sequential Enrichment of Hydrocarbon-Degrading Bacteria on Crude Oil in Supplemented Sea Water (Horowitz et al., 1975)

Inoculate the following sterile medium with a pure culture of an n-paraffin-oxidizing bacterium (which can be obtained by standard enrichment culture procedures): One liter filtered water, 10 mg $K_2HPO_4 \cdot 3H_2O$, 450 mg urea, and 0.7 ml crude oil. After 3 days incubation with shaking at 30°C, the residual oil is extracted with l liter of benzene-pentane-ether (3:l:1, v/v/v). The oil remaining after evaporation of the organic solvent in vacuo is referred to as "bacteria-depleted oil." An enrichment culture is now carried out using the "bacteria-depleted oil" in place of crude oil as the sole source of carbon and energy.

The general failure of investigators to isolate microorganism on highly water-insoluble, solid hydrocarbons, such as anthracene, may be due to the fact that the cells remain firmly bound to the substrate. Thus, a standard enrichment culture procedure in which a portion of the bulk water phase is transferred would select against rather than for these specific microorganism. It may be that for successful enrichments the solid phase should be used as the inoculum during the sequential transfers.

Enrichment of Hydrocarbon-Degrading Bacteria on Bunker C Fuel Oil in Minimal Salts medium (Mulkins-Phillips and Stewart, 1974a)

One gram of beach sand sample or 1 ml of a water sample was added to the following minimal medium containing 0.125% Bunker C oil (steam-sterilized at 121°C and 15 psi for 15 min in tightly capped flasks to prevent evaporation):

Minimal salts medium:

Distilled water	l liter
NaCl	28.4 g
K_2HPO_4	4.74 g
KH_2PO_4	0.56 g
$MgSO_4$	0.50 g
$CaCl_2$	0.1 g
NH_4NO_3	2.5 g
Trace element stock (pH 7.1)	1 ml

Flasks were incubated at 20°C for 14 days and 120 rpm on a refrigerated gyratory shaker bath. Pure cultures of hydrocarbon-utilizing bacteria were isolated from the enrichment culture by streaking onto minimal salts medium to which 2% washed Ionagar No. 2 (Oxoid) was added. The carbon source consisted of 0.5 ml of the following hydrocarbon mixture added to sterile filter paper secured in the lids of the Petri dishes. The dishes were then inverted and incubated at the appropriate temperature for 1–3 weeks.

Hydrocarbon mixture:

Naphthalene	0.1 g
Anthracene	0.1 g
Dibenzothiophene	0.1 g
Decalin	5 ml
Hexadecene-1	5 ml
Hexadecane	5 ml
Octadecane	0.1 g
Dodecane	5 ml
Iso-octane	5 ml

Enrichment of Polyaromatic Hydrocarbon-Degrading Bacteria (PAHs) (Churchill et al., 1999)

Small amounts of fresh sediment known to be contaminated with PAHs were inoculated into the following mineral salts medium (g/liter):

$(NH_4)2SO_4$	10
KH_2PO_4	5.0
$MgSO_4 \cdot 7H_2O$	0.1
$Fe(NH)_2(SO_4)_2$	0.005
Pyrene	40

Trace metals (Beauchop and Elsden, 1960)

After adjusting the pH to 7.0 with NaOH, the flasks were shaken for 1 week. Pyrene-degrading bacteria were detected on pyrene-coated mineral medium (as above) agar plates. Zones of clearing around colonies indicated pyrene degradation. The same procedure can be used with other PAHs replacing the pyrene.

Enrichment on Liquid Aromatic Hydrocarbons (Gibson, 1971)

Liquid aromatic hydrocarbons, such as benzene, toluene, and ethylbenzene, are toxic to bacteria when present in the liquid phase. However, if these carbon sources are introduced in the vapor phase, good growth can be obtained. Figure 2 illustrates two methods that can be used for growing bacteria on volatile toxic hydrocarbons. Since the liquid hydrocarbons do not come in direct contact with the salts medium, they need not be sterilized. When the reservoir of volatile hydrocarbons is exhausted, it can easily be refilled with a Pasteur pipette.

Enrichment for Nitrogen-Fixing Hydrocarbon Oxidizers (Coty, 1967)

Hydrocarbon-oxidizing bacteria able to grow in the absence of added nitrogen compounds were isolated by addition of 0.1 g soil to 25 ml of mineral salts medium of the following composition (g/liter):

Na_2HPO_4	0.3
KH_2PO_4	0.2
$MgSO_4 \cdot 7H_2O$	0.1
$FeSO_4 \cdot 7H_2O$	0.005
$Na_2MoO_4 \cdot 2H_2O$	0.002

The containers were incubated in an atmosphere of air and hydrocarbon vapors. After turbidity developed, the cultures were streaked and reincubated on the above mineral salts medium containing 1.5% washed agar. Purification was achieved after several restreakings and culturing on nitrogen-free mineral salts agar medium. Bacteria able to utilize atmospheric nitrogen on addition of naphthenic acid, n-butane, n-tetradecane, or sodium cyclohexane carboxylate were reported to be isolated by this procedure.

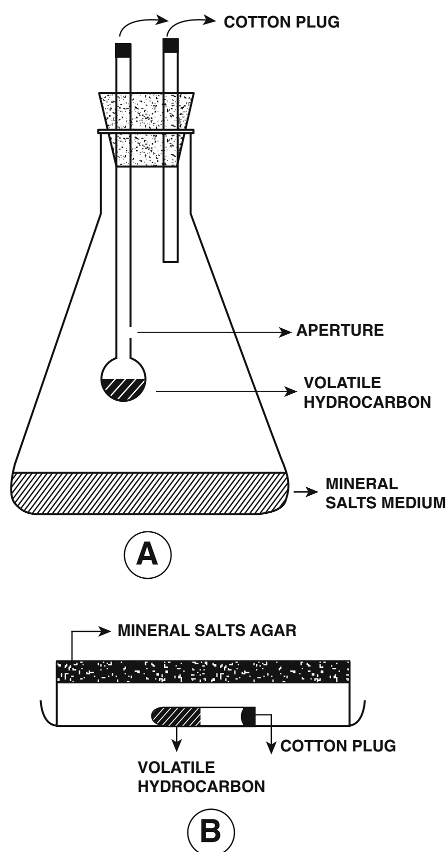

Fig. 2. Two methods for the growth of bacteria on volatile hydrocarbons using (A) liquid media and (B) solid media.

Enrichment for Solid Hydrocarbon-Degrading Bacteria (Miller and Bartha, 1989)

A slurry of soil in 0.1 M phosphate buffer, pH 7.0, with 0.1% octadecane was incubated for 1 week, with shaking. This enrichment culture was transferred (1:100 ratio) to the following medium (g/liter):

Na_2HPO_4	0.4
KH_2PO_4	0.15
NH_4Cl	0.1
$MgSO_4 \cdot 7H_2O$	0.02
Iron ammonium citrate	0.005
$CaCl_2$	0.001
Octadecane	0.1

To obtain pure cultures, the enrichment was streaked on the above medium solidified with 2% agar. The *Pseudomonas* sp. that was isolated grew on solid alkanes such as hexatriacontane (C_{36}).

Identification

The variation in bacterial populations isolated by enrichment culture depend largely on the hydrocarbon substrate used in the enrichment, the culture conditions, and the source of the inoculum. Many species capable of hydrocarbon degradation have been isolated (Table 2). The most frequently isolated bacterial genera are *Pseudomonas*, *Acinetobacter*, *Flavobacterium*, *Corynebacterium*, and *Arthrobacter*. Most of the investigations on the degradation of aromatic hydrocarbons have been carried out using *Pseudomonas putida*, and species of *Beijerinckia* and *Nocardia* (Gibson, 1971). Westlake et al. (1974) studied the effect of oil quality and incubation temperature on the genetic composition of hydrocarbon-decomposing populations isolated from an area in British Columbia that had been exposed to chronic pollution with diesel fuel. All of the populations consisted predominantly of Gram-negative rods, including species of *Pseudomonas*, *Acinetobacter*, *Xanthomonas*, *Arthrobacter* and *Alcaligenes*.

An extensive study of petroleum-degrading bacteria isolated from Chesapeake Bay waters and sediments was carried out by Austin et al. (1977a, 1977b). A total of 99 strains were examined for 48 biochemical, cultural, morphological, and physiological characteristics. A statistical analysis revealed 14 phonetic groups, comprising about 85% of the hydrocarbon-degrading bacteria. These groups were characterized as actinomycetes, coryneforms, *Enterobacteriaceae*, *Klebsiella aerogenes*, species of *Micrococcus*, *Nocardia* and *Pseudomonas* and *Sphaerotilus* natans.

Physiological Properties

There are two essential characteristics that define hydrocarbon-oxidizing bacteria: 1) hydrocarbon-group-specific oxygenases and 2) mechanisms for optimizing contact between the bacterium and the hydrocarbon.

Group-Specific Oxygenases

Several reviews have appeared on the microbial metabolism of straight-chain and branched alkanes (Asperger and Kleber, 1991; Singer and Finnerty, 1984), cyclic alkanes (Perry, 1984), and aromatic hydrocarbons (Gibson, 1977; Cerniglia, 1984). It has been established that the first step in the degradation of hydrocarbons by bacteria is the introduction of both atoms of molecular oxygen into the hydrocarbon. In the case of aromatic hydrocarbons, ring fission requires a dihydroxylation reaction, the introduction of two atoms of oxygen, and the subsequent formation of a *cis*-dihydrodiol (Gibson, 1968). This reaction is catalyzed by a dioxygenase which is a multicomponent, membrane-bound enzyme system (Cerniglia, 1992). Further oxidation of the *cis*-dihydrodiol leads to the formation of catechols that are substrates for another dioxygenase that catalyzes ring fission.

Table 2. Genera of hydrocarbon-degrading bacteria.

Genus	Reference[a]	
	From soil	From aquatic environment
Achromobacter	9, 12, 27	5, 8, 10, 20, 21, 25, 28
Acinetobacter	9, 23, 27, 34	5, 8, 17, 24, 26
Actinomyces	12	4, 28, 31
Aeromonas		7, 26
Alcaligenes	9, 16, 23, 27	6, 8, 9
Arthrobacter	9–12, 14, 15, 18	5, 7, 10, 25
Bacillus	14, 23	4, 7, 10, 20, 28
Beneckea		10
Brevibacterium	10	5
Corynebacterium	12, 14, 15, 22, 27	4, 5, 7, 10, 25, 26, 28
Cycloclasticus	30	
Cytophaga	9, 27	
Erwinia	1	4
Flavobacterium	1, 13, 15, 22, 27	2, 7, 9, 10, 20, 21
Klebsiella		2
Lactobacillus		2
Leucothrix	1	2
Micrococcus	13, 14, 22	
Moraxella		2
Mycobacterium		29
Myxobacterium	3, 14, 23, 32	28
Nocardia	14, 15, 23	2, 4, 5, 10, 21, 26
Peptococcus		7
Pseudomonas	1, 9, 11–14, 16, 18, 19, 23, 27, 33	2, 4, 5, 10, 20, 21, 26, 28
Rhodococcus	35	
Sarcina	14, 22	20
Serratia	1	
Spherotilus		4
Spirillum	10	20
Vibrio	1, 30	4, 5, 10, 20, 21, 26, 28
Xanthomonas	9, 10	4

It is important to emphasize that the biochemical mechanism of aromatic hydrocarbon oxidation in prokaryotes is fundamentally different from that of eukaryotes. Fungi and mammalian cells metabolize aromatics using the cytochrome P-450 monooxygenase system, which leads to the formation of arene oxides. These active epoxides can form covalent bonds with nucleophilic sites in DNA, leading to mutations and carcinogenesis. Aromatic hydrocarbons that have been shown to serve as substrates for bacterial oxygenases include benzene, toluene, xylene, naphthalene, phenanthrene, anthracene, benz(a)-anthracene, biphenyl, and several of their methylated derivatives. The enzymes necessary for aromatic hydrocarbon degradation are specified, in part, by degradative catabolic plasmids.

In general, alkanes are terminally oxidized to the corresponding alcohol, aldehyde, and fatty acid (Asperger and Kleber, 1991). The hydroperoxides may serve as unstable intermediates in the formation of the alcohol (Singer and Finnerty, 1984). Fatty acids.derived from alkanes are then further oxidized to acetate and propionate (odd-chain alkanes) by inducible β-oxidation systems. The group specificity of the alkane oxygenase system is different in various bacterial species. For example, *Pseudomonas putida* PpG6 (oct) grows on alkanes of 6 to 10 carbons in chain length (Nieder and Shapiro, 1975), whereas *Acinetobacter* sp. HOI-N is capable of growth on long-chain alkanes (Singer and Finnerty, 1984). The ability of *P. putida* to grow on C^6–C^{10} alkanes was shown to be plasmid

encoded (Chakrabarty, 1973). In contrast, all activities necessary for growth of *Acinetobacter* sp. HOI-N and *A. calcoaceticus* BD413 appear to be coded by chromosomal genes (Singer and Finnerty, 1984).

Subterminal alkane oxidation apparently occurs in some bacterial species (Markovetz, 1971). This type of oxidation is probably responsible for the formation of long-chain secondary alcohols and ketones. Pirnik (1977) and Perry (1984) have reviewed the microbial oxidation of branched and cyclic alkanes, respectively.

Physical Interactions Between Bacteria and Hydrocarbons: Adhesion, Desorption, and Emulsification

The low solubility of hydrocarbons in water, coupled to the fact that the first step in hydrocarbon degradation involves a membrane-bound oxygenase, makes it essential for bacteria to come into direct contact with their hydrocarbon substrates. Two general biological strategies have been suggested for enhancing contact between bacteria and water-insoluble hydrocarbons: 1) specific adhesion mechanisms and 2) emulsification of the hydrocarbon.

To understand the special cell surface properties of bacteria that allow them to grow on hydrocarbons, it is necessary to consider the dynamics of petroleum degradation in natural environments. Following an oil spill in the sea, the hydrocarbons rise to the surface and come into contact with air. Some of the low molecular weight hydrocarbons volatilize; the remainder are metabolized relatively rapidly by microorganisms, such as *Pseudomonas* sp., which take up soluble hydrocarbons. These bacteria do not adhere to oil and do not have a high cell-surface hydrophobicity (Rosenberg and Rosenberg, 1985). The next stage of degradation involves microorganisms with high-cell-surface hydrophobicity, which can adhere to the residual high-molecular-weight hydrocarbons. In the case of *A. calcoaceticus* RAG-1, this adherence is due to thin hydrophobic fimbriae (Rosenberg et al., 1982). Mutants lacking these fimbriae failed to adhere to hydrocarbons and were unable to grow on hexadecane. Other bacteria exhibit high-cell-surface hydrophobicity as a result of a variety of fimbriae and fibrils, outer-membrane and other surface proteins and lipids, and certain small cell-surface molecules, such as gramicidin S (Rosenberg et al., 1985) and prodigiosin (Rosenberg et al., 1989). Bacterial capsules and other anionic exopolysaccharides appear to inhibit adhesion to hydrocarbons (Rosenberg et al., 1983).

Desorption from the hydrocarbon is a critical part of the growth cycle of petroleum-degrading bacteria. Petroleum is a mixture of thousands of different hydrocarbon molecules. Any particular bacterium is only able to use a part of the petroleum. As the bacteria multiply at the hydrocarbon/water interface of a droplet, the relative amount of nonutilizable hydrocarbon within the droplet continually increases until the cells can no longer grow. For bacteria to continue to multiply, they must be able to move from the depleted droplet to a fresh oil droplet. *A. calcoaceticus* RAG-1 has an interesting mechanism for desorption and for ensuring that it only reattaches to a droplet of fresh oil. When cells become starved on the "used" hydrocarbon drop or tar ball, they release their capsule. The capsule is composed of an anionic heteropolysaccharide, with fatty acid side-chains, referred to as emulsan (Rosenberg, 1986). The extracellular, amphipathic emulsan attaches avidly to the hydrocarbon/water interface, thereby displacing the cells to the aqueous phase. Each "used" oil droplet or tar ball is then covered with a monomolecular film of emulsan. The hydrophilic outer surface of the emulsan-coated hydrocarbon prevents reattachment of the RAG-1 cells. The released capsule-deficient bacteria are hydrophobic and readily adhere to fresh hydrocarbon substrate.

Many hydrocarbon-degrading microorganisms produce extracellular emulsifying agents (Desai and Banat, 1997; Rosenberg and Ron, 1997). In some cases, emulsifier production is induced by growth on hydrocarbons (Hisatsuka et al., 1971). Mutants that do not produce the emulsifier grow poorly on hydrocarbons (Itoh and Suzuki, 1972). Pretreatment of oil with emulsifying agents can both inhibit and stimulate oil biodegradation (e.g., Foght et al., 1989; Nakahara et al., 1981; Tiehm, 1994; Thibault et al., 1996; Liu et al., 1995; Zhang and Miller, 1994). As discussed above, emulsification may be a by-product of a cell/hydrocarbon detachment process. An entire chapter of this book is devoted to bioemulsifiers (Rosenberg and Ron, 1997).

Acinetobacter sp. HOI-N accumulates extracellular membrane vesicles of 20-50 nm in diameter when grown on hexadecane (Kappeli and Finnerty, 1980). The isolated vesicles partition exogenously supplied hydrocarbons in the form of a microemulsion. These vesicles appear to play a role in the uptake of alkanes. Miller and Bartha (1989) have been able to overcome the difficulties involved in the transport of water-insoluble, solid hydrocarbons by using unilamellar vesicles. A *Pseudonomas* isolate grew on octadecane (C_{18}) and hexatri-acontane (C_{36}) with K_s values of 2,450 and 2,700 mgliter $^{-1}$, compared to 60 and 41 mgliter $^{-1}$, respectively, when the hydrocarbon was presented in the form of liposomes. The data clearly demonstrate the importance of transport in the microbial metabolism of recalcitrant hydrocarbons.

Applications

Petroleum microbiology began as an applied subject, and the applied aspects continue to provide the primary impetus for research in this field. Current areas of applied interest are:

1. Microbial spoilage of petroleum products.
2. Treatment of oil spills and disposal of petroleum wastes.
3. Enhanced oil recovery.
4. Production of surface-active agents.
5. Hydrocarbons as substrates in industrial fermentation processes.

Biodeterioration of petroleum products, such as fuels, lubricating oils, and oil emulsions, has obvious economic implications. Genner and Hill (1981) have reviewed the data on the microbial spoilage of petroleum products and emphasized that spoilage only occurs when the petroleum products come in contact with water. In addition to avoiding water, spoilage can sometimes be retarded by the use of biocides (Rogers and Kaplan, 1968) or membrane filtration.

In considering the microbial treatment of oil spills, it is essential to distinguish between open systems (e.g., the ocean) and closed ones (e.g., oil storage tanks). In the latter case, it is possible to supplement the system with appropriate sources of nitrogen, phosphones, oxygen, and seed bacteria to enhance microbial growth and petroleum degradation, emulsification, or both. Two early published accounts of the use of these fundamental microbiological principles to enhance oil conversion in a restricted area are the treatment of oily ballast water from an oil tanker (Gutnick and Rosenberg, 1977) and of contaminated soil (Raymond et al., 1976). More recently, petroleum pollution has been treated by composting (Kirchmann and Ewnetu, 1998), thermophilic bacteria (Mueller and Nielsen, 1996), in soil-water slurries (Zhang and Bouwer, 1997), and the use of water-insoluble fertilizers (Rosenberg et al., 1996). In an open system, such as the sea, the ability of resident bacteria to extensively degrade a large oil slick is limited primarily by the concentration of nitrogen and phosphorus. Since there is no economical technology for overcoming these nutrient limitations in an open system, there is at present no practical microbial solution for oil spills at sea.

The use of microorganism in tertiary oil recovery has been the subject of several international conferences and literature reviews (e.g., Westlake, 1984; Moses and Springham, 1982). After primary and secondary recovery (water-flooding) processes, approximately 70% of the reservoir oil remains underground, trapped in pore spaces and bound to inorganic minerals. The potential use of microorganisms in situ to release this oil depends on the anaerobic production of organic solvents, such as ethanol and butanol, gases such as methane and carbon dioxide, and organic acids. These materials can help overcome the physical forces holding the oil in the reservoir. Also, acid production can dissolve carbonates thus increasing the permeability of the reservoir. In addition, microbial products could enhance oil recovery by producing surface-active material and viscosity-altering polymers. Although the evidence for the positive role of microorganism in enhanced oil recovery is limited to a few poorly controlled experiments (Hitzman, 1983), the enormous potential of this technology warrants further investigation. In recent years, interest in bioemulsifiers and other microbial surface active agents has been growing. Many of these compounds are produced by hydrocarbon-degrading microorganisms (Rosenberg, 1986; Rosenberg and Ron, 1997; Desai and Banat, 1997). The advantages of microbially produced surfactants include: 1) biodegradability and controlled inactivation; 2) diversity of structure and function for different applications; 3) selectivity for specific hydrocarbon/water interfaces; and 4) characteristic surface modifications.

The use of hydrocarbons as inexpensive raw materials for the production of single cell protein (SCP) was stimulated by the publications of Champagnat and Llewelyn (1962) and Champagnat et al. (1963). During the 1960s, many large oil and fermentation companies were involved in large-scale research and development projects for the conversion of petroleum fractions into SCP. Although the anticipated market for SCP in human and animal nutrition was not realized, these technological developments have provided a rich source of information about how bacteria grow on petroleum, how a continuous process can be scaled-up, and how bulk products can be recovered economically. In the 1970s, several fermentation plants were operating with capacities of 100,000 tons of SCP per year. These were the largest biotechnology plants ever built. Because of the increased cost of hydrocarbon feedstock and more stringent governmental regulations governing its use in fermentation industry, there are presently no large-scale commercial fermentation processes based on hydrocarbon substrates. There are, however, a number of excellent microbial processes that have already been developed; these could be activated under the right set of economic conditions. These include processes for producing alcohols, organic acids, and ketones from specific alkanes, single-cell (food) oil from mixed n-paraffins, and large numbers of microbiological metabolites, including vitamins, amino

acids, pigments, polysaccharides, enzymes and alkanes.

CHAPTER 1.19

Cellulose-Decomposing Bacteria and Their Enzyme Systems

EDWARD A. BAYER, YUVAL SHOHAM AND RAPHAEL LAMED

Introduction

From an anthropocentric point of view, for millennia, human culture has been intricately involved with cellulose, the major component of the plant cell wall. The development of the wood, paper and textile industries has served to incorporate cellulosic materials into the fabric of our society. Within the past century, however, cellulosic wastes, derived mainly from the same industries, have also become a major source of environmental pollution. This chapter will concentrate mainly on cellulose and the cellulolytic bacteria, in view of their importance to mankind and world ecology. Nevertheless, the true substrate of these bacteria—i.e., the complement of plant cell wall polysaccharides in general—is much more complex than cellulose alone. Likewise, the complement of enzymes—both the cellulolytic and the non-cellulolytic glycosyl hydrolases—are produced concurrently in these bacteria for the purpose of efficient synergistic degradation of the complete substrate composite as it appears in nature. Consequently, when we discuss the cellulose-decomposing bacteria and their enzyme systems, we cannot ignore the related noncellulolytic enzymes, and these will also be treated, albeit secondarily, in the present chapter.

It should also be noted that this chapter of the *The Prokaryotes* is a sequel to the previous chapter of the same title (authored by M.P. Coughlan and F. Mayer) from the second edition of this treatise (Coughlan and Mayer, 1992). The reader is cordially invited to consult the earlier chapter (to be considered as Part A) as an excellent complement to our own (Part B).

The plant cell wall consists of an intricate mixture of polysaccharides (Carpita and Gibeaut, 1993); cellulose, hemicellulose and lignin are its major constituents. These polymers are of a very robust nature. They both equip the plant with a stable structural framework and protect the plant cell from the perils of its environment. Despite its recalcitrant nature, in the guise of dead or dying plant matter, the polysaccharides of the plant cell wall provide an exceptional source of carbon and energy, and a multitude of different microorganisms has evolved which are capable of degrading plant cell wall polysaccharides.

In any given ecosystem, the polysaccharide-degrading microbes are not alone, but rely on the complementary contribution of other bacterial and/or fungal species (Bayer and Lamed, 1992; Bayer et al., 1994; Ljungdahl and Eriksson, 1985). The polymer-degrading strains play a primary and crucial role in the ecosystem by converting the plant cell wall polysaccharides to the respective simple sugars and other degradation products (Fig. 1). They are assisted by satellite microbes, which cleanse the microenvironment from the breakdown products, producing, in the final analysis methane and carbon dioxide.

In a given polysaccharide-degrading microorganism, the enzymes that catalyze the degradation may occur either in the free state and/or in discrete complexes with other similar types of enzymes. The latter are called "cellulosomes." Both the free enzymes and cellulosomal components are usually modular proteins, which contain a multiplicity of functional domains. The "free" enzymes comprise a single polypeptide chain, which contains a catalytic domain usually connected to a cellulose-binding domain or CBD. Cellulosomes are exocellular macromolecular machines, designed for efficient degradation of cellulose and associated plant cell wall polysaccharides (Bayer et al., 1998). In contrast to the free enzymes, the cellulosome complex is composed of a collection of subunits, each of which comprises a set of interacting functional modules. Thus, one type of cellulosomal module, the CBD, is selective for binding to the substrate. Another family of modules, the catalytic domains, is specialized for the hydrolysis of the cellulose chains. Yet another complementary pair of domains—the cohesins and dockerins—serves to integrate the enzymatic subunits into the complex and the complex, in turn, into the cell surface. Multiple copies of the cohesins form an integrating subunit called "scaffoldin" to which the dockerin-containing

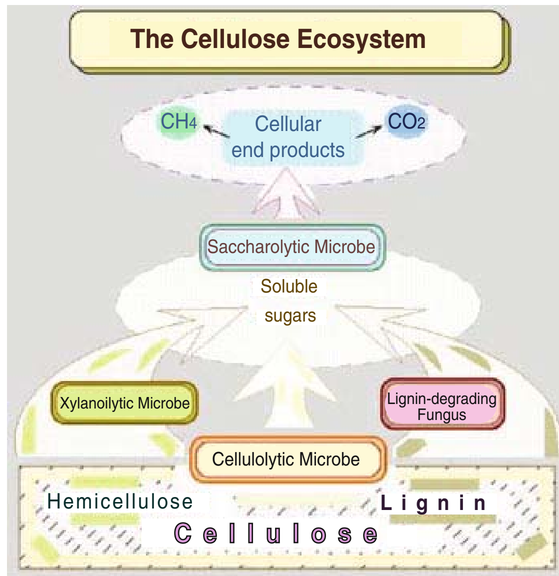

Fig. 1. Simplified schematic description of a typical ecosystem comprising degrading plant matter. Cellulolytic, xylanolytic and ligninolytic microbes combine to decompose the major polysaccharide components to soluble sugars. "Satellite" microorganisms assimilate the excess sugars and other cellular end products, which are ultimately converted to methane and carbon dioxide.

enzymes are attached. This "Lego™"-like arrangement of the modular subunits generates an intricate multicomponent complex, the enzymes of which are bound en bloc to the insoluble substrate and act synergistically towards its complete digestion.

Inherent to the study of cellulases and related enzymes is their potential industrial application—particularly towards conversion of cellulosic biomass. For reviews on the potential uses of these enzymes, the reader is referred to appropriate reviews on the subject (Bhat, 2000; Himmel et al., 1999; Lynd et al., 1991).

Plant Cell Wall Polysaccharides

Plant cells produce a composite matrix of hardy and durable polysaccharides on the outer surface of the plasma membranes, called "the cell wall" (Carpita and Gibeaut, 1993). The cell wall confers a protective coating to the plant cell, providing structure, turgidity and durability, which renders the cell resistant to the outer elements, including mechanical, chemical and microbial assault. Different types of plant cell tissues exhibit different ratios of the three major types of cell wall component; on the average, the cell wall contains roughly 40% cellulose, 30% hemicellulose and 20% lignin, but the exact composition of an individual type of plant varies greatly. The first two polymers are indeed polysaccharides. On the other hand, lignin is a heterogeneous, high-molecular-weight hydrophobic polymer, which consists of nonrepeating aromatic monomers connected via phenoxy linkages (Higuchi, 1990; Lewis and Yamamoto, 1990). Unlike cellulose and hemicellulose, which are degraded aerobically or anerobically, lignin degradation requires oxygen and is limited to filamentous prokaryotes (e.g., the Actinomycetes Streptomyces viridans) and fungi (e.g., *Phanerochaete chrysosporium*, *Bejerkendera adusta* and *Pleurotus ostreatus*), which produce a complicated set of enzymes that hydrolyze the polymer. In fact, the recalcitrant lignin interferes severely with the access of enzymes to the cellulose component, and is rate limiting for anaerobic degradation of cellulose. In any case, the lignin component must be degraded or removed, before efficient degradation of cellulose can take place. Nevertheless, considering lignin is not a polysaccharide, it will not be discussed further in this chapter.

Cellulose

Cellulose is the major constituent of plant matter and thus represents the most abundant organic polymer on Earth. Cellulose is a remarkably stable homopolymer, consisting of a linear (unbranched) polymer of β-1,4-linked glucose units. Chemically, the repeating unit is simply glucose, but structurally, the repeating unit is the disaccharide cellobiose, i.e., 4-*O*-(β-D-glucopyranosyl)-D-glucopyranose, inasmuch as each glucose residue is rotated 180° relative to its neighbor (Fig. 2). The individual cellulose chains contain from about 100 to more than 10,000 glucose units, packed tightly in parallel fashion into microfibrils by extensive inter- and intrachain hydrogen bonding interactions, which account for the rigid structural stability of cellulose. The microfibrils exhibit variable amounts of crystalline and amorphous components, again depending on the degree of polymerization, the extent of hydrogen bonding and, ultimately on the source of the cellulose. The microfibrils themselves are further assembled into plant cell walls, the tunic of some sea animals, pellicles from bacterial origin, etc. Highly crystalline forms of cellulose include cotton, bacterial cellulose (from *Acetobacter xylinum*) and the cellulose from the algae, *Valonia ventricosa*, which exhibit crystallinity levels of about 45%, 75% and 95%, respectively. The following reviews are available for more information on the structure of cellulose (Atalla, 1999; Atalla and VanderHart, 1984; Chanzy, 1990; O'Sullivan, 1997).

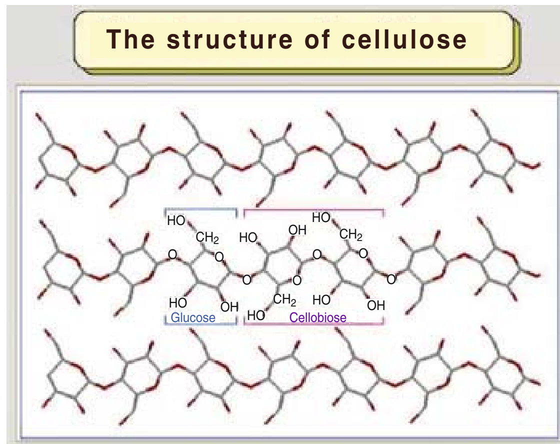

Fig. 2. Structure of cellulose. Three parallel chains that form the 0, 1, 0 face are shown, and a glucose moiety and repeating cellobiose unit are indicated. The model was built by Dr. José Tormo, based on early crystallographic data. The diagram was drawn using RasMol 2.6.

Hemicellulose

Hemicelluloses are relatively low-molecular-weight, branched heteropolysaccharides associated with both cellulose and lignin and together build the plant cell wall material (Puls and Schuseil, 1993; Timell, 1967). The main backbone of hemicellulose is usually made of one or two sugars, which determines their classification. For example, the main backbone of xylan is composed of 1,4-linked-β-D-xylopyranose units. Similarly, the backbone of galactoglucomannans is made of linear 1,4-linked β-D-glucopyranose and β-D-mannopyranose units with a-1,6-linked galactose residues. Other common hemicelluloses include arabinogalactan, lichenins (mixed 1,3-1,4-linked β-D-glucans) and glucomannan. Most hemicellulases are based on a 1,4-β-linkage and the main backbone is branched, whereas the individual sugars may be acetylated or methylated. For example, the linear xylan backbone is highly substituted with a variety of saccharide and nonsaccharide components (Fig. 3). In the

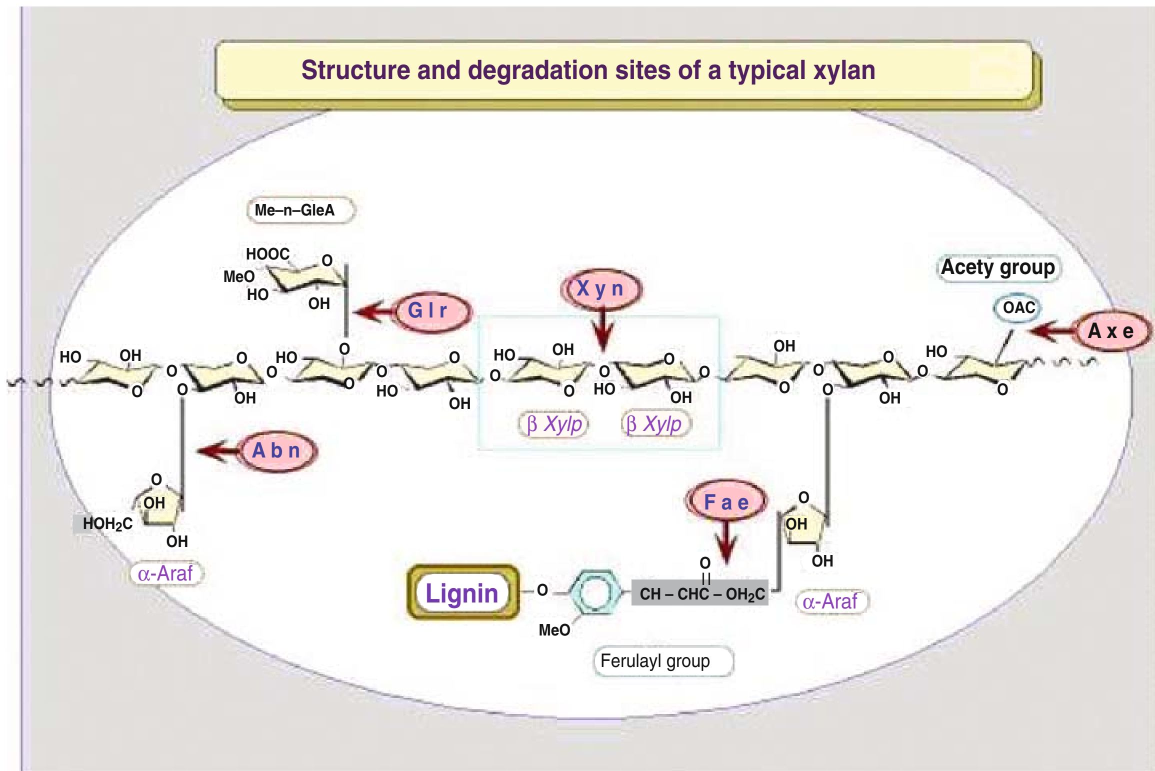

Fig. 3. Composition of a typical xylan component of hemicellulose. The xylobiose unit (β-Xylp-β-Xylp) is indicated by the blue-sided box, as are major substituents: MeaGlcA, methylglucuronic acid; αAraf, arabinofuranosyl; OAc, acetyl group. A presumed lignin attachment site to a feruloyl substituent of xylan is also illustrated. Sites of cleavage by selected hemicellulases and carbohydrate esterases are also shown: Xyn, xylanase; Abn, arabinofuranosidase; Glr, glucuronidase; Axe, acetyl xylan esterase; Fae, ferulic acid esterase.

plant cell wall, xylan is closely associated with other wall components. The 4-*O*-methyl-α-D-glucuronic acid residues can be ester-linked to the hydroxyl groups of lignin, providing cross-links between the cell walls and lignin (Das et al., 1984). Similarly, feruloyl substituents serve as crosslinking sites to either lignin or other xylan molecules. Thus, the chemical complexity of xylan is in direct contrast to the chemical simplicity of cellulose. Likewise, the structural diversity of the xylans is in contrast to the structural integrity of the cellulose microfibril. Consequently, unlike the crystalline-like character of cellulose, the hemicellulose component adopts a gel-like consistency, providing an amorphous matrix in which the rigid crystalline cellulose microfibrils are embedded.

Cellulose-Degrading Bacteria

The cellulolytic microbes occupy a broad range of habitats. Some are free living and rid the environment of plant polysaccharides by converting them to the simple sugars, which they assimilate. Others are linked closely with cellulolytic animals, residing in the digestive tracts of ruminants and other grazers or in the guts of wood-degrading termites and worms (Haigler and Weimer, 1991). Cellulose-based ecosystems include soils, swamps, marshes, rivers, lakes and seawater sediments, rotting grasses, leaves and wood, cotton bales, sewage sludge, silage, compost heaps, muds and decaying vegetable matter in hot and volcanic springs, acid springs, and alkaline springs (Ljungdahl and Eriksson, 1985; Stutzenberger, 1990).

The cellulolytic microorganisms include protozoa, fungi and bacteria and are ubiquitous in nature. The cellulose-decomposing bacteria include aerobic, anaerobic, mesophilic and thermophilic strains, inhabiting a great variety of environments, including the most extreme vis-à vis temperature, pressure and pH. Cellulolytic bacteria also have been found in the gut of wood-eating worms, termites and vertebrate herbivores, all of which exploit anaerobic symbionts for the digestion of wood and fodder.

In nature, many cellulolytic species exist in symbiotic relationships with secondary microorganisms (Ljungdahl and Eriksson, 1985). The primary microorganisms degrade cellulose directly to cellobiose and glucose. Only part of the breakdown products is assimilated by the polymer degrading strain(s), and the rest is utilized by the satellite microorganisms. Removal of the excess of sugars promotes further cellulose degradation by the primary species because cellobiose-induced inhibition of cellulase action and repression of cellulase synthesis are precluded.

Modern interest in cellulolytic microorganisms was spawned by the decay of cotton fabric in army tents and military clothing in the South Pacific jungles during World War II. The basic research program that resulted from this military problem led to the establishment of the United States Army Natick Laboratories (Reese, 1976). The resultant research led to the discovery that the causative agent for the costly problem was a cellulolytic fungi, *Trichoderma viride* (subsequently renamed *Trichoderma reesei*). Subsequent research, originally from the Natick Laboratories and later spreading to other research institutes and universities, led to the identification and classification of thousands of different strains of cellulolytic fungi and bacteria. Many of the major types of cellulolytic bacteria have been listed in Part A of the second edition of *The Prokaryotes* (Coughlan and Mayer, 1992). Since the latter publication, the major emphasis in the area has not concentrated on the discovery or description of new cellulolytic strains. Rather, research in the area during the past decade has centered on characterizing the enzymes and enzyme systems from selected bacteria that degrade cellulose in particular and plant cell wall polysaccharides in general.

Enzymes That Degrade Plant Cell Wall Polysaccharides

The chemical and structural intricacy of plant cell wall polysaccharides is matched by the diversity and complexity of the enzymes that degrade them. The cellulases and hemicellulases are family members of the broad group of glycosyl hydrolases, which catalyze the hydrolysis of oligosaccharides and polysaccharides in general (Gilbert and Hazlewood, 1993; Kuhad et al., 1997; Ohmiya et al., 1997; Schülein, 1997; Tomme et al., 1995a; Viikari and Teeri, 1997; Warren, 1996; Wilson and Irwin, 1999).

Historically, the type of substrate and manner in which a given enzyme interacted with its substrate were decisive in the classification of the glycosidases, as established first by the Enzyme Commission (EC) and later by the Nomenclature Committee of the International Union of Biochemistry (IUB). Enzymes were usually named and grouped according to the reactions they catalyzed. Thus, cellulases, xylanases, mannanases and chitinases were grouped a priori in different categories. Moreover, enzymes that cleave polysaccharide substrates in the middle of the chain ("endo"-acting enzymes) versus those which clip at the chain ends ("exo"-acting enzymes) were also placed in different groups.

For example, in the case of cellulases, the endoglucanases were grouped in EC 3.2.1.4, whereas the exoglucanases (i.e., cellobiohydrolases) were classified as EC 3.2.1.91.

The historical division of enzymes is inappropriate for classification of the cellulases and other glycosyl hydrolases. Like other enzymes (e.g., proteases, etc.), previous classification systems of the glycosyl hydrolases centered on the types of substrates and the bonds cleaved by a given enzyme. The problem with the glycosyl hydrolases is that the polysaccharide substrates and particularly the bonds they cleave are all quite similar, and classification of the different types of enzymes according to conventional criteria often misses the mark. Consequently, alternative approaches were pursued. The recent trend is to classify the different glycosyl hydrolases into groups based on common structural fold and mechanistic themes (Davies and Henrissat, 1995; Henrissat, 1991; Henrissat and Bairoch, 1996; Henrissat and Davies, 1997; Henrissat et al., 1998). A comprehensive website that provides a catalog of the different glycosyl hydrolase families is now available (Coutinho and Henrissat, 1999a; Coutinho and Henrissat, 1999c; [Carbohydrate-Active Enzymes server (afmb.cnrs-mrs.frl)]. The website also provides excellent introductory explanatory material, and the interested reader is encouraged to use this site extensively.

It is interesting that the distinction between endo- and exo-acting enzymes is also reflected by the architecture of the respective class of active site, even within the same family of enzymes (Fig. 4). The endoglucanases, for example, are commonly characterized by a groove or cleft, into which any part of a linear cellulose chain can fit. On the other hand, the exoglucanases bear tunnel-like active sites, which can only accept a substrate chain via its terminus. The exo-acting enzyme apparently threads the cellulose chain through the tunnel, wherein successive units (e.g., cellobiose) would be cleaved in a sequential manner. The sequential hydrolysis of a cellulose chain is a relatively new notion of growing importance, which has earned the term “processivity” (Davies and Henrissat, 1995), and processive enzymes are considered to be key components which contribute to the overall efficiency of a given cellulase system.

Though instructive, there is growing dissatisfaction with the endo/exo terminology. As our understanding of the nature of catalysis by these enzymes progresses, it has become clear that some enzymes are capable of both endo- and exo-action (Johnson et al., 1996; Morag et al.,

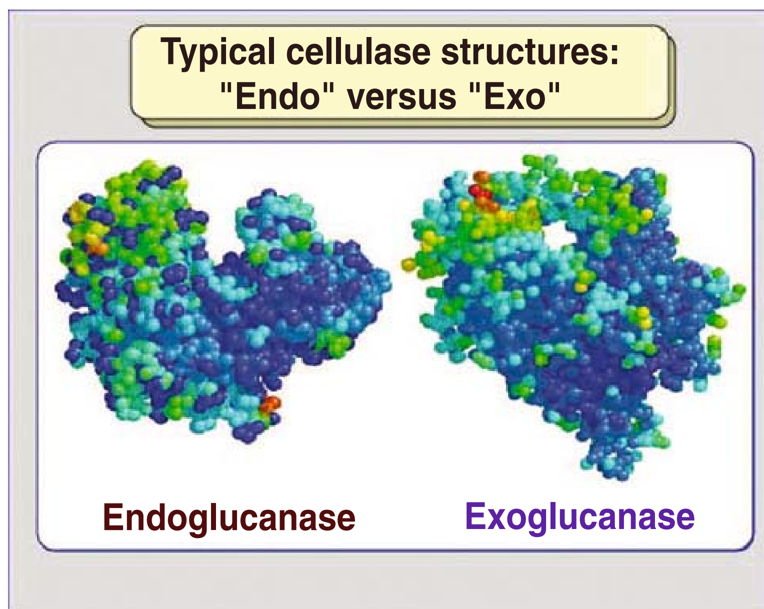

Fig. 4. Structures of a typical endoglucanase and exoglucanase. In each case, the structure is viewed from a perspective, which demonstrates the comparative architecture of the respective active site. Despite the sequence similarity of both enzymes and their classification as family-6 glycosyl hydrolases, their respective active-site architecture is different. The endoglucanase (endoglucanase E2 from the bacterium, *Thermomonospora fusca*, PDB code 1TML) is characterized by a deep cleft to accommodate the cellulose chain at any point along its length, whereas the active site of the exoglucanase (cellobiohydrolase CBHI from the cellulolytic fungus, *Trichoderma reesei*, PDB code 1CEL) bears an extended loop that forms a tunnel, through which one of the termini of a cellulose chain can be threaded. The ribbon diagrams, showing the secondary structures (α-helices and β-strands) of the two enzymes, were drawn using RasMol 2.6.

1991; Reverbel-Leroy et al., 1997; Sakon et al., 1997). Moreover, some glycosyl hydrolase families include both endo- and exoenzymes, again indicating that the mode of cleavage can be independent of sequence homology and structural fold. In this context, relatively minor changes in the lengths of relevant loops in the general proximity of the active site, may dictate the endo- or exo-mode of action without significant differences in the overall fold.

Owing to subtle but diverse chemical and structural aspects of the substrates involved, plant cell wall degrading enzymes do not follow the same rules as common enzyme standards, such as simple proteases, DNAse, RNAse and lysozyme. In fact, the cellulases and hemicellulases are usually very large enzymes, whose molecular masses often exceed those of proteases by factors of 2–5 and more. Their polypeptide chains partition into a series of functional modules and linker segments (frequently glycosylated), which together determine their overall activity characteristics and interaction with their substrates and/or with other components of the cellulolytic and hemicellulolytic system.

Cellulases

The cellulases include the large number of endo- and exoglucanases which hydrolyze β-1,4-glucosidic bonds within the chains that comprise the cellulose polymer (Béguin and Aubert, 1994; Haigler and Weimer, 1991; Tomme et al., 1995b). Thus, in principle, the degradation of cellulose requires the cleavage of a single type of bond. Nevertheless, in practice, we find that cellulolytic microorganisms produce a variety of complementary cellulases of different specificities from many different families.

It may seem somewhat surprising that the combined effect of so many different enzymes are required to degrade such a chemically simplistic substrate. This complexity reflects the difficulties an enzyme system encounters upon degrading such a highly crystalline substrate as cellulose. As described in the previous section, cellulases that degrade the cellulose chain can be either "endo-acting" or "exo-acting." Moreover, the degradation of crystalline cellulose should be viewed three-dimensionally and in situ, where the cellulose chains are packed within the microcrystal, thus generating the remarkably stable physical properties of the crystalline substrate. The enzymes have to bind to the cellulose surface, localize and isolate suitable chains, destined for degradation. It would seem logical that amorphous regions or defects in the crystalline portions of the substrate would be favorable sites for initiation of the process. The structural as opposed to chemical heterogeneity of the substrate dictates the synergistic action of a complex set of complementary enzymes towards its complete digestion.

Various models have been suggested to account for the observed synergy between and among two or more different types of cellulases. For example, an endo-acting enzyme can produce new chain ends in the internal portion of a polysaccharide backbone, and the two newly exposed chains would then be available for action of exo-acting enzymes. In addition, two different types of exoglucanases may exhibit different specificities by acting on a cellulose chain from opposite ends (i.e., the reducing versus the nonreducing end of the polymer). Likewise, an endoglucanase may be selective for only one of the two sterically distinct glucosidic bonds on the cellulosic surface. In addition, some cellulases may display high levels of activity at the beginning of the degradative process, i.e., on the highly crystalline material, whereas others would be selective for newly exposed, partially degraded chains, otherwise embedded within the crystal. Still others would show very high levels of activity after the degradative process has advanced, and cellulose chains that have been freed of the crystalline setting would then be hydrolyzed quite rapidly. A collection of various enzymes, which exhibit complementary specificities and modes of action, would account for the observed synergistic action of the complete cellulase "system" in digesting the cellulosic substrate.

In addition to endo- and exoglucanases, included in the overall group of cellulases are the β-glucosidases (EC 3.2.1.21), which hydrolyzes terminal, nonreducing β-D-glucose residues from cello-oligodextrins. In particular, this type of enzyme cleaves cellobiose—the major end product of cellulase digestion—to generate two molecules of glucose. Some β-glucosidases are specific for cellobiose whereas others show broad specificity for other β-D-glycosides, e.g., xylobiose. Often, the β-glucosidases are associated with the microbial cell surface and hydrolyze cellobiose to glucose before, during or after the transport process.

Hemicellulases

Strictly speaking, hemicellulases are not the precise subject of this chapter, since they do not directly sever the β-1,4-glucosidic bond of cellulose. Nevertheless, in nature, they are essential to the bacterial degradation of insoluble cellulose because the natural bacterial substrate—the plant cell wall—comprises an architecturally

cogent composite of cellulose and hemicellulose. In natural systems, the two types of polysaccharides cannot be easily separated, and microbial systems have to deal simultaneously with both. The xylan component is particularly of interest for several reasons: 1) xylan is a major hemicellulosic component of the plant cell wall, 2) the xylanases are well defined enzymes, closely associated with the cellulase and 3) the repeating units (both xylose and xylobiose) bear striking structural resemblance to their cellulosic counterparts (i.e., glucose and cellobiose).

In contrast to cellulose degradation, the degradation of the hemicelluloses imposes a somewhat different challenge, since this group of polysaccharides includes widely different types of sugars or non-sugar constituents with different types of bonds. Thus, the complete degradation of hemicellulose requires the action of different types of enzymes. These enzymes, the hemicellulases, can differ in the chemical bond they cleave, or, as in the case of the cellulases, they may cleave a similar type of bond but with different substrate- or product specificity (Biely, 1985; Coughlan and Hazlewood, 1993; Eriksson et al., 1990; Gilbert and Hazlewood, 1993).

Hemicellulases can be divided into two main types, those that cleave the mainchain backbone, i.e., xylanases or mannanases, and those that degrade sidechain substituents or short end products, such as arabinofuranosidase, glucuronidase, acetyl esterases and xylosidase. Like the cellulases, hemicellulases can be of the endo- or exo-types. A schematic view of the types of bonds that would be hydrolyzed by different types of hemicellulases is presented in Fig. 3.

XYLAN-DEGRADING ENZYMES. The xylanases are by far the most characterized and studied of the hemicellulases and involve the cleavage of a major mainchain backbone. Endoxylanases (1,4-β-D-xylan xylanhydrolase, EC 3.2.1.8) hydrolyze the 1,4-β-D-xylopyranosyl linkage of xylans, such as D-glucurono-D-xylans and L-arabino-D-xylan. These single-subunit enzymes from both fungi and bacteria exhibit a broad range of physiochemical properties, whereby two main classes have been described: alkaline proteins of low M_r (<30,000) and acidic proteins of high M_r. This general classification scheme correlates with their assignment into glycosyl hydrolase families 10 and 11, whereby the former represents the high M_r xylanases and the latter coincides with the low M_r enzymes. The two families also differ in their catalytic properties, such that the family 10 enzymes seem to display a greater versatility towards the substrate than that observed for those of family 11, and are thus typically able to hydrolyze highly substituted xylan more efficiently. The family 10 xylanases exhibit a (β/α)8 topology whereas those from family 11 form a β-jelly roll fold. Both families show a retaining catalytic mechanism of hydrolysis.

MANNAN-DEGRADING ENZYMES. Glucomannans and galactoglucomannans are branched heteropolysaccharides found in hardwood and softwood. The degradation of these polymers again involve many hydrolytic enzymes, including endo-1,4-β-mannanase (EC 3.2.1.78), β-mannosidase (EC 3.2.1.25), β-glucosidase (EC 3.2.1.21), and α-galactosidase (EC 3.2.1.22). 1,4-β-D-Mannanases hydrolyze mainchain linkages of D-mannans and D-galacto-D-mannans. These enzymes, both of the endo- or exo-types, are produced in various microorganisms, including *Bacillus subtilis*, *Aspergillus niger* and intestinal and rumen bacteria and commonly occur in families 5 and 26.

LICHENIN-DEGRADING ENZYMES. Lichenase (1,3-1,4-β-D-glucan 4-glucanohydrolase, EC 3.2.1.73) is a mixed linkage β-glucanase, which cleaves the β-1,4 linkages adjacent to the β-1,3 bonds of the lichenin substrate. According to [{afmb.cnrs-mrs.fr/~pedro/CAZY/db.html}{modern structure-based classification, lichenases can be members of families 8, 16 or 17.

β-D-XYLOSIDASES. The 1,4-β-D-xylosidases (1,4-β-D-xylan xylohydrolase, EC 3.2.1.37) hydrolyze xylo-oligosaccharides (i.e., xylan breakdown products and mainly xylobiose) to xylose. These enzymes are either intracellular or extracellular components and are closely associated with hemicellulolytic activities. Monomeric, dimeric and tetrameric xylosidases have been found with Mrs of 26,000 to 360,000. Many of the xylosidases act on a variety of substrates. For example, *Aspergillus niger* produces an enzyme classified as a β-xylosidase that can hydrolyze β-galactosides, β-glucosides and α-arabinosides, in addition to β-xylosides.

SIDECHAIN-DEGRADING ENZYMES. α-D-Glucuronidases (EC 3.2.1.39) catalyze the cleavage of the α-1,2 glucosidic bond of 4-*O*-methyl-α-D-glucuronic acid side chain. This bond has a stabilizing effect on the neighboring xylosidic bonds of the main chain. Several α-glucuronidase genes have recently been cloned and sequenced and usually occupy family 67.

α-L-Arabinofuranosidases (α-L-arabinofuranoside arabinofuranohydrolase, EC 3.2.1.55) is another important enzyme that cleaves non-reducing terminal α-L-arabinofuranosidic linkages in arabinoxylan, L-arabinan, and other

L-arabinose containing polysaccharides. These enzymes are found either in the cell-associated or extracellular form and can be members of families 43, 51 or 62.

1,4-β-Mannosidases hydrolyze 1,4-linked β-D-mannosyl groups from the nonreducing end. These enzymes (similar to β-xylosidases) hydrolyze mainly the end products of the mannanases, i.e. mannobiose and mannotriose.

Carbohydrate Esterases

The side chain substituents of xylan are composed not only of sugars but also of acidic residues, such as acetic, ferulic (4-hydroxy-3-methoxycinnamic) or *p*-coumaric (4-hydroxycinnamic) acids. Carbohydrate esterases that cleave these residues (see Fig. 3) are found in enzyme preparations from both hemicellulolytic and cellulolytic cultures (Borneman et al., 1993). Such enzymes sometimes represent separate modules, separated by linker segments from other cellulolytic or hemicellulolytic catalytic modules in the same polypeptide chain. Like the glycosyl hydrolases, the carbohydrate esters are currently classified according to sequence homology and common structural fold.

Cellulases and Hemicellulases are Modular Enzymes

The initial contribution of biochemical methods for determining the characteristics of a given cellulase was extended immeasurably by the contribution of molecular biology and bioinformatics. By comparing the sequences of the cellulases and related enzymes, an entirely new view of these enzymes emerged.

Cellulases and hemicellulases are composed of a series of separate modules. This fact explains the very large size of some of these enzymes and gives us some insight into their complex mode of action. Each module or domain comprises a consecutive portion of the polypeptide chain and forms an independently folding, structurally and functionally distinct unit (Coutinho and Henrissat, 1999; Gilkes et al., 1991; Teeri et al., 1992). Each enzyme contains at least one catalytic module, which catalyzes the actual hydrolysis of the glycosidic bond and provides the basis for classification of the simple enzymes (i.e., those containing a single catalytic module). Other accessory or "helper" domains assist or modify the primary hydrolytic action of the enzyme, thus modulating the overall properties of the enzyme. Some of the different themes illustrating the modular compositions of the cellulases and related enzymes are illustrated in Fig. 5.

The Catalytic Modules—Families of Enzymes

The definitive component of a given enzyme is the catalytic domain. Former EC-based classification schemes according to substrate specificity are now considered somewhat obsolete because they fail to take into account the structural features of the enzymes themselves. The catalytic domains of glycosyl hydrolases are presently categorized into families according to amino acid sequence homology (Coutinho and Henrissat, 1999; Henrissat, 1991; Henrissat and Bairoch, 1996; Henrissat and Davies, 1997; Henrissat et al., 1998). For more information, see the Carbohydrate-Active Enzymes (CAZy), designed and maintained by Pedro Coutinho and Bernard Henrissat.

The enzymes of a given glycosyl hydrolase family display the same topology, and the positions of the catalytic residues are conserved with respect to the common fold. In recent years, X-ray crystallography has provided a general overview of the structural themes of the glycosyl hydrolases and their interaction with their intriguing set of substrates (Bayer et al., 1998; Davies and Henrissat, 1995; Henrissat and Davies, 1997).

The mechanism of cellulose and hemicellulose hydrolysis occurs via general acid catalysis and is accompanied by either an overall retention or an inversion of the configuration of the anomeric carbon (Davies and Henrissat, 1995; McCarter and Withers, 1994; White and Rose, 1997; Withers, 2001). In both cases, cleavage is catalyzed primarily by two active-site carboxyl groups. One of these acts as a proton donor and the other as a nucleophile or base. Retaining enzymes function via a double-displacement mechanism, by which a transient covalent enzyme-substrate intermediate is formed (Fig. 6A). In contrast, inverting enzymes employ a single-step mechanism as shown schematically in Fig. 6B. The distance between the acid catalyst and the base represents the major structural difference between the two mechanisms. In retaining enzymes, the distance between the two catalytic residues is about 5.5 Å, whereas in inverting enzymes the distance is about 10 Å. In the inverting enzymes, additional space is provided for a water molecule, involved directly in the hydrolysis, and the resultant product exhibits a stereochemistry opposite to that of the substrate. In all cases, the mechanism of hydrolysis is conserved within a given glycosyl hydrolase

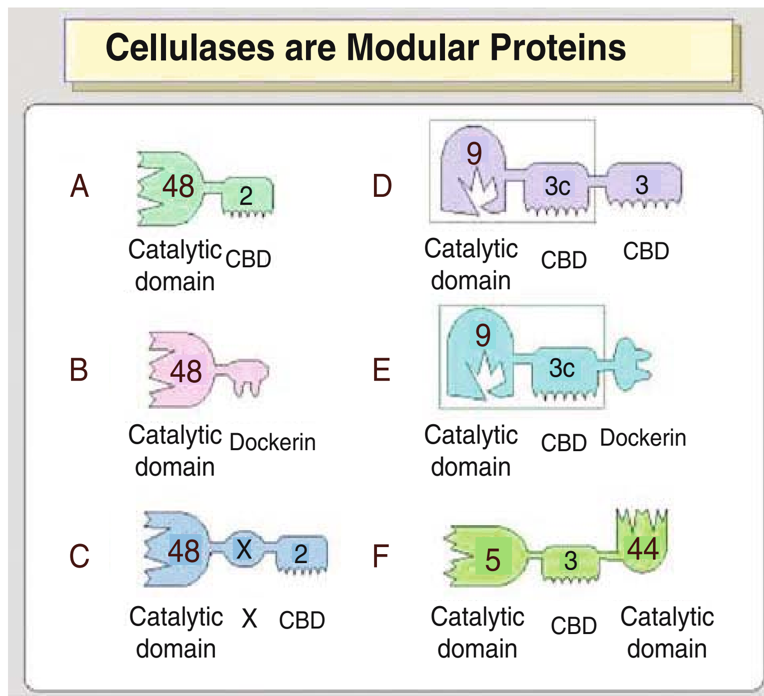

Fig. 5. Scheme illustrating the diversity of the modular architecture of cellulases and other glycosyl hydrolases. The different modules are grouped into families according to conserved sequences as shown here symbolically. A. One of the most common types of cellulases consists of a catalytic module or domain, flanked by a cellulose-binding domain (CBD) at its *N*- or *C*-terminus. This particular enzyme shown in "A" comprises a catalytic domain from family 48 and a family-2 CBD. B. Cellulosomal enzymes are characterized by a "dockerin domain" attached to a catalytic domain. In this case, the same type of enzyme as in "A," carrying a family-48 catalytic module, harbors a dockerin domain instead of a CBD. C. Many cellulases contain "X domains," i.e., domains of unknown (as yet undefined) function. D. Some enzymes have more than one CBD or other type of carbohydrate-binding module (CBM). Often, one CBD, such as the family-3 CBD shown here, serves to bind the cellulase strongly to the flat surface of the insoluble substrate, whereas the other one (the family-3c CBD) acts in concert with the catalytic module by binding transiently to a single cellulose or hemicellulose chain. E. Some cellulosomal cellulases have a CBD or CBM together with a dockerin in the same polypeptide chain. F. Some cellulases have more than one type of catalytic module, such as the family-5 and family-44 modules shown here, and the two probably work in concerted fashion to degrade the substrate efficiently.

family (Coutinho and Henrissat, 1999; Davies and Henrissat, 1995; Henrissat and Davies, 1997).

Cellulose-Binding Domains Versus Carbohydrate-Binding Modules

In addition to the catalytic module, free cellulases and hemicellulases usually contain at least one cellulose-binding domain (CBD) as an integral part of the polypeptide chain (Linder and Teeri, 1997; Tomme et al., 1995a). The CBD serves predominantly as a targeting agent to direct and attach the catalytic domain to the insoluble crystalline substrate. Like the catalytic domains, the CBDs are categorized into a series of families according to sequence homology and consequent structural fold.

In some cases, the term "CBD" is deceptive because not all of the CBDs bind to crystalline cellulose. Some families (or subfamilies or family members) bind either preferentially or additionally to other insoluble polysaccharides, e.g., xylan or chitin. For example, the family-5 CBD and some of the members of the family-3 CBDs bind to chitin as well as cellulose (Brun et al., 1997; Morag et al., 1995). Moreover, the family-2 CBDs can be divided into two subfamilies, one of which indeed binds preferentially to insoluble cellulose, but the other binds to xylan (Boraston et al., 1999). The molecular basis for this was proposed to reflect the fact that in the first subfamily, 3 surface-exposed tryptophans contribute to cellulose binding (Simpson et al., 1999b; Williamson et al., 1999). However, in the case of the xylan-binding members, one of these tryptophans is missing, whereas the other two assume a different conformation, thereby allowing them to stack against the hydrophobic surfaces of two xylose rings of a xylan substrate. Other types of CBD prefer less crystalline substrates (e.g., acid-swollen cellulose), single

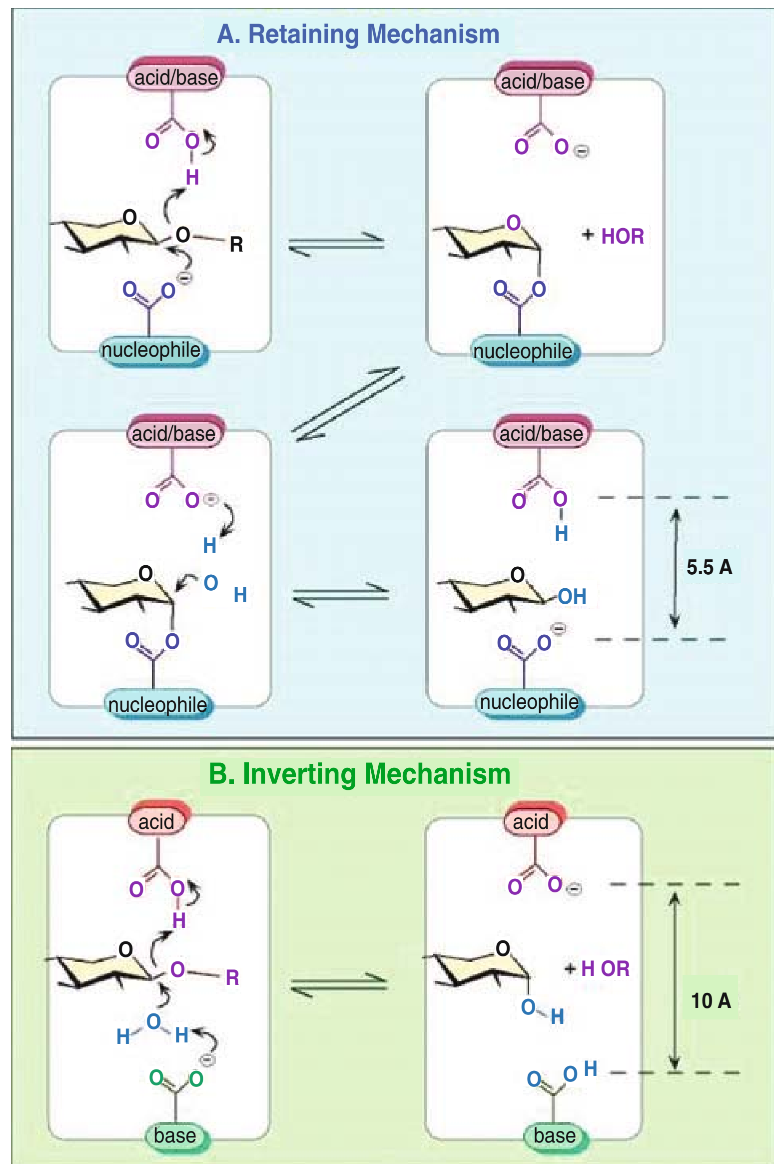

Fig. 6. The two major catalytic mechanisms of glycosidic bond hydrolysis. A. The retaining mechanism involves initial protonation of the glycosidic oxygen via the acid/base catalyst with concomitant formation of a glycosyl-enzyme intermediate through the nucleophile. Hydrolysis of the intermediate is then accomplished via attack by a water molecule, resulting in a product that exhibits the same stereochemistry as that of the substrate. B. The inverting mechanism involves the single-step protonation of the glycosidic oxygen via the acid/base catalyst and concomitant attack of a water molecule, activated by the nucleophile. The resultant product exhibits a stereochemistry opposite to that of the substrate. The type of mechanism is conserved within a given glycosyl hydrolase family and dictated by the active-site architecture and atomic distance between the acid/base and nucleophilic residues (aspartic and/or glutamic acids).

cellulose chains and/or soluble oligosaccharides, e.g, laminarin (1,3-β-glucan) and barley 1,3/1,4-β-glucan (Tomme et al., 1996; Zverlov et al., 2001). Still others exhibit alternative accessory function(s), a topic to be described below in more detail. Moreover, the CBDs responsible for the primary binding event may further disrupt hydrogen bonding interactions between adjacent cellulose chains of the microfibril (Din et al., 1994), thereby increasing their accessibility to subsequent attack by the hydrolytic domain.

Consequently, the concept of CBD has been broadened and redefined as "CBM" i.e., carbohydrate-binding module (Boraston et al., 1999; Coutinho and Henrissat, 1999). To date (March 2001), 26 different CBM families have been described. The structures of CBDs from a number of families and subfamilies have been determined, and an understanding of their structures has provided interesting information regarding the mode of binding to cellulose. Those that bind to crystalline substrates, appear to do so via a similar type of mechanism. One of the surfaces of such CBDs is characteristically flat and appears to complement the flat surface of crystalline cellulose. A series of aromatic amino acid residues on this flat surface form a planar strip (Mattinen et al., 1997; Simpson and Barras, 1999a; Tormo et al., 1996) that stack opposite the glucose rings of a single cellulose chain. In addition, to the planar aromatic strip, several polar amino acid residues on the same surface appear to anchor the CBD to two adja-

cent cellulose chains. The binding of the CBD to crystalline cellulose would thus involve precisely oriented, contrasting hydrophobic and hydrophilic interactions between the reciprocally flat surfaces of the protein and the carbohydrate substrate. Together they provide a selective biological interaction, which contributes to the specificity that a CBD exhibits towards its structure.

In contrast to the interaction with the crystalline cellulose surface, other CBMs seem to interact with single cellulose chains. The family-3c and family-4 CBDs preferentially bind to noncrystalline forms of cellulose and clearly have a different function in nature (Johnson et al., 1996; Sakon et al., 1997; Tomme et al., 1996). For example, the role of family-4 CBD may be to recognize, bind to and deliver an appropriate catalytic module to a cellulose chain, which has been loosened or liberated from a more ordered arrangement within the cellulose microfibril. The binding of the family-3c CBD to single cellulose chains and its remarkable role in cellulose hydrolysis will be discussed later (Fig. 9).

The Family-9 Cellulases: An Example

This section pertains to enzyme diversity and how a single type of catalytic module can be modified by the class of helper module(s) that flank its *C*- or *N*-terminus. We are only at the beginning in our understanding of how the modular arrangement affects the overall activity and function of a given enzyme.

In its simplest form, an enzyme would presumably consist of a single catalytic domain, usually with a standard CBM, which would target the enzyme to the crystalline substrate. Indeed, this is the norm for many individual glycosyl hydrolase families. However, in others, e.g., the family-9 cellulases, the catalytic domains commonly occur in tandem with a number of accessory modules. Although the story is still rather incomplete, we can discuss the currently available information regarding family 9 and draw several interesting conclusions from the few publications on this currently developing subject.

Family-9 Theme and Variations. The crystal structure of the family-9 catalytic module is known and displays an $(\alpha/\alpha)6$-barrel fold and inverting catalytic machinery. However, few of the prokaryotic family-9 enzymes consist of a solitary catalytic module (Fig. 7A). Actually, there are numerous family-9 cellulases of plant origin, the great majority of which are such lone catalytic modules that lack accessory modules. Another type of eukaryotic family-9 cellulase that lacks helper modules is produced by the termite. The prokaryotic family-9 enzymes, however, are almost invariably decorated with a variety of subsidiary modules that modulate the activity of the catalytic module.

Microbial family-9 cellulases commonly conform to one of the themes shown in Fig. 7. In one of these, the catalytic module is followed immediately downstream by a fused family-3c CBM (Fig. 7B). This particular type of CBM imparts special characteristics to the enzyme (see below). A second theme consists of an immunoglobulin-like (Ig) domain (of unknown function) immediately upstream to the catalytic domain (Fig. 7C). A variation of the latter theme includes a family-4 CBM at the *N*-terminus of the enzyme, followed by an Ig domain and family-9 catalytic domain (Fig. 7D). In addition to the above-described modular arrangement, each of the free prokaryotic enzyme systems includes a standard CBD that binds strongly to crystalline cellulose.

Until very recently, there has been but one example in the prokaryotic world of a family-9 enzyme that contains no helper domain. This is the family-9 glycosyl hydrolase of the cellulosomal scaffoldin from the cellulolytic anaerobic bacterium, *Acetivibrio cellulolyticus* (Ding et al., 1999). The *A. cellulolyticus* enzyme forms part of a multimodular scaffoldin, but the catalytic module appears to be a functionally distinct entity that lacks adjoining helper modules. The other modules are conventional scaffoldin-associated modules, e.g., cohesins and a true cellulose-binding CBD. More recently, a dockerin-containing cellulosomal family-9 enzyme from *Clostridium cellulovorans* has been sequenced and also seems to lack adjoining helper modules (Tamaru et al., 2000b).

This thematic arrangement of the family-9 cellulases is mirrored in the respective sequences of the catalytic modules. The divergent sequences are reflected by the phylogenetic relationship of the parent cellulases (Fig. 8). Thus, the simplest cellulases (the group A eukaryotic cellulases from plants) that lack adjacent helper modules are all phylogenetically related (theme A). Interestingly, the catalytic module of CipV from *A. cellulolyticus* is distinct from the other groups designated in Fig. 8, but closest to the plant enzymes, as might be anticipated from its lack of a helper module. In a similar manner, catalytic modules from cellulases that are fused to a family-3c CBD (group B), all map within the same branch (theme B). On the other hand, the catalytic modules that bear an adjacent Ig-like domain all fall into a cluster on the opposite side of the tree. Cellulases which have the Ig-like domain only (theme C) occupy a small separate branch and those that also include a family-4 CBD (theme D) that develop distally to form a separate subcluster.

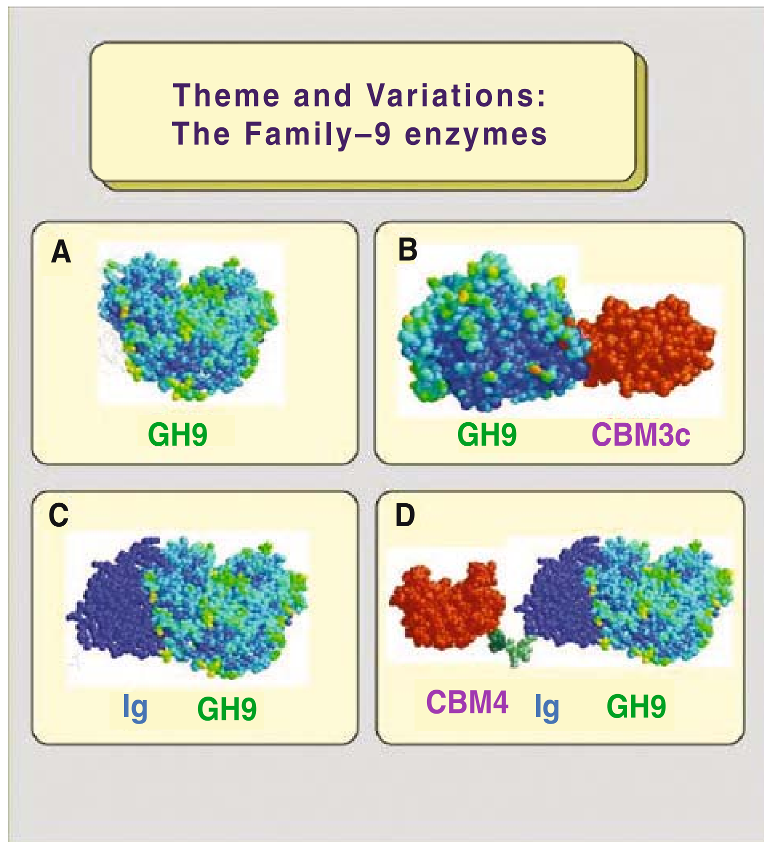

Fig. 7. Theme and variations: schematic view of the modular arrangement of the family-9 glycosyl hydrolases. A. The solitary catalytic domain. B. The catalytic domain and fused family-3c cellulose-binding domain (CBD). *C. Immunoglobulin*-like (Ig) domain, fused to the catalytic domain. D. Successive family-4 CBD, Ig and catalytic domains. The representations of the different modules are based on their known structures and are presented sequentially, left-to-right, from the *N*- to *C*-terminus. Structures (Ribbon diagrams produced by RasMol 2.6) in "A" and "B" are derived from cellulase E4 from *Thermomonospora fusca* (PDB code, 1TF4), those in "C" and "D" are from the CelD endoglucanase of *C. thermocellum* (PDB code, 1CLC). The figure used for the family-4 CBD in "D" is derived from the nuclear magnetic resonance (NMR) structure of the *N*-terminal CBD of *Cellulomonas fimi* β-1,4-glucanase CenC (PDB code, 1ULO). The structures in "B" and "C" are authentic views of the respective crystallized bi-domain protein components. The CBD in "D" has been placed manually to indicate its *N*-terminal position in the protein sequence, but its spatial position in the quaternary structure and the structure of the linker segment remains unknown.

Theme A enzymes: CipV Acece, CipV scaffoldin from the cellulolytic bacterium, *A. cellulolyticus* (AF155197); and plant (eukaryotic) cellulases from *Prunus persica* (X96853), *Populus alba* (D32166), *Citrus sinensis* (AF000135), *Persea americana* (M17634), *Pinus radiata* (X96853), *Arabidopsis thaliana* (X98543), *Phaseolus vulgaris* (M57400), *Capsicum annuum* (X97189), *Lycopersicon esculentum* (U20590).

Theme B enzymes: CelF Clotm, endoglucanase F from *Clostridium thermocellum* (X60545); CelZ Closr, exoglucanase Z from *Clostridium stercorarium* (X55299); CelA Calsa, cellulase A from Caldocellum saccharolyticum (L32742); CelG Cloce, endoglucanase G from *Clostridium cellulolyticum* (M87018); CelI Clotm, endoglucanase I from *Clostridium thermocellum* (L04735); CelB Celfi, endoglucanase B from *Cellulomonas fimi* (M64644); E4 Thefu, endo/exoglucanase E4 from *Thermomonospora fusca* (M73322).

Theme C enzymes: CelJ Clotm, cellulase J from *Clostridium thermocellum* (D83704); CelD Clotm, endoglucanase D from *Clostridium thermocellum* (X04584); CelC Butfi, endoglucanase C from *Butyrivibrio fibrisolvens* (X55732).

Theme D enzymes: CbhA Clotm, cellobiohydrolase A from *Clostridium thermocellum* (X80993); CelA Psefl, endoglucanase A from *Pseudomonas fluorescens* (X12570); CelC Celfi, endoglucanase C from *Cellulomonas fimi* (X57858); CelI Strre, endoglucanase I from *Streptomyces reticuli* (X65616); E1 Thefu, endoglucanase E1 from *Thermomonospora fusca* (L20094).

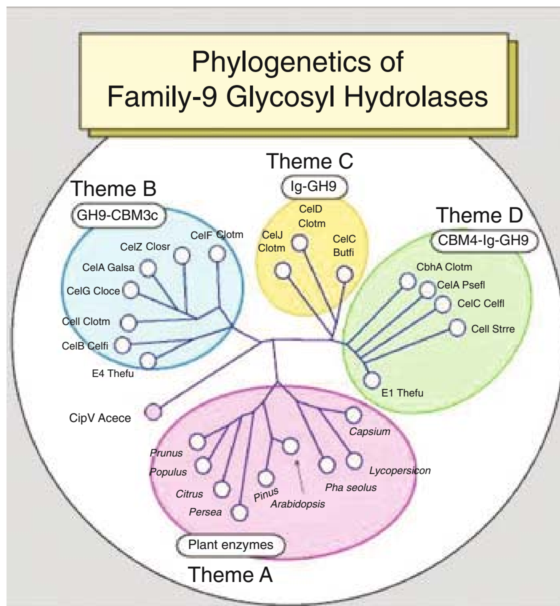

Fig. 8. Phylogenetic analysis of the *N*-terminal family-9 catalytic module of CipV and its relationship with other family-9 members. The various theme groupings roughly follow the groups shown in Fig. 7. Theme A (group A) enzymes lack associated helper modules. Theme B (group B) enzymes carry a fused family-3c cellulose-binding domain (CBD) downstream to the catalytic module. Theme C (group C) and theme D (group D) enzymes carry an immunoglobulin-like (Ig) domain upstream to the catalytic module, the theme D enzymes having an additional *N*-terminal family-4 CBM.

The analysis of the designated catalytic modules was performed using GenBee, based on the respective GenBank sequences (accession codes in parentheses).

Family-9 Crystal Structures. Two crystal structures of family-9 cellulases have been elucidated, representing two subtypes of this particular family of glycosyl hydrolase. These are cellulase E4 from Thermomonospora fusca (recently reclassified as *Thermobifida fusca*; Sakon et al., 1997) and CelD from *Clostridium thermocellum* (Juy et al., 1992). These two examples are architecturally distinct—the E4 cellulase being an example of a theme B family-9 enzyme (see Figs. 7B and 8) and the CelD cellulase being a theme C enzyme. Fortunately, in both cases, one of the neighboring modules co-crystallized with the catalytic module, thus providing primary insight into their combined structures. In the case of *T. fusca* E4, the catalytic domain and neighboring family-3c CBM were found to be interconnected by a long, rigid linker sequence, which envelops about half of the catalytic domain until it connects to the adjacent CBM (Fig. 9A). In contrast, in the *C. thermocellum* CelD, the catalytic domain is adjoined at its *N*-terminus by a 7-stranded immunoglobulin-like (Ig) domain of unknown function. The comparison between the E4 and CelD cellulases indicates that a given type of catalytic module can be structurally and functionally modulated by different types of accessory domains.

Helper Modules. The family-3c CBM is special. To date, this particular type of CBM has been found in nature associated exclusively with the family-9 catalytic domain. Structurally, the CBM is homologous to the other family-3 CBMs, but contains substitutions in many important surface residues. The three-dimensional crystal structure of the E4 cellulase revealed the close interrelationship between the family-9 catalytic domain and the family-3c CBM, thus suggesting a functional role as a helper module. This CBM seems not to bind directly to crystalline cellulose but appears to act in concert with the catalytic domain by binding transiently to the incoming cellulose chain, which is then fed into the active-site cleft pending hydrolysis (Gal et al., 1997; Irwin et al., 1998; Sakon et al., 1997; Fig. 9B).

The information derived from the family-9 enzymes suggests that the activity of catalytic domains can be modulated by accessory modules. The accessory modules can either supplement or otherwise alter the overall properties of an enzyme (Bayer et al., 1998). The recurrent appearance in nature of a given type of module adjacent to a specific type of neighboring catalytic domain may indicate a functionally significant theme. These observations raise the possibility of a more selective role for certain types of CBM and other modules, whereby their association with certain types of catalytic domains could signify a "helper" role. The helper module would provide hydrolytic efficiency and alter the catalytic character of the enzyme.

New Developments in Cellulase Analysis

The biochemical characterization of cellulases is in many cases a difficult task owing to the large variety of enzyme types and modes of action. At first glance, it is an intriguing phenomenon that for such a simple reaction (i.e., the hydrolysis of the β-1,4-glucose linkage in a linear glucose chain), Nature has evolved so many types of cellulases. The vast varieties of enzymes are found not only among the different species of cellulolytic bacteria but also within the same organism. The reason for this extensive diversity comes from the insoluble nature of cellulose and the fact that, although the chemical com-

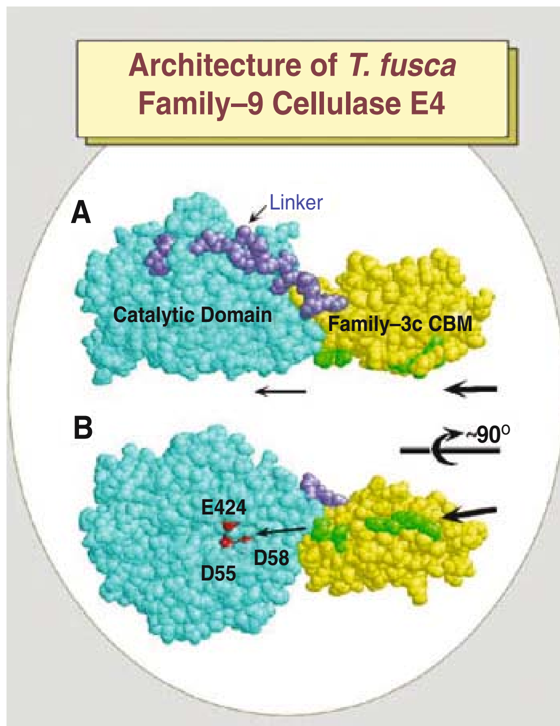

Fig. 9. Structural aspects of family-9 theme-B cellulase E4 from *Thermobifida fusca*. A. "Side view" of the E4 molecule, drawn using RasMol in spacefill mode. Shown are the family-9 catalytic module (turquoise, at left), the family-3c carbohydrate-binding module (CBM; in yellow, at right) and the intermodular linker (dark blue strip). The presumed path of a single cellulose chain, from the CBM to the catalytic domain, is shown at the bottom of the structure (arrows). The enzyme also possesses a fibronectin-like domain (FN3) and a cellulose-binding family-2 CBM (not shown). Note that the linker appears to serve a defined structural role by which the family-3c CBM is clamped tightly to the catalytic domain. Selected surface residues on the catalytic domain along the interface of both the linker and the CBM3c also serve to fasten both features tightly to the catalytic module. B. "Bottom view" of the E4 molecule (~90° rotation of "A"). From this perspective, the proposed catalytic residues (red), positioned in the active site cleft, are clearly visible. The path of the cellulose chain (arrows) passes through a succession of polar residues (green) on the bottom surface of the CBM, which would conceivably bind to the incoming cellulose chain and serve to direct it towards the active-site acidic residues of the catalytic domain.

position of the homopolymer is rather trivial, the physical and three-dimensional arrangement of the chains within the crystalline and amorphous regions of the microfibril can differ significantly.

Regarding the enzymes that degrade the substrate, the modular nature of the cellulases contributes additional degrees of complexity in our quest to characterize a given enzyme. Thus, the number, types, and arrangement of the accessory modules vis-à-vis the catalytic domain are important structural features that modulate the overall activity of the enzyme in question. This descriptive information should always be defined for a recombinant enzyme. Whenever possible, it is desirable to determine the relative contribution of the individual accessory modules to the activity of the enzyme. In this regard, the affiliation of a given module, e.g., CBM, into a defined family does not necessarily define its contribution to enzyme activity, as different specificities and functions have been attributed to different members of the same family of module. Moreover, sequences for almost 70 different "X" modules (i.e., modules for which the function remains undefined) are currently available (Coutinho and Henrissat, 1999b; Coutinho and Henrissat, 1999c), most of which probably play a binding or processing role in assisting the catalytic domain(s) in its capacity to hydrolyze the substrate.

A decade ago, the range of cellulases and hemicellulases within a given species was assessed mainly by biochemical techniques. In some cases, individual enzymes were isolated and their properties assessed using desired insoluble or soluble substrates. Another approach involved electrophoretic separation of cell-derived or cell-free extracts, and analysis of desired activities using zymograms. There are advantages and disadvantages with each of these strategies, and the employment of combined complementary approaches is always advisable.

More recently, molecular biology techniques have been used to reveal cellulase and hemicellulase genes, which can often be characterized on the basis of sequence homology with related, known genes (Béguin, 1990; Hazlewood and Gilbert, 1993). If further information is required on the structure or action of a given enzyme, the gene can then be expressed in an appropriate host organism, and the properties of the product can be characterized.

It is always instructive to compare the properties of an expressed gene product with those of the same protein isolated from the original bacterial culture. The results may be surprising; there are hazards inherent to both approaches. Expression of a gene may yield preparations with reduced or altered enzymatic properties. In this context, the expressed gene product may not have been folded properly. It is of course assumed that the investigator has taken the time and trouble to sequence the cloned gene to ensure no mutations have occurred. Unlike a gene expressed in a host cell environment, the native counterpart may have undergone post-translational modifications (e.g., glycosylation, proteolytic truncation, etc.) that improve its

physicochemical properties. Moreover, since the cellulase system in the native environment includes numerous enzyme types, often exhibiting similar molecular masses and other physical characteristics, the reputed purification of a given extracellular cellulase may still include contaminating enzymes that alter (usually increasing greatly due to synergistic action of two or more enzymes) the true enzymatic properties of the desired enzyme. The onus belongs to the conscience of the investigating scientist when publishing the properties of a given enzyme. Too often, erroneous data that enter the scientific literature are taken as fact. One should particularly be wary of comparing enzymatic activities of the same or similar types of enzymes (e.g., members of the same family) that have been published at different times and by different laboratories.

The assessment of cellulase activity is indeed a complicated undertaking, and there is no clear or standard methodology for doing so. This predicament apparently reflects a combination of factors, including the complex nature of the substrate, the multiplicity of enzymes and their synergistic action, and the variety of products formed. The fact that cellulose is an insoluble substrate converted to lower-order cello-oligosaccharide products is a further complication. It must be noted that as the cello-oligomers increase in length, they become less soluble, such that cello-octaose of 8 glucose units is no longer soluble in aqueous solutions. Moreover, the accumulation of one (particularly cellobiose) or more of the cellulose degradation products may be inhibitory towards enzymatic activity.

Today, the study of cellulase action usually includes, in addition to conventional biochemical assays, the analysis of the primary structure and the assignment of the various domains into known families. The catalytic domains can usually be assigned into one of the known glycoside hydrolase families (Henrissat and Bairoch, 1996; Henrissat and Davies, 1997). Whenever the sequence of a known polysaccharide-degrading enzyme failed to match a known family, a new family of glycosyl hydrolase was established. This approach was extensively developed in the last decade, owing to the increasing number of available DNA sequences and bioinformatics analysis tools. At the same time, an increasing number of crystal or solution structures of various catalytic and accessory domains were published that allow us to examine a new protein sequence in light of its structure. Sometimes, the publication of the structure of an accessory domain precedes determination of its function.

We can divide the analysis of a newly described prospective cellulase into several stages, such that a variety of complementary approaches are currently in use to classify the enzyme. Some of the questions one may ask are:

1) What is the primary structure (the amino acid sequence) of the enzyme? What are the binding residues and/or binding module(s) associated with the enzyme? What are its other accessory domains and their respective role(s) in catalysis or stability?
2) Is the enzyme a "true" cellulase, i.e., its preferred substrate is cellulose or cellulose degradation products, or whether the enzyme can act alone on insoluble cellulose.
3) What is the mode of action? Does the enzyme act as an endoglucanase, an exoglucanase or a processive enzyme?
4) What is the stereochemistry of the reaction? Does the enzyme exhibit an inverting or retaining mechanism?
5) What are the catalytic residues: the acid/base residue and the nucleophile that characterize a glycosyl hydrolase?

In the past ten years, several extensive reviews and book chapters dealing with different assays of cellulose degradation have been published (Ghose, 1987; Wood and Kellogg, 1988). In this treatise, we will briefly summarize the various approaches currently in use and direct the reader to the relevant literature.

While characterizing the activity of a new enzyme preparation, one has to bear in mind several secondary or indirect issues, such as the purity of the protein preparation, the sensitivity of the assay used, and the crossreactivity of the expected enzymatic activities. In some cases, only detailed kinetic analysis can provide appropriate characterization of the enzyme. As for many other types of glycosyl hydrolases, cellulases can exhibit crossreactivity with substrates of similar structure. This is particularly true when using, for example, *p*-nitrophenyl derivatized substrates that provide highly sensitive assays. However, in many cases such a soluble synthetic chromogenic substrate can fit the active-site pocket of a related but atypical enzyme, which catalyzes its hydrolysis. For example, family-10 glycosyl hydrolases are typically xylanases but can readily hydrolyze *p*-nitrophenyl cellobioside, which is a typical cellulase substrate. Without a detailed comparative kinetic analysis (kcat/Km) using different substrates, the true specificity of the enzyme might be overlooked. Given the amino acid sequence of the protein, its assignment to a given glycosyl hydrolase family will in many cases provide a reasonable general indication of its activity. The description of the modular structure provides additional knowledge that can imply how the catalytic function might be modulated, but this knowledge can also be

misleading. In the final analysis, there is no substitute for extensive biochemical and biophysical characterization of the given protein (recombinant or native) and its catalytic properties.

General procedures for assaying for cellulase and hemicellulase activities are very well documented in the *Methods in Enzymology* volume 160 (Wood and Kellogg, 1988). Conventional procedures for cellulase assay have been defined precisely by the International Union of Pure and Applied Chemists (IUPAC; Ghose, 1987). However, owing to the complexity of the substrate and enzyme systems, these procedures can only provide a starting point for understanding the true nature of the enzyme in question.

Since the publication of Part A of this treatise (Coughlan and Mayer, 1992), many of the previously reported assays of cellulase activity are still in common use. These include the use of soluble, derivatized forms of cellulose, e.g., carboxymethyl cellulose and hydroxymethyl cellulose as conventional substrates for determining endoglucanase activity. In addition, a derivatized, colored form of insoluble cellulose, i.e., azure cellulose, is frequently used as an indication of cellulase activity. Zymograms with such colored embedded substrates are useful in detecting endoglucanase or xylanase activities (Béguin, 1983). Individual soluble cello-oligomers (cellotetraose, cellopentaose, cellohexaose, etc.) are still used as substrates for analyzing enzyme action, but the reliance on these substrates as determinants for assessing cellulase activity is no longer a definitive approach. In the past decade or so, newly developed substrate analogues and reagents include thioglycoside substrates (Driguez, 1997), fluoride-derivatized sugars (Williams and Withers, 2000), chromophoric and fluorescent cello-oligosaccharides (Claeyssens and Henrissat, 1992; O'Neill et al., 1989; van Tilbeurgh et al., 1985). Recently, an ultraviolet-spectrophotometric method and an enzyme-based biosensor have been described (Bach and Schollmeyer, 1992; Hilden et al., 2001). In addition, a novel and intriguing bifunctionalized fluorogenic tetrasaccharide has been developed as an effective reagent for measuring the kinetic constants of cellulases by resonance energy transfer (Armand et al., 1997).

The thio-oligosaccharides serve as competitive inhibitors that mimic natural substrates but are enzyme resistant (Driguez, 1997). In this type of oligosaccharide, the oxygen of a bond to be cleaved is replaced by sulfur. The thio-oligodextrins are sometimes more soluble than the native cellodextrins and longer chains can be synthesized. The modified sugars can be used in biochemical studies or crystallographic studies to gain some information about the geometry of the active site or determine the mechanism of action of an enzyme.

Determination of "True" Cellulase Activity: Solubilization of Crystalline Cellulose Substrates True cellulase activity is usually defined as the ability to solubilize to an appreciable degree insoluble, "crystalline" forms of cellulose. The extent of hydrolysis can be evaluated by turbidity assays, weight loss of insoluble material, generation of reducing power, and accumulation of soluble sugars. It is important to realize that crystalline cellulose is not of uniform composition and therefore the rate of catalysis is in most cases not linear with time or enzyme concentration. Notably, the different preparations of crystalline cellulose contain varying levels of loosely associated loops and chains. The latter are readily accessible to hydrolysis by a given enzyme and lead to relatively high initial rates of activity, which do not reflect the actual degree of true cellulase activity. For example, such loose chains can be degraded by a relatively ineffectual enzyme, whereas the crystalline portions of the substrate will be immune to further hydrolysis by the same enzyme. To overcome these difficulties, IUPAC suggests determining the amount of enzyme required to achieve digestion of 5.2% of the insoluble substrate (e.g., filter paper) in 16 h (Ghose, 1987; Irwin et al., 1993).

Cellulose substrates commonly in use include Avicel, filter paper, cotton, Solka Floc, and more recently bacterial cellulose from *Acetobacter aceti* and algal cellulose prepared from *Valonia*. Consequently, these assays should be treated as a relative and not quantitative assessment. The nature of the original substrate selected—especially its extent of crystallinity—should always be taken into account. Proper controls and reference substrates should always be used. One should be wary about comparison among results reported by different laboratories and even by different researchers in the same laboratory. Nevertheless, such assays give an excellent indication of whether a given enzyme preparation exhibits substantial activity towards crystalline cellulose substrates.

Endoglucanase Versus Exoglucanase Activity As discussed earlier in this chapter, the cellulases have traditionally been divided into either endoglucanases or exoglucanases (Fig. 4). The biochemical or enzymatic assays that discriminate between these two modes of action usually involve soluble forms of cellulose, i.e., carboxymethyl or hydroxymethyl derivatives of cellulose. The action of a given enzyme on these substrates is followed by determining the

amount of reducing ends generated by the enzyme and the degree of polymerization (DP). The reducing power is usually determined either by using reagents such as 3,5-dinitrosalicylic acid (DNS; Miller et al., 1960), ferricyanide (Kidby and Davidson, 1973), or copper-arseno molybdate (Green et al., 1989; Marais et al., 1966).

Despite their traditional popularity, these two methods are intrinsically disadvantageous, owing to interference by metal ions and certain buffers. Moreover, such assays are sensitive to the chain length of the reducing end. A more recent approach involves the use of disodium 2,2′-bicinchoninate (BCA) for determination of reducing sugar. This procedure is more sensitive than the conventional methods and gives comparable values of reducing sugars for cellodextrins of different lengths (Doner and Irwin, 1992; Garcia et al., 1993; Vlasenko et al., 1998; Waffenschmidt and Jaenicke, 1987).

Viscosity-based measurements represent the most common approach for assessing the degree of polymerization. This approach is highly sensitive for internal bond cleavage, which leads to significant reduction of the average molecular weight of the substrate. The comparison between the amount of reducing sugars generated and the average molecular weight (i.e., viscosity or fluidity of the soluble cellulose substrate) gives a very good indication whether an enzyme is essentially exo- or endo-acting.

The average degree of polymerization also can be evaluated by size-exclusion chromatography either alone (Srisodsuk et al., 1998; Teeri, 1997) or combined with multiangle laser light scattering (Vlasenko et al., 1998). Mass spectometric procedures also can be applied to determine the identity and distribution of degradation products following hydrolysis of cellulosic substrates by an enzyme (Hurlbert and Preston, 2001; Rydlund and Dahlman, 1997). The mode of enzymatic action also can be appraised by determining the increase in reducing power associated with the insoluble versus the soluble fraction of the substrate. Increase in the proportion of reducing sugars associated with the soluble fraction indicates an exo-type of activity whereas a relatively large increase in the insoluble fraction would suggest an endo-type of activity (Barr et al., 1996).

Exocellulases can exhibit different specificities depending on their preference for the reducing or nonreducing end of the cellulose chain (Barr et al., 1996; Teeri, 1997). This feature of an exocellulase can be determined either by using oligosaccharide substrates labeled by tritium or 18O at the reducing end. Other procedures involve NMR, HPLC and/or mass spectrometric analysis of products released from native (unlabeled) cello-oligosaccharides. Within the past decade, the 3-D structures of enzyme-substrate complexes have been obtained, and the specificities of the enzyme can be interpreted directly from the data (Davies and Henrissat, 1995; Davies et al., 1998; Divne et al., 1998; Juy et al., 1992; Notenboom et al., 1998; Parsiegla et al., 1998; Rouvinen et al., 1990; Sakon et al., 1997; Zou et al., 1999).

Processivity One of the major recent conceptual advances in assessing the mode of enzymatic action of a cellulase is the concept of "processivity." Processive enzyme action can be defined as the sequential cleavage of a cellulose chain by an enzyme. In effect, exoglucanases are by nature and structure processive enzymes. Their tunnel-like active site thus allows processive action on the cellulose chain. Endoglucanases, however, were thought to be intrinsically nonprocessive. However, the traditional distinction between exo- and endocellulases was modified recently.

Experiments combining two or more purified cellulases have shown that synergism can even be detected upon mixing two different types of exo-acting enzymes. Such experiments led to the recognition that the exo enzymes can operate on both ends (i.e., the reducing and nonreducing ends) of the cellulose chain. Some enzymes, however, exhibit both endo and exo activities, although in such cases, the endocellulase activity is usually very low. In attempts to explain these phenomena, the concept of processivity was proposed, by which the activity of the enzyme is characterized by the sequential hydrolysis of the cellulose chain. Implicit in this concept is the notion that the catalytic site of the enzyme remains in continual and intimate contact with a given chain of the cellulose substrate.

A more complete mechanistic picture of the processive nature of such cellulases was revealed with the advent of high-resolution 3-D structures. It was thus demonstrated that the cellulose chain makes contact with the protein at multiple sites, either via a tunnel-shaped structural element (such as that observed in the family-48 enzymes) or by a special type of CBM (such as the family-9 theme B cellulases). These arrangements allow the threading of the cellulose chain into the active site, and, following initial cleavage at the end of the chain, the enzyme can move along the chain and position itself for the next cleavage. In addition to this processive nature of the active site, these enzymes also can make classic endo cleavages thus generating new ends.

Biochemically processive enzymes exhibit characteristics between endo- and exoenzymes. They have low but detectable endo activity towards soluble derivatives of cellulose (i.e.,

CMC), and may or may not possess exo activity on such substrates. With insoluble substrates, they will generate reducing power with a ratio between the soluble to the insoluble fractions of about 7. Endocellulases usually give a ratio of less than 2, whereas exocellulases produce a ratio of 12 to 23 (Irwin et al., 1998).

Once the processive nature of an enzyme has been indicated experimentally, molecular insight into the mechanisms responsible for this feature can be gained by determining the 3-D crystal structure of the active site together with model cellodextrins. In the case of the cellulases, the crystal structure of the catalytic domain together with the fused module, combined with accumulating enzymatic activity data, allowed further postulation as to the accessory role of the fused module. The fused CBM presumably interacts with a single cellulose chain and feeds it into the active site. Interestingly, this domain does not bind crystalline cellulose, but is inferred to act in dynamic binding of the single cellulose chain prior to its hydrolysis, thereby imparting the quality of processivity to the enzyme. Once such a property is associated with a given type of enzyme, the primary structure of the protein can now be used as an indication for all such enzymes. In the case of the family-9 theme B enzymes, it is now possible to identify the catalytic domain (e.g., glycosyl hydrolase family 9) and the additional accessory domains (in this case, family-3c CBM). Thus, the primary structure may by itself give a strong indication of the nature of the enzyme itself. Of course, the ultimate identification as to the mechanism of enzyme activity will come from the detailed 3-D structure of the enzyme-substrate complex.

An intriguing recent development in the analysis of the cellulolytic action of a given cellulase or a mixture of cellulase is the direct transmission electron microscopic (TEM) observation of the enzymatic action on bacterial cellulose ribbons. The approach provides information as to the endo or exo preference of the enzyme, the extent of processivity as well as the directionality of hydrolysis (i.e., from the reducing to the nonreducing ends or vice versa). This strategy has been used to study the hydrolysis of bacterial cellulose ribbons by individual purified enzymes, mixtures of purified enzymes, and intact cellulosomes.

Mechanism of Catalysis The mechanism of catalysis of cellulases address issues such as stereochemistry, binding and active-site residues and transition state intermediates. Excellent reviews have been published recently covering many of these (Ly and Withers, 1999; McCarter and Withers, 1994; Rye and Withers, 2000; Sinnott, 1990; White and Rose, 1997; Withers, 2001; Withers and Aebersold, 1995; Zechel and Withers, 2000). The fact that the stereochemistry and catalytic residues are conserved between members of the same family allows the putative identification of these elements if one member of the given (glycosyl hydrolase) has been characterized biochemically (Henrissat and Bairoch, 1996; Henrissat et al., 1995; Henrissat and Davies, 1997).

The sterochemistry of the reaction can in most cases be determined by proton NMR spectroscopy or by using chromatography systems that allow the resolution of anomeric species. In the case of NMR, the reaction between the test enzyme and its substrate is carried out in deuterated water (D_2O) and the appearance of the anomeric proton can be easily detected. Thus, for the degradation of cellulose, a retaining enzyme would produce a product in the β configuration whereas an inverting enzyme would yield the α-sugar.

The catalytic residues can be identified by performing site-directed mutagenesis on conserved acidic residues and studying the catalytic properties of the mutants with substrates bearing different leaving groups. Commonly used phenol substituents include the following, listed in order of leaving group ability (pKa values shown parenthetically): 2,4-dinitro (3.96) > 2,5-dinitro (5.15) > 3,4-dinitro (5.36) > 2-chloro-4-nitro (5.45) > 4-nitro (7.18) > 2-nitro (7.22) > 3,5-dichloro (8.19) > 3-nitro (8.39) > 4-cyano (8.49) > 4-bromo (9.34; Tull and Withers, 1994). In retaining enzymes, the nucleophilic residue can be identified directly by trapping the intermediate with an appropriate inhibitor. Such inhibitors include model saccharides containing a fluorine substituent in the 2- or 5-position and a good leaving group, such as fluoride or dinitrophenolate (Williams and Withers, 2000). The substituted substrate forms a relatively stable covalent substrate-enzyme complex, involving the nucleophile residues. The complex is then subjected to proteolytic cleavage and sequencing of the glycosylated peptide. Recently, the use of protocols involving combined liquid chromatography and mass spectrometry has facilitated the identification of the modified residues.

The acid-base residue in a retaining enzyme can be identified by a combination of kinetics-based methodologies. Mutation of this residue (usually to alanine) should affect the rate of both chemical steps, i.e., glycosylation and deglycosylation, though the effect on each step should be different. The effect on the glycosylation step will depend strongly on the leaving group ability of the aglycon. Thus, rates of hydrolysis for substrates with a poor leaving group should be affected much more strongly than those with a

good leaving group. The deglycosylation step, however, will be affected equally for all substrates carrying different leaving groups, because the same glycosyl enzyme intermediate is hydrolyzed during this step. Thus, detailed kinetic analysis (i.e., determination of k_{cat} and K_m) with substrates bearing different leaving groups can reveal whether the corresponding mutation is the acid-base residue. It should be noted that this approach requires synthetic substrates that are not necessarily recognized by all families of enzymes and are not necessarily commercially available. For example, the family-11 xylanases fail to hydrolyze *p*-nitrophenyl xylobioside, which is an excellent substrate for the family-10 xylanases. The assignment of the acid-base catalyst can also be examined by use of external nucleophilic anions, such as azide. In this approach, termed "azide rescue," the small azide anion enters the vacant space created by alanine replacement of the acidic amino acid residue. The azide reacts with the anomeric carbon instead of a water molecule to form the corresponding β-glycosyl azide product. In the absence of an acid-base catalyst, which normally provides general base catalysis during the second step, the deglycosylation step is severely affected. Thus, the acceleration of the reaction by the mutant enzymes in the presence of these external anions (provided that the second step is rate limiting) is a good indication that a mutant residue is the acid-base catalyst. Finally, the assignment of the acid-base catalyst can be tested by comparing the pH-dependence profiles for the wild-type and mutant enzymes. The profile for the native enzyme would approximate a perfect bell shape curve, reflecting the ionization of the two active site carboxylic acids, whereas the no reduction of activity at high pH values would be observed for the mutant. This pH dependency approach is also applicable for identifying the nucleophile residues and the catalytic residues in inverting enzymes.

Prokaryotic Cellulase Systems

The cellulolytic bacteria produce a variety of different cellulases and related enzymes, which together convert the plant cell wall polysaccharides to simple soluble sugars that can subsequently be assimilated. The complement of cellulases and hemicellulases that are synthesized by a given bacterium for this purpose is referred to as its "cellulase system." Different bacteria exploit different strategies for the ultimate degradation of their substrates. The given strategy is reflected by the complement and type(s) of enzymes produced by a given bacterium. The bacterial cellulase system may be characterized by free enzymes, cell-bound enzymes, multifunctional enzymes, cellulosomes, or any combination of the latter.

Cellulase enzyme systems are comprised of several different types of components, each type may exist in a multiplicity of forms. To add to the complexity, the same component may exist as free individual entities in the culture fluid, as individual entities bound to cellulose, or associated with the cell surface. Alternatively, an individual component may be organized as part of a multicomponent cellulosome complex attached to the cell surface, to the cellulose, to both, or as free complexes in the culture fluid. Furthermore, the situation existing during growth under one set of conditions (e.g., pH, temperature, distribution of carbon source, etc.) may not exist under another, or may change considerably during the course of cultivation. The bacterium reacts to these changes and its production of cellulases and/or cellulosomes may reflect the dynamics of the growth conditions.

Free Enzymes

As mentioned earlier in this chapter, the free enzymes in their simplest form comprise a catalytic module alone with no accessory domains or modules. Such enzymes often specialize in degrading soluble oligosaccharide breakdown products. Alternatively, such single-modular enzymes may rely on an intrinsic association with insoluble polysaccharide substrate such as cellulose, perhaps related to the active site of the enzyme.

A higher order level of organization and activity are free enzymes composed of a polypeptide chain that includes both a catalytic domain together with a CBM. This basic bi-modular arrangement can be further extended by the inclusion of additional types of modules or repeating units of the same module, all of which serve to modulate the activity of the catalytic domain on the substrate. The intact free enzyme, however, remains unattached to other enzymes and can work in an independent manner on a given substrate.

Cell-Bound Enzymes

Some enzymes are connected directly to the cell wall. In Gram-positive bacteria, this is frequently accomplished via a specialized type of module, the SLH (S-layer homology) module, previously shown to be associated with the cell surface of Gram-positive bacteria (Lupas et al., 1994). This arrangement may have evolved to provide a more economic degradation of insoluble substrates and to reduce competition with other bac-

teria for the soluble products, subject to diffusion in the media. As opposed to free enzymes, diffusion of an attached enzyme would itself be prevented.

Examples of enzymes, which are bound to the cell surface via an SLH module include, a family-5 cellulase and family-13 amylase-pullulanase from *Bacillus*, a family-10 xylanase from *Caldicellulosiruptor* (Saul et al., 1990), a family-5 endoglucanase from *Clostridium josui*, a family-16 lichenase and family-10 xylanase from *Clostridium thermocellum* (Jung et al., 1998), and a variety of enzymes (family-10 xylanases, a family-5 mannanase and a family-13 amylase-pullulanase) from different species of *Thermoanaerobacter* (Matuschek et al., 1996). The modular architecture of these enzymes may be particularly complicated, containing several different modules in a single polypeptide chain, thus forming extremely large enzymes sometimes comprising over 2,000 amino acids (Fig. 10).

Multifunctional Enzymes

Some cellulases exhibit a more complex architecture in that more than one catalytic domain and/or CBD may be included in the same protein. Examples of such enzymes are the very similar cellulases from *Anaerocellum thermophilum* (Zverlov et al., 1998) and *Caldocellum saccharolyticum* (Te'o et al., 1995), both of which contain a family-9 and a family-48 catalytic domain. Other paired catalytic domains include those from family 44 and either family 5 or 9. Such an arrangement might indicate a close cooperation between two particular catalytic domains, which may lead to synergistic action on the cellulosic substrate, thus portending on a smaller scale the advent of cellulosomes.

Like the cellulases, xylanases also tend to exhibit a modular structure, being composed of multiple domains joined by linker sequences. Family-10 and -11 xylanases may be linked in the same polypeptide chain either to each other, to catalytic domains from families 5, 16 and 43 or to carbohydrate esterases (Flint et al., 1993; Laurie et al., 1997). One particularly interesting combination of multifunctional catalytic modules that appear in the same polypeptide chain is a typical xylanase together with a feruloyl esterase. Such a combination would allow the rapid cleavage of hemicellulose from the lignin in natural systems, i.e., the plant cell wall (see Fig. 3). In this manner, the xylan chain would be severed by the xylanase component (Xyn in Fig. 3) and the lignin-xylan association would be disconnected simultaneously by the feruloyl acid esterase (Fae in Fig. 3).

Indeed, some xylanases are extremely complex in their modular architecture (Fig. 11). In addition to multiple catalytic modules, these enzymes often contain several different types of CBMs. Why would such a xylanase contain several types of CBM? And why would a xylanase contain a cellulose-specific CBD? Unlike the case of various cellulases, for which the CBD is usually essential for degrading insoluble crystalline cellulose, the CBMs of a hemicellulase do not necessarily bind the hemicellulose component (xylan). In some cases, its CBM is in fact an authentic CBD that situates the hemicellulase on the insoluble plant cell wall material by utilizing the most abundant and most stable cell-wall component—cellulose. Indeed, the three family-3 CBDs (CBM3) shown in Fig. 11 apparently bind to crystalline cellulose. Why would this xylanase require three tandem copies of the same type of CBD is yet another mystery that should eventually be addressed experimentally. At any rate, once bound via the

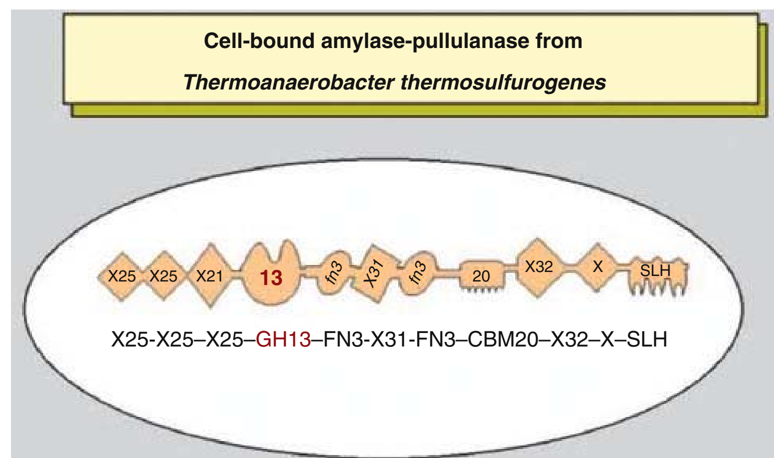

Fig. 10. A very large, cell-surface enzyme from *Thermoanaerobacter thermosulfurogenes*. The 1861-residue enzyme contains an SLH module, which is believed to mediate the attachment of the enzyme to the cell surface in Gram-positive bacteria. The enzyme contains a multiplicity of modules, which apparently serve to regulate the hydrolytic action of its single family-13 catalytic module with the complex substrate. Several X domains of unknown function may either represent as yet undescribed catalytic functions, carbohydrate-binding activities or structural entities.

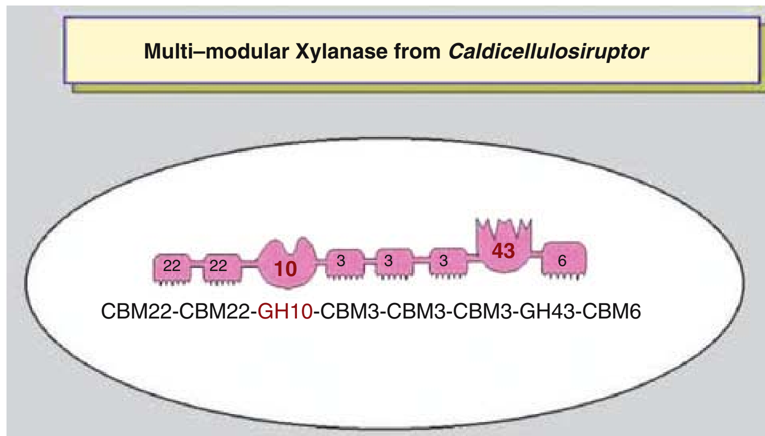

Fig. 11. A very large, multimodular xylanase from *Caldicellulosiruptor*. The 1,795-residue enzyme contains 8 separate modules, including 2 catalytic modules from families 10 (invariably a xylanase) and 43 (frequently an arabinofuranosidase). These are modulated by numerous carbohydrate-binding modules, which include 3 from family 3 (likely for binding to crystalline cellulose), 2 from family 22 (newly classified and shown to function in xylan binding and one from family 6.

cellulose component of the plant cell wall composite substrate, the immobilized enzyme then acts on the accessible and appropriate hemicellulose components. Once thus situated on the plant cell wall, another type of CBM on the same molecule would then assist in the binding to the xylan (or mannan, etc.) component to direct the appropriate catalytic module to its true substrate. Hence, the modular proximity of the xylanase shown in Fig. 11 would presumably indicate that the two CBM22s would modulate the action of the family-10 catalytic module, and the C-terminal CBM6 would facilitate the catalysis by the family-43 module. Together, the two catalytic modules would act synergistically to degrade susceptible plant cell wall components. In this context, the complex architecture of a xylanase would reflect the complex chemistry of its substrate and the neighboring polymers of its immediate environment in the plant cell wall.

Cellulosomes

Cellulosomes are multienzyme complexes, which bind to and catalyze the efficient degradation of cellulosic substrates. The first cellulosome was discovered while studying the anaerobic thermophilic bacterium, *Clostridium thermocellum* (Bayer et al., 1983; Lamed et al., 1983). Since its initial description in the literature, the cellulosome concept has been subject to numerous reviews (Bayer et al., 1996; Béguin and Lemaire, 1996; Belaich et al., 1997; Doi et al., 1994; Doi and Tamura 2001; Felix and Ljungdahl, 1993; Karita et al., 1997; Lamed and Bayer, 1988; Lamed and Bayer, 1991; Lamed and Bayer, 1993; Lamed et al., 1983; Shoham et al., 1999).

Cellulosomes in *C. thermocellum* exist in both cell-associated and extracellular forms, the cell-associated form being associated with polycellulosomal protuberance-like organelles on the cell surface. Later, cellulosomes were detected in other cellulolytic organisms (Lamed et al., 1987; Mayer et al., 1987), including *Acetivibrio cellulolyticus*, *Bacteroides cellulosolvens*, *Clostridium cellulovorans* and *Ruminococcus albus*, all of which contained protuberance-like organelles on their surfaces (Bayer et al., 1994; Lamed and Bayer, 1988; Fig. 12).

The cellulosomes contain numerous components, many of which were shown to display enzymatic activity. They also contain a characteristic nonenzymatic high-molecular-weight component. This component proved to be highly antigenic and glycosylated (Bayer et al., 1985). The cellulosomal enzymatic subunits from this organism showed a broad range of different cellulolytic and xylanolytic activities (Morag et al., 1990). Ultrastructural evidence indicated the multisubunit nature of the cellulosome (Fig. 13).

Eventually, genetic engineering techniques led to the sequencing of cellulosomal genes in *C. thermocellum* and several other bacteria, thus confirming the existence of cellulosomes as a major paradigm of prokaryotic degradation of cellulose and related plant cell wall polysaccharides.

Clostridium Thermocellum Cellulosomal Subunits and Their Modules

A simplified schematic view of the cellulosome from *C. thermocellum* and its interaction with its substrate is shown in Fig. 14. The cellulosomal enzyme subunits were found to be united into a complex by means of a unique class of nonenzymatic, multimodular polypeptide subunit, termed “scaffoldin” (Bayer et al., 1994). The

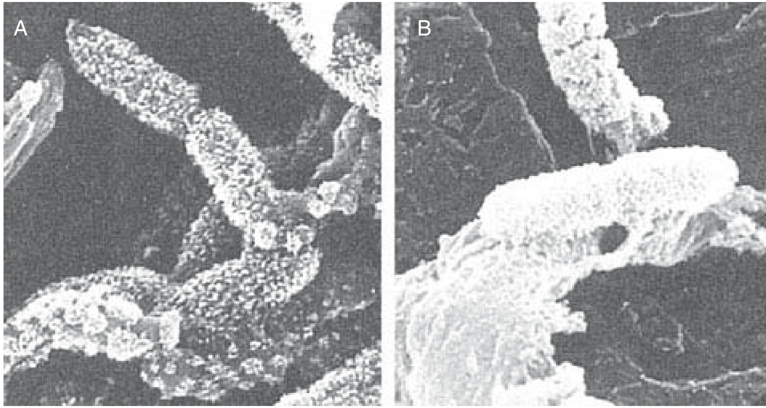

Fig. 12. Scanning electron microscopy (SEM) of *Acetivibrio cellulolyticus* showing the presence of large characteristic protuberance-like structures on the cell surface. Cells are shown in the free state (A) or bound to cellulose (B). Cell preparations were treated with cationized ferritin before processing. Cationized ferritin has been shown to stabilize such surface structures, thus allowing their ultrastructural visualization (Lamed et al., 1987a; Lamed et al., 1987b). Without pretreatment with cationized ferritin, these structures are invisible. In (B), the cellulose-bound cells appear to be connected to the substrate via structural extensions of the cell-surface protuberances. Such a mechanism was originally observed for other cellulolytic prokaryotes, e.g., *C. thermocellum* (Bayer and Lamed, 1986).

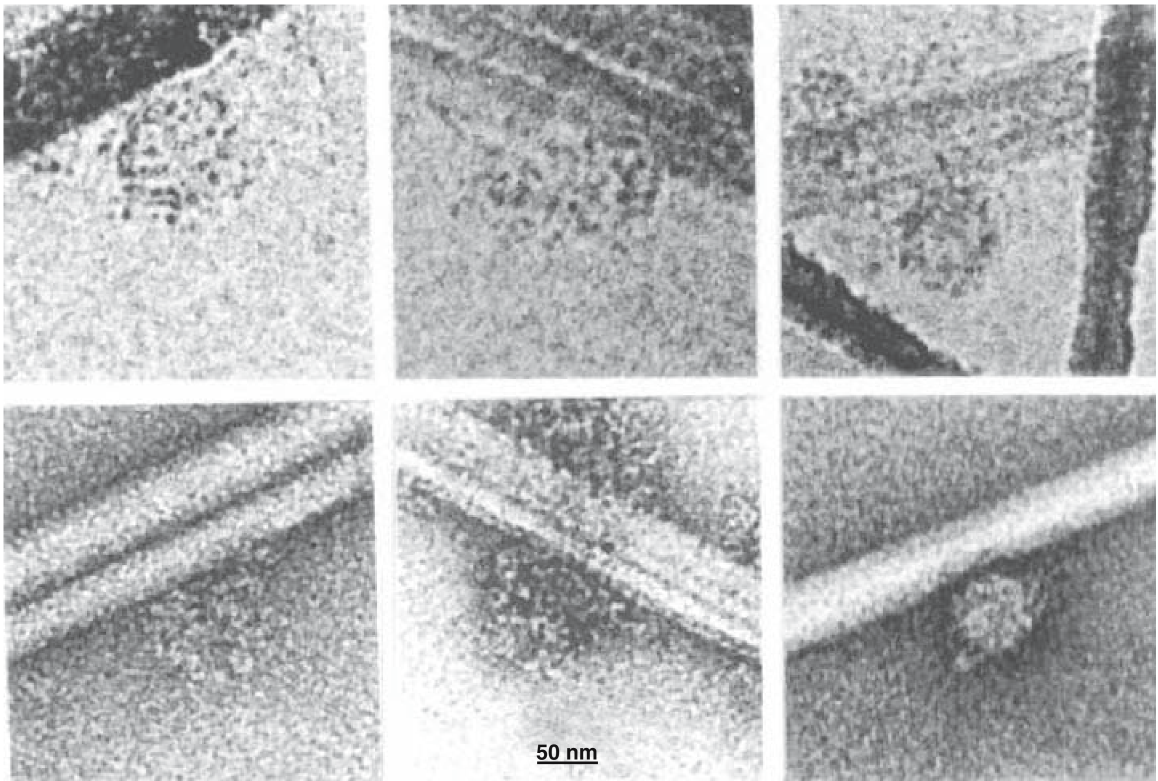

Fig. 13. Comparison between negative staining (bottom) and cryo images (top) of the purified cellulosome from *C. thermocellum*, adsorbed on cellulose microcrystals from the algae, *Valonia ventricosa*. The images illustrate the diversity of shapes of the cellulosomes, which adopt either compact or loosely organized ultrastructure. In the cryo images, the subunits of the cellulosomes (i.e., the individual enzymatic components) are clearly visible. Micrographs courtesy of Claire Boisset and Henri Chanzy (CNRS—CERMAV, Grenoble, France).

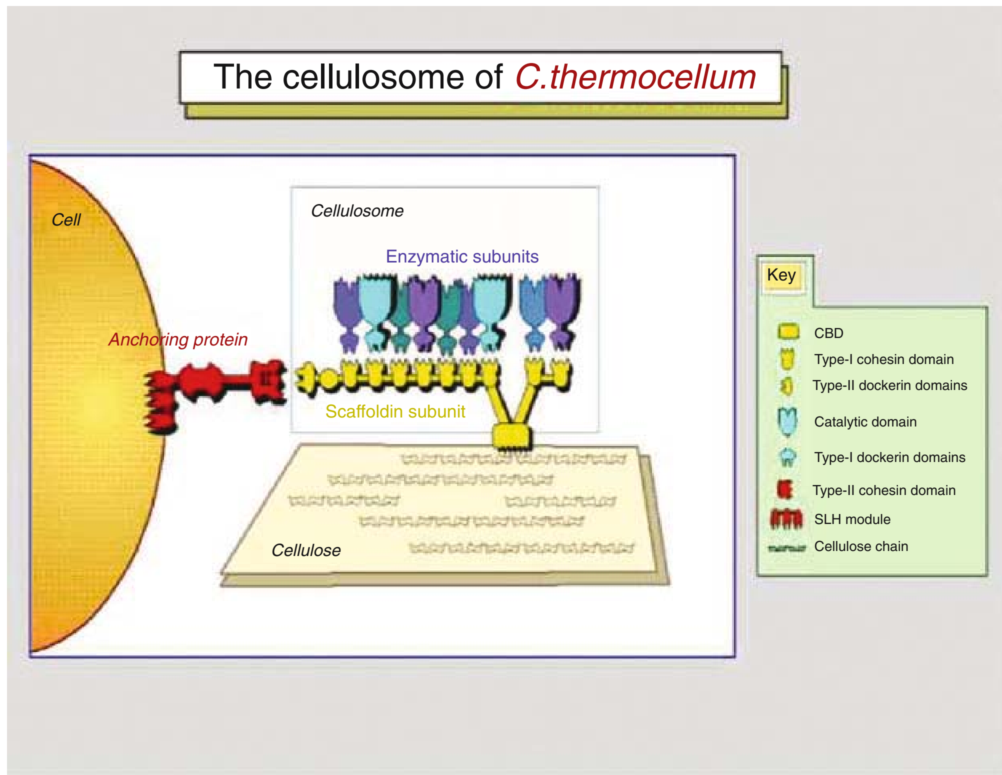

Fig. 14. Simplified schematic view of the molecular disposition of the cellulosome and one of the associated anchoring proteins on the cell surface of *C. thermocellum*. The key defines the symbols used for the modules, from which the different cellulosomal proteins are fabricated. The progression of cell to anchoring protein to cellulosome to cellulose substrate is illustrated. The SLH module links the parent anchoring protein to the cell. The cellulosomal scaffoldin subunit performs three separate functions, each mediated by its resident functional domains: 1) its multiple type-I cohesins integrate the cellulosomal enzymes into the complex via their resident type-I dockerins, 2) its family-IIIa CBD binds to the cellulose surface, and 3) its type-II dockerin interacts with the type-II cohesin of the exocellular anchoring protein.

scaffoldins usually contain a family-3 CBD that provides the cellulose-binding function. The scaffoldins also contain multiple copies of a definitive type of module, called "the cohesin domain." The cellulosomal enzyme subunits, on the other hand, contain a complementary type of module, called "the dockerin domain." The interaction between the cohesin and dockerin domains provides the definitive molecular mechanism that integrates the enzyme subunits into the cellulosome complex (Salamitou et al., 1994; Tokatlidis et al., 1991; Tokatlidis et al., 1993). Cohesin and dockerins are considered to be cellulosome "signature sequences"—i.e., their presence is a good indication of a cellulosome in a given bacterium (Bayer et al., 1998).

The major difference between free enzymes and cellulosomal enzymes is that the free enzymes usually contain a CBD for guiding the catalytic domain to the substrate, whereas the cellulosomal enzymes carry a dockerin domain that incorporates the enzyme into the cellulosome complex. Otherwise, both the free and cellulosomal enzymes contain very similar types of catalytic domains. The cellulosomal enzymes rely on the Family-3a CBD of the scaffoldin subunit for collective binding to crystalline cellulose.

The incorporation of the multiplicity of enzyme subunits into the cellulosome complex is a function of the repeated copies of the cohesin module borne by the scaffoldin subunit. For most species of scaffoldin, the cohesins have been classified as type-I on the basis of sequence homology. The cohesin module is composed of about 150 amino acid residues. The basic structure of the cohesin is known and comprises a nine-stranded β sandwich with a jelly-roll topology (Shimon et al., 1997; Spinelli et al., 2000; Tavares et al., 1997).

The dockerin domain contains about 70 amino acids and is distinguished by a 22-residue duplicated sequence (Chauvaux et al., 1990), which bears similarity to the well-characterized EF-hand motif of various calcium-binding proteins (e.g., calmodulin and troponin C). Within this repeated sequence is a 12-residue calcium-binding loop, indicating that calcium-binding is an important characteristic of the dockerin

domain. This assumption was eventually confirmed experimentally (Yaron et al., 1995). The specificity characteristics of the cohesin-dockerin interaction also have been investigated. The results showed that four suspected residues may serve as recognition codes for interaction with the cohesin domain (Mechaly et al., 2000; Mechaly et al., 2001; Pagès et al., 1997). The three-dimensional solution structure of the 69-residue dockerin domain of a *Clostridium thermocellum* cellulosomal cellulase subunit was recently determined (Lytle et al., 2001). As predicted earlier (Bayer et al., 1998; Lytle et al., 2000; Pagès et al., 1997), the structure consists of two Ca^{2+}-binding loop-helix motifs connected by a linker; the E helices entering each loop of the classical EF-hand motif are absent from the dockerin domain.

The scaffoldin of *C. thermocellum* also contains a special type of dockerin domain. This dockerin failed to bind to the cohesins from the same scaffoldin subunit, but instead interacted with a different type of cohesin—termed "type-II cohesins"—identified on the basis of sequence homology (Salamitou et al., 1994). These cohesins are somewhat different than those of type I, having an additional segment and diversity in the latter half of the sequence. The type-II cohesins were discovered as component parts of a group of noncatalytic cell-surface "anchoring" proteins on *C. thermocellum* (Leibovitz and Béguin, 1996; Leibovitz et al., 1997; Lemaire et al., 1995; Salamitou et al., 1994). The three known anchoring proteins in *C. thermocellum* contain different copy-numbers of the type-II cohesins as illustrated in Fig. 15. Each of these anchoring proteins also contains an S-layer homology (SLH) module, analogous to those of the cell-bound enzymes mentioned above. The intervening sequences, however, between the cohesins and SLH domains are different. In any case, the type-II cohesins selectively bind the type-II dockerins, and the cellulosome (i.e., the scaffoldin subunit together with all of its enzyme subunits) is thereby incorporated into the cell surface of *C. thermocellum*.

Similarity and Diversity of Scaffoldins from Different Species

The modular architecture of the known scaffoldins and their comparison to that of *Clostridium thermocellum* is presented in Fig. 16. Two new scaffoldins have recently been described for *Acetivibrio cellulolyticus* and *Bacteroides cellulosolvens* that, like *C. thermocellum*, carry dockerin domains at their C terminus (Ding et al., 1999; Ding et al., 2000). The *A. cellulolyticus* genome also includes a gene (immediately downstream of the scaffoldin gene) that contains type-II

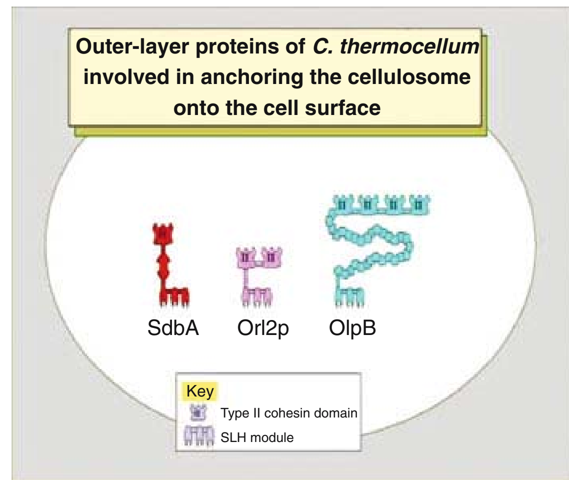

Fig. 15. Schematic representation of the known anchoring proteins of the *C. thermocellum* cell surface. Each protein bears an SLH domain that connects the protein to the cell surface via yet undefined surface components. The different proteins carry different numbers of type-II cohesins. SdbA has one cohesin, Orf2p has 2 and OlpB has 4, presumably allowing the corresponding number of scaffoldins (i.e., cellulosomes) to be attached to the given protein.

cohesins that may represent an anchoring protein. It thus seems that the arrangement of the cellulosome on the cell surface of these latter strains may be analogous to that of *C. thermocellum*. It is interesting to note that the cohesins of the *Bacteroides cellulosolvens* scaffoldin are clearly type-II cohesins and not of type I. This infers that there is not a clear linkage between the type-II cohesins and anchoring proteins.

The scaffoldins from the other clostridial species thus far described all lack "type-II dockerin" domains, the inference being that cells of *C. cellulovorans*, for example, would apparently not bear anchoring proteins that contain type-II cohesins. It thus follows that either their cellulosomes are not surface bound or, if indeed they are surface components, then their anchoring thereto is accomplished via an alternative molecular mechanism. Recently (Doi and Tamura, 2001; Tamaru and Doi, 1999a; Tamaru et al., 1999b), a cell-surface binding function has been proposed for a domain of unknown function, designated "X2" (Coutinho and Henrissat, 1999b; Coutinho and Henrissat, 1999c) of the scaffoldin from *C. cellulovorans*. On the basis of sequence alignment of a few conserved identical amino acids with S-layer proteins from Mycoplasma hyorhinis and Plasmodium reichenowi, the authors consider that this domain may be recognized as an SLH domain. The four X2 domains of the *C. cellulovorans* scaffoldin are very similar in sequence to the X-domains from the scaffoldins of *C. cellulolyticum* and *C. josui*,

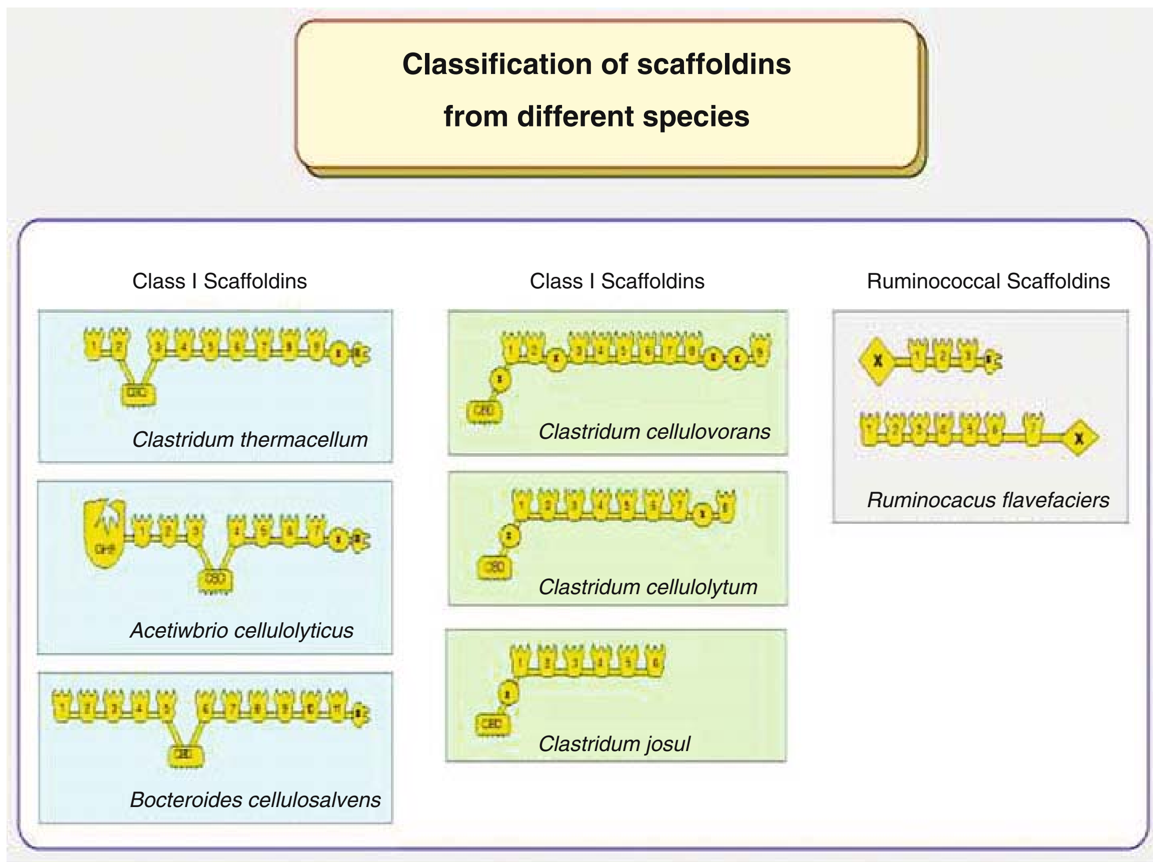

Fig. 16. Schematic view of the modular similarity and diversity of scaffoldins from different cellulosome species. Class-I scaffoldins feature an internal CBD and a *C*-terminal type-II dockerin domain. Class-II scaffoldins exhibit an *N*-terminal CBD and lack a dockerin domain. The newly described scaffoldins from *Ruminococcus flavefaciens* lack a defined CBD. The functional role of the two different X domains in the two *R. flavefaciens* scaffoldins is currently unknown. All of these scaffoldins contain multiple copies of cohesin domains.

which contain only two and one copies of this domain, respectively. If this domain functions in attaching the scaffoldin with its complement of enzymes to the cell surface, it is unclear why there would be different copy numbers of the domain in the different scaffoldins. Likewise, one of the *C. cellulovorans* cellulosomal enzyme components (EngE) also contains a triplicated segment of unknown function, designated "X48" (Coutinho and Henrissat, 1999b; Coutinho and Henrissat, 1999c) that the authors consider to be involved in cell-surface attachment (Tamaru and Doi, 1999a). In any case, final proof of the function of the X2 and X48 domains awaits biochemical examination, as has been clearly achieved for the SLH domain of the *C. thermocellum* anchoring proteins (Chauvaux et al., 1999; Lemaire et al., 1998).

Finally, two new scaffoldins have recently been sequenced from the rumen bacterium, *Ruminococcus flavefaciens* (Ding et al., 2001). Although each of the two proteins contains multiple cohesins, their sequences indicate that they are neither of type-I or type-II, but occupy their own phylogenetic branch. Interestingly, the ruminococcal scaffoldins lack a known type of CBD. Both have dissimilar X domains of unknown function, the sequences of which bear no resemblance to any other known module. Both X domains were expressed, but the resultant proteins failed to bind to cellulose. The lack of a scaffoldin CBD raises the question as to how the ruminococcal cellulosome(s) and/or the bacterium bind to the substrate. Perhaps it does so like another closely related species, *R. albus*, which binds cellulose via a noncellulosomal cell-surface protein (Pegden et al., 1998).

Schematic Comparison of Prokaryotic Cellulase Systems

In this section, we will describe schematically the similarity and diversity of representative enzyme systems, demonstrating different strategies, from

different plant cell wall degrading bacteria. It is emphasized that the accumulating information is based on what is known currently from biochemical data combined with gene sequencing and bioinformatics. The information is still rather sketchy but quite revealing when compared among different bacteria. As time progresses and the entire genomes of cellulolytic microorganisms become known, the data concerning the complement of enzymes produced by a given bacterium will be complete, and we will be able to speculate with heightened certainty how the various cellulase systems might have evolved. A survey of genes, however, does not inform us how a given bacterial system is regulated and what role(s) the bacterium and its enzyme system may play in nature. The explosive development of molecular biology techniques, however revealing, cannot supplant the fundamental contribution of biochemical and ecological approaches to the study of microbial degradation of cellulose and other plant cell wall polysaccharides.

Free Enzyme Systems

Many cellulolytic microorganisms show a very similar pattern in the types of enzymes that comprise the complement of their cellulase system. For the purposes of this discussion, the concept of "cellulase system" will include the complement of all plant cell wall hydolyzing enzymes and other glycosyl hydrolases, including the different cellulases per se, the hemicellulases (e.g., xylanases and mannanases), etc.

The cellulase system of the mesophilic cellulolytic aerobe, *Cellulomonas fimi*, is one of the first studied, and has since been one of the most studied bacterial cellulase systems (O'Neill et al., 1986; Shen et al., 1995; Whittle et al., 1982). The enzymes of this bacterium are essentially free enzymes, which allowed their early isolation and characterization. Moreover, the genes of the cellulases from this bacterium were of the earliest to have been sequenced. To date, about 10 glycosyl hydrolases have been sequenced from *Cellulomonas fimi*. Their modular composition and family associations are shown symbolically in Fig. 17. As an example of a free enzyme system, most of the enzymes bear a substrate-targeting CBM—in this bacterium, most of the CBMs are from family 2. Several of the enzymes have multiple copies of the fibronectin 3 (FN3) domain, the function of which is still unknown.

The *Cellulomonas* system includes two family-6 enzymes—an endoglucanase and an exoglucanase (cellobiohydrolase) of the types described in Fig. 4. The modularity of the endoglucanase is very simple, having the family-6 catalytic module together with a family-2 CBM. The cellobiohydrolase is a bit more complex with three additional FN3 domains that separate the same two types of modules. Another cellobiohydrolase (that exhibits processive cleavage of the substrate) is from family 48. Its general modular architecture is similar to that of the family-6 cellobiohydrolase with the substitution of the catalytic module from a different family. The cellulase system from this organism also includes two family-9 cellulases with modular themes B and D, familiar to us from the earlier description (Fig. 7). In addition, a simple family-5 cellulase and an interesting cell-borne family-26 mannanase are components of the system. The fact that an enzyme bears an SLH domain and is presumably cell-associated would underscore its importance to the cell. Finally, three xylanases are currently known for Cellulomonas fimi. One of these xylanases is a simple enzyme consisting of a family-10 catalytic domain connected to a family-2 CBM. The other two are more complicated, each containing two catalytic domains—either a family-10 or -11 domain and a carbohydrate esterase (in both cases, probably an acetyl xylan esterase; Fig. 3)—plus several CBMs. This rather complex system is probably not nearly complete, and more enzymes will inevitably be described in the future.

A second example of a free enzyme system, from the aerobic thermophilic bacterium *Thermobifida fusca* (formerly classified as *Thermomonospora fusca*), has also been studied extensively (Wilson, 1992; Wilson and Irwin, 1999). A brief comparison of its known enzyme components (Fig. 18) shows a striking resemblance to those of *Cellulomonas* (compare Figs. 17 and 18). According to known data, both species produce similar types of cellulases from families 5, 6, 9 and 48 plus xylanases from families 10 and 11. Nevertheless, the modular repertoire of the corresponding enzyme in *T. fusca* is generally somewhat simpler. For example, two of the *T. fusca* cellulases include single FN3 domains, whereas several *Cellulomonas* cellulases harbor multiple copies of the same domain. Some *T. fusca* enzymes lack accessory modules other than a cellulose-binding CBM, whereas the corresponding *Cellulomonas* enzyme is elaborated by multiple copies of accessory modules. In some cases though, the respective CBMs appear on opposite termini of the polypeptide chain (i.e., the family-48 and family-5 cellulases).

The complement of enzymes and their modular content of the free enzyme systems from *Cellulomonas* and *T. fusca* are not necessarily similar in other free enzyme systems. Many free enzyme systems, such as those of *Butyrivibrio fibrisolvens*, *Pseudomonas fluorescens*, *Fibro-*

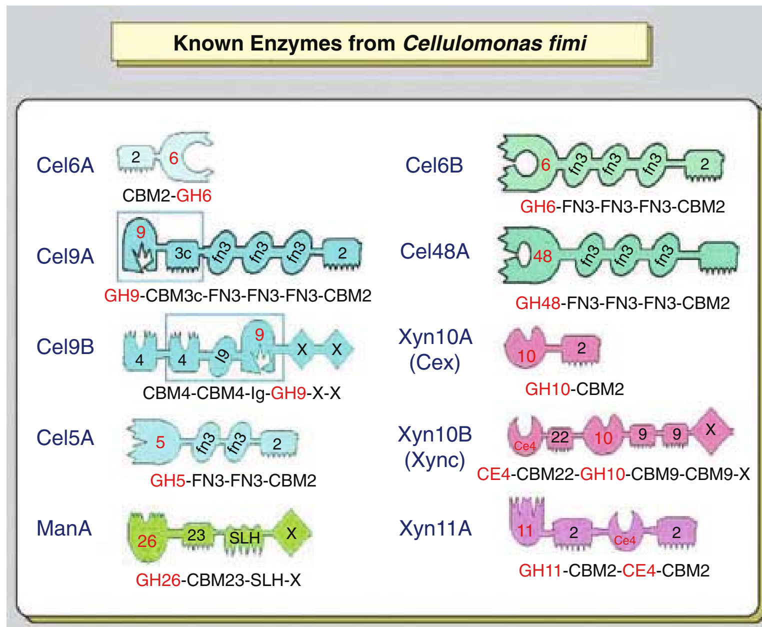

Fig. 17. *Cellulomonas fimi* cellulase system: Symbolic view of the enzyme components and their modular architecture. An example of a cell-free enzyme system. The modular content of the enzymes in this and subsequent figures is shown from (left to right) the *N*-terminus to the *C*-terminus of the polypeptide chain. The family numbers of the given domains are enumerated, the catalytic modules given in red. Key to symbols: GH, glycosyl hydrolase (e.g., cellulase, xylanase and mannanase); CE, carbohydrate esterase (e.g., acetyl xylan esterase and ferulic acid esterase); CBM, carbohydrate-binding module (e.g., CBD, cellulose-binding domain); SLH, S-layer homology (domain); FN3, fibronectin-3 (domain); Ig, immunoglobulin-like domain; and X, domain of unknown function.

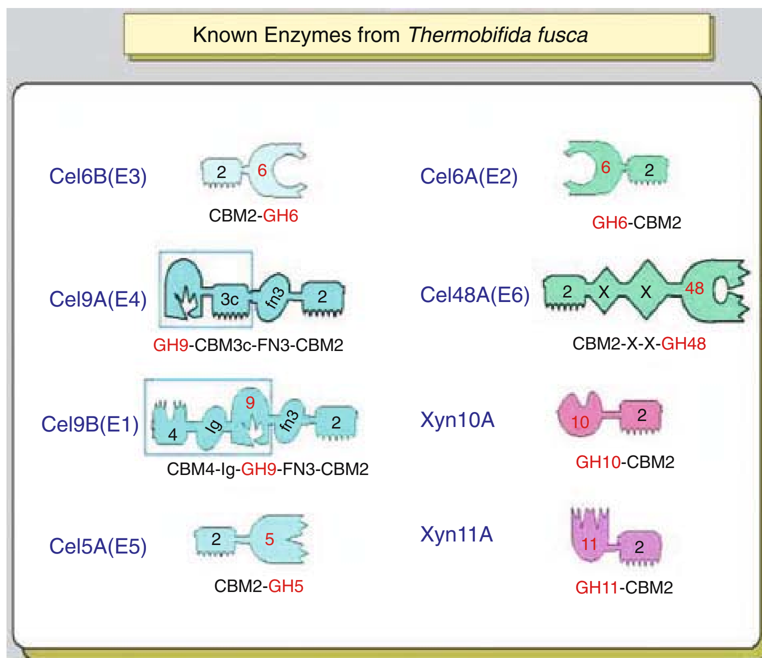

Fig. 18. *Thermobifida fusca* cellulase system. A cell-free enzyme system. The modular content of the enzymes is shown from (left to right) the *N*-terminus to the *C*-terminus of the polypeptide chain. Compare with the *Cellulomonas* system (Fig. 17). Key to symbols: GH, glycosyl hydrolase (e.g., cellulase, xylanase and mannanase); CBM, carbohydrate-binding module (e.g., CBD, cellulose-binding domain); FN3, fibronectin-3 (domain); Ig, immunoglobulin-like domain; and X, domain of unknown function.

bacter succinogenes, various species of *Streptomyces*, *Erwinia* and *Thermatoga*, appear to have several cellulases, xylanases and mannanases from the common families, together with other glycosyl hydrolases, e.g., arabinosidases, lichenases, amylases, pullulanases, galactanases, polygalacturonase, glucuronidases and pectate lyases. In many of these bacterial enzymes, the family-2 CBM appears to predominate as a common cellulose-binding domain, but in others (e.g., *Erwinia*) relevant enzymes usually bear a cellulose-binding CBM from family-3. Nevertheless, in many of the free systems, many enzymes are characterized by CBMs from other families as well as other noncatalytic domains of unknown function (X domains). Once again, until the genome sequences of cellulolytic prokaryotes are widely available, we are still lim-

ited in our capacity to compare among the enzyme systems because our knowledge of their enzyme sequences is incomplete.

Multifunctional Enzyme Systems

In an extremely thermophilic bacteria, classified as *Caldicellulosiruptor*, the enzymes currently characterized in this system also appear to be free enzymes, but their modular organization is of a higher order (Daniel et al., 1996; Gibbs et al., 2000; Reeves et al., 2000). Many of the enzymes of this system are bifunctional in that they contain two separate catalytic modules in the same polypeptide chain (Fig. 19). As mentioned earlier, the appearance of two catalytic modules in the same enzyme would infer a distinctive synergistic action between the two. Thus, in CelA, the family-9 and -48 catalytic modules would be expected to work in concerted fashion on crystalline cellulose. In another type of enzyme, the family-10 xylanase and family-5 cellulase would likely be most effective on regions of the plant cell wall that are characterized by cellulose-xylan junctions. The diversity in the modular architecture of the family-10 xylanases is particularly striking, and the various combinations of this type of catalytic module are apparently important to the sustenance of the bacterium in its environment. One of these xylanases appears to be attached to the cell surface via SLH domains. In contrast to the *Cellulomonas* and *T. fusca* enzymes that often harbor a family-2 CBM, the module responsible for binding to cellulosic substrates in *Caldicellulosiruptor* enzymes is usually one or more copies of a family-3 CBM.

Other bacterial strains that include at least one free bifunctional enzyme in their enzyme systems are *Anaerocellum thermophilum*, *Bacillus stearothermophilus*, *Fibrobacter succinogenes*, *Prevotella ruminicola*, *Ruminococcus albus*, *Ruminococcus flavefaciens*, *Streptomyces chattanoogensis* and the thermophilic anaerobe NA10. Unlike the *Caldicellulosiruptor* system, most of the free bifunctional enzymes in the latter strains appear to be isolated cases in the given system, rather than being a common character of their enzymes.

Cellulosomal Systems

The inclusion of enzymes into a cellulosome via the noncatalytic scaffoldin subunit represents a higher level of organization. The association of complementary enzymes into a complex is considered to contribute sterically to their synergistic action on cellulose and other plant cell wall polysaccharides. As mentioned earlier, in the case of *Clostridium thermocellum*, *Acetivibrio cellulolyticus* and *Bacteroides cellulosolvens*, the cellulosomes appear to be attached to the cell surface. The cellulosomes of *C. cellulolyticum*, *C. cellulovorans* and *C. josui* may also be cell-associated, but if so, the lack of a scaffoldin-borne dockerin and reciprocal anchoring protein would suggest an alternative mechanism.

The cellulosomes of *C. cellulolyticum*, *C. cellulovorans* and *C. josui* are very similar. The genes encoding for many or most of the enzymes in all

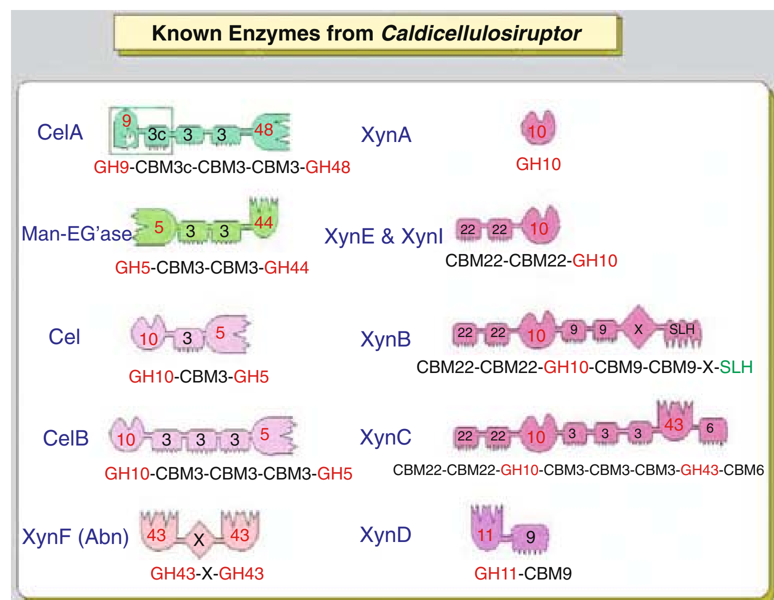

Fig. 19. Caldicellulosiruptor enzyme system. An example of a cell-free enzyme system that includes several multifunctional enzymes. The modular content of the enzymes is shown from (left to right) the *N*-terminus to the *C*-terminus of the polypeptide chain. Key to symbols: GH, glycosyl hydrolase (e.g., cellulase, xylanase and mannanase); CBM, carbohydrate-binding module (e.g., CBD, cellulose-binding domain); and SLH, S-layer homology (domain).

three cellulosomal systems are arranged in a large cluster on the chromosome. Some of the cellulosomal genes, however, are located outside of the cluster in other regions of the chromosome. The majority of the cellulosome gene clusters from *C. cellulolyticum* and *C. cellulovorans* have been sequenced (Bagnara-Tardif et al., 1992; Belaich et al., 1999; Tamaru et al., 2000b). In contrast, the cellulosomal genes from *C. thermocellum* are generally scattered over a large portion of the chromosome (Guglielmi and Béguin, 1998). A few small clusters of cellulosomal genes are apparent in the genome, including a scaffoldin-containing cluster that also contains several cell-surface anchoring proteins (Fujino et al., 1993). The following descriptive analysis serves to compare the cellulosomal system of these three microorganisms.

Cellulosomal components from *Clostridium cellulolyticum*. All of the sequenced enzymes from this organism are relatively common cellulases (Belaich et al., 1999). None of the known cellulosomal enzymes yet described for this species contains more than one catalytic module (Fig. 20). The largest one, CelE (estimated at 94 kDa), is a theme-D family-9 cellulase (Gaudin et al., 2000). The critical family-48 cellulase (CelF) is also a major cellulosome component (Reverbel-Leroy et al., 1997). Interestingly, the gene cluster of *C. cellulolyticum* contains three copies of other family-9 cellulases (CelG, CelH and CelJ), all of which contain the theme-B fused family-3c CBM (Belaich et al., 1998; Fig. 8). The currently known cellulosome system in this bacterium also contains two family-5 cellulases (CelA and CelD), a family-5 mannanase (ManK, which bears an *N*-terminal rather than *C*-terminal dockerin) and a family-8 cellulase (CelC).

Biochemical characterization of the *C. cellulolyticum* cellulosome demonstrated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) a 160-kDa scaffoldin band and up to 16 smaller bands, representing putative enzyme subunits (Gal et al., 1997). Many of these were clearly identified as known gene products. Only two cellulosomal cellulase genes are currently known to be located outside of the gene cluster. Further work on the enzyme system of this species may yet provide more complicated multimodular enzymes and/or other types of enzymes, such as hemicellulases. In this context, recent biochemical evidence has suggested that xylanases from *C. cellulolyticum* are also organized in a cellulosome-like complex, but defined xylanase sequences are still lacking from this organism (Mohand-Oussaid et al., 1999). The known activity of this organism on other plant cell wall polysaccharides would indicate that numerous other enzymes, either cellulosomal or not, remain as yet undiscovered.

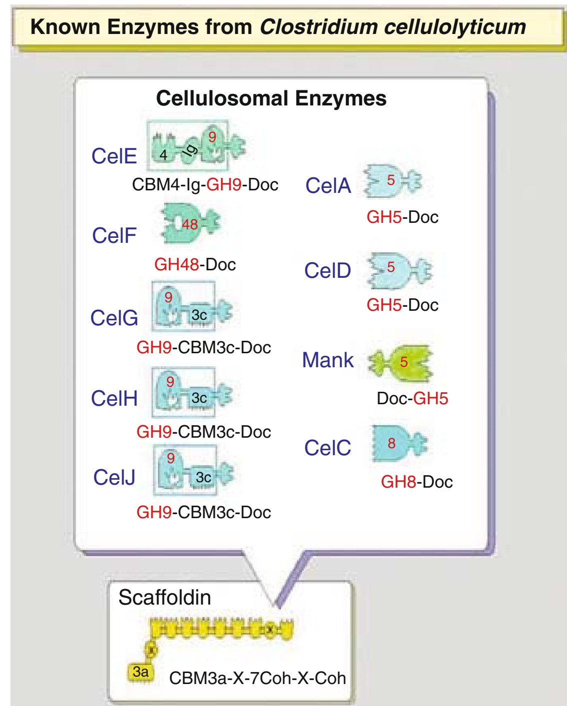

Fig. 20. *Clostridium cellulolyticum* enzyme system. An example of a cellulosomal system. The modular content of the enzymes is shown from (left to right) the *N*-terminus to the *C*-terminus of the polypeptide chain. Key to symbols: GH, glycosyl hydrolase (e.g., cellulase, xylanase and mannanase); CBM, carbohydrate-binding module (e.g., CBD, cellulose-binding domain); and Doc, dockerin domain.

Cellulosomal components from *Clostridium cellulovorans*. Like *C. cellulolyticum*, the cellulases from this organism are relatively simple (Fig. 21). In addition to the cellulosomal enzymes thus described, at least three non-cellulosomal endoglucanases have also been partially or totally sequenced (Doi et al., 1998; Tamaru et al., 1999b).

Several of the cellulosomal enzymes are architecturally synonymous to those of the *C. cellulolyticum* system (compare Figs. 20 and 21). This includes the critical family-48 cellulase (ExgS; Liu and Doi, 1998), two copies of the theme-B family-9 cellulase (EngH and EngY), a family-5 endoglucanase and a family-5 mannanase that bears an N-terminal dockerin (Tamaru and Doi, 2000a). Rather than a single theme-D family-9 cellulase as in *C. cellulolyticum*, the *C. cellulovorans* system contains two such enzymes (EngK and EngM). The *C. cellulovorans* cellulosome also appears to contain an unusual theme-A

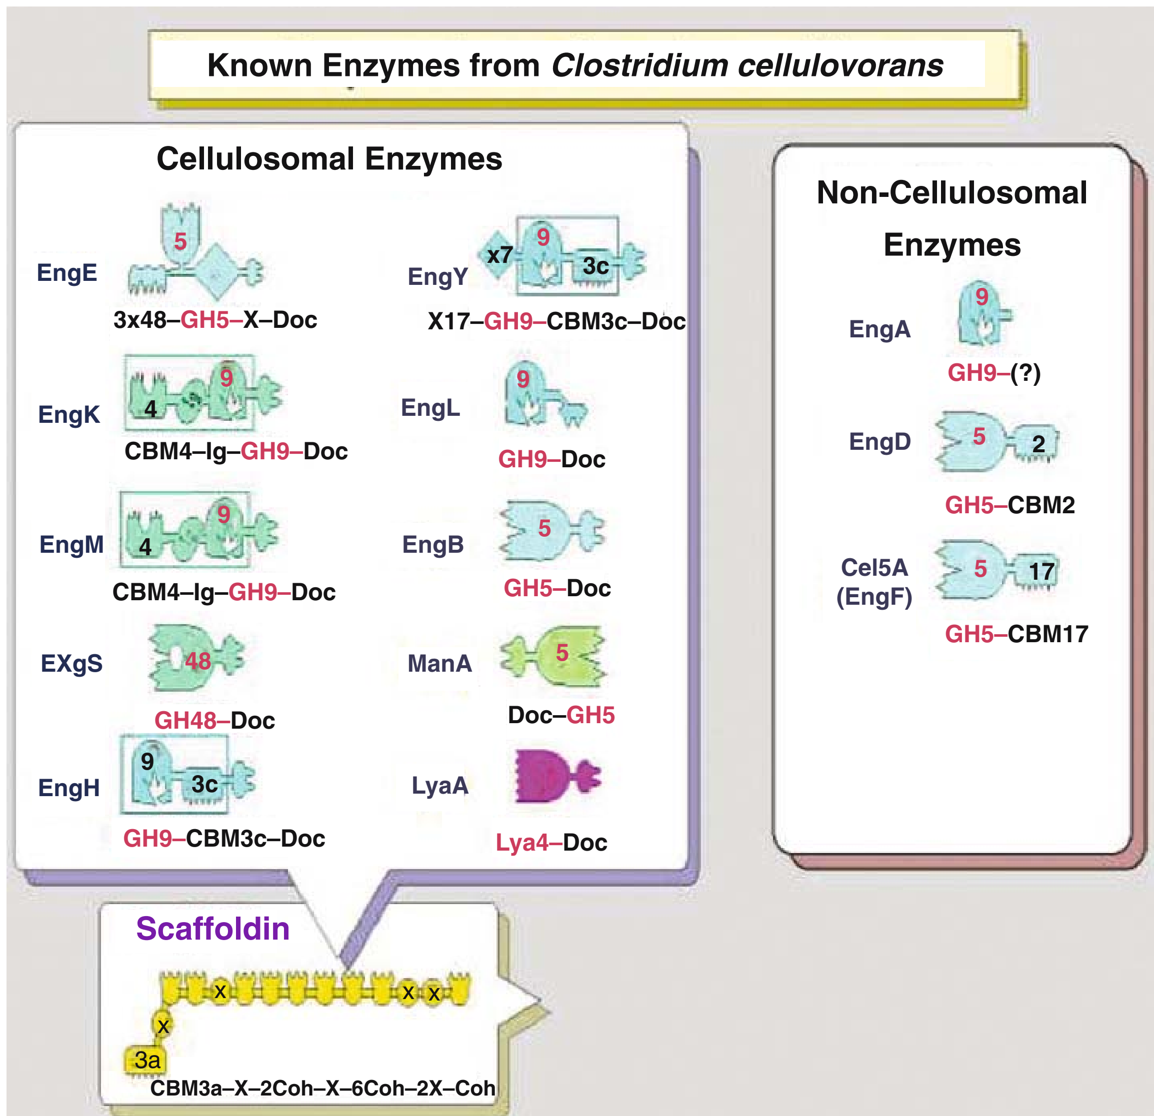

Fig. 21. *Clostridium cellulovorans*: A second cellulosomal system. The modular content of the enzymes is shown from (left to right) the *N*-terminus to the *C*-terminus of the polypeptide chain. Key to symbols: GH, glycosyl hydrolase (e.g., cellulase, xylanase and mannanase); CBM, carbohydrate-binding module (e.g., CBD, cellulose-binding domain); Doc, dockerin domain; SLH, S-layer homology (domain); Ig, immunoglobulin-like domain; and X, domain of unknown function.

family-9 cellulase (EngL) that lacks helper domains. The remaining two known cellulosomal enzymes are thus far unique to *C. cellulovorans*. A dockerin-bearing pectate lyase (LyaA) infers that the bacterium would degrade pectin (Tamaru and Doi, 2001). Indeed, early evidence (Sleat et al., 1984) indicated that, in addition to cellulose, *C. cellulovorans* is capable of assimilating a wide variety of other plant cell wall polysaccharides, including, xylans, pectins and mannans. As in the case of *C. celluolyticum*, it seems that future work will yield new sequences of many other types of cellulosomal and noncellulosomal enzymes.

More significant to the cellulosomal system of *C. cellulovorans*, perhaps, is the large family-5 enzyme that purportedly comprises both an *N*-terminal SLH domain and a *C*-terminal dockerin (Tamaru and Doi, 1999a). This arrangement may imply that the entire cellulosome is bound to the cell surface via this enzyme. If this proves to be the case, it is interesting to speculate whether the *C. cellulolyticum* and *C. josui* cellulosomes are also connected to the cell surface by a similar, but as yet undiscovered enzyme that bears both SLH and dockerin domains.

Cellulosomal components from Clostridium thermocellum. Compared to the cellulosomal

systems of *C. cellulovorans* and *C. cellulolyticum*, the enzymes from *C. thermocellum* are relatively large proteins, ranging in molecular size from about 40–180 kDa (Bayer et al., 1998; Bayer et al., 2000; Béguin and Lemaire, 1996; Felix and Ljungdahl, 1993; Lamed and Bayer, 1988; Shoham et al., 1999). Examination of Fig. 22 reveals why these enzymes are so big—many of the larger ones contain multiple types of catalytic domains as well as other functional modules as an integral part of a single polypeptide chain (see Table I in Bayer et al., 1998, for a list of relevant references). In addition to the cellulosomal enzymes, several noncellulosomal enzymes have also been described from this organism (Morag et al., 1990). These include two free enzymes (one of which lacks a CBM) and two cell-associated (SLH-containing) enzymes. Consequently, the potent cellulose- and plant cell wall-degrading activities of *C. thermocellum* are clearly reflected in its cellulase system, which displays an exceptional wealth, diversity and intricacy of enzymatic components, thus representing the premier cellulose-degrading organism currently known.

Many of the *C. thermocellum* cellulosomal enzymes are cellulases, which include both endo- and exo-acting β-glucanases. Some of the important exoglucanases and processive cellulases include CelS, CbhA, CelK and CelF. The CelS subunit is a member of the family-48 glycosyl hydrolases, and this particular family is now recognized as a critical component of bacterial cellulosomes (Morag et al., 1991; Morag et al., 1993; Wang et al., 1993; Wang et al., 1994; Wu et al., 1988). Several other processive cellulases are members of the family-9 glycosyl hydrolases. CelF and CelN are theme-B family-9 enzymes (Navarro et al., 1991; Fig. 7). The other two are remarkably similar theme-D enzymes, which exhibit nearly 95% similarity along their common regions (Kataeva et al., 1999a; Kataeva et al., 1999b; Zverlov et al., 1998; Zverlov et al., 1999). The main difference between CbhA and CelK is the presence in the former of three extra modules (a family-3 CBD and two modules of unknown function). The functional significance of these supplementary modules to the activity of CbhA has not been elucidated.

The fact that the cellulosome from this organism contains many different types of cellulases is, of course, to be expected if we consider that growth of *C. thermocellum* is restricted to cellulose and its breakdown products, particularly cellobiose. Consequently, it is surprising to discover, in addition to the cellulases, at least five classic xylanases, i.e., those belonging to glycosyl hydrolase families 10 and 11. In addition, two of the larger enzymes, CelH and CelJ, contain hemicellulase components, i.e., family-26 and -44 catalytic modules (a mannanase and a xylanase, respectively), together with a standard cellulase module in the same polypeptide chain (Ahsan et al., 1996; Yagüe et al., 1990). It is also interesting to note the presence of carbohydrate esterases together with xylanase or cellulase modules in some of the enzyme subunits (i.e., XynU/A, XynY, XynZ and CelE), thus conferring the capacity to hydrolyze acetyl or feruloyl groups from hemicellulose substrates (Blum et al., 2000; Fernandes et al., 1999). Finally, the *C. thermocellum* cellulosome includes a typical family-16 lichenase, a family-26 mannanase and a family-18 chitinase.

The non-cellulosomal enzymes include another theme-B family-9 cellulase (CelI), and cell-bound forms of a xylanase (XynX) and a lichenase (LicA), both of which contain multiple CBMs adjacent to the catalytic module. In the midst of all this complexity, the *C. thermocellum* non-cellulosomal cellulase system includes a simple family-5 cellulase, CelC, which is completely devoid of additional accessory modules.

Why does this bacterium—which subsists exclusively on cellulosic substrates—need all these hemicellulases? The inclusion of such an impressive array of non-cellulolytic enzymes in a strict cellulose-utilizing species would suggest that their major purpose would be to collectively purge the unwanted polysaccharides from the milieu and to expose the preferred substrate—cellulose. The ferulic acid esterases, in concert with the xylanase components of the parent enzymes, could grant the bacterium a relatively simple mechanism by which it could detach the lignin component from the cellulose-hemicellulose composite. The lichenase (LicB) and chitinase (ChiA) are also intriguing components of the cellulosome. The former would provide the bacterium with added action on cell-wall β-glucan components from certain types of plant matter. It is not clear whether the presence of the latter cellulosomal enzyme would reflect chitin-derived substrates from the exoskeletons of insects and/or from fungal cell walls. Whatever the source, the chitin breakdown products, like those of the hemicelluloses, would presumably not be utilized by the bacterium itself, but would be passed on to appropriate satellite bacteria for subsequent assimilation.

Phylogenetics of Cellulase and Cellulosomal Systems

Early in the history of the development and establishment of the cellulosome concept, it was noted that the apparent occurrence of cellulo-

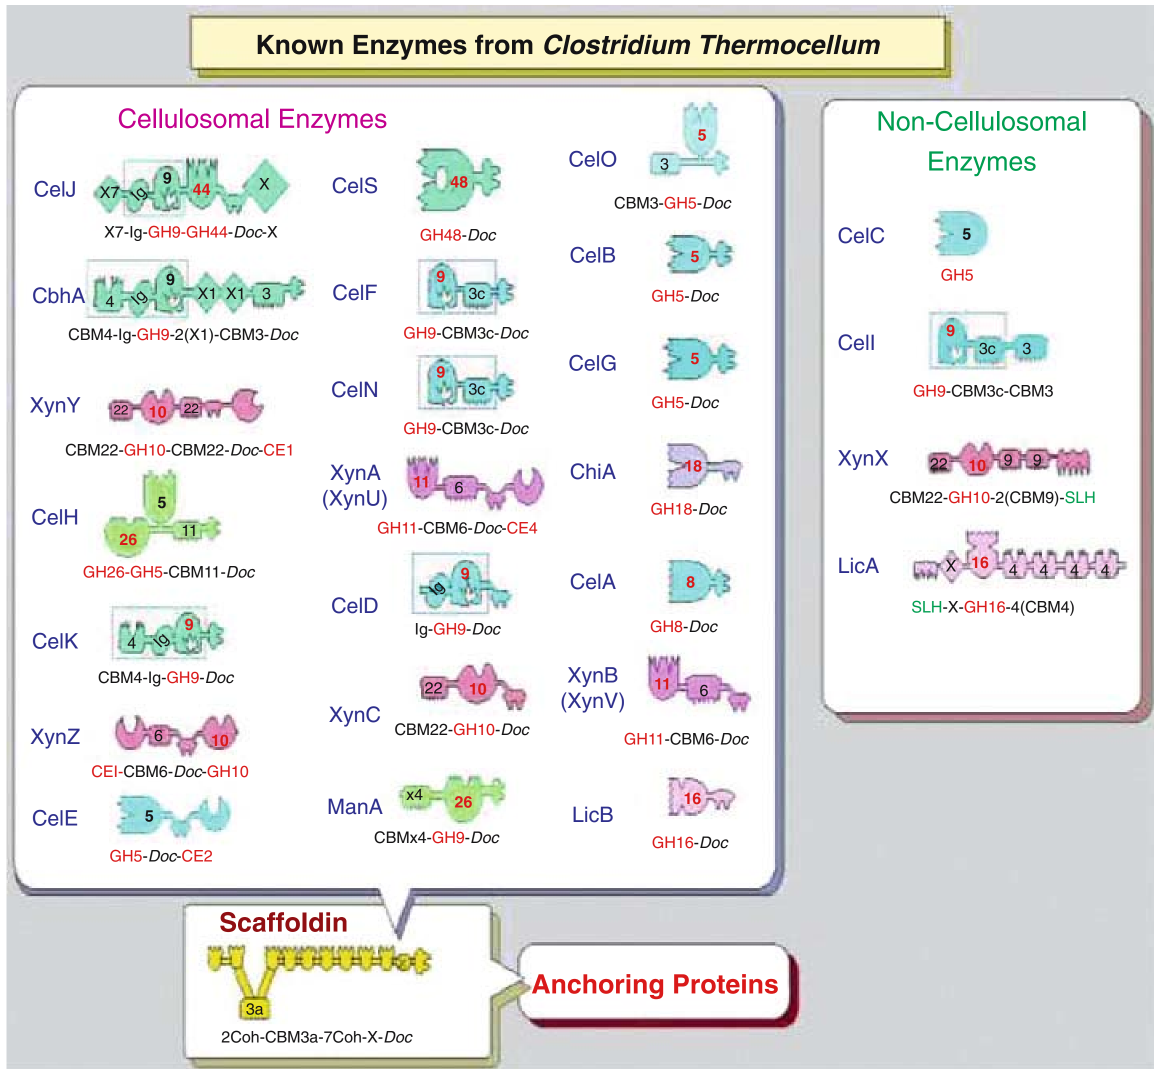

Fig. 22. *Clostridium thermocellum*: A very complex cellulosomal system. The modular content of the enzymes is shown from (left to right) the *N*-terminus to the *C*-terminus of the polypeptide chain. Key to symbols: GH, glycosyl hydrolase (e.g., cellulase, xylanase and mannanase); CE, carbohydrate esterase (e.g., acetyl xylan esterase and ferulic acid esterase); CBM, carbohydrate-binding module (e.g., CBD, cellulose-binding domain); Doc, dockerin domain; SLH, S-layer homology (domain); Ig, immunoglobulin-like domain; and X, domain of unknown function.

somes in different microorganisms tended to cross ecological, physiological and evolutionary boundaries (Lamed et al., 1987). Initial biochemical and immunochemical evidence to this effect has been supported by the accumulated molecular biological studies.

Various lines of evidence indicate that the modular enzymes that degrade plant cell wall polysaccharides have evolved from a restricted number of common ancestral sequences. Much of the information in this direction remains as a legacy, inherently encoded in the sequences of the functional domains that comprise the different enzymes. By comparing sequences of the various cellulosomal and noncellulosomal enzymes within and among the different strains, we can gain insight into the evolutionary rationale of the multigene families that comprise the glycosyl hydrolases.

Horizontal Gene Transfer

It is clear that very similar enzymes which comprise a given glycosyl hydrolase family are prevalent among a variety of different bacteria and fungi, thus indicating that they were not inherited through conventional evolutionary processes. The widespread occurrence of such conserved enzymes among phylogenetically different species argues that horizontal transfer of

genes has been a major process by which a given microorganism can acquire a desirable enzyme. Once such a transfer event has taken place, the newly acquired gene would then be subjected to environmental pressures of its new surroundings, i.e., the genetic and physiological constitution of the cell itself. Following such selective pressure, the sequence of the gene would be adjusted to fit the host cell.

Gene Duplication

Sequence comparisons have also revealed the presence of very similar genes within a genome that may have very similar or even identical functions. One striking example is the tandem appearance of *cbhA* and *celK* genes in the chromosome of *Clostridium thermocellum*. Other examples are *xynA* and *xynB* also of *C. thermocellum* and *xynA* of the anaerobic fungus *Neocallimastix patriciarum*, which includes two very similar copies of family-11 catalytic modules within the same polypeptide chain. These examples imply a mechanism of gene duplication (Chen et al., 1998; Gilbert et al., 1992), whereby the duplicated gene can serve as a template for secondary modifications that could result in two very similar enzymes with different properties, such as substrate and product specificities. A similar process could also account for the multiplicity of other types of modules (i.e., CBDs, cohesins or helper modules) within a polypeptide chain. Comparison of the modular architectures of similar genes from different species would suggest that individual modules can undergo a duplication process. This is exemplified by the multiple copies of FN3 in CelB from *Cellulomonas fimi* versus the single copy of the same domain in cellulase E4 from *Thermobifida fusca*. But innumerable other examples are evident from the databases, whenever multiple copies of the same modular type exist in the same protein.

Domain Shuffling

Another observation from the genetic composition of the glycosyl hydrolases argues for an alternative type of process, which would propagate new or modified types of enzymes. It is clear that many microbial enzyme systems contain individual hydrolases that carry very similar catalytic domains but include different types of accessory modules (Gilkes et al., 1991). An example that demonstrates this phenomenon is the observed species preference of otherwise very similar glycosyl hydrolases for a given family of crystalline cellulose-binding CBD, which is entirely independent of the type of catalytic module borne by the complete enzyme. In this context, as we have seen above, the free enzymes of some bacteria, such as *Cellulomonas fimi*, *Pseudomonas fluorescens* and *Thermomonospora fusca*, invariably include a family-2 CBD, irrespective of the type of catalytic domain. In contrast, those of other bacteria, e.g., *Bacillus subtilis*, *Caldocellum saccharolyticum*, *Erwinia carotovora* and various clostridia, appear to prefer family-3 CBDs. Moreover, the position of the CBD in the gene may be different for different genes. For example, the CBD may occur upstream or downstream from the catalytic domain; it may be positioned either internally (sandwiched between two other modules) or at one of the termini of the polypeptide chain. The same pattern is characteristic of several other kinds of modules associated with the plant cell wall hydrolases. This is particularly evident in family-9 cellulases and family-10 xylanases, where the number and types of accessory modules may vary greatly within a given species. It seems that individual domains can be transferred en bloc and incorporated independently into appropriate enzymes. Once again, the modular architectures and sequence similarities between *Clostridium thermocellum* cellulosomal enzyme pairs (CbhA and CelK; XynA and XynB) are particularly revealing: in both cases, following an apparent gene duplication event, one or more additional modules appear to have been incorporated into the duplicated enzyme. Taken together, the information suggests that domain shuffling is an important process by which the properties of such enzymes can be modified and extended.

Proposed Mechanisms for Acquiring Cellulase and Cellulosomal Genes

Like the free enzyme systems, the phylogeny of cellulosomal components seems to have been driven by processes that include horizontal gene transfer, gene duplication and domain shuffling. In cellulolytic/hemicellulolytic ecosystems, the resident microorganisms are usually in close contact, often under difficult conditions and in competition or cooperation with one another toward a common goal: the rapid degradation of recalcitrant polysaccharides and assimilation of their breakdown products.

A possible scenario for the molecular evolution of a cellulase/hemicellulase system in a prospective bacterium could involve the initial transfer of genetic material from one microbe to another in the same ecosystem. The size and type of transferred material could vary, such as a gene or part of gene (e.g., selected functional modules) or even all or part of a gene cluster. The process could then be sustained by gene duplica-

tion, which would propagate the insertion of repeated modules, e.g., the multiple cohesin domains in the scaffoldins, or even smaller units, such as the linker sequences or the duplicated calcium-binding loop of the dockerin domain. Domain shuffling can account for the observed permutations in the arrangement of domains in scaffoldin subunits from different species (Fig. 16). Finally, conventional mutagenesis would then render such products more suitable for the cellular environment or for interaction with other components of the cellulase system.

The available data suggest that there are no set of rules, which would, at this stage, enable us to anticipate the nature of a given cellulase system from a given microorganism. It seems that phylogenetically dissimilar organisms can possess similar types of cellulosomal or non-cellulosomal enzyme systems, whereas phylogenetically related organisms that inhabit similar niches may be characterized by different types of enzyme systems. It is clear that to shed further light on this apparent enigma, we require more information about more types of enzyme systems. In addition to more sequences and structures, we will need more information—biochemical, physiological and ecological—to sharpen existing notions regarding the enzymatic degradation of plant cell wall polysaccharides or to formulate new ones.

CHAPTER 1.20

Aerobic Methylotrophic Prokaryotes

MARY E. LIDSTROM

Introduction

Methylotrophic bacteria are those organisms with the ability to utilize (as their sole source of carbon and energy) reduced carbon substrates with no carbon-carbon bonds. By this definition the group includes bacteria that can grow on substrates such as methane, methanol, methylated amines, halogenated methanes and methylated sulfur species. Methylotrophic bacteria are quite widespread in nature, being found in a variety of aquatic and terrestrial habitats (King, 1992). They appear to play an important role in the cycling of carbon in specific habitats (King, 1992), and they comprise the principal biological sink for methane and other methylated greenhouse gases, highlighting an important role in global warming (King, 1992; Oremland and Culbertson, 1992). Although many anaerobic methylotrophic bacteria are known, especially among the methanogens, this chapter will cover only the aerobic and facultatively anaerobic methylotrophs (for convenience, termed "aerobic methylotrophs"). Table 1 lists the major groups of aerobic methylotrophs with examples of the genera that have been described to contain methylotrophs.

Aerobic methylotrophic bacteria are phylogenetically diverse, with representatives found among the Proteobacteria as well as the high and low G+C Gram-positive bacteria (Firmicutes; Table 1). Many of the known strains of methylotrophic bacteria are obligately methylotrophic species, that is, they are incapable of growing on any compounds containing carbon-carbon bonds. However, especially among the group of bacteria that grow on methanol, a variety of facultative organisms are known that can grow either on multi-carbon compounds or on one-carbon (C_1) compounds (Table 1). Two functional groups of methylotrophs may be distinguished: those capable of growth on methane, called "methanotrophs," and those capable of growth on methanol and/or other methylated compounds but not on methane. The methanotrophs are characterized by the presence of internal membrane systems (Hanson and Hanson, 1996). Many but not all of the methylotrophs also can use N_2 as a nitrogen source and therefore are considered to be diazotrophs (Table 1). In addition, several of the methylotrophs also affect the nitrogen cycle by carrying out transformations of ammonia and nitrate (Anthony, 1982). Some methylotrophs are known that can use methylated sulfur species, and these appear to play an important role in sulfur cycling (DeBont et al., 1981; Kelly and Murrell, 1999). A number of methylotrophs can grow on halogenated methanes (Leisinger and Braus-Stromeyer, 1995) and have the potential to play an important role in the detoxification of these pollutants.

The ability to grow on reduced C_1 compounds requires the presence of unique biochemical pathways for both energy and carbon metabolism. So far, a limited number of variations of these metabolic pathways are known. Figure 1 gives an outline of methylotrophic metabolism, showing how different methylotrophic substrates are fed into central metabolic pathways. A key feature of aerobic methylotrophy is the role of formaldehyde as a central intermediate. In most methylotrophs, the pool of formaldehyde generated from methylotrophic substrates is split, with part being oxidized to CO_2 for energy and part being assimilated into cell carbon via one of two unique pathways, the serine cycle or the ribulose monophosphate cycle. Other methylotrophs, sometimes called "pseudomethylotrophs" or "autotrophic methylotrophs" (Anthony, 1982), are capable of growth on reduced C_1 compounds by oxidizing these compounds to CO_2 and then assimilating the CO_2 via the classical Calvin-Benson-Bassham cycle. The diagram shown in Fig. 1 is an amalgam of the known diversity of methylotrophic metabolism, and no single methylotroph can carry out all of these types of metabolism. In fact, the major phylogenetic divisions mirror distinct physiological classes. For instance, all of the known methylotrophs containing the serine cycle for formaldehyde assimilation are clustered in the α-Proteobacteria, all of the restricted obligate methylotrophs that do not use methane are clustered in the β-

and physiological groups may not hold up, as new strains are identified and characterized.

Dissimilatory Metabolism

Aerobic methylotrophs contain specialized pathways for dissimilatory metabolism during methylotrophic growth. In general, the methyl groups of methylotrophic substrates are oxidized to the level of formaldehyde by oxidases and/or dehydrogenases. The dehydrogenases are generally coupled to energy metabolism at the level of cytochromes and the oxidases are usually non-energy conserving. Formaldehyde is then further oxidized to the formyl level by one of a number of formaldehyde oxidation systems, which usually generate a reduced pyridine nucleotide. Carbon at the level of formate is then oxidized to CO_2 via another pyridine nucleotide-linked step.

Methane Oxidation

The enzyme that oxidizes methane to methanol in the methanotrophic bacteria is a mixed-function oxidase called "methane monooxygenase" (MMO; Fig. 1). Two different enzymes are known, a membrane-bound form, known as "the particulate MMO" (pMMO), and a soluble form, called "the soluble MMO" (sMMO; Hanson and Hanson, 1996). The soluble MMO has so far been documented in only a few strains and it is not yet known how widely distributed it is in methanotrophs. It has been found in all tested strains of *Methylosinus* and *Methylococcus*, and in a few strains of *Methylomonas Methylomicrobium* and *Methylocystis* (Hanson and Hanson, 1996; Fuse et al., 1998; Shigematsu et al., 1999; Grosse, 1999). However, pMMO appears to be present in all known strains of methanotrophs.

The sMMO has been purified from both type I and type II methanotrophs (Lipscomb, 1994), and it is similar in all cases. It consists of three components: a hydroxylase (consisting of three polypeptides and a non-heme iron center), component B (with no cofactors), and a reductase that contains FAD and and an Fe_2S_2 cluster (Lipscomb, 1994). The sMMO uses NADH as a source of reducing power, and contains an hydroxo-bridged di-iron center in its active site (Lipscomb, 1994). It is characterized by an extremely broad substrate specificity, being able to oxidize or hydroxylate a wide variety of aliphatic straight chain, branched, aromatic, and halogenated hydrocarbons (Lipscomb, 1994; Hanson and Hanson, 1996). The broad substrate range of this enzyme has attracted a great deal of attention as a result of the use of methanotrophs for bioremediation of a variety of toxic hydrocarbons (Hanson and Hanson, 1996). Crystal structures are available for the hydroxylase and component B from two different methanotrophs (Walters et al., 1999; Elango et al., 1997; Chang et al., 1999; Rosenzweig et al., 1997). Genes for the subunits of the sMMO (*mmo* genes) have been cloned and sequenced from a number of methanotrophs, and they have a similar organization with high similarity at the amino acid level (Murrell, 1994; Shigematsu et al., 1999; McDonald et al., 1997).

The pMMO is highly unstable and has proven more difficult to analyze. However, recently, pMMO was purified in an active state from *Methylococcus capsulatus* Bath by two groups (Zahn and DiSpirito, 1996; Nguyen et al., 1998). In both cases, the pMMO had 3 subunits, PmoABC, of approximately 27, 45 and 22 kDa, respectively, and was a copper-containing enzyme. In one case no other metals were present (Nguyen et al., 1998), whereas in the other iron was also present (Zahn and DiSpirito, 1996). The pMMO has a narrower substrate range than the sMMO (Hanson and Hanson, 1996). The genes encoding the pMMO are present in multiple copies in most methanotrophs (Semrau et al., 1995). In both a type I and type II methanotroph, evidence exists that the copies are nearly identical in sequence (Stolyar et al., 1999; Gilbert et al., 2000), and mutant evidence has shown that in *Methylococcus capsulatus* Bath the copies are functionally redundant (Stolyar et al., 1999).

In methanotrophs containing both pMMO and sMMO, the expression of each enzyme is regulated by copper. In copper sufficiency, pMMO is expressed, and in copper limitation,

sMMO is expressed. In *Methylococcus capsulatus* Bath and *Methylosinus trichosporium*, it has been shown that this regulation occurs at the transcriptional level (Nielsen et al., 1997).

Methanol Oxidation

Methanol is widespread, produced in nature as a result of demethylation reactions (Anthony, 1982), especially from plants (Holland and Polacco, 1994). Methanol is oxidized to formaldehyde by three classes of enzymes, a quinoprotein methanol dehydrogenase (MDH) found in the Gram-negative methylotrophs (Goodwin and Anthony, 1998), an NAD-linked enzyme found in the *Bacillus* strains (Arfman et al., 1997), and a methanol:*N*,*N'*-dimethyl-4-nitrosoaniline oxidoreductase (MNO) found in other Gram-positive strains (Bystrykh et al., 1993; Bystrykh et al., 1997). In general, methanol oxidation is an energy-conserving step, either generating reduced cytochromes or reduced pyridine nucleotides.

Quinoprotein Methanol Dehydrogenase

All of the known Gram-negative methanol- and methane-utilizing bacteria contain a periplasmic enzyme for oxidizing methanol called "methanol dehydrogenase." This enzyme, which oxidizes primary alcohols to their corresponding aldehydes, has an $\alpha_2\beta_2$ structure and contains the cofactor pyrroloquinoline quinone (PQQ; Goodwin and Anthony, 1998). Electrons from the oxidation of PQQ are transferred from PQQ to a specific cytochrome *c*, and from there through other carriers to the terminal oxidase (Goodwin and Anthony, 1998). The primary sequences and structures for methanol dehydrogenase from diverse methylotrophs are highly conserved (Goodwin and Anthony, 1998). These enzymes contain a Ca^{2+} near the active site and also have an unusual disulfide bridge in the same region (Goodwin and Anthony, 1998; Anthony and Ghosh, 1998).

NAD-Linked Methanol Dehydrogenases

An NAD-linked methanol dehydrogenase has been purified and characterized from methylotrophic *Bacillus* strains (Arfman et al., 1997). This enzyme oxidizes C_1–C_4 primary alcohols, and is composed of ten identical 43,000-Mr subunits. Each MDH subunit contains a tightly, but noncovalently bound NAD(H) molecule, in addition to 1 Zn^{2+} and 1 or 2 Mg^{2+} ions. This MDH also interacts with a 50,000-Mr activator protein, which appears to facilitate the oxidation of the reduced NADH cofactor of MDH (Arfman et al., 1997). The structural gene for this MDH shows identity with type II alcohol dehydrogenases (de Vries et al., 1992).

Methanol:N,N′-dimethyl-4-nitrosoaniline Oxidoreductase (MNO)

Other Gram-positive methylotrophs (*Amycolatopsis* and *Mycobacterium*) oxidize methanol via a methanol:*N*,*N'*-dimethyl-4-nitrosoaniline oxidoreductase (MNO), which is a decameric protein with 50-kDa subunits, each carrying a tightly bound NADPH (Bystrykh et al., 1997). This protein also has been isolated as a complex containing two other components that impart a tetrazolium-dye-linked methanol dehydrogenase activity (Bystrykh et al., 1997).

Oxidation of Methylated Amines

Methylated amines are also widespread in the environment, being produced as degradation products of some pesticides, of carnitine and lecithin derivatives, and of trimethylamine oxide. The latter is especially prevalent in fish and in marine environments (Anthony, 1982). A variety of bacteria are known that are capable of growing on methylated amines. In general, the methyl groups of methylated amines are oxidized to formaldehyde, either by an oxidase or a dehydrogenase, with energy conservation occurring in the latter case. Growth on formaldehyde occurs via normal methylotrophic assimilatory and dissimilatory pathways (Fig. 1).

Trimethylamine and Dimethylamine

Trimethylamine is oxidized to dimethylamine and formaldehyde by trimethylamine dehydrogenase (Fig. 2). This enzyme is a flavoprotein, that also contains two Fe_2S_2 clusters and two molecules of ADP (McIntire, 1990). A second pathway for utilization of trimethylamine occurs in which a trimethylamine monooxygenase oxidizes trimethylamine to trimethylamine *N*-oxide. The *N*-oxide is subsequently demethylated by trimethylamine demethylase to dimethylamine and formaldehyde (Anthony, 1982). Dimethylamine is oxidized to methylamine and formaldehyde by dimethylamine monooxygenase (Fig. 2). Gene sequences suggest that trimethylamine and dimethylamine dehydrogenases are evolutionarily related (Yang et al., 1995).

Methylamine

Four possible routes are known in bacteria for utilizing methylamine (Fig. 2). The first of these involves the periplasmic enzyme, methylamine dehydrogenase (MADH), which is another quinoprotein shown to contain the cofactor,

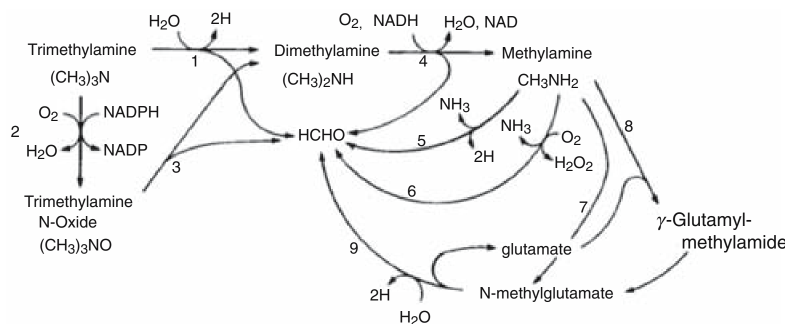

Fig. 2. Pathways for converting methylated amines to formaldehyde in methylotrophic bacteria. 1, trimethylamine dehydrogenase; 2, trimethylamine monooxygenase; 3, trimethylamine *N*-oxide demethylase; 4, dimethylamine monooxygenase; 5, methylamine dehydrogenase; 6, methylamine oxidase; 7, *N*-methylglutamate synthase; 8, γ-glutamylmethylamide synthetase; and 9, *N*-methyl glutatmate dehydrogenase. From Anthony (1982).

tryptophan tryptophylquinone (TTQ), instead of the PQQ found in MDH. This TTQ is formed by covalent crosslinking of two tryptophan residues in the small subunit of MADH, and incorporation of two oxygen atoms into one of the indole rings to form a quinone (Davidson, 1999). The MADH converts primary amines to their corresponding aldehydes plus ammonia, and electrons are transferred to a small copper protein, amicyanin. These electrons are transferred to the respiratory chain via a *c*-type cytochrome (Davidson, 1999). Structural, kinetic and site-directed mutagenesis studies have characterized protein-protein interactions, and mechanisms of catalysis and electron transfer by TTQ. In addition, the genes encoding the functions required for active MADH (*mau* genes) have been studied from several bacteria, and they are similar in both amino acid sequence and genetic organization (van der Palen et al., 1995; Chistoserdov, 1994a; Chistoserdov, 1994b; Gak et al., 1997; Graichen et al., 1999).

In *Arthrobacter* P1, methylamine is utilized by another quinoprotein, methylamine oxidase. This enzyme is a blue copper amine oxidase similar to mammalian copper amine oxidases, which generate hydrogen peroxide (Levering et al., 1981; McIntire and Hartman, 1993; Fig. 2). This enzyme contains the cofactor 6-hydroxydopa quinone, which is formed posttranslationally from a tyrosine residue in the amino acyl chain (McIntire and Hartman, 1993). A few methylotrophs contain indirect pathways, which involve the conversion of methylamine to *N*-methylglutamate, and finally to formaldehyde; *N*-methylglutamate can be synthesized directly, via *N*-methylglutamate synthase, or indirectly via a γ-glutamylmethylamide intermediate, as shown in Fig. 2, although the latter pathway is still uncertain (Anthony, 1982).

Utilization of Methylated Sulfur Species

A few organisms have been isolated that are capable of utilizing methylated sulfur compounds such as dimethylsulfoxide (DMSO), dimethylsulfide (DMS), and dimethyldisulfide (DMDS). Most of these strains have been *Hyphomicrobium* species (DeBont et al., 1981; Suylen and Kuenen, 1986), but a few *Thiobacillus* strains and a *Methylophaga* strain have been reported (Kanagawa and Kelly, 1986; De Zwart et al., 1996). The *Hyphomicrobium* strains apparently reduce DMSO to DMS and then convert the DMS to methanethiol and formaldehyde (Fig. 3). The methanethiol is then oxidized by an oxidase to H_2S and formaldehyde with the production of hydrogen peroxide (DeBont et al., 1981). Formaldehyde is utilized by standard methylotrophic pathways (Fig. 1).

DMS arises in marine environments through the cleavage of dimethyl-β-propiothetin, one of the products of sulfur metabolism of marine algae (Andreae, 1980). Also, DMS has been thought to play an important role in the transport of reduced sulfur compounds between aquatic and terrestrial environments and from terrestrial environments into the atmosphere (Andreae and Raemdonck, 1983; Banwart and Bremner, 1976). The distribution of bacteria capable of utilizing methylated sulfur compounds has not been well studied. However, it seems likely that these organisms are widespread and are present in many environments in which DMS is produced.

Some specialized methylotrophs (including *Methylosulfonomonas*, *Marinosulfonomonas*, and strains of *Hyphomicrobium* and *Methylobacterium*) can use methanesulfonate as a carbon and energy substrate to support growth (Kelly and Murrell, 1999; Pol et al., 1994). Methane-

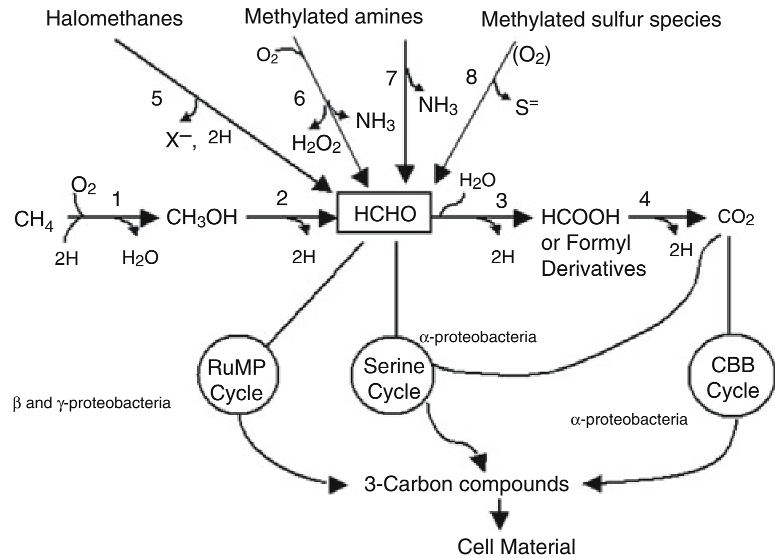

Fig. 3. Proposed pathway for converting methylated sulfur species to formaldehyde in *Hyphomicrobium* species Adapted from DeBont et al. (1981).

sulfonate is oxidized to sulfite and formaldehyde by NADH-dependent methanesulfonate monooxygenase, and utilization of formaldehyde proceeds by normal serine-cycle-dependent methylotrophic metabolism (Kelly and Murrell, 1999). The methanesulfonate monooxygenase has been shown to consist of three components: 1) a 200-kDa hydroxylase complex containing two major polypeptides of around 50 and 20 kDa with a Rieske [2Fe-2S] center; 2) a 16-kDa ferredoxin component; and 3) the putative reductase component, a 36-38 kDa-monomeric protein catalyzing the NADH-dependent reduction of several electron acceptors, including cytochrome *c* (Kelly and Murrell, 1999).

Halomethanes

A number of methylotrophic bacteria are known that are capable of aerobic growth on halomethanes such as chloromethane, bromomethane and dimethylchloride (Leisinger, 1994; Leisinger and Baus-Stromeyer, 1995; Hancock et al., 1998). These bacteria are generally found in the genera *Methylobacterium*, *Hyphomicrobium* or *Methylophilus*, although two strains using monohalomethanes also have been identified that class together in a new subgroup of α-proteobacterial methylotrophs within a clade of rhizobia (Schaefer, 1999; Coulter, 1999). Dichloromethane degradation involves a glutathione-linked dehalogenase that produces formaldehyde (Leisinger, 1994), and the rest of metabolism proceeds by general methylotrophic pathways. Chloromethane degradation has been shown to involve a corrinoid-dependent methyltransferase with sequence identity to methanogen methyltransferases (Studer et al., 1999; Coulter, 1999). In *Methylobacterium* strain CM4, the methyltransferase reaction is coupled to tetrahydrofolate derivatives to produce formate, followed by formate oxidation (Vannelli, 1999; Fig. 4). Assimilation occurs via methylene tetrahydrofolate and the serine cycle. In strain CC495, which is one of the chloromethane utilizers that classes near rhizobia, evidence is presented for a bisulfide-coupled reaction in which methanethiol is the product (Coulter, 1999). In that case, it has been proposed that methanethiol is oxidized to formaldehyde, and metabolism proceeds by general methylotrophic pathways.

Formaldehyde Oxidation

Although it is theoretically possible for methylotrophs to grow on formaldehyde, this substrate is usually too toxic to sustain growth in batch cultures. A few cultures of both methane and methanol utilizers have been reported to grow on formaldehyde (Whittenbury et al., 1981; Hirt et al., 1978), but the growth is poor and usually requires that the substrate be provided in the gas phase. *Arthrobacter* P1 has been grown in a formaldehyde-limited chemostat by first establishing cultures on choline, then adding low levels of formaldehyde, and finally eliminating the choline gradually (Levering et al., 1986). It seems likely that other methylotrophs could be grown on formaldehyde using a similar technique.

A number of formaldehyde oxidation systems are known in methylotrophs (Figs. 4 and 5). The simplest of these is formaldehyde dehydrogenase, which converts formaldehyde to formate. A number of NAD-linked and dye-linked (presumably PQQ-containing and cytochrome-linked) formaldehyde dehydrogenases have been identified from methylotrophs, but the low activity and general lack of inducibility of these

NAD NADH$_2$

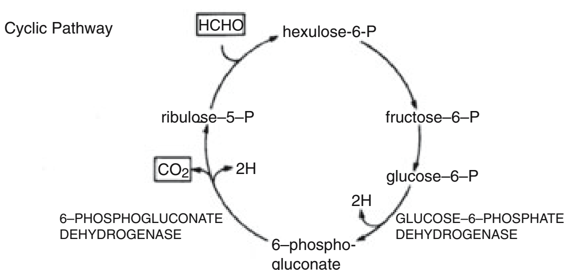

Fig. 5. Cyclic pathway of formaldehyde oxidation, involving enzymes of the RuMP pathway. Adapted from Anthony (1982).

enzymes has called their physiological role into question (Hirt et al., 1978; Stirling, 1978; Anthony, 1982; Marison and Attwood, 1982; Weaver and Lidstrom, 1985; Van Ophem and Duine, 1990; Chistoserdova et al., 1991; Attwood et al., 1992; Speer et al., 1994). It is likely that these enzymes are involved in formaldehyde detoxification rather than playing a major dissimilatory role (Chistoserdova et al., 1991; Vorholt et al., 1999).

NAD- and Mycothiol-Linked Formaldehyde Dehydrogenase

Recent studies have suggested that alternate routes are involved in formaldehyde dissimilation. In Gram-positive methylotrophs, the major formaldehyde dehydrogenase appears to be an enzyme that had previously been described as NAD-linked factor-dependent formaldehyde dehydrogenase (Van Ophem et al., 1992; Van Ophem and Duine, 1994; Duine,

1999; Fig. 4). It is now known that this factor is mycothiol (1-*O*-(2′-[*N*-acetyl-L-cysteinyl]amido-2′-deoxy-α-D-glucopyranosyl)-D-myoinositol), a compound also found in *Mycobacterium* strains (Misset-Smiths et al., 1997; Duine, 1999). This trimeric enzyme consists of a single type of subunit containing Zn (Van Ophem et al., 1992).

NAD- and GSH-Linked Formaldehyde Dehydrogenase

An analogous enzyme coupled to glutathione (GSH) is involved in formaldehyde dissimilation in a variety of Gram-negative methylotrophs, including *Paracoccus* and *Rhodobacter* (Ras et al., 1995; Harms et al., 1996; Barber and Donohue, 1998; Fig. 4). In this case, two enzymes act in concert, an NAD- and GSH-linked dehydrogenase that generates the formyl-GSH derivative, and a hydrolase that releases GSH and formate. Analysis of the genes encoding these enzymes (*flh* genes) suggests they are similar to genes involved in formaldehyde detoxification in a variety of organisms (Harms et al., 1996; Barber and Donohue, 1998).

Folate-Linked Formaldehyde Oxidation Pathways

Two additional linear formaldehyde oxidation pathways are known in methylotrophs, both linked to folates. The first of these involves a standard tetrahydrofolate (H_4F) oxidation pathway, similar to the C_1 interconversion pathways found in most organisms, which oxidizes methylene tetrahydrofolate to formate and tetrahydrofolate (Fig. 4). This pathway was suggested to be the major dissimilatory route for formaldehyde oxidation in serine cycle methylotrophs (Marison and Attwood, 1982). However, in *Methylobacterium extorquens* AM1, this pathway appears to be a minor one (Chistoserdova et al., 1998). In addition, the methylene H_4F dehydrogenase is unusual for bacteria, in that it only carries out this first step instead of both steps as does the normal, coupled enzyme (encoded by *folD*). The gene sequence is highly divergent from other methylene H_4F dehydrogenases (Chistoserdova and Lidstrom, 1994b), and *Methylobacterium extorquens* also contains an unusual methenyl H_4F cyclohydrolase (Pomper et al., 1999).

The major dissimilatory pathway has been suggested to be an analogous tetrahydromethanopterin-linked (H_4MPT-linked) pathway (Fig. 4), similar to that found in the archeaon *Archaeoglobus fulgidis*, and to the reversal of the first few steps of the CO_2 reduction pathway found in archaeal methanogens. This pathway involves a cofactor that had been thought to be specific to archaea, tetrahydromethanopterin (H_4MPT), and the genes encoding the archaeal-like enzymes show significant identity to the corresponding archaeal genes (Chistoserdova et al., 1998). Therefore, it has been suggested that this pathway was acquired by an early methylotroph by horizontal gene transfer from an archaea (Chistoserdova et al., 1998). The archaeal H_2- or F_{420}- enzymes that interconvert methylene and methenyl H_4MPT are not found in the aerobic methylotrophs. Instead, two enzymes have been identified that oxidize methylene H_4MPT to methenyl H_4MPT, one linked to NAD and the other to NADP (Vorholt et al., 1998; Hagemeier et al., 2000). The NAD-linked enzyme is specific to H_4MPT and shows similarity to the NADP-linked enzyme (Hagemeier et al., 2000). The NADP-linked enzyme has activity with both H_4MPT and H_4F, although the activity with the latter is 10% that of the former, and it appears to be the only methylene H_4F-dehydrogenase during methylotrophic growth (Vorholt et al., 1998). Activity and genes are present for methanofuran-utilizing enzymes, but no evidence exists for the presence of methanofuran in methylotrophs. Therefore, the details of the final oxidation step in this pathway are still not known.

Cyclic Formaldehyde Oxidation Pathway

Another formaldehyde pathway is cyclic and involves the condensation of the C_1 compound with a five-carbon acceptor molecule, followed by oxidation of the resulting six-carbon compound (Fig. 5). The enzymes carrying out these reactions are those of the ribulose monophosphate cycle for formaldehyde assimilation, with the exception of one novel enzyme, the 6-phosphogluconate dehydrogenase. A second enzyme is also needed, glucose-6-phosphate dehydrogenase, but this may or may not be a part of the RuMP cycle depending upon the variant utilized. These genes have been cloned and sequenced from *Methylobacillus flagellatum* (Chistoserdova et al., 2000). In those organisms that carry out the cyclic pathway of formaldehyde oxidation, glucose-6-phosphate dehydrogenase activity utilizes both NADP and NAD. However, in *Methylophilus methylotrophus* and *Methylobacillus flagellatum*, two different 6-phosphogluconate dehydrogenases have been found, one of which is active with both NADP and NAD, and the other specific for NAD only (Beardsmore et al., 1982; Kiriuchin et al., 1988). It has been speculated that the flow of carbon at the branch point between oxidation and assimilation in the cyclic pathway is regulated allosterically by these two isoenzymes (Beardsmore et al., 1982).

Distribution of Formaldehyde Oxidation Pathways in Methylotrophs

Although some methylotrophs appear to have only one dissimilatory formaldehyde oxidation pathway, others have multiple routes. Many methylotrophs contain low activities of one or more formaldehyde dehydrogenases, and these may play a largely protective role in formaldehyde detoxification. Of the main dissimilatory pathways, the mycothiol-linked formaldehyde dehydrogenase has so far been found only in Gram-positive methylotrophs (Duine, 1999). The GSH-linked formaldehyde oxidation system has been found mainly in the Gram-negative autotrophic methylotrophs (Harms, 1996; Barber and Donohue, 1998), whereas the H_4F-linked pathway is found in the serine cycle methylotrophs (Vorholt et al., 1999). The cyclic formaldehyde oxidation pathway occurs mainly in the obligate methylotrophs containing the RuMP cycle (Anthony, 1982; Grundig and Babel, 1987). Although it also is found in *Arthrobacter* P1 (Levering et al., 1981), it has been found not to be effective in formaldehyde resistance and may not be a major dissimilatory pathway (Grundig and Babel, 1989). Likewise, although enzyme activities of both pathways exist in the obligate methanotrophs containing the RuMP cycle, the low activities of the glucose-6-phosphate and 6-phosphogluconate dehydrogenases suggest that an alternate pathway must dominate in vivo (Zatman, 1981). This latter conclusion is supported by the fact that the H_4MPT-linked pathway is found in both serine-cycle and RuMP-cycle methanotrophs, at high activity (Vorholt et al., 1999). This pathway has a broad distribution, being found in all tested Gram-negative methylotrophs with either the serine cycle or the RuMP cycle (Vorholt et al., 1999). It was not found in the Gram-positive methylotrophs tested, nor in most of the autotrophic methylotrophs. However, it was present in the autotrophic *Xanthobacter* strains (Vorholt et al., 1999). These results suggest that methylotrophs either have one of the thiol-linked formaldehyde oxidation systems (mainly Gram-positive and autotrophic methylotrophs), or they have the H_4MPT-linked formaldehyde oxidation system (all other methylotrophs). In addition, they may have the H_4F-linked pathway or the cyclic oxidation pathway. In the β-proteobacterial obligate-RuMP-cycle methylotroph *Methylobacillus flagellatum* KT, mutational analysis suggested that the cyclic oxidation pathway was the major dissimilatory pathway, whereas the H_4MPT-linked pathway played a detoxification role (Chistoserdova et al., 2000). An analysis of partial sequences of genes encoding one of the diagnostic enzymes for the H_4MPT-linked pathway, methenyl H_4MPT cyclohydrolase, showed that the bacterial genes grouped in a cluster separate from the cluster of archaeal genes, and the branching pattern for the bacterial genes roughly mirrored the branching pattern of the 16S rRNA genes (Vorholt et al., 1999).

Formate Oxidation

In methylotrophs that have one of the linear oxidation pathways, formate is generally thought to be oxidized to CO_2 by an NAD-linked formate dehydrogenase (Anthony, 1982). Two classes of soluble formate dehydrogenase have been identified in methylotrophs, a dimeric enzyme described in a *Mycobacterium* strain (Galkin, 1995) and in an unidentified Gram-negative methylotroph (Lamzin et al., 1992); these show similar properties and gene sequences (Galkin et al., 1995). However, most methylotrophs appear to have an enzyme (composed of 4 subunits, containing iron, molybdenum and flavin; Jollie and Lipscomb, 1991) similar in properties and at the gene sequence level to a formate dehydrogenase found in *Ralstonia eutropha* (Friedebold and Bowien, 1993). A membrane-bound formate dehydrogenase has been reported in *Amycolatopsis methanolica*, but it has not been characterized (Khmelenina et al., 1997).

No mutants have been reported in formate dehydrogenase in a methylotroph, and so the physiological role of this enzyme has not yet been confirmed.

Assimilatory Metabolism

Three main pathways of assimilatory metabolism are known in aerobic methylotrophs: two that assimilate carbon at the level of formaldehyde (the serine cycle and the ribulose monophosphate cycle), and one that assimilates carbon at the level of CO_2 (the Calvin-Benson-Bassham or CBB cycle). Both pathways for the assimilation of formaldehyde involve cycles in which a condensation reaction between a C_1 compound and a multicarbon compound occurs, followed by regeneration of the acceptor molecule and production of a C_3 compound (Figs. 1, 6 and 7).

Serine Cycle

The serine cycle for formaldehyde assimilation is shown in Fig. 6. This pathway initiates with the condensation of methylene tetrahydrofolate and glycine to form serine. This 3-carbon compound then undergoes a series of transformations to phosphoenolpyruvate, which is carboxylated to form malate. The malate is cleaved into two 2-carbon compounds, which are then converted

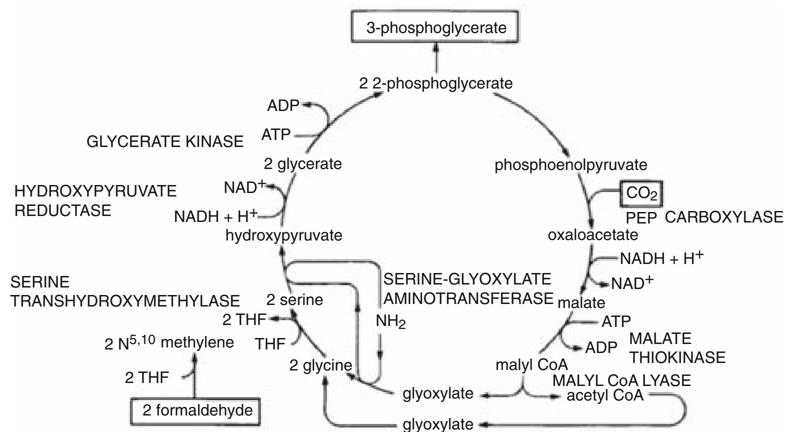

Fig. 6. The serine cycle for formaldehyde assimilation. Adapted from Anthony (1982).

back into glycine, thus completing the cycle. In most organisms that have the serine cycle, it is not clear how acetyl CoA is converted to glyoxylate. The usual route for this conversion involves isocitrate lyase, but this enzyme is only present in a few strains (Anthony, 1982; Chistoserdova and Lidstrom, 1996).

The enzymes specific to the serine cycle are noted in the figure and most of the genes encoding these enzymes have been cloned and sequenced from *Methylobacterium extorquens* AM1 (Chistoserdova and Lidstrom, 1994a; Chistoserdova and Lidstrom, 1994b; Chistoserdova and Lidstrom, 1996; Chistoserdova and Lidstrom, 1997) or *Hyphomicrobium methylovorum* (Yoshida et al., 1994; Hagishita et al., 1996; Tanaka et al., 1997). Two isoenzymes are known to exist for phosphenol pyruvate (PEP) carboxylase (Newaz and Hersh, 1975; McNerney and O'Connor, 1980). The C_1-specific PEP carboxylase is acetyl-CoA independent, unlike the classical acetyl-CoA-dependent anapleurotic enzyme (Newaz and Hersh, 1975), and the gene sequence for this enzyme is on the order of 30% identical to genes encoding the anapleurotic enzyme (Chistoserdova and Lidstrom, 1997). For each C_3 compound that is generated by the serine cycle two carbons are derived from formaldehyde and one from CO_2.

Ribulose Monophosphate Cycle

The ribulose monophosphate cycle (RuMP cycle) is shown in Fig. 7. Formaldehyde is condensed with the acceptor molecule (ribulose monophosphate) by the enzyme hexulose phosphate synthase to produce hexulose phosphate. The six-carbon molecule is then isomerized to fructose 6-phosphate by phosphohexulose isomerase, and a series of interconversions occur that regenerate the five-carbon acceptor molecule. The condensation of three formaldehyde molecules results in the net production of one C_3 compound (Anthony, 1982). As shown in Fig. 7, four different variants of the ribulose monophosphate pathway are possible. However, only three of the possible combinations have been shown to exist. In those obligate methylotrophs that use the RuMP pathway, the combination that appears to occur is that involving 6-P-gluconate (right) and not dihydroxyacetone phosphate (left). The two key enzymes for this variant are 2-keto, 3-deoxy, 6-phosphogluconate aldolase and transaldolase. In the facultative methylotrophs the existing evidence suggests that some strains such as *Bacillus* PM6 (Colby and Zatman, 1975) contain the combination involving fructose bisphosphate (center) and sedoheptulose bisphosphate (lower), and the two key enzymes in this case are fructose bisphosphatase and sedoheptulose bisphosphatase. Other facultative strains, such as *Arthrobacter* P1, contain the combination involving the enzymes fructose bisphosphatase (center) and transaldolase (left; Levering et al., 1982).

Genes encoding hexulose phosphate synthase and phosphohexuloisomerase (*rmpA* and *rmpB*) have been cloned and sequenced from both Gram-positive and Gram-negative methylotrophs (Yanase et al., 1996; Sakai et al., 1999; Mitsui et al., 2000). Surprisingly, genes with identity to hexulose phosphate synthase are common in non-methylotrophic bacteria and in archaea, and for the most part their role is not known (Reizer et al., 1997). However, *Bacillus subtilis* contains orthologs to both *rmpA* and *rmpB*, and evidence has been presented that these genes encode functional enzymes involved in protection of the cell from formaldehyde (Yasueda et al., 1999).

Those organisms that utilize the Calvin-Benson-Bassham pathway for CO_2 fixation appear to utilize the standard pathway without alternations (Anthony, 1982).

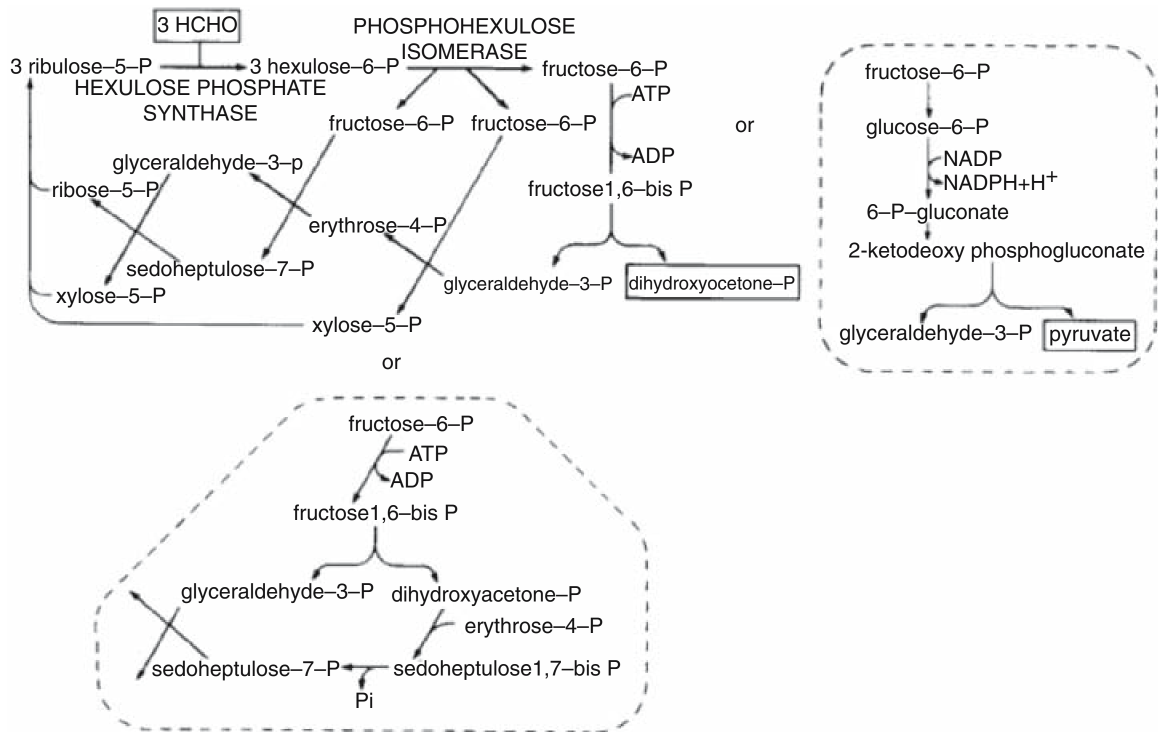

Fig. 7. The ribulose monophosphate (RuMP) cycle for formaldehyde assimilation, showing the two variants for cleavage and the two variants for acceptor regeneration. Adapted from Anthony (1982).

Methylotrophic Bacteria

Methanotrophs

Methanotrophs are a subgroup of the methylotrophic bacteria, which have the ability to grow on methane as sole carbon and energy source. They are found in most environments in which methane and O_2 meet, and have been isolated from a variety of environments including those with extremes of pH and temperature (Hanson and Hanson, 1996; Bodrossy et al., 1997; Bowman et al., 1997; Dedysh et al., 2000). They contain characteristic intracytoplasmic membrane systems (Hanson and Hanson, 1996), either stacks of membrane disks in the type I strains (γ-Proteobacteria), rings of membranes at the periphery of the cell in the type II strains (*Methylosinus* and *Methylocystis*), or vesicular membranes in *Methylocella* (Dedysh et al., 2000). So far, all well-studied methanotrophs have been obligate methylotrophs, unable to grow on compounds with C–C bonds, but reports have been made of a facultative *Mycobacterium* strain capable of growth on methane (Reed and Dugan, 1987) and a mutant of a type I methanotroph has been described that is capable of growth on glucose (Zhao and Hanson, 1984). Some methanotrophs are capable of growth on methanol (Anthony, 1982; Hanson and Hanson, 1996). Some methanotrophs contain nitrogenase and are capable of growth with N_2 as a nitrogen source, mainly *Methylococcus* and *Methylosinus* strains (Hanson and Hanson, 1996). Methanotrophs contain either the serine cycle or RuMP cycle, and so far no autotrophic methanotrophs have been identified (Table 1). Methanotrophs exist as symbionts in mussels, clams and *Pogonophora*, and although the 16S rRNA sequences class with type I methanotrophs, they have not yet been isolated in pure culture (Distel and Cavanaugh, 1994).

Non-Methane Utilizing Methylotrophs

The bacteria capable of growth on methanol and other methylated compounds but not on methane are more diverse than those capable of growing on methane. So far, all of the Gram-positive and α-proteobacterial strains are facultative methylotrophs, whereas the β-proteobacterial and γ-proteobacterial strains are either obligate methylotrophs or restricted facultative methylotrophs (capable of poor growth on a restricted range of multicarbon compounds; Anthony, 1982; Table 1). Most of these bacteria can grow on methanol and may grow on other methylated compounds, but a few strains are known that grow on methylated amines and in some cases also grow on other methylated compounds, but

do not grow on methanol (Anthony, 1982). These include the *Aminobacter* (Urakami et al., 1992) and some of the strains that grow on halogenated methanes (Hancock et al., 1998). The non-methane-utilizing methylotrophic bacteria do not generate intracytoplasmic membrane systems characteristic of the methanotrophs, with the exception of the photosynthetic membranes in the phototrophs. The phototrophs that grow on methanol use it as an electron donor for photosynthesis and in some cases as a carbon source (Quayle and Pfennig, 1975). A number of the Gram-negative methylotrophs contain nitrogenase and are capable of growth with N_2 as a nitrogen source (Table 1).

These bacteria are widely distributed in terrestrial, freshwater and marine habitats (Anthony, 1982). Bacteria capable of utilizing methylated amines are particularly prevalent in the marine environment where it is postulated that they may play a role in carbon cycling in the photic zone (Strand and Lidstrom, 1984). The pink-pigmented *Methylobacterium* strains are common epiphytes on plant leaves, and some evidence exists to suggest a mutualistic symbiosis (Holland and Polacco, 1994).

Genetics in Aerobic Methylotrophs

Genetic Capabilities

A variety of genetic capabilities are available in Gram-negative methylotrophic bacteria, mostly based on broad-host range vectors of the incompatibility (Inc)PI or IncQ groups, including both general cloning vectors and promoter probe vectors based on either *lacZ* or *xylE* as reporters (Holloway et al., 1987; Lidstrom and Sterling, 1990; Harms and van Spanning, 1991; De Vries et al., 1990; Barta and Hanson, 1993; Murrell et al., 2000). However, IncQ vectors are unstable in the *Methylobacterium* strains, and serve as suicide vectors (Biville et al., 1989). Targeted mutants can be generated from cloned genes by recombinational insertion in these strains using suicide vectors, most of them based on ColE1 replicons (Harms, 1996; Barta and Hanson, 1993; Chistoserdov and Lidstrom, 1994a; Murrell et al., 2000). The most common mode of transfer of these vectors into these methylotrophs is by conjugation using a helper plasmid, but electroporation protocols also have been reported for some of the non-methanotrophs (Ueda et al., 1991; Kim and Wood, 1997; Gliesche et al., 1997; Toyama et al., 1998). So far, electroporation has not been successful for methanotrophs (Murrell et al., 2000). Random transposon mutagenesis has been reported for a number of Gram-negative methylotrophs (Whitta et al., 1985; Gliesche and Hirsch, 1992; Studer, 1999; Kang et al., 1999), but not for methanotrophs (Murrell et al., 2000).

In the Gram-positive methylotrophs, cloning vectors have been developed for individual strains. The IncQ vectors and electroporation have been used for *Brevibacterium methylicum* (Nesvera et al., 1994), whereas in *Bacillus methanolicus* and *Amycolatopsis methanolica*, shuttle plasmids were developed using replicons from endogenous plasmids (Vrijbloed et al., 1995; Cue et al., 1997). In the latter two cases, genetic transformation systems were developed for vector transfer.

Genomics

A number of genome sequencing projects are underway for methylotrophic bacteria, including *Methylobacterium extorquens* AM1, *Methylococcus capsulatus* Bath, *Rhodopseudomonas palustris*, *Rhodobacter sphaeroides* and *Rhodobacter capsulatus*.

CHAPTER 1.21

Dissimilatory Fe(III)- and Mn(IV)-Reducing Prokaryotes

DEREK LOVLEY

Introduction

Dissimilatory Fe(III) reduction is the process in which microorganisms transfer electrons to external ferric iron [Fe(III)], reducing it to ferrous iron [Fe(II)] without assimilating the iron. A wide phylogenetic diversity of microorganisms, including archaea as well as bacteria, are capable of dissimilatory Fe(III) reduction. Most microorganisms that reduce Fe(III) also can transfer electrons to Mn(IV), reducing it to Mn(II).

As detailed in the next section, dissimilatory Fe(III) and Mn(IV) reduction is one of the most geochemically significant events that naturally takes place in soils, aquatic sediments, and subsurface environments. Dissimilatory Fe(III) and Mn(IV) reduction has a major influence not only on the distribution of iron and manganese, but also on the fate of a variety of other trace metals and nutrients, and it plays an important role in degradation of organic matter. Furthermore, dissimilatory Fe(III)-reducing microorganisms show promise as useful agents for the bioremediation of sedimentary environments contaminated with organic and/or metal pollutants. Despite their obvious environmental significance, Fe(III) and Mn(IV)-reducing microorganisms are among the least studied of any of the microorganisms that carry out important redox reactions in the environment.

The Fe(III)- and Mn(IV)-reducing microorganisms are also of intrinsically interesting because they have unique metabolic characteristics. Foremost is the ability of these microorganisms to transfer electrons to external, highly insoluble electron acceptors such as Fe(III) and Mn(IV) oxides, as well as extracellular organic compounds such as humic substances. Furthermore, microbiological and geological evidence suggests that dissimilatory Fe(III) reduction was one of the earliest forms of microbial respiration. Thus, insights into Fe(III) reduction mechanisms may aid in understanding the evolution of respiration in microorganisms.

Significance of Fe(III)- and Mn(IV)-Reducing Microorganisms

Some claims for the significance of Fe(III)-reducing microorganisms may be exaggerated, such as the assertion that “if it were not for the bacterium GS-15 [a Fe(III)-reducing microorganism] we would not have radio and television today” (Verschuur, 1993). However, it is also clear that Fe(III)-reducing microorganisms are of vitally important to the proper functioning of a variety of natural ecosystems and have practical applications. Detailed reviews of the literature covering many of these aspects of Fe(III) and Mn(IV) reduction are available (Lovley, 1987a; Lovley, 1991a; Lovley, 1993a; Nealson and Saffarini, 1994; Lovley, 1995a; Lovley et al. 1997c). Therefore only highlights of the significance of Fe(III)-reducing microorganisms, abstracted from these reviews, will be briefly summarized here.

Oxidation of Organic Matter in Anaerobic Environments

Microbial oxidation of organic matter coupled to the reduction of Fe(III) and Mn(IV) is an important mechanism for organic matter oxidation in a variety of aquatic sediments, submerged soils, and in aquifers. Depending on the aquatic sediments or submerged soils considered, Fe(III) and/or Mn(IV) reduction have been estimated to oxidize anywhere from 10% to essentially all of the organic matter oxidation in the sediments (Lovley, 1991a; Canfield et al., 1993; Lovley, 1995b; Lovley et al., 1997c). An important factor that enhances the significance of Fe(III) and Mn(IV) reduction in aquatic sediments is bioturbation which leads to the reoxidation of Fe(II) and Mn(II) so that each molecule of iron and manganese can be used as an electron acceptor multiple times prior to permanent burial. In deep pristine aquifers, there are often extensive zones exist in which Fe(III) reduction is the predominant mechanism for organic matter oxidation

(Chapelle and Lovley, 1992; Lovley and Chapelle, 1995c). The ability of Fe(III)-reducing microorganisms to outcompete sulfate-reducing and methanogenic microorganisms for electron donors during organic matter degradation is an important factor limiting the production of sulfides and methane in some submerged soils, aquatic sediments, and the subsurface (Lovley, 1991a; Lovley, 1995b).

A model for the oxidation of organic matter in sedimentary environments in which Fe(III) reduction is the predominant terminal electron-accepting process has been suggested (Lovley et al., 1997c). This model is based upon the known physiological characteristics of Fe(III)- and Mn(IV)-reducing microorganisms available in pure culture as well as on studies on the metabolism of organic matter metabolism by natural communities of microorganisms living in various sedimentary environments in which Fe(III) reduction is the terminal electron-accepting process (TEAP). In this model (Fig. 1), complex organic matter is hydrolyzed to simpler components by the action of hydrolytic enzymes from a variety of microorganisms. Fermentative microorganisms are the principal consumers of fermentable compounds such as sugars and amino acids and these compounds are converted primarily to fermentation acids and, possibly to hydrogen. Acetate is by far the most important fermentation acid produced (Lovley and Phillips, 1989a). Acetate also may be produced as the result of incomplete oxidation of some sugars by some Fe(III)-reducing microorganisms (Coates et al., 1999a). Other Fe(III)-reducing microorganisms oxidize the acetate and other intermediary products. Some Fe(III)-reducing microorganisms also can oxidize aromatic compounds and long-chain fatty acids. Thus, through the activity of diverse microorganisms, complex organic matter can be oxidized to carbon dioxide with Fe(III) serving as the sole electron acceptor. A similar model probably is probably appropriate for organic matter oxidation in sediments in which Mn(IV) reduction is the TEAP. This model emphasizes that acetate is likely to be the major electron donor for Fe(III) or Mn(IV) reduction in environments in which naturally occurring, complex organic matter is the major substrate for microbial metabolism. However, when otherwise organic-poor environments, such as sandy aquifers, are contaminated with a specific class of organic compounds, such as aromatics, then these contaminants may be the most important direct electron donors for Fe(III) or Mn(IV) reduction.

Influence on Metal and Nutrient Geochemistry and Water Quality The reduction of Fe(III) to Fe(II) is one of the most important geochemical changes as anaerobic conditions develop in submerged soils and aquatic sediments (Ponnamperuma, 1972). The Fe(II) produced as the result of Fe(III) reduction is the primary reduced species responsible for the negative redox potential in many anaerobic freshwater environments. The reduction of Fe(III) oxides and of the structural Fe(III) in clays typically results in a change in soil color from the red-yellow of Fe(III) forms to the green-gray of Fe(II) minerals (Lovley, 1995c). The oxides of Fe(III) and Mn(IV) oxides bind trace metals, phosphate, and sulfate, and Fe(III) and Mn(IV) reduction is associated with the release of these compounds into solution (Lovley, 1995a). Also, typically the pH, ionic strength of the pore water, and the concentration of a variety of cations are increased (Ponnamperuma, 1972; 1984). All of these changes influence water quality in aquifers and can affect the growth of plants in soils.

The solubility of Fe(II) and Mn(II) is greater than that of Fe(III) and Mn(IV) and thus Fe(III) and Mn(IV) reduction result in an increase in dissolved iron and manganese in pore waters. Undesirably high concentrations of iron and manganese may be toxic to plants (Lovley, 1995b) and are particularly significant in groundwaters sources of drinking water, being one of the most prevalent groundwater quality problems (Anderson and Lovley, 1997).

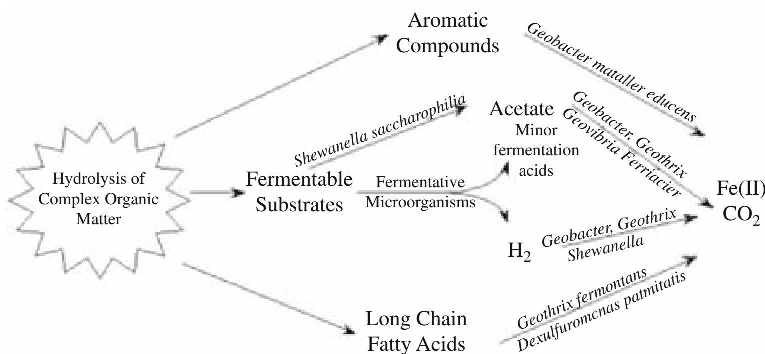

Fig. 1. Proposed pathways for organic matter degradation in mesophilic environments in which Fe(III) reduction is the predominant terminal electron-accepting process.

Most of the Fe(II) and Mn(II) produced from microbial Fe(III) and Mn(IV) reduction is found in solid phases, often in the form of Fe(II) and Mn(II) minerals of geochemical significance (Lovley, 1995c). The most intensively studied mineral that is formed during microbial Fe(III) reduction is the magnetic mineral magnetite (Fe_3O_4) (Lovley et al., 1987c; Lovley, 1990a; Lovley, 1991a). The magnetite produced during microbial Fe(III) reduction can be an important geological signature of this activity. For example, large quantities of magnetite at depths up to 6.7 km below the Earth's surface provided some of the first evidence for a deep, hot biosphere (Gold, 1992). The massive magnetite accumulations that comprise the Precambrian Banded Iron Formations provide evidence for the possible activity of Fe(III)-reducing microorganisms on early Earth. Formation of magnetite as the result of microbial Fe(III) reduction may contribute to the magnetic remanence of soils and sediments. The magnetic anomalies that aid in the localization of subsurface hydrocarbon deposits may result from the activity of hydrocarbon-degrading Fe(III) reducers. Formation of other Fe(II) and Mn(II) minerals such as siderite ($FeCO_3$) and rhodochrosite ($MnCO_3$) also may provide geological signatures of microbial Fe(III) and Mn(IV) reduction.

As detailed below, many Fe(III)- and Mn(IV)-reducing microorganisms can use other metals and metalloids as electron acceptors. Microbial reduction of the soluble oxidized form of uranium, U(VI), to insoluble U(IV) may be an important mechanism for the formation of uranium deposits and the reductive sequestration of uranium in marine sediments, the process which prevents dissolved uranium from building up in marine waters (Lovley et al., 1991a; Lovley and Philips, 1992). Reduction of other metals such as vanadium, molybdenum, copper, gold, and silver, as well as metalloids such as selenium and arsenic, can affect the solubility and fate of these compounds in a variety of sedimentary environments and may contribute to ore formations (Lovley, 1993a; Oremland, 1994a; Newman et al., 1998; Kashefi and Lovley, 1999).

Bioremediation of Organic and Metal Contaminants Iron [Fe(III)]-reducing microorganisms have been shown to play a major role in removing organic contaminants from polluted aquifers. For example, Fe(III)-reducing microorganisms naturally remove aromatic hydrocarbons from petroleum-contaminated aquifers (Lovley et al., 1989b; Lovley, 1995c; Lovley, 1997a; Anderson et al., 1998) and this process can be artificially enhanced with compounds that make Fe(III) more available for microbial reduction (Lovley et al., 1994a; Lovley, 1997a). The Fe(II)-minerals formed as the result of microbial Fe(III) reduction can be important reductants for the reduction of nitroaromatic contaminants (Heijman et al., 1993; Hofstetter et al., 1999). Minerals containing Fe(II) also may serve to reductively dechlorinate some chlorinated contaminants (Fredrickson and Gorby, 1996).

The ability of Fe(III)-reducing microorganisms to substitute other metals and metalloids in their respiration may be exploited for remediation of metal contamination (Lovley, 1995a; Lovley, 1995b; Fredrickson and Gorby, 1996; Lovley and Coates, 1997b). Reduction of soluble U(VI) to insoluble U(IV) can effectively precipitate uranium from contaminated groundwaters and surface waters. Microbial uranium reduction can be coupled with a simple soil-washing procedure to concentrate uranium from contaminated soils. Iron [Fe(III)]-reducing microorganisms can precipitate technetium from contaminated waters by reducing soluble Tc(VII) to insoluble Tc(IV). Soluble radioactive Co(III) complexed to EDTA can be reduced to Co(II) which is less likely to be associated with the EDTA found in contaminated groundwaters and more likely to adsorb to aquifer solids. Some Fe(III) reducers convert soluble, toxic Cr(VI) to less soluble less toxic Cr(III). Reduction of soluble selenate to elemental selenium can effectively precipitate selenium in sediments or remove selenate from contaminated waters in bioreactors.

A Possible Early Form of Microbial Respiration Iron [Fe(III)] reduction may have been one of the earliest forms of microbial respiration (Vargas et al., 1998). Biological evidence for this hypothesis is the finding from 16S rRNA phylogenies that all of microorganisms that are the most closely related to the last common ancestor of extant microorganisms are Fe(III)-reducing microorganisms. All of the deeply branching bacteria and archaea that have been examined can oxidize hydrogen with the reduction of Fe(III). Several that have been examined in more detail can conserve energy to support growth from this metabolism. Of most interest in this regard is *Thermotoga maritima*, which was previously considered to be a fermentative organism because it could not conserve energy to support growth from the reduction of other commonly considered electron acceptors. However, *T. maritima* it does grow via Fe(III) respiration. This result and the apparent conservation of the ability to reduce Fe(III) in all these deeply branching organisms suggests that the last common ancestor was a hydrogen-oxidizing, Fe(III)-reducing microorganism.

The concept that Fe(III) reduction is an early form of respiration agrees with geological scenarios that suggest the presence of large quanti-

ties of Fe(III) on prebiotic Earth (Cairns-Smith et al., 1992; de Duve, 1995) and elevated hydrogen levels (Walker, 1980)—conditions that would be conducive to the evolution of a hydrogen-oxidizing, Fe(III)-reducing microorganism. The large accumulations of magnetite in the Precambrian iron formations (discussed above) indicate that the accumulation of Fe(III) on prebiotic Earth was biologically reduced early in the evolution of life on Earth. This and other geochemical considerations suggest that Fe(III) reduction was the first globally significant mechanism for organic matter oxidation (Walker, 1987; Lovley, 1991a).

Fe(III)- and Mn(IV)-Reducing Microorganisms Available in Pure Culture

Dissimilatory Fe(III)- and Mn(IV)-reducing microorganisms can be separated into two major groups, those that support growth by conserving energy from electron transfer to Fe(III) and Mn(IV) and those that do not. Early investigations on Fe(III) and Mn(IV) reduction in pure culture were conducted exclusively with organisms that are not considered to be conservers of energy from Fe(III) or Mn(IV) reduction (Lovley, 1987a). However, within the last decade, a diversity of microorganisms has been described in which Fe(III) and Mn(IV) reduction are linked to respiratory systems capable of ATP generation. It is these Fe(III)- and Mn(IV)-respiring microorganisms (abbreviated here as FMR) that are likely to be responsible for most of the Fe(III) and Mn(IV) reduction in many sedimentary environments (Lovley, 1991a). A brief description of the known metabolic and phylogenetic diversity of dissimilatory Fe(III)- and Mn(IV)-reducing microorganisms follows.

Fermentative Fe(III)- and Mn(IV)-Reducing Microorganisms Many microorganisms which grow via fermentative metabolism can use Fe(III) or Mn(IV) as a minor electron acceptor during fermentation (Table 1). Growth is possible in the absence of Fe(III) or Mn(IV). In this form of Fe(III) and Mn(IV) reduction, most of the electron equivalents in the fermentable substrates are recovered in organic fermentation products and hydrogen. Typically, less than 5% of the reducing equivalents are transferred to Fe(III) or Mn(IV) (Lovley, 1987a; Lovley and Phillips, 1988b). However, significant amounts of Fe(II) and Mn(II) can accumulate in cultures of these fermentative organisms when Fe(III) or Mn(IV) is provided as a potential electron sink. Although thermodynamic calculations have demonstrated that fermentation with Fe(III) reduction [electron transfer to Fe(III)] is more energetically favorable than fermentation without Fe(III) reduction (Lovley and Phillips, 1989a), it has not been demonstrated that the minor transfer of electron equivalents to Fe(III) or Mn(IV) during fermentation causes any increase in cell yield. In contrast to these fermentative microorganisms, several microorganisms can partially or completely oxidize fermentable sugars and amino acids with the reduction of Fe(III) and conserve energy from this metabolism, as discussed below.

Sulfate-Reducing Microorganisms Many respiratory microorganisms that grow anaerobically with sulfate serving as the electron acceptor also have the ability to enzymatically reduce iron [Fe(III); Table 1]. Electron donors that support Fe(III) reduction are the same ones that support sulfate reduction by sulfate-reducing microorganisms. However, none of these sulfate reducers have been shown to grow with Fe(III) serving as the sole electron acceptor (Lovley et al., 1993b). This is true despite the fact that sulfate reducers have a higher affinity for hydrogen, and possibly for other electron donors, than for sulfate when Fe(III) serves as the electron acceptor (Coleman et al., 1993; Lovley et al., 1993c).

The advantage to sulfate reducers in reducing Fe(III), if there is one, has not been thoroughly investigated. Because it has been found that the intermediate electron carrier, cytochrome c_3, can function as an Fe(III) reductase (Lovley et al., 1993), intermediate electron carriers involved in sulfate reduction may inadvertently reduce Fe(III) because it has been found that the intermediate electron carrier, cytochrome c_3 can function as an Fe(III) reductase (Lovley et al., 1993b). Alternatively, Fe(III) reduction by sulfate reducers may be a strategy to hasten Fe(III) depletion and enhance conditions for sulfate reduction. Furthermore, the possibility that sulfate-reducing microorganisms may be able to generate ATP as the result of Fe(III) reduction, even if they can not grow with Fe(III) as the sole electron acceptor, has not been ruled out (Lovley et al., 1993c).

In contrast to the sulfate-reducing microorganisms discussed above, which could not be grown with Fe(III) as the sole electron acceptor, it has been suggested (Tebo and Obraztsova, 1998) that the sulfate-reducing microorganism "Desulfotomaculum reducens" could also conserve energy to support growth by reducing Fe(III), Mn(IV), U(VI), and Cr(VI) (Tebo and Obraztsova, 1998). However, the data supporting the claim that energy is gained from electron transport to metals is curious. For example, when the culture was grown on 400 μM U(VI), the cell yield was greater than when the culture reduced 8 mmol Fe(III). This occurs despite the fact that the number of electrons transferred to Fe(III)

Table 1. Organisms known to reduce Fe(III) but not known to conserve energy from Fe (III) reduction.

Organism	Electron donor	Form of Fe(III) reduced[a]	Reference
Fermentative bacteria

[a]Fe(III) forms: Poorly crystalline Iron Oxide (PCIO), Ferric citrate [Fe(III)-Cit], Ferric nitriloacetic acid [Fe(III)-NTA], Ferric pyrophosphate [Fe(III)-P], Fe(III) chloride [Fe(III)-Cl_3].

was ten-fold higher than the electron transfer to U(VI) and that Fe(III) reduction is energetically more favorable than U(VI) reduction. Cell yields with metals as the electron acceptor were comparable to those during sulfate reduction even though electron transfer to sulfate was at least 250-fold, and in some instances 2500-fold, greater than electron transfer to the metals. These results suggest that the presence of the metals had some additional influence on growth other than just serving as an electron acceptor.

Several sulfate-reducing microorganisms can oxidize S° to sulfate, with Mn(IV) serving as the electron acceptor, but were not found to conserve energy to support growth from this reaction (Lovley and Phillips, 1994a). Enrichment cultures that are established at circumneutral pH with S° as the electron donor and Mn(IV) or Fe(III) as the electron acceptor typically yield microorganisms which that disproportionate S° to sulfate and sulfide (Thamdrup et al., 1993). The Fe(III) or Mn(IV) serve to abiotically reoxidize the sulfide produced.

Microorganisms that Conserve Energy to Support Growth from Fe(III) and Mn(IV) Reduction

The Fe(III)- and Mn(IV)-respiring microorganisms (FMR) which are known to conserve energy to support growth from Fe(III) and Mn(IV) reduction (Table 2) are phylogenetically (Fig. 2) and morphologically (Fig. 3) diverse. Most of the FMR grow by oxidizing organic compounds or hydrogen with the reduction of Fe(III) or Mn(IV), but S° oxidation coupled to Fe(III) reduction also can provide energy to support growth of microorganisms growing at low pH. The various types of FMR are briefly described below.

Geobacteraceae Most of the known FMR, available in pure culture, that can oxidize organic compounds completely to carbon dioxide with Fe(III) or Mn(IV) serving as the sole electron acceptor are in the family *Geobacteraceae* in the delta *δ-Proteobacteria* (Fig. 2; Table 2). The family *Geobacteraceae* is comprised of the genera *Geobacter*, *Desulfuromonas*, *Desulfuromusa* and *Pelobacter.* With the exception of the *Pelobacter* species, all of the *Geobacteraceae* genera contain microorganisms that oxidize acetate to carbon dioxide. This metabolism is significant because, as discussed above, acetate is probably the primary electron donor for Fe(III) reduction in most sedimentary environments. Many of these *Geobacteraceae* also can use hydrogen as an electron donor for Fe(III) reduction. Various species in the *Geobacteraceae* oxidize a variety of other organic acids, including in some instances long-chain fatty acids (Table 2). Several species of *Geobacter* have the ability to anaerobically oxidize aromatic compounds, including the hydrocarbon toluene.

Fig. 2. Phylogenetic tree, based on 16S rDNA sequences, of microorganisms known to conserve energy to support growth from Fe(III) reduction. The tree was inferred using the Kimura two-parameter model in TREECON for Windows (Van der Peer and De Wachter, 1994). Bootstrap values at nodes were calculated from one hundred replicates.

Table 2. Organisms known to conserve energy to support growth from Fe(III) reduction.

Organism	Source	Electron donors oxidized with Fe(III)[a]	Oxidation with Fe(III)[b]	Fe forms reduced[c]	Other electron acceptors[d]	Growth Temp (°C)	Morphology	Reference[e]
Aeromonas hydrophila	Freshwater and sewage	Glyc, Lac, Succ	Complete	PCIO, Fe(III)-Cit	U(VI), Co(III), selenate, nitrate, Fum, O_2	37	Rod	Knight and Blakemore, 1998
Bacillus infernus	Deep subsurface	For, Lac	Incomplete	Fe(III)-Cl_3	Mn(IV), nitrate, TMAO	60	Rod	Boone et al., 1995
Deferribacter thermophilus	North Sea oil field	Ac, CAA, H_2, Lac, Mal, Pept, Pyr, Succ, Try, Valr, YE	ND[f]	PCIO, Fe(III)-Cit	Mn(VI), nitrate	60	Rod	Greene et al., 1997
Desulfuromonas acetexigens	Anoxic muds	Ac	Complete	PCIO	Mn(VI), S°, polysulfides, Fum, Mal	30	Rod	Coates et al., 1995
Desulfuromonas acetoxidans	Marine sediments	Ac, BtOH, EtOH Prop, Pyr	Complete	Fe(III)-Cit, Fe(III)-NTA	Mn(IV), Glut, Mal, Fum	30	Rod	Roden and Lovley, 1993
Desulfuromonas chloroethenica	Freshwater sediments	Ac, Pyr	ND	Fe(III)-NTA	PCE, TCE, Fum, S^{2-}	21–31	Rod	Krumholz, 1997
Desulfuromonas palmitatis	Marine sediments	Ac, Fum, Lac, Lau, Pal, Ste, Succ	Complete	PCIO, Fe(III)-Cit, Fe(III)-NTA, Fe(III)-P	Mn(IV), AQDS, S^0, Fum	40	Rod	Coates et al., 1995
Desulfuromusa bakii	Marine and freshwater muds	Ac	Complete	Fe(III)-NTA	S°, Mal, Fum	25	Rod	Lonergan et al., 1996
Desulfuromusa kysingii	Freshwater anoxic muds	Ac	Complete	Fe(III)-Cit, Fe(III)-NTA	S°, Mal, Fum, DMSO, nitrate	30	Rod	Liesack and Finster, 1994 Lonergan et al., 1996
Desulfuromusa succinoxidans	Marine sediments	Ac	Complete	Fe(III)-NTA	S°, Mal, Fum	30	Rod	Lonergan et al., 1996
Ferribacterium limneticum	Mine-impacted lake sediments	Ac	Complete	PCIO, Fe(III)-P	Nitrate, Fum	25	Rod	Cummings et al., 1999
Ferrimonas Balearica	Marine sediments	Lac	ND	PCIO, Fe(III)-Cit	Mn(IV), Nitrate	37	Rod	Rossello-Mora et al., 1995
"*Geobacter akaganeitreducens*"	Freshwater ditch	Ac, EtOH, For, Fum, H_2, Mal, Prop, PrOH, Pyr, Succ	ND	PCIO, Akaganeite	Mn(IV), S°, Fum, Mal	30	Rod	Straub et al., 1998
"*Geobacter arculus*"	Freshwater ditch	Ac, BtOH, Buty, Bzo, EtOH, For, Fum, H_2, Lac, Mal, Prop, PrOH, Pyr, Succ	ND	PCIO	Mn(IV), S^0, Fum, Mal	30	Rod	Straub et al., 1998
"*Geobacter chapellei*" (strain 172)	Deep subsurface	Ac, EtOH For, Lac	Complete	PCIO, Fe-NTA,	Mn(IV), AQDS, Fum	25	Rod	Coates et al., 1996
"*Geobacter grbicium*" (strain TACP-2)	Aquatic sediments	Ac, Buty, EtOH, For, Prop, Pyr	Complete	PCIO, Fe(III)-Cit	AQDS	30	Rod	Coates et al., 1996

[a]Abbreviations for electron donors and acceptors: Acetate(Ac), Anthraquinone-2,6-disulfonic acid (AQDS), Alanine(Ala), Aspartate (Asp), Benzaldehyde (Bz), Benzoate(Bzo), Benzylalcohol (BzOH), 1,2 butanediol (1,2 Bu), Butanol (BtOH), Butyrate (Buty), Casamino acids (CAA), Casein (Cas), Cystine (Cyst), Dimethylsulfoxide (DMSO), Ethanol (EtOH), Formate (For), Fumarate (Fum), Gelatin (GE), Glucose (Glu), Glutamate (Glu), Glutathione, oxidized (Glut), Glycerol (Glyc), *p*-hydroxybenzoate (*p*-HB), *p*-hydroxybenzaldehyde (*p*-HBz), *p*-hydroxybenzylalcohol (*p*-HBzOH), *p*-cresol (*p*-Cr), Hydrogen (H_2), Inositol (Ino), Isobutyrate (IsoB), Isovalerate (IsoV), Lactate (Lac), Laurate (Lau), Malate (Mal), Maleate (Mle), Nitriloacetic acid (NTA), Oxaloacetate (OAA), Palmitate (Pal), Peptone (Pept), Phenol (Ph), Proline (Pro), Propanol (PrOH), Propionate (Prop), Pyruvate (Pyr), Ribose (Rib), Stearate (Ste), Succinate (Succ), Sucrose (Suc), Tetrachloroethylene (PCE), Trichloroethylene TCE), Toluene (Tol), Trimethylene oxide (To), Trimethylamine oxide (TMAO), Tryptone (Try), Valerate (Valr), Yeast extract (YE), Xylose (Xyl).

[b]Complete oxidation of multicarbon compounds to CO_2, or incomplete, typically to acetate.

[c]Fe(III) forms: Poorly crystalline iron oxide (PCIO), ferric citrate [Fe(III)-cit]; ferric nitriloacetic acid, [Fe(III)-NTA]; ferric pyrophosphate, [Fe(III)-P]; Fe(III) chloride, [Fe(III)-Cl_3]; Fe(III) ethylenediamine-tetraacetic acid.

[d]* Organism has the ability to reduce the metal but not determined whether energy to support growth is conserved from reduction of this metal.

[e]Reference in which the capacity to grow via Fe(III) reduction is described.

[f]ND = Not determined.

Superscript for electron acceptors if growth occurs.

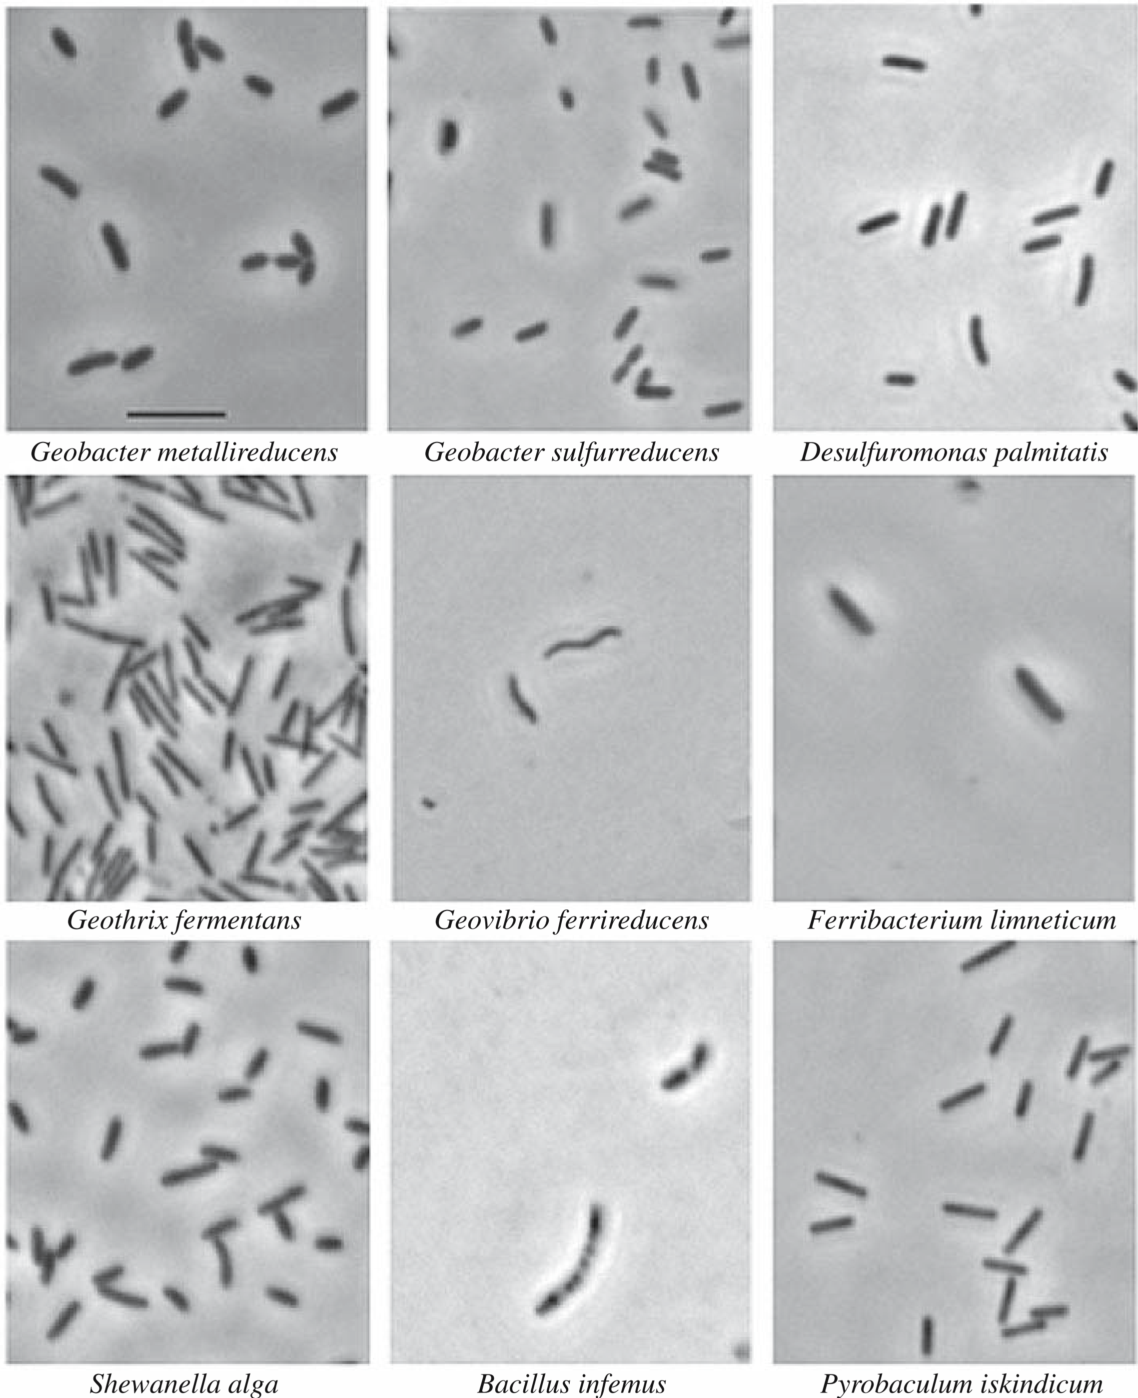

Fig. 3. Phase contrast micrographs of various organisms that conserve energy to support growth from Fe(III) reduction. Bar equals 5 μm, all micrographs at equivalent magnification.

Geobacteraceae are the Fe(III) reducers most commonly recovered from a variety of sedimentary environments when the culture media contains acetate as the electron donor and Fe(III) oxide or the humic acid analog, anthraquinone-2,6-disulfonate (AQDS) as the electron acceptor (Coates et al., 1996; Coates et al., 1998). Furthermore, analysis of 16S rDNA sequences in sandy aquifer sediments in which Fe(III) reduction was the predominant terminal electron accepting process indicated that *Geobacter* species were a major component of the microbial community

(Rooney-Varga et al., 1999; Synoeyenbos-West et al., 1999).

Geothrix *Geothrix fermentans* and closely related strains have been recovered from the Fe(III)-reducing zone of petroleum-contaminated aquifers (Anderson et al., 1998; Coates et al., 1999b). Like *Geobacter* species, *G. fermentans* can oxidize short-chain fatty acids to carbon dioxide with Fe(III) serving as the sole electron acceptor. It can also use long-chain fatty acids, as well hydrogen as an electron donor for Fe(III) reduction (Table 2) and can grow fermentatively on several organic acids. *G. fermentans*, along with *Holophaga foetida*, is part of a deeply branching group in the kingdom *Acidobacterium*. The 16S rDNA sequences from this kingdom are among the most common recovered from soil, but few organisms from this kingdom have been cultured (Barns et al., 1999). Studies in which Fe(III)-reducing microorganisms were recovered in culture media suggested that organisms closely related to *G. fermentans* might be as numerous as *Geobacter* species in the Fe(III) reduction zone of a petroleum-contaminated aquifer (Anderson et al., 1998). However, analyses of 16S rDNA sequences have indicated that *Geothrix* sp. are probably several orders of magnitude less numerous than *Geobacter* species in such environments (Rooney-Varga et al., 1999; Synoeyenbos-West et al., 1999).

Geovibrio ferrireducens and Deferribacter thermophilus Culturing from hydrocarbon-impacted soils and a petroleum reservoir have led to the recovery of the mesophile, *Geovibrio ferrireducens* (Caccavo et al., 1996) and the thermophile, *Deferribacter thermophilus* (Greene et al., 1997). These organisms are more closely related to each other than to any other known Fe(III)-reducing microorganisms and grow with similar electron donors for Fe(III)-reduction. *G. ferrireducens* has been shown to completely oxidize its carbon substrates to carbon dioxide and it is assumed that *D. thermophilus* can as well, but this has not been directly tested. An interesting feature of the metabolism of these organisms is the ability to use some amino acids as electron donors for Fe(III) reduction. The environmental distribution of these organisms has not been studied in detail.

Ferribacter limneticum *Ferribacter limneticum* (Cummings et al., 1999) is the only organism in the β-subclass of the *Proteobacteria* that is known to conserve energy to support growth from Fe(III) reduction. Unlike many Fe(III)-reducing microorganisms it does not utilize Mn(IV) as an electron acceptor. To date, this organism has only been recovered from mining-impacted lake sediments.

Shewanella–Ferrimonas–Aeromonas In contrast to the organisms discussed above, which only grow anaerobically, several genera within the γ-*Proteobacteria*, can grow aerobically, and under anaerobic conditions can use Fe(III), Mn(IV), or other electron acceptors (Table 2). These include species of *Shewanella*, *Ferrimonas*, and *Aeromonas*. Although many of these organisms can use a wide range of electron donors when oxygen is available as an electron acceptor, their range of electron donors with Fe(III) and Mn(IV) is generally restricted to hydrogen and small organic acids. An exception is *Shewanella saccharophila*, which also can use glucose as an electron donor for Fe(III) reduction. The *Shewanella* species, which have been studied in detail, incompletely oxidize multicarbon organic electron donors to acetate.

Another Fe(III)-reducing microorganism that may be related to this group is an unidentified microorganism referred to as a "pseudomonad," which was the first organism found to grow with hydrogen as the electron donor and Fe(III) as the electron acceptor (Balashova and Zavarzin, 1980). However, this organism does not appear to be available in culture collections for further study, and its true phylogenetic placement is unknown.

The FMR in the γ-*Proteobacteria* have been recovered from a variety of sedimentary environments including various aquatic sediments (Myers and Nealson, 1988; Caccavo et al., 1992; Coates et al., 1999a) and the subsurface (Pedersen et al., 1996; Fredrickson et al., 1998). However, in contrast to the organisms in the *Geobacteraceae* which are found to be numerous in both molecular and culturing analysis of widely diverse environments where Fe(III) reduction is important, the distribution of *Shewanella* is more variable. For example, *Shewanella* were found to account for ca. 2% of the microbial population in some surficial aquatic sediments, but could not be detected in other sediments (DiChristina and DeLong, 1993). *Shewanella* 16S rDNA sequences could not be recovered from aquifer sediments in which Fe(III) reduction was the predominant terminal electron-accepting process TEAP (Synoeyenbos-West et al., 1999). This was the case even when electron donors, such as lactate and formate, that are preferred by *Shewanella* species, were added to stimulate Fe(III) reduction.

Sulfurospirillum barnesii *Sulfurospirillum barnesii* which was initially isolated based on its ability to use selenate as an electron acceptor

(Oremland et al., 1994b), also can grow using the reduction of Fe(III) and the metalloid As(V) (Laverman et al., 1995). Although it has commonly been found that if one organism in a close phylogenetic group has the ability to reduce Fe(III) then others in the group also will be Fe(III) reducers (Roden and Lovley, 1993a; Lovley et al., 1995c; Lonergan et al., 1996; Kashefi and Lovley, 1999), *Sulfurospirillum arsenophilum* does not reduce iron [Fe(III); Stolz et al., 1999)]. *Wolinella succinogenes*, which is also in the ε-subclass of the *Proteobacteria*, also can reduce Fe(III) and metalloids (Lovley et al., 1997c; 1999b), but whether *W. succinogenes* conserves energy to support growth from metal reduction has not been determined.

Acidophilic Fe(III)-Reducing Microorganisms Although Fe(III) is highly insoluble at the circumneutral pH at which most Fe(III)-reducing microorganisms have been studied, Fe(III) is soluble at low pH. The redox potential of the Fe^{+3}/Fe^{+2} redox couple is significantly more positive than the Fe(III) oxide/Fe^{+2} redox couple and the oxidation of electron donors (such as S°) that might be unfavorable at circumneutral pH with Fe(III) oxides as the electron acceptors might be favorable in acidic pH where more Fe^{+3} is available. *Thiobacillus ferroxidans* can grow anaerobically with S° as the electron donor and Fe(III) as the electron acceptor (Das et al., 1992; Pronk et al., 1992). *Thiobacillus thiooxidans* also has been shown to reduce Fe(III) with S° as the electron donor (Brock and Gustafson, 1976), but the culture was grown aerobically and energy conservation from Fe(III) reduction was not demonstrated. This was also true of the thermophile, *Sulfolobus acidocaldarius* (Brock and Gustafson, 1976).

Acidophilic thermophiles that can reduce Fe(III) with glycerol or thiosulfate as the electron donor have been described (Bridge and Johnson, 1998), but the ability of these organisms to conserve energy to support growth from Fe(III) reduction has not been examined in detail. An acidophilic mesophile, designated strain SJH, exhibited Fe(III)-dependent growth in a complex organic medium containing glucose and tryptone (Johnson and McGinness, 1991), but further characterization of the electron donors for Fe(III) reduction and a detailed description of the organism were not provided.

Hyperthermophilic and Thermophilic Archaea and Bacteria In addition to *D. thermophilus* mentioned above, a number of other thermophiles and hyperthermophiles can conserve energy to support growth from Fe(III) reduction. The first thermophilic FMR reported was the deep subsurface isolate, *Bacillus infernus*, which has a temperature optimum of 60°C (Boone et al., 1995). It was also the first Gram-positive FMR identified. In contrast to all other members of the *Bacillus* genus, *B. infernus* is a strict anaerobe and can grow by fermentation when Fe(III) or other electron acceptors are not available. Other thermophilic FMR recovered from subsurface environments include *Thermoterrabacterium ferrireducens* (Slobodkin et al., 1997) and a *Thermus* species (Kieft et al., 1999).

As summarized in Tables 1 and 2, a wide phylogenetic diversity of hyperthermophilic microorganisms can transfer electrons to iron [Fe(III); Vargas et al., 1998)]. However, only three of these organisms, *Pyrobaculum islandicum*, *P. aerophilum*, and *Thermotoga maritima*, have been shown to conserve energy to support growth from Fe(III) reduction. *P. islandicum* and *T. maritima* grow with hydrogen as the electron donor and Fe(III) as the electron acceptor and *P. islandicum* and *P. aerophilum* also can grow with complex organic matter (peptone, yeast extract) as the electron donor and Fe(III) as the electron acceptor (Kashefi and Lovley, 1999).

Forms of Fe(III) and Mn(IV) That Can Serve as Electron Acceptors Unlike other types of respiration that use soluble electron acceptors, Fe(III) and Mn(IV) reduction require the reduction of insoluble electron acceptors in most environments. The insoluble Fe(III) and Mn(IV) oxides that are the most environmentally relevant forms of Fe(III) and Mn(IV) at circumneutral pH can be found in a wide diversity of forms (Dixon and Skinner, 1992; Schwertmann and Fitzpatrick, 1992). The nature of the oxides have a major impact on the rate and extent of Fe(III) and Mn(IV) reduction (Lovley, 1991a; Lovley, 1995a).

Pure cultures of Fe(III)-reducing microorganisms reduce a variety of insoluble Fe(III) and Mn(IV) forms (Lovley, 1991a), including the Fe(III) oxides naturally found in sedimentary environments (Lovley et al., 1990b; Coates et al., 1996). Early studies on Fe(III) reduction by fermentative microorganisms often employed highly crystalline Fe(III) oxides as the Fe(III) form (Table 1). However, studies on Fe(III) reduction in sediments suggested that the primary form of Fe(III) that FMR reduced in aquatic sediments was poorly crystalline Fe(III) oxides and that poorly crystalline Fe(III) oxides promoted the complete oxidation of organic compounds to carbon dioxide with Fe(III) serving as the electron acceptor (Lovley and Phillips, 1986a; Lovley and Phillips, 1986b; Phillips et al., 1993).

The use of poorly crystalline Fe(III)-oxide as the Fe(III) form permitted the first recovery of

a microorganism that could completely oxidize organic compounds to carbon dioxide with Fe(III) serving as the electron acceptor (Lovley et al., 1987c). Most subsequent studies that have enriched for Fe(III)-reducing microorganisms from the environment or that have evaluated mechanisms for Fe(III) oxide reduction by pure cultures of FMR have used poorly crystalline Fe(III) oxide as the electron acceptor.

FMR have been shown to reduce some of the more crystalline Fe(III) oxides, including hematite, goethite, akaganeite, and magnetite, under some conditions (Table 2; Lovley, 1991a; Kostka and Nealson, 1995; Roden and Zachara, 1996). However, the rates of reduction of the crystalline Fe(III) oxides are generally much slower than the reduction of poorly crystalline Fe(III) oxide. In most instances, sustained growth is difficult to maintain in consecutive transfer of pure cultures with crystalline Fe(III) oxides as the electron acceptor. In evaluating the potential for reduction of crystalline Fe(III) oxides, it is important to omit complex organic matter or organic acids, which chelate and solubilize Fe(III) from the Fe(III) oxides. The FMR reduction of crystalline Fe(III) oxides in soils and sediments has not been demonstrated conclusively.

An alternative, environmentally relevant, source of insoluble Fe(III) is structural Fe(III) in clays. Reduction of Fe(III) in clays is often observed in flooded soils and FMR have been shown to reduce this iron [Fe(III); Kostka et al., 1996; Lovley et al., 1998)].

Soluble Fe(III) forms are often used for culturing FMR. Although soluble Fe(III) may not represent an environmentally significant form of Fe(III), it provides an easy method for culturing FMR. Pure cultures generally reduce soluble Fe(III) forms faster than poorly crystalline Fe(III) oxide, and less insoluble precipitates are formed during reduction of soluble Fe(III). Furthermore, unlike poorly crystalline Fe(III) oxide, some soluble Fe(III) forms do not have to be synthesized because they are commercially available.

Fe(III)-citrate is the most commonly used form of soluble Fe(III) for the culture of FMR. It is highly soluble and can readily be provided at concentrations as high as 50 mM, even in media with a high salt content. However, Fe(III)-citrate may be toxic to some Fe(III)-reducing microorganisms (Lovley et al., 1990a; Lovley et al., 1993b; Roden and Lovley, 1993b). The Fe(III) chelated with nitrilotriacetic acid (Fe(III)-NTA) is a useful alternative. The limitations of Fe(III)-NTA are its frequent toxicity at concentrations above 10 mM and its tendency to precipitate as Fe(III) oxide when Fe(III)-NTA is added to media with high salt content or at temperatures of 60°C or above. Unlike Fe(III)-citrate, Fe(III)-NTA is not commercially available and must be synthesized, as described below. "Ferric pyrophosphate" has been successfully used for the culture of FMR (Caccavo et al., 1994; Caccavo et al., 1996). This is a somewhat undefined mixture that contains not only Fe(III) and phosphate, but also citrate and nitrilotriacetic acid which are likely to play an important role in maintaining the solubility of Fe(III) in this mixture.

The most commonly used form of Mn(IV) oxide in studies of Mn(IV) reduction by FMR is birsnessite, a readily synthesized Mn(IV) oxide (see method for synthesis below). However, there is a wide diversity of Mn(IV) oxides is found in the environment and rates of Mn(IV) reduction can be dependent upon the form of Mn(IV) oxide available (Burdige et al., 1992).

Products of Fe(III) and Mn(IV) Reduction

Products Fe(II) and Mn(II) are more soluble than Fe(III) and Mn(IV) and thus microbial Fe(III) and Mn(IV) reduction results in a marked increase in dissolved iron and manganese in anaerobic environments and in cultures of FMR. However, in both cultures and sediments, most of the Fe(II) and Mn(II) produced during microbial reduction of insoluble Fe(III) and Mn(IV) oxides often remains in solid forms (Lovley, 1991a; Lovley, 1995a; Schnell et al., 1998). In culture, microbial Fe(III) and Mn(IV) reduction has been shown to form such minerals as magnetite (Fe_3O_4) siderite ($FeCO_3$), vivianite ($Fe_3PO_4 \cdot 8H_2O$) and rhodochrosite ($MnCO_3$; Lovley, 1991a; Lovley, 1995b). The formation of such minerals in culture provides a model for the geologically significant deposition of iron and manganese minerals described above.

The fact that most of the Fe(II) and Mn(II) produced from microbial Fe(III) and Mn(IV) reduction is insoluble means that quantitative analysis of Fe(III) or Mn(IV) reduction either in cultures or environmental samples requires quantifying the amount of insoluble Fe(II) or Mn(II) produced. The Fe(II) may be solubilized in HCl (Lovley and Phillips, 1986a) or oxalate (Phillips and Lovley, 1987; Lovley and Phillips, 1988c) before measurement with Fe(II)-specific reagents such as ferrozine (Stookey, 1970) or ion chromatography (Schnell et al., 1998). Loss of Fe(III) in acid-solubilized samples also can be monitored (Lovley and Phillips, 1988b; Schnell et al., 1998).

Methods for quantitatively measuring Mn(IV) reduction are not as well established. Much of the Mn(II) produced during Mn(IV) reduction adsorbs onto the Mn(IV) oxide or forms insoluble Mn(II) minerals. Mn(II) can be solubilized in acid and soluble manganese measured with atomic absorption spectroscopy (Lovley and

Phillips, 1988c), but this is technically difficult because acid will also eventually dissolve the Mn(IV) oxide. A better strategy might be to solubilize all the manganese and specifically measure the Mn(II) produced with ion chromatography (Schnell et al., 1998).

Mechanisms for Electron Transfer to Fe(III) and Mn(IV) The mechanisms by which Fe(III)- and Mn(IV)-reducing microorganisms transfer electrons to insoluble Fe(III) and Mn(IV) are poorly understood. It is generally stated that Fe(III) and Mn(IV) reducers must directly reduce Fe(III) and Mn(IV) oxides by establishing contact with the oxides (Lovley, 1991a). Until recently, the primary evidence of the need for contact was the finding that Fe(III) and Mn(IV) were not reduced when Fe(III) or Mn(IV) oxides and Fe(III)- and Mn(IV)-reducing microorganisms were separated by semipermeable membranes, which should permit the passage of soluble substances. This result as well was considered evidence that Fe(III)- and Mn(IV)-reducing microorganisms do not produce chelators to solubilize Fe(III) or Mn(IV) and do not produce compounds that could serve as soluble electron-shuttles between Fe(III)- and Mn(IV)-reducing microorganisms and the insoluble oxides. However, recent studies have demonstrated that this approach is flawed because even when chelators or electron shuttles were added to cultures, Fe(III)-reducing microorganisms still did not significantly reduce Fe(III) oxide held within dialysis tubing (Nevin and Lovley, 1999a). Studies with strains of *Shewanella alga*, which were deficient in the ability to attach to Fe(III) oxides, continued to reduce Fe(III), suggesting that attachment to Fe(III) oxide was not necessary for Fe(III) oxide reduction (Caccavo et al., 1997). Thus, although studies have documented the association of Fe(III)-reducing microorganisms with Fe(III)-oxide particles, the current evidence is not definitive to clearly state that Fe(III)- and Mn(IV)-reducing microorganisms must attach to Fe(III) and Mn(IV) oxides in order to reduce them.

It was suggested that *Geobacter sulfurreducens* might reduce Fe(III) oxide in culture by releasing a low molecular weight (9.6 kDa) *c*-type cytochrome into the medium which could serve as a soluble electron shuttle between *G. sulfurreducens* and the Fe(III) oxide (Seeliger et al., 1998). However, further investigation has demonstrated that this c-type cytochrome is not an effective electron shuttle and that in healthy, actively growing cultures of *G. sulfurreducens*, little, if any, of the 9.6 kDa cytochrome is released into the growth medium (Lloyd et al., 1999). Therefore, the proposed shuttling mechanism is unlikely.

Iron [Fe(III)]-reducing microorganisms can use humics and other extracellular quinones as electron shuttles to promote Fe(III) oxide reduction (Lovley et al., 1996; Lovley et al., 1998; Lovley et al. 2000). As discussed below, humics and other extracellular quinones can serve as electron acceptors for Fe(III)-reducing microorganisms. The hydroquinone moieties that are generated as the result of the reduction of extracellular quinones can transfer electrons to Fe(III) oxides through a strictly abiotic reaction. This reduction of Fe(III) regenerates quinone moieties that can then again serve as electron acceptors for Fe(III)-reducing microorganisms. In this manner a small amount of extracellular quinone can promote a significant increase in the rate of reduction of poorly crystalline Fe(III) oxide. For example, studies with cultures and aquifer sediments have demonstrated that there is a significant potential for electron shuttling with as little as 100 nM AQDS (Lloyd et al., 1999; Nevin and Lovley, 1999b). Although electron shuttling to Mn(IV) oxides have not been studied in detail, a similar phenomenon is expected.

However, both the evidence that Fe(III)- and Mn(IV)-reducing microorganisms can reduce Fe(III) and Mn(IV) oxides in cultures without added electron shuttling compounds and chelators and the lack of evidence for release of electron shuttling or chelating compounds by the microorganisms (Nevin and Lovley, 1999a) suggests that FMR can directly transfer electrons to Fe(III) and Mn(IV) oxides. The Fe(III)-reductase activity is primarily localized in the membranes of Fe(III)- and Mn(IV)-reducing microorganisms such as *G. metallireducens* (Gorby and Lovley, 1991), *S. putrefaciens* (Myers and Myers, 1993), and *G. sulfurreducens* (Gaspard et al., 1998; Magnuson et al., 1999). The involvement of cytochromes of the *c*-type has been suggested to be involved in electron transport to Fe(III) in *G. metallireducens* (Lovley et al., 1993c) and *S. putrefaciens* (Myers and Myers, 1992; Myers and Myers, 1997; Beliaev and Saffarini, 1998). A NADH-dependent Fe(III) reductase complex was purified from *G. sulfurreducens* and a 90-kDa *c*-type cytochrome in the complex served as the Fe(III) reductase (Magnuson et al., 1999). However, no study has as yet definitively identified as yet the physiologically relevant Fe(III) or Mn(IV) reductase in any organism capable of conserving energy to support growth via Fe(III) or Mn(IV) reduction.

Other Respiratory Capabilities of FMR

Many FMR can reduce other electron acceptors well-known to support anaerobic respiration such as fumarate, nitrate, and S° (Table 2). Fumarate is reduced to succinate, and S° is

reduced to sulfide. In those documented instances of nitrate reduction, nitrite or ammonia has been found to be the product. It is interesting that nearly all microorganisms with the ability to reduce Fe(III) also can reduce S° to sulfide. In fact, screening of known S°-reducing microorganisms already available in culture has been a fruitful approach for discovering new FMR (Roden and Lovley, 1993a; Lonergan et al., 1996; Vargas et al., 1998).

Electron Transfer to Other Metals and Metalloids Many Fe(III)-reducing microorganisms can transfer electrons to metals other than iron or manganese [Fe(III) or Mn(IV); Table 2]. For example, *G. metallireducens* and *S. putrefaciens* can grow with U(VI) as the sole electron acceptor (Lovley et al., 1991b). Cell suspensions of other FMR have been found to transfer electrons to U(VI), but their ability to obtain energy to support growth from U(VI) reduction has not been evaluated. Many sulfate-reducing microorganisms, can effectively reduce U(VI), but attempts to grow these organisms with U(VI) as the sole electron acceptor have been unsuccessful (Lovley et al., 1993b).

U(VI), which is soluble in bicarbonate-based media is reduced to U(IV) that precipitates as the mineral uraninite (Gorby and Lovley, 1992; Lovley and Phillips, 1992). Visualization of microbial U(VI) reduction can be enhanced with the use a fluorescent light. The U(VI)-containing liquid cultures or agar plates fluoresce green, whereas the uraninite does not significantly fluoresce. Loss of U(VI) during U(VI) reduction can be monitored as loss of soluble uranium by monitoring total uranium concentrations in culture filtrates, but since U(IV) precipitation is not instantaneous (Gorby and Lovley, 1992), more quantitative estimates of U(VI) reduction can be more quantitatively estimated by monitoring loss of U(VI) with a kinetic phosphorescence analyzer (Lovley et al., 1991b) or by using ion chromatography.

Several Fe(III)-reducing microorganisms can reduce the oxidized form of the radioactive metal technetium, Tc(VII) to reduced forms (Table 2). Growth with Tc(VII) as the sole electron acceptor has not yet been documented as yet in any organism. Tc(VII) reduction can be monitored by following the formation of reduced technetium forms with paper chromatography and a phosphorimager (Lloyd and Macaskie, 1996).

FMR can reduce a variety of other metals and metalloids (Table 2). Several can reduce Cr(VI) to Cr(III), but growth with Cr(VI) as the sole electron acceptor has not been demonstrated (Lovley, 1995c). The FMR, *S. barnesii* can conserve energy from the reduction of Se(VI) to Se° and As(V) to As(III) (Laverman et al., 1995).

Electron Transfer to and from Humic Substances and Other Extracellular Quinones All FMR that have been evaluated to date, including the hyperthermophiles, have the ability to transfer electrons to humic substances (humics) or other extracellular quinones such as the humics analog, anthraquinone-2,6-disulfonate (AQDS) Lovley et al., 1996; Lovley et al., 1998; Lovley et al., 2000). In those organisms in which the potential for growth has been evaluated, energy to support growth is from electron transport to humics and this capability is conserved. Electron-spin resonance (ESR) studies have suggested that quinones are important electron-accepting groups in the humics (Scott et al., 1998). The ESR studies with AQDS as the sole electron acceptor have directly demonstrated that energy can be conserved from electron transfer to extracellular quinones has been directly demonstrated in studies with AQDS as the sole electron acceptor (Lovley et al., 1996; Coates et al., 1998; Lovley et al., 1998). Humics can chelate Fe(III) that is also available for microbial reduction (Benz et al., 1998; Lovley and Blunt-Harris, 1999a), but the concentration of microbially reducible Fe(III) in humics is a minor fraction of the total electron-accepting capacity (Lovley and Blunt-Harris, 1999a).

A wide diversity of humics can serve as electron acceptors for Fe(III)-reducing microorganisms (Lovley et al., 1996; Scott et al., 1998). Highly purified reference humics that have been extracted from diverse environments can be obtained from the International Humic Substances Society. Other commercially available humics are highly impure, differ from humics found in soils and sediments, and therefore should be avoided for definitive studies because commercially available humics are highly impure and their characteristics are unlike the humics found in soils and sediments (Malcolm and MacCarthy, 1986).

The expense and technical difficulty of conducting studies with humics makes it preferable to carry out some studies on microbial reduction of extracellular quinones with humics analogs, such as AQDS (Lovley et al., 1996; Lovley et al., 1998). The advantages of AQDS are its low cost, high solubility, and its easy detection [an orange color develops when AQDS is reduced to anthrahydroquinone-2,6-disulfonate (AHQDS)].

Several FMR have the ability to use reduced extracellular quinones as an electron donor for reduction of electron acceptors such as nitrate and fumarate (Lovley et al., 1999b). *Shewanella alga* and *Geobacter sulfurreducens* grew with

AHQDS as the electron donor. However, other FMR that could oxidize AHQDS in cell suspensions could not be grown with AHQDS as the sole electron acceptor. The ability of FMR to both reduce and oxidize extracellular quinones permits their use with other quinone-oxidizing and quinone-reducing microorganisms as an interspecies electron transfer system in which quinones serve as the electron shuttle between the microorganisms (Lovley et al., 1999b).

Proton Reduction in Syntrophic Association with Hydrogen-Consuming Microorganisms In the absence of Fe(III) or other suitable electron acceptors, some organisms in the *Geobacteraceae* can transfer electrons to protons to produce hydrogen gas. For hydrogen production to be thermodynamically favorable, a sink for hydrogen, such as a hydrogen-consuming microorganism, must keep hydrogen concentrations low enough. For example, several *Pelobacter* species can oxidize ethanol to acetate and carbon dioxide when grown in association with hydrogen-consuming microorganisms (Schink, 1992). *G. sulfurreducens* can oxidize acetate to carbon dioxide when cultured with *Wolinella succinogenes*, which oxidizes hydrogen with concomitant reduction of nitrate (Cord-Ruwisch et al., 1998).

Reductive Dechlorination Several Fe(III)-reducing microorganisms are capable of using chlorinated compounds as electron acceptors. *Desulfuromonas chlorethenica*, which was isolated as a tetrachloroethylene-respiring microorganism (Krumholz et al., 1996; Krumholz, 1997), was found to grow also with Fe(III) as the electron acceptor, as expected for microorganisms within the family *Geobacteraceae* (Lonergan et al., 1996). Other *Geobacteraceae* that were evaluated did not reduce tetrachloroethylene. *Desulfitobacterium dehalogenans* which can use chlorophenolic compounds as an electron acceptor (Utkin et al., 1994), also can grow with Fe(III) as the electron acceptor (Lovley et al., 1998). Another chlorophenol-respiring species in the same genus, *Desulfitobacterium hafniense*, was reported to reduce Fe(III), but it was not reported whether growth was conserved from Fe(III) reduction (Christiansen and Ahring, 1996).

Recovery of Fe(III)- and Mn(IV)-Reducing Microorganisms in Culture

Localizing Zones of Fe(III) and Mn(IV) Reduction Although FMR can be recovered from nearly any soil or sediment sample, it is generally of interest to study organisms from habitats in which Fe(III) and Mn(IV) are ongoing processes. Dissimilatory Fe(III) and Mn(IV) reduction are geochemically most significant in anaerobic environments such as freshwater and marine sediments; flooded soils or the anaerobic interior of soil aggregates; the deep terrestrial subsurface; and shallow aquifers contaminated with organic compounds. In aquatic sediments and the terrestrial subsurface Fe(III) and Mn(IV) reduction are most apparent in discrete anoxic sediment layers in which the endproducts of Fe(III) and Mn(IV) reduction, Fe(II) or Mn(II), are accumulating. In the typical zonation of respiratory processes found with depth in aquatic sediments or along the groundwater flow path in the subsurface, the zones of Fe(III) and Mn(IV) reduction are typically bounded on one side by the zone of nitrate reduction and on the other side by the zone of sulfate reduction (Lovley and Chapelle, 1995c). In addition to these larger discrete zones of Fe(III) reduction and Mn(IV) reduction in sedimentary environments, it is important to recognize that many soils and sediments that are predominately aerobic also may contain abundant anaerobic microzones in which Fe(III) and Mn(IV) reduction may be taking place.

Although accumulation of dissolved Fe(II) and Mn(II) in groundwater or porewater can be used to help identify the zones of Fe(III) and Mn(IV) reduction in subsurface or aquatic sediments, such standard geochemical measurements can often fail to accurately locate the metal reduction zones (Lovley et al., 1994b). A primary reason for this failure is that high concentrations of Fe(II) and Mn(II) may be found in sediments in which other TEAPs, such as methanogenesis, predominate.

In environments where conditions approach steady-state, such as aquatic sediments and aquifers, measurements of dissolved hydrogen can be used to identify zones in which Fe(III) reduction is the TEAP (Lovley and Goodwin, 1988a; Lovley et al., 1994c). This is because there is a unique range of dissolved hydrogen that is associated with Fe(III) reduction that is the predominant TEAP in steady-state environments. Hydrogen measurements have not been used to localize Mn(IV)-reducing zones because: 1) hydrogen concentrations under Mn(IV)-reducing conditions are very low and difficult to accurately measure accurately; 2) hydrogen concentrations for Mn(IV) and nitrate reduction are similar; and 3) the low concentrations of Mn(IV) in many soils means that the Mn(IV) reduction zone is not extensive.

An alternative method for determining the zone of Fe(III) reduction in soils and sediments is to use [2-^{14}C]-acetate (Lovley, 1997a). The reduction of Fe(III) can be considered to be the

TEAP if: 1) a tracer quantity of [2-^{14}C]-acetate added to the sediments is converted to $^{14}CO_2$ with no production of $^{14}CH_4$; 2) the production of $^{14}CO_2$ is not inhibited with the addition of molybdate; 3) the sediments are depleted of nitrate; and 4) the sediments contain some Fe(II). The reasoning for this is that: 1) lack of $^{14}CH_4$ production rules out methanogenesis as a TEAP; 2) molybdate inhibits acetate oxidation by sulfate reducers so the lack of inhibition with molybdate rules out sulfate reduction as the TEAP; 3) nitrate reduction can not be an important TEAP in the absence of nitrate; and 4) Mn(IV) reduction can not be the TEAP in the presence of Fe(II) because Fe(II) rapidly reacts with Mn(IV) (Lovley and Phillips, 1988b) and thus Fe(II) will only be found if reactive Mn(IV) has been depleted.

The rates of other TEAPs can often be quantified in sediments with the use of radiotracers. Unfortunately, attempts to measure rates of Fe(III) reduction in sediments with radioactively labeled Fe(III) were unsuccessful (Roden and Lovley, 1993b). This was because there was rapid isotope exchange between the radiolabelled Fe(III) and other iron pools, including Fe(II), was rapid. Thus, it was not possible to monitor rates of microbial Fe(III) reduction by measuring the production of radiolabeled Fe(II) from labeled Fe(III).

Rates of Fe(III) and Mn(IV) reduction in sediments can be estimated from anaerobic incubations of sediments by monitoring the accumulation of Fe(II) and Mn(II) are monitored over time. It is important that the solid phase Fe(II) and Mn(II) pools be measured after acidic extractions or some other technique because most of the Fe(II) and Mn(II) are not recovered in the dissolved phase (Lovley and Phillips, 1988c; Lovley, 1991a). Geochemical modeling has been used to estimate rates of Fe(III) and Mn(IV) reduction in some aquatic sediments and subsurface environments and potentially could be used to identify zones of Fe(III) and Mn(IV) reduction (Lovley, 1995a).

Isolation Procedures Although some FMR also can use oxygen as an electron acceptor or are tolerant of exposure to air, many are strict anaerobes. Therefore, unless the goal is to specifically select for facultative FMR, the use of strict anaerobic technique is preferable in initial enrichment and/or isolation procedures. To date, most FMR have been recovered using slight modifications of standard (Miller and Wolin, 1974; Balch et al., 1979) anaerobic techniques. This involves the use of culture tubes or bottles fitted with thick butyl rubber stoppers; removing traces of oxygen from gases by passing the gases through a column of heated copper filings; and carrying out transfers with syringes and needles or under a stream of anoxic gas.

Culture media can be prepared with the classical approach (Hungate, 1969) of boiling the media under a stream of anoxic gas to remove dissolved oxygen and then dispensing into tubes or bottles under anaerobic conditions. Alternatively, aerobic media may be dispensed into individual tubes or bottles and then the media can be vigorously bubbled with anoxic gas to strip dissolved oxygen from the media (Lovley and Phillips, 1988c). Both media preparation approaches appear to yield similar organisms. Reducing agents such as Fe(II)—typically supplied at 1–3 mM as ferrous chloride—cysteine (0.25–1 mM), or sulfide (0.25–1 mM) can be added to dispensed media from anoxic stocks just prior to inoculation. In addition to reacting with any trace oxygen in the media, cysteine and sulfide will reduce Fe(III) and Mn(IV) in the media, producing Fe(II) and Mn(II). Fe(II) rapidly reacts with traces of oxygen, forming Fe(III). Manganese [Mn(II)] will only slowly react abiotically with oxygen. Many FMR have been recovered without the addition of reducing agents to the media. Once Fe(III) reduction begins, the Fe(II) formed serves as protection against oxygen contamination. Reducing agents are rarely used in media designed for liquid-to-liquid transfer of Fe(III)-reducing cultures because the inoculum of the Fe(III)-reducing cultures typically contain millimolar quantities of dissolved Fe(II), which will scavenge traces of oxygen from the media to which the inoculum has been added.

A variety of media has been successfully employed for the enrichment and isolation of FMR, many of which are given in the references provided with each of the organisms in Table 2. An example of a freshwater and a marine medium are provided below. No definitive comparative studies of the efficacy of various media in recovering FMR have been carried out. However, it has been found that the freshwater medium described here can be used to recover *Geobacter* species with 16S rDNA sequences that are closely related to the 16S rDNA sequences that predominate in the Fe(III) reduction zone of sandy aquifers (Rooney-Varga et al., 1999; Synoeyenbos-West et al., 1999).

Most successful isolations of pure cultures of Fe(III)- and Mn(IV)-reducing microorganisms have used either organic acids, primarily acetate or lactate, or hydrogen as the electron donor. If an enrichment step is used in the initial stages of recovery of the organisms, then fermentable compounds such as glucose generally result in the enrichment of fermentative microorganisms. However, as summarized above, some Fe(III)- and Mn(IV)-reducing microorganisms can use sugars and amino acids as electron donors and

these electron donors potentially could be be used for direct isolation of FMR.

A variety of Fe(III) and Mn(IV) forms that were discussed above can be used as electron acceptors for enrichment or isolation. Iron added as Fe(III)-citrate and Fe(III) pyrophosphate is not ideal for enrichment cultures as the citrate is rapidly degraded by microorganisms other than Fe(III) reducers. Once the citrate is degraded, the Fe(III) from the Fe(III)-citrate precipitates as an insoluble Fe(III) oxide and thus defeats the purpose of adding the chelator. The compound Fe(III)-NTA is relatively resistant to anaerobic degradation and can be used as a soluble source of Fe(III) for enrichment of Fe(III) reducers. However, as noted above, it is not suitable for use in media with marine salinities or at high temperature. Both Fe(III)-citrate and Fe(III)-NTA are toxic to some Fe(III) reducers. Although solubilization of Mn(IV) with various chelators for use in recovery of Mn(IV)-reducing microorganisms may be possible, this approach has not been widely used.

As noted above, poorly crystalline Fe(III) oxide is typically the insoluble Fe(III) oxide of choice for culturing. A wide diversity of other Fe(III) oxides can be synthesized (Schwertmann and Cornell, 1991), if desired. If the media is dispensed aerobically into culture vessels, then a slurry of the Fe(III) or Mn(IV) oxide can be added to the vessels prior to addition of the media. An advantage of using poorly crystalline Fe(III) oxide as the electron acceptor is that most Fe(III)-reducing microorganisms convert the poorly crystalline Fe(III) oxide to the magnetic mineral magnetite during reduction. This is visually apparent as the reddish, non-magnetic Fe(III) oxide is transformed into a black, highly magnetic precipitate (Lovley et al., 1987c). Reduction of the Mn(IV) oxide is also visually apparent in bicarbonate-buffered media because reduction of the dark Mn(IV) oxide results in its dissolution and concomitant accumulation of rhodochrosite, a white Mn(II) carbonate mineral.

An alternative electron acceptor that can be used for the recovery of Fe(III)- and Mn(IV)-reducing microorganisms is the humics analog, AQDS, which is typically provided at 5 mM. All of the Fe(III)-reducing microorganisms that have been evaluated can reduce AQDS, whereas microorganisms that do not reduce Fe(III) can not reduce AQDS (Lovley et al., 1996; Lovley et al., 1998; Lovley et al., 2000). Recovery of AQDS-reducing microorganisms either through enrichment and isolation procedures or dilution-to-extinction approaches yield organisms that also can reduce iron [Fe(III); Coates et al., 1998)]. The reduction of AQDS to AHQDS is visually apparent as the conversion of the relatively colorless AQDS to the orange, AHQDS.

Fe(III)- and Mn(IV)-reducing microorganisms can be obtained in pure culture through standard anaerobic approaches of isolating colonies in tubes or on plates or through dilution-to-extinction in liquid media. Soluble Fe(III) forms or AQDS are often used for isolating colonies on agar-solidified media, but colonies also can be obtained by incorporating Fe(III) and Mn(IV) oxides into solidified media. The Fe(III)- and Mn(IV)-reducing microorganisms that have the ability to use other electron acceptors often can be successfully purified from Fe(III)- or Mn(IV)-reducing enrichment cultures with these alternative electron acceptors. Common alternative electron acceptors include nitrate, fumarate, sulfur, and oxygen.

Suggested Media for Enrichment and Culturing of FMR Freshwater and marine media suitable for culturing a diversity of mesophilic FMR are described below. A variety of other media have also been used which can be found in the references for the individual organisms. The media described here have a bicarbonate-carbon dioxide buffer system and the headspace gas typically contains 20% carbon dioxide to establish an initial pH of ca. 6.8.

Freshwater Medium

To 900 ml water add:

$NaHCO_3$	2.50 g
NH_4Cl	0.25 g
$NaH_2PO_4 \cdot H_2O$	0.60 g
KCl	0.10 g
Vitamin Solution	10.0 ml
Mineral Solution	10.0 ml

Bring solution to a final volume of 1 liter. Media is dispensed, sparged with an 80:20 mixture of N_2:CO_2 gas and then autoclaved.

Marine Medium

Medium contains, per liter:

NaCl	20.0 g
KCl	0.67 g
$NaHCO_3$	2.5.0 g
Vitamin solution	10.0 ml
Mineral solution	10.0 ml
RST minerals stock	20.0 ml
Salt stock*	50.0 ml

*Add salt solution aseptically and anaerobically after autoclaving.

RST Minerals Stock 50X

Stock contains, per 100 ml:

NH_4Cl	5.0 g
KCl	0.5 g
KH_2PO_4	0.5 g
$MgSO_4 \cdot 7H_2O$	1.0 g
$CaCl_2 \cdot 2H_2O$	0.1 g

Salt Stock

Stock contains, per 100 ml:

$MgCl_2 \cdot 6H_2O$	21.2 g
$CaCl_2 \cdot 2H_2O$	3.04 g

Vitamin Solution

Solution contains, per liter:

Biotin	2.0 mg
Folic acid	2.0 mg
Pyridoxine HCl	10.0 mg
Riboflavin	5.0 mg
Thiamine	5.0 mg
Nicotinic acid	5.0 mg
Pantothenic acid	5.0 mg
B-12	0.1 mg
p-Aminobenzoic acid	5.0 mg
Thioctic acid	5.0 mg

Mineral Solution

grams per liter

Trisodium nitrilotriacetic acid	1.5 g
$MgSO_4$	3.0 g
$MnSO_4 \cdot H_2O$	0.5 g
NaCl	1.0 g
$FeSO_4 \cdot 7H_2O$	0.1 g
$CaCl_2 \cdot 2H_2O$	0.1 g
$CoCl_2 \cdot 6H_2O$	0.1 g
$ZnCl_2$	0.13 g
$CuSO_4 \cdot 5H_2O$	0.01 g
$AlK(SO_4)_2 \cdot 12H_2O$	0.01 g
H_3BO_3	0.01 g
Na_2MoO_4	0.025 g
$NiCl_2 \cdot 6H_2O$	0.024 g
$Na_2WO_4 \cdot 2H_2O$	0.025 g

Preparation of Fe(III) and Mn(IV) Forms

Poorly Crystalline Fe(III) Oxide Dissolve $FeCl_36H_2O$ in water to provide final concentration of 0.4M. Stir continually while SLOWLY adjusting the pH to 7.0 dropwise with 10 M NaOH solution. It is extremely important not to let the pH rise above pH 7 even momentarily during the neutralization step because this will result in an Fe(III) oxide that is much less available for microbial reduction. Continue to stir for 30 minutes once pH 7 is reached and recheck pH to be sure it has stabilized at pH 7. To remove dissolved chloride, centrifuge the suspension at 5,000 rpm for 15 minutes. Discard the supernatant, resuspend the Fe(III) oxide in water, and centrifuge. Repeat six times. On the last wash, resuspend the Fe(III) oxide to a final volume of approximately 400 ml, and after determining iron content, adjust Fe(III) concentration to approximately 1 mole per liter. Typically, Fe(III) oxide is added to individual tubes of media to provide 100 mmol per liter.

Fe(III)-Citrate Prior to the addition of any of the media constituents, heat 800 ml of water on a stirring hot-plate to near boiling. Add Fe(III)-citrate [typically 13.7 g to provide a final concentration of ca. 50 mM Fe(III)]. Once the ferric citrate is dissolved quickly cool the medium to room temperature in an ice bath. Adjust pH to 6.0 using 10N NaOH. When the pH approaches 5.0, add the NaOH dropwise. Add medium constituents as outlined above. Bring to a final volume of 1 liter. Do not expose this media to direct sunlight to prevent photoreduction of the Fe(III).

Fe(III) Nitrilotriacetic Acid To make a stock of 100 mM Fe(III)-NTA, dissolve 1.64 g of $NaHCO_3$ in 80 ml water. Add 2.56 g $C6H6NO6Na_3$ (sodium nitrilotriacetic acid) and then 2.7 g $FeCl_36H_2O$. Bring the solution up to 100 ml. Sparge the solution with N_2 gas and filter sterilize into a sterile, anaerobic serum bottle. Do not autoclave. Typically, 100 mM Fe(III)-NTA stock is added to individual tubes of media to provide a final concentration of 5 or 10 mmol of Fe(III).

Goethite Prepare a 0.4M $FeCl_36H_2O$ solution. With continual stirring, adjust the pH to between 11 and 12 with 10 M NaOH solution. The suspension will become very thick. Ensure continual stirring and rinse the pH electrode frequently. The color of this suspension will turn to an ochre color as goethite is formed. One week at room temperature followed by 16 hours at 90°C is sufficient to convert the Fe(III) to goethite. The suspension should be washed to remove chloride, as described above for poorly crystalline Fe(III) oxide. The formation of goethite should be confirmed by X-ray diffraction analysis. The Fe(III) oxide also should be tested with extractants (Lovley and Phillips, 1987b; Phillips and Lovley, 1987) to ensure that it does not contain poorly crystalline Fe(III) oxide.

Hematite Hematite is readily available from chemical supply companies as "Ferric Oxide."

Manganese Oxide To 1 liter of a solution containing 80 mM NaOH and 20 mM $KMnO_4$ slowly add 1 liter of 30 mM $MnCl_2$ with mixing. Wash the manganese oxide precipitate, as described above for poorly crystalline Fe(III) oxide, to lower the dissolved chloride concentration.

Enumeration of Fe(III)- and Mn(IV)-Reducing Microorganisms The FMR in environments can be enumerated with standard most-probable-number (MPN) culturing techniques using variations of media described above. Enumerations typically use Fe(III) or AQDS as the electron acceptor with the understanding that the Fe(III)-reducing microorganisms recovered are likely to

have the ability to reduce Mn(IV) as well. Poorly crystalline Fe(III) oxide or Fe(III)-NTA is preferred over Fe(III)-citrate and Fe(III)-pyrophosphate, which promote the growth of fermentative microorganisms. One successful approach has been to add a combination of poorly crystalline Fe(III) oxide (100 mmol/liter) and 4 mM NTA to provide a supply of chelated Fe(III).

FMR also can be counted in plate counts in which Fe(III)-NTA or AQDS has been added as the electron acceptor. Clearing zones develop around FMR reducing Fe(III)-NTA, and growth with AQDS as the electron acceptor results in the formation or orange colonies or zones.

When possible, molecular enumeration rather than viable culturing enumeration techniques are the preferred methods because of the potential biases associated with the latter. The wide phylogenetic diversity of dissimilatory Fe(III) reducing microorganisms and the lack of an identified conserved gene associated with Fe(III) reduction make it impossible to enumerate Fe(III)-reducing microorganisms with one specific gene sequence (Lonergan et al., 1996). However, target 16S rRNA sequences that are selective for known groups of Fe(III)-reducing microorganisms have been identified and have been used to study the distribution of Fe(III)-reducing microorganisms in sedimentary environments (DiChristina and DeLong, 1993; Anderson et al., 1998; Rooney-Varga et al., 1999; Synoeyenbos-West et al., 1999).

Summary

Microbial reduction of Fe(III) and Mn(IV) is of environmental significance in a variety of aquatic sediments and the subsurface, influencing both the carbon cycle and the fate of many metals and metalloids, in both pristine and contaminated environments. Geological and microbiological evidence suggests that Fe(III) reduction was one of the earliest forms of respiration. A wide phylogenetic diversity of Fe(III)- and Mn(IV)-reducing microorganisms have been recovered in pure culture, but with the exception of the recently recognized importance of *Geobacter* in subsurface environments, little is known about the distribution or relative contributions of the various Fe(III)-reducing microorganisms. The study of the mechanisms of Fe(III) and Mn(IV) reduction are also in their infancy. However, now that methods for culturing these organisms are well developed, it seems likely that increased insight into the ecophysiology of Fe(III)- and Mn(IV)-reducing microorganisms is forthcoming.

CHAPTER 1.22

Dissimilatory Sulfate- and Sulfur-Reducing Prokaryotes

RALF RABUS, THEO A. HANSEN AND FRIEDRICH WIDDEL

Introduction

A unique characteristic in the prokaryotic world is the multiplicity of life strategies without any involvement of oxygen. Actually, life in anoxic habitats is prokaryotic to a large extent. Prokaryotes have evolved not only various fermentation pathways, but also the capacity to couple the oxidation of organic substrates to the reduction of inorganic compounds (other than O_2) to conserve energy for anaerobic growth. Electron acceptors reduced by prokaryotes under anoxic conditions are nitrate, manganese(IV), ferric iron, sulfate, elemental sulfur, other sulfur species (e.g., thiosulfate), carbon dioxide, protons and even oxidized forms of naturally less abundant elements such as arsenate(V), chromate(VI), selenate and uranium(VI). In several prokaryotes, even the electron donor may be inorganic, which results in purely inorganic (lithotrophic) redox reactions for energy conservation under anoxic conditions; notable examples are the oxidation of sulfur species with nitrate, or of molecular hydrogen with nitrate, iron(III), sulfate, sulfur or CO_2. Two organic compounds with some relationship to inorganic electron acceptors are dimethylsulfoxide (DMSO) and trimethylamine-N-oxide (TMAO). In these compounds, anaerobic microorganisms reduce the oxygenated sulfur or nitrogen moiety, respectively. In most cases, the electron transport to the inorganic electron acceptors is associated with a mode of energy conservation that may be regarded as an anaerobic analogue to respiration with O_2. This is particularly evident if the only electron donor is H_2. In such a process, ATP synthesis can be only explained by a chemiosmotic transmembrane process rather than by fermentative substrate-level phosphorylation. Because of this analogy to the known respiratory chain, growth by utilization of inorganic electron acceptors other than O_2 is usually termed "anaerobic respiration". In some microorganisms, inorganic compounds (as for instance ferric iron or sulfur) may be reduced in by-reactions without obvious connection to respiration-like chemiosmotic energy conservation. Such by-reactions may facilitate fermentation (disposal of reducing equivalents) but they should not be termed "anaerobic respirations". Interestingly, most types of anaerobic respirations have not been encountered so far in the eukaryotic domain. The only (thus far reported) case of anaerobic respiration in a eukaryote is nitrate-reduction by a flagellate (Finlay et al., 1983). The microbial reduction of inorganic compounds contributes significantly to the global cycling of elements and represents the counterpart to oxidative microbial processes, e.g., nitrification, iron oxidation and sulfur oxidation.

Among the anaerobic respirations, the reduction of sulfur species is most striking because it gives rise to a conspicuous end product, hydrogen sulfide (H_2S), which is commonly known as a toxic chemical with a characteristic smell. By its chemical reactivity (e.g., toward iron minerals and oxygen), H_2S has a pronounced impact on the chemistry of the environment. Despite of its toxicity, sulfide serves as electron donor for a great diversity of aerobic chemotrophic and anoxygenic phototrophic microorganisms that may form visible blooms in sulfidic habitats. The natural reduction and oxidation of sulfur species is known as the sulfur cycle. Because sulfate is the thermodynamically stable and most abundant form of sulfur in our oxic biosphere, sulfate reduction forms the basis of the biological sulfur cycle (Henrichs and Reeburgh, 1987; Jørgensen, 1987; Skyring, 1987; Widdel, 1988). A great diversity of sulfate-reducing microorganisms has been isolated from aquatic habitats.

The chemical and biological oxidation processes of sulfide do not always lead directly to sulfate, but often yield intermediate oxidation states such as elemental sulfur or thiosulfate. These may serve as electron acceptors for anaerobic microorganisms that cannot reduce sulfate. Among these, sulfur-reducing anaerobic microorganisms have been isolated most frequently, and their diversity is comparable to that of sulfate-reducing microorganisms.

The present chapter gives an overview of prokaryotes that reduce sulfate or elemental

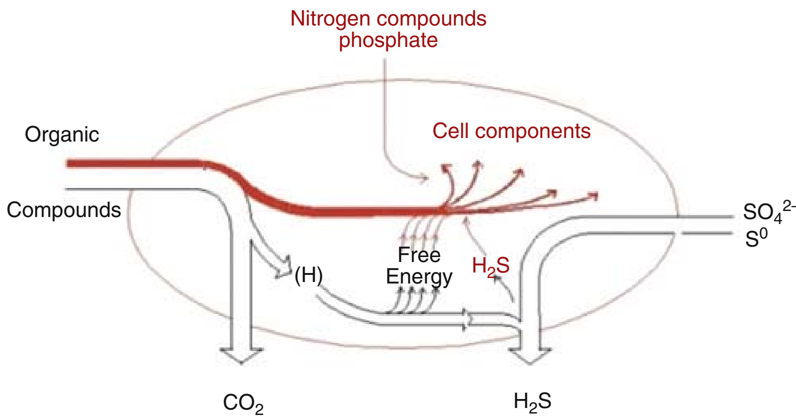

Fig. 1. Metabolic principle of sulfate-reducing bacteria. As in other anaerobic bacteria, the main part of the electron donor is oxidized for energy conservation, and only a minor fraction is assimilated into cell mass. Catabolism (energy metabolism) is shown in black; anabolism (cell synthesis) is shown in red.

sulfur in their energy metabolism (see Fig. 1). Growth by reduction of other sulfur species is also included. Such bacteria have also been summarized as sulfidogenic bacteria (sulfide-forming) bacteria (Zeikus, 1983; Lupton et al., 1984); however, strictly speaking, this term would also apply to putrefying bacteria that liberate sulfide from sulfur-containing organic molecules during their degradation.

Sulfate- or sulfur-reducing microorganisms are long-established functional groups, like denitrifying, sulfur-oxidizing, methylotrophic or phototrophic bacteria. They are not necessarily coherent from the viewpoint of modern molecular systematics such as grouping based on 16S rRNA sequences. Nevertheless, the treatment of such functional groups besides molecular systematic groups is still the most appropriate basis for an understanding and comparison of physiological, bioenergetic and enzymatic properties and the roles of microorganisms in their natural habitat. Hence, the present chapter is mostly organized according to functional aspects, but it will distinguish between the phylogenetic domains and treat bacterial and archaeal sulfate-reducers and sulfur reducers separately.

Historical Overview

Sulfate-Reducing Bacteria

Meyer (1864) and Cohn (1867) first recognized the production of striking concentrations of H_2S in aquatic habitats as a biologically mediated reduction of sulfate. Hoppe-Seyler (1886) demonstrated a complete oxidation of cellulose in anaerobic enrichment cultures with mud if gypsum ($CaSO_4$) was provided as a source of sulfate; the latter was reduced to sulfide. Beijerinck's (1895) investigations into microbial sulfide production resulted in the first isolation of a sulfate-reducing bacterium (named *Spirillum desulfuricans*), which was recognized as a strict anaerobe. The culture was isolated with malate and aspartate. Van Delden (1903a, 1903b) grew sulfate-reducing bacteria on lactate, which is often still used for cultivation. The first thermophilic sulfate reducer with an optimal growth temperature of 55°C was described by Elion (1925). Rubentschik (1928) observed a utilization of acetate and butyrate by sulfate reducers. In a comprehensive nutritional study, Baars (1930) demonstrated that *Vibrio desulfuricans* oxidized lactate or ethanol to acetate. Another type, *Vibrio rubentschikii*, was used in addition to acetate, propionate, butyrate and other compounds that were completely oxidized to CO_2; unfortunately, this species was not preserved. *Vibrio desulfuricans* was the former *Spirillum* which finally became *Desulfovibrio* (Kluyver and van Niel, 1936; Stephenson and Strickland, 1931) observed an oxidation of H_2 by sulfate reducers. The first described spore-forming sulfate-reducing bacteria were thermophiles named *Clostridium nigrificans* (Werkman and Weaver, 1927) and *Sporovibrio desulfuricans* (Starkey, 1938); they were later recognized as the same species (Campbell et al., 1957).

In the 1950s and 1960s, principal insights into the biochemistry of sulfate-reducing bacteria were achieved. *Desulfovibrio* was the first anaerobe in which a cytochrome was detected (Ishimoto et al., 1954b; Postgate, 1953). Earlier, this type of pigment was thought to be associated only with O_2 respiration. The type of cytochrome discovered in *Desulfovibrio* was termed c_3. Investigations into the biochemistry of dissimilatory sulfate-reduction revealed differences from the pathway of assimilatory sulfate reduction known at that time (Lipmann, 1958). In *Desulfovibrio*, adenosine-5′-phosphosulfate (APS) was not further phosphorylated to 3′-phosphoadenosine-5′-phosphosulfate (PAPS), as

in the assimilatory pathway, but rather directly reduced to sulfite and AMP (Peck, 1959; 1962; 1965). Furthermore, electron transfer was demonstrated to be coupled to phosphorylation (Peck, 1966). A green protein, desulfoviridin, was first described by Postgate (1956) and subsequently recognized as sulfite-reductase. The mechanism of sulfite-reduction to sulfide was less understood. In addition to the electron acceptor sulfate, the metabolic fate of selected organic substrates, such as pyruvate and cysteine, was studied in sulfate-reducing bacteria (Senez, 1954a; Senez and Leroux-Gilleron, 1954b). Cultures of sulfate-reducing bacteria existing at that time oxidized their substrates (such as lactate, ethanol or malate) incompletely to acetate. Sulfate reducers formerly grown on acetate or higher fatty acids (Rubentschik, 1928; Baars, 1930) had not been preserved.

In the 1960s, also a need for a proper classification of existing strains emerged. All sporeforming strains were classified or reclassified in the new genus *Desulfotomaculum* (Campbell and Postgate, 1965); the nonsporeforming, vibrio-shaped isolates were described as *Desulfovibrio* species (Postgate and Campbell, 1966). Later, nutritionally similar new mesophilic and thermophilic rod-shaped sulfate reducers were included in the genus *Desulfovibrio* (Rozanova and Khudyakova, 1974; Rozanova and Nazina, 1976); later, these sulfate reducers were reclassified as *Desulfomicrobium* and *Thermodesulfobacterium*, respectively.

In the 1970s major advances were achieved in the characterization of various electron carriers, e.g., the resolution of the crystal structure of cytochrome c_3 from *Desulfovibrio* (DerVartanian and LeGall, 1974). Furthermore, first evidence for a periplasmic location of hydrogenase emerged (Bell et al., 1974). In the field of biogeochemistry, new insights into the role of sulfate-reducing bacteria in natural habitats were rendered possible by the introduction of the radiotracer technique using $^{35}SO_4^{2-}$ (Sorokin, 1972). More than 50% of the organic carbon in marine sediments was shown to be mineralized via sulfate reduction (Jørgensen and Fenchel, 1974; Jørgensen, 1977; Jørgensen, 1982). This process could not be explained by the incomplete substrate oxidation to acetate in the sulfate-reducing bacteria (*Desulfovibrio* and *Desulfotomaculum* species) known at that time.

Anaerobic enrichment studies with various organic substrates lead to the recognition of diverse catabolic capacities including the degradation of aromatic organic acids in this group of microorganisms. Also, the capacity for acetate oxidation and complete mineralization of organic substrates, described in old reports (Hoppe-Seyler, 1886; Rubentschik, 1928; Baars, 1930), were confirmed to exist in sulfate-reducing bacteria and found in several novel types of this group. Some new species were facultatively autotrophic. The diversity of the isolates required the establishment of a new *Desulfotomaculum* species (Widdel and Pfennig, 1977) and new genera, such as *Desulfobacter*, *Desulfococcus*, *Desulfonema*, *Desulfobulbus* and *Desulfosarcina* (Widdel and Pfennig, 1977; Widdel, 1980; Widdel and Pfennig, 1981b; Pfennig et al., 1981c; Widdel and Pfennig, 1982; Widdel et al., 1983).

In the 1980s, main insights into enzymatic reactions and bioenergetics of entire metabolic pathways in sulfate-reducing bacteria were achieved and studies of functional genes began. Precise ATP balances of sulfate-reduction with H_2 were calculated from chemostat studies (Badziong and Thauer, 1978; Nethe-Jaenchen and Thauer, 1984). In carbon metabolism, two alternative pathways for complete oxidation of acetyl-CoA, the citric acid cycle (Brandis-Heep et al., 1983; Gebhardt et al., 1983) and the oxidative CO-dehydrogenase pathway (Schauder et al., 1986; Schauder et al., 1989; Spormann and Thauer, 1988) were shown to be operative in distinct groups of sulfate-reducing bacteria that oxidized their substrate completely to CO_2. In autotrophic sulfate-reducing bacteria (Widdel, 1980; Klemps et al., 1985; Brysch et al., 1987), the synthesis of acetyl-CoA from CO_2 was demonstrated to occur via the reductive citric-acid cycle (Schauder et al., 1987) or the reductive CO-dehydrogenase pathway (Jansen et al., 1984; 1985; Schauder et al., 1989). Investigations into the metal clusters and cellular localization of hydrogenases led to the recognition of three different types of this enzyme in *Desulfovibrio*, the [Fe], [NiFe] and [NiFeSe] hydrogenase (Huynh et al., 1984a; Rieder et al., 1984; Teixeira et al., 1986; for summary see Fauque et al., 1988). First investigations into the molecular biology and genetics of sulfate-reducing bacteria included the study of plasmids (Postgate et al., 1984c; Postgate et al., 1986; Postgate et al., 1988; Powell et al., 1989) and genes for nitrogenase (Postgate et al., 1986; Kent et al., 1989), hydrogenase (Voordouw and Brenner, 1985a; Voordouw et al., 1985b), cytochromes (van Rooijen et al., 1989; Pollock et al., 1991), other redox proteins (Krey et al., 1988; Curley and Voordouw, 1988; Brumlik and Voordouw, 1989) and genes for biosynthetic enzymes (Li et al., 1986; Fons et al., 1987) in *Desulfovibrio* species. Also, genetic exchange systems were established for *Desulfovibrio* strains (Rapp and Wall, 1987; van den Berg et al., 1989; Powell et al., 1989). Furthermore, basic insights into the energy-mode of sulfate transport in various genera of sulfate-reducing bacteria were obtained

(Cypionka, 1987; Cypionka, 1989; Warthmann and Cypionka, 1990).

Attempts to enrich acetate-oxidizing anaerobes with sulfur-oxo anions other than sulfate led to the discovery of growth by disproportionation of sulfite and thiosulfate (Bak and Pfennig, 1987). The fact that anaerobic bacteria in natural habitats may be confronted with oxic conditions led to studies on the relation of various species of sulfate-reducing bacteria to O_2 (Widdel, 1980; Cypionka et al., 1985; Dilling and Cypionka, 1990).

Until the early 1980s, sulfate reducers were traditionally classified by phenotypic characteristics, such as nutrition, morphology and chemical, or biochemical markers, or both (Pfennig et al., 1981c; Postgate, 1984a; Widdel and Pfennig, 1984). Examples for applied chemotaxonomic markers are desulfoviridin (Postgate, 1959), lipid fatty acids (Boon et al., 1977; Ueki and Suto, 1979; Taylor and Parkes, 1983; Dowling et al., 1986), or menaquinones (Collins and Widdel, 1986). As the application of 16S rRNA sequence analysis became more and more common for the elucidation of natural relationships among microorganisms, this approach became decisive in the systematics of sulfate-reducing bacteria. The first comparative analysis of 16S rRNA sequence of a sulfate-reducing bacterium, *Desulfovibrio desulfuricans*, revealed relationships to *Myxococcus* and phototrophic purple bacteria (Oyaizu and Woese, 1985). A following comprehensive study based on the 16S rRNA oligonucleotide catalogs included the spore-forming *Desulfotomaculum* species and various nonsporeforming sulfate-reducing bacteria (Fowler et al., 1986). *Desulfotomaculum* was shown to branch with Gram-positive bacteria, as already indicated by the electron microscopy of the cell wall structure (Sleytr et al., 1969; Nazina and Pivavora, 1979). All other sulfate reducers were found to affiliate with a branch of Gram-negative bacteria that also included the sulfur-reducing *Desulfuromonas* as well as *Myxococcus* and *Bdellovibrio* species. This branch of Gram-negative bacteria was termed the δ-subdivision of the purple bacteria and their nonphototrophic relatives (Woese, 1987), even though a phototroph belonging to this subdivision has not been discovered thus far. Later, this phylogenetic assemblage became known as δ-subclass of the Proteobacteria (Stackebrandt et al., 1988). Most described genera of sulfate-reducing bacteria affiliate with this subclass. Somewhat later, attempts were made to group the nutritionally diverse genera in meaningful higher taxa based on 16S rRNA sequences. First, two families were suggested within the sulfate-reducing bacteria of the δ-subclass, the *Desulfovibrionaceae* and the *Desulfobacteriaceae* (Devereux et al., 1990; Widdel and Bak, 1992). However, the number of new isolates of sulfate-reducing and other bacteria and recognizable phylogenetic lineages within the δ-subclass increased further. Today, a systematic structure of the δ-subclass needs the establishment of several families and even orders. A novel thermophilic sulfate-reducing bacterium, *Thermodesulfobacterium*, was isolated in 1983 (Zeikus et al., 1983). Metabolically it resembled *Desulfovibrio*, however the lipids were ether-linked (Langworthy et al., 1983). Later, this organism was recognized as a deeply branching line of decent within the eubacteria, distant from the δ-subclass of Proteobacteria (Henry et al., 1994). An earlier isolated thermophilic sulfate-reducing bacterium was recognized as a member of the same branch (Rozanova and Pivavora, 1988b). An overview of the major groups of sulfate-reducing bacteria and archaea (see following section) within the 16S rRNA-based tree of life is shown in Fig. 2.

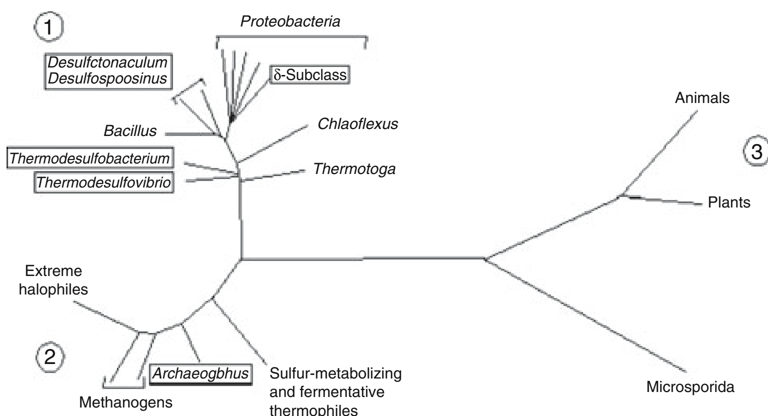

Fig. 2. Phylogenetic trees reflecting the relationships of groups of sulfate-reducing bacteria to other organisms on the basis of 16S rRNA sequences. (A) Overview showing the three domains of life: (1), Eubacteria; (2), Archaebacteria; (3), Eukaryotes. The tree was adapted from Achenbach-Richter et al. (1987) and Devereux et al. (1989). (B) More refined tree with genera. The tree was constructed using the ARB database and programs implemented therein (Ludwig et al., 1998). Scale bar represents 10 inferred nucleotide substitutions per 100 nucleotides.

Fig. 2. *Continued*

In the 1990s, many advances were achieved in the study of individual proteins, genes, degradative capacities and ecology of sulfate-reducing bacteria. Among the hydrogenases studied in various microorganisms, the first crystal structure was obtained from the enzyme in a sulfate-reducing bacterium, *Desulfovibrio gigas* (Volbeda et al., 1995). Structural and functional investigations into hydrogenases continued steadily (Volbeda et al., 1996; Higuchi et al., 1997; Nicolet et al., 1999) and included the recognition of cyanide and CO as ligands of the active-site iron atom. Crystal structures of cytochrome c_3 molecules from various *Desulfovibrio* sp. were also determined at high resolution (Matias et al., 1993; Czjzek et al., 1994; Fritz, 1999) and revealed a similar overall structure. Another contribution of general significance to biochemistry was the elucidation of the crystal structure of aldehyde oxidoreductase from *Desulfovibrio gigas* (Romão et al., 1995). The crystal structure was not only the first to be resolved within the xanthine oxidase family, but also provided the correct structure of a widespread class of co-factors, the molybdopterins. The first crystal structure of a dissimilatory nitrate reductase was again determined from a sulfate-reducing bacterium, *Desulfovibrio desulfuricans* (Dias et al., 1999).

Genetic studies were mainly carried out with *Desulfovibrio desulfuricans* and *D. vulgaris* because of the ease of cultivation and the applicability of antibiotics as selecting agents for mutants. Methods for the exchange of genetic material such as transduction, conjugation and transformation were further developed (for review see Voordouw and Wall, 1993b). Plasmids were constructed that can be applied as shuttle vectors for recombinant DNA (e.g., Rousset et al., 1998a). Transposons (Wall et al., 1996) and plasmids carrying the counterselectable marker *sacB* (Keon et al., 1997) were

applied to sulfate-reducing bacteria to create mutants.

In the 1990s, pure cultures of sulfate-reducing bacteria were isolated that could oxidize alkanes (Aeckersberg et al., 1991; Aeckersberg et al., 1998; So and Young, 1999a), toluene (Rabus et al., 1993; Beller et al., 1996), xylenes (Harms et al., 1999) or naphthalene (Galushko et al., 1999) completely to CO_2. Furthermore, it was demonstrated that sulfate-reducing bacteria could grow with crude oil as the sole source of organic substrates (Rueter et al., 1994; Rabus et al., 1996), an aspect that contributes to our understanding of sulfide production in oil reservoirs and oil production plants. Anaerobic degradation of hydrocarbons as chemically sluggish molecules requires a suite of unusual reactions (e.g., the fumarate-dependent activation of toluene to benzylsuccinate; Beller and Spormann, 1997b; Rabus and Heider, 1998) as first discovered in denitrifiers (Biegert et al., 1996). In addition to hydrocarbons, other organic molecules were newly recognized as organic substrates for sulfate-reducing bacteria. Glycolate can be oxidized completely to CO_2 by the novel sulfate reducer *Desulfocystis glycolicus* (Friedrich and Schink, 1995; Friedrich et al., 1996). Utilization of the sulfur compound dimethylsulfoniopropionate (DMSP) was demonstrated with several sulfate-reducing bacteria (van der Maarel et al., 1996a, b; Jansen and Hansen, 1998). Another type of novel sulfate-reducing bacterium was shown to oxidize a reduced inorganic phosphorous compound, phosphite (Schink and Friedrich, 2000).

The introduction of molecular methods, especially those based on 16S rRNA sequences, into microbial ecology was also fruitful for the study of natural populations of sulfate-reducing bacteria. After the first construction of 16S rRNA-targeted probes for *Desulfovibrio* species (Amann et al., 1990) and other groups of sulfate-reducing bacteria (Devereux et al., 1992), these and other probes were subsequently applied to biofilms (Ramsing et al., 1993; Santegoeds et al., 1999; Schramm et al., 1999), marine water columns (Ramsing et al., 1996; Teske et al., 1996), various sediments (Llobet-Brossa et al., 1998; Rooney-Varga et al., 1998; Sass et al., 1998; Sahm et al., 1999a), microbial mats (Fukui et al., 1999; Minz et al., 1999a) and an enrichment culture with crude oil (Rabus et al., 1996). Probe hybridization of rRNA after extraction or in whole cells, often in combination with counting series, confirmed the significance of sulfate-reducing bacteria in aquatic habitats, as shown in biogeochemical studies. Further approaches for the study of sulfate-reducing bacteria in habitats were based on reverse sample genome probing (Voordouw et al., 1991), hydrogenase genes (Wawer et al., 1997) or sulfite-reductase genes (Wagner et al., 1998; Minz et al., 1999b). Molecular methods in combination with cultivation and biogeochemical studies also provided basic insights into sulfate-reducing populations in cold sediments, which cover large areas of the ocean floor. Sulfate-reduction rates measured off Svalbard in the Arctic Ocean were comparable to those in marine sediments from temperate climate sites (Sagemann et al., 1998). Several previously unknown types of psychrophilic sulfate-reducing bacteria (e.g., *Desulfotalea*, *Desulfofaba*) could be isolated in pure cultures (Knoblauch et al., 1999a, b; Knoblauch and Jørgensen, 1999c) and shown to constitute a significant fraction of the natural cold-adapted population (Sahm et al., 1999b). The combination of pure-culture studies and molecular approaches also provided new insights into the ecology of gliding, filamentous sulfate-reducing bacteria, genus *Desulfonema* (Fukui et al., 1999).

Sulfate-Reducing Archaea

When, during the early 1980s, several breakthroughs occurred in the discovery of novel, extremely thermophilic Archaea (see for instance Stetter, 1985), the novel isolates initially comprised methanogenic, fermentative, sulfur-reducing and some aerobic microorganisms, but no sulfate reducers. Thermophilic sulfate-reducing microorganisms known at that time were bacteria with temperature optima below 75°C. In 1987, however, enrichment and isolation studies with samples from hydrothermal systems revealed the existence of archaeal sulfate reducers with a growth optimum of 83°C (Stetter et al., 1987). The new sulfate reducer named *Archaeoglobus fulgidus* (Stetter, 1988) contains the cofactor F_{420}, tetrahydromethanopterin (Stetter et al., 1987), and methanofuran (White, 1988; Gorris et al., 1991), which were known before only from methanogens. Furthermore, *Archaeoglobus* was shown to be phylogenetically more closely related to methanogens than to thermophilic archaeal sulfur-reducers or sulfur oxidizers (Achenbach-Richter et al., 1987). Further new species of the genus were *A. profundus* (Burggraf et al., 1990) and *A. lithotrophicus* (Stetter et al., 1993).

Because the existing biochemical knowledge about mesophilic sulfate-reducing bacteria and methanogens could be applied to the study of *Archaeoglobus*, progress in the understanding of its metabolic pathways, enzymes and underlying genes was rapid. In the carbon metabolism, the pathway for complete oxidation of lactate to CO_2 could be elucidated. It was recognized as an archaeal parallel of the CO dehydrogenase pathway in mesophilic sulfate-reducing bacteria

(Schauder et al., 1986; Schauder et al., 1989), with the involvement of the archaeal cofactors (Möller-Zinkhan et al., 1989; Möller-Zinkhan and Thauer, 1990; Schmitz et al., 1991; Klein et al., 1993; Schwörer et al., 1993). Also, enzymes in the transport of reducing equivalents were investigated (Kunow et al., 1994; Kunow et al., 1995). Autotrophic CO_2 fixation in *A. lithotrophicus* was recognized to occur via the reductive CO dehydrogenase pathway (Vorholt et al., 1995), again a parallel to CO_2 assimilation in sulfate-reducing bacteria (Jansen et al., 1984; 1985; Schauder et al., 1989). The reduction of sulfate was shown to involve the same enzymatic steps as in bacterial sulfate reducers. Enzymes of the sulfate-reduction pathway in *Archaeoglobus* were purified and compared to the analogous bacterial enzymes, especially on the gene level (Speich and Trüper, 1988; Dahl et al., 1990; 1993; 1994; 1999a; Speich et al., 1994; Sperling et al., 1998; Sperling et al., 1999).

In 1997, the complete genome sequence of *A. fulgidus* was published (Klenk et al., 1997). This was the first genome sequence of a sulfate-reducing prokaryote.

Sulfur-Reducing Bacteria

Biological reduction of sulfur to sulfide with endogenous or added organic electron donors has been reported several times since the end of the 19th century (Beijerinck, 1895; Starkey, 1937; Woolfolk, 1962; for overview see Roy and Trudinger, 1970). The reaction has been observed in bacteria, cell extracts, fungi, other plants, and in animal tissues. In several instances, the early observed processes of sulfur reduction appear to be by-reactions (incidental sulfur reduction) in an artificially created situation without bioenergetic or ecological significance.

First evidence for sulfur reduction as the sole source of energy for microbial growth was furnished by Pelsh (1936) who enriched novel vibrioid bacteria from mud using sulfur and H_2 as defined substrates. The first pure cultures definitely growing by sulfur reduction was *Desulfuromonas acetoxidans*, an obligately anaerobic mesophile using acetate as electron donor (Pfennig and Biebl, 1976). The bacterium was discovered as the chemotrophic partner in a deep-green phototrophic culture originally known as "*Chloropseudomonas ethylica*"; this culture was thought to be related to green sulfur bacteria, but differed from them by the ability to grow on acetate and even ethanol without addition of sulfide as electron donor. The actual process in this culture was elucidated as a sulfur-sulfide cycle involving a green phototrophic sulfur bacterium that oxidized sulfide to elemental sulfur, and *Desulfuromonas* that reduced sulfur with organic compounds (Pfennig and Biebl, 1976). *Desulfuromonas* was also the first pure culture of an obligate anaerobe shown to oxidize acetate and other organic substrates completely to CO_2 (Pfennig and Biebl, 1976); earlier, anaerobic acetate oxidation was only known in denitrifying bacteria. Subsequently, similar mesophilic bacteria including obligate sulfur reducers were isolated with organic compounds and sulfur (Pfennig, 1984; for overview see Widdel, 1988; for more recent classification see Finster et al., 1997b). Several of these sulfur reducers were shown to grow on acetate and fumarate.

The formerly observed growth by sulfur respiration with H_2 (Pelsh, 1936) was confirmed by isolation of a spirilloid bacterium (strain 5175) which in addition used formate (Wolfe and Pfennig, 1977). Fumarate was used as alternative electron acceptor. Subsequently, further morphologically similar, spirilloid bacteria with an anaerobic catabolism of fumarate (or aspartate) were recognized as facultative sulfur-reducing bacteria that oxidized H_2 or formate. These were a tentative *Campylobacter* species (Laanbroek et al., 1977; Laanbroek et al., 1978), a spirillum isolated on lactate and DMSO (Zinder and Brock, 1978a), and *Wolinella* (formerly *Vibrio*) *succinogenes* (Macy et al., 1986).

Neither *Desulfuromonas* nor the spirilloid sulfur-reducers were able to reduce sulfate. However, the capacity for growth by sulfur reduction was also detected in sulfate-reducing bacteria. Growth on lactate or ethanol in the presence of sulfur was observed with *Desulfovibrio gigas* (Biebl and Pfennig, 1977; Fauque et al., 1979), with an isolate tentatively named *Desulfovibrio multispirans* (He et al., 1986), and with nutritionally similar but rod-shaped, desulfoviridin-negative, sulfate reducers (Biebl and Pfennig, 1977) affiliating with the later proposed genus *Desulfomicrobium* (Rozanova and Nazina, 1976; Rozanova et al., 1988a). Later, anaerobes originally isolated as ferric iron-reducing bacteria were shown to be facultative sulfur reducers (Balashova, 1985; Myers and Nealson, 1988; Caccavo et al., 1994) and, vice versa, sulfur-reducing *Desulfuromonas* was shown to reduce ferric iron (Roden and Lovley, 1993). Furthermore, a *Pelobacter* species that had been originally isolated as a fermentative bacterium was recognized as facultative reducer of sulfur and ferric iron (Lovley et al., 1995c).

A novel moderately thermophilic type of sulfur-reducing, acetate-oxidizing anaerobe was designated *Desulfurella acetivorans* (Bonch-Osmolovskaya et al., 1990). Furthermore, the thermophiles Aquifex (Huber et al., 1992), *Ammonifex* (Huber et al., 1996) and *Desulfuro-*

bacterium (L'Haridon et al., 1998) were described as hydrogen-utilizing sulfur-reducing bacteria; *Ammonifex* was originally isolated as a nitrate-reducing bacterium.

Natural relationships of sulfur-reducing bacteria were first investigated by 16S rRNA oligonucleotide cataloguing of *Desulfuromonas* (Fowler et al., 1986); it affiliates with the δ-subclass of Proteobacteria and branches within completely oxidizing sulfate-reducing bacteria; the result was later confirmed by near-complete sequencing when similar species were classified as *Desulfuromusa* (Liesack and Finster, 1994). The phylogenetic branch that comprises spirilloid sulfur-reducing bacteria was termed the ε-subclass of Proteobacteria. The first isolate (strain 5175; Wolfe and Pfennig, 1977) was classified as *Sulfurospirillum deleyanum* (Schumacher et al., 1992). *Desulfurella* species were recognized as a distinct branch within the ε-subclass with no specific relationship to sulfate-reducing bacteria or *Desulfuromonas* (Rainey et al., 1993; Miroshnichenko et al., 1998).

The first biochemical studies of sulfur-reducing bacteria were devoted to certain redox proteins and metal centers (Probst et al., 1977; Bache et al., 1983) as well as to the metabolism of acetate (Gebhardt et al., 1985). Acetate oxidation was shown to occur via the citric acid cycle, either with initial activation by CoA transfer from succinyl-CoA as in *Desulfuromonas* (Gebhardt et al., 1985), or with ATP-dependent acetate activation as in *Desulfurella* (Schmitz et al., 1990).

For the investigation of the biochemistry and bioenergetics of sulfur respiration, *Wolinella* (formerly *Vibrio*) *succinogenes* was a highly suitable model organism. This bacterium had been originally isolated as a fumarate-respiring organism (Wolin et al., 1961). The experimental approaches and results from the detailed studies of the electron transport from formate (or H_2) to fumarate in *Wolinella* as a model of anaerobic respiration (see e.g., Kröger and Winkler, 1981; Graf et al., 1985; Hedderich et al., 1999) provided an important basis also for investigations into sulfur respiration by this bacterium. Evidence was provided that polysulfide and not elemental sulfur is the actual electron acceptor (Klimmek et al., 1991; Schauder and Kröger, 1993; Schauder and Müller, 1993; Fauque et al., 1994), and there was increasing support for a periplasmic rather than a cytoplasmic orientation of the active site of polysulfide reductase, as in the case of formate dehydrogenase and hydrogenase in *Wolinella* (Schröder et al., 1988; Krafft et al., 1992; Schauder and Kröger, 1993; Krafft et al., 1995). The three subunits of the polysulfide reductase were analyzed with respect to bound cofactors (e.g., molybdopterin, FeS centers) and the underlying genes (Krafft et al., 1992; Krafft et al., 1995). A protein that increased the efficacy (viz. decreased the K_M value) of polysulfide reduction was identified and termed Sud protein; it was suggested that Sud scavenges free polysulfide in the periplasm and transports it to the active site of the reductase (Kreis-Kleinschmidt et al., 1995; Klimmek et al., 1998).

Sulfur-Reducing Archaea

In the early 1970s, the first extremely thermoacidophilic microorganisms were reported (Brock et al., 1972; Brierley and Brierley, 1982). The organisms classified as *Sulfolobus* were aerobic sulfur oxidizers. Somewhat later, they were recognized as members of a new "kingdom" of life termed "Archaebacteria" (Woese and Fox, 1977; Woese et al., 1978). These findings stimulated (in the early 1980s) the search for further, novel thermophiles under alternative conditions for enrichment cultures. Anoxic media were used that contained complex organic substrates, H_2 as well as elemental sulfur, a potential electron acceptor known from mesophilic bacteria (see above). Indeed, novel extremely thermophilic archaea were detected that grew anaerobically and produced sulfide (Fischer et al., 1983; Stetter, 1982; 1983a; 1983b; Zillig et al., 1981; 1982; 1983), and the number of novel isolates increased steadily in subsequent years (for overview see e.g., Stetter et al., 1990; 1996). Several isolates seemed to reduce sulfur in a by-reaction or as mere electron sink to facilitate fermentation (Zillig et al., 1982; for more recent overview see Schönheit and Schäfer, 1995; Hedderich et al., 1999). Nevertheless, evidence for sulfur respiration as a mode of energy metabolism in archaea was clearly provided in cultures of *Thermoproteus* and *Pyrodictium* species that grew with H_2 as the only electron donor in the absence of organic compounds (Fischer et al., 1983; Stetter et al., 1983b). Further, newly isolated archaea that definitely grow by sulfur respiration, viz on H_2 and sulfur, were *Stygioglobus azoricus* (Segerer et al., 1991), *Pyrobaculum islandicum* (Huber et al., 1987) and *Stetteria hydrogenophila* (Jochimsen et al., 1997).

A unique versatility in sulfur metabolism was found in new lithoautotrophic thermophilic isolates, *Acidianus infernus* (Segerer et al., 1985; Segerer et al., 1986) and *Desulfurolobus* (originally *Sulfolobus*) *ambivalens* (Zillig et al., 1985; Zillig et al., 1986) that grew aerobically by sulfur oxidation as well as anaerobically by sulfur reduction with H_2.

In carbon assimilation during sulfur reduction with H_2, the reductive citric acid cycle and more recently the hydroxypropionate pathway were shown to be operative in *Thermoproteus neutro-*

philus (Schäfer et al., 1986) and *Acidianus* (Menendez et al., 1999), respectively. In the course of investigations into the sugar metabolism in several hyperthermophiles (for overview see Selig et al., 1997), pathways also were investigated in the sulfur-respiring, facultatively organotrophic *Thermoproteus tenax* (Siebers and Hensel, 1993). Evidence was provided for a non-phosphorylated Entner-Doudoroff pathway and a modified Embden-Meyerhof-pathway. Furthermore, complete oxidation of organic substrates via the citric acid cycle was demonstrated in the facultatively organotrophic sulfur-respiring species *Thermoproteus tenax* and *Pyrobaculum islandicum* (Selig and Schönheit, 1994). So far, these are the only extremely thermophilic sulfur-reducing microorganisms shown to couple sulfur reduction to complete mineralization of organic compounds, analogous to *Desulfuromonas* and *Desulfurella* (see above). The electron transport during sulfur reduction with H_2 was studied in *Pyrodictium brockii* (Phil et al., 1992; Maier, 1996) and *Pyrodictium abyssii* (Dirmeier et al., 1998); these species employ different transport chains.

Overview of Principal Properties

Sulfate-Reducing Bacteria and Archaea

Sulfate-reducing bacteria gain energy for cell synthesis and growth by coupling the oxidation of organic compounds or molecular hydrogen (H_2) to the reduction of sulfate (SO_4^{2-}) to sulfide (H_2S, HS^-), as schematically shown in Fig. 1. Hence, sulfate-reducing bacteria are easily recognized by the production of high sulfide concentrations (with non-limiting electron donor and sulfate, usually in the range of several millimolar) concomitantly with growth and the strict dependence of this process on the presence of free sulfate. This process is also termed "dissimilatory sulfate reduction," to allow clear differentiation from assimilatory sulfate reduction. Assimilatory sulfate reduction generates reduced sulfur for biosynthesis (e.g., of cysteine) and is a widespread biochemical capacity in prokaryotes and plants. Assimilatory sulfate reduction does not lead to the excretion of sulfide. Only upon decay (putrefaction) of the biomass is the assimilated reduced sulfur released as sulfide. The amounts of sulfide produced by dissimilatory sulfate reduction with a given amount of biomass is by orders of magnitude higher than the amount of sulfide liberated from the organic sulfur during putrefaction of the same amount of biomass. If the average formula of biomass is approximately written as that of a carbohydrate (CH_2O), an amount 1,000 g (33.3 mol) would yield 133 mol [H], and thus allow formation of 16.7 mol or 567 g H_2S by sulfate reduction (8 [H] needed per SO_4^{2-}). With the approximate natural content of 1% organic sulfur, the same amount of biomass would only yield 10 g of H_2S if degraded by merely putrefying bacteria.

The production of high concentrations of H_2S often indicates the activity and presence of sulfate-reducing microorganisms in natural habitats. The presence of H_2S is obvious by its characteristic smell, black precipitation of ferrous sulfide when iron minerals are present, and white patches of elemental sulfur as an oxidation product formed in contact with air. Such signs for the activity of sulfate reducers are often encountered if organic substances accumulate in the presence of sulfate under anoxic conditions. Growth conditions for sulfate-reducing microorganisms prevail in sediments of virtually all aquatic habitats, which may be cold, moderate or geothermally heated up to ca. 105°C. But also flooded soils such as rice paddies and technical aqueous systems (as for instance sludge digestors, oil tanks or vats in the paper-making industry) may offer suitable growth conditions for sulfate-reducing microorganisms.

From such habitats, in particular marine sediments, a great variety of sulfate-reducing microorganisms has been isolated. The classification of the major groups of sulfate-reducing microorganisms is today based on 16S rRNA sequence analysis. This method is usually relevant for the definition of the more refined taxa, viz. genera and sometimes species; nevertheless, phenotypic features such as nutritional capacities or chemotaxonomic properties may be decisive as well on the genus level, and in combination with DNA-DNA hybridization, in particular on the species level. Bacterial sulfate reducers fall into three major branches, the δ-subclass of Proteobacteria with more than twenty-five genera, the Gram-positive bacteria with the genera *Desulfotomaculum* and *Desulfosporosinus*, and branches formed by *Thermodesulfobacterium* and *Thermodesulfovibrio* (Fig. 2). Sulfate reducers in the latter branch are thermophilic, whereas the two other branches comprise psychrophilic, mesophilic as well as thermophilic species. Currently recognized genera of sulfate-reducing bacteria and archaea are summarized in Table 1.

Sulfate-reducing bacteria are morphologically diverse; cell forms include cocci, rods, curved (vibrioid) types, cell aggregates (sarcina-like) and multicellular gliding filaments. Sulfate-reducing microorganisms are strict anaerobes, even though certain species may tolerate and reduce oxygen for a limited period of time. Many sulfate-reducing microorganisms can grow by

Table 1. Morphological and physiological properties of the genera of sulfate-reducing bacteria and archaea.

Genus	Morphology	Optimum temperature (°C)	Desulfoviridin[a]	Electron acceptors for growth (other than SO_4^{2-})	Oxidation of organic electron donors[b]	Electron donors[c]

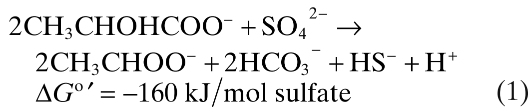
[e]Utilized by a few unnamed strains but not by the validly published species.

[f]May be utilized with thiosulfate as electron acceptor.

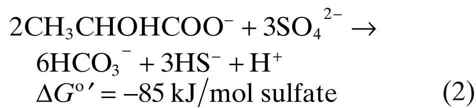
[g]For further description see Daumas et al., 1988; Min and Zinder, 1990; Nazina et al., 1988; and Widdel, 1988.

[h]Thermophilic species.

utilizing sulfite or thiosulfate as alternative electron acceptors, which are also reduced to sulfide. Fewer species have been described to utilize elemental sulfur or nitrate as electron acceptors (for growth), which are reduced to sulfide or ammonia, respectively. The involvement of an external electron acceptor in the energy metabolism allows anaerobic growth even on highly reduced compounds that cannot be utilized by purely fermentative bacteria. Indeed, the electron donors of sulfate-reducing microorganisms include end products of fermentative bacteria. Bacterial sulfate reducers are known to utilize a great variety of low-molecular mass organic compounds, including mono- and dicarboxylic aliphatic acids, alcohols, polar aromatic compounds and even hydrocarbons. Growth with polymers, such as polysaccharides, as in the case of archaeal sulfate reducers, has not been observed. Oxidation of organic compounds may be incomplete, leading to acetate (often simultaneously with CO_2) as an end product, or complete, leading entirely to CO_2. In the case of lactate, a relatively common substrate, the two possibilities for its metabolism are as follows:



$$2CH_3CHOHCOO^- + SO_4^{2-} \rightarrow 2CH_3CHOO^- + 2HCO_3^- + HS^- + H^+ \quad \Delta G^{o\prime} = -160\ \text{kJ/mol sulfate} \quad (1)$$



$$2CH_3CHOHCOO^- + 3SO_4^{2-} \rightarrow 6HCO_3^- + 3HS^- + H^+ \quad \Delta G^{o\prime} = -85\ \text{kJ/mol sulfate} \quad (2)$$

Incomplete oxidation of organic substrates is due to the lack of a mechanism for the terminal oxidation of acetyl-CoA. Because of this fundamental catabolic difference, it is common to distinguish between two physiological groups, the incomplete and complete oxidizers. However, these are purely physiological or functional groups that overlap only partly with molecular systematic groups.

The energy gain from dissimilatory sulfate-reduction is relatively low in comparison to aerobic respiration. For instance, the free energy change ($\Delta G°$) of the complete oxidation of acetate or lactate with sulfate as electron acceptor is –48 or –128 kJ, respectively, whereas acetate or lactate oxidation with O_2 provides –844 or –1323 kJ, respectively (here caluclated per mol of the organic substrate). Accordingly, by far the greater part of the organic substrate (or of H_2) consumed by sulfate-reducing bacteria is oxidized in the energy metabolism (Fig. 1), as is obvious from relatively low growth yields. Examples of measured dissimilatory growth yields ($Y_{Sulfate}$, cell dry mass formed per mol sulfate reduced) are as follows: *Desulfovibrio vulgaris*, H_2 (with acetate and CO_2 as carbon source), 8.3 g (Badziong and Thauer, 1978); *Desulfobacter postgatei*, acetate, 4.8 g (Widdel and Pfennig, 1981b); *Desulfovibrio inopinatus*, lactate (incompletely oxidized), 17.8 g (Reichenbecher and Schink, 1997); *Desulfococcus multivorans*, benzoate (completely oxidized), 6.2 g (Widdel, 1980); strain NaphS2, naphthalene (completely oxidized), 6.4 g (average; Galushko et al., 1999). The portions of the organic electron donors and carbon sources assimilated into cell material were ca. 9% (acetate) and 11% (lactate, benzoate, naphthalene). However, growth yields are not constants. They may be influenced by substrate limitation and resulting growth rate (Badziong and Thauer, 1978), the sulfide concentration (Widdel and Pfennig, 1977), and temperature (Isaksen and Jørgensen, 1996a; Sass et al., 1998b; Knoblauch and Jørgensen, 1999c). Variable growth yields of the same bacterial species (growing on one type of substrate) may be interpreted as a variable efficacy of coupling between electron transport and energy conservation, or a variable portion of the conserved energy (viz. ATP) that is needed for maintenance and hence does not contribute to net cell growth.

As in other bacteria, there is no strict, causal connection between free energy changes and highest growth rates (μ_{max}) that can be reached under optimum conditions. Still, the tendency has been often observed that electron donors which allow high free energy changes and involve simple, common enzyme mechanisms (e.g. H_2, formate, ethanol, lactate, malate) allow, in principle, faster growth than electron donors that provide less energy and require more complicated, "unusual" enzyme mechanisms (e.g. aromatic compounds, alkanes). But there are exceptions. Some specialized species may utilize the former type of substrates (if used at all) more slowly than one of the latter. Growth rates observed with sulfate-reducing bacteria under optimal conditions (in synthetic media in the laboratory, with saturating or almost saturating substrate concentrations) cover a wide range, as illustrated with a few examples: *Desulfovibrio vulgaris*, H_2, 0.15 h^{-1} (doubling time, 4.6 h; Badziong and Thauer, 1978); *Desulfobacter* species, acetate, 0.035–0.039 h^{-1} (doubling time 20–18 h; Widdel and Pfennig, 1981b; Widdel, 1987); strain NaphS1, naphthalene, ca. 0.004 h^{-1} (doubling time, 1 week; Galushko et al., 1999). The resulting highest specific sulfate reduction rates ($V_{max} = \mu_{max}/Y_{Sulfate}$) with H_2, acetate and naphthalene were 18, 7.3–8.1, and 0.64 mmol sulfate per g cell dry mass and hour, respectively.

Most sulfate-reducing bacteria tolerate more than 10 mM sulfide, as repeatedly shown during

characterization of various species (for references see Table 1). Sulfate-reducing bacteria utilizing aromatic hydrocarbons formed as much as 20–25 mM sulfide before growth ceased (Harms et al., 1999; Rueter et al., 1994). In contrast, some *Desulfotomaculum* species appear to be more sensitive to sulfide, which affects their growth at concentrations of 4–7 mM (Klemps et al., 1985; Widdel and Pfennig, 1977).

In comparison to bacterial sulfate reducers, archaeal sulfate reducers have been detected relatively recently and fewer species are known. As thermophilic microorganisms with optimal growth at temperatures around 80°C or higher, archaeal sulfate reducers are less ubiquituous than their bacterial counterparts. Rather, archaeal sulfate reducers appear to be restricted to habitats like hydrothermal vents, hot springs and deep, warm oil reservoirs. So far, fewer substrates are known for archaeal than for bacterial sulfate reducers. However, archaeal sulfate reducers were shown to utilize the polymers, starch and peptides. Oxidation of organic compounds is always complete, in the case of lactate according to equation (2).

Sulfur-Reducing Bacteria and Archaea

In addition to sulfate-reducing microorganisms, a variety of prokaryotes exists that reduce elemental sulfur (or other, lower oxidation states of this element) but not sulfate. Among the lower oxidation states, the element sulfur (often written as S^0, S_8) is probably the most widespread sulfur species in sediments and geological deposits. Many chemical and biological oxidation processes of H_2S do not directly lead to sulfate (the highest oxidation state) but rather to elemental sulfur, which therefore may accumulate. Prokaryotes that reduce sulfur do not form phylogenetically coherent groups of bacteria or archaea.

Many prokaryotes have been directly enriched and isolated with sulfur as an electron acceptor (e.g., Pfennig and Biebl, 1976; Wolfe and Pfennig, 1977; Bonch-Osmolovskaya et al., 1990; Stetter, 1985). Furthermore, the capacity for growth with sulfur as electron acceptor has been documented for bacteria that were originally isolated on the basis of growth with other electron acceptors such as manganese (IV) (Myers and Nealson, 1988) or iron (III) (Caccavo et al., 1994). Conversely, microorganisms isolated with sulfur are often able to reduce other electron acceptors such as nitrate, iron(III), or thiosulfate. In contrast to dissimilatory sulfate reduction, the capacity for sulfur reduction also has been observed in bacteria that grow definitely with O_2 and which are, therefore, facultative anaerobes. However, many sulfur-reducing microorganisms are strictly anaerobic.

Among the sulfate-reducing bacteria, only a few species can grow with elemental sulfur (Biebl and Pfennig, 1977; Table 1). Other sulfate-reducing bacteria may produce some H_2S in a by-reaction not leading to growth when transferred from sulfate-grown cultures to media with crystalline (rhombic) or colloidal sulfur. Growth of many species of sulfate reducers is even inhibited by sulfur (e.g., Widdel and Pfennig, 1981b; Widdel et al., 1983; Bak and Widdel, 1986a; 1986b; Burggraf et al., 1990), probably because elemental sulfur as an oxidant shifts the potential of redox couples in the medium and cells to unfavorable, positive values.

Analogous to capacities in sulfate-reducing bacteria, the oxidation of organic substrates in sulfur-reducing bacteria may be incomplete and lead to acetate as an end product (as for instance in *Sulfos pirillum*, *Wolinella*, *Shewanella* and *Pseudomonas mendocina*), or complete and lead to CO_2 as the final product (as for instance in *Desulfofuromonas* or *Desulfurella*).

Whereas bacterial sulfur reducers may be mesophilic or moderately thermophilic, archaeal sulfur reducers are all extremely thermophilic. Typical habitats of the hyperthermophilic sulfur reducers are solfataric fields, hot springs and hydrothermal systems in the deep sea, whereas mesophilic bacterial sulfur reducers can be isolated from almost every freshwater or marine sediment, or even from wet soil.

Unlike sulfate reduction, the reduction of the lower oxidation states of sulfur is not always a respiratory process. The compounds may only serve as hydrogen sinks for a "facilitated fermentation," or they may even be reduced in by-reactions without an obvious bioenergetic benefit. These processes vary, forming a spectrum ranging between true sulfur respiration and sulfur reduction as a mere by-reaction. A freshwater Beggiatoa was found to reduce stored sulfur under anoxic conditions with added acetate (Nelson and Castenholz, 1981). A certain increase in cell mass indicated that the process allowed a limited energy conservation. A Chromatium species and the cyanobacterium *Oscillatoria limnetica* was found to reduce photosynthetically formed intracellular or extracellular sulfur, respectively, in the dark under anaerobic conditions, using storage carbohydrate (van Gemerden, 1968; Oren and Shilo, 1979); growth did not occur. The reactions probably sustained a maintenance metabolism. However, it is not quite clear whether energy was gained only by substrate-level phosphorylation during sugar degradation or in addition by sulfur respiration.

We propose to apply the term "sulfur-reducing bacteria" to those bacteria in which sulfur reduction is associated with a respiratory type of energy conservation (sulfur respiration). An overview of the morphological and physiological properties of bacteria and archaea definitely capable of S^0-respiration is provided in Table 2. Additional microorganisms that can reduce S^0 to H_2S, even though a respiratory function remains unclear, have been summarized by Hedderich et al. (1999).

Physiology, Biochemistry and Molecular Biology

Sulfate-Reducing Bacteria

Much of the research on sulfate-reducing microorganisms has been devoted to their unique metabolism in which five major aspects may be distinguished: 1) Sulfate reduction to sulfide, which is biochemically more complicated than O_2 reduction in aerobic organisms, requires an array of enzymes. Like carbon and nitrogen, sulfur may occur in eight different oxidation states. In biochemistry, sulfur may form bonds to hydrogen, carbon and oxygen, but also chains with S-S-bonds. Oxidation states lower than +VI (sulfate) are rather reactive and may undergo interconversions or autoxidation even at room temperature. This reactivity complicates analyses of intermediates in sulfur metabolism, but also confronts research with interesting questions. 2) Sulfate-reducing bacteria utilize a wide variety of organic compounds. Even though these are of low molecular mass and relatively simple in their structure, their oxidation under anoxic conditions often involves biochemically intriguing reactions. 3) The flow of reducing equivalents ([H], electrons) from the electron donors to the electron acceptor is associated with the respiratory energy conservation, and a great variety of electron carriers seem to be involved. 4) Synthesis of cell material from most organic substrates is expected to proceed via pathways commonly known from other bacteria and therefore has not been a major field of research. However, the capacity of a number of sulfate-reducing bacteria for cell synthesis solely from CO_2 (and mineral salts) during growth on H_2 and SO_4^{2-} as sole energy source has attracted particular attention. 5) A fifth main aspect, metabolic regulation, is widely unexplored in sulfate-reducing bacteria. In the study of all these aspects, molecular and genetic analyses are of increasing importance.

Reduction of Sulfate to Sulfide Reduction of sulfate to sulfide is an eight-electron step process that occurs via a number of intermediates. However, unlike many nitrate-reducing bacteria, sulfate-reducing bacteria usually do not excrete the intermediate oxidation states, but only the final product sulfide. Only in two cases, excretion by *Desulfovibrio desulfuricans* of minor concentrations of sulfite or thiosulfate has been reported (Vainshtein et al., 1980; Fitz and Cypionka, 1990); this does not necessarily indicate that thiosulfate is a direct intermediate.

Sulfate Transport Because all enzymatic steps leading from sulfate to sulfide occur in the cytoplasm or in association with the inner side of the cytoplasmic membrane, sulfate has to be transported into the cell. Sulfate uptake in sulfate-reducing bacteria is driven by an ion-gradient, as demonstrated in studies with *Desulfovibrio species*, *Desulfobulbus propionicus* and *Desulfococcus multivorans* (Cypionka, 1987; Cypionka, 1989; Cypionka, 1994; Cypionka, 1995; Warthmann and Cypionka, 1990). In the freshwater species (*Desulfovibrio desulfuricans*, *Desulfobulbus propionicus*), sulfate is transported simultaneously with protons, as revealed by instantaneous pH shifts in active cell suspensions upon addition of sulfate. In contrast, sulfate uptake in moderately salt-dependent species (*Desulfovibrio salexigens*, *Desulfococcus multivorans*) is driven by sodium ions (Warthmann and Cypionka, 1990; Stahlmann et al., 1991; Kreke and Cypionka, 1992). Cells grown at very limiting (e. g., micromolar) sulfate concentrations as in a chemostat (Cypionka and Pfennig, 1986) most likely transported sulfate with three protons or sodium ions, which allowed sulfate to accumulate by factors of 10^3 to 10^4 (Stahlmann et al., 1991). If the efflux of a neutral end product, H_2S, is taken into account, sulfate transport is electrogenic under these conditions. The driving force for sulfate transport was mainly the electric component of the electrochemical potential and to a lesser extent the cation concentration gradient. There is evidence for an H^+/Na^+ antiporter which creates a sodium gradient across the cytoplasmic membrane of sulfate-reducing bacteria (Varma et al., 1983; Kreke and Cypionka, 1992). With increasing sulfate concentration in the growth medium, the high-accumulating sulfate-transport system was no longer detectable. Instead, cells obviously produced a low-accumulating system causing sulfate concentration inside the cell by a factor not higher than 10^2, thus avoiding the buildup of deleterious sulfate concentrations. The latter system probably transported sulfate with two H^+ or Na^+ ions. At very high (28 mM) sulfate concentration as in seawater or most laboratory cultures, another regulation system seemed to attenuate

Table 2. Morphological and physiological properties of Bacteria and Archaea capable of respiratory reduction of elemental sulfur.

Species	Morphology	Optimum temperature (°C)	Oxidation of organic electron donors[a]	Electron donors				Electron acceptors

[b]Not tested, but likely to be utilized.

[c]*Desulfitobacterium chlororespirans* can also grow on lactate coupled to reductive dehalogenation of 3-chloro-4-hydroxybenzoate.

[d]Utilized during fementative metabolism.

[e]Low partial pressure (microaerobic conditions).

[f]Obligate lithoautotrophs that do not oxidize organic compounds.

even the low-accumulating system to prevent excess buildup of sulfate. Most likely, the sulfate transport systems operate near equilibrium (Cypionka, 1994; Cypionka, 1995). This means that the free energy from the gradient of the cotransported cations is not completely dispersed, but rather conserved more or less in the resulting sulfate gradient, rendering subsequent reactions of sulfate energetically more favorable than they would be at the lower ambient sulfate concentration. Hence, the consumption of $^1/_4$–$^1/_3$ ATP equivalent per sulfate (assuming consumption of one electrogenically produced H^+ ion, and a 3–4 H^+/ATP stoichiometry of ATP synthase; Thauer and Morris, 1984; Stock et al., 1999) for sulfate transport at very low concentration must be regarded as energetically highly economic (Cypionka, 1995). The need for such reversible, energy-conserving transport processes in the catabolism is understandable in view of the relatively low ATP gain per mol sulfate.

Sulfate uptake solely for biosynthesis (assimilatory sulfate reduction) differs completely from that in dissimilatory sulfate reduction. Sulfate transport in *Escherichia coli* for assimilation was shown to occur via an ABC transporter involving a periplasmic binding protein (Hryniewicz et al., 1990; Sirko et al., 1990). Such a mechanism for sulfate uptake is also likely in the cyanobacterium, Anacystis (Jeanjean and Broda, 1977). Sulfate uptake via ABC transporters for anabolic (assimilatory) purposes is irreversible (1 ATP/SO_4^{2-}); however, this dissipation of energy is negligible in view of the relatively low portion of reduced sulfur needed for cell synthesis (around 1% of dry mass).

Activation of Sulfate The free sulfate dianion (SO_4^{2-}) with its oxygen atoms in a tetrahedral arrangement is chemically sluggish and not easily reduced. The redox potential of the free anion pair SO_4^{2-}/ SO_3^{2-} is lower (E_0' = –0.516 V) than redox potentials of most catabolic redox couples (Fig. 3). Before being reduced, sulfate is activated by ATP sulfurylase (Peck, 1959; Peck, 1962); the product is adenosine-5′-phosphosulfate (APS), which is also termed adenylylsulfate. The ATP sulfurylase has been studied in several sulfate-reducing bacteria belonging to the genera *Desulfovibrio* and *Desulfotomaculum* (Fauque et al., 1991). Sulfate assimilation in nonsulfate-reducing bacteria and plants is also initiated by ATP sulfurylase; in the assimilatory pathways, APS either undergoes direct reduction, as in dissimilatory sulfate reduction, or phosphorylation to 3′-phospho-adenosine-5′-phosphosulfate (PAPS) before reduction (Trudinger and Loughlin, 1981; Fischer, 1988; Peck and Lissolo, 1988).

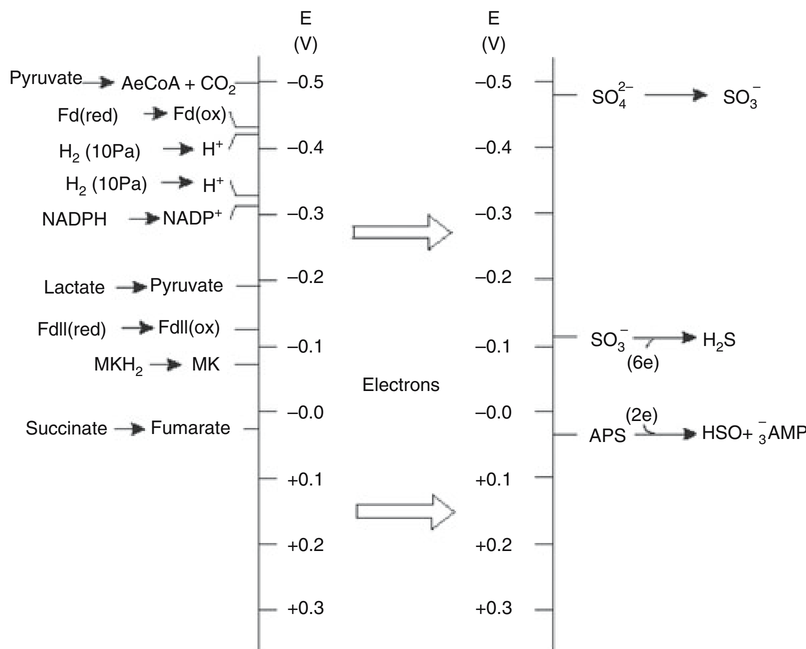

Fig. 3. Comparison of redox potentials of some important electron-donating and electron-accepting reactions in sulfate-reducing bacteria. As mechanism of sulfite reduction to sulfide, a direct reduction with six electrons (6 e^-) is assumed. For ferredoxin, an average of the E_0' (–0.440 V) given by Fauque et al. (1991) and the E_0' (–0.400 V) given by Thauer (1988) and Thauer et al. (1989b) is indicated. Abbreviations: Fd, ferredoxin; MK, menaquinone.

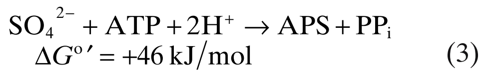
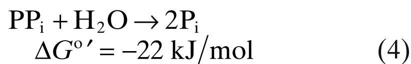
The equilibrium of the ATP sulfurylase reaction is far on the side of the reactants (K_{eq} around 10^{-8}; Akagi and Campbell, 1962), as has also been observed for the reaction in yeast (Robbins and Lipmann, 1958; Wilson and Bandurski, 1958). The hydrolysis of formed pyrophosphate (PP_i) by a pyrophosphatase pulls the ATP sulfurylase reaction and thus favors APS formation (Wilson and Bandurski, 1958), according to the following reactions:

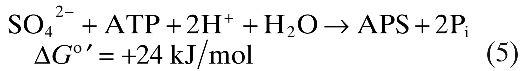


$$SO_4^{2-} + ATP + 2H^+ \rightarrow APS + PP_i \quad \Delta G^{o\prime} = +46\ kJ/mol \tag{3}$$



$$PP_i + H_2O \rightarrow 2P_i \quad \Delta G^{o\prime} = -22\ kJ/mol \tag{4}$$

Sum reaction:



$$SO_4^{2-} + ATP + 2H^+ + H_2O \rightarrow APS + 2P_i \quad \Delta G^{o\prime} = +24\ kJ/mol \tag{5}$$

High pyrophosphatase activities were found in *Desulfovibrio* (Fauque et al., 1991), *Desulfobulbus* (Kremer and Hansen, 1988a), *Desulfosporosinus orientis* (Thebrath et al., 1989). Lower activities were observed in other *Desulfotomaculum* strains. However, earlier claims that PP_i in this genus is used for an indirect phosphorylation of ADP via PP_i:acetate kinase and acetate kinase (Liu and Peck, 1981a) have been questioned and are not supported by more recent experimental data (Thebrath et al., 1989). Still, use of PP_i instead of ATP for certain phosphorylations during cell synthesis cannot be ruled out (Thauer, 1989a). Also, the possibility of energy conservation from PP_i hydrolysis by using this reaction for proton translocation has been considered (Thebrath et al., 1989; Cypionka, 1995). On the other hand, any energy-conserving reaction that makes use of PP_i has a certain reversible character and would diminish the pulling effect needed in reaction (4). Even with PP_i hydrolysis, the thermodynamic equilibrium of the net reaction is still in favor of the reactants. With an assumed approximate concentration of sulfate, ATP and phosphate of a few millimolar (Thauer et al., 1977; Cypionka, 1995), the concentration of APS would have to be less than 0.1 μM to allow a net reaction according to equation (5). This indicates the need for effective scavenging of APS by reduction. One possibility to achieve this would be a close association of enzymes or enzyme complexes, in which molecules can be channelled between reaction centers and are not released into a cytoplasmic pool until the final product, sulfide, has been formed. However, such assumptions are presently speculative in view of experimental data.

Also in the activation of sulfate, the assimilatory and dissimilatory processes differ. Recent studies of assimilatory sulfate-reduction in *E. coli* K12 have revealed a novel mechanism for overcoming the unfavorable energetics of APS formation. In *E. coli* the intracellular concentration of PP_i may be too high (ca. 0.5 μM; Kukko-Kalske et al., 1989) to allow formation of a substantial APS concentration. However, ATP-sulfurylase in this organism was found to catalyze GTP hydrolysis in addition to APS formation. ATP-sulfurylase is a tetramer built of two heterodimers; each dimer consists of a CysN (53 kDa) subunit, which carries the GTPase activity, and a CysD (23 kDa) subunit, which carries the APS-synthesizing activity (Leyh et al., 1988; Liu et al., 1998). The presence of saturating concentrations of GTP stimulates APS formation by more than 100 fold (Leyh and Suo, 1992). The stoichiometry of GTP hydrolysis and APS formation was found to be 1 : 1 (Liu et al., 1998). The energy from GTP hydrolysis is transferred via conformational change to the formation of APS (Wei and Leyh, 1998; Wei and Leyh, 1999). The ATP-sulfurylase in *E. coli*, therefore, has been termed the "ATP sulfurylase-GTPase system". The assimilatory ATP sulfurylase from *E. coli* and the dissimilatory enzyme from *Desulfovibrio* species also differ markedly on the structural level. A recent study on the composition of ATP-sulfurylase from two sulfate-reducing bacteria, *Desulfovibrio desulfuricans* and *Desulfovibrio gigas*, demonstrated that here the ATP-sulfurylase is a homotrimer and contains the metals cobalt and zinc (Gavel et al., 1998).

Reduction of APS APS is the actual electron acceptor, which is converted to sulfite or bisulfite and AMP. The $E^{o\prime}$ of the APS/SO_3^- + AMP couple is –0.060 V. The actual redox potential may be more negative because of the expected low APS concentration (see above). APS reduction is catalyzed by a reductase that has been purified from *Desulfovibrio* strains (Bramlett and Peck, 1975; Lampreia et al., 1987), *Desulfobulbus propionicus* (Stille and Trüper, 1984), and *Thermodesulfobacterium mobile* (formerly *Desulfovibrio thermophilus*; Fauque et al., 1986). Presence of APS reductase was also demonstrated in *Desulfobacter*, *Desulfococcus* and *Desulfosarcina* (Stille and Trüper, 1984). Moreover, a type of this enzyme is found in some of the lithotrophic phototrophic purple and green bacteria and a few thiobacilli (Kelly, 1988; Fischer, 1988; Brune, 1989; Trüper, 1989). In these bacteria, APS reductase catalyzes the inverse reaction. All APS reductases are nonheme iron-sulfur flavoproteins. Purification of APS reductase from *Desulfovibrio desulfuricans* and *Desulfovibrio*

vulgaris under strictly anoxic conditions yielded highly active enzymes. The purified enzyme has a heterodimeric structure (αβ), the total molecular mass being 95 kDa. Based on a characteristic motif in the primary structures, the α-subunit is proposed to carry one flavin adenine dinucleotide (FAD) molecule and the β-subunit to contain two [4Fe-4S] centers (Fritz, 1999).

Two possible mechanisms for the reduction of APS to sulfite by APS reductase have been discussed. In the first proposed mechanism, the FAD group in the α-subunit is the active site. APS reacts with reduced flavin, $FADH_2$, by a nucleophilic attack of the N^5-atom. AMP is released and an $FADH_2$-sulfite adduct is formed. Dissociation of sulfite with the binding electron pair then yields the oxidized FAD and protons (Peck and Bramlett, 1982a; Fig. 4). A formation of an $FADH_2$-sulfite adduct as a possible intermediate during APS reduction was already suggested by Michaelis et al. (1970) and inferred from studies with artificial sulfite-flavin adducts (Müller and Massey, 1969). More recent studies furnished increasing evidence for this mechanism. For instance, binding of APS, AMP and $FADH_2$ could be demonstrated by spectroscopic measurements (Fritz, 1999). In the second proposed mechanism, a thiolate anion ($R\text{-}S^-$) at the active site carries out a nucleophilic attack on the sulfur atom of APS. Such a reaction would result in the cleavage of the S-O-P bond, the release of AMP and the formation of a thiosulfonate group ($R\text{-}SSO_3^-$). Subsequent reduction of the thiosulfonate group with two electrons releases sulfite and restores the thiolate group of the active site (Fig. 5). The assumption that a thiolate group serves as active site was based on the finding that thiol-blocking agents inhibited the APS reductase from *Desulfovibrio desulfuricans* (Peck et al., 1965). However the recent experimental evidence that blockage of the thiol groups did not abolish but only reduce the activity rendered this mechanism unlikely (Fritz, 1999). In principle, the thiolate mechanism would resemble that in

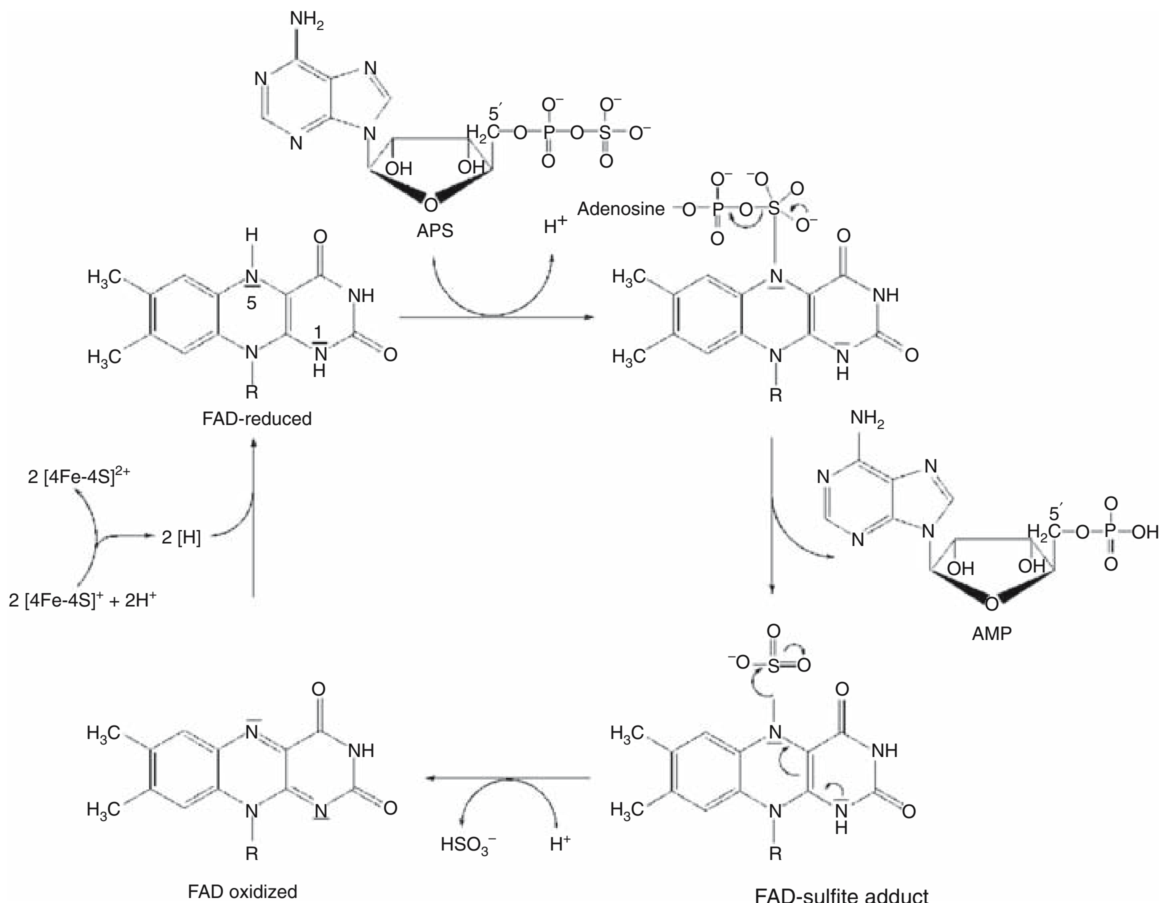


Fig. 4. Proposed mechanism of APS reduction to sulfite with FAD as the catalytically active component. FAD is bound via a residue (R) to the enzyme. Electrons for the reduction of FAD are delivered by the [4Fe-4S] centers, the oxidation of which is indicated by the change of charge. Nucleophilic attack of N-5 results in binding of APS sulfur to reduced FAD. The FAD-sulfite adduct is formed upon release of AMP. Separation of sulfite from the enzyme yields oxidized FAD, which can reenter the reaction cycle. Abbreviations: APS, adenosine-5′-phosphosulfate; FAD, flavin adenine dinucleotide.

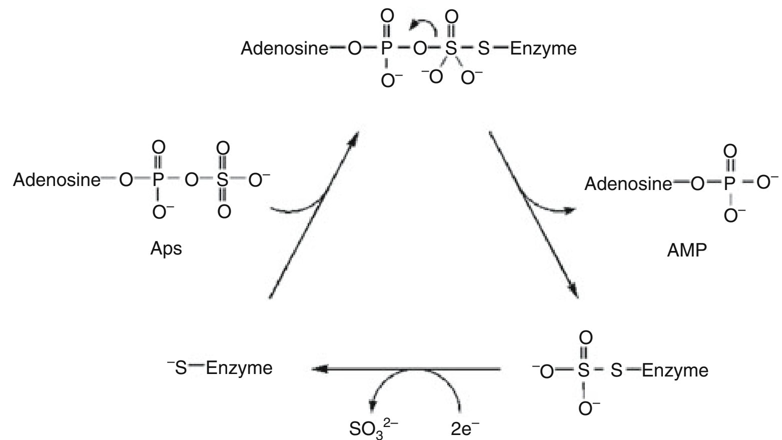

Fig. 5. Proposed mechanism of adenosine-5′-phosphosulfate (APS) reduction to sulfite with a thiolate group as the catalytically active component. Nucleophilic attack of the enzyme-bound thiolate group leads to binding of APS. Upon release of AMP, a sulfite-enzyme adduct is formed. Reduction by two electrons (2 e^-) allows separation of sulfite and regeneration of free thiolate.

one of the assimilatory pathways. In the known assimilatory pathways, the sulfonate moiety from APS or PAPS is also transferred to a thiol, which can be glutathione or thioredoxin, to yield an organic thiosulfonate; this is either reduced to the corresponding organic persulfide (RSS^-) or reductively cleaved with formation of sulfite, respectively (Trudinger and Loughlin, 1981; Imhoff, 1982; Fischer, 1988; Peck and Lissolo, 1988).

In general, it is not known what electron donor is used in the cell to reduce APS. However, from *Desulfovibrio vulgaris* (strain Hildenborough), Chen et al. (1994d) isolated a flavin mononucleotide containing protein which not only catalyzed the oxidation of NADH by O_2 with a concomitant formation of hydrogen peroxide (H_2O_2), but also fully reduced APS reductase with NADH as electron donor.

Reduction of Sulfite Sulfite ($:SO_3^{2-}$) or the protonated form bisulfite (tautomeric forms, $[:SO_2O\text{-}H]^-$ and $[H\text{-}SO_2O:]^-$), which are approximately equally abundant at pH 7.0 ($pK_{a2} = 6.99$), are pyramidal molecules with free electron pairs at the sulfur and much more reactive than sulfate. Their metabolism needs no further activation by ATP. Early reports have suggested that bisulfite rather than sulfite is the actual substrate in the reduction to sulfide (Suh and Akagi, 1969; Drake and Akagi, 1977), and subsequently sulfite reductase has often been referred to as bisulfite reductase (Hatchikian, 1994). The reduction of sulfite (+IV) to sulfide (–II) by sulfite reductase involves the transfer of six electrons (equation 6).

$$SO_3^{2-} + 6e^- + 8H^+ \rightarrow H_2S + 6H_2O \qquad (6)$$

The active centers of dissimilatory and assimilatory sulfite reductases (and nitrite reductases) are characterized by two metallo-cofactors, a reduced porphyrin of the isobacteriochlorin class, the siroheme (Murphy and Siegel, 1973a; Murphy et al., 1973b; Murphy et al., 1974; Scott et al., 1978; Cole, 1988) and an iron-sulfur cluster ([FeS]). These metallo-cofactors function in the transfer of the electrons to the substrate, as indicated schematically in Fig. 6. Siroheme-containing reductases have been isolated from a wide range of organisms. Siroheme was identified in assimilatory sulfite reductase from *Escherichia coli* (Murphy et al., 1973b), dissimilatory sulfite reductase from *Desulfovibrio* species (Murphy et al., 1973c), the dissimilatory "reverse" sulfite reductase of thiobacilli (Schedel et al., 1975; Trüper, 1994) and Chromatium (Schedel et al., 1979), and in the ammonium-producing dissimilatory nitrite reductase from *Escherichia coli* (Jackson et al., 1981; Lin and Kuritzkes, 1987), higher plants (Hucklesby et al., 1976; Vega and Kamin, 1977), algae (Zumft, 1972) and fungi (Vega and Garret, 1975).

Four major types of dissimilatory sulfite reductases are distinguished in sulfate-reducing bacteria, according to ultraviolet/visible absorption spectra and other molecular characteristics, the green protein desulfoviridin, the reddish brown colored desulforubidin and desulfofuscidin and P582 (Table 3; Fauque et al., 1991). Dissimilatory sulfite reductases generally have an $\alpha_2\beta_2$ tetrameric subunit composition (Crane and Getzoff, 1996). However a third type of subunit (γ) has been observed in a desulfoviridin-type of dissimilatory sulfite reductase in *Desulfovibrio vulgaris* (Pierik et al., 1992a) and *Desulfovibrio desulfuricans* strain Essex (Steuber et al., 1995), suggesting a hexameric structure ($\alpha_2\beta_2\gamma_2$). The γ-subunit is not encoded in the same operon as the α- and β-subunits and is not expressed coordinately with the α- and β-subunits (Karkhoff-Schweizer et al., 1993). The molecular mass of

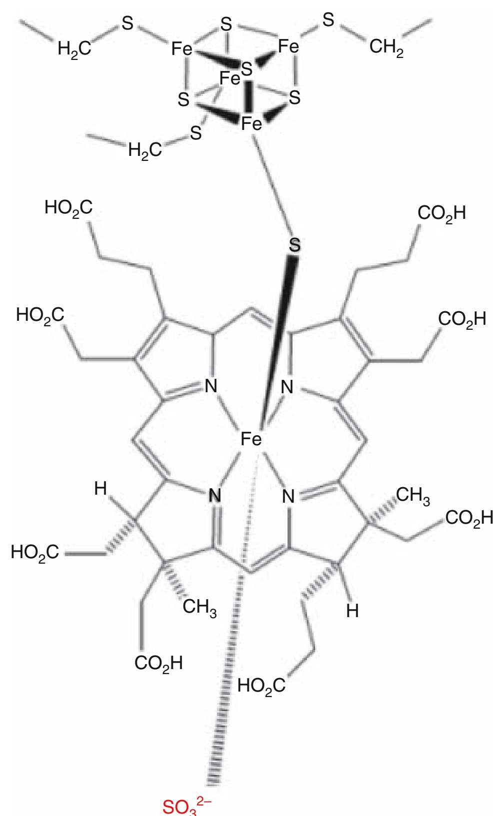

Fig. 6. Prosthetic group of sulfite reductase. Two metallo-cofactors, the [FeS] cluster and siroheme, are covalently coupled via a sulfur bridge. Sulfite is ligated to the iron atom of siroheme from the opposite direction on the non-bridging side.

dissimilatory sulfite reductases ranges between 145 and 225 kDa. *Desulfoviridin* has been identified in virtually all *Desulfovibrio species* and has since been regarded as a taxonomic marker for this genus (Lee and Peck, 1971; Lee et al., 1973a; Postgate, 1984b). However, desulfoviridin also has been detected in *Desulfococcus multivorans* (Widdel, 1980) and most *Desulfonema* species (Fukui et al., 1999), which are unrelated to *Desulfovibrio*. *Desulfoviridin* is unique among the dissimilatory sulfite reductases in that it does not react with CO and contains siroheme (two per $\alpha_2\beta_2$ holoenzyme) that is partly iron-free (viz. partly present as sirohydrochlorin). Siroheme and sirohydrochlorine are relatively easily released. The release of sirohydrochlorin is responsible for the red fluorescence in UV light of cells or extracts treated with dilute alkali (Postgate, 1956; Postgate, 1959). Siroheme prepared from desulfoviridin was found to catalyze the reduction of sulfite to sulfide and thiosulfate in the presence of artifical electron donors (Seki and Ishimoto, 1979). Analysis of the total iron content and spectroscopic investigations led to architectural models of the siroheme and the [FeS] clusters in desulfoviridin. Hagen and coworkers reported that each molecule of desulfoviridin from *Desulfovibrio vulgaris* contains 20 iron ions and a demetallated siroheme. EPR and Mössbauer spectroscopy revealed an unusually high cluster spin of S = 9/2 of a putative $[Fe_6S_6]$ prismane supercluster. Based on this finding, a superspin cluster was suggested with similarity to an $[Fe_6S_6]$ prismane cluster observed in another redox protein from *Desulfovibrio vulgaris* (Marritt and Hagen, 1996). In the latter protein, four iron atoms probably form a core that is flanked on opposite sites by two iron atoms of more ionic character; the latter couple ferromagnetically through the core (Pierik et al., 1992b; Pierik et al., 1992c). Such a cluster should be able to accept more than one electron. However, other analyses of the crystal structure of the protein revealed the presence of only four Fe ions in a novel [4Fe-3S-2O] cluster structure (Arendsen et al., 1998). Furthermore, EPR spectra of dissimilatory sulfite reductase purified under strict exclusion of O_2 yielded only weak signals, which also contradict the presence of a prismane-type super cluster (Fritz, 1999). Based on these findings, it is supposed that resonance signals previously thought to originate from a super cluster may actually result from oxidative damage of the [FeS] cluster of dissimilatory sulfite reductase. *Desulfoviridin* (containing 80% demetallated siroheme) from *Desulfovibrio desulfuricans* was reported to contain a total of 24 Fe ions (Steuber et al., 1995). Other reports on desulfoviridin from *Desulfovibrio vulgaris* furnished evidence for a total content of 10 Fe ions, and the presence of rhombic $[Fe_4S_4]$ clusters (Moura et al., 1988; Wolfe et al., 1994). *Desulforubidin* was identified in a *Desulfomicrobium* strain (formerly regarded as a *Desulfovibrio desulfuricans* strain), which lacks desulfoviridin (Lee et al., 1973b), and in *Desulfosarcina variablis* (Arendsen et al., 1993). The *Desulfomicrobium* desulforubidin has been reported to possess an $\alpha_2\beta_2$ structure (Moura et al., 1988; DerVartanian, 1994), whereas the corresponding enzyme from *Desulfosarcina* was demonstrated to have an $\alpha_2\beta_2\gamma_2$ structure (Arendsen et al., 1993). Reports from the same authors on the total iron content and structure of the [FeS] cluster also suggest differences from the aforementioned results. *Desulfofuscidin* was purified and characterized from thermophilic sulfate-reducing bacteria, *Thermodesulfobacterium commune* (Hatchikian and Zeikus, 1983; Hatchikian, 1994) and *Thermodesulfobacterium mobile* (Fauque et al., 1990). In both *Thermodesulfobacterium* species, the structure of desulfofuscidin was of the $\alpha_2\beta_2$ type. In contrast to the two aforementioned dissimilatory sulfite reductases (des-

[a]aSir, sulfite reductase.

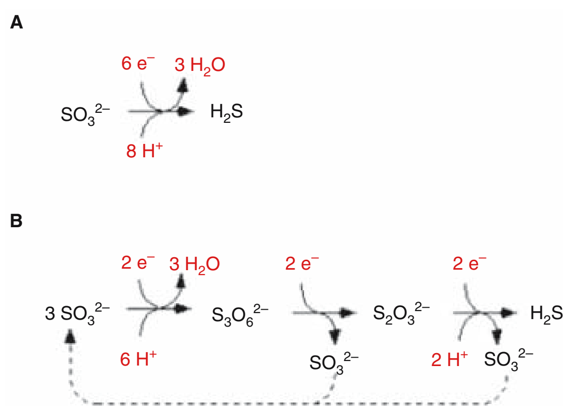

Fig. 7. Possible pathways of sulfite reduction to sulfide. (A) Direct reduction with six electrons without the formation of intermediates. (B) Trithionate pathway. The reduction occurs via three consecutive two-electron steps with the formation of tetrathionate and trithionate as intermediates.

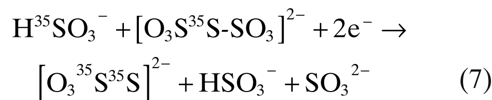
ulfoviridin and desulforubidin), four instead of two siroheme cofactors per enzyme were found in desulfofuscidin. P582 was identified in the spore-forming *Desulfotomaculum nigrificans* (Trudinger, 1970; Akagi and Adams, 1973).

Two different pathways for the reduction of sulfite to sulfide are discussed (Fig. 7): a sequential reduction in three two-electron steps with the formation trithionate and thiosulfate as intermediates, and a direct six-electron reduction without the formation of the aforementioned intermediates. Evidence for the first pathway, termed trithionate pathway (Fig. 7b) is mostly based on in vitro studies (Kobayashi et al., 1972; Akagi, 1983). In the in vitro experiments methyl- or benzylviologen were used as artificial electron donors; they were in a coupled system generated by reduction with hydrogen/hydrogenase. Under these conditions, trithionate and thiosulfate were identified in addition to sulfide as products of sulfite reduction. Under certain assay conditions, trithionate and thiosulfate were formed at concentrations similar to those of sulfide (Kobayashi et al., 1974). Also the enzymes in support of the proposed trithionate pathway, viz. trithionate reductase and thiosulfate reductase, were identified (Akagi et al., 1994). The purified desulfoviridin from *Desulfovibrio gigas* reduced sulfite with reduced methylviologen exclusively to trithionate (Lee and Peck, 1971). A "thiosulfate-forming" enzyme was isolated from *Desulfovibrio vulgaris* which formed thiosulfate from bisulfite and trithionate. Labeling experiments with ^{35}S demonstrated that the sulfur of formed thiosulfate originated from bisulfite and the inner S atom of trithionate, according to the following equation (Drake and Akagi, 1977).



$$H^{35}SO_3^- + [O_3S^{35}S\text{-}SO_3]^{2-} + 2e^- \rightarrow [O_3^{35}S^{35}S]^{2-} + HSO_3^- + SO_3^{2-} \qquad (7)$$

Also purified from *Desulfovibrio vulgaris* was a "trithionate-reducing system", which could form thiosulfate from trithionate and sulfite with flavodoxin (reduced by hydrogenase) serving as electron donor. In this system, a second protein was acting in close association with desulfoviridin and was required for trithionate formation (Kim and Akagi, 1985). A thiosulfate reductase that stoichiometrically reduced thiosulfate to sulfite and sulfide was purified from *Desulfotomaculum nigrificans* (Nakatsukasa and Akagi, 1969), *Desulfovibrio gigas* (Hatchikian, 1975) and *D. vulgaris* (Badziong and Thauer, 1980; Aketagawa et al., 1985). In summary, the stoichiometric formation of sulfite during the reduction of trithionate to thiosulfate and the reduction of thiosulfate to sulfite would add two loops to the pathway of sulfite reduction, as proposed by Kobayashi et al. (1974; Fig. 7b). Fitz and Cypionka (1990) reported the formation of trithionate and thiosulfate during reduction of sulfite with deenergized cells of *Desulfovibrio desulfuricans*. The occurrence of a trithionate pathway would be understandable from certain viewpoints of bioenergetics. The formation of trithionate would provide a relatively strong oxidant ($E_0' = +0.225$ V) and thus a favorable acceptor even for high potential electron donors, as for instance from dehydrogenation of succinate (E_0' = +0.030 V). The nature of the natural electron donor of the three two-electron reduction steps of the trithionate pathway has not been been resolved unequivocally (Peck and Lissolo, 1988). Furthermore, there are also arguments against a trithionate pathway (Chambers and Trudinger, 1975; Trudinger and Loughlin, 1981). The formation of trithionate and thiosulfate may be regarded as by-reactions. These may become dominant under in vitro conditions, for instance due to the relatively high concentrations of added bisulfite. Excess bisulfite or sulfite could react with intermediates bound to siroheme (Trudinger and Loughlin, 1981). Also, a reaction of bisulfite with formed H_2S seems possible. Bisulfite and sulfide are known to react chemically to thiosulfate and thionates, especially at low pH (Heunisch, 1976). If the side-activities of certain proteins facilitated such a reaction under in vitro conditions, the produced sulfide would not accumulate but rather be scavenged to give rise to the observed oxo-anions. Trithionate and thiosulfate reductases may serve for utilization of their substrates from the environment or for scavenging them as byproducts of the bisulfite reductase reaction. Low concentrations (5–100 μM) of thiosulfate formed in deenergized

cells from added sulfite (Fitz and Cypionka, 1990) or in cells growing on sulfate (Vainshtein et al., 1980) also may be interpreted as byproducts resulting from a reversely operating thiosulfate reductase with sulfide and sulfite as reactants; the electrons from this low potential reaction ($E_0' = -0.402$ V) could be easily consumed by other reductive processes. Evidence for the six-electron reduction of bisulfite to sulfide was achieved in a reconstitution assay with membrane-bound desulfoviridin, cytochrome c_3 and hydrogenase, all from *Desulfovibrio desulfuricans* (Steuber et al., 1994); thiosulfate and trithionate were only detected in small amounts. This experiment also indicated that cytochrome c_3 can act as electron donor for desulfoviridin, an observation that is topologically not yet understandable. The view of a six-electron reduction without the formation of free trithionate or thiosulfate as intermediates is favored if one compares sulfite reductases in dissimilatory and assimilatory sulfate metabolism and assumes that these enzymes, which are both siroheme proteins, employ in principle the same mechanism.

In assimilatory sulfur metabolism, the assimilatory sulfite reductase generates sulfide for the synthesis of the sulfur-containing amino acid cysteine. Methionine and cofactors (like coenzyme A) derive their sulfur from cysteine. In contrast to dissimilatory sulfite reductase, none of the known assimilatory sulfite reductases (aSiRs) forms detectable amounts of trithionate or thiosulfate in vitro (Lee et al., 1973a; Peck and Lissolo, 1988). Thus aSiRs reduce sulfite with high fidelity directly via a six-electron reduction to sulfide. A sulfite reductase isolated from the sulfate-reducing bacterium *Desulfovibrio vulgaris* shared the high fidelity reduction of sulfite to sulfide with the aSiR from *Escherichia coli.* Therefore it was termed "assimilatory-like sulfite reductase" (Lee et al., 1973a). The enzyme has been studied in much detail. The aSiR from *Desulfovibrio vulgaris* was also functionally expressed in other *Desulfovibrio* hosts (Tan et al., 1994). The aSiRs from sulfate-reducing bacteria differ from the aSiR from *Escherichia coli* and the dissimilatory sulfite reductases from sulfate-reducing bacteria. The former are composed of only one polypeptide and do not form multimeric proteins; they have low-spin iron instead of high-spin iron and only one siroheme and [FeS]-cluster per molecule (Huynh et al., 1984a; Huynh et al., 1984b; Moura and Lino, 1994). Tan and Cowan (1991) proposed a mechanism for the the six-electron reduction catalyzed by aSiR, which may also serve as a working hypothesis to understand other sulfite reductases. The sulfur atom of sulfite binds the Fe^{2+} ion of the siroheme from the nonbridging face. A two-electron reduction prepares the O-atom of the S-O bond for protonation so that a hydroxyl anion can be eliminated. Through repeated reduction by two electrons and subsequent protonation, the oxygen atoms are stepwise removed from the sulfur resulting in the formation of sulfide (Fig. 8). According to the model presented by Tan and Cowan (1991), the electrons for the reduction steps are "pushed" from the electron loaded [FeS]-clusters via the siroheme into the sulfite. In addition, the local environment in the sulfite-binding pocket may participate in the reduction reaction by providing protons from amino acid side chains to the O-atoms of sulfite. Such a mechanism would correspond to the "push and pull" paradigm, which has also been used to describe the cleavage of O-O bonds of peroxides by heme-containing oxygenases (Dawson, 1988; Poulos, 1988). Lui and Cowan (1994) have also proposed a six-electron reduction via a push-and-pull mechanism for dissimilatory sulfite reductase from *Desulfovibrio vulgaris.* In intact desulfoviridin, sulfite can only bind to reduced siroheme, whereas sulfite can bind to free siroheme in its oxidized state. These observations suggested a gating mechanism of dissimilatory sulfite reductase where a redox-linked structural transformation is required for substrate binding (Lui and Cowan, 1994).

Insight into the mechanism of sulfite reduction and the structure of sulfite reductase have also benefited to a great extent from studies of the aSiR from *Escherichia coli.* This enzyme consists of eight flavoprotein subunits (α-subunits), which accept electrons from NADPH, and four hemoprotein subunits (β-subunits), which accept the electrons from the flavoprotein subunits and catalyze the six-electron reduction of sulfite to sulfide. Thus aSiR from *E. coli* has an overall $\alpha_8\beta_4$-structure. Each hemoprotein-subunit carries one siroheme and one $[Fe_4S_4]$-cluster (Siegel et al., 1974; Siegel and Davis, 1974; Siegel et al., 1982). A chemical link between the siroheme and the $[Fe_4S_4]$-cluster was indicated by electronic exchange coupling observed by spectroscopic studies (Christner et al., 1984). The analysis of the crystallographic structure of the hemoprotein at a resolution of 3 Å suggested that a sulfur anion of a cysteine (Sγ) covalently links the central iron in siroheme with one of the Fe ions in the cluster (McRee et al., 1986). A more recent analysis of the crystallographic structure of the hemoprotein at a resolution as high as 1.6 Å (Crane et al., 1995; Crane and Getzoff, 1996) demonstrated that the Sγ is provided by Cys^{483}. This bridge was found to be maintained in all reduction states of the enzyme studied so far on a structural level. The 1.6 Å structure also allowed recognition of further refined details of the structure. The hemoprotein consists of three

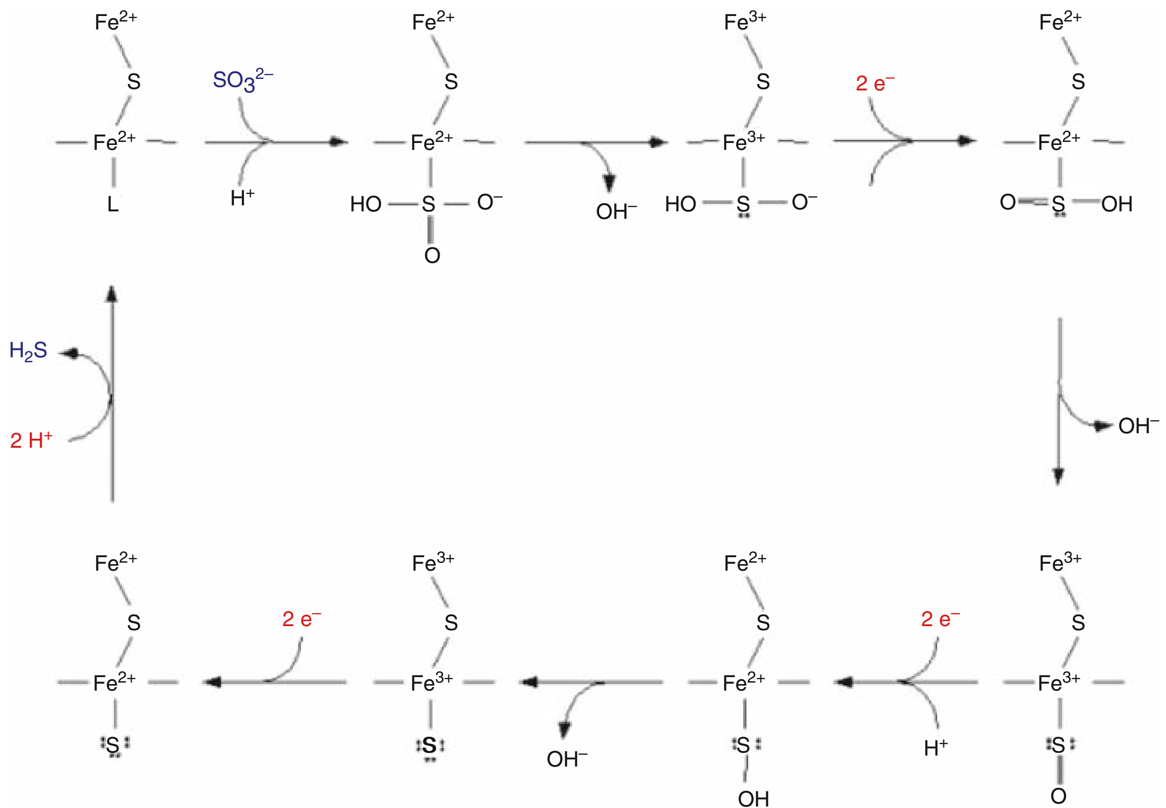


Fig. 8. Suggested mechanism for the reduction of sulfite to sulfide by subsequent two-electron steps. The [4Fe-4S] cluster that is coupled to the Fe atom of siroheme via a sulfur bridge is represented by only one Fe-ion. The L represents the protein ligand that coordinates the Fe ion of siroheme. During catalysis, L is substituted by sulfite. Modified from Moura and Lino (1994).

domains that ligate the two metallo-cofactors at their interface. This interface is predominantly formed by β-sheets which are flanked at the outside by solvent-exposed α-helices. Domain 1 and 1′ form a novel architecture reminiscent of a parachute and project harness hairpins into the interface-cofactor area. Domain 2 contributes the residues for the siroheme binding and positively charged residues that form the binding pocket for the anion substrate at the distal face of the siroheme. Domain 3 provides four cysteine residues (including the bridging ligand Cys^{483}) to ligate the $[Fe_4S_4]$-cluster at the proximal side of the siroheme. The anion-binding pocket facing the distal side of the siroheme is remarkably rich in positively charged side chains, for instance Arg and Lys residues. Thus a strongly polarizing and proton-rich environment is established which may "pull" electrons of the S-O bond into the direction of the O-atom. Also water molecules could be positioned to interact directly with the anion substrate. Thus the structural details of the active site support the earlier model of a "push-and-pull" mechanism of the six-electron reduction of sulfite to sulfide. The structure of the hemoprotein from *E. coli* is characterized by a vertical pseudo-twofold axis that relates an N-terminal sequence repeat (domain 1 and 2) to a C-terminal sequence repeat (domain 1′ and 3); this suggests that the hemoprotein arose by gene duplication. Furthermore, analysis revealed the presence of five homologous regions in the sequence of the hemoprotein. Three of them (homology regions 1–3) encompass regions essential for the active center and for stabilization of the protein structure. Such homology regions have also been observed in dissimilatory sulfite reductases and therefore support the idea that dissimilatory sulfite reductases exhibit similar structure and also catalyze a six-electron reduction without formation of intermediates (Crane et al., 1995; Crane and Getzoff, 1996).

There is a striking similarity between sulfite reductase and another enzyme with the capacity for a six-electron reduction, the ammonifying nitrite reductase (not to be confused with NO-forming nitrite reductase in denitrifiers), which catalyzes the dissimilatory reduction of nitrite to ammonia (equation 8). Such types of nitrite

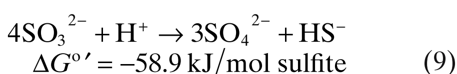
reductases also contain siroheme in the active center.

$$NO_2^- + 6e^- + 8H^+ \rightarrow NH_4^+ + 2H_2O \quad (8)$$

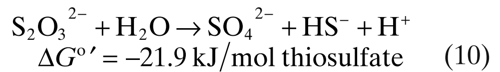
Cytochrome *c* nitrite reductase from Sulfurospirillum deleyianum not only catalyzes the six-electron reduction of nitrite to ammonia, but also that of sulfite to sulfide. Interestingly, the analysis of the crystal structure of this enzyme (Einsle et al., 1999) revealed marked structural differences from the aSiR from *E. coli*. The former enzyme is a homodimer that is predominately composed of α-helices and contains 10 closely arranged hemes. Apparently, different structures and probably also varied mechanisms have evolved to accomplish a six-electron reduction. A membrane-bound cytochrome *c*-containing nitrite reductase (also isolated from *Desulfovibrio desulfuricans*) catalyzes the six-electron reduction of nitrite to ammonia as well as that of sulfite to sulfide (Liu et al., 1994; Pereira et al., 1996).

Sequence analysis of the genes (*dsr*) encoding dissimilatory sulfite reductases from *Desulfovibrio vulgaris*, *Archaeglobus fulgidus* and *Chromatium vinosum* demonstrated that the three proteins are true homologues (Dahl et al., 1993; Hipp et al., 1997; Karkhoff-Schweizer et al., 1995). A more detailed study by Wagner et al. (1998) revealed that the evolutionary relationships derived from *dsr* sequences of sulfate-reducing microorganisms were nearly identical to relationships inferred from the 16S rRNA sequences. The authors concluded that bacterial and archaeal dissimilatory sulfite reductases originated from a common ancestor.

Dismutation of Sulfur Species A unique metabolic capacity of certain sulfate-reducing bacteria is growth by dismutation (disproportionation) of sulfite or thiosulfate, a process which may be formally described as an inorganic fermentation (Bak and Pfennig, 1987). The reactions are carried out by *Desulfovibrio sulfodismutans*, *Desulfobacter curvatus* and a so far unnamed species, strain NTA3, that grew significantly better by dismutation than by sulfate reduction. Growth by disproportionation of thiosulfate was also reported for an anaerobic bacterium, designated strain DCB-1 (Mohn and Tiedje, 1990a). Disproportionation of thiosulfate was demonstrated by radiotracer experiments in marine sediments and recognized as an important part of the sulfur cycle (Jørgensen, 1990; Jørgensen and Bak, 1991).



$$4SO_3^{2-} + H^+ \rightarrow 3SO_4^{2-} + HS^- \quad \Delta G^{o\prime} = -58.9\ kJ/mol\ sulfite \quad (9)$$



$$S_2O_3^{2-} + H_2O \rightarrow SO_4^{2-} + HS^- + H^+ \quad \Delta G^{o\prime} = -21.9\ kJ/mol\ thiosulfate \quad (10)$$

A dismutation of elemental sulfur with standard activities of the products is thermodynamically unfavorable. However, because the activity of the insoluble, elemental sulfur is always equal to 1, the free energy of the reaction is strongly influenced by the concentrations of the products and the pH:

$$4S + 4H_2O \rightarrow SO_4^{2-} + 3HS^- + 5H^+ \quad (11)$$

Standard concentrations; pH = 7: $\Delta G^{o\prime} = +10.2$ kJ/mol sulfur

SO_4^{2-} and HS^-, 0.001 M; pH = 7: $\Delta G^{o\prime} = +6.9$ kJ/mol sulfur

SO_4^{2-} and HS^-, 0.001 M; pH = 8: $\Delta G = -11.3$ kJ/mol sulfur

A purely chemical dismutation of sulfur to H_2S or polysulfide and oxygen-containing sulfur compounds was favored by elevated temperature and pH values above 7 (Belkin et al., 1985). If bacteria dismutated the formed sulfur-oxygen compounds to sulfide and sulfate, reactions (9) and (10) would result. Evidence for a microbial disproportionation of sulfur to sulfate and sulfide was provided by Thamdrup et al. (1993), who demonstrated this process in marine-enrichment cultures. The disproportionation of sulfur by these enrichment cultures was accompanied by a fractionation of the sulfur isotopes; sulfate was enriched in ^{34}S and sulfide depleted in ^{34}S (Canfield and Thamdrup, 1994). The sulfate reducer *Desulfobulbus propionicus* was the first microorganism shown to disproportionate sulfur in pure culture, even though growth under these conditions was very slow (Lovley and Phillips, 1994b; Fuseler and Cypionka, 1995). Two species of the new genus *Desulfocapsa*, *D. thiozymogenes* and *D. sulfoexigens*, grew well by disproportionation of sulfur. Both species required the presence of a sulfide scavenger (e.g., ferrihydrite) for growth with sulfur as sole source of energy and also can grow by disproportionation of thiosulfate and sulfite. *Desulfocapsa thiozymogenes*, but not *Desulfocapsa sulfoexigens*, can grow by reduction of sulfate to sulfide as the mode of energy conservation (Janssen et al., 1996; Finster et al., 1998).

Evidence has been furnished that the disproportionation of sulfite or thiosulfate to sulfate and sulfide proceeds via a reversal of the reactions of dissimilatory sulfate reduction (Krämer and Cypionka, 1989). Thus, ATP sulfurylase and not ADP sulfurylase, which is found in many lithotrophic purple phototrophs (Brune, 1989; Fischer, 1988; ; 1989) and some thiobacilli (Kelly,

1988; Kelly, 1989), is involved in the formation of sulfate from APS and allows "inorganic" substrate-level phosphorylation; it has not yet been established how stoichiometric amounts of PP_i are formed for the conversion of APS to sulfate and ATP. Reducing equivalents are derived from conversion of bisulfite to APS, which has a relative positive potential ($E_0' = -0.060$ V; see also Fig. 3). For the reductive part leading to H_2S, shifting of these reducing equivalents by reversed electron transport seems to be necessary; this was indeed indicated by the sensitivity of the dismutation to uncouplers (Krämer and Cypionka, 1989).

Electron Acceptors Other Than Sulfate

Inorganic Sulfur Species Most sulfate-reducing bacteria can use thiosulfate and sulfite as electron acceptors in addition to sulfate (Table 1). *Desulfotomaculum acetoxidans* (Widdel and Pfennig, 1981b), *Desulfonema magnum* (Widdel et al., 1983), *Desulfocella halophila* (Brandt et al., 1999), and some sulfate reducers originally assigned to *Desulfobacterium* did not reduce sulfite in growth tests. Inasmuch as sulfite is assumed to be generally a free intermediate in dissimilatory sulfate reduction, the failure of sulfate-reducing bacteria to grow with sulfite at nontoxic concentrations may be due to the lack of a specific transport system.

Oxoanions (other than sulfite and thiosulfate) have scarcely been tested in cultures of sulfate reducers. *Desulfovibrio* strains have been reported to reduce trithionate ($S_3O_6^{2-}$), tetrathionate ($S_4O_6^{2-}$), and dithionite ($S_2O_4^{2-}$) (Postgate, 1951; Ishimoto et al., 1954a; Fitz and Cypionka, 1990).

Among the sulfate-reducing bacteria, some species such as of the genera *Desulfohalobium*, *Desulfofustis*, *Desulfuromusa* and *Desulfospira* can grow with elemental sulfur (see Sulfur-reducing bacteria). Other sulfate reducers may produce some H_2S in a by-reaction without growth after transfer of sulfate-grown cells to media with crystalline (rhombic) or colloidal sulfur. Growth of many species of sulfate reducers is even inhibited by sulfur (e.g.,Widdel and Pfennig, 1981b; Widdel et al., 1983; Bak and Widdel, 1986b), probably because sulfur as an oxidant shifts the potential of redox couples in the medium and cells into an unfavorable range. In sulfate-reducing bacteria able to grow with sulfur, its reduction is probably directly catalyzed by the tetraheme cytochrome c_3 (Fauque et al., 1979; Fauque et al., 1980; Cammack et al., 1984).

Sulfonates, DMSO Reduction of sulfonates by sulfate-reducing bacteria was first described by Lie et al. (1996). These authors demonstrated utilization of cysteate, isethionate (2-hydroxyethanesulfonate), and acetaldehyde-2-sulfonate by *Desulfovibrio desulfuricans* strain IC1. Isethionate was converted to sulfide and acetate. Cysteate was also used as an electron acceptor by strains of *Desulfomicrobium baculatum* DSM 1741 and *Desulfobacterium autotrophicum*. The former strain and *Desulfovibrio desulfuricans* ATCC 29577 also used isethionate. *Desulfovibrio strain* RZACYSA can use taurine (aminoethanesulfonate), cysteate, isethionate and aminoethanesulfonate as electron acceptors (Laue et al., 1997b). Cysteate and taurine also can be fermented by some sulfate-reducing bacteria (see below).

Utilization of dimethylsulfoxide (DMSO) as an electron acceptor for growth of sulfate-reducing bacteria resulting in the production of dimethylsulfide was first reported by Jonkers et al. (1996). Out of eight strains of sulfate reducers isolated from a marine or high-salt environment, five were shown to use DMSO; most of them were *Desulfovibrio* strains. In addition, one strain of the barophilic *Desulfovibrio profundus* was also shown to use DMSO by Bale et al. (1997); the same study also demonstrated DMSO reduction by the type strain of *Desulfovibrio salexigens*, which was reported by Jonkers et al. (1996) not to reduce this electron acceptor. Sulfate and DMSO were reduced simultaneously.

Nitrate, Nitrite Nitrate is reduced by a few *Desulfovibrio* species (Seitz and Cypionka, 1986; Keith and Herbert, 1983; McCready et al., 1983; Mitchell et al., 1986), *Desulfobulbus propionicus* (Widdel and Pfennig, 1982) and *Desulfobacterium catecholicum* (Szewzyk and Pfennig, 1987; Moura et al., 1997). Nitrate may be preferred over sulfate (Seitz and Cypionka, 1986), or vice versa (Widdel and Pfennig, 1982). Dalsgaard and Bak (1994) showed that in an isolate from rice paddy soil, *Desulfovibrio desulfuricans* strain C4S, nitrate reduction was strongly inhibited by sulfide; at 0.46 mM sulfide, the specific growth rate was less than 10% of the maximum value, and no growth occurred at 0.75 mM sulfide. As the authors suggested, this implies that some negative results from growth tests of sulfate reducers with nitrate may be questioned because of the inclusion of 0.5 mM sulfide as a reducing agent in the media.

In sulfate and sulfur reducers, the end product of nitrate reduction, which occurs via nitrite, is ammonia and not N_2 as in denitrifying bacteria. The nitrate reductase of *Desulfovibrio desulfuricans* was purified and shown to be a monomeric

74-kDa protein with a [4Fe-4S] center and a molybopterin guanine dinucleotide cofactor (Moura et al., 1997). The crystal structure of this periplasmic enzyme has been determined (Dias et al., 1999); this is the first resolution of the three-dimensional structure of a nitrate reductase. Although bisulfite reductases also show activity toward nitrite, specific nitrite reductases appear to be involved in the subsequent reduction of formed nitrite to ammonium. A hexaheme cytochrome c_3 acting as nitrite reductase and consisting of 62-kDa and 19-kDa subunits has been isolated from *Desulfovibrio desulfuricans* (Liu and Peck, 1981b; Moura et al., 1997).

Iron (III) Whereas several non-sulfate-reducing members of the δ-subclass of Proteobacteria, including sulfur-reducing bacteria, can grow with iron(III) compounds as electron acceptors, this capacity has only been occasionally observed in sulfate-reducing bacteria. Reduction of chelated iron(III) was demonstrated in enzymatic tests with several *Desulfovibrio* species, *Desulfobacterium autotrophicum* and *Desulfobulbus propionicus* (Lovley et al., 1993b), and in growth tests with *Desulfovibrio profundus* (Bale et al., 1997) and several psychrophilic species (Knoblauch et al., 1999b). Among the latter, *Desulfotalea psychrophila* also reduced insoluble (nonchelated) inorganic ferric iron (ferrihydrite); however, growth was not observed.

Oxygen The study of the influence of O_2 on bacteria with an anaerobic metabolism is an ecologically relevant and biochemically interesting topic. Exposure of anaerobic bacteria to O_2 is a frequent, natural event in environments with fluctuating O_2 penetration and at the anoxic/oxic interface. Furthermore, if oxic environments such as soils or oligotrophic sediments turn anoxic due to flooding or eutrophication, respectively, communities of anaerobic bacteria gradually become established; this is most likely to occur via passage of "inocula" through the oxic environment, as for instance oxic water.

Studies of the effects of O_2 on anaerobic bacteria include several aspects; these are, for instance, anaerobe tolerance of O_2 and survival under oxic conditions, the possibility that O_2 at low concentrations may even serve as electron acceptor and allow energy conservation, and the protection of cells against harmful effects.

Pure cultures of sulfate-reducing bacteria in aerated media in laboratory experiments died off at different rates, depending on the species (Hardy and Hamilton, 1981; Cypionka et al., 1985; Abdollahi and Wimpenny, 1990). Simultaneous presence of sulfide sometimes increased the detrimental effect of O_2 (Cypionka et al., 1985). This sensitivity to long-term oxic conditions suggest that permanently oxic waters or soil usually do not harbor nonsporeforming sulfate-reducing bacteria. Only endospores of *Desulfotomaculum* species may be present in such environments at significant numbers (Widdel, 1988). However, in dense aquatic microbial populations, nonsporeforming sulfate-reducing bacteria were also observed in oxic zones. Studies on the natural distribution of sulfate-reducing bacteria revealed high numbers in zones that are exposed to rapid changes of the O_2 concentration or that are even oxic over prolonged periods, e.g., in biofilms (Ramsing et al., 1993) and microbial mats (Canfield and Des Marais, 1991; Krekeler et al., 1997; Teske et al., 1998). The existence of anoxic microniches (Jørgensen, 1977) in such zones, which might explain the occurrence of active sulfate-reducing bacteria in oxic environments, is questionable; in microbial aggregates, the O_2-reducing activity with the available electron donors was not sufficient to cope with O_2 penetration (Plough et al., 1997).

The effect of O_2 on pure cultures of sulfate-reducing bacteria in horizontal oxic/anoxic transition zones was studied in sulfidic agar with an organic electron donor under an oxic head space. In opposed O_2-sulfide gradients, several species of sulfate-reducing bacteria exhibited growth, even though sulfate was absent (Widdel, 1980; Cypionka et al., 1985). However, there was evidence that the sulfate reducers used a chemical oxidation product of sulfide, most probably thiosulfate, as electron acceptor, without getting into direct contact with O_2. The oxidation product was again reduced to sulfide. The resulting sulfur cycle mediated between the sulfate-reducing bacteria and the otherwise harmful O_2 that served indirectly as final electron acceptor. Such a mediating cycle also may occur in natural habitats as long as electron donors are available.

However, there is also evidence that sulfate-reducing bacteria are able to utilize O_2 directly. In experiments with cell suspensions of *Desulfovibrio*, O_2 was shown to serve directly as electron acceptor for H_2 oxidation, and to enable significant proton translocation (Dilling and Cypionka, 1990; Dannenberg et al., 1992). Growth due to O_2 utilization has not been observed in these experiments. Nevertheless, owing to the high rates of O_2 consumption, which were even higher than in aerobic bacteria (Krekeler et al., 1997; Kuhnigk et al., 1996), the respiratory activity of *Desulfovibrio* may be of

considerable ecological relevance for the scavenging of O_2 and an ATP gain for survival, if the habitat turns transiently oxic. The underlying mechanism of the buildup of a proton gradient with O_2 as electron acceptor is not understood. It is true that cytochrome c_3 can directly react with O_2; however, as a periplasmic enzyme and electron acceptor of hydrogenase, cytochrome c_3 reacting with O_2 would not allow the generation of a proton gradient. Hence, O_2 is expected to react with one or some of the redox proteins of the electron transport chain so that a proton gradient can be formed. From the viewpoint of thermodynamics, O_2 is the most favorable of all electron acceptors and could replace any of the intermediates from the pathway of sulfate reduction. The problem lies in a controlled reaction of O_2 that avoids instantaneous damage of proteins and redox centers by reactive oxygen species (e.g., superoxide or peroxide).

In other experiments, O_2 at concentrations as low as 0.24 to 0.48 μM were observed to support growth of *Desulfovibrio vulgaris* strain Hildenborough in lactate medium with a strongly limiting sulfate concentration (Johnson et al., 1997). However, it cannot be completely excluded that O_2 was only indirectly reduced via a mediating sulfur cycle as suggested before (Cypionka et al., 1985). At concentrations above approximately 1 μM, O_2 arrested growth of *D. vulgaris* (Johnson et al., 1997). In other experiments using four different strains of sulfate-reducing bacteria, the rate of sulfate reduction was strongly affected by an O_2 concentration of 15 μM (Marshall et al., 1993).

Reduction of O_2 by sulfate-reducing bacteria may occur not only with electron acceptors directly utilized from the medium, but also with storage compounds. *Desulfovibrio gigas* and *Desulfovibrio salexigens* both can accumulate massive amounts of polyglucose during anaerobic growth with lactate and sulfate (Stams et al, 1983; van Niel et al., 1996; van Niel et al., 1998). Polyglucose utilization was shown to be involved in the survival under oxic conditions. In *Desulfovibrio gigas*, NADH produced during the breakdown of polyglucose was reoxidized by NADH:rubredoxin oxidoreductase, a dimeric flavoprotein consisting of a 27- and a 32-kDa subunit, and containing two molecules of each, FAD and FMN per enzyme molecule (LeGall and Xavier, 1996). The rubredoxin is oxidized with O_2 at a flavoheme protein, yielding water as the end product (Gomes et al., 1997).

A further argument for the assumption that O_2 is not only a harmful agent, but at low concentrations, also a potential electron acceptor for respiratory energy conservation in sulfate-reducing bacteria comes from the observation of aerotaxis in *Desulfovibrio* species. In medium with lactate and without (or limiting) sulfate in capillary tubes, *Desulfovibrio* species positioned themselves in bands at low O_2 concentration (Johnson et al., 1997; Eschemann et al., 1999). *Desulfovibrio oxyclinae* formed ring-shaped bands around O_2 bubbles (Krekeler et al., 1998). Band formation was dependent on the presence of an electron donor. Measurements of the O_2 gradient with microelectrodes revealed that the side of the bands facing the bubbles was exposed to O_2 concentrations of up to 50 μM, whereas the other side of the band was anoxic. This indicates an intensive O_2 respiration within the band. Thus aerotactic band formation and O_2 respiration can be regarded as a means to decrease the O_2 concentration completely and restore anoxic conditions within a narrow zone (Eschemann et al., 1999). The attraction of sulfate-reducing bacteria by O_2 at low concentrations is so far unique among anaerobic bacteria; they are usually assumed to be repelled by O_2 (Armitage, 1997).

A molecular key element of bacterial chemotactic response is the presence of methyl-accepting chemotaxis proteins (MCPs), which receive and transmit the attracting or repelling signal. MCPs consist of a periplasmic N-terminal domain which binds the attractant or repellent, a transmembrane spanning segment, and a cytoplasmic C-terminal domain which functions as signal transducer. These proteins have been well studied in *Escherichia coli* and *Salmonella typhimurium* (Stock and Surette, 1996). A 73-kDa protein discovered in *Desulfovibrio vulgaris* (and named DcrA) shows in its C-terminal domain similarities to that of MCPs in *E. coli*; the C-terminal domain in the latter is the site of methylation. There is also evidence for a cytoplasmic location of the C-terminal domain of DcrA, in accordance with that of MCPs in *E. coli* (Dolla et al., 1992; Deckers and Voordouw, 1994b). In contrast, the N-terminal domain of DcrA did not exhibit significant sequence homology with known MCPs. The N-terminus of DcrA was found to harbor a *c*-type heme. Addition of O_2 or the reducing agent dithionite resulted in a decrease or increase, respectively, in the methylation of DcrA. DcrA, a *c*-type cytochrome that was unknown before, may function in sensing O_2 or the redox potential of the medium (Fu et al., 1994). To further elucidate the role of DcrA in chemotaxis, a knock-out mutant of the coding gene, *dcrA*, was constructed. However, phenotypic analysis of the mutant did not reveal a deficiency in aerotaxis (Fu and Voordouw, 1997). Subsequent analysis of a genome library of *D. vulgaris* strain Hildenborough revealed the presence of at least 11 additional *dcr* genes (*dcrB* to *dcrL*; Deckers and Voordouw, 1994a). Phylogenetic analysis suggested that the *dcr* family is

distinct from the *mcp* families in other eubacteria and arose early in evolution (Deckers and Voordouw, 1996).

Also, proteins that might be involved in the detoxification of damaging oxygen species have been identified in sulfate-reducing bacteria. Superoxide dismutase and catalase activity have been detected in *Desulfovibrio* species (Bruschi et al., 1977; Hatchikian et al., 1977). *Desulfoferredoxin* (Moura et al., 1990) and neelaredoxin (Chen et al., 1994c) are mononuclear non-heme iron proteins that have been purified from *Desulfovibrio* species found to catalyze removal of superoxide (Romão et al., 1999; Silva et al., 1999b). Neelaredoxin is encoded in an operon with two additional open reading frames (ORFs) which putatively encode two chemotaxis proteins (Silva et al., 1999b). Interestingly, significant sequence similarities between desulfoferredoxin and neelaredoxin from *Desulfovibrio* and neelaredoxin and superoxide oxidoreductase from *Pyrococcus furiosus* were reported; the latter does not dismutate, but rather catalyzes a net reduction to H_2O_2 (Jenney et al., 1999). This observation indicates a mechanism of superoxide detoxification in sulfate-reducing bacteria that is different from the mechanism of superoxide dismutase. The genes *rub* and *rbo*, which code for rubredoxin and a putative rubredoxin oxidoreductase, respectively, were identified in *Desulfovibrio vulgaris* (Hildenborough) as one transcriptional unit (Brumlik et al., 1989). The *rub-rob* genes from *Desulfoarculus baarsii* complemented an *Escherichia coli* mutant that was deficient in superoxide dismutase (Pianzzola et al., 1996). The gene product Rob is suggested to scavenge superoxide not via dismutation as superoxide dismutase, but via a reductive mechanism using electron donors such as NAD(P)H (Liochev and Fridovich, 1997), possibly comparable to the abovementioned superoxide oxidoreductase.

Definite aerobic growth of sulfate-reducing bacteria (viz. for an infinite number of generations in oxic media) has not been observed so far, despite their capacity to couple O_2 reduction with energy conservation, their chemotaxis toward microaerobic zones, and their detoxification mechanisms. From the viewpoint of biochemistry, there is no obvious reason to assume that the capacity for dissimilatory sulfate reduction and aerobic growth in the same bacterium are mutually exclusive.

Fumarate Some *Desulfovibrio* species ferment fumarate or malate. In the presence of an additional electron donor (e.g., H_2 or formate), fumarate and malate are quantitatively reduced to succinate (Grossmann and Postgate, 1955; Miller and Wakerley, 1966; Barton et al., 1970; Wolfe and Pfennig, 1977), which represents a purely respiratory type of energy conservation (fumarate respiration; Graf et al., 1985; Kröger, 1987). *Desulfovibrio desulfuricans* reduced fumarate even prior to sulfate.

Acrylate Reduction of acrylate as an alternative electron acceptor by sulfate-reducing bacteria was discovered by van der Maarel et al. (1996c). Acrylate can be formed in marine sediments by the cleavage of dimethylsulfoniopropionate (DMSP), an osmolyte of many marine algae; such a cleavage can be carried out by the acrylate-reducing sulfate reducer *Desulfovibrio acrylicus*. The DMSP lyase from this organism has been purified (van der Maarel et al., 1996b). Acrylate reduction to propionate also occurs in the presence of sulfate.

Reductive Dehalogenation Reductive dehalogenation coupled to anaerobic bacterial growth was first demonstrated with 3-chlorobenzoate in a mixed culture (Dolfing and Tiedje, 1987). The organism responsible for the reaction was identified as a new type of sulfate-reducing bacterium named *Desulfomonile tiedje* (DeWeerd et al., 1990). 3-Chlorobenzoate and 3,5-dichlorobenzoate were used as electron acceptors for growth with formate as electron donor (Dolfing, 1990; Mohn and Tiedje, 1990b). *Desulfovibrio strain* TBP-1 can grow by coupling the oxidation of lactate to the reductive dehalogenation of 2,4,6-tribromophenol to phenol (Boyle et al., 1999); other halogenated compounds that are used as alternative electron acceptors include 2-, 4-, 2,4- and 2,6-bromophenol.

Arsenate, Chromate and Uranium Anaerobic reduction of arsenate coupled to the oxidation of acetate was originally demonstrated with *Chrysiogenes arsenatis*. This strictly anaerobic bacterium cannot reduce sulfate (Macy et al., 1996). *Desulfotomaculum auripigmentum* is the first example of a sulfate-reducing bacterium that can grow with arsenate as a terminal electron acceptor (Newman et al., 1997b). This bacterium reduced arsenate to arsenite and preferred arsenate to sulfate when both were included in the medium; under such conditions, precipitation of As_2S_3 took place both intra- and extracellularly (Newman et al., 1997a). Two sulfate-reducing bacteria, *Desulfomicrobium* strain Ben-RB and *Desulfovibrio* strain Ben-RA, can reduce sulfate and arsenate concomitantly (Macy et al., 2000). Studies on bacterial utilization of arsenate as electron acceptor have been summarized by Stolz and Oremland (1999b).

Reduction of chromate(VI) with H_2 as electron donor was observed with whole cells of *Desulfovibrio vulgaris*; reduction in cell-free extracts depended on cytochrome c_3 (Lovley and Phillips, 1994a). Cytochrome c_3 from *D. vulgaris* is also capable of uranium(VI) reduction (Lovley et al., 1993a).

Electron Carriers and Possible Functions The reduction of one molecule sulfate to sulfide consumes eight electrons that are ultimately provided by the electron-donor substrate. Unlike the situation in aerobic respiration in mitochondria and bacteria, there is not one terminal-oxidase analogue in sulfate reducers. These bacteria possess at least two simultaneously operating enzymes that are functionally analogous to a terminal oxidase, namely APS reductase and bisulfite reductase; two other enzymes, trithionate reductase and thiosulfate reductase, could have such a function in the case of stepwise sulfite reduction or with trithionate or thiosulfate as external electron acceptors. Unlike oxidases in aerobic respiration, the reductases of the sulfate-reducing bacteria were in most cases not found to be associated with the cytoplasmic membrane. In immunoelectron microscopy, the bisulfite reductases of *Desulfovibrio vulgaris*, *D. gigas* and *Thermodesulfobacterium mobile* (formerly *D. thermophilus*) and the APS reductases of *D. vulgaris* and *D. gigas* appeared to be cytoplasmic enzymes; only APS reductase of *T. mobile* was mainly membrane-associated (Kremer et al., 1988c). In the construction of electron flow models for chemiosmotic energy conservation by dissimilatory sulfate reduction, the frequent finding of bisulfite reductases and APS reductases in the cytoplasm and the possible involvement of two other reductases (trithionate reductase and thiosulfate reductase) are complicating factors. There is evidence that certain redox carriers have highly specific roles in the electron flow by transporting reducing equivalents to particular acceptors only (LeGall and Fauque, 1988; Peck and Lissolo, 1988; Fauque et al., 1991).

Suggested mechanisms of energy conservation are discussed in connection with particular electron donors (see Energy Conservation in this Chapter). In the following subsections, a few characteristics of major redox proteins are presented. More detailed information is given by Fauque et al. (1990) and LeGall and Fauque (1988).

Cytochromes Several different types of cytochromes, which differ in molecular mass, subunit composition and heme content, have been identified in sulfate-reducing bacteria (Widdel, 1988; Fauque et al., 1991; LeGall and Fauque, 1988). The physiological function of cytochromes with respect to their position in electron transfer is not yet completely understood. Principal types of cytochromes that have been recognized are the tetraheme cytochrome c_3, the hexadecaheme high molecular mass cytochrome (Hmc), and the small cytochrome c_{553}.

The type of cytochrome that was named c_3 has been identified in all *Desulfovibrio* species (Postgate, 1984a; LeGall and Fauque, 1988; Fauque et al., 1991), *Desulfobulbus elongatus* (Samain et al., 1986a) and both *Thermodesulfobacterium* species (Hatchikian et al., 1984; LeGall and Fauque, 1988; Fauque et al., 1991). Cytochrome c_3 (M_r of ca. 13,000) consists of one polypeptide chain and contains four hemes with midpoint potentials ranging from –0.125 to –0.325 V; it is also termed tetraheme cytochrome c_3. The ligands of each iron atom are two histidine molecules. The observed occurrence of cytochrome c_3 in the periplasm (Badziong and Thauer, 1980; LeGall and Fauque, 1988; Fauque et al., 1991) has been confirmed by the signal sequence in the gene (Voordouw and Brenner, 1986). In cell-free systems, tetraheme cytochrome c_3 is required for the reduction of ferredoxin, flavodoxin and rubredoxin by hydrogenase and apparently plays a key role in H_2 metabolism (Fauque et al., 1991; LeGall and Fauque, 1988). Still, the mode of electron transfer by cytochrome c_3 in vivo is unsatisfactorily understood. Cytochrome c_3 may interact with the transmembrane spanning Hmc complex to channel electrons through the membrane into the cytoplasm (Voordouw, 1995). The crystal structures of cytochrome c_3 from *Desulfovibrio vulgaris* Miyazaki (Higuchi et al., 1984), *D. vulgaris* Hildenborough (Matias et al., 1993), *D. desulfuricans* (Norway; Czjzek et al., 1994) and *D. desulfuricans* (Essex; Fritz, 1999) were resolved at resolutions lower than 2 Å. The three cytochromes had a similar overall structure with an extended α-helix and a short β-strand as the prominent secondary structure elements. The four heme groups are all solvent exposed and arranged in pairs (termed heme I/II and heme III/IV pairs). Conserved lysine residues surrounding heme IV are proposed to be essential for the contact between cytochrome c_3 and the electron-delivering hydrogenase. *D. africanus* contains two different types of tetraheme cytochrome c_3, one being acidic and another being basic. In contrast to the basic c_3, the acidic c_3 showed only poor reactivity towards either [Fe] or [NiFe] hydrogenase (Pieulle et al., 1996; Magro et al., 1997).

An octaheme cytochrome c_3 that is found in most *Desulfovibiro* species is structurally rather different from tetraheme cytochrome c_3, but also can react with hydrogenase (Fauque et al., 1991;

LeGall and Fauque, 1988). Studies with mutants have indicated that heme IV is most likely the interactive heme in the cytochrome-hydrogenase complex, and that Tyr73 has an important structural function (Aubert et al., 1997; Aubert et al., 1998a). Octaheme cytochrome c_3 may be involved in the supposed thiosulfate reduction of the trithionate pathway.

A high molecular mass cytochrome *c* was isolated from *Desulfovibrio vulgaris* (Hildenborough); it had an estimated mass of 70 kDa and contained 16 heme groups (Higuchi et al., 1987). From the same organism, a dimeric 26-kDa cytochrome c_3 (also referred to as cytochrome cc_3) was isolated that possessed four identical heme groups in each subunit (Loutfi et al., 1989). A DNA probe designed from a partial amino acid sequence of cytochrome cc_3 led to the identification of the *hmc* gene, coding for the hexadecaheme cytochrome Hmc in *Desulfovibrio vulgaris* (Hildenborough). In addition, the amino acid composition of the two cytochromes proved to be highly similar, thus suggesting that cytochrome c_3 and Hmc are identical (Pollock et al., 1991). The *hmc* gene from *D. vulgaris* (Hildenborough) was overexpressed in *D. desulfuricans* G200 and the recombinant Hmc protein was purified. Studies on the arrangement of the heme-binding sites of this Hmc revealed that the protein contained three complete cytochrome c_3-like and one incomplete c_3-like domain, suggesting that Hmc arose via gene duplication (Bruschi et al., 1992). The *hmc* gene of *D. vulgaris* (Hildenborough) is part of an operon containing eight open reading frames, Orf1 to Orf6 (also termed *hmcA* to *hmcF*), Rrf1 and Rrf2. The open reading frame Orf1 represents the *hmc* gene. Based on sequence homologies, putative functions and cellular locations were suggested for the other open reading frames: Orf2 is a putative transmembrane protein containing four [FeS] clusters, Orf3 to Orf5 are membrane integral proteins, and Orf6 is a cytoplasmic protein containing two [FeS] clusters. It is proposed that Hmc and Orf2 to Orf6 are assembled in one transmembrane protein complex that functions in transferring electrons from the periplasm to the cytoplasm (Rossi et al., 1993). The two genes *rrf1* and *rrf2* code for regulatory proteins. Deletion of genes *rrf1* and *rrf2* resulted in an overexpression of the *hmc* operon and a more rapid growth on H_2 and sulfate. From these results, it was concluded that the Hmc-complex mediates the electron transfer between periplasmic hydrogenase and the cytoplasmic enzymes involved in sulfate reduction (Keon et al., 1997). Even though Hmc from *D. vulgaris* (Hildenborough) can in principle accept electrons directly from [NiFe] hydrogenase, the rates of electron transfer are increased by the presence of cytochrome c_3, suggesting that this cytochrome acts as a mediator between hydrogenase and Hmc (Pereira et al., 1998). However, an Hmc isolated from *Desulfovibrio gigas* could accept electrons directly from hydrogenase (Chen et al., 1994a).

In the case of a transmembrane hexaheme cytochrome *c* from *Desulfovibrio desulfuricans*, a function of the protein as nitrite reductase could be demonstrated (Liu and Peck, 1981b).

A "split-Soret" cytochrome, which is a dimer with two identical 26 kDa subunits and two heme groups per subunit, was isolated from *Desulfovibrio desulfuricans* (Liu et al., 1988). The complete amino acid sequence of this cytochrome *c* revealed that the C-terminal part contained the heme-binding site, similar to that in cytochrome c_3, and an additional domain that could harbor a putative non-heme iron-containing cluster (Devreese et al., 1997).

During investigations on the natural electron acceptor of formate dehydrogenase of *D. vulgaris*, a small cytochrome with a mass of 6.5 kDa was isolated and (in accord with its absorption maximum) termed "cytochrome c_{553}" (Yagi, 1969; Sebban et al., 1995). The purified protein could be reduced by formate dehydrogenase but not by hydrogenase (Yagi, 1979). Cytochrome c_{553} also can function as primary electron acceptor of lactate dehydrogenase (Ogata et al., 1981). Recognition of a leader sequence in the structural gene furnished evidence for a periplasmic location of cytochrome c_{553} (van Rooijen et al., 1989). Cytochrome c_{553} is a monoheme cytochrome with methionine and histidine as axial ligands (Fauque et al., 1991). The complete amino acid sequences of cytochromes c_{553} from *D. vulgaris* strains Hildenborough and Miyazaki revealed that the two proteins were not closely related (Nakano and Kikumoto, 1983). Apart from its small size, cytochrome c_{553} shows two further peculiar characteristics: 1) it has a low redox potential (ca. 0.01 V; Bertrand et al., 1982) and 2) it undergoes a conformational change during the transition from the oxidized to the reduced state (Senn et al., 1983). Structural analysis by means of NMR spectroscopy revealed that cytochrome c_{553} contains three conserved helices around the heme group, which resides in a cleft, and an additional fourth helix (Marion and Guerlesquin, 1992; Blackledge et al., 1995). In addition, the existence of two conformations of cytochrome c_{553} was recognized with NMR studies of the purified recombinant protein (Blanchard et al., 1993). The tyrosine residue Tyr64, which is positioned at the interface between the heme group and the central cleft of the protein, is thought to play a key role in structural stability (possibly affecting electron exchange with formate dehydrogenase;

Blanchard et al., 1994; Sebban-Kreuzer et al., 1998a; Sebban-Kreuzer et al., 1998b). Further studies attempting to elucidate this electron transfer involve ^{15}N labeling of cytochrome c_{553} and analysis with NMR techniques (Morelli et al., 1999).

In addition to sulfate-reduction, *Desulfomonile tiedjei* DCB-1 can also employ reductive dehalogenation as a mode of energy conservation. A new type of cytochrome was found to be co-induced with the dehalogenating activity. This cytochrome is probably located toward the periplasmic aspect of the membrane because the protein was extracted from the membrane fraction and carries an N-terminal signal sequence. The coding gene of the new cytochromes was cloned by means of primers developed from the N-terminal sequence of the purified protein. Two *c*-type heme-binding motifs were identified in the C-terminus. However, the protein sequence was found to have no substantial similarities with sequences deposited in databases. Thus this protein is considered as a new *c*-type cytochrome (Louie et al., 1997).

Ferredoxins Ferredoxins are very common in sulfate-reducing and sulfur-reducing bacteria (Probst et al., 1978; Bache et al., 1983; Gebhardt et al., 1983; LeGall and Fauque, 1988; Fauque et al., 1991). Several types have been described, but possible physiological roles are known only in a few cases. In *Desulfovibrio gigas*, ferredoxin I ($E_0' = -0.440$ V), a protein with one [4Fe-4S] cluster, is active in the cleavage of pyruvate (viz. pyruvate:ferredoxin oxidoreductase reaction). In case of the assumed tetrathionate pathway, the midpoint potential of ferredoxin I would make it an appropiate electron donor for the thiosulfate reductase reaction. Ferredoxin II ($E_0' = -0.130$ V) from *D. gigas* has one [3Fe-4S] cluster and has been suggested to function as electron donor in the reduction of bisulfite to sulfide (Fauque et al., 1991; LeGall and Fauque, 1988). There is evidence for an interconversion of the different clusters in these ferredoxins. In *Desulfobacter* as well as in the sulfur reducers (*Desulfuromonas* and *Desulfurella*), a ferredoxin is the acceptor in the 2-oxoglutarate dehydrogenase reaction (Gebhardt et al., 1983; Paulsen et al., 1986; Schmitz et al., 1990; Thauer, 1988; Thauer et al., 1989b).

Flavodoxins In some but not all *Desulfovibrio* and *Desulfomicrobium* species, flavodoxins have been found. The two oxidation states, F/FH((E_0' = –0.140 V) and FH(/FH_2 (E_0' = –0.440 V) have midpoint potentials comparable to those of ferredoxin I and II, and the corresponding proteins could replace each other in their function as electron carriers (Fauque et al., 1991). Flavodoxin was not active as electron donor for the purified thiosulfate reductase of *Desulfovibrio vulgaris* strain Miyazaki F (Aketagawa et al., 1985). The three-dimensional structure and the gene sequence of flavodoxin from *Desulfovibrio vulgaris* is known (Curley and Voordouw, 1988).

Rubredoxins Rubredoxins are low molecular mass single-iron proteins (M_r ca. 6,000) which carry only electrons, like cytochromes and ferredoxins. They are present in all *Desulfovibrio* strains studied and also in *Thermodesulfobacterium commune* (LeGall and Fauque, 1988; Shimizu et al., 1989); the amino acid sequences of some of them have been determined, and the sequence of the gene in *Desulfovibrio vulgaris* (Hildenborough) coding for rubredoxin is known (Voordouw, 1988a; Voordouw, 1988b; Shimizu et al., 1989). Because of their rather positive midpoint potentials (–0.050 to +0.005 V), questions have been raised as to the physiological role of this protein in dissimilatory sulfate reduction (LeGall and Fauque, 1988; Brumlik and Voordouw, 1989). Kremer et al. (1988b) speculated about a role of rubredoxin as electron donor in the reduction of APS to bisulfite. However, such a role would be likely only if the actual potential of APS/HSO_3^- + AMP at the in vivo concentrations is more positive than the midpoint potential (–0.060 V), which may not be the case (see Reduction of APS in this Chapter). Experimental evidence for such a role has not been found so far. Rubredoxin may play a major role in channeling electrons to O_2 consumption or O_2 detoxification (See Oxygen in this Chapter).

Rubrerythrin A high-potential redox protein, rubrerythrin (midpoint potential +0.23 V), has been purified from *Desulfovibrio vulgaris* and *Desulfovibrio desulfuricans* (Fauque et al., 1991); if this redox carrier is involved in sulfate reduction, a possible function that can be envisaged is in the reduction of trithionate to thiosulfate and bisulfite ($E_0' = +0.225$ V). Recent studies indicate that the major role of rubrerythrin and nigerythrin may lie in protection against deleterious effects of O_2. The proteins from *Desulfovibrio vulgaris* were shown to have NADH peroxidase activity (Coulter et al., 1999).

Menaquinone All sulfate-reducing prokaryotes examined contain menaquinones (Collins and Widdel, 1986; Schmitz et al., 1990; Tindall et al., 1989). The number of isoprenoid units per side chain varies between 5 and 9. Terminal saturation of the side chain may occur in other bacteria

(Collins and Widdel, 1986). Judging from their general occurrence in sulfate-reducing microorganisms, menaquinones seem to be obligate components of electron transport chains. Involvement in the electron transport during oxidation of acetate (Kröger et al., 1988; Möller-Zinkhan and Thauer, 1988; Möller-Zinkhan and Thauer, 1989; Thauer et al., 1989b; Figs. 6 and 8) or lactate (Fauque et al., 1991) has been discussed.

METABOLISM OF ELECTRON DONORS AND ENERGY CONSERVATION A great variety of low molecular mass compounds serve a electron donors for dissimilatory sulfate reduction (and often simultaneously as carbon sources for cell synthesis). Many of these are products from the fermentative breakdown of biomass, which reflects the importance of sulfate-reducing bacteria as terminal degraders in anoxic, sulfate-rich habitats such as marine sediments.

The study of several electron donors of sulfate-reducing bacteria is closely connected to investigations into structure and function of special enzymes such as hydrogenase. Furthermore, the study of electron donors has led to the discovery of previously unknown anaerobic pathways or capacities (e.g., a modified, anaerobic citric acid cycle, the oxidative C_1/CO-dehydrogenase pathway, reactions at aromatic molecules or the capacity for alkane oxidation without O_2).

The bioenergetic processes of sulfate-reducing bacteria are determined by the electron donors. The catabolism of organic electron donors connected to the reduction of an external electron acceptor generally offers two advantages over a purely fermentative catabolism. First, with an external electron acceptor, substrate level phosphorylation can be performed to a larger extent than in purely fermentative metabolism in which a part of the organic substrate has to be sacrified for the disposal of surplus reducing equivalents (e.g., regeneration of $NADP^+$). With external electron acceptors, substrate-level phosphorylation and growth is even possible with non-fermentable compounds, as for instance butyrate or higher fatty acids. In the vast number of sulfate-reducing bacteria that excrete acetate, substrate-level phosphorylation via phosphate acetyltransferase and acetate kinase can be expected. Substrate-level phosphorylation in *Desulfobacter* species occurs via ATP-citrate lyase, and in sulfate-reducing bacteria employing the C_1/CO-dehydrogenase pathway most likely during formation of free formate from formyltetrahydropterin. Further substrate-level reactions may occur in the few species of sulfate-reducing microorganisms that grow with carbohydrates. Second and most importantly, the reduction of the external electron acceptor can be associated with an electron transport chain that allows generation of a transmembrane proton gradient and chemiosmotic ATP synthesis. In microorganisms utilizing organic compounds without an external electron acceptor, chemiosmotic energy conservation occurs only in special metabolic types, as for instance propionate-forming bacteria (Schink, 1988a) or methanogens. In sulfate-reducing bacteria, numerous enzymes catalyzing redox-reactions as well as potentially electron-carrying proteins and menaquinones have been studied in detail, and electron transport chains have been proposed. However, there is no unifying theory of electron transport in sulfate-reducing bacteria. In view of the various electron donors, metabolically diverse species and differences in the redox protein outfit, the development of a unifying model of electron transport is unlikely, except for steps in the pathway of sulfate reduction.

In the following, physiological, enzymatic and energetic aspects of the utilization of various electron donors for sulfate reduction are presented.

Molecular Hydrogen Molecular hydrogen (H_2) is (besides acetate) a key intermediate in the natural mineralization of organic substances in sediments, sludge digestors and other anoxic ecosystems. Also the fact that many species of various genera of sulfate-reducing bacteria utilize H_2 as sole electron donor (Table 1) reflects the ecological importance of the lightest of all molecules. Hydrogen at standard pressure is an energetically favorable electron donor ($2\ H^+/H_2$, $E_0' = -0.414$ V); the free energy change at various partial pressures is depicted in Fig. 11. Cell material during growth on H_2 and sulfate may be synthesized from acetate and CO_2 (chemolithoheterotrophic species) or alone from CO_2 (see autotrophic species; Carbon Assimiliaton).

Growth on H_2 has been observed in many of the known genera of sulfate-reducing bacteria (Table 1). Hydrogenase activities have been demonstrated in strains of the genera *Desulfovibrio* (Fauque et al., 1991), *Desulfobulbus* (Samain et al., 1986b; Kremer and Hansen, 1988a), *Desulfobacter*, *Desulfobacterium*, *Desulfosarcina* (Schauder et al., 1986), *Desulfotomaculum* (Cypionka and Dilling 1986) and *Thermodesulfobacterium* (Fauque et al., 1992). Hydrogenase activity has even been found in *Desulfobacter* species that cannot grow on H_2 (Lien and Torsvik, 1990); the role of the enzyme in such bacteria is unknown. Hydrogenases may

act not only in the uptake of H_2 at various partial pressures (see last paragraph of this section), but also in the production of H_2 during growth of certain species by fermentation or in syntrophic co-cultures (see Fermentative and Syntrophic Growth in the Absence of Sulfate in this Chapter).

Hydrogenases catalyze the reversible heterolytic cleavage of H_2 and oxidation of the resulting hydride ion, according to:

$$H_2 \rightleftharpoons H^+ + H^- \rightleftharpoons 2H^+ + 2e^- \quad (12)$$

Detailed information on the biochemistry, coding genes and mechanism of function of hydrogenases (in sulfate-reducing bacteria) is so far only available from *Desulfovibrio* species. Hydrogenases are probably the most intensely studied enzymes in sulfate-reducing bacteria. Their investigation has significantly contributed to our understanding of hydrogenases in general. The first resolution of the three-dimensional structure of a hydrogenase was achieved with the enzyme from *Desulfovibrio gigas* (Volbeda et al., 1995). Based on their metal composition, three types of hydrogenases are distinguished in *Desulfovibrio* species, the [Fe] hydrogenases (Huynh et al., 1984a), the [NiFe] hydrogenases (Teixeira et al., 1986) and the [NiFeSe] hydrogenases (Rieder et al., 1984; Teixeira et al., 1987). All three types of hydrogenases have heterodimeric αβ-structures and are mostly located in the periplasm (Odom and Peck, 1981a; Fauque et al., 1988). There are marked differences between the three types of enzymes (Table 4) with respect to their H_2-uptake and H_2-evolving activities, their sensitivity to CO, NO, NO_2^- and acetylene (e.g., He et al., 1989), and their molecular structures (Prickril et al., 1987; Fauque et al., 1988). The three types of hydrogenase are not uniformly distributed among *Desulfovibrio* species. Voordouw et al. (1990) analyzed the distribution of the hydrogenase encoding genes in 22 different *Desulfovibrio* species. The genes for the [NiFe] hydrogenase could be identified in all tested strains, whereas the distribution of [Fe] and [NiFeSe] hydrogenases were limited. Individual strains may contain only one type of hydrogenase (e.g., [NiFe] hydrogenase in *D. vulgaris* strain Groningen), two types of hydrogenases (e.g., [NiFe] and [NiFeSe] hydrogenase in *D. vulgaris* strain Miyazaki; [NiFe] and [Fe] hydrogenases in *D. desulfuricans* strain El Agheila) or all three types of hydrogenases (in *D. vulgaris* strain Hildenborough).

Genes coding for hydrogenases have been cloned and sequenced from various *Desulfovibrio* spp. and from *Desulfomicrobium baculatum* (Table 8). An extensive sequence comparison of hydrogenase genes including those from sulfate-reducing bacteria has been carried out by Wu and Mandrand (1993). The [NiFe] and [NiFeSe] hydrogenases from sulfate-reducing bacteria were related to each other and also to [NiFe] hydrogenases from species from other subclasses of the Proteobacteria such as *Rhodobacter*, *Rhizobium*, *Azotobacter*, *Escherichia* or *Wolinella*. These hydrogenases were not related to [Fe] hydrogenases from *Desulfovibrio* species, which have their own line of enzymatic evolution.

The [Fe] hydrogenases were purified from *Desulfovibrio vulgaris* strain Hildenborough (Huynh et al., 1984a), *D. desulfuricans* (Hatchikian et al., 1992) and *D. fructosovorans* (Casalot et al., 1998). In the case of [Fe] hydrogenases from *D. vulgaris* and *D. desulfuricans*, an atypical Fe-cluster and two ferredoxin-type [4Fe-4S] clusters were identified. The atypical Fe-cluster, also known as the H-cluster, is assigned to the H_2 activation site. The [4Fe-4S] clusters, which are also referred to as F-clusters, transfer electrons between the H-cluster and the external electron carrier (Adams, 1990). The crystal structure of the [Fe]hydrogenase from *D. desulfuricans* was the first to be determined of this type of hydrogenase (Nicolet et al., 1999). The three-dimensional structure revealed that this hydrogenase displays a novel protein fold, and that the H-cluster is composed of a typical [4Fe-4S] clus-

Table 4. Brief overview of characteristics of different types of hydrogenases found in *Desulfovibrio* species[a]

	[Fe]hydrogenase	[NiFe]hydrogenase	[NiFeSe]hydrogenase
Catalytic activity			
H_2 uptake	very high	moderate	low
H_2 evolution	high	moderate	moderate
Sensitivity to			
CO	very high	high	moderate

[a]Adapted from Fauque et al., 1991.

ter bridged to a binuclear Fe center as the active site. The two Fe ions at the active site probably possess CO and CN^- as binuclear ligands, as found in [NiFe] hydrogenases. The structural analysis of the [Fe] hydrogenase corroborates the earlier finding that one of the two active-site irons could be ligated by intrinsic CN^- and CO (Pierik et al., 1998). In contrast to the [NiFe] hydrogenases, the binuclear active site as well as the [4Fe-4S] clusters in [Fe] hydrogenase reside on one subunit. Channel-like paths have been identified that allow the transport of protons and H_2 to or from the active site buried in the center of the protein. The second subunit of the [Fe] hydrogenase from D. desulfuricans forms a belt around the other subunit. The [Fe] hydrogenase from the anaerobic Gram-positive bacterium *C. pasteurianum* has an active center similar to the one in the *D. desulfuricans* enzyme, even though the former consists of only a single polypeptide (Adams, 1990; Peters et al., 1998; Peters, 1999; Cammack, 1999). The *hydA* and hydB genes coding for the large and small subunits, respectively, of [Fe] hydrogenase in *D. vulgaris* (Hildenborough) and *D. vulgaris* subsp. oxamicus are highly homologous (Voordouw et al., 1989b); however, there is no significant homology between the [Fe] hydrogenases and the [NiFe] hydrogenases (see next paragraph). A gene probe for the [Fe] hydrogenase did not hybridize with the DNA of sulfate-reducing bacteria without a [Fe] hydrogenase (Voordouw et al., 1987). Deckers et al. (1990) demonstrated that *D. vulgaris* strain Miyazaki F lacks the [Fe] hydrogenase genes.

In *D. fructosovorans* a new type of [Fe] hydrogenase, which reacts with $NADP^+$, was identified; it may be regarded as a fourth type of hydrogenase present in *Desulfovibrio*. The $NADP^+$-reducing hydrogenase is assumed to be a heterotetrameric enzyme complex that is encoded by the hndABCD genes (Malki et al., 1995). Mutants with deleted hndABCD genes showed reduced hydrogenase activity (Malki et al., 1997). Homology studies implicated that HndA and HndC form the NADP-reducing moiety, and that HndD harbors the H_2-activating site of a [Fe] hydrogenase; the function of HndB is presently unknown. The purified HndA subunit contains a [2Fe-2S] cluster which belongs to the family of [2Fe-2S] ferredoxins (DeLuca et al., 1998a). Studies with antisera raised against the four putative subunits overexpressed in (and purified from) *Escherichia coli* demonstrated that the active $NADP^+$-reducing hydrogenase in the sulfate reducer is indeed a complex, even though the complex itself has not been purified so far (DeLuca et al., 1998b). Thus the $NADP^+$-reducing hydrogenase appears to differ structurally from the three other types of hydrogenases.

The [NiFe] hydrogenases have been purified from *D. desulfuricans* (Krüger et al., 1982), *D. gigas* (Moura et al., 1982), *D. multispirans* (Czechowski et al., 1984) and *D. africanus* (Niviere et al., 1986). A [NiFe] hydrogenase was also isolated from the thermophilic sulfate reducer *Thermodesulfobacterium mobile* (Fauque et al., 1992). The [NiFe] hydrogenase from *D. gigas* has been studied most intensively. Analysis of the coding genes, *hynA* and *hynB*, suggested that the large subunit (62 kDa) carries the Ni ion and that the small subunit (26 kDa) could ligate at least two [FeS] clusters due to the presence of 12 cysteines (Voordouw et al., 1989a). Spectroscopic analysis of [NiFe] hydrogenase from *D. gigas* indicated the presence of two [4Fe-4S] clusters, one [3Fe-xS] cluster, one Ni ion and one unknown redox component, which was hypothesized to be a special Fe ion (Huynh et al., 1987; Albracht, 1994). The structure of the [NiFe] hydrogenase from *D. gigas* was determined at 2.85 and 2.54 Å resolution (Volbeda et al., 1995; Volbeda et al., 1996). The two subunits interact extensively, and the large subunit has a unique topology. The presence of Fe as the second metal ion, besides Ni, in the active site of the large subunit was demonstrated. The distance between the two metal ions was suggested to be around 3 Å. A coordination of intermediate species of H_2 between the two metal ions (Ni and Fe) in the active site is suggested to function in catalysis (Volbeda et al., 1995). The Ni ion is anchored to the protein via sulfur bridges from two cysteine residues (Cys65 and Cys530) and coordinately bound to the Fe ion again by two sulfur bridges provided by Cys68 and Cys533. The Fe ion possesses three intrinsic dinuclear ligands, which were demonstrated to be two CN^- groups and one CO molecule (Pierik et al., 1999). High resolution X-ray structural analysis (1.8 Å) of the [NiFe] hydrogenase from *Desulfovibrio vulgaris* (Miyazaki) indicated that this protein is similar to the [NiFe] hydrogenase from *Desulfovibrio gigas* with respect to the folding pattern, the arrangement of the metal center and the probable presence of SO, CO and CN^- as dinuclear ligands of the Ni-Fe center (Higuchi et al., 1997). These dinuclear ligands generate unusual infrared bands, which have been observed in several [NiFe] and [Fe] hydrogenases from *Desulfovibrio* species and other microorganisms like *Chromatium vinosum* (Bagley et al., 1995; van der Spek et al., 1996). Thus [NiFe] hydrogenases appear to contain $NiFeCO(CN)_2$ as prosthetic group, the finding of which would be unprecedented in the study of biological systems (Fig. 9; Happe et al., 1997); the function of the dinuclear ligands remains unclear. The three

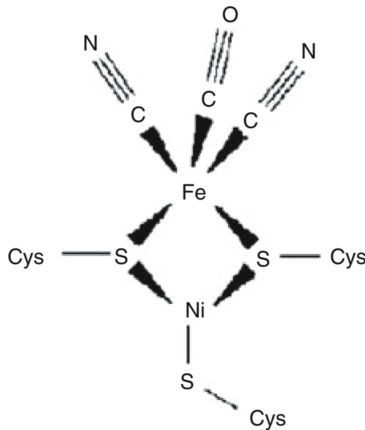

Fig. 9. Suggested prosthetic group of [NiFe] hydrogenases. Three dinuclear, non-protein ligands (2 CN^-, 1 CO) coordinate the Fe atom in the active center (Happe, 1997; Higuchi et al., 1997; Pierik et al., 1999).

[FeS] clusters of the small subunit of [NiFe] hydrogenase from *D. gigas* are arranged in one line with the two low potential [4Fe-4S] clusters at the proximal and distal sides and the high potential [3Fe-4S] cluster in the middle. It was suggested that an electron channel is formed from the center of the protein, where H_2 is oxidized at the active site, to the surface of the [NiFe] hydrogenase, where the electrons would be accepted by cytochrome c_3. However, the role of the median [3Fe-4S] cluster is uncertain, considering the high potential of this cluster for the electron transfer is unfavorable. To study the role of the [3Fe-4S] cluster in the electron transfer, the [3Fe-4S] cluster was converted to a [4Fe-4S] cluster by site-directed mutagenesis in [NiFe] hydrogenase from *D. fructosovorans.* Because the catalytic activities of this mutant were similar to those of the wild-type, it was speculated that the [3Fe-4S] cluster may serve a structural function rather than participate in electron transfer (Rousset et al., 1998b). Studies by Higuchi et al. (1994) demonstrated the presence of three [FeS] clusters and one Ni ion in the [NiFe] hydrogenase of *D. vulgaris* strain Miyazaki F, suggesting a similar structure as the one for *D. gigas* [NiFe] hydrogenase.

The first [NiFeSe] hydrogenase in sulfate-reducing bacteria was recognized by Rieder et al. (1984) in *Desulfomicrobium norvegicum*, formerly *Desulfovibrio desulfuricans* strain Norway 4 (Sharak Genthner et al., 1997). The coding genes for the small and large subunit of the [NiFeSe] hydrogenase exhibited much sequence similarity with the corresponding genes of [NiFe] hydrogenase from *Desulfovibrio gigas* (Voordouw et al., 1989a). The large subunit of [NiFeSe] hydrogenase contains equimolar amounts of selenium and nickel. Another [NiFeSe] hydrogenase was purified from *Desulfovibrio salexigens* (Teixeira et al., 1986). Spectroscopic studies suggested that selenocysteine takes part in the coordination of the active-site nickel ion in the [NiFeSe] hydrogenase of *Desulfomicrobium baculatum* (Eidsness et al., 1989), formerly *Desulfovibrio baculatus* (Rozanova et al., 1988a). Comparative studies suggest that the [NiFeSe] hydrogenases are distinct from [NiFe] hydrogenases in terms of catalytic properties (Teixeira et al., 1987). The mechanism of selenium incorporation into proteins has been well studied with formate dehydrogenase from *Escherichia coli*. Selenium is present in proteins as selenocysteine, the 21st amino acid, which is cotranslationally incorporated into the nascent polypeptide from selenocysteyl-tRNASec. This selenocysteyl-tRNASec is synthesized from seryl-tRNASec and selenophosphate by selenocysteine synthase (Böck et al., 1991; Heider and Böck, 1993). Selenocysteyl-tRNASec recognizes an in-frame UGA codon that otherwise terminates translation (Leinfelder et al., 1988). Efficient read-through of the UGA codon is dependent on a specific secondary structure of the mRNA downstream of the UGA codon (Zinoni et al., 1990). The selenocysteine-loaded tRNASec is directed to the UGA codon by a specialized elongation factor, SelB (Baron et al., 1993). The corresponding triplet was identified in the sequence of the coding gene for [NiFeSe] hydrogenase from *Desulfomicrobium baculatum* (Menon et al., 1987; 1993). The gene coding for the selenocysteine-inserting tRNASec (*selC*) was cloned and sequenced from *Desulfomicrobium baculatum* (Tormay et al., 1994). A lacZ-fusion of the gene coding for the large subunit of the [NiFeSe] hydrogenase from *Desulfomicrobium baculatum* was constructed to study its heterologous expression in *E. coli*. Interestingly, in *E. coli*, selenocysteine was not incorporated into the *D. baculatum* hydrogenase subunit, demonstrating that the UGA codon was suppressed. Gel-shift experiments showed that purified SelB from *E. coli* in comparison to that from *D. baculatum* had a lower affinity for the hydrogenase mRNA from *D. baculatum*. Thus it appears that the specific interaction of SelB and target mRNA is a prerequisite for proper synthesis of the selenoprotein (Tormay and Böck, 1997).

First evidence for a periplasmic location of a [NiFe] hydrogenases came from purification procedures that only required cells to be washed in slightly alkaline solution (Bell et al., 1974). Further studies on the localization revealed that hydrogenase in various sulfate-reducing bacteria are often localized in the periplasm. Investigated

species are *Desulfovibrio vulgaris* strain Marburg (Badziong and Thauer, 1980), *Desulfovibrio vulgaris* strain Hildenborough (van der Westen et al., 1978), *Desulfovibrio desulfuricans* (Steenkamp and Peck, 1981), *Desulfovibrio gigas* (Bell et al., 1974), *Desulfomicrobium norvegicum* (Rieder et al., 1984). Association of hydrogenases with the cytoplasmic membrane was demonstrated in *Desulfovibrio vulgaris* by means of immunocytochemical labeling and electron microscopy. In this species, the [NiFe] hydrogenase was located on the periplasmic side and the [NiFeSe] hydrogenase on the cytoplasmic side of the membrane (Rohde et al., 1990). In the case of *Desulfovibrio desulfuricans* (Essex 6) and the Gram-positive *Desulfotosporosinus orientis*, a cytoplasmic location of hydrogenase has been demonstrated by the use of inhibiting agents (Cypionka and Dilling, 1986a; Fitz and Cypionka, 1989). In the case of periplasmic hydrogenases, an export mechanism for these enzymes must exist. Indeed, the gene for the small subunit of the [Fe] hydrogenase of *D. vulgaris* was shown to encode a protein with a signal peptide of 34 amino acids (Prickril et al., 1986). There is, however, no evidence for a leader sequence in the gene for the large subunit. The situation is similar in the case of the periplasmic [NiFe] hydrogenase of *Desulfovibrio gigas* and of the [NiFeSe] hydrogenase of *Desulfomicrobium baculatum*. The mature small-subunit sequences are preceded by N-terminal signal sequences of 32 and 50 amino acids, respectively, whereas no leader sequences were found for the large subunits (Voordouw et al., 1989a; Menon et al., 1987). Also the small subunit of [NiFe] hydrogenase from *Desulfovibrio desulfuricans* contains a signal peptide with 50 amino acids (Rousset et al., 1990). The presence of an internal signal sequence in the large subunit of the *D. vulgaris* hydrogenase that might be involved in the translocation of the protein to the periplasm has been the subject of speculation. Alternatively, the immature small subunit might function as a carrier for the large subunit in the translocation process (Prickril et al., 1986). Some evidence for the latter model was presented by van Dongen et al. (1988). Homology studies revealed a consensus box containing two consecutive arginine residues in the N-terminal leader sequence of the small subunit of hydrogenases (Voordouw, 1992; Berks, 1996). A similar export mechanism was suggested for the periplasm-orientated HydB subunit of the membrane integral [NiFe] hydrogenase from the sulfur reducer *Wolinella succinogenes* (Gross et al., 1999). Fusion of the signal peptide from [NiFe] hydrogenase of *Desulfovibrio vulgaris* (Hildenborough) to the β-lactamase from *Escherichia coli* lacking its own leader sequence allowed export of the enzyme. Exchange of one of the two arginines in the leader sequence to glutamate by site-directed mutagenesis inhibited export of β-lactamase completely (Nivière et al., 1992). These results demonstrated an essential role of the two subsequent arginines of the consensus box in the export of hydrogenase (Berks, 1996). The large subunit of the [NiFe] hydrogenase from *Desulfovibrio gigas* was shown to be processed by cleavage of 15 amino acids from the carboxy terminus (Menon et al., 1993). Hatchikian et al. (1999) demonstrated that also the large subunit of [Fe] hydrogenase from *Desulfovibrio desulfuricans* is subjected to a C-terminal processing in which 24 amino acids are cleaved. This finding is in agreement with the structural analysis of the same enzyme (Nicolet et al., 1999). Hatchikian et al. (1999) speculated that the C-terminal processing may play a role in the export of the protein to the periplasm. Export of the [NiFe] hydrogenase from *Desulfovibrio fructosovorans* may employ yet another mechanism involving an additional protein. Downstream of the structural *hynA* and *hynB* genes a third open reading frame (hydC) was identified. All three genes were found to constitute a single operon with a strong (^{70}-like promoter. The HydC protein possesses an amphipathic segment and is speculated to mediate the integration of hydrogenase into the membrane or the export of the enzyme to the periplasm (Rousset et al., 1993).

Primary acceptors for the electrons produced by hydrogenase is the periplasmic cytochrome c_3 which contains multiple heme groups. Initial indication for the electron transfer between hydrogenase and cytochrome c_3 arose from the co-localization of the two proteins in the periplasm (Bell et al., 1974). The interaction between hydrogenases and cytochrome c_3 has been demonstrated with [Fe] hydrogenase from *Desulfovibrio vulgaris* strain Hildenborough (Brugna et al., 1998), [NiFe] hydrogenase from *Desulfovibrio gigas* (Moreno et al., 1993) and [NiFeSe] hydrogenase from *Desulfovibrio desulfuricans* strain Norway (Haladjian et al., 1991). The structural analysis of the cytochrome c_3 molecules from *Desulfovibrio vulgaris* strain Hildenborough (Matias et al., 1993), *Desulfovibrio desulfuricans* strain Norway (Czjzek et al., 1994) and *Desulfovibrio gigas* (Fritz et al., 1999) revealed an overall similar molecular structure and arrangement of the four heme groups. Two types of interactions were identified, one between hemes I and II and another between hemes III and IV. A point mutation of the tyrosine 73 residue in cytochrome c_3 from *Desulfovibrio desulfuricans* (Norway) resulted in a change of the heme IV environment and an

alteration of the hydrogenase-cytochrome interaction (Aubert et al., 1997; Aubert et al., 1998a). The positive charges surrounding the surface-exposed heme IV of cytochrome c_3 are supposed to mediate the contact to hydrogenase. In *Desulfovibrio vulgaris* (Hildenborough), further transfer of electrons is assumed to proceed from cytochrome c_3 to the 16 heme containing high-molecular-mass cytochrome c, termed Hmc (Pollock et al., 1991; Bruschi et al., 1992; Voordouw, 1995; Pereira et al., 1998). The Hmc, which is localized to the periplasmic aspect of the membrane, is part of a multisubunit protein complex that contains membrane integral components (Rossi et al., 1993). Electrons from reduced Hmc are proposed to be transferred via the membrane integral subunits of the Hmc complex to the [Fe-S] cluster-containing gene product of Orf6 that is also part of the Hmc complex and is located at the inner aspect of the membrane. Further transfer of electrons may proceed directly to APS reductase or sulfite reductase or may involve cytoplasmic electron carriers such as flavodoxin (Voordouw, 1995). Mutants of *Desulfovibrio vulgaris* (Hildenborough) that had an elevated expression of the *hmc* operon grew more rapidly than the wildtype on H_2, supporting the involvement of the Hmc complex in the electron transfer from H_2 to sulfate (Keon et al., 1997). In *Desulfovibrio gigas,* Hmc was shown to accept electrons directly from hydrogenase (Chen et al., 1994a). Similarily, the [NiFe] hydrogenase from *Desulfovibrio desulfuricans* can reduce the Hmc-analogous nonaheme cytochrome *c* in addition to tetraheme cytochrome c_3 (Fritz, 1999). These findings imply that cytochrome c_3 may not always be required as a connecting link for the electron transfer from periplasmic hydrogenase to membrane-localized Hmc complex.

The finding of periplasmic hydrogenase in sulfate-reducing bacteria led to the hypothesis of energy conservation by so-called vectorial electron transport, the simplest transmembrane process that can generate a proton gradient for chemiosmotic ATP synthesis. The protons from H_2 oxidation are released by hydrogenase into the periplasm, while abstracted electrons are transported via redox-active centers of transmembrane proteins to the cytoplasm (or cytoplasmic aspect of the membrane) and used for sulfate reduction. This charge separation, which is driven by the exergonic process of sulfate reduction, is compensated by a simultaneous (somewhat “retarded”) proton flow via ATPase into the cytoplasm; ATPase finally conserves the energy from the redox process in a phosphoric anhydride bond. The generation of a proton gradient by simple charge separation (vectorial electron transport) by a periplasmic hydrogenase would leave eight extracellular protons per mol sulfate to be reduced. Because (at least) one of these electrogenically produced protons enters the cell during sulfate-transport (Cypionka, 1989), no more than seven protons would be left for chemiosmotic energy conservation yielding $1^3/_4$ to $2^1/_3$ mol ATP, if one assumes a ratio of 3–4 H^+/ATP (Schink, 1988a; Thauer and Morris, 1984; Stock et al., 1999) per mol sulfate reduced with H_2 (Fig. 10). Because sulfate activation is associated with a net consumption of 2

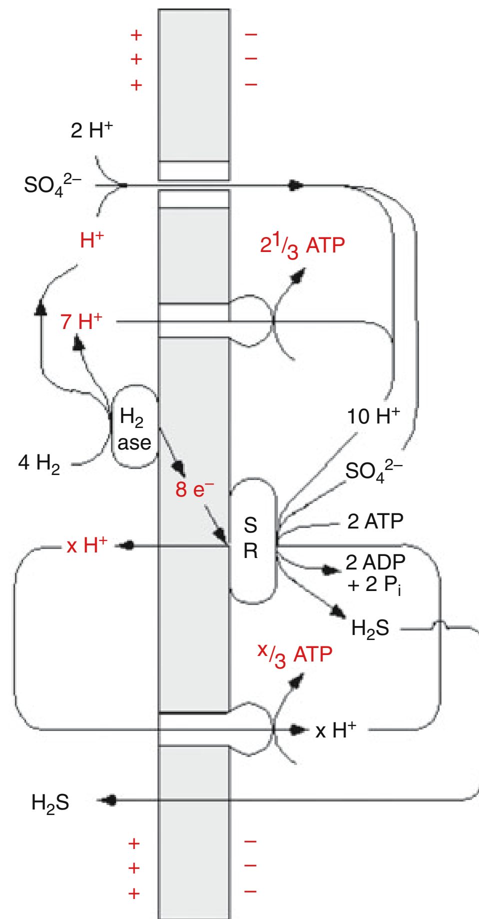

Fig. 10. Possible generation of a proton-motive force (pmf) during growth of *Desulfovibrio* on H_2 and sulfate (low concentration). Electrogenic transport of sulfate with three protons is assumed (Cypionka, 1989). In addition to a proton-translocating mechanism during sulfate reduction, vectorial electron transport from a periplasmic hydrogenase (H_2ase) via the membrane may contribute to the generation of a pmf. Periplasmic cytochrome c_3 and membrane–spanning, high-molecular-mass cytochrome (Hmc) mediate the electron flow between H_2 oxidation and sulfate reduction. Activation of sulfate consumes 2 ATP because AMP liberated by the adenosine-5′-phosphosulfate (APS) reductase from APS has to be converted to ADP by adenylate kinase (myokinase). Abbreviation: SR, enzymes and other components involved in sulfate reduction to H_2S.

ATP/SO_4^{2-}, a maximum of $^1/_3$ mol ATP would remain for cell synthesis. This is much less than the estimates from growth yields, which suggest a net synthesis of 1.3 mol ATP per mol sulfate (Nethe-Jaenchen and Thauer, 1984). Hence, a proton gradient seems to be generated in addition by proton pumping, provided the $3H^+/ATP$ ratio used in the calculations is a correct estimate. Indeed, proton translocation with H_2 and sulfate has been measured in *Desulfovibrio desulfuricans* strain Essex 6 in which the hydrogenase present under the applied growth conditions was reported to be cytoplasmic or at least on the cytoplasmic aspect of the membrane (Fitz and Cypionka, 1989). Strains of other *Desulfovibrio* species translocated protons with H_2 and nitrite, even though hydrogenase and nitrite reductase were both periplasmic enzymes (Barton et al., 1983; Steenkamp and Peck, 1981); this location excludes generation of a proton gradient by simple vectorial electron flow via the membrane. Finally, growth of the Gram-positive *Desulfotosporosinus orientis* on H_2 with high cell yields demonstrated that chemiosmotic ATP synthesis does not require a periplasmic hydrogenase (Cypionka and Pfennig, 1986). Hence, vectorial electron transport due to periplasmic hydrogenase appears to be only an additional mechanism for energy conservation in a number of *Desulfovibrio* species. The main mechanism is obviously vectorial proton transport (e.g., by proton-pumping redox proteins or "Mitchell-type" loops, involving the menaquinones that are commonly present in sulfate-reducing bacteria). Nothing is known about the possibility of a Q-cycle (Peck and Lissolo, 1988); considering this translocates two protons for one electron, the process would require significant differences in the redox potential between two couples, which is not very likely in the anaerobic respiratory chain in sulfate-reducing bacteria.

An energetically intriguing, not sufficiently understood, aspect is the growth of sulfate-reducing bacteria with H_2 over a wide range of partial pressures. At standard pressure, H_2 is one of the energetically most favorable electron donors ($\Delta G°' = -152.2$ kJ/mol sulfate). However, *Desulfovibrio* was shown to scavenge H_2 below 10 Pa (10^{-4} atm; Cord-Ruwisch et al., 1988). In natural anoxic habitats where sulfate-reducing bacteria thrive, even H_2 partial pressures as low as >5 Pa ($>5 \cdot 10^{-5}$ atm; Sørensen et al., 1981) $2.5 \cdot 10^{-2}$ Pa ($2.5 \cdot 10^{-7}$ atm, would be at the thermodynamic equilibrium; Scranton et al., 1984) and 1.1 Pa ($1.1 \cdot 10^{-5}$ atm; Lovley et al., 1982) have been measured. The free energy of sulfate reduction with H_2 at varying partial pressure is depicted in Fig. 11. Assuming that net ATP synthesis coupled to any catabolic overall

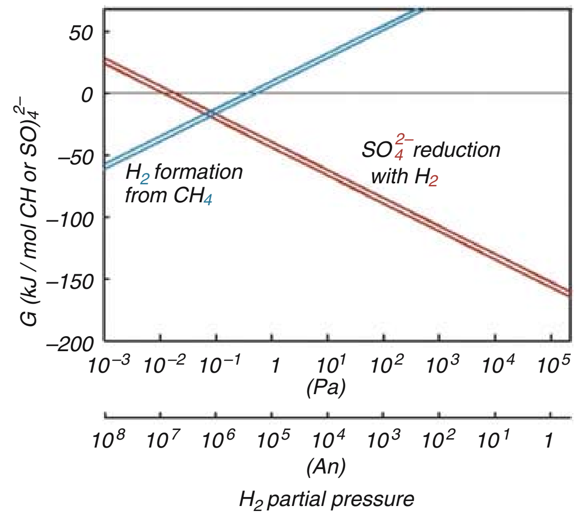

Fig. 11. Free energy change of sulfate reduction and "reverse" methanogenesis related to H_2 partial pressure. Reduction of SO_4^{2-} with H_2 is shown in red line; H_2 formation from CH_4 is shown in blue lines. Full lines represent values calculated for pH 7 and dashed lines those for pH 8.

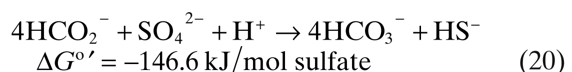
reaction has irreversible character and requires around 70 kJ/mol ATP, the ATP gain at the natural, low H_2 pressures has to be much less than the gain measured with optimal supply of the electron donor. Hence, electrons from H_2 at low partial pressure cannot be transported via a chain with the same number of energy-conserving steps ("coupling sites") as electrons from H_2 at standard pressure. One may speculate that electrons from H_2 at various partial pressures enter the electron transport chain at different levels, and that different types of hydrogenases are involved.

Formate Formate is a fermentation product in several anaerobic bacteria, as for instance in enterobacteria. In addition, formate has been discussed as a means for an interspecies transfer of reducing equivalents and as an alternative to H_2 in natural anaerobic bacterial communities (Thiele et al., 1988a; Thiele and Zeikus, 1988b); formate transfer was most likely to occur in a sulfate-reducing coculture (Zindel et al., 1988). However, syntrophisms based on interspecies H_2 transfer are more important (Schink, 1997). Also energetically, formate may be regarded as an electron donor that is equivalent to H_2. The redox potential of the couples 2 H^+/H_2 and $HCO_3^-/HCOO^-$ are very similar ($E^{0\prime}$ around –0.41 V). Hence, formate is a favorable electron donor:



$$4HCO_2^- + SO_4^{2-} + H^+ \rightarrow 4HCO_3^- + HS^- \quad \Delta G°' = -146.6 \text{ kJ/mol sulfate} \tag{20}$$

The ability to grow with formate has been observed in most genera of sulfate-reducing eubacteria. Formate dehydrogenase has been found in *Desulfovibrio* (Fauque et al., 1991; LeGall and Fauque, 1988) and in completely oxidizing sulfate reducers except for *Desulfobacter* (Schauder et al., 1986; Spormann and Thauer, 1988; Aeckersberg et al., 1991; Rabus et al., 1993; Fukui et al., 1999).

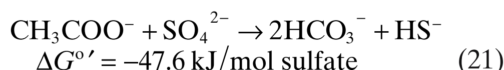
Formate dehydrogenase in *Desulfovibrio* is a periplasmic protein (Odom and Peck, 1981a). It was partially purified from *Desulfovibrio vulgaris* (Miyazaki); purified cytochrome c_{553} functioned as an electron acceptor but cytochrome c_3 did not (Yagi, 1979). The formate dehydrogenase of *Desulfovibrio gigas* is thought to use cytochrome c_3 as electron acceptor (Riederer-Henderson and Peck, 1986). The periplasmic formate dehydrogenase of *Desulfovibrio vulgaris* (Hildenborough) was purified by Sebban et al. (1995). The enzyme is composed of three subunits. The large 83.5-kDa subunit contains a molybdenum cofactor and most likely presents the active site. A 27-kDa subunit with an [Fe-S] center is similar to the [Fe-S]-containing subunit of the formate dehydrogenase from *Escherichia coli*. The 14-kDa subunit holds a *c*-type heme. Cytochrome c_{553} is thought to be the natural electron acceptor of this formate dehydrogenase (Sebban-Kreuzer et al., 1998b). Recently, a tungsten-containing formate dehydrogenase was purified from *Desulfovibrio gigas* and characterized. This protein was found to have a heterodimeric structure (subunits 92 kDa and 27 kDa) and to contain approximately seven Fe per molecule most probably in two [4Fe-4S] clusters; the tungsten is most likely bound to a molybdopterin guanine dinucleotide-type cofactor (Almendra et al., 1999). This is the second W-protein that has been isolated from *Desulfovibrio gigas* (see dissimilation of ethanol). The formate dehydrogenase of *Desulfovibrio desulfuricans* was also found to contain molybdenum, iron-sulfur centers and heme (Costa et al., 1997).

Completely oxidizing sulfate-reducing bacteria employ the C_1/CO dehydrogenase pathway for acetyl-CoA oxidation, always contain formate dehydrogenase (see next section) and often grow on formate. Growth of the completely oxidizing *Desulfotomaculum acetoxidans* on formate is poor and difficult to achieve (Widdel and Pfennig, 1981b), despite the high formate dehydrogenase activity (Spormann and Thauer, 1988). This can be explained by the lack of a proper transport system. Formic acid is less lipophilic and has a lower pK_a value (3.75) than acetic acid (4.75) and probably cannot enter the cell by diffusion via the membrane. Formate dehydrogenases that are part of the C_1/CO-pathway were found to be membrane-associated, probably with the reactive site toward the cytoplasm. Their natural electron acceptor is not known. The reduction of NAD^+ with formate probably occurred via a transhydrogenase.

Terminal Oxidation and Utilization of Acetate

The oxidation of organic substrates in sulfate-reducing bacteria may be complete, leading entirely to CO_2, or incomplete with acetate being the end product; in the latter case a mechanism for acetyl-CoA oxidation is lacking. A complete oxidation of organic compounds by sulfate reducers without the capacity for acetate oxidation is possible only with C_1-compounds such as formate or methanol (Klemps et al., 1985; Nanninga and Gottschal, 1987; Ollivier et al., 1988), or with C_2-compounds that are more oxidized than acetate (e.g., glycine; Stams et al., 1985), glycolate (Friedrich and Schink, 1995) or oxalate (Postgate, 1963).

The capacity for complete oxidation of various organic substrates, viz. the presence of a pathway for acetyl-CoA oxidation, usually includes also the ability to use free acetate as a growth substrate:



$$CH_3COO^- + SO_4^{2-} \rightarrow 2HCO_3^- + HS^- \quad \Delta G^{o\prime} = -47.6 \text{ kJ/mol sulfate} \qquad (21)$$

Desulfobacter species use acetate preferentially or even exclusively. In certain complete oxidizers, however, growth on acetate may be very poor, even though other compounds are readily oxidized to CO_2. Complete oxidizers may excrete acetate if growing, e.g., on ethanol or butyrate (Imhoff-Stuckle and Pfennig, 1983; Laanbroek et al., 1984; Schauder et al., 1986; Widdel and Pfennig, 1981b). With limiting amounts of substrates, the excreted acetate may be oxidized further. Species using acetate very poorly may leave the acetate once formed almost untouched (Imhoff-Stuckle and Pfennig, 1983). An explanation for the acetate excretion by complete oxidizers is that formation of acetyl-CoA proceeds faster than its terminal oxidation. The formation of 1 mol acetate per mol butyrate oxidized has been explained by the use of 1 mol acetyl-CoA (from 2 mol formed per mol of butyrate) for the activation of butyrate by a CoA transferase (Schauder et al., 1986); see also section "Butyrate and other fatty acids"). The marginal capacity or inability of some complete oxidizers to use free acetate is not clearly understood.

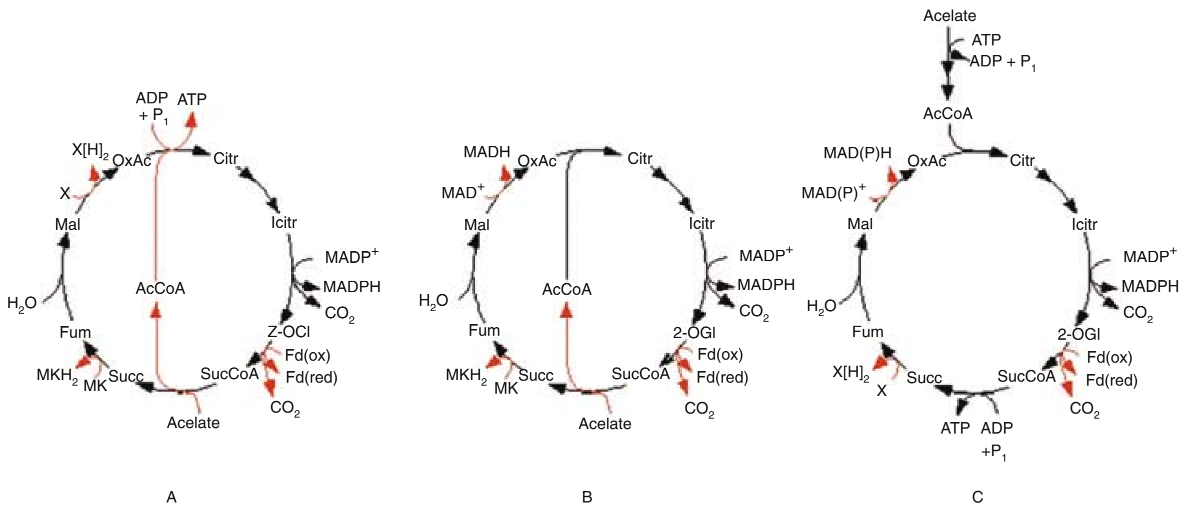


Fig. 12. Modifications of the citric acid cycle for the anaerobic oxidation of acetate in three species of sulfate- and sulfur-reducing bacteria: (A) *Desulfobacter postgatei*; (B) *Desulfuromonas acetoxidans*; and (C) *Desulforella acetivorans*. The reactions leading from citrate to succinyl-CoA are the same in all three cycles. The H^+ ions, water, and some other reactants are not indicated. Abbreviations: AcCoA, acetyl-CoA; Citr, citrate; Fd(ox), oxidized ferredoxin; Fd(red), reduced ferredoxin; Fum, fumarate; Icitr, isocitrate; Mal, malate; MK, menaquinone; 2-OGl, 2-oxoglutarate (α-ketoglutarate); OxAc, oxaloacetate; Succ, succinate; SucCoA, succinyl-CoA; X, unknown physiological electron or hydrogen carrier. Adapted from Thauer (1988) and Thauer et al. (1989b).

Organic end products other than acetate are formed in incomplete or complete oxidizers if substrate oxidation leads to products that cannot be degraded further by the enzymatic outfit. Examples are the oxidation of *n*-propanol, *n*-butanol or isobutanol to propionate, butyrate or isobutyrate, respectively (Mechalas and Rittenberg, 1960), the formation of propionate from C-odd fatty acids (Pfennig and Widdel, 1981b; Widdel, 1980; Widdel and Pfennig, 1981b) or of benzoate from phenylpropionate (Brysch et al., 1987).

The pathways for acetyl-CoA oxidation have been elucidated by enzymatic measurements and growth experiments with ^{14}C-labeled substrates.

In *Desulfobacter postgatei*, all enzymes of a citric acid cycle were found (Brandis-Heep et al., 1983; for an overview see Kröger et al., 1988; Thauer, 1988; Thauer, 1989a; Thauer et al., 1989b). Also with position-labeled [^{14}C]-acetate as growth substrate, the labeling pattern in aspartate and glutamate that are derived from oxaloacetate and 2-oxoglutarate were in agreement with an operating citric acid cycle (Gebhardt et al., 1983). The cycle differs in some aspects from the cycles in mitochondria and aerobic bacteria. Acetate in *Desulfobacter* is not activated via acetate thiokinase (acetyl-CoA synthetase) or acetate kinase and phosphotransacetylase (phosphate acetyltransferase), but via succinyl-CoA:acetate CoA transferase (Fig. 12). Dehydrogenation of isocitrate occurs with $NADP^+$, as in most eubacteria. However, the conversion of 2-oxoglutarate to succinyl-CoA does not couple to NAD^+, but rather to a ferredoxin, as electron acceptor. The hydrogen acceptor for succinate oxidation to fumarate, so far known, is menaquinone and not ubiquinone, as in mitochondria and most Gram-negative bacteria. A remarkable finding was that condensation of acetyl-CoA and oxaloacetate to citrate in *Desulfobacter* is associated with ATP synthesis (Möller et al., 1987). The enzyme, ATP-citrate lyase, enables the conservation of the energy of the thioester; the citrate synthase reaction in the common citric acid cycle wastes this energy by hydrolysis of the intermediary citryl-CoA. The ATP-citrate lyase reaction is reversible ($\Delta G^{\circ\prime}$ (0 kJ). Indeed, before being found in *Desulfobacter*, the reaction was only known to proceed in vivo in its opposite direction. In the cytosol of eukaryotic cells, ATP-citrate lyase cleaves citrate that functions as the acetyl carrier across the two mitochondrial membranes. Green sulfur bacteria fix CO_2 via a reverse citric acid cycle which was found to include the ATP-citrate lyase reaction (Ivanovsky et al., 1980). Citrate formation in *Desulfobacter* species occurs with Si-face stereospecificity. The acceptor for malate-dehydrogenase is neither NAD^+ nor $NADP^+$. The reduction of the artificial acceptor 2,6-

dichlorophenol indophenol (DCPIP) was inhibited by the menaquinone antagonist 2(n-heptyl)-4-hydroxyquinoline-N-oxide (HQNO). From this and the occurrence of the activity in the membrane, one may speculate that menaquinone serves as hydrogen acceptor in malate oxidation. However, in vitro tests with substitutes for menaquinone (naphthoquinone, dimethylnaphthoquinone) yielded no or marginal activity (Möller-Zinkhan and Thauer, 1988). Still, it is most likely that *Desulfobacter* employs a more positive acceptor for malate oxidation than other bacteria. The reversible, energy-conserving ATP-citrate lyase reaction in *Desulfobacter* necessitates the use of a more positive acceptor for malate oxidation to favor the concentration of the product. The citric acid cycle in *Desulfobacter hydrogenophilus* has the same reactions as in *D. postgatei* (Schauder et al., 1987). A comparison of the modifications of the citric acid cycle found in sulfate- and sulfur-reducing bacteria is presented in Fig. 12.

In completely oxidizing sulfate reducers other than *Desulfobacter*, 2-oxoglutarate dehydrogenase could not be detected (Schauder et al., 1986). Inasmuch as most completely oxidizing sulfate reducers grow very poorly on acetate, [3-^{14}C]-pyruvate was used for them as growth substrate in labeling studies (Schauder et al., 1986). For *Desulfotomaculum acetoxidans*, [^{14}C]-acetate could be used. The labeling in aspartate and glutamate showed that a citric acid cycle was not operating. Citrate synthase of the incomplete cycle seemed to have re-specificity. All complete oxidizers without 2-oxoglutarate dehydrogenase contained high activities of CO dehydrogenase, which was absent in *Desulfobacter* species. In labeling experiments, cell extracts of species without 2-oxoglutarate dehydrogenase catalyzed an equilibrium exchange of the C_1-position in acetyl-CoA with free CO_2. Furthermore, these species formed traces of methane indicating a reactive methyl group as an intermediate; such a mini-methane formation was not observed in *Desulfobacter*. All these findings led to the conclusion that completely oxidizing genera other than *Desulfobacter*, viz. the majority of sulfate reducers, cleave acetyl-CoA into bound CO and a bound methyl group; both C_1 units are then oxidized to CO_2 (Schauder et al., 1986; Spormann and Thauer, 1988; Fig. 13). The carrier of the methyl group in *Desulfotomaculum acetoxidans* was tetrahydrofolate (Spormann and Thauer, 1988). For two steps, namely the dehydrogenation of methylenetetrahydrofolate and formate, NAD^+ wasthe natural electron acceptor. The conversion of formyl-tetrahydrofolate to free formate is associated with ATP synthesis. In *Desulfobacterium autotrophicum*, the C_1-carrier is a homologue of tetrahydrofolate, tetrahydropteroyltetraglutamate, which has four glutamate residues instead of one (Länge et al., 1989). Dehydrogenation of the methylene group in this species occurs with $NADP^+$ (Schauder et al., 1989). The results demonstrated for the first time that the pathway of acetyl-CoA synthesis known from homoacetogenic bacteria (Fuchs, 1986; Wood et al., 1986) can operate in the reverse direction for terminal oxidation of organic substrates. Thereafter, the pathway was also found in a syntrophic thermophile that oxidized acetate to CO_2 and H_2 of low partial pressure (Lee and Zinder, 1988), and in the archaeal sulfate reducer, *Archaeoglobus* (Möller-Zinkhan et al., 1989).

The bioenergetic implications of the pathways for acetate oxidation and terminal oxidation of other organic compounds in sulfate- and sulfur-reducing bacteria have been discussed (Kröger et al., 1988; Thauer, 1988; Thauer et al., 1989b). The free energy gain from reduction with acetate (equation 21) is much lower than from sulfate reduction with H_2 at standard pressure (Fig. 11). However, due to the stoichiometric factors in the equations, the free energy per mol of sulfate reduced is less concentration-dependent in the case of acetate oxidation than in the case of hydrogen oxidation.

Net ATP yields available for cell synthesis may be estimated from growth yields. The highest growth yield measured with an acetate-oxidizing sulfate reducer, *Desulfobacter postgatei*, in batch cultures was 4.8 g dry mass/mol acetate (or sulfate). Theoretical maximum growth yields (Y_{max}) from extrapolation to infinite growth rates ($\mu = \infty$) have not been determined. Nevertheless, the growth yield may be compared to that of other bacteria at similar growth rates. The doubling time of *D. postgatei* was around 20 hours. At this doubling time, *Desulfovibrio vulgaris* growing on H_2 and sulfate with acetate as carbon source for cell synthesis would have a growth yield of 7.7 g dry weight/mol sulfate (calculated from Nethe-Jaenchen and Thauer, 1984). A yield of 1.3 mol ATP/mol sulfate was estimated for *D. vulgaris* (Nethe-Jaenchen and Thauer, 1984). *Desulfobacter postgatei* should thus gain around 0.8 mol ATP/mol acetate.

Comparison of the free energy available from reactions (21) with the generally observed requirement of >70 kJ/mol ATP (Schink, 1988a; Thauer et al., 1977) again indicates that acetate-oxidizing sulfate-reducing bacteria obtain less than 1 mol ATP/mol sulfate.

In *Desulfobacter*, ATP-citrate lyase enables net gain of 1 ATP by substrate-level phosphorylation during acetate oxidation; however, 2 ATP are needed for sulfate activation (assuming that pyrophosphate is irreversibly hydrolyzed). The energy requirement for sulfate transport in

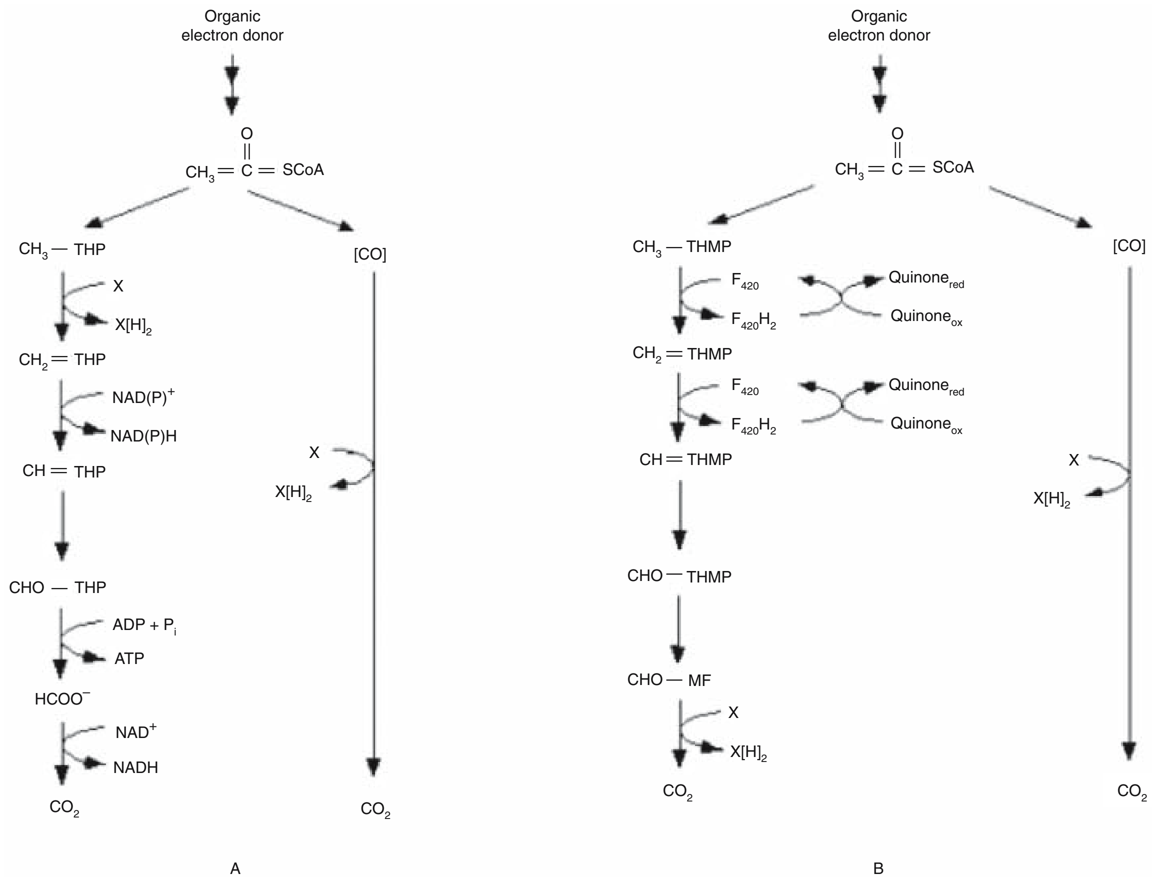

Fig. 13. Terminal oxidation of acetyl-CoA via the C_1/carbon monoxide dehydrogenase pathway in sulfate-reducing bacteria. The H^+ ions, water, and some other reactants are not indicated. (A) Reactions in *Desulfotomaculum acetoxidans*, *Desulfobacterium autotrophicum*, and presumably other completely oxidizing sulfate-reducing bacteria (except for *Desulfobacter* species). The former species uses NAD^+, and the latter $NADP^+$ for dehydrogenation of the methylene group; in *Desulfotomaculum*, NAD^+ is probably not the direct electron acceptor for formate dehydrogenase but reduced via an unknown, primary acceptor. THP is tetrahydrofolate in *D. acetoxidans*, and tetrahydropteroyltetraglutamate in *D. autotrophicum*. (B) Reactions in the archaeon *Archaeoglobus fulgidus*. Abbreviations: [H], unknown physiological electron or hydrogen carrier; MF, methanofuran; THMP, tetrahydromethanopterin; THP, tetrahydropterin; F_{420}, formate dehydrogenase. Adapted from Thauer (1988) and Thauer et al. (1989b).

Desulfobacter is unknown. *Desulfobacter* occurs mainly in brackish or marine environments with high sulfate concentrations. It is therefore likely that an electrogenic transport of sulfate (Warthmann and Cypionka, 1990) is not required under such conditions. Thus, for a net ATP gain, more than 1 ATP has to be synthesized by chemiosmosis. In *Desulfuromonas*, there is no substrate-level phosphorylation. In *Desulfobacter postgatei*, the transport of reducing equivalents from NADPH to MK-7 ($\Delta E_0' =$ 0.25 V) could be associated with a translocation of 2 H^+/2 [H], which are 4 H^+/acetate (Kröger et al., 1988; Thauer, 1988). The preceding reduction of $NADP^+$ with ferredoxin ($\Delta E_0' = 0.1$ V) has been discussed as another energy-conserving step allowing the translocation of 1 H^+ (Fig. 14A). With the assumed requirement of 3–4 H^+/ATP, chemiosmosis in *Desulfobacter postgatei* should produce $^5/_4$ to $^5/_3$ ATP and thus allow a net ATP gain of $^1/_4$ to $^2/_3$ per sulfate for cell synthesis. The latter value is more likely in view of the aforementioned calculations based on growth yields. In *Desulfobacter*, succinate oxidation to fumarate ($E_0' = +0.033$ V) with menaquinone ($E_0' = -0.074$ V) is endergonic from the viewpoint of standard potentials. Still, the reaction appears possible with shifted concentration ratios of involved redox couples, or by specific coupling to a favorable redox reaction of the sulfate reduction pathway. It is true that from a mere thermodynamic viewpoint any unfavorable partial reaction is rendered possible if embedded in an exergonic overall reaction. In biological systems,

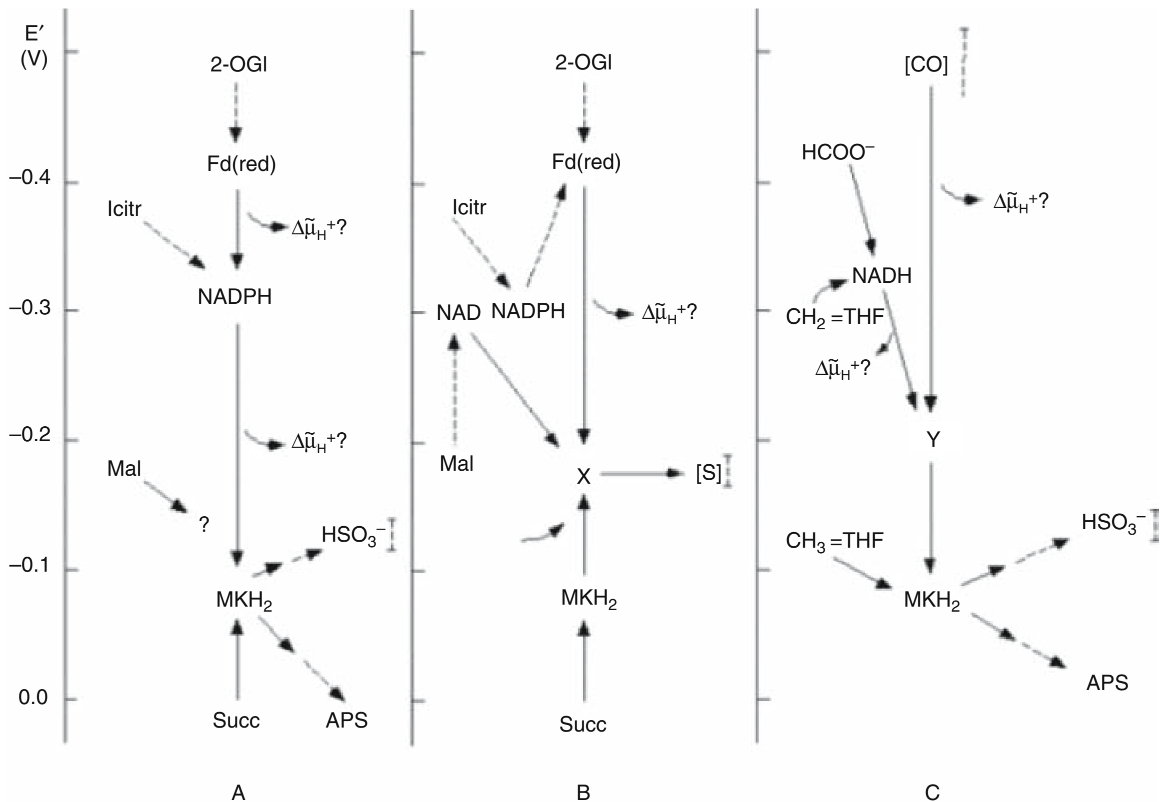

Fig. 14. Flow of reducing equivalents during terminal oxidation of *acetyl-CoA* in sulfate- and sulfur-reducing bacteria. Electron-donating and electron-accepting redox couples are presented only as the reduced or oxidized forms, respectively. In most cases, the midpoint potential is indicated (often concentration-independent, with E' being identical to E_0'); the exact redox potential in the cell may differ, according to concentrations of reaction partners. The redox potential of APS reduction refers to concentrations of 1 mM. The redox potential of bisulfite reduction given for a six-electron step refers to 1 mM HSO_3^- and a range of 1 to 10 mM H_2S (dotted redox span). The concentration range of H_2S for sulfur reduction is also 1 to 10 mM. Bound CO probably has a less negative midpoint potential than free CO. The value of the former is not exactly known. (A) *Desulfobacter postgatei*, growing on acetate and sulfate. (B) *Desulfuromonas acetoxidans*, growing on acetate and sulfur. X is a carrier, presumably a cytochrome *c* that donates electrons to sulfur reduction. (C) *Desulfotomaculum acetoxidans*, growing on acetate and sulfate. Y is an unknown electron carrier. Symbols and abbreviations: arrows (in full lines), reactions catalyzed by membrane-associated enzymes; arrows (in dashed lines), reactions catalyzed by soluble enzymes; APS, adenosine-5′-phosphosulfate. Fd(red), reduced ferredoxin; Icitr, isocitrate; Mal, malate; Succ, succinate; THF, tetrahydrofolate; 2-OGl, 2-oxoglutarate. Adapted from Möller-Zinkhan and Thauer (1988) and Thauer (1988).

however, also the rates are important. In a thermodynamically very unfavorable partial reaction, the very low product concentration may not be sufficient to allow appropriate rates with the enzyme of the subsequent reaction. The equilibrium of unfavorable reactions can in principle be shifted by an input of energy, which in case of redox reactions is known as reversed electron transport. Indeed, a membrane preparation catalyzed a strictly ATP-dependent oxidation of succinate with sulfur or NAD^+ (Paulsen et al., 1986). The reaction was sensitive to the ATPase inhibitor DCCD6 or to the protonophore TTFP7, indicating that ATP acted indirectly via formation of a proton gradient as the driving force for succinate oxidation. The primary hydrogen acceptor of succinate oxidation was apparently menaquinone (MK-8); its analogue dimethylnaphthoquinone was reduced with succinate without addition of ATP, as in *Desulfobacter*. Hence, the proton gradient-driven reaction is probably the oxidation of menaquinone with the subsequent electron carrier that feeds into sulfur reductase. This electron carrier might be one of the membrane-bound *c*-type cytochromes with a midpoint potential more negative than –200 mV. It has been estimated that two to three protons have to reenter the cell to promote the oxidation of one molecule of succinate (Kröger et al., 1988; Thauer, 1988). With the remaining one to two protons, the net energy conservation in the sulfur

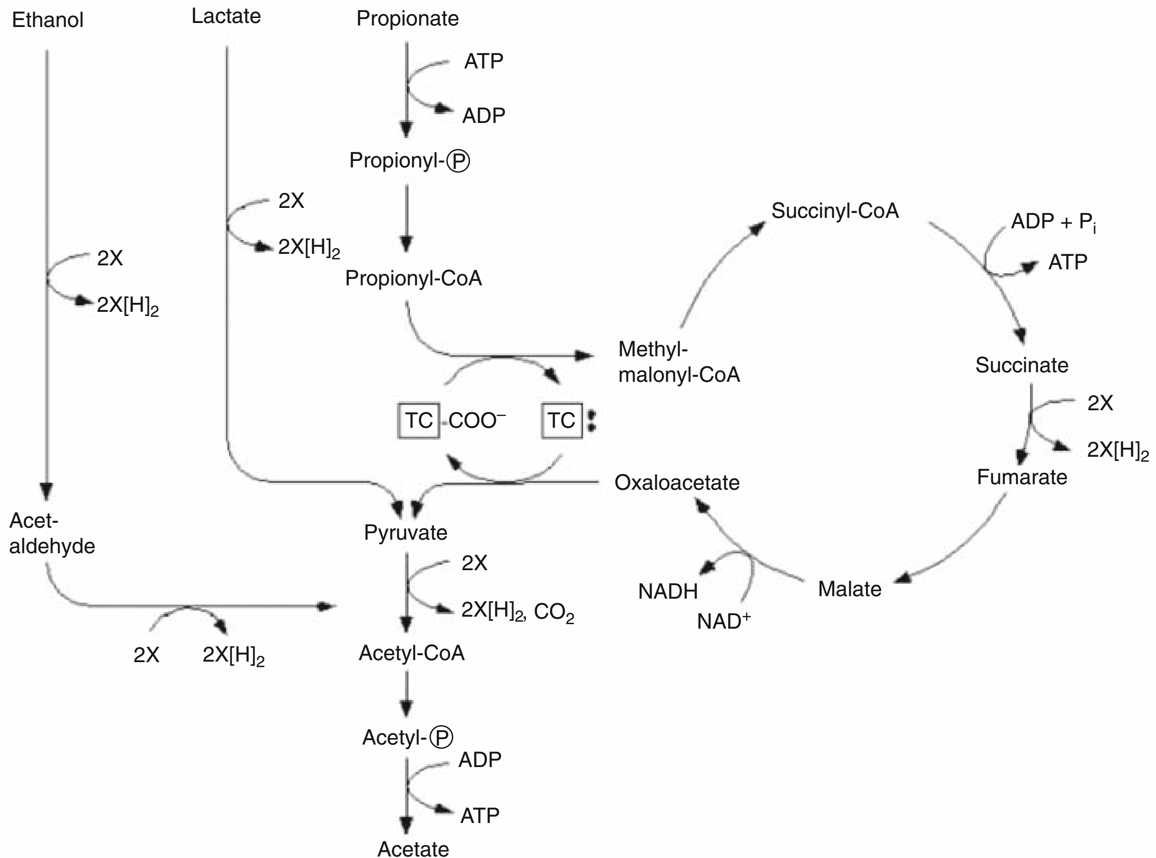

Fig. 15. Oxidation of ethanol, lactate, and propionate to acetate in *Desulfobulbus propionicus*. Methylmalonyl-CoA is formed by carboxylation of propionyl-CoA with CO_2 bound to transcarboxylase (TC). The "X" is the unknown physiological electron or hydrogen carrier.

reducer would be $^1/_3$ to $^2/_3$ ATP per molecule of acetate.

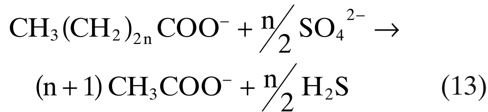
Suggested proton-translocating reactions in the C_1/CO-dehydrogenase-pathway are indicated in Fig. 14C.

Propionate Propionate serves as electron donor and carbon source for the incompletely oxidizing *Desulfobulbus* species and several completely oxidizing sulfate reducers (Table 2). Propionate in *Desulfobulbus* is oxidized to acetate via a randomizing pathway with succinate, a symmetric molecule, as free intermediate (Kremer and Hansen, 1988a; Fig. 15). The principle of this pathway in *Desulfobulbus* was first elucidated in its reverse direction, the formation of propionate from fermentable substrates in the absence of sulfate (see Fermentative and Syntrophic Growth in the Absence of Sulfate). A succinate dehydrogenase/fumarate reductase was purified from *Desulfobulbus elongatus*; it consists of three subunits and contains one cytochrome *b*, flavin and eight non-heme iron atoms (Samain et al., 1987). The oxidation of propionate to CO_2 by *Desulfococcus multivorans* was also shown to proceed via the succinate pathway (Stieb and Schink, 1989). Unlike *Desulfobulbus*, *Desulfococcus* can oxidize the pyruvate formed via the C_4-dicarboxylic acid sequence further than the acetate level; acetyl-CoA is oxidized to CO_2 via the C_1/CO-dehydrogenase-pathway (see preceding section). Not unexpectedly therefore, the molar growth yield of *Desulfococcus*, if related to propionate, was more than twice as high as that of *Desulfobulbus* (approximately 10 and 4 g dry mass per mol propionate, respectively; Stieb and Schink, 1989; Stams et al., 1984); if related to sulfate, the yields are rather similar (approximately 5.7 and 5.3 g dry mass per mol sulfate, respectively).

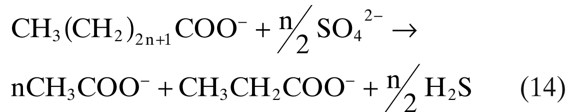
Butyrate and Other Fatty Acids Butyrat and higher fatty acids are oxidized by many incompletely and completely oxidizing sulfate-

reducing bacteria (Widdel, 1980; Pfennig and Widdel, 1981b; Widdel, 1988; Table 2).

The incomplete oxidation of C-even fatty acids yields only acetate. The C-odd fatty acids are oxidized to acetate and propionate. Measured degradation balances were in agreement with the following general equations:



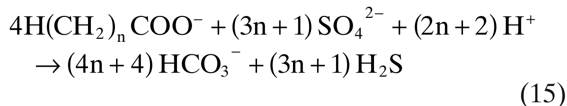
$$CH_3(CH_2)_{2n}COO^- + \frac{n}{2}SO_4^{2-} \rightarrow (n+1)\,CH_3COO^- + \frac{n}{2}H_2S \quad (13)$$



$$CH_3(CH_2)_{2n+1}COO^- + \frac{n}{2}SO_4^{2-} \rightarrow nCH_3COO^- + CH_3CH_2COO^- + \frac{n}{2}H_2S \quad (14)$$

The ratio is explained by a β-oxidation. In the case of C-odd fatty acids, propionyl-CoA is left, which obviously cannot be metabolized by most incomplete fatty acid oxidizers and therefore has to be excreted. If 2-methylbutyrate is used by incomplete oxidizers, propionate is formed too. β-Oxidation of acetyl-CoA is in principle not hampered by a 2-methyl group; this leads to formation of propionyl-CoA rather than acetyl-CoA from the first part of the fatty acid chain.

Most complete oxidizers can degrade the propionyl residue; therefore, also C-odd fatty acids and, if metabolized, 2-methylbutyrate are oxidized like C-even fatty acids:



$$4H(CH_2)_nCOO^- + (3n+1)\,SO_4^{2-} + (2n+2)\,H^+ \rightarrow (4n+4)\,HCO_3^- + (3n+1)\,H_2S \quad (15)$$

Nevertheless, complete oxidizers may excrete acetate, probably as a result of an "imbalance" between β-oxidation and acetyl-CoA oxidation. *Desulfobacterium autotrophicum* formed one mol acetate per mol butyrate (Schauder et al., 1986). It is concluded from this ratio that acetate was formed by CoA transfer from acetyl-CoA to activate butyrate. Free acetate is used very poorly by this sulfate reducer. *Desulfotomaculum acetoxidans*, which is a complete oxidizer but cannot utilize propionate, oxidizes valerate to propionate (Widdel and Pfennig, 1982).

Sulfate reducers using isobutyrate and 3-methylbutyrate (isovalerate) are always complete oxidizers. The pathway of isobutyrate degradation has been elucidated in a *Desulfococcus multivorans* strain (Stieb and Schink, 1989). The reactions are in principle the same as found in aerobic organisms' metabolism of valine. The initial degradation steps in *Desulfococcus* were mediated by two enzymes that are involved in the catabolism of *n*-butyrate. Isobutyryl-CoA is first converted via butyryl-CoA dehydrogenase and enoyl-CoA hydratase to 3-hydroxyisobutyryl-CoA, which is then hydrolyzed to the free acid and oxidized to methylmalonate semialdehyde. CoA-dependent dehydrogenation of the semialdehyde and decarboxylation leads to propionyl-CoA. This is oxidized to acetyl-CoA as in *Desulfobulbus propionicus* (see foregoing section). Acetyl-CoA is then oxidized via the C_1-pathway (Schauder et al., 1986). By means of a succinyl-CoA:acid CoA transferase, the conversion of succinyl-CoA to succinate is coupled to the activation of the free isobutyrate to isobutyryl-CoA. In contrast to the sulfate-reducing culture, a methanogenic coculture isomerized isobutyrate to butyrate that was oxidized to two acetate residues (Stieb and Schink, 1989). The pathway for isovalerate degradation has not been examined in sulfate-reducing bacteria.

Lactate and Pyruvate Lactate, the "classical" substrate for cultivation of sulfate-reducing bacteria, is utilized by most species of almost each genus and may be oxidized completely or incompletely (equations 1 and 2, respectively). *Desulfoarculus baarsii* (formerly *Desulfovibrio*; Widdel, 1980), several *Desulfobacter* species (Widdel and Pfennig, 1981a; Widdel, 1987) and some species of the genera *Desulfobacterium*, *Desulfonema* (Widdel et al., 1983) and *Desulfotomaculum* (Widdel and Pfennig, 1981b) cannot use lactate.

The oxidation of L- and D-lactate to pyruvate is mediated by $NAD(P)^+$-independent lactate dehydrogenases that occur mainly membrane-bound. None of the enzymes from sulfate-reducing bacteria have been purified to homogeneity. D-Lactate dehydrogenase of *Desulfovibrio desulfuricans* was present in the particulate fraction, and detergents were required for its solubilization (Czechowski and Rossmoore, 1980), but in *Desulfovibrio vulgaris* strain Miyazaki, part of the enzyme activity was soluble (Ogata et al., 1981). L-lactate dehydrogenase activities were demonstrated in a *Desulfomicrobium baculatum*-like strain (formerly a *Desulfovibrio desulfuricans* strain; Stams and Hansen, 1982), *Desulfovibrio desulfuricans*, *Desulfovibrio gigas* (Peck and LeGall, 1982b) and *Desulfovibrio vulgaris* (Pankhania et al., 1988).

In *Desulfovibrio vulgaris* strains, pyruvate has been shown to be oxidatively decarboxylated to acetyl-CoA with ferredoxin or flavodoxin as electron acceptor (Suh and Akagi, 1966; Ogata and Yagi, 1986). The low potential ferredoxin I was found to be particularly active in the pyruvate:acceptor oxidoreductase reaction of *Desulfovibrio gigas* (LeGall and Fauque, 1988; Fauque et al., 1991). Pyruvate:ferredoxin oxi-

doreductase (POR) has been purified from *Desulfovibrio africanus*. The enzyme is a homodimer of 256 kDa and contains thiamine pyrophosphate (TPP) and three iron-sulfur clusters. Spectroscopic analysis of the activated enzyme indicated the presence of a free radical (Pieulle et al., 1995). A catalytic mechanism involving a free radical had been demonstrated before for the POR from the extremely halophilic bacterium *Halobacterium halobium* (Cammack et al., 1980). The gene for POR of *D. africanus* was cloned and the enzyme overexpressed in *E. coli* (Pieulle et al., 1997) so that enzyme quantities sufficient for crystallization could be obtained. The enzyme from *D. africanus* is the first POR to have its crystal structure determined (Chabriere et al., 1999a; Chabriere et al., 1999b; Pieulle et al., 1999a; for review see Charon et al., 1999). The substrate pyruvate is bound at the active site in the proximity of TPP. The three [4Fe-4S] clusters are located between TPP and the protein surface, indicating that this arrangement serves as the path for electron transfer within the protein. Further transfer of electrons from POR to the external ferredoxin probably requires electrostatic interactions (Pieulle et al., 1999b).

In the incomplete oxidation of organic substrates, acetyl-CoA produced from pyruvate is converted to acetate by means of phosphotransacetylase and acetate kinase (Brown and Akagi, 1966; Ogata and Yagi, 1986), which allows phosphorylation of ADP to ATP.

The incomplete oxidation of lactate to acetate in *Desulfovibrio* species gave the first hint that oxidation of organic substrates in sulfate-reducing bacteria is associated with chemiosmotic energy conservation (formerly, electron transport phosphorylation) in addition to substrate-level phosphorylation. A simple yet basic calculation (Peck, 1966) revealed, that the net ATP gain by substrate-level phosphorylation during growth of *Desulfovibrio* on lactate and sulfate is zero. The two molecules of lactate oxidized per molecule of reduced sulfate (equation 1) yield two molecules of ATP during liberation of acetate via acetate kinase; these two ATP molecules are consumed for the activation of sulfate, namely one for the ATP sulfurylase reaction and one for regeneration of ADP from AMP (adenylate kinase reaction) formed during APS reduction (see Activation of Sulfate in this Chapter). Hence, there has to be an additional mechanism for ATP formation.

A unique mechanism for generation of a proton gradient with lactate as electron donor was suggested by Odom and Peck (1981b). Their so-called hydrogen-cycling model for growth on lactate of a *Desulfovibrio* involved the cytoplasmic production of H_2 as a result of the oxidation of lactate to pyruvate and pyruvate to acetyl-CoA; after diffusion through the cytoplasmic membrane, the H_2 would be oxidized in the periplasm as described for H_2 as electron donor. An involvement of periplasmic [Fe] hydrogenase in growth of *Desulfovibrio vulgaris* (Hildenborough) on lactate was also suggested by van den Berg et al. (1991). Reduction of the amount of this hydrogenase by means of antisense RNA resulted in a pronounced reduction of growth yields on lactate. The [NiFeSe] hydrogenase, which is located at the cytoplasmic aspect of the cytoplasmic membrane, might function as the H_2-evolving hydrogenase, and the [Fe] and the [NiFe] hydrogenases are thought to function as the H_2-oxidizing enzymes (Rohde et al., 1990). On the other hand, there are also arguments against free H_2 as an obligatory intermediate in the catabolism of lactate. Important in this respect is the lack of a strong inhibition of lactate oxidation by an H_2 atmosphere, unlike what should be expected for thermodynamic reasons in the H_2-cycling model (e.g., Pankhania et al., 1986); furthermore, a *Desulfovibrio* mutant was isolated that does not grow on H_2 plus sulfate but does grow on lactate plus sulfate (Odom and Wall, 1987). Also, there are other sulfate reducers growing well on lactate and other substrates without possessing hydrogenase, e.g., *Desulfobotulus sapovorans* or *Desulfococcus multivorans*. Hydrogen production linked to the oxidation of lactate to pyruvate has been even shown to be an energy-dependent process (Pankhania et al., 1988). The investment of energy makes H_2 cycling as a mode of energy conservation on lactate unlikely. It is true that, with pyruvate as growth substrate for *Desulfovibrio vulgaris*, H_2 cycling was directly demonstrated by employing membrane-inlet mass spectrometry (Peck et al., 1987). However, under natural conditions, cycling by *Desulfovibrio* of H_2 from pyruvate oxidation is probably not a significant reaction. In natural habitats, pyruvate is probably not a major free product of fermentative bacteria and a less important substrate, if at all, for sulfate reducers than lactate. With pyruvate added to artificial media, a rapid pyruvate:ferrodoxin oxidoreductase (PFOR) reaction may cause a burst of H_2 which is then scavenged mainly by periplasmic hydrogenase (Tsuji and Yagi, 1980). To our understanding, the production of some H_2 during growth on lactate and sulfate (Lupton et al., 1984) is neither a proof for H_2 cycling nor a proof for a specific mechanism that controls the redox state of electron carriers involved in lactate oxidation. One possible explanation is that part of the reducing power during growth on lactate and sulfate simply diffuses off via a constitutive hydrogenase; the H_2 partial pressure may reflect the degree of

imbalance between electron-producing and electron-consuming reactions. Another explanation can be given in view of the capacity of *Desulfovibrio* species to grow by interspecies H_2-transfer in sulfate-free cocultures with methanogens. Lactate conversion to acetate, H_2 and CO_2 in the absence of sulfate seems to be one of the ecological roles of *Desulfovibrio* species (Bryant et al., 1977; Zellner et al., 1987; Zellner and Winter, 1987; section Fermentative growth and syntrophy). In the presence of sulfate, the H_2-evolving system (Pankhania et al., 1988) may not be completely suppressed and lead to a minor loss of reducing power as H_2.

Ethanol and Acetaldehyde Ethanol is a very common electron donor and carbon source for incompletely and completely oxidizing sulfate reducers (Table 1). Ethanol is oxidized via acetaldehyde to acetate, which may be further oxidized. Some *Desulfovibrio* species can oxidize choline to acetate and trimethylamine. There is some evidence that acetaldehyde formed as the first intermediate from choline degradation is oxidized to acetate via acetyl-CoA (Hayward, 1960).

With primary alcohols as electron donors, some sulfate-reducing bacteria form strong smelling byproducts which might be chemical adducts of sulfide and aldehydes that are formed as free intermediates (F. Widdel, unpublished observation).

During growth on ethanol plus sulfate, *Desulfovibrio gigas* and three other examined *Desulfovibrio* strains contained high NAD^+-dependent alcohol dehydrogenase activities. In lactate-grown cells, these activities were lower or absent. NAD^+-dependent alcohol dehydrogenases have been purified from *Desulfovibrio gigas* and from *Desulfovibrio strain* HDv; the latter organism is now known as *Desulfovibrio burkinensis* (Ouattara et al., 1999). Both enzymes were oxygen-labile; the proteins were decameric, with subunits of 43 and 48 kDa, respectively, and contained zinc (Hensgens et al., 1993; Hensgens et al., 1995a). The first 21 N-terminal amino acids of the enzyme from *Desulfovibrio* strain HDv were identical to those of the alcohol dehydrogenase from *Desulfovibrio gigas*; on the basis of the N-terminal amino acid sequences, the enzymes are members of the so-called family III of alcohol dehydrogenases which is not related to the family that includes the major yeast and mammalian alcohol dehydrogenases (Reid and Fewson, 1994). The alcohol dehydrogenases from *Desulfovibrio* are only highly active toward short primary alcohols; unlike the decameric family III enzyme from *Bacillus methanolicus*, however, they show no activity with methanol.

A molybdenum iron-sulfur protein from *D. gigas* was shown to have some aldehyde dehydrogenase activity (Turner et al., 1987). Somewhat later, aldehyde oxidation was studied in more detail (Kremer et al., 1988b). Coenzyme A or phosphate dependency was not found, indicating that acetyl-CoA and acetyl phosphate are not intermediates in the conversion of acetaldehyde to acetate (Kremer et al., 1988b). Furthermore, it was shown that acetaldehyde can be oxidized in *Desulfovibrio gigas* by two completely different enzymes, a molybdenum-containing enzyme which can be assayed with DCPIP as artificial electron acceptor, and a tungsten-containing enzyme reacting with benzylviologen as an acceptor; the latter is strongly stimulated by K^+ ions (Kremer et al., 1988b). The synthesis of the enzymes appeared to be strongly affected by the presence of molybdate and tungstate in the growth media (Hensgens et al., 1994). Extracts of cells grown in the presence of both tungstate and molybdate have only very low levels of the DCPIP-dependent enzyme. The benzylviologen-linked tungsten-containing aldehyde dehydrogenase allows much faster growth with ethanol than the molybdenum enzyme. During growth on ethanol of *Desulfovibrio gigas*, in media without tungstate, transient excretion of acetaldehyde was observed. The molydenum-containing aldehyde oxidoreductase is a homodimer of subunits with 907 amino acid residues and contains a molybdopterin cofactor and two different [2Fe-2S] centers. It is a member of the xanthine oxidase family, and it is the first molybdenum enzyme with a molybdopterin cofactor (the crystal structure of which was determined; Romão et al., 1995). The tungsten-containing aldehyde oxidoreductase of *Desulfovibrio gigas* was active towards several aldehydes. This enzyme consists of two subunits of 62 kDa and was found to contain approximately 0.7 W, 4.8 Fe and 3.2 labile S per subunit; EPR studies indicated the presence of a [4Fe-4S] center (Hensgens et al., 1995b). Most likely, the tungsten-containing aldehyde oxidoreductase is related to similar enzymes from hyperthermophilic archaea and from Gram-positive anaerobic bacteria (Kletzin and Adams, 1996; Romão et al., 1997; Hu et al., 1999). The presence of a tungsten-containing aldehyde dehydrogenase, supposedly using flavins as natural cofactors, in *Desulfovibrio* simplex was demonstrated in experiments with cell-free extracts (Zellner and Jargon, 1997).

Other Monovalent Alcohols and Polyols Methanol is a less common electron donor for sulfate-

reducing bacteria and growth on methanol is usually slower. Enrichment cultures with methanol usually select for methanogenic bacteria, despite the presence of sulfate. Methanol can be used by some *Desulfotomaculum* species such as the mesophilic *Desulfotosporosinus orientis* (Klemps et al., 1985), the thermophilic *Desulfotomaculum kuznetsovii* (Nazina et al., 1988), a few *Desulfovibrio* species (e.g., *Desulfovibrio carbinolicus*; Nanninga and Gottschal, 1987), *Desulfobacterium anilini* (Schnell et al., 1989) and *Desulfobacterium catecholicum* (Szewzyk and Pfennig, 1987). The mechanism of methanol oxidation is unknown.

Primary alcohols higher than ethanol, for instance 1-propanol and 1-butanol, can also act as H_2 donors for sulfate-reducing bacteria. Oxidation by *Desulfovibrio* species is incomplete and leads to the formation of the corresponding acids (propionate, butyrate, respectively; Mechalas and Rittenberg, 1960). *Desulfobulbus* strains oxidize 1-propanol incompletely to acetate (Widdel and Pfennig, 1982). Species of other genera may oxidize these alcohols completely.

Certain *Desulfovibrio* strains were shown to dehydrogenate a secondary alcohol such as 2-propanol to acetone (Widdel, 1986; Zellner et al., 1989a; Tanaka, 1992) or 2-butanol to 2-butanone (Tanaka, 1992). *Desulfococcus biacutus* (Platen et al., 1990) and *Desulfococcus multivorans* strains except for the type strain (Widdel, 1988) oxidize 2-propanol completely to CO_2.

Metabolism of diols by *Desulfovibrio* strains involves either an initial oxidation of the primary alcohol group yielding an hydroxyaldehyde, or the dehydration of the diol to an aldehyde. Thus, 1,2-propanediol can be metabolized to acetate with lactaldehyde as a presumed intermediate, or to propionate via propanal (see Hansen, 1994). Oxidation of 1,3-propanediol leads to 3-hydroxypropionate or to acetate production as the major product (Nanninga and Gottschal, 1987; Qatibi et al., 1991; Tanaka, 1990; Tanaka, 1992); oxidation of 1,4-butanediol and 1,5-pentanediol yielded the corresponding hydroxyacids (Tanaka, 1992). Oppenberg and Schink (1990) suggested a pathway involving malonylsemialdehyde for the conversion of 1,3-propanediol to acetate by *Desulfovibrio* strain OttPd1.

Some *Desulfovibrio* species were shown to grow on glycerol (e.g., Stams et al., 1985; Kremer and Hansen, 1987; Nanninga and Gottschal, 1987; Ollivier et al., 1988). In two marine *Desulfovibrio strains*, glycerol is degraded to acetate and CO_2 via glycerol-3-phosphate, dihydroxyacetone phosphate and subsequent reactions known from the glycolytic pathway (Kremer and Hansen, 1987). *Desulfovibrio carbinolicus* oxidizes glycerol to 3-hydroxypropionate (Nanninga and Gottschal, 1987). In the case of *Desulfovibrio fructosovorans*, acetate is the normal product during sulfate reduction, but during syntrophic growth with a methanogenic archaeon as H_2 scavenger, glycerol is oxidized to 3-hydroxypropionate (Qatibi et al., 1998).

Sugars Batch enrichment cultures with sugars commonly select for fermentative bacteria rather than for sulfate reducers, due to faster growth of the former. Nevertheless, some species of sulfate reducers isolated on other substrates were shown to use fructose in the absence or presence of sulfate (Klemps et al., 1985; Ollivier et al., 1988; Zellner et al., 1989a; Trinkerl et al., 1990). *Desulfotomaculum nigrificans* was originally reported to utilize glucose (Campbell et al., 1957; Akagi and Jackson, 1985). However, later growth tests with filter-sterilized sugars revealed that fructose rather than glucose is utilized by this species. When glucose had been autoclaved rather than filter sterilized, growth was observed, indicating partial conversion to a utilizable sugar, probably fructose (Klemps et al., 1985).

Acetone Desulfococcus biacutus (Platen et al., 1990) and *Desulfococcus multivorans* strains other than the type strain (Widdel, 1988) used acetone that was completely oxidized to CO_2. *Desulfobacterium cetonicum* is the other known sulfate-reducing bacterium that can grow with acetone as sole source of carbon and energy (Galushko and Rozanova, 1991). Acetone degradation was shown to depend on CO_2 in cell suspensions of *Desulfococcus biactus*. Enzyme studies with the same microorganism indicated that it metabolized acetone via initial carboxylation to acetoacetyl-CoA. The latter is then thiolytically cleaved to two acetyl-CoA, which are further oxidized to CO_2. The energy gain with acetone as substrate is low because degradation requires carboxylation and activation to acetoacetyl-CoA (Platen et al., 1990; Janssen and Schink, 1995a). Similar results were obtained for acetone metabolism of *Desulfobacterium cetonicum* (Janssen and Schink, 1995b). An ATP-dependent carboxylation of acetone under anaerobic conditions was also demonstrated in cell-free extracts of the photosynthetic bacterium *Rhodobacter capsulatus* (Birks and Kelly, 1997) and other bacteria (Ensign et al., 1998).

Recently, an enrichment culture of sulfate-reducing bacteria was described that could utilize the long-chain ketones hexadecan-2-one and 6,10,14-trimethylpentadecan-2-one. The oxida-

tion of these ketones also involved a carboxylation reaction (Hirschler et al., 1998).

Glycolate Glycolate is a widespread byproduct of autotrophic organisms (e.g. cyanobacteria and algae) in oxic environments with limiting CO_2 concentrations. Ribulose-1,5-bisphosphate carboxylase of the Calvin cycle may incorporate O_2 instead of CO_2 in the substrate, such that one moiety is released as glycolate. It can be oxidized completely to CO_2 by *Desulfofustis glycolicus*, an organism which was isolated from marine sediment (Friedrich et al., 1996). With methylene blue as an electron acceptor, a rather high activity of a membrane-bound glycolate dehydrogenase was detected (Friedrich and Schink, 1995).

Malate, Fumarate, Succinate and Other Dicarboxylic Acids Dicarboxylic acids known from the citric acid cycle are relatively common substrates of incompletely and completely oxidizing sulfate reducers (Postgate, 1984a; Postgate, 1984b; Widdel, 1988). Growth on fumarate and malate is usually faster than on succinate. Some species may utilize only one or two of these compounds because certain transport systems might be limited or lacking. Growth yields of *Desulfovibrio* strains on succinate are far lower than on malate (Kremer et al., 1989). This may be explained by a partial investment of the conserved energy for reverse electron transport from the oxidation of succinate (fumarate/succinate, $E_0' = +0.033$ V).

In various *Desulfovibrio* strains, the C_4-dicarboxylic acids are oxidized via a reaction sequence with an $NADP^+$-dependent malic enzyme (a decarboxylating malate dehydrogenase); the activity was dependent on divalent cations (Mn^{2+} or Mg^{2+}) and stimulated by K^+ (Kremer et al., 1989). The $NADP^+$-dependent malic enzyme of *Desulfovibrio gigas* was found to be a monomeric 45-kDa protein (Chen et al., 1995).

The C_5 and C_7 dicarboxylic acids, glutarate and pimelate, respectively, can serve as substrates for some complete oxidizers (Bak and Widdel, 1986b; Imhoff-Stuckle and Pfennig, 1983; Schnell et al., 1989; Szewzyk and Pfennig, 1987).

Amino Acids Utilization of amino acids as electron donors and carbon sources mainly has been reported for marine species. They include several *Desulfovibrio* strains; alanine utilization seems to be widespread and has been reported for *Desulfotomaculum ruminis* (Coleman, 1960), *Desulfovibrio salexigens* (Zellner et al., 1989a; van Niel et al., 1996), *Desulfovibrio strains* 20020 and 20028 (Stams et al., 1985), *Desulfovibrio acrylicus* (van der Maarel et al., 1996c), and *Desulfovibrio zosterae* (Nielsen et al., 1999). *Desulfocella halophila*, which was isolated from sediment of the Great Salt Lake, is also able to use L-alanine as an electron donor (Brandt et al., 1999). *Desulfovibrio acrylicus* and *Desulfovibrio strains* 20020 and 20028 also have been shown to utilize serine, glycine and cysteine; even other amino acids are used by *Desulfovibrio* strains 20020 and 20028. Several *Desulfobacterium* strains use glutamate (Imhoff-Stuckle and Pfennig, 1983; Bak and Widdel, 1986b; Brysch et al., 1987; Szewzyk and Pfennig, 1987; Heijthuijsen and Hansen, 1989; Schnell et al., 1989; van der Maarel et al., 1996a; Rees et al., 1998). Some other amino acids were also utilized by *Desulfobacterium* strain PM4, the *Desulfobacterium*-like strain WN, and *Desulfobacetrium vacuolatum* (Heijthuijsen and Hansen, 1989; van der Maarel et al., 1996a; Rees et al., 1998). *Desulfovibrio aminophilus*, which was isolated from an anaerobic lagoon of a dairy wastewater plant, degraded six amino acids including alanine in the presence of sulfate (Baena et al., 1998).

L-Alanine was found to be oxidized to pyruvate by an NAD^+-dependent alanine dehydrogenase in *Desulfovibrio* strains 20020 and 20028 and in *Desulfotomaculum ruminis* (Stams and Hansen, 1986).

Furfural Desulfovibrio furfuralis has been isolated with furfural; several other, previously known species of this genus also turned out to use this compound (Folkerts et al., 1989).

On the basis of feeding experiments with ^{13}C-labeled furfural, a reaction sequence was postulated for the breakdown of the substrate in *D. furfuralis* with succinic semialdehyde as a key intermediate (Folkerts et al., 1989); furfuryl alcohol and 2-furoic acid transiently accumulated in the culture supernatants as important intermediates.

Methylated N- and S-compounds (Glycine, Betaine, Dimethylsulfoniopropionate and Dimethylsulfide) Glycine betaine (trimethylglycine) is widely used as an osmolyte in many bacteria (for summary, see Galinski, 1995). Dimethylsulfoniopropionate is an osmolyte in many marine algae.

Growth with glycine betaine as organic substrate has been demonstrated for a number of isolates belonging to the *Desulfobacterium*/*Desulfobacter* cluster of the δ-Proteobacteria; they include *Desulfobacterium autotrophicum*, *Desulfobacterium niacini*, *Desulfobacterium vacuolatum*, a strain named WN which clusters in

between *Desulfobacterium* and *Desulfobacter* (Heijthuijsen and Hansen, 1989; van der Maarel et al., 1996a), and *Desulfospira joergensenii* (Finster et al., 1997a). Glycine betaine (trimethylglycine) was demethylated to dimethylglycine as end product. It was speculated that the oxidation of the methyl group in these strains, which contain CO dehydrogenase, is mediated via the methyl branch of the oxidative C_1-pathway normally used for the oxidation of the methyl moiety of the acetyl group in acetyl-CoA (Heijthuijsen and Hansen, 1989). Most organisms that can oxidize glycine betaine also grow by demethylation of dimethylsulfoniopropionate (DMSP) with 3-methylthiopropionate as the product; *Desulfobacterium autotrophicum* did not grow on DMSP (van der Maarel et al., 1996a). In cell extracts of DMSP-grown strain WN and other strains, a high DMSP:tetrahydrofolate methyltransferase activity was detected (Jansen and Hansen, 1998). Certain sulfate-reducing bacteria have been shown to metabolize DMSP in a different way, namely by cleaving the DMSP to acrylic acid and dimethylsulfide and by reducing the acrylate to propionate (van der Maarel et al., 1996c; see below for a discussion of acrylate reduction).

Dimethylsulfide is a widespread degradation product of dimethylsulfoniopropionate in marine environments. As a trace gas in the atmosphere, dimethylsulfide leads to sulfuric acid that forms condensation nuclei for water and thus influences cloud formation. Dimethylsulfide oxidation by mesophilic sulfate-reducing bacteria from marine sediments was inferred from experiments with labeled substrates and inhibitor studies (Kiene et al., 1986). Oxidation of dimethylsulfide by a thermophilic *Desulfotomaculum* strain has been reported (Tanimoto and Bak, 1994) but utilization of dimethylsulfide by pure cultures of mesophilic sulfate reducers remains to be demonstrated.

Polar Aromatic Compounds (Non-Hydrocarbons) The utilization of various nonfermentable aromatic compounds in the absence of O_2 or nitrate seems to be one of the domains of sulfate-reducing bacteria. In contrast, aromatic compounds with more than two hydroxyl groups (e.g. gallic acid, pyrogallol or phloroglucinol) are readily degraded by fermentative bacteria (Schink and Pfennig, 1982; Schink, 1988a; Schink, 1988b). Several new types of sulfate-reducing bacteria have been directly isolated with aromatic compounds (Widdel, 1980; Imhoff-Stuckle and Pfennig, 1983; Widdel et al., 1983; Bak and Widdel, 1987; Szewzyk and Pfennig, 1987; Schnell et al., 1989; Kuever et al., 1993; Gorny and Schink, 1994). Most of these isolates are very versatile sulfate reducers that also use many aliphatic compounds. Benzoate is the most commonly and most readily utilized aromatic substrate. Representatives of other classes of aromatic compounds oxidized by sulfate reducers are phenol, *p*-cresol (Bak and Widdel, 1986b), aniline (Schnell et al., 1989), and the N-heterocyclic compounds nicotinate (Imhoff-Stuckle and Pfennig, 1983), indole and quinoline (Bak and Widdel, 1986a). An overview of non-hydrocarbon aromatic substrates utilized by pure cultures of sulfate-reducing bacteria is presented in Table 5.

So far, most sulfate-reducing bacteria that degrade aromatic compounds are complete oxidizers. The only known exception is *Desulfovibrio inopinatus*, which degrades the relatively oxidized compound hydroxyhydroquinone (1,2,4-trihydroxybenzene) incompletely to acetate (Reichenbecher and Schink, 1997). Little is known about reactions at the aromatic ring in sulfate-reducing bacteria. Aerobic bacteria employ oxygenases which require O_2 (as co-substrate) to activate (hydroxylate) and cleave the aromatic ring. The pathways in the anaerobic sulfate-reducing bacteria are therefore expected to be completely different from those of aerobic bacteria and to involve novel biochemical reactions. Most insights into the degradative pathways of aromatic compounds under anoxic conditions were obtained from studies with denitrifying and phototrophic bacteria (for overview see e.g., Berry et al., 1987; Evans and Fuchs, 1988; Tschech, 1989a; Heider and Fuchs, 1997a; Heider and Fuchs, 1997b; Harwood et al., 1999). Important principles of aromatic compound degradation recognized in the nonsulfate-reducing bacteria are that the degradative pathways can be classified into three categories. First, many aromatic compounds are converted via so-called peripheral reactions to a central intermediate, benzoyl-CoA. Second, a central sequence of reactions abolishes aromaticity of benzoyl-CoA and leads to ring cleavage. Third, certain polyhydroxybenzoates or polyhydroxybenzenes undergo reactions that lead to aliphatic intermediates without the involvement of benzoyl-CoA.

Examples of peripheral reactions are phosphorylation/carboxylation to convert phenol to *p*-hydroxybenzoate (Knoll and Winter, 1989; Tschech and Fuchs, 1989b; Lack and Fuchs, 1992; Lack and Fuchs, 1994), the involvement of an α-oxidation reaction in the conversion of phenylacetate to benzoyl-CoA (Mohamed et al., 1993), the reductive removal of hydroxyl groups (Tschech and Schink, 1986; Gibson et al., 1997). Free benzoate is simply activated to benzoyl-CoA in an ATP-consuming reaction (Geissler et al., 1988; Altenschmidt et al., 1991). Some

Table 5. Sulfate-reducing bacteria with the capacitiy to use aromatic compounds as growth substrates.

Organism	Aromatic substrate[a]	Reference
Non-hydrocarbon aromatic compounds		
Desulfonema magnum	Benzoate, 4-hydroxybenzoate, phenylacetate, 3-phenylpropionate, hippurate	Widdel et al., 1983
Desulfococcus niacim[b]	Nicotinic acid, 3-phenylpropionate	Imhoff-Stuckle and Pfennig, 1983
Desulfobacterium indolicum[c]	Indole, 2-aminobenzoate, quinoline	Bak and Widdel, 1986a
Desulfobacterium phenolicum[d]	Phenol, *p*-cresol, benzoate, phenylacetate, indole, 4-hydroxyphenylacetate, 2-hydroxybenzoate, 4-hydroxybenzoate, phenylalanine, 2-aminobenzoate	Bak and Widdel, 1986b
Desulfobacterium catecholicum[e]	Catechol, resorcinol, 4-hydroxybenzoate, hydroquinone, benzoate 2-aminobenzoate, protocatechuate, phloroglucinol, pyrogallol	Szewzyk and Pfennig, 1987
Desulfobacterium anilini[c]	Aniline, 2-aminobenzoate, 4-aminobenzoate, indolylacetate, quinoline	Schnell et al., 1989
strain Cat2[c]	Phenol, catechol, *m*-cresol, *p*-cresol, benzoate, phenylacetate, phenylpropionate 4-hydroxybenzoate, 3,4-dihydroxybenzoate, phenylalanine	Schnell et al., 1989
strain SAX[c]	Benzoate, *p*-hydroxybenzoate, phenol, phenylacetate, phenylalanine	Drzyzga et al., 1993
Desulfotomaculum strain Groll[f]	Catechol, phenol, *m*-cresol,, *p*-cresol, benzoate, 3-hydroxybenzoate, benzaldehyde benzyl alcohol, phenylacetate, phenylpropionate	Kuever et al., 1993
Desulfovibrio inopinatus	Hydroxyhydroquinone (1,2,4-trihydroxybenzene)	Reichenbecher and Schink, 1997
Aromatic hydrocarbons		
"Desulfobacula toluolica"	Toluene, *p*-cresol, benzaldehyde, benzoate, phenylacetate, *p*-hydroxybenzoate *p*-hydroxybenzaldehyde	Rabus et al., 1993
strain PRTOL1[g]	Toluene, *p*-cresol, benzaldehyde, benzoate, phenylacetate, phenylpropionate *p*-hydroxybenzoate	Beller et al., 1996
strain mXyS1[c]	Toluene, *m*-xylene, *m*-ethyltoluene, *m*-isopropyltoluene, benzoate, *m*-methylbenzoate	Harms et al., 1999
strain oXyS1[h]	Toluene, *o*-xylene, *o*-ethyltoluene, *o*-methylbenzyl alcohol benzoate, *o*-methylbenzoate, benzylsuccinate	Harms et al., 1999
strain NaphS2[h]	Naphthaline, 2-naphthoate, benzoate	Galushko et al., 1999

[a]Information about additional aromatic substrates is provided in the respective references.
[b]Has to be reclassified as "*Desulfobacterium niacim*" (J. Kuever, F. A. Rainey and F. Widdel, personal communication).
[c]Has to be classified/reclassified as new genus (J. Kuever, F. A. Rainey and F. Widdel, personal communication).
[d]Has to be reclassified as "*Desulfobacula phenolicum*" (J. Kuever, F. A. Rainey and F. Wuddel, personal communication).
[e]Has to reclassified (J. Kuever, F. A. Rainey and F. Widdel, personal communication).
[f]Has been classified as *Desulfotomaculum gibsoniae* (Kuever et al., 1999).
[g]Has to be classified as a new species of the genus *Desulforhabdus* (J. Kuever, F. A. Rainey and F. Widdel, personal communication).
[h]Has to be classfied as a new species of the genus *Desulfosarcina* (J. Kuever, F. A. Rainey and F. Widdel, personal communication).
[i]Strain NaphS2 affiliates closely with strain mXyS1 (Galushko et al., 1999) and will therefore be classified into the same new genus (J. Kuever, F. A. Rainey and F. Widdel, personal communication).

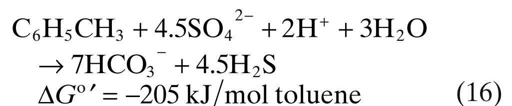
peripheral reactions for the degradation of aromatic compounds also have been suggested thus far in sulfate-reducing bacteria. Degradation of aniline by *Desulfobacterium anilini* is initiated by a carboxylation probably yielding 4-aminobenzoate, which via ligation with acetyl-CoA and reductive deamination is supposed to yield benzoyl-CoA (Schnell and Schink, 1991). *p*-Cresol was first suggested to be converted to *p*-hydroxybenzyl alcohol by an anaerobic *p*-cresol methylhydroxylase (McIntire et al., 1985; Suflita et al., 1989); further oxidation to the corresponding aldehyde and acid, ligation with coenzyme A and reductive dehydroxylation (or vice versa) could yield benzoyl-CoA. Such a pathway would be in agreement with the ability of *p*-cresol-utilizing sulfate reducers to grow with benzoate. Furthermore, an anaerobic degradation of *m*-cresol by *Desulfotomaculum* strain (Groll) is proposed to proceed via a methyl-group oxidation to 3-hydroxybenzoate because the latter compound was detected in *m*-cresol-

degrading cultures (Londry et al., 1997). However, in the light of recent findings about the anaerobic activation of toluene by methyl condensation with fumarate (see Aromatic Hydrocarbons) methyl hydroxylation reactions may be questioned and reactions analogous to toluene activation may be assumed. Indeed, an activation of *m*-cresol by a fumarate-dependent reaction to 3-hydroxybenzylsuccinate was demonstrated in cell-free extracts of *Desulfobacterium cetonicum* (Müller et al., 1999). Catechol degradation by *Desulfobacterium* strain Cat2 was proposed to be initiated by a carboxylation to protocatechuate, because high activities of a protocatechuate decarboxylase and low activities of an ATP/HCO_3^--dependent protocatechuyl-CoA-forming enzyme synthetase could be measured in extracts of catechol grown cells. Further degradation to benzoyl-CoA would involve reductive dehydroxylation reactions (Gorny and Schink, 1994).

The further metabolism of benzoyl-CoA has been studied most intensely in denitrifying *Thauera aromatica* strain K172. The stable aromatic state is abolished by benzoyl-CoA reductase. This novel enzyme contains FAD as prosthetic group and uses ferredoxin as the natural electron donor. It requires two ATP to generate and transfer two electrons into the ring of benzoyl-CoA to yield cyclohexa-1,5-diene-1-carboxyl-CoA (Boll and Fuchs, 1995; Boll and Fuchs, 1998); the first electron has to have an extremely negative redox potential. Different enzymes have been measured and isolated from *Thauera aromatica* (Laempe et al., 1998) and *Rhodopseudomonas palustris* (Perrotta and Harwood, 1994; Pelletier and Harwood, 1998) that are involved in further reduction and cleavage of the ring structure to yield the open chain pimelyl-CoA, which can be further degraded to acetyl-CoA via reactions such as β-oxidation. Thus, somewhat different pathways for benzoate degradation are employed by these two organisms (Harwood and Gibson, 1997; Harwood et al., 1999), suggesting that variations of pathways exist for the anaerobic degradation of benzoate. Considering the high energy requirement of anaerobic benzoate degradation in the aforementioned microorganisms, it appears rather unlikely that sulfate-reducing bacteria with their relatively low ATP yield employ the same reactions for ring reduction. *Desulfococcus multivorans* required selenite in addition to molybdate for the degradation of benzoate, but not for growth on aliphatic substrates (Widdel, 1980). However, neither the role of these trace elements in *Desulfococcus* nor the pathway of benzoate degradation is known.

Heterocyclic aromatic compounds utilized by sulfate-reducing bacteria are nicotinate (Imhoff-Stuckle and Pfennig, 1983), indole and quinoline (Bak and Widdel, 1986a). *Desulfobacterium niacini* requires traces of selenite for the oxidation of nicotinate (Imhoff-Stuckle and Pfennig, 1983), as *Clostridium barkeri* does for fermentation of this compound. In the latter, the degradation of nicotinic acid is initiated by a conversion to 6-hydroxynicotinate via nicotinate dehydrogenase, which is probably a selenoenzyme (Imhoff and Andreesen, 1979). Nicotinate dehydrogenase, also detected in *Desulfobacterium niacini* (W. Buckel, personal communication), may explain the selenium requirement.

Aromatic Hydrocarbons Aromatic hydrocarbons as apolar molecules are biochemically less reactive than their aromatic counterparts carrying functional groups. Degradation of aromatic hydrocarbons under anaerobic conditions was long considered to be impossible. However, studies with anaerobic sediment and enrichment cultures of mixed methanogenic cultures (Gribc-Galic and Vogel, 1987), denitrifying (Kuhn et al., 1988) and sulfate-reducing bacteria (Edwards et al., 1992) demonstrated that aromatic hydrocarbons such as toluene were indeed degradable under anoxic conditions. The first pure cultures that could anaerobically degrade toluene were obtained under denitrifying (Dolfing et al., 1990; Altenschmidt and Fuchs, 1991; Evans et al., 1991; Schocher et al., 1991) and ferric-iron reducing (Lovley et al., 1990) conditions. The first pure culture of a toluene-degrading sulfate-reducing bacterium, "*Desulfobacula toluolica*," was isolated from marine sediment (Rabus et al., 1993). This new isolate oxidized toluene completely to CO_2 according to equation (16), as demonstrated by measurement of the degradation balance. Another toluene-degrading sulfate reducer, strain PRTOL1, was isolated from fuel-contaminated subsurface soil (Beller et al., 1996).



$$C_6H_5CH_3 + 4.5SO_4^{2-} + 2H^+ + 3H_2O \rightarrow 7HCO_3^- + 4.5H_2S \quad \Delta G^{o\prime} = -205\ \text{kJ/mol toluene} \quad (16)$$

A marine enrichment culture that grew anaerobically on crude oil with concomitant sulfate reduction to sulfide (Rueter et al., 1994) was the source for the isolation of the *o*-xylene-degrading strain oXyS1 and the *m*-xylene-degrading strain mXyS1 (Harms et al., 1999). Both strains also used toluene for growth by sulfate reduction. Furthermore, strain oXyS1 oxidized *o*-ethyltoluene, and strain mXyS1 oxidized *m*-ethyltoluene and *m*-isopropyltoluene anaerobically. Sulfate-reducing strain NaphS2 was isolated as the first pure culture which can

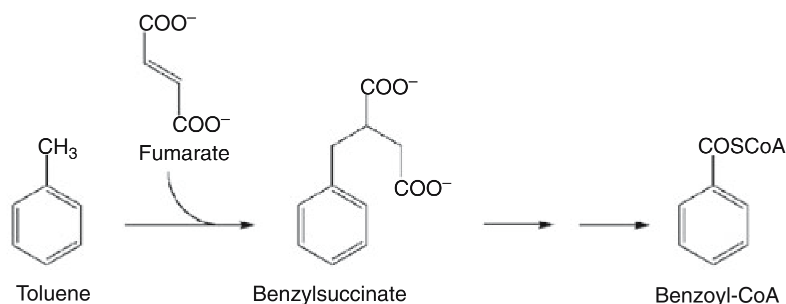


Fig. 16. Anaerobic, fumarate-dependent activation of toluene to benzylsuccinate in *Desulfobacula toluolica* and strain PRTOL1. Further degradation of benzylsuccinate to the central intermediate benzoyl-CoA is not completely understood.

utilize the bicyclic aromatic hydrocarbon naphthalene (Galushko et al., 1999). Anaerobic degradation of other aromatic hydrocarbons with sulfate as electron acceptor has been demonstrated in enriched sediment communities, but not so far in pure cultures. These hydrocarbons are benzene (Lovley and Phillips, 1995b; Phelps et al., 1996) and the polyaromatic hydrocarbons phenanthrene and fluorene (Coates et al., 1997). Oxidation was shown by the formation of $^{14}CO_2$ from the ^{14}C-labeled hydrocarbon substrates.

The best known anaerobic pathway of an aromatic hydrocarbon is that of toluene. Understanding of anaerobic toluene metabolism has greatly benefited from studies with denitrifying bacteria. Benzylsuccinate, first identified as a metabolite in toluene-grown cultures of a denitrifyer (Evans et al., 1992), a sulfate-reducing enrichment culture (Beller et al., 1992) and *Desulfobacula toluolica* (Rabus and Widdel, 1995), was shown to be the initial activation product in denitrifying bacteria (Biegert et al., 1996; Beller and Spormann, 1997a). It was formed from toluene and fumarate. Fumarate-dependent formation of benzylsuccinate from toluene was subsequently reported with permeabilized cells of sulfate-reducing strain PRTOL1 (Beller and Spormann, 1997b) and in cell-free extracts of *Desulfobacula toluolica* (Rabus and Heider, 1998). The further demonstration of benzylsuccinate formation in a toluene-utilizing phototroph that is unrelated to denitrifying or sulfate-reducing bacteria (Zengler et al., 1999b) suggests that this is a general anaerobic activation mechanism for toluene, a naturally widespread trace hydrocarbon (Heider et al., 1999). Genetic analysis of genes underlying the benzylsuccinate-forming enzyme (benzylsuccinate synthase) indicates that this is a glycyl radical enzyme (Coschigano et al., 1998; Leuthner et al., 1998); the radical is supposed to attack the methyl group of toluene yielding a benzyl radical which then combines with fumarate (Fig. 16). Further degradation of benzylsuccinate is proposed to proceed via reactions analogous to β-oxidation of α-methyl-branched fatty acids and to yield benzoyl-CoA as a central intermediate. In agreement with this, toluene-utilizing sulfate-reducing bacteria can also grow on benzoate.

Hints as to the initial reaction in anaerobic degradation of naphthalene were obtained from enriched sediment communities under sulfate-reducing conditions. The finding of 2-naphthoate (naphthalene-2-carboxylate) suggested a carboxylation as the initial activation of the bicyclic aromatic hydrocarbon (Zhang and Young, 1997). In agreement with this, naphthalene-degrading strain NaphS2 is able to grow on 2-naphthoate, but not on 1-naphthoate (Galushko et al., 1999). A different initial mechanism of anaerobic napthalene degradation was suggested in a study of freshwater microcosms under conditions of sulfate reduction; in these communities, a naphthol (isomer unknown) was detected as a possible intermediate (Bedessem et al., 1997).

Saturated Hydrocarbons Saturated hydrocarbons (n-alkanes, branched-chain alkanes and cycloalkanes) are the chemically least reactive organic compounds. The chemical recalcitrance is explained by the exclusive presence of apolar s bonds. Because of these structural properties and the fact that aerobic bacteria initiate alkane activation always with O_2 as co-substrate (monoxygenase reaction), the possibility of an anaerobic alkane oxidation has often been doubted. Nevertheless, evidence for the anaerobic oxidation of alkanes in enriched microbial communities and pure cultures has been repeatedly provided.

In the 1940s, enrichment cultures and pure cultures of *Desulfovibrio* strains were reported to grow or to reduce sulfate with long-chain alkanes (Novelli and ZoBell, 1944; Rosenfeld, 1947). The techniques available at that time to guarantee strictly anoxic conditions in the experiments were not described in detail. The cultures have not been preserved. In experiments with suspensions of other *Desulfovibrio* species, sulfate reduction was stimulated by octadecane and a

Table 6. Sulfate-reducing bacteria with the capacitiy to use aliphatic hydrocarbons as growth substrates.

		Aliphatic hydrocarbon utilized[a]

[a]So far tested; more detailed information on growth substrates can be obtained from the respective references.
[b]Has tentatively been classified as "*Desulfobacterium oleovorans*" (Aeckersberg et al., 1991). The genus name has to be reclassified (J. Kuever, F. A. Rainey and F. Widdel, personal communication).
[c]Has to be classified as a new genus (J. Kuever, F. A. Rainey and F. Widdel, personal communication).
[d]Has been tentatively classified as "*Desulfothermus naphthae*" (Ehrenreich, 1996).
[e]Has to be classified into the same new genus as strain Hxd3 (J. Kuever, F. A. Rainey and F. Widdel, personal communication).

small part (around 0.4%) of ^{14}C-labeled alkane was recovered as CO_2 (Davis and Yarbrough, 1966). The possibility of anaerobic alkane oxidation with sulfate was again examined in connection with a study of sulfate reducers in oil fields. A sulfate-reducing bacterium that nutritionally and morphologically differed from *Desulfovibrio* was isolated with hexadecane (Aeckersberg et al., 1991). Quantitative degradation experiments in anoxic, fused glass (air-excluded) ampullas showed that up to ca. 90% of the added hexadecane was oxidized with sulfate. A control experiment with a *Desulfovibrio* strain did not reveal alkane utilization. Three other pure cultures of alkane-degrading sulfate-reducing bacteria, two mesophilic strains (Aeckersberg et al., 1998; So and Young, 1999a) and a thermophilic strain (Rueter et al., 1994) were subsequently described. The range of alkanes utilized by these isolates and other characteristics are summarized in Table 6. Anaerobic utilization of various long-chain *n*-alkanes was also observed with enriched communities in marine sediment under conditions of sulfate reduction (Caldwell et al., 1998).

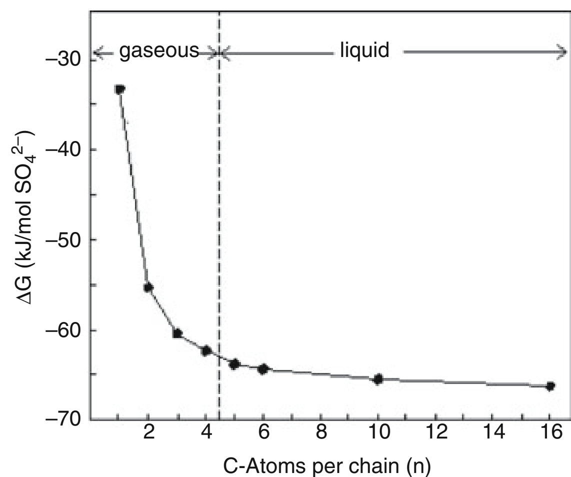

Fig. 17. Free energy change of sulfate reduction with *n*-alkanes of various chain lengths (methane through hexadecane) at 25°C, pH = 7, SO_4^{2-} and HCO_3^- concentrations = 10^{-2} M, and HS^- concentration = 10^{-3} M. Individual stoichiometric equations are derived from $CnHn+_2 + (3n+1)/4\ SO_4^{2-} \rightarrow n\ HCO_3^- + (3n+1)/4\ HS^- + (n-1)/4\ H^+ + H_2O$, with n being the number of carbon atoms per chain. Free energy values were calculated from data given by Dean (1992); Thauer et al. (1977) and Zengler et al. (1999a).

The biochemical problem in anaerobic alkane degradation is the first step, the activation of an apolar molecule, rather than in the free energy change of the overall reaction. With the exception of methane oxidation (see next section), the amount of free energy per mol of sulfate reduced with alkanes (see Fig. 17) is comparable to that available from acetate or propionate oxidation. The activation has to start with a cleavage of a C-H bond that is not activated. A resulting alkyl radical would not have the possibility for stabilization by delocalization, as in the case of an aryl radical (e.g., benzyl radical; see preceding section). Studies on changes in the cellular fatty acid composition in response to the growth substrate provided first hints at possible activation reactions of alkanes in a sulfate-reducing bacterium, strain Hxd3 (Aeckersberg et al., 1998). If cells were grown on hexadecane ($C_{16}H_{34}$), the chains of cellular fatty acids were mainly C-odd. Conversely, cells grown on heptadecane ($C_{17}H_{36}$) contained mainly C-even fatty acids in the lipid fraction. It was concluded from these results that the alkane chain was altered by a C_1-unit during activation, possibly by the terminal addition of a C_1-compound. However, with a second, phylogenetically related alkane-degrading sulfate reducer, strain Pnd3, a C-even alkane yielded C-even fatty acids, and a C-odd alkane yielded C-odd fatty acids. Assuming a mechanism principally as in strain Hxd3, activation at the second carbon atom was proposed as one possible explanation for the findings with strain Pnd3.

Also, addition to fumarate was discussed as hypothetical activation mechanism, which could differ from toluene activation by a lack of radical stabilization in the substrate molecule (Aeckersberg et al., 1998). Chemical analysis with a third alkane-degrading sulfate reducer, strain AK-01, yielded methyl-branched cellular fatty acids resulting from the *n*-alkane provided as substrate (So and Young, 1999b). Labeling studies suggested that a carbon compound, which is not derived from bicarbonate, is subterminally added to the alkane such that the terminal methyl group of the *n*-alkane becomes a methyl branch in the fatty acid formed via subsequent reactions.

Methane Methane, the only existent stable C_1-hydrocarbon, can be regarded as the first member of the homologous series of alkanes. It is chemically even somewhat more stable than higher alkanes. Methane is formed as an end product of anaerobic degradation processes involving methanogenic archaea in sediments that are depleted of electron acceptors other than CO_2. Because of the important role of methane in the carbon cycle in aquatic habitats and on a global scale, the possibility of an anaerobic oxidation of this hydrocarbon has been frequently investigated. In anoxic marine habitats, sulfate would be the most important terminal electron acceptor for anaerobic methane oxidation.

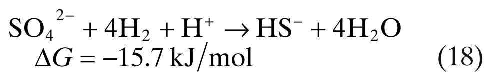
Hints on an anaerobic methane oxidation came mostly from biogeochemical investigations in marine sediments. Geochemical evidence is based on three different observations. First, methane in marine habitats often disappears far below the oxic zone, and the depth profile of the methane concentration exhibits a concave-up curvature, which indicates a methane sink (Devohl and Ahmed, 1981; Reeburgh, 1976; Barnes and Goldberg, 1976; Martens and Berner, 1977; Alperin and Reeburgh, 1984); an increase ("second maximum") of the sulfate reduction rate in the depth profile was observed to coincide with the zone of anaerobic methane depletion (Alperin and Reeburgh, 1985; Iversen and Jørgensen, 1985; Reeburgh and Alperin, 1988; Hansen et al., 1998). Second, $^{13}C/^{12}C$ analyses are in favor of an anaerobic methane oxidation. Residual methane in the zone of its anaerobic depletion is ^{13}C-enriched (and ^{2}H-enriched), indicating a biochemical consumption reaction (Alperin et al., 1988). In addition, inorganic carbon (CO_2, HCO_3^-, CO_3^{2-}) in the zone of methane depletion was shown to be relatively poor in ^{13}C (Reeburgh, 1980; Reeburgh and Alperin, 1988; Blair and Aller, 1995); this finding suggested that oxidation of isotopically light methane added to the signature of the isotopically heavier background of inorganic carbon. Third, after addition of ^{14}C-labeled methane to anoxic marine sediment cores or slurries, formation of radioactive CO_2 could be measured (Reeburgh, 1980; Iversen and Blackburn, 1981; Alperin and Reeburgh, 1984; Alperin and Reeburgh, 1985; Iversen and Jørgensen, 1985; Hansen et al., 1998). The rates of anaerobic methane oxidation calculated from data of the biogeochemical investigations were always rather low; they ranged between 1 and 67 μmol $\cdot$liter^{-1} $\cdot$day^{-1}, or were even lower. However, at a gas seep, volumetric sulfate reduction rates as high as 2.5 mmol $\cdot$liter^{-1} $\cdot$day^{-1} were attributed to methane as the electron donor (Aharon and Baoshun, 2000); this implies that methane oxidation at this site has the same rate.

An organism that can consume methane anaerobically has not been enriched and isolated thus far. A partial conversion of $^{14}CH_4$ to $^{14}CO_2$ during methanogenesis but no net oxidation of methane has been measured in cultures of methanogenic archaea (Zehnder and Brock, 1979; Zehnder and Brock, 1980), which provided the first hint of a "reverse methanogenesis". Because biologically produced methane, which is usually used for labeling experiments, may contain traces of CO as a by-product, ^{14}C-methane was purified from this by-product and applied to active methanogenic bacteria (Harder, 1997). Again, a partial oxidation of methane without net consumption was demonstrated. The reaction was not detectable in cultures of sulfate-reducing and homoacetogenic bacteria.

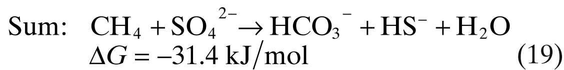
The assumption that anaerobic oxidation of methane is a reversed methanogenesis and catalyzed by methanogenic archaea (or at least by a phylogenetically closely related group) is supported by microbiological in situ analysis of bacterial populations on the basis of biomarkers and 16S rRNA gene sequences. Special isoprene lipids and hydrocarbons such as crocetane (2,6,11,15-tetramethylhexadecane) that occurred in the zone of methane depletion and exhibited an unusually low $^{13}C/^{12}C$-ratio were assumed to belong to the methane-utilizing anaerobes (Elvert and Suess, 1999; Hinrichs et al., 1999); also retrieved 16S rRNA gene sequences forming a distinctive cluster within the *Methanosarcinales* were tentatively assigned to these microorganisms (Hinrichs et al., 1999). From these and earlier studies (Hoehler et al., 1994; Hansen et al., 1998), it was concluded that methane is not directly utilized by sulfate-reducing bacteria, but rather by a group of archaea (eventually identified as methanogens)

that convert methane in a "reversed methanogenesis" to CO_2 and an intermediate, possibly H_2; the latter is then scavenged and kept at low concentration by the activity of sulfate-reducing bacteria. The free energy yield from anaerobic methane oxidation with sulfate near natural concentrations is relatively low ($\Delta G = -33$ kJ/mol sulfate). This amount would have to be shared between two partners (Fig. 11). Assuming an equal share of the free energy with H_2 as the intermediate (conditions see below following equations), the partial pressure of the latter would have to be around 0.12 Pa (corresponding to: $0.9 \cdot 10^{-9}$ M dissolved H_2; $E' = -0.269$ V at pH 7.5) to render methane oxidation thermodynamically feasible.

$$CH_4 + 3H_2O \rightarrow HCO_3^- + 4H_2 + H^+ \quad \Delta G = -15.7\ \text{kJ/mol} \qquad (17)$$



$$SO_4^{2-} + 4H_2 + H^+ \rightarrow HS^- + 4H_2O \quad \Delta G = -15.7\ \text{kJ/mol} \qquad (18)$$



$$\text{Sum:}\ CH_4 + SO_4^{2-} \rightarrow HCO_3^- + HS^- + H_2O \quad \Delta G = -31.4\ \text{kJ/mol} \qquad (19)$$

(calculated for 25°C; pH = 7.5; CH_4 partial pressure = 10^5 Pa; H_2 partial pressure = 0.12 Pa; SO_4^{2-} concentration = $2 \cdot 10^{-2}$ M; HCO_3^- concentration = 10^{-2} M; HS^- concentration = $2 \cdot 10^{-3}$ M; activity coefficients of SO_4^{2-}, HCO_3- and HS^- in seawater of 0.1, 0.5 and 0.5, respectively; data for calculation from Stumm and Morgan, 1981, and Thauer et al., 1989b).

Measurement of H_2 at partial pressures in the indicated range is technically possible. However, because the partial pressure is the result of a dynamic equilibrium between production and consumption, sampling procedures that affect substrate availability are expected to have a significant influence on the H_2 partial pressure. Hydrogen partial pressures reported for conditions of sulfate reduction were 5 Pa in marine sediment (Sørensen et al., 1981), 0.17 Pa in sulfate-amended lake sediment (Lovley et al., 1982), and between 0.05 and 0.4 Pa in the anoxic seawater of Cariaco Trench (Scranton et al., 1984). Hence, the partial pressures determined in the latter samples would be roughly in the range required if anaerobic methane oxidation occurred via free H_2.

Sulfate reduction at the calculated very low H_2 concentrations is expected to be very slow, even if sulfate-reducing bacteria are closely associated with the H_2-producing partners. With the most favorable kinetic parameters reported for cells of sulfate-reducing bacteria, viz. a maximum rate (V_{max}) of 90 mol H_2 $g^{-1} \cdot h^{-1}$ (see Overview of Principal Properties, Sulfate-Reducing Bacteria and Archaea in this Chapter) and a half-saturation constant (K_M) of $0.7 \cdot 10^{-6}$ mol $\times$ H_2 l^{-1} (Widdel, 1988), the specific rate (related to cell dry mass) of H_2 oxidation would be 0.12 mol $\times$ $g^{-1} \cdot h^{-1}$; hence the rate of sulfate reduction or methane oxidation would be 0.03 mol $g^{-1} \cdot h^{-1}$. (The rate at substrate concentrations K_M is calculated by multiplication of the first-order rate constant, V_{max}/K_M, with the substrate concentration.) Since members of the *Methanosarcinales* are metabolically versatile, also a transfer of metabolites other than H_2 may be assumed. However, organic compounds known as methanogenic substrates would require concentrations even lower than that of hydrogen to allow reverse methanogenesis and an approximately equal energy share of both partners (acetate, $3 \cdot 10^{-11}$ M; concentrations of methanol and methylsulfide even lower). Hydrogen or electron carriers with midpoint potentials close to the redox potential calculated above (–0.269 V) would allow kinetically more favorable concentrations for a transfer of their oxidized and reduced forms between the partners.

Special Inorganic Electron Donors (Other than H_2) An economically important inorganic electron donor for sulfate-reducing bacteria is metallic iron. Oxidation of metallic iron with sulfate as electron acceptor is regarded as the principal reaction in anaerobic corrosion (Hamilton, 1985; Postgate, 1984c; Sequeira and Tiller, 1988; Von Wolzogen Kuhr and van der Vlught, 1934; Widdel, 1992). Anaerobic corrosion, a process with significant economic impact, has been frequently observed to cause pitting and destruction of pipelines and other iron and steel constructions exposed to sulfate-containing, oxygen-depleted waters. Because of the negative redox potential (Fe^{2+}/Fe, $E_0 = -0.44$ V; even more negative in carbonate-rich or sulfidic medium), iron can liberate H_2 ($2H^+/H_2$, $E_0' = -0.41$ V) in aqueous surroundings (according to $2\ Fe + 2\ H^+ \rightarrow 2\ Fe^{2+} + H_2$) and may in this way indirectly act as an electron donor for sulfate-reducing bacteria that possess hydrogenase (Cord-Ruwisch and Widdel, 1986). However, a direct utilization of electrons (liberated according to $Fe \rightarrow Fe^{2+} + 2\ e^-$) by cells associated with the iron surface and involving redox proteins at the cell surface (outer membrane) has been discussed as another mechanism in anaerobic corrosion (Van Ommen Kloeke et al., 1995; Widdel, 1992). Such a direct withdrawal of electrons may be kinetically more favorable than consumption of the electrochemically formed H_2.

Another inorganic, unique electron donor for dissimilatory sulfate reduction is phosphite

($H_2PO_3^-$), that has been used for the enrichment and isolation of a novel type of sulfate-reducing bacterium (Schink and Friedrich, 2000). The isolate is phylogenetically related to *Desulfobacula* and *Desulfospira*. Phosphite was oxidized to phosphate ($H_2PO_4^-$). The natural role of this capacity is unknown. The occurrence of a "dissimilatory phosphate reduction" in natural habitats as a source of reduced phosphorous compounds is very unlikely, because the redox potentials of the reduction steps of phosphorus (ranging from +V to –III) are extremely low (E_0' lower than –0.48 V; Schink and Friedrich, 2000; Widdel, 1992). Reduction of H+ to H_2 would be easier to achieve (see redox potential above).

Fermentative and Syntrophic Growth in the Absence of Sulfate In the absence of sulfate or other inorganic electron acceptors, several types of sulfate reducers can grow by fermentation of several organic substrates. Some *Desulfovibrio* species (for overview see Widdel, 1988), *Desulfobacterium* species (Brysch et al., 1987) and *Desulfosarcina variabilis* (Widdel, 1980) ferment fumarate and, with the exception of the latter species, malate; the fermentation products are succinate, acetate, CO_2, and sometimes propionate.

Pyruvate is easily fermented by many sulfate-reducing bacteria that can use lactate. Pyruvate fermentation by *Desulfovibrio desulfuricans* produces acetate, CO_2 and H_2 (e.g., Postgate, 1984a; Stams et al., 1985). In *Desulfovibrio sapovorans*, which also ferments pyruvate but does not possess a hydrogenase (Widdel, 1980), lactate, acetate and CO_2 are the expected fermentation products.

Lactate or ethanol plus CO_2 allow fermentative growth of some *Desulfobulbus* strains that form propionate and acetate (Laanbroek et al., 1982; Widdel and Pfennig, 1982). Propionate is formed in *Desulfobulbus* via a randomizing pathway involving a methylmalonyl-CoA:pyruvate transcarboxylase and free succinate as a symmetric molecule (Stams et al., 1984). This pathway is very similar to the one used by Propionibacterium except that the activation of succinate to succinyl-CoA is not directly linked to the formation of propionate from propionyl-CoA. The succinate pathway in the inverse direction also is used for the oxidation of propionate to acetate and CO_2 in the presence of sulfate (see Propionate in this Chapter; Kremer and Hansen, 1988a; Fig. 15).

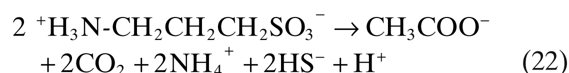
Desulfovibrio desulfuricans can ferment choline to trimethylamine, ethanol, and acetate (e.g., Fiebig and Gottschalk, 1983). *Desulfovibrio fructosovorans* and *Desulfotomaculum nigrificans* fermented fructose in the absence of sulfate (Klemps et al., 1985; Ollivier et al., 1988). The former was shown to form succinate, acetate and ethanol.

Furthermore, a fermentation of cysteine with liberation of sulfide and ammonia has been reported for a sulfate reducer, probably a *Desulfovibrio* strain (Senez and Leroux-Gilleron, 1954b).

Desulfotosporosinus orientis grew slowly by converting formate, methanol, or the methyl groups of 3,4,5-trimethoxybenzoate via a homoacetogenic metabolism to acetate (Klemps et al., 1985). Lactate was fermented by this species to acetate as the only organic product, which is in agreement with the observed de novo acetate formation as it occurs in homoacetogenic bacteria. Also in *Desulfobacterium* species, fermentation of lactate and malate yielded an acetate to substrate ratio that can only be explained by an additional de novo synthesis of acetate from reducing equivalents and CO_2 (Brysch et al, 1987; F. Widdel, unpublished observation).

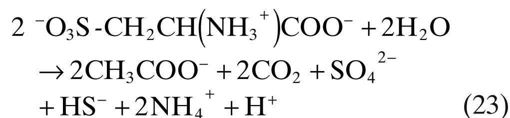
Desulfovibrio carbinolicus and *Desulfovibrio fructosovorans* ferment glycerol to 1,3-propanediol and 3-hydroxypropionate (Nanninga and Gottschal, 1987; Ollivier et al., 1988).

The marine sulfate-reducing bacterium *Desulforhopalus singaporensis* was isolated from an anaerobic enrichment culture with taurine (2-aminoethanesulfonate) as the only source of carbon, energy, and nitrogen (Lie et al., 1999). The degradation of taurine, that includes a reduction of the oxidized sulfur, could be described by the following equation (22):



$$2\ {}^{+}H_3N\text{-}CH_2CH_2CH_2SO_3^{-} \rightarrow CH_3COO^{-} + 2CO_2 + 2NH_4^{+} + 2HS^{-} + H^{+} \quad (22)$$

Another sulfonate that was reported to be fermented by a sulfate reducer is cysteate (Laue et al., 1997a). The fermentation of cysteate by *Desulfovibrio* strain GRZCYSA could be approximated by the following equation (23):



$$2\ {}^{-}O_3S\text{-}CH_2CH(NH_3^{+})COO^{-} + 2H_2O \rightarrow 2CH_3COO^{-} + 2CO_2 + SO_4^{2-} + HS^{-} + 2NH_4^{+} + H^{+} \quad (23)$$

Desulfovibrio species may grow with ethanol or lactate in the absence of sulfate if co-cultured with H_2-scavenging methanogenic bacteria (Bryant et al., 1977). In these syntrophic associations, the sulfate reducers serve as syntrophic, H_2-producing acetogenic bacteria. Without a H_2-scavenging partner in the absence of sulfate,

Desulfovibrio forms H_2-partial pressures of up to 1.5 kPa, without growth (Pankhania et al., 1988). Hydrogen formation in *Desulfovibrio* from lactate in the absence of sulfate was inhibited by protonophores and inhibitors of proton-translocating ATPase, whereas H_2 formation from pyruvate was not inhibited under such conditions (Pankhania et al., 1988). This observation indicated that the reducing equivalents from lactate dehydrogenation were converted to H_2 in an energy-driven process, as also suggested by the concerning redox couples (pyruvate/lactate, $E_0' = -0.190$ V; 2 H^+/H_2, $E_0' = -0.414$ V). This process may be a reversed electron transport driven by the proton gradient, as in substrate oxidation of other syntrophic bacteria (Schink, 1997). The assumption of a chemiosmotically driven dehydrogenation of lactate is further supported by the fact that lactate dehydrogenase is associated with the cytoplasmic membrane (see section on lactate). The energy for lactate dehydrogenation in *Desulfovibrio* is presumably derived from the subsequent exergonic conversion of pyruvate via acetyl-CoA (Acetyl-CoA + CO_2/pyruvate, $E_0' = -0.5$ V) and acetyl phosphate to free acetate; the latter step allows substrate-level phosphorylation and generation of a proton gradient through ATP hydrolysis at the ATPase.

In a coculture with a methanogenic bacterium, a *Desulfovibrio* species converted choline to trimethylamine, acetate, and H_2; the latter was used by the methanogenic partner (Fiebig and Gottschalk, 1983).

Desulfonema limicola, *Desulfosarcina variabilis*, and species of the genera *Desulfobulbus*, *Desulfobacterium*, and *Desulfotomaculum* did not grow in cocultures with methanogens in sulfate-free medium on lactate, ethanol, fatty acids or benzoate, even though the tested sulfate reducers possessed hydrogenase (C. Schneider and F. Widdel, unpublished observation). Apparently, there is no special mechanism in these sulfate reducers for the transfer of reducing equivalents to the redox-level of H_2, as it probably occurs in *Desulfovibrio* (Pankhania et al., 1988).

However, further sulfate-reducing bacteria that grow syntrophically with H_2 scavengers were detected during investigations on methanogenesis from propionate. The propionate-utilizing, syntrophic partners, that were named as Syntrophobacter species, turned out to be sulfate-reducing bacteria and members of the δ-subclass (Dörner, 1992; Harmsen et al., 1993; Wallrabenstein et al., 1995; for review see Schink, 1997). Growth with propionate and sulfate was extremely slow. If simultaneously an H_2-scavenging *Desulfovibrio* strain was present in sulfate-containing medium, the propionate-oxidizing strains grew syntrophically by interspecies H_2 transfer rather than by utilizing sulfate themselves. Apparently, the pathway of sulfate reduction is poorly developed in the propionate oxidizers.

Carbon Assimilation

Heterotrophic Growth The organic compounds utilized as electron acceptors by sulfate-reducing bacteria serve simultaneously as carbon sources for cell synthesis. Carbon dioxide is an important additional carbon source for various carboxylation reactions during biosynthesis. With several H_2-utilizing species, the capacity for autotrophic growth with CO_2 as the only carbon source was demonstrated (see next section). Hydrogen-utilizing sulfate-reducing bacteria of the genus *Desulfovibrio*, which are complete oxidizers, require acetate in addition to CO_2 for cell synthesis (Mechalas and Rittenberg, 1960; Postgate, 1960; Sorokin, 1966a; Sorokin, 1966b; Sorokin, 1966c; Badziong et al., 1979; Brandis and Thauer, 1981; Brysch et al., 1987). Also species of the genera *Desulfobulbus* and *Thermodesulfobacterium*, and *Desulfomicrobium norvegicum* (formerly *Desulfovibrio* desulfuricans strain Norway 4) required acetate as organic carbon source (Brysch et al., 1987; F. Widdel, unpublished observation). The observation that approximately one third of cell carbon is derived from CO_2 and two thirds derived from acetate (or molar CO_2 : acetate = 1 : 1; Sorokin, 1966a; Sorokin, 1966b; Sorokin, 1966c) is explained by the pyruvate synthase reaction. Pyruvate synthase or pyruvate:ferredoxin oxidoreductase (PFOR), that carboxylates acetyl CoA reductively (acetyl-CoA + CO_2 + $2e^-$ + $2H^+ \rightarrow$ 2 pyruvate + CoA) is a central metabolic enzyme (Badziong et al., 1979; Brandis-Heep et al., 1983; Schauder et al., 1987). The biosynthetic reaction is always required if the carbon source is acetate or a substrate that yields exclusively acetyl-CoA, e.g., ethanol or C-even fatty acids (or CO_2 in autotrophs; see below). Hence, sulfate-reducing bacteria growing on ethanol or C-even fatty acids without the capacity for complete oxidation are expected to strictly require external CO_2 for growth. It is unknown whether sulfate-reducing bacteria employ the same PFOR for acetyl-CoA assimilation and for pyruvate oxidation, e.g., during growth on lactate, or whether there are specifically regulated isoenzymes.

Several further assimilatory enzymes have been studied in *Desulfobacter* species that employ a citric acid cycle for acetyl-CoA oxidation (Brandis-Heep et al., 1983; Schauder et al., 1987). In addition to pyruvate synthase, anaplerotic reactions include acetate activation via acetyl-CoA synthetase (acetate + ATP $\rightarrow$ acetyl-

CoA + PP_i; in addition to succinyl-CoA: acetate transferase), phosphoenolpyruvate (PEP) synthetase (pyruvate + ATP → PEP + AMP + P_i), and PEP carboxylase (PEP + HCO_3^- → oxaloacetate + P_i) to compensate for the withdrawal of α-ketoacids for biosynthesis. Phosphoenolpyruvate is also expected to serve for synthesis of triose and higher sugar phosphates. In incompletely oxidizing sulfate-reducing bacteria, similar reactions may provide PEP and oxaloacetate; further biosynthetic precursors can then be synthesized via sequences of an incomplete citric acid cycle. A citrate synthase with (R)-specificity has been studied in incompletely oxidizing *Desulfovibrio* species (Gottschalk, 1968).

Autotrophic Growth When sulfate-reducing bacteria were shown to use H_2 as an inorganic electron donor, also the possibility that cell synthesis might occur autotrophically from CO_2 became of interest (Stephenson and Strickland, 1931). Carbon autotrophy was reported for sulfate-reducing enrichment cultures (Wight and Starkey, 1945) and *Desulfovibrio* strains (Butlin and Adams, 1947; Sisler and ZoBell, 1951). Later however, growth experiments and labeling studies with *Desulfovibrio* species revealed repeatedly that these sulfate reducers were lithoheterotrophs that required acetate in addition to CO_2 for cell synthesis (Mechalas and Rittenberg, 1960; Postgate, 1960; Sorokin, 1966a; Sorokin, 1966b; Sorokin, 1966c; Badziong et al., 1979; Brandis and Thauer, 1981; Brysch et al., 1987). However, several newly isolated, completely oxidizing sulfate-reducing bacteria grew with H_2 plus CO_2 (or formate) in the absence of other carbon compounds (Widdel, 1980; Widdel and Pfennig, 1981; Pfennig et al., 1981c). Labeling studies with formate-utilizing *Desulfoarculus* (formerly *Desulfovibrio*) *barsii* (Jansen et al., 1984; 1985) and H_2-utilizing *Desulfobacterium* species, *Desulfobacter hydrogenophilus*, *Desulfosarcina variabilis*, *Desulfonema limicola* and *Desulfotosporosinus orientis* (Brysch et al., 1987) clearly demonstrated the capacity for autotrophic growth. Several autotrophic strains excreted traces of acetate if incubated with H_2 plus CO_2 (or formate), with limiting sulfate concentrations. Enrichment cultures with H_2 plus CO_2 in sulfate-containing media were shown to yield mixed cultures of non-autotrophic *Desulfovibrio* species and autotrophic homoacetogenic bacteria, the latter providing acetate to the former (Brysch et al., 1987). Such mixed cultures grew faster than truly autotrophic sulfate-reducing bacteria; hence direct enrichment of the latter (autotrophic bacteria) from natural samples under autotrophic conditions is unlikely.

With the exception of *Desulfotosporosinus orientis*, the facultative lithoautotrophic sulfate reducers are complete oxidizers (Brysch et al., 1987). Indeed, the mechanisms of CO_2 fixation were found to be reverse reactions from the pathways which during organotrophic growth serve for acetyl-CoA oxidation. Whereas *Desulfobacter hydrogenophilus* assimilated CO_2 via a reductive citric acid cycle (Schauder et al., 1987), *Desulfobacterium autotrophicum* used the inverse C_1-pathway or Wood pathway (Schauder et al., 1989), viz. a sequence of reactions observed in homoacetogenic bacteria. The former has to reactivate acetate liberated in the succinyl-CoA:acetate CoA-transferase reaction. Formed acetyl-CoA from both pathways is then converted to pyruvate (see preceding section). Lithoautotrophically and organotrophically grown cells of *D. autotrophicum* exhibited different patterns of CO dehydrogenase aggregates during gel electrophoresis (Schauder et al., 1989). Obviously, the reductive and oxidative pathway, respectively, employed somewhat different enzymes. This indicates that formation of enzymes for the reductive and the oxidative pathways is regulated depending on whether H_2 or organic electron donors are present. *Desulfotosporosinus orientis* can grow autotrophically but cannot oxidize organic substrates completely to CO_2 (Klemps et al., 1985). The CO-dehydrogenase activity (R. Klemps and F. Widdel, unpublished observation) and a weak capacity for homoacetogenic growth (Klemps et al., 1985) suggests that this sulfate reducer also uses the C_1-pathway for CO_2 fixation. It is not understood why the assimilatory pathway in this species cannot be reversed for acetyl-CoA oxidation. Another incomplete oxidizer, *Desulfomicrobium apsheronum* also has been reported to grow autotrophically (Rozanova et al., 1988a).

Assimilation of Nitrogen Compounds Ammonium represents the most readily used nitrogen source for sulfate-reducing bacteria and for other bacteria. Ammonium ions are common in anoxic habitats as a result of biomass degradation. In cultivation media for sulfate-reducing bacteria, ammonium salts are usually included. In sulfate reducers that can use nitrate as electron acceptor, its dissimilatory reduction to ammonium provides simultaneously a nitrogen source.

Diazotrophic growth has been demonstrated in species of the genera *Desulfovibrio* (Riederer-Henderson and Wilson, 1970; Lespinat et al., 1987; Postgate and Kent, 1985; Moura et al., 1987), *Desulfobacter* (Widdel, 1987), *Desulfobulbus* (Bomar M. and F. Widdel, unpublished

observation) and *Desulfotomaculum* (Postgate, 1970). The DNA carrying *nifH*/*nifD* hybridized with DNA from 13 diazotrophic strains of *Desulfovibrio* belonging to 5 different species; from *D. gigas*, the *nifH* gene coding for the Fe protein of the nitrogenase system was sequenced (Postgate et al., 1988; Kent et al., 1989).

SULFATE-REDUCING ARCHAEA *Archaeoglobus fulgidus* was isolated from a submarine hydrothermal area and was identified as the first representative of the archaeal domain of life that could conserve energy via dissimilatory sulfate reduction (Stetter et al., 1987; Stetter, 1988; Zellner et al., 1989b). Two other *Archaeoglobus* species, *A. profundus* (Burggraf et al., 1990) and *A. lithotrophicus* (Stetter et al., 1993), are further archaeal sulfate reducers. A fourth *Archaeoglobus* species, *A. veneficus*, uses sulfite but not sulfate as electron acceptor (Huber et al., 1997). *Archaeoglobus* species typically grow optimally at temperatures above 80°C and require at least 10 g NaCl/liter for growth (Stetter, 1992). Phylogenetic analyses revealed that the genus Archaeglobus represents a lineage within the Euryarchaeota (Woese et al., 1991) with particular relationships to methanogenic archaea; Archaeglobus is unrelated to the sulfur-metabolizing and fermentative extreme thermophiles of the Crenarchaeota. An overview of physiological properties of sulfate-reducing *Archaeoglobus* species is given in Table 7. Another member of this lineage is the hyperthermophilic archaeum Ferroglobus placidus, which can use thiosulfate as electron acceptor for the oxidation of H_2 (Hafenbradl et al., 1996).

Reduction of Sulfate to Sulfide Transport of sulfate has not been studied so far in *Archaeoglobus*. The general pathway of sulfate reduction to sulfide in *Archaeoglobus* is analogous to the one established for sulfate-reducing bacteria (Dahl and Trüper, 1999b). The presence of the enzymatic activities essential for dissimilatory reduction of sulfate (ATP sulfurylase, APS reductase and sulfite reductase) were demonstrated in *A. fulgidus* (Speich and Trüper, 1988; Dahl et al., 1994). In Table 3, the sulfite-reductase from *A. fulgidus* is compares the sulfite-reductase from other prokaryotes mentioned.

Activation of Sulfate Prior to reduction, sulfate is activated in an ATP-dependent reaction to APS, a reaction catalyzed by ATP sulfurylase. The dissimilatory ATP sulfurylase was purified from *A. fulgidus* and found to have a molecular weight of about 150 kDa (Dahl et al., 1988;

Table 7. Physiological properties of sulfate-reducing *Archaeoglobus* species.[a]

Species	Temp. Opt. [°C]	Organic substrates utilized with SO_4^{2-} and/or $S_2O_3^{2-}$: Formate	Acetate	Lactate	Pyruvate	Others	H_2 utilization: Lithoautotrophic with SO_4^{2-}	Lithoautotrophic with $S_2O_3^{2-}$	Lithoheterotrophic (+acetate) with SO_4^{2-}
A fulgidus strain VC-16[b]	83	+	nr	+	nr	Formamide, glucose, starch, peptone, methanol, ethanol	−	+	nr
A fulgidus strain Z[b]	75–80	+	−	+	+	2,3-Butandiol, fumarate	−	+	nr
A fulgidus strain 7342[b]	76	−	−	+	+	Valerate	−	−	+
A profundus strain AV18[b]	82	nr	+[c]	+[c]	+[c]		−	−	+ (obligate lithoheterotrophic)
A lithotrophicus	80	nr	nr	nr	nr		+	nr	nr

Symbols: +, utilized; −, not utilized; nr, not reduced.

[a]Species of the genus *Archaeglobus* are the only sulfate-reducing Archaea known so far. *A veneficus* strain SNP6 does not reduce sulfate, even though this species is capable of sulfite and thiosulfate reduction (Huber et al., 1997).

[b]Data obtained from: *A fulgidus* strain VC-16 (Stetter, 1988), *A fulgidus* strain Z (Zellner et al., 1989b), *A fulgidus* strain 7342 (Beeder et al., 1994), *A profundus* strain AV18 (Burggraf et al., 1990), *A lithotrophicus* (Stetter et al., 1993).

[c]Utilization strictly dependent on the presence of H_2. It is presently unknown whether these compounds are co-metabolically utilized as electron donors, or only as carbon sources.

1990). The coding gene for sulfate adenylyltransferase (*sat*) was cloned and found to exhibit homology with the coding genes of homo-oligomeric ATP sulfurylases from various bacteria and eukaryotes. The *sat* gene was cloned and overexpressed in *E. coli* and the recombinant protein was purified. It was found to be a homodimer. Activity testing proved that the recombinant protein could indeed form ATP from APS and PP_i (Sperling et al., 1998; Sperling et al., 1999).

Reduction of APS The enzyme APS reductase catalyzes the two-electron reduction of APS to sulfite and AMP. The enzyme was purified from *A. fulgidus* and characterized. An apparent molecular mass of 160 kDa was determined and the protein was found to contain one FAD and [FeS] clusters (Speich and Trüper, 1988; Dahl et al., 1994). Spectroscopic studies of the purified enzyme demonstrated that the enzyme contained two distinct [4Fe-4S] clusters which showed similarity to the ones identified in the APS reductase from *Desulfovibrio gigas* (Lampreia et al., 1991). Analysis of the purified APS reductase on SDS-PAGE revealed two bands corresponding to molecular masses of 80 kDa and 18.5 kDa. Taking the apparent molecular mass of the holoenzyme into account, this finding suggested a $\alpha_2\beta$ structure for the enzyme. The presence of two different subunits was confirmed by the analysis of the genes coding for the α- and β-subunit, *aprA* and *aprB*, respectively. The *aprA* and *aprB* genes encoded a 73.3 kDa and a 17.1 kDa polypeptide, respectively. The *aprA* gene product showed homologies to flavoproteins from *Escherichia coli* and *Bacillus subtilis*, whereas the *aprB* gene contained sequences for cysteine clusters that could ligate the [FeS] centers identified by the spectroscopic analyses (Speich et al., 1994).

Reduction of Sulfite The six-electron reduction of sulfite to sulfide is catalyzed by the sulfite reductase. This enzyme was purified from *A. fulgidus* and exhibited characteristics similar to those of dissimilatory sulfite reductases from other bacteria. The native enzyme had an apparent molecular mass of 218 kDa and consisted of two subunits with molecular masses of 40 and 50 kDa, suggesting a $\alpha_2\beta_2$ structure. Furthermore, the holoenzyme contained two sirohemes and six [4Fe-4S] clusters. The genes encoding the α- and β-subunit, *dsrA* and *dsrB*, were cloned, and found to be arranged in an operon structure. The deduced DsrA peptide contains the cysteine residues required for the coordination of siroheme-[4Fe-4S] complexes. Furthermore, both deduced peptides, DsrA and DsrB, contain additional cysteine residues which are characteristic of binding motifs for ferredoxin-like [4Fe-4S]-clusters. Thus the findings of the sequence analyses corroborated the biochemical data directly obtained from the purified protein. The *dsrA* and *dsrB* genes showed a high degree of similarity suggesting that these genes arose by duplication from an ancestral gene. Comparative sequence analyses of sulfite reductases from various microorganisms revealed that only sulfite reductases from *A. fulgidus* and *Salmonella typhimurium* contained a ferredoxin-like domain in the proximity of the conserved putative siroheme-[4Fe-4S]-binding cysteine residues (Dahl et al., 1993; 1994). The *dsrAB* genes of *A. fulgidus* were also highly homologous to the dsvAB genes that code for desulfoviridin of *Desulfovibrio vulgaris* (Karkhoff-Schweizer et al., 1995).

A dissimilatory sulfite reductase was also isolated from the hyperthermophilic archaeon *Pyrobaculum islandicum*. This archaeon cannot reduce sulfate; however, it is capable of organotrophic growth with sulfite as electron acceptor (Huber et al., 1987). The purified sulfite reductase was shown to have a $\alpha_2\beta_2$ structure and to contain siroheme and [FeS] clusters. Two coding genes (*dsrA* and *dsrB*) could be cloned and found to be organized in an operon. Downstream of the *dsrB* gene, a third gene, *dsrC*, was identified which was homologous to the proposed γ-subunit of the sulfite reductase from *Desulfovibrio vulgaris* (Molitor et al., 1998; Dahl et al., 1999a).

Electron Acceptors Other Than Sulfate In addition to sulfate, *A. fulgidus* can utilize thiosulfate and sulfite as electron acceptor. The utilization of sulfite is understandable because it is an intermediate during sulfate reduction. The reduction of thiosulfate in *A. fulgidus* has not been studied in more detail.

Electron Carriers

Ferredoxin Ferredoxin is an electron carrier which has been frequently encountered in sulfate-reducing bacteria. It has also been identified in *A. fulgidus*. Ferredoxin is involved in catabolic reactions in *A. fulgidus*, such as pyruvate:ferredoxin oxidoreductase (Kunow et al., 1995) and the acetyl-CoA decarbonylase/synthase (CO-dehydrogenase-containing) complex (Dai et al., 1998), and possibly also in pyruvate synthesis from acetyl-CoA in lithoheterotrophic species that use acetate as organic carbon sources.

Menaquinone Tindall et al. (1989) discovered a novel menaquinone in *A. fulgidus*. This menaquinone possesses a fully saturated hepta-

prenyl side chain ($MK\text{-}7H_{14}$) and is the major lipoquinone in *A. fulgidus*.

Metabolism of Electron Donors *Archaeoglobus* species may grow chemolithoautotrophically with H_2 and CO_2, chemoorganotrophically on formamide, lactate, pyruvate, glucose and complex organic substrates (starch, peptone), or lithoheterotrophically on H_2 and acetate, lactate, pyruvate or other organic compounds (Stetter, 1992). An overview of the metabolism of electron donors by *Archaeoglobus* species is given in Table 7. The occurrence of *Archaeoglobus* species in marine and terrestrial oil-field waters has been reported several times (Stetter et al., 1993; Beeder et al., 1994; L'Haridon et al., 1995) and has suggested that *Archaeoglobus* species may utilize constituents of crude oil. However a utilization of hydrocarbons, the main constituents of crude oil, could not be demonstrated.

Lactate, Pyruvate, and Acetate *A. fulgidus* completely oxidizes lactate to CO_2 with sulfate as electron acceptor (Möller-Zinkhan et al., 1989; Zellner et al., 1989b). Lactate is oxidized to acetyl-CoA via lactate-dehydrogenase and pyruvate:ferredoxin oxidoreductase (PFOR; Möller-Zinkhan et al., 1989). Based on its predicted function as lactate dehydrogenase, a gene (*dld*) was cloned from the completely sequenced genome of *A. fulgidus* (Klenk et al., 1997) and heterologously overexpressed in *Escherichia coli*. The purified recombinant protein possessed D-lactate dehydrogenase activity, contained Zn^{2+} and the flavin cofactor FAD (Reed and Hartzell, 1999). The PFOR has been purified from *A. fulgidus* and found to have an apparent molecular mass of 120 kDa, a heterotetrameric ($\alpha\beta\gamma\delta$) structure and to contain thiamine pyrophosphate and iron-sulfur clusters (Kunow et al., 1995). Further oxidation of acetyl-CoA to CO_2 proceeds via a C_1/CO-dehydrogenase pathway that may be regarded as an archaeal analogue of the pathway in sulfate-reducing bacteria (Fig. 11B). A unique characteristic of the archaeal pathway is the involvement of the cofactors F_{420}, tetrahydromethanopterin and methanofuran that had been detected before in methanogenic archaea (Stetter et al., 1987; Möller-Zinkhan et al., 1989; Möller-Zinkhan and Thauer, 1990). The CO dehydrogenase is part of a multienzyme complex termed acetyl-CoA decarbonylase synthase (ACDS) that was isolated and characterized (Dai et al., 1998). This multienzyme complex consists of five different subunits ranging from 18.5 to 89 kDa in molecular mass and catalyzes the cleavage of acetyl-CoA into a bound methyl-group and bound CO, or the reverse reaction. The methyl carrier is tetrahydromethanopterin (H_4MPT); also, tetrahydrosarcinopterin reacts as methyl carrier with the complex. Ferredoxin is employed as electron carrier by this multienzyme complex. Prior to the study presented by Dai et al. (1998), ACDS complexes had been detected only in methanogens. Structural and functional properties of the ACDS complex from *A. fulgidus* are similar to those of the complex from methanogens. Therefore much insight into the function of the ACDS complex in *A. fulgidus* is based on the studies of this complex in the methanogens. The complex from *Methanosarcina barkeri*, which has been studied best, also consists of five subunits and has a $(\alpha\beta\gamma\delta)_6$ structure, giving rise to the remarkable total molecular mass of ca. 2.0 MDa for the entire complex (Grahame, 1991). Carbon monoxide and CO_2 can be used for carbonylation of methylated tetrahydrosarcinopterin. A hydrogenase that was resolved from the multienzyme complex was capable of reconstituting the acetyl-CoA synthesis of the complex (Grahame and DeMoll, 1995). Separation of the ACDS complex from *Methanosarcina* by limited proteolytic digestion allowed specific catalytic functions to individual subunits: the CO-dehydrogenase reaction is performed by the α component; the methyltransferase is located on the γ-subunit and parts of the δ-subunit; and the binding of CoA or acetyl-CoA occurs on the β-subunit (Grahame and DeMoll, 1996). The CH_3-group from acetyl-CoA cleavage in *Archaeoglobus fulgidus* is further oxidized to CO_2 via N^5,N^{10}-methylene-H_4MPT reductase, N^5,N^{10}-methylene-H_4MPT dehydrogenase, N^5,N^{10}-methenyl-H_4MPT cyclohydrolase, formylmethanofuran:H_4MPT formyltransferase and formylmethanofuran dehydrogenase (Möller-Zinkhan et al., 1989). Purification of the corresponding enzymes from *A. fulgidus* allowed the C_1-pathway of methyl oxidation to be unequivocally established and demonstrated that the enzymes from *A. fulgidus* had very similar molecular and catalytic properties as those of the acetate-degrading methanogens (Schmitz et al., 1991; Klein et al., 1993; Schwörer et al., 1993). Factor F_{420} serves as H_2 acceptor for N^5,N^{10}-methylene-H_4MPT reductase and N^5,N^{10}-methylene-H_4MPT dehydrogenase. The natural electron acceptor for formylmethanofuran dehydrogenase is unknown. A membrane-bound $F_{420}H_2$:quinone oxidoreductase complex was purified from *A. fulgidus*. This enzyme complex is presumed to be involved in the chemiosmotic conservation (Kunow et al., 1994).

Similarities in the enzymes and cofactors of the C_1-pathway in *Archaeoglobus* and methanogens suggest a metabolic relationship. Indeed, *Archaeoglobus* was suggested to represent a link between hyperthermophilic sulfur-reducing (nonsulfate-reducing) and methanogenic

archaea. However, *Archaeoglobus* does not possess the cofactors (mercaptoethanesulfonate, mercaptoheptanoyl threonine phosphate) and enzymes (methyltransferase, methyl-CoM reductase, heterodisulfide reductase) that are involved in the terminal step of CH_4 formation from the H_4MPT-bound methyl group. The formation of low amounts of CH_4 observed in *Archaeoglobus* (Stetter et al., 1987) (and in sulfate-reducing bacteria; Schauder et al., 1986) is a by-reaction of the methyl group transferred by CO dehydrogenase.

Malate, Isocitrate and Glutamate Even though *Archaeoglobus* performs oxidation of acetate via the C_1-pathway and not via the TCA cycle, activities of malate dehydrogenase and isocitrate dehydrogenase were measured in cell extracts of (Möller-Zinkhan et al., 1989). These enzymes presumably function in biosynthesis (Langelandsvik et al., 1997; Steen et al., 1997). Both enzymes were purified and found to possess pronounced thermostability. Malate-dehydrogenase was specific for NAD^+, whereas isocitrate dehydrogenase has a high preference for $NADP^+$. Also a thermostable $NADP^+$-specific glutamate dehydrogenase was purified from this archaeon. This enzyme accounts for 0.8% of the total cell extract protein, which is relatively large in view of the assumed function in the assimilation of ammonia (Aalén et al., 1997).

Autotrophic Growth Autotrophic growth on H_2 and sulfate as energy source and CO_2 as carbon source was studied in *Archaeoglobus lithotrophicus*. All enzymatic activities and coenzymes required for the fixation of CO_2 via the reductive CO dehydrogenase pathway were demonstrated in cell extracts of *A. lithotrophicus* (Vorholt et al., 1995). This reductive CO dehydrogenase pathway is, in principle, the reverse of the oxidative C_1/CO-dehydrogenase pathway employed by *A. fulgidus* for the oxidation of acetyl-CoA. The same study by Vorholt et al. (1995) showed that CO dehydrogenase was lacking in *A. profundus*, which explained why this archaeon requires acetate for biosynthesis during growth on H_2.

Genome *A. fulgidus* strain VC-16 is the first sulfate- and sulfur-reducing microorganism and the second archaeon after *Methanococcus jannaschii* (Bult et al., 1996) the complete genomic sequence of which has been determined (Klenk et al., 1997).

The genome consists of a single chromosome of about 2.2 Mb and has an average G+C content of 48.5 mol%. A total of 2,436 ORFs were identified with an average size of 822 bp. Putative functions could be assigned to 1,797 ORFs, whereas the remaining 639 ORFs had no database matches. Two thirds of these unidentified ORFs are shared with *M. jannaschii*. Of the ORFs with assigned function, 719 genes can be classified into 242 families. The largest of these families is the superfamily of ATP-binding subunits of ABC transporters, which comprises 40 members in *A. fulgidus*. The genome of *A. fulgidus* contains three regions of short repeats (>40 bp), which are similar to those found in *M. jannaschii*, and nine classes of long repeated sequences (<500 bp).

Synthesis of Basic Macromolecules (Examples), and Chemotaxis Putative components of the replicatory, DNA-repair and cell division machinery were identified that showed sequence homology to those known from either *M. jannaschii*, bacteria or eukaryotes. For example, the B-type DNA polymerase of *A. fulgidus* is related to the δ polymerase from eukaryotes. The genes for gyrases, topoisomerases and a type I restriction-modification system were identified in *A. fulgidus*.

Genes for 46 tRNAs were identified, however no gene with homology to the gene *selC* was detected that codes for selenocysteine-inserting tRNASec in *E. coli*. The presence of complex sensory and regulatory networks in *A. fulgidus* is suggested by presence of genes resembling those of the bacterial chemotaxis system (Che); furthermore these chemotaxis-related genes are located adjacent to an operon that was assigned to the flagellar biosynthesis.

Transporters Around 120 ORFs were identified that may code for proteins functioning in the transport of amino acids, peptides, amines, carbohydrates, alcohols and acids. The presence of transporters for various organic compounds is in agreement with the observation that *A. fulgidus* grows optimally in media with complex organic nutrients such as yeast extract. Transport of inorganic cations and anions is supposed to be mediated by 10 distinct types of transporters, among them also members of the large superfamily of ABC transporters. Genes belonging tentatively to the latter show homologies to the *cysA* and *cysT* genes, coding for the ATP-binding protein and permease, respectively, of the sulfate transporter in bacteria. However, it is unknown whether *A. fulgidus* indeed transports sulfate via an ATP-driven transporter. This would result in the consumption of as much as three molecules of ATP for the formation of one molecule of APS (assuming requirement of two ATP for activation). Subsequent APS reduction to sulfide with

a suitable electron donor would have to yield more than three ATP.

Catabolic and Biosynthetic Metabolism Several genes coding for acetyl-CoA synthetase, which converts acetate and ATP to acetyl-CoA, AMP and PP_i, were identified. However, growth with acetate as an externally added electron donor and carbon source has not been demonstrated. Many genes were recognized that were similar to those coding for β-oxidation enzymes in bacteria but have not been described in archaea. Many of the genes encoding β-oxidation enzymes in *A. fulgidus* are present in multiple copies, suggesting a considerable metabolic differentiation. For instance, there are 10 copies of 3-hydroxyacyl-CoA dehydrogenase encoded. Again, growth with fatty acids as electron donors and carbon sources, which would require the pathway of β-oxidation, has not been reported for *A. fulgidus*. Genes coding for enzymes of central pathways of the intermediary sugar metabolism as known from bacteria were also identified in *A. fulgidus*. According to such genes, glycolysis, the pentose-phosphate pathway, the Entner-Doudoroff pathway and reactions for gluconeogenesis are expected to be either completely or partially present. Interestingly, no gene coding for a glutamate dehydrogenase was identified, even though such an enzyme has been purified from a different strain (strain 7324) of *A. fulgidus* (Aálen et al., 1997).

Biosynthetic pathways for amino acids, cofactors, carriers, purines and pyrimidines were also identified on the gene level. Many of the recognized biosynthetic pathways show a high degree of similarity with those identified in *M. jannaschii*.

Energy Conservation Apart from the F_{420}: quinone oxidoreductase complex, no electron transport components involved in chemiosmotic energy conservation have been identified on the protein level in *Archaeoglobus*. However, the genomic sequence revealed genes tentatively coding for heterodisulfide reductase, and for several molybdopterin-containing oxidoreductases that react with polysulfide, NO_3^-, DMSO and $S_2O_3^{2-}$ as potential electron acceptors. This finding indicates that *A. fulgidus* may have more electron transport systems than known from physiological studies.

Comparison to the Genome of *M. jannaschii* A comparison of the genomes from *A. fulgidus* and *M. jannaschii* revealed that various degrees of conservation exist in different categories of genes. Among the genes of *A. fulgidus* that are related to either translation, replication or biosynthetic pathways, 80% are homologous to genes of the same categories in *M. jannaschii*. The conservation of genes related in the central metabolism of low molecular mass intermediates (essentially catabolism and energy metabolism) is far lower. Only 35% of those genes from *A. fulgidus* have homologues in *M. jannaschii*, which is in agreement with the distinct types of energy metabolism in these archaea. The methanogen *M. jannaschii* utilizes H_2 and CO_2 as substrates, but cannot degrade acetate. However, because it is an autotroph, *M. jannaschii* is expected to possess the enzymes for the reductive C_1/CO-dehydrogenase pathway for acetyl-CoA synthesis.

Sulfur-Reducing Bacteria In research of the biochemistry of sulfur-reducing bacteria, the reduction of the electron acceptor and the associated process of electron transport and energy conservation has been a main topic. This has been mainly studied in *Wolinella succinogenes*. In addition, oxidation pathways of acetate, viz. the capacity for terminal oxidation of organic substrates, have been investigated in *Desulfuromonas* and *Desulfurella*. The metabolism of other organic substrates in sulfur-reducing bacteria, in contrast to that in sulfate-reducing bacteria, has been of marginal research interest.

Sulfur reduction not coupled to a respiratory mechanism (for example, the incidental reduction found in various organisms) may result from its reaction with sulfhydryl groups of proteins or glutathione that are oxidized to disulfides as shown below (Roy and Trudinger, 1970; Starkey, 1937).

$$2RSH + S \longleftrightarrow RSSR + H_2S \qquad (24)$$

Because research of the biochemistry of sulfur reducers has focused on fewer organisms and fewer substrates, organization of the following section is somewhat different from those treating the sulfate-reducing bacteria.

Bioavailability of Elemental Sulfur In contrast to sulfate, elemental sulfur is chemically relatively reactive and requires no energy-dependent activation before a reduction can take place. However, a problem in the utilization of elemental sulfur is usually seen in its low solubility in water (5 µg or 0.16 µmol per liter at 25°C; Boulégue, 1978). It has therefore been questioned whether pure elemental sulfur (e.g., rhombic sulfur) can directly serve as the substrate for sulfur reductase. A form that is more

likely to be available in aqueous medium is the so-called "hydrophilic sulfur", which is elemental sulfur associated with small portions of oxocompounds such as polythionates ($^{-}O_3S\text{-}S_n\text{-}SO_3^{-}$) that may allow some pseudosolubilization. Aqueous suspensions of sulfur, especially chemically precipitated colloidal ones, and sulfur formed by sulfide-oxidizing microorganisms, contain varying portions of such hydrophilic sulfur (Steudel et al., 1988; Steudel, 1989a; Steudel et al., 1989b). Another possibility for solubilization of sulfur exists, if sulfide is present, which is usually the case in the environment of sulfur reducers. In aqueous solutions of sulfide (H_2S/HS^-, pK_{a1} = 7.02), the S_8-ring of elemental sulfur is cleaved by a nucleophilic attack of the HS^- anion which results in the formation of polysulfide (Steudel et al., 1986) according to equation (25).

$$\frac{n}{8} S_8 + HS^- \leftarrow\rightarrow S_{n+1}^{2-} + H^+ \qquad (25)$$

In media around a pH of 7, the predominant species of polysulfide are tetrasulfide (S_4^{2-}) and pentasulfide (S_5^{2-}). These two polysulfides interconvert rapidly, as shown in equation 25, and are also in equilibrium with lower concentrations of other polysulfides. Therefore it is unknown which of the two polysulfides is the preferred substrate for polysulfide reductase.

PP_i formed from sulfide and tetrathionate was shown to be reduced by formate-utilizing cells of *W. succinogenes* (Klimmek et al., 1991). The concentration of polysulfide in medium containing 1 mM sulfide (HS^- + H_2S) at pH > 6 was shown to exceed 10 µM (Schauder and Müller, 1993), which is close to the apparent K_M (about 20 µM) determined for polysulfide respiration in *W. succinogenes* (Klimmek et al., 1998). Thus there is evidence for the use of polysulfide as the actual electron acceptor in sulfur respiration.

In the study of sulfur reduction, it must not be forgotten that other bacteria grow with elemental sulfur without the possibility of solubilization in the form of polysulfide. These are anaerobes that disproportionate elemental sulfur in the presence of sulfide-scavenging ferric minerals (Thamdrup et al., 1993) or aerobic bacteria that oxidize extracellular sulfur. It is unknown how these bacteria cope with the low solubility of sulfur in water. In photoautotrophic purple bacteria and possibly in aerobic sulfide oxidizers forming intracellular sulfur globules as intermediates, the sulfur is topologically periplasmatic ("extracytoplasmatic") and associated with proteins; these complexes are assumed to control formation or further oxidation of the sulfur (Dahl, 1999b). Examples of other microorganisms growing with insoluble substrates are bacteria reducing ferric minerals, or bacteria or yeasts oxidizing long-chain alkanes. Ferric minerals are probably reduced in direct contact with the cells (Lovley, 1995a), or by an extracellular cytochrome (Seeliger et al., 1998). Long-chain alkanes are also utilized in direct contact with the cells, or via pseudosolubilization with biotensides (Bühler and Schindler, 1984).

Research on Wolinella succinogenes *Wolinella* was originally isolated as a fumarate-reducing bacterium utilizing H_2 or formate as electron acceptor. The capacity for microaerobic growth has been formerly mentioned but not the subject of more recent studies. *Wolinella* was then shown to reduce sulfur (Macy et al., 1986), like *Sulfurospirillum deleyanium*, the former *spirillum* 5175 (Wolfe and Pfennig, 1977), a facultative microaerophile. In addition to H_2 or formate, both sulfur reducers oxidize some other organic compounds such as lactate. Oxidation is incomplete and leads to acetate. *Wolinella* and *Sulfurospirillum* are not only metabolically, but also phylogenetically related; they belong to the ε Proteobacteria.

The Sud Protein In a study in which the involvement of polysulfide in sulfur respiration of *Wolinella succinogenes* was questioned, Fe^{2+} [as $Fe(OH)_2$] was added to the medium to precipitate all sulfide formed by *W. succinogenes* as FeS and thus prevent formation of polysulfide. Under these conditions, *W. succinogenes* still grew anaerobically with formate and elemental sulfur, indicating that sulfur reduction is in principle possible without the involvement of polysulfide as an intermediate (Ringel et al., 1996). From the iron(II)-containing culture of *W. succinogenes*, a soluble sulfur-containing fraction was isolated that by treatment with CN^- could be separated further into a yet unidentified sulfur species and the so-called Sud protein (Hedderich et al., 1999). The coding *sud* gene was isolated from *W. succinogenes* and its sequence indicated the presence of a signal peptide and only one cysteine in the polypeptide chain. The recombinant Sud protein was purified after heterologous expression in *Escherichia coli*. The enzyme consists of two identical subunits (14 kDa), lacks any prosthetic groups or heavy metals and is located in the periplasm. The synthesis of the Sud protein is induced during growth on elemental sulfur and polysulfide (Kreis-Kleinschmidt et al., 1995). Further studies with a His-tagged Sud protein (Sud-His_6), which was also purified from *E. coli*, demonstrated a catalysis of the formation of thiocyanate from cyanide and polysulfide with an apparent K_M of less than 20 µM polysulfide. The monomer of Sud-His_6 was found to bind up to 10 sulfur atoms from polysulfide. Addition of small amounts of Sud-His_6 to membrane fractions of

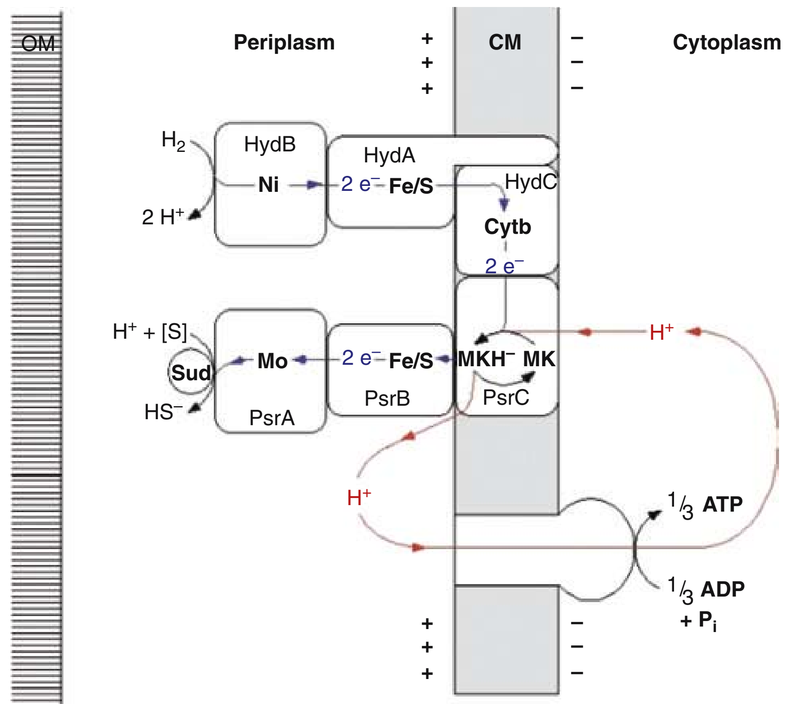


Fig. 18. Possible generation of a proton-motive force (pmf) during growth of *Wolinella succinogenes* or other spirilloid sulfur reducers on H_2 and sulfur. Diffusion and collision of HydC and PsrC is assumed to be required for electron transfer. The mechanism for generation of a proton gradient is not known. Possibly, protons are translocated via protein-bound menaquinone to the periplasm. Abbreviations: HydABC, subunits of hydrogenase; PsrABC, subunits of polysulfide reductase; Sud, protein that increases the availability of polysulfide (formerly termed "sulfide dehydrogenase"). [S] indicates a soluble form of sulfur, most probably polysulfide. The scheme was adapted from Hedderich et al. (1999).

W. succinogenes stimulated the electron transport from H_2 to polysulfide (Klimmek et al., 1998). A deletion mutant of the *sud* gene (Δ*sud*) was constructed in *W. succinogenes* by homologous recombination. However, growth of the Δ*sud* deletion mutant on formate and polysulfide as compared to that of the wild type was not affected (Kotzian et al., 1996). By site directed mutagenesis, the single cysteine residue in the Sud protein (Cys109) was replaced by a serine residue. The modified Sud protein (C109S)Sud-His_6 showed marked differences from the Sud-His_6 protein. The (C109S)Sud-His_6 protein neither catalyzed formation of thiocyanate from cyanide and polysulfide nor stimulated the electron transport to polysulfide. Moreover, the Cys109 residue was found to be required for binding polysulfide-sulfur to the Sud protein. Despite some inconsistent results from growth experiments, the Sud protein is assumed to function in transferring sulfur from aqueous polysulfide to the active site of polysulfide reductase (Klimmek et al., 1999). The Sud protein and polysulfide reductase (Psr) were present in nearly equimolar amounts when *W. succinogenes* was grown on polysulfide, and it is assumed that Sud is bound to Psr (Fig. 18; Hedderich et al., 1999).

Polysulfide Reductase The enzyme that catalyzes the reduction of polysulfide sulfur to sulfide is termed "polysulfide reductase" (Psr). This enzyme is encoded by the polysulfide reductase operon (*psrABC*; Krafft et al., 1992). The nucleotide sequence of the *psrABC* genes indicates that Psr is a heterotrimer consisting of three subunits (PsrA, B and C). The PsrA (81 kDa) and PsrB (21 kDa) subunits are hydrophilic proteins, whereas PsrC (34 kDa) is of hydrophobic nature with eight putative transmembrane-spanning segments and is assumed to function as membrane anchor of the Psr holoenzyme. The PsrA subunit was found to be homologous to known molybdoenum-containing oxidoreductases, such as formate dehydrogenase of *E. coli*. Indeed, a molybdopterin guanine dinucleotide was identified in the purified protein (Jankielewicz et al., 1994). The PsrA subunit is assumed to be the catalytic subunit of the Psr protein. The *psrA* gene also includes the coding sequence for a leader peptide indicating an orientation of the PsrA subunit toward the periplasm. Moreover, PsrA was identified in the periplasmic fraction of a Δ*psrC* mutant. Based on the predicted presence of 16 cysteine residues, PsrB is assumed to contain several [FeS] clusters involved in electron transfer. Even though the *psrB* gene does not contain a coding sequence for a leader peptide, a periplasmic orientation of PsrB is postulated (Krafft et al., 1992). The purified Psr contains 1 mol menaquinone per mol of protein. Menaquinone is assumed to serve as acceptor for electrons transferred from hydrogenase and as direct electron donor for polysulfide/sulfur reduction.

The purified Psr protein catalyzes the reduction of polysulfide to sulfide with BH_4^- as hydride donor, and the oxidation of sulfide to polysulfide by 2,3-dimethyl-1,4-naphthoquinone, a soluble analogue of menaquinone (Krafft et al., 1992). In wild type *W. succinogenes*, polysulfide reductase activity is still present and active when cells are grown with fumarate as electron acceptor (Lorenzen et al., 1993). Deletion mutants of Psr (Δ*psrC*, Δ*psrBC* and Δ*psrABC*) were grown with fumarate and cell fractions were analyzed for their capacity to oxidize sulfur and to transfer electrons from formate to polysulfide (Krafft et al., 1995). The Δ*psrC* mutant catalyzed the oxidation of sulfide with dimethylnaphthoquinone, which was not observed with the Δ*psrABC* or Δ*psrBC* mutant. This indicated that PsrA and PsrB, but not PsrC, were directly involved in the transfer of reducing equivalents to a quinone site. However, the capacity of the Δ*psrC* mutant to perform the entire electron transfer from formate to polysulfide was only 5% of the wild type activity, suggesting that PsrC is required for further electron transport reactions. If the Δ*psrABC* mutant was grown on polysulfide instead of fumarate, activity for sulfide oxidation and polysulfide reduction could still be measured. A so far unidentified protein could be extracted from the membranes of the polysulfide-grown mutant that seems to replace polysulfide reductase.

Electron Transport from Formate or H_2 to Polysulfide *Wolinella succinogenes* utilizes either H_2 or formate as electron donors (Macy et al., 1986). The same hydrogenase and formate dehydrogenase are operative if either sulfur or fumarate are used as electron acceptors (Schröder et al., 1988). A hydrogenase deletion mutant (Δ*hydABC*) did not grow with H_2 and polysulfide, or with H_2 and fumarate. Growth could be restored by complementing the mutant with the *hydABC* operon (Gross et al., 1998a; Gross et al., 1998b). Electrons from hydrogenase and formate-dehydrogenase have to be transferred to polysulfide reductase.

Electron transfer reactions were most intensely studied with formate. Even though the substrate-binding sites of formate dehydrogenase and hydrogenase are both orientated toward the periplasm (Kröger and Winkler, 1981), formate does not diffuse through membrane bilayers and thus allows more defined studies in vesicles than H_2. Electron transfer from formate was studied in vesicles as a function of the ratio between phospholipid and membrane proteins, by dilution of the membrane fraction of *W. succinogenes* with phospholipid. Based on these experiments, a model of diffusion and collision was suggested. Collision of hydrogenase or formate dehydrogenase, respectively, with the polysulfide reductase is regarded as a requirement for this electron transfer. In addition to the collision of proteins, menaquinone bound to PsrC is essential (Hedderich et al., 1999). In contrast, electron transport to fumarate reductase in the cytoplasmic membrane of *W. succinogenes* does not involve direct collision of proteins but rather occurs via freely diffusible menaquinone in the cytoplasmic membrane (Jankielewicz et al., 1995; Hedderich et al., 1999).

Properties of hydrogenase in *W. succinogenes* have been studied in detail. The enzyme is membrane-bound, contains nickel, and catalyzes the reduction of dimethylnaphthoquinone or benzylviologen with H_2 (Unden et al., 1982). It could be isolated from the membrane fraction of *W. succinogenes* and was found to consist of three subunits, HydA (30 kDa), HydB (60 kDa) and HydC (23 kDa). A deletion mutant without the hydrogenase (Δ*hydABC*) cannot grow with H_2 and either polysulfide or fumarate. The three subunits of hydrogenase are encoded by three adjacent genes, *hydABC*. The HydA subunit is a hydrophilic protein that is likely to be localized in the periplasm because the gene, *hydA*, contains a coding sequence for a leader peptide. The HydA subunit contains eight cysteine residues, some of which are possible ligands for [FeS] clusters. The C-terminus of HydA contains about 20 hydrophobic residues that could constitute a membrane anchor by forming a transmembrane helix and in this way a membrane anchor for the protein. The HydB protein, the catalytic subunit of hydrogenase, is hydrophilic and contains eight cysteine residues that are likely to coordinate [FeS] clusters. The Cys546 residue is possibly functioning in ligation of Ni. The catalytic subunit HydB of the intact hydrogenase is located in the periplasm as demonstrated with activity tests and western blot analyses of cell fractions. The HydA and HydB proteins are homologous to the corresponding subunits of other known Ni-hydrogenases. The HydC subunit is a hydrophobic protein with four putative transmembrane-spanning segments. Biochemical studies indicated that HydC represents a cytochrome *b*, with the two heme-B groups ligated by four His residues. Mutants created by substitution of the heme-ligating His residues no longer had the activity to reduce quinone with H_2 and to transfer electrons to polysulfide reductase. These results indicate that the menaquinone bound as a prosthetic group to the PsrC is the primary acceptor for electrons from cytochrome *b* of HydC. This finding supports the assumption that also hydrogenase has

to be associated with polysulfide reductase for electron transfer in the membrane (Dross et al., 1992; Gross et al., 1998b) as in the case of formate dehydrogenase.

The exact mechanism for the generation of the electrochemical proton gradient with formate or H_2 as electron donors is not known. Possibly PsrC couples electron transfer via bound menaquinone to polysulfide to a translocation of protons (Hedderich et al., 1999; Fig. 18).

Polysulfide and fumarate respiration in *W. succinogenes* differ not only with respect to the involvement of quinone. Also, the orientation of the two reductases is different. Whereas the substrate-binding site of polysulfide reductase is oriented toward the periplasm, that of fumarate reductase is localized on the cytoplasmic side of the membrane (Kröger et al., 1980). The substrate-binding sites of hydrogenase and of formate dehydrogenase both face the periplasm (Kröger and Winkler, 1981).

Regulation of Sulfur Respiration Growth cultures of *W. succinogenes* on sulfur and formate in medium that also contained nitrate or fumarate, reduced sulfur but neither of the other two electron acceptors. This indicated that the energetically less favorable electron acceptor, sulfur, represses the utilization of the more favorable electron acceptors. In contrast, cells that were grown with nitrate or fumarate could respire both of these electron acceptors. Polysulfide reductase activity in fumarate-grown cells was as high as in sulfur-grown cells, but rather low in nitrate-grown cells (Lorenzen et al., 1993). In conclusion, regulation of anaerobic respiration with alternative electron acceptors is not clearly in accordance with their energetic "hierarchy."

Electron Acceptors Other Than Sulfur *Wolinella succinogenes* also can grow with nitrate and fumarate as electron acceptors. Nitrate is reduced to ammonia and not to N_2 as in "true" denitrifying bacteria. A hexaheme cytochrome c_3 acting as nitrite reductase has been isolated from *Wolinella succinogenes* (Liu et al., 1983). Another nitrogen compound reduced by *Wolinella succinogenes* is N_2O; unlike nitrate (or nitrite), N_2O is reduced to N_2 (Yoshinari, 1980). Furthermore, spirilloid sulfur reducers closely related to *Wolinella succinogenes* were shown to reduce dimethylsulfoxide to dimethylsulfide (Zinder and Brock, 1978; Widdel, 1988). In connection with the initial characterization of *Wolinella succinogenes*, microaerobic growth has been reported (Wolin et al., 1961). Microaerobic growth was also shown in related spirilloid sulfur-reducing bacteria (Wolfe and Pfennig, 1977; Widdel, 1988).

Research on Desulfuromonas *and* Desulfurella Among the sulfur-reducing bacteria, the capacity for a complete oxidation of organic substrates occurs necessarily in those genera and species that grow on acetate (*Desulfuromonas* and *Desulfurella*).

Desulfuromonas (Pfennig and Biebl, 1976) and *Desulfurella* (Bonch-Osmolovskaya et al., 1990) were directly isolated with acetate and sulfur. Both are obligate anaerobes. They are members of the δ Proteobacteria, with a specific relationship of *Desulfuromonas* to completely oxidizing sulfate-reducing bacteria. In addition to acetate, *Desulfuromonas* species may utilize a number of simple organic compounds (Table 2).

Oxidation of Acetate via the Citric Acid Cycle The presence of all enzymes of the citric acid cycle could be demonstrated in *Desulfuromonas acetoxidans* and *Desulfurella acetivorans* (Gebhardt et al., 1985; Schmitz et al., 1990; for overview see Kröger et al., 1988; Thauer, 1988; Thauer, 1989a; Thauer et al., 1989b). [^{14}C]-labeling experiments demonstrated a functioning citric acid cycle in *Desulfuromonas acetoxidans* (Gebhardt et al., 1985). *Desulfuromonas* activates acetate like *Desulfobacter* via succinyl-CoA:acetate CoA transferase (Fig. 12). In *Desulfurella acetivorans*, however, the formation of succinate from succinyl-CoA is associated with the synthesis of one ATP; this amount is used again to activate acetate by acetate kinase (Schmitz et al., 1990; Fig. 12 C). Citrate formation in *Desulfuromonas acetoxidans* occurs with si-specificity, as in *Desulfobacter*, but without coupling to ATP formation. Malate in *Desulfuromonas* and *Desulfurella* is dehydrogenated with NAD^+, as in mitochondria and most bacteria; *Desulfurella* has in addition $NADP^+$-specific malate dehydrogenase. The reduction of $NAD(P)^+$ ($E_0' = -0.32$ V) with malate ($E_0' = -0.166$ V) in the sulfur reducers is understood in view of the way of citrate synthesis. By not being coupled to ATP formation, the reaction is exergonic and "pulls" the energetically unfavorable dehydrogenation of malate with pyridine nucleotides. Furthermore, an NADP:ferredoxin oxidoreductase has been detected (Kröger et al., 1988). A comparison of the modifications of the citric acid cycle found in sulfate- and sulfur-reducing bacteria is presented in Fig. 12.

Inasmuch as neither *Desulfuromonas* nor *Desulfurella* gain net ATP by substrate-level phosphorylation, energy conservation must be achieved by chemiosmosis. The electron transport from ferredoxin, which might accept electrons from 2-oxoglutarate and via (NADP), from

isocitrate, to the postulated electron donor for the sulfur reductase (ΔE' around 0.2 V) could pump $2H^+/2e^-$ or $4H^+$/acetate. As in *Desulfobacter*, succinate oxidation in *Desulfuromonas acetoxidans* to fumarate (E_0' = +0.033 V) with menaquinone (E_0' = –0.074 V) is endergonic from the viewpoint of standard potentials. It appears unlikely that the reaction is made feasible solely by shifting concentration ratios of involved redox couples, or by specific coupling to a favorable redox reaction (see *Desulfobacter*), because electrons from menaquinone have to be transported further to sulfur reductase (S/H_2S, E′ = –0.19 V for 10 mM H_2S; Fig. 14B). It is more likely that electron transport from succinate (oxidation) to sulfur (reduction) with a redox span of ΔE′ = –0.22V is driven by chemiosmosis (reversed electron transport). With the consumption of 2 H^+ for the energy-driven oxidation of 1 succinate, 2 H^+/acetate remain for ATP synthesis, yielding $^1/_2$ to $^2/_3$ mol ATP/mol acetate. This is in relatively good agreement with energetic considerations based on growth yields. The growth yield of *Desulfuromonas acetoxidans* growing on acetate and sulfur was 4.2 g dry mass/mol acetate at an average doubling time of 3.8 hours (Pfennig and Biebl, 1976). The yield of *Desulfovibrio vulgaris* at this doubling time with acetate as C-source (H_2 as electron donor) was 9.1 g/mol sulfate (Nethe-Jaenchen and Thauer, 1984). Assuming a similar maintenance and YATP, *Desulfuromonas acetoxidans* should have a net yield of around 0.6 mol ATP/mol acetate.

Cytochromes Sulfur-reducing bacteria of the genus *Desulfuromonas* contain large amounts of various cytochromes (Pfennig and Biebl, 1976; Bache et al., 1983). A triheme *c*-type cytochrome, referred to as cytochrome $c_{551\text{·}5}$ or c_7, has been characterized (Probst et al., 1977; Fiechtner and Kassner, 1979). A *c*-type cytochrome has been suggested to transport electrons to sulfur reductase in *Desulfuromonas* (Kröger et al., 1988). Indeed, the cytochrome $c_{551\wedge.5}$ was demonstrated to reduce polysulfide in *Desulfuromonas acetoxidans*, which is indicative of its function in terminal reduction (Pereira et al., 1997). In addition, the cytochrome $c_{551\wedge.5}$ from *Desulfuromonas acetoxidans* was shown to function in Fe(III) reduction (Roden and Lovley, 1993; Lojou et al., 1998); the final reduction of insoluble Fe(III)-minerals must occur in direct contact with the cell and therefore requires electron transport through the cytoplasm. The structural gene of cytochrome $c_{551\wedge.5}$ was cloned and heterologously overexpressed in *Desulfovibrio desulfuricans*. The purified recombinant cytochrome $c_{551\wedge.5}$ had the same biochemical and metal-reducing properties as the protein from *Desulfuromonas acetoxidans* (Aubert et al., 1998b). Structural analysis revealed strong analogies between the triheme cytochrome $c_{551\wedge.5}$ and the tetraheme cytochrome c_3. The region that harbors the heme II group in c_3 is not present in $c_{551\wedge.5}$. However, the orientation of the other three heme groups is very similar in the two cytochromes (Banci et al., 1996; Coutinho et al., 1996; Turner et al., 1997).

Recently two new *c*-type cytochromes were isolated from *Desulfuromonas acetoxidans*, a monoheme cytochrome *c* (M = 10 kDa) and a tetraheme cytochrome *c* (M = 50 kDa), both of which are located in the periplasm (Bruschi et al., 1997). Hexaheme and octaheme cytochromes also have been isolated from *Desulfuromonas acetoxidans* (Pereira et al., 1997).

Sulfur-Reducing Archaea The capacity to reduce elemental sulfur to sulfide is found in several genera of hyperthermophilic archaea (Stetter, 1996; Hedderich et al., 1999). If growth occurs with H_2 as electron donor (+CO_2), energy conservation can be only explained by a chemiosmotic process rather than by substrate-level phosphorylation. If such prokaryotes utilize alternatively organic compounds as electron donors (and carbon sources), one may assume that also the metabolism of these substrates involves chemiosmotic energy conservation during sulfur reduction. This section will primarily treat such sulfur-respiring or "true" sulfur-reducing archaea, as far as their biochemistry has been investigated. In addition, results from investigations on *Pyrococcus furiosus* are included; fermentative growth of this archaeon is stimulated by sulfur. Biochemistry of this species has been investigated intensively.

Reduction of Sulfur and Polysulfide Archaeons of the genus Pyrodictium grow chemolithotrophically by sulfur respiration at around 100°C (Fischer et al., 1983; Stetter et al., 1993). A H_2:sulfur-oxidoreductase complex was isolated from the membrane fraction of Pyrodictium abyssi isolate TAG11. This enzyme complex was shown to consist of nine polypeptides with an estimated total molecular mass of 520 kDa. The enzyme complex contains several uncharacterized [FeS] clusters, Ni and Cu ions, two cytochrome b and one cytochrome c. The enzyme complex is proposed to encompass hydrogenase- and sulfur-reductase activity as well as electron carrier components; the molecular arrangement is supposed to allow the coupling of S^0 reduction with H_2 to energy conservation (Dirmeier et al., 1998). The organization of the different components in such a large enzyme complex may allow stabilization of the interacting components and represent a strategy in hyperthermophiles to

perform sulfur respiration at temperatures of around 100°C.

Pyrococcus furiosus grows at 100°C by fermentation of carbohydrates to acetate, CO_2 and H_2. If sulfur is present in the medium, H_2S is produced in addition to H_2, and the growth yield increases (Fiala and Stetter, 1986; Schicho et al., 1993). There are doubts whether sulfur reduction is a respiratory, chemiosmotically coupled process. Sulfur may serve as an electron sink for certain dehydrogenations and render fermentation more effective. Growth with H_2 + sulfur as energy source has not been observed. An "H_2-evolving" hydrogenase was purified from *P. furiosus* which had a heterotrimeric (αβγ) structure and contained one [2Fe-2S] cluster and Ni (Bryant and Adams, 1989). Polysulfide can be reduced to H_2S by this hyperthermophile and is assumed to be the natural substrate during sulfur reduction (Blumenthals et al., 1990). Two different enzymes (sulfhydrogenase and sulfide dehydrogenase) were identified to catalyze reduction of sulfur in *P. furiosus*. The "bifunctional" sulfhydrogenase was isolated from the cytoplasm and shown to be identical with the aforementioned hydrogenase. Sulfhydrogenase can reduce both, sulfur and polysulfide, and oxidize H_2 (Ma et al., 1993). Isolation of the coding genes for sulfhydrogenase revealed that this enyzme actually consists of four subunits (β,γ,δ and α) encoded in a transcriptional unit, *hydBCDA*. Homology studies revealed a similarity of HydB and HydG with subunits of sulfite reductase from *Salmonella typhimurium* (Pedroni et al., 1995). Further biochemical and spectroscopic studies provided a more detailed insight into the molecular architecture of sulfhydrogenase and revealed that more [FeS] clusters were present in this enzyme than previously identified. The hydrogenase activity is localized at the αδ-subunits and the sulfur reductase activity at the βγ-subunits. Redox centers are proposed to be arranged as follows. Three [4Fe-4S] cubanes reside in the δ-subunit, two [4Fe-4S] cubanes in the β-subunit, one [2Fe-2S] cluster and one FAD in the γ-subunit and the NiFe center in the α-subunit (Arendsen et al., 1995; Silva et al., 1999a). Sulfide dehydrogenase, which was also identified in the cytoplasm, catalyzes the reduction of polysulfide to H_2S with NADPH as electron donor. This enzyme was found to have a heterodimeric structure and to contain flavin and four [FeS] centers (Ma and Adams, 1994). A possible physiological role of sulfhydrogenase and sulfide dehydrogenase is assumed to be that of an electron sink (Ma and Adams, 1994; Hedderich et al., 1999). During fermentative degradation of glucose to acetate, liberated electrons are transferred to ferredoxin by oxidoreductases (Schäfer and Schönheit, 1992; Mukund and Adams, 1991). Reoxidation of reduced ferredoxin could be directly achieved by sulfhydrogenase. Moreover, NADPH accumulating during glutamate fermentation (Robb et al., 1992) could be reoxidized by sulfide dehydrogenase.

The formation of high concentrations of H_2S from sulfur with H_2 or methanol has been observed in cultures of methanogens (Stetter and Gaag, 1983a). However, growth due to this reaction has not been demonstrated.

Metabolism of Organic Electron Donors

Carbohydrates Most of the archaeal sulfur-reducers grow either lithotrophically on H_2 or heterotrophically on complex substrates such as meat or yeast extracts. Only a few isolates like *Thermoproteus* species and *Pyrococcus* species were found to utilize defined carbohydrates (for review see Adams, 1994; Schönheit and Schäfer, 1995; Kengen et al., 1996; Hedderich et al., 1999).

The thermoacidophilic, sulfur-reducing archaeon *Thermoproteus tenax* utilizes, besides other substrates, glucose for growth by sulfur-respiration (Zillig et al., 1981; Fischer et al., 1983). Part of the glucose can be transiently stored as glycogen (König et al., 1982). Glucose in the energy metabolism is completely oxidized (Selig and Schönheit, 1994). Labeling experiments with [^{13}C]- and [^{14}C]-glucose and enzymatic studies demonstrated that *T. tenax* employs in parallel a modified Embden-Meyerhof-Parnas (EMP) pathway and the nonphosphorylated Entner-Doudoroff (ED) pathway to metabolize glucose (Siebers and Hensel, 1993; Selig et al., 1997). Of the two pathways, the EMP-pathway is used predominantly for glucose metabolism. It was suggested that the preference for one of the two pathways is regulated in response to physiological conditions (Schönheit and Schäfer, 1995). The key enzyme of the modified EMP-pathway in *T. tenax* is the PP_i-dependent phosphofructokinase (PP_i-PFK). In contrast to ATP-PFK, which is present in most organisms, the PP_i-PFK uses PP_i rather than ATP to phosphorylated fructose-6-phosphate. Purified PP_i-PFK from *T. tenax* was found to be a multimeric enzyme of ca. 100 kDa mass and not to be regulated by ATP, ADP or fructose-2,6-bisphosphate, the classical effectors of ATP-PFK (Siebers et al., 1998). Phylogenetic analysis of the PP_i-PFK encoding gene sequence demonstrated that the *T. tenax* PFK is of early descent (Siebers et al., 1997). Glucose dehydrogenase, which is the first enzyme of the ED pathway, was also purified from *T. tenax*. The active form of the enzyme is a homodimer with a total mass of 84 kDa and uses $NADP^+$ as cosubstrate for

glucose oxidation (Siebers et al., 1997). Decarboxylation of pyruvate to acetyl-CoA is catalyzed by pyruvate:ferredoxin oxidoreductase (Selig and Schönheit, 1994; Schönheit and Schäfer, 1995). This enzyme is also operative in *Pyrobaculum islandicum* and *Pyrococcus furiosus* (Schäfer and Schönheit, 1991). Further oxidation of acetate to CO_2 in *T. tenax* and *P. islandicum* involves the citric acid cycle (Selig and Schönheit, 1994).

The sugar metabolism in *Pyrococcus furiosus*, which has been intensively investigated, has many parallels to that in *Thermoproteus tenax* (Mukund and Adams, 1991; Schäfer and Schönheit, 1992; Kengen et al., 1994; Kengen et al., 1996; Schäfer et al., 1994). *P. furiosus*, in which sulfur reduction facilitates fermentation, has no capability for complete oxidation and forms acetate as an organic end product (Schönheit and Schäfer, 1995).

Peptides *Thermoproteus tenax* and *Pyrobaculum islandicum* (Huber et al., 1987) have been reported to utilize peptides with sulfur as electron acceptor. Considering the capacity of these two archaea to oxidize acetate completely to CO_2 via the citric acid cycle (Selig and Schönheit, 1994), it can be assumed that also peptides are completely oxidized to CO_2.

Autotrophic Carbon Assimilation *Thermoproteus neutrophilus* (Zillig et al., 1981; Fischer et al., 1983) is a facultative autotroph that can use either CO_2 or acetate as carbon source during growth on H_2 and sulfur. The pathway for CO_2 fixation was studied by ^{14}C-labeling experiments and measurement of enzyme activities. The key enzyme of the Calvin-cycle, ribulose-1,5-bisphosphate carboxylase (for summary see Watson and Tabita, 1997), was not detected in extracts of *T. neutrophilus* cells. Results rather suggested the presence of a reductive citric acid cycle (Schäfer et al., 1986). Enzyme activities corroborating this CO_2 fixation pathway, including the ATP citrate lyase, were subsequently demonstrated (Beh et al., 1993).

Acidianus is a genus of facultatively anaerobic Archaea that can grow aerobically by sulfur oxidation or anaerobically by sulfur reduction with H_2. In both cases, growth is autotrophic (Segerer et al., 1986; Segerer and Stetter, 1992). Enzyme studies with extracts of autotrophically grown *A. infernus* cells indicated that acetyl-CoA carboxylase and propionyl-CoA carboxylase function as the main CO_2-fixation enzymes. A 3-hydroxypropionate cycle is proposed for this organisms as route of CO_2 fixation (Menendez et al., 1999), where two moieties of CO_2 are fixed by the aforementioned enzymes, and glyoxylate is formed for further synthesis of organic compounds from malyl-CoA, while acetyl-CoA is concomitantly regenerated. This pathway has originally been detected in the phototrophic bacterium *Chloroflexus aurantiacus* (Holo, 1989; Strauß et al., 1992).

Detoxification of Superoxide Superoxide reductase (SOR), was purified from *Pyrococcus furiosus*, and proposed to function in scavenging superoxide via a net reduction to H_2O_2 rather than via dismutation to H_2O_2 and O_2 as is known from superoxide dismutase (Jenney et al., 1999). Reduced rubredoxin is suggested as the primary source of reducing power for SOR. Reduction of rubredoxin is catalyzed by NAD(P)H:rubredoxin oxidoreductase that has also been purified from *P. furiosus* (Ma and Adams, 1999).

Reductive scavenging of superoxide appears to be a widespread mechanism in anaerobes to protect against the deleterious superoxide species. Homologs of the SOR encoding gene have been identified in many complete genomes of anaerobic microorganisms, but not in those of aerobic organisms. In contrast, genes coding for superoxide dismutase are not generally present in anaerobic microorganisms. The SOR encoding gene also shows homology to the redox proteins desulfoferredoxin and neelaredoxin from *Desulfovibrio desulfuricans* and *D. gigas*, respectively (Jenney et al., 1999).

Microorganisms Reducing Sulfur Compounds Other Than Sulfate or Sulfur

Bacteria The capacity for the dissimilatory reduction of sulfur compounds other than sulfate and sulfur, especially sulfite and thiosulfite, has been frequently observed among sulfate-reducing microorganisms and also among some sulfur-reducing microorganisms. However, there are also prokaryotes that neither reduce sulfate nor elemental sulfur but instead utilize other sulfur compounds as electron acceptors.

There are several reports on tetrathionate and thiosulfate reduction in bacteria other than sulfate or sulfur reducers (Barrett and Clark, 1987). A reduction of these sulfur species seems to be abundant especially among enterobacteria. Often, the capacities to reduce tetrathionate and thiosulfate coincide, which is explained by one reductase for both compounds (Oltmann et al., 1975; Barrett and Clark, 1987). Tetrathionate is first reduced to thiosulfate. In *Citrobacter* and *Proteus*, there is evidence for an electron transport chain to tetrathionate allowing respiratory

energy conservation (Oltmann et al., 1975; Novotny and Kapralek, 1979); the growth substrates were sugars. A complete oxidation (viz. acetyl-CoA oxidation) associated with tetrathionate reduction has not been reported for the enterobacteria. Formed thiosulfate may be further reduced to sulfide and sulfite, the latter being often an end product that is not reduced further. For energetic reasons, such an incomplete reduction of thiosulfate probably does not allow a chemiosmotic process and thus appears to be a by-reaction. Suspensions of the phototroph, *Thiocapsa floridana*, reduced thiosulfate with endogeneous hydrogen donors in the dark (Trüper and Pfennig, 1966). A marine *Pseudomona*s-like strain grew anaerobically on lactate in the presence of thiosulfate or sulfite and formed sulfide. Lactate alone was not utilized (Tuttle and Jannasch, 1973). It is unknown whether sulfite reduction was of a respiratory type or just a facilitated fermentation. Reduction of thiosulfate or sulfite, probably as a mere hydrogen sink, has also been observed in mesophilic and thermophilic saccharolytic clostridia. The sulfite reductase in *Clostridium pasteurianum* was induced by sulfite and distinctive from the assimilatory enzyme (Harrison et al., 1984). Even yeast cells catalyzed a reduction of thiosulfate to sulfite and sulfide, and of sulfite to sulfide (Neuberg and Welde, 1914; Hollaus and Sleytr, 1972; McCready and Kaplan, 1974; Stratford and Rose, 1985); sulfite reduction was observed in an aerated culture. The reductions seemed to be by-reactions.

An organic sulfur compound used by several bacteria as electron acceptor is $(CH_3)_2SO$, dimethylsulfoxide (DMSO), which is reduced to dimethylsulfide (DMS). The utilization of DMSO was first shown in the phototroph *Rhodobacter capsulatus* that did not grow anaerobically on sugars in the dark unless the acceptor was added (Yen and Marrs, 1977). It was first assumed that DMSO serves merely as a H_2 sink allowing substrate-level phosphorylation (Madigan and Gest, 1978; Madigan et al., 1980). Later, however, *Rhodobacter capsulatus* and also *Rhodospirillum rubrum* were reported to grow by DMSO reduction most likely in a respiratory manner (Schultz and Weaver, 1982). Among other substrates, also acetate allowed anaerobic growth in the dark when DMSO was present. Earlier, a definitive respiratory DMSO reduction had been already shown with a *spirillum* isolated with lactate as electron donor (Zinder and Brock, 1978a). The *spirillum* grew with H_2 if acetate as a carbon source and some yeast extract as sulfur source for assimilation were present. In addition to DMSO, the organism reduced sulfur, sulfite and thiosulfate and resembled *Desulfospirillum delyianum* (*spirillum* 5175) isolated with sulfur (Wolfe and Pfennig, 1977). The latter also turned out to reduce DMSO (N. Pfennig, personal communication). Anaerobic growth due to DMSO reduction with H_2 was also observed with *Escherichia coli* (Yamamoto and Ishimoto, 1978). The obvious respiratory character of DMSO reduction was confirmed by measurements with H_2 and glycerol (Bilous and Weiner, 1985). However, as with nitrate (Thauer, 1988), there is no evidence that DMSO is an electron acceptor for acetyl-CoA oxidation in *E. coli*; the citrate cycle is not operative in *E. coli* under anoxic conditions, and acetate is an end product. Some other enterobacteria, *Pseudomonas aeruginosa* and *Bacillus subtilis*, reduced DMSO in complex glucose medium (Zinder and Brock, 1978b). However, DMSO reduction seemed to be not very effective (<0.5 mM/day). Bacteria reducing DMSO usually can also reduce trimethylamine-N-oxide (TMAO).

Archaea The archaeon *Archaeoglobus veneficus*, a phylogenetic relative of sulfate-reducing *Archaeoglobus* species cannot reduce sulfate but only sulfite (Huber et al., 1997). *A. veneficus* is the only hyperthermophile reported so far to grow with free acetate as electron donor and organic carbon source.

Genetic Systems

Approaches from molecular biology and genetics have been applied in the study of sulfate-reducing and sulfur-reducing microorganisms since the 1980s. These approaches included cloning and heterologous expression of genes for the analysis of sequences, operon structures and confirmation of gene products; in addition, several possibilities for genetic manipulation of sulfate- and sulfur-reducing bacteria have been established to study genes and gene products in homologous systems and thus in a natural, functional context.

Sulfate-Reducing Bacteria

Genome Sizes Bacterial and archaeal genomes range between 0.6 to 8.7 Mb, which are the sizes as determined for *Mycoplasma genitalium* and *Bradyrhizobium japonicum*, respectively (Cole and Girons, 1994). Early studies using two-dimensional electrophoresis to separate fragments of double-digested genomic DNA suggested genome sizes of 1.6 Mb for *Desulfovibrio gigas* and 1.7 Mb for *Desulfovibrio vulgaris* (Postgate et al., 1984c). Later on, however, application of pulsed-field gel electrophoresis (PFGE) of linearized, full-length chromosomal

DNA revealed genome sizes of 3.1, 3.6 and 3.7 Mb in *Desulfovibrio desulfuricans*, *Desulfovibrio vulgaris* and *Desulfobulbus propionicus*, respectively (Devereux et al., 1997). Thus it appears that genomes of sulfate-reducing bacteria are considerably larger than the 2.2 Mb genome of the archaeal sulfate reducer *Archaeoglobus fulgidus* (Klenk et al., 1997).

Cloning, Sequencing and Expression of Genes The *hydAB* genes (coding for hydrogenase) from *Desulfovibrio vulgaris* (Hildenborough) were the first genes from a sulfate-reducing bacterium that were cloned, sequenced and expressed in *E. coli* (Voordouw and Brenner, 1985a; Voordouw et al., 1985b). Expression of the cloned *hyd* genes in *E. coli* yielded proteins, the N-terminal sequence of which corresponded to the sequence of the cloned gene. However, the expressed *Desulfovibrio* hydrogenase was inactive. Evidence that the transcriptional/translational machinery of *E. coli* can in principle produce functional enzymes from *D. vulgaris* genes was provided by complementation experiments with a gene from the biosynthetic machinery. The auxotrophic *E. coli* $PyrF^{-}$ mutant carries a disrupted orotidine-5'-phosphate decarboxylase and is therefore deficient in the biosynthesis of pyrimidines. Complementation of the *E. coli* $PyrF^{-}$ mutant with the structural gene from *D. vulgaris* abolished the auxotrophic phenotype (Li et al., 1986). Subsequently, many genes coding for catabolic enzymes, regulatory proteins or electron carriers were cloned, sequenced and expressed (Voordouw, 1993a). They have already been mentioned in the subsection on Physiology, Biochemistry and Molecular Biology of Sulfate-Reducing Bacteria. Genes cloned from sulfate-reducing bacteria are listed in Table 8.

Physiological and Practical Prerequisites for Genetic Studies in Sulfate-Reducing Bacteria Studies aiming at genetic manipulation of sulfate-reducing bacteria have mostly been carried out thus far with *Desulfovibrio desulfuricans* and *D. vulgaris* strains because various proteins in these species have been studied in great detail and because these species can be cultivated relatively easily. Other practical reasons for choosing these species were high plating efficiencies and antibiotic sensitivities for potential selection of mutants (Voordouw and Wall, 1993b; van Dongen et al., 1994).

In the application of plating techniques for sulfate-reducing bacteria, anoxic growth conditions have to be guaranteed. van den Berg et al. (1989) developed a plating technique with a recovery of 50 to 100%. Aerobically prepared agar plates were stored under an anoxic atmosphere until use. *Desulfovibrio vulgaris* was then plated under oxic conditions in an agar overlay of 3 ml. Immediately after solidification of the agar, the plates were incubated under argon $(Ar)/CO_2$ in the presence of $Na_2S_2O_4$ as O_2 scavenger in the incubation container. Hence, anoxic conditions were necessary during growth, but not during plating.

The presence of alternative modes of energy conservation is important for genetic studies of catabolic capacities. *Desulfovibrio* species can gain energy either from a respiratory metabolism with H_2 or organic electron donors and with sulfate or sometimes nitrate as electron acceptors (Table 1), or from fermentative degradation of pyruvate. This allows the genetic inactivation of genes involved in one process while other processes are still operative to sustain viability. A mutant of *Desulfovibrio desulfuricans* was generated by chemical mutagenesis that could no longer use H_2 for the reduction of sulfate, but could still grow with lactate and sulfate (Odom and Wall, 1987).

The use of DNA inserts with resistance markers and application of antibiotics is a common method of generating and selecting mutants. Even though sulfate-reducing bacteria are generally resistant to many antibiotics (Saleh et al., 1964), some antibiotics proved to be useful. Plasmid-borne resistance to streptomycin and sulfonamides was expressed in *Desulfovibrio desulfuricans* (Powell et al., 1989), and resistance to chloramphenicol in *D. vulgaris* (van den Berg, 1989).

Delivery Systems for DNA A prerequisite for defined genetic manipulation is the availability of tools to deliver genetic information into cells. All tools commonly used in genetic studies of other microorganisms have also been applied to sulfate-reducing bacteria.

Transduction Knowledge about the occurrence of bacteriophages in sulfate-reducing bacteria and their applicability for transduction is limited. Handley et al. (1973) presented first evidence for bacteriophages in sulfate-reducing bacteria. They observed bacteriophage-like particles in cultures of *Desulfovibrio vulgaris* that had been treated with mitomycin C. A defective bacteriophage, termed Dd1, was demonstrated to mediate transduction in *Desulfovibrio desulfuricans* strain ATCC (Rapp and Wall, 1987). Mixing and incubating *D. desulfuricans* strains resistent to either rifampicin or nalidixic acids resulted in the development of colonies simultaneously resistant to both antibiotics at higher rates than expected for spontaneous mutations. The phage Dd1 was identified as the transducing agent of

[b]The genus *Desulfovibrio* is abbreviated with *D*.

the resistance markers and found to resemble morphologically the coliphages T7 and T3. A practical limitation to the use of bacteriophage Dd1 is its inability to transfer resistance to other strains of *Desulfovibrio desulfuricans* or to other *Desulfovibrio* species (Voordouw and Wall, 1993b). A different bacteriophage was isolated from marine sediment that could lyse cells of *Desulfovibrio salexigens*, as demonstrated by plaque formation. Morphological and molecular characteristics suggested a relation of the isolate to the lysogenic bacteriophage λ but the potential of this phage for genetic transfer was not investigated (Kamimura and Araki, 1989). Treatment with UV light allowed the induction of lytic bacteriophages in *Desulfovibrio vulgaris* (Hildenborough). Subsequent mapping studies indicated the presence of two prophages in *D. vulgaris* (Seyedirashti et al., 1991; Seyedirashti et al., 1992).

Conjugation Conjugation has been used several times to transfer broad host-range plasmids belonging to the incompatibility group Q (IncQ) from *Escherichia coli* to *Desulfovibrio* species. Derivatives of plasmid pSUP104 were transferred with a frequency of about 10^{-2} from *Escherichia coli* to *Desulfovibrio vulgaris*. Stable maintenance of the plasmids in *D. vulgaris* could be demonstrated (van den Berg et al., 1989). At the same time, Powell et al. (1989) reported on a retrotransfer of plasmid R300B from *Desulfovibrio* back to *E. coli*. The cytochrome c_3-encoding *cyc* gene from *Desulfovibrio vulgaris* (Hildenborough) was ligated into plasmid pJRDC800-1, transferred by conjugation from *E. coli* to *Desulfovibrio desulfuricans* G200 and then functionally expressed in the new host (Voordouw et al., 1990). Interestingly, broad host-range plasmids from the incompatibility group P and W (IncP and IncW) could not be transferred to *D. desulfuricans* G100A (Argyle et al., 1992). This finding pointed at the specificities in the ability of *Desulfovibrio* to receive or maintain broad host-range plasmids.

Endogenous Plasmids The presence of plasmids in several *Desulfovibrio* species was previously reported (Postgate et al., 1984a; Postgate et al., 1986). *Desulfovibrio gigas* (NCIMB 9332) carries two plasmids of the sizes 105 kb and 60 kb, and *D. vulgaris* (Hildenborough; NCIMB 8303) a single plasmid of 195 kb. *D. desulfuricans* strain Berre sol and *D. vulgaris* strain Wandle both carry a single plasmid. No plasmids could be detected in 10 other *Desulfovibrio* species, including *D. salexigens* and *D. africanus.*

A small 2.3 kb plasmid, designated pBG1, was isolated from *Desulfovibrio desulfuricans* strain G100A and sequenced (Wall et al., 1993). Plasmid pBG1 was present in about 20 copies per genome. This plasmid replicates in *D. desulfuricans* strain G100A and *D. fructosovorans,* but not in *Escherichia coli*. The analysis of the sequence of plasmid pBG1 allowed a replicon area to be assigned to a sequence. Integration of pBG1 fragments that included this small replicon into derivates of the IncQ plasmid RSF1010 generated composite plasmids that were stable and replicated in *E. coli*, *D. desulfuricans* strain G100A and *D. fructosovorans*. Several recombinant plasmids that are most effective in *Desulfovibrio* were constructed that carried genes for resistance to antibiotics, e.g., chloramphenicol. These plasmids could be transferred by either electroporation or conjugation (Rousset et al., 1998a).

Transformation The first successful transformation of a sulfate-reducing bacterium was reported by Rousset et al. (1991). A recombinant plasmid belonging to the IncQ group was transformed into *Desulfovibrio fructosovorans* by means of electroporation (Dower et al., 1988). Transformation via electroporation has also been successfully applied to *Desulfovibrio desulfuricans* (Aubert et al., 1998b).

Creation of Mutants Stability and function of recombinant DNA introduced into *Desulfovibrio* species or other sulfate-reducing bacteria could be hampered in principle by an endogenous restriction/modification system. Only little is known about these systems in sulfate-reducing bacteria. Two restriction endonucleases, DdeI and DdeII were discovered in *D. desulfuricans* (Norway). Genes coding for DdeI endonuclease and methylase were identified (Howard et al., 1986; Sznyter et al., 1987).

Chemical Mutagenesis Mutants of *Desulfovibrio desulfuricans* strain ATCC 27774 that were deficient in H_2 utilization but could still grow on lactate were generated by exposure to UV light (Odom and Wall, 1987).

Transposon Mutagenesis Transposons can insert principally near or in any gene on the chromosome and completely annihilate gene function as a result of gene disruption (Maloy et al., 1996). Wall et al. (1996) developed a transposon-based method for random mutagenesis in *Desulfovibrio desulfuricans* strain G20. No evidence was found for transposition of wild-type transposon Tn5, Tn9 and Tn10 in this sulfate reducer. The transposon Tn7 was found to insert into the genome of *D. desulfuricans* (G20) with a frequency of 10^{-4} to 10^{-3}. The transposon Tn7 is

target specific and inserts specifically into the attTn7 site. This directed insertion is mediated by the Tn7-encoded TnsD protein (Craig, 1991; Bainton et al., 1993). Southern blot analysis demonstrated that transposon Tn7 inserted also in *D. desulfuricans* strain G20, specifically into the attTn7 site. By inactivation of the *tnsD* gene, Wall et al. (1996) were able to create a mutated Tn7, designated Tn7-IN1, that transposed randomly in the chromosome at a frequency of 10^{-6}. An improved version of the transposon, designated Tn7K-IN1, carried a kanamycin-resistance cassette and mediated a Knr-phenotype after transposition. This transposon as part of gene constructs allows the integration of single copies of recombinant genes at neutral spots in the chromosome. Plasmids used for the delivery of Tn7, its derivatives and adjacent genes by conjugation are not maintained in *D. desulfuricans*.

The insertion element ISD1, which was discovered in *D. vulgaris* strain Hildenborough, is the first described transposable element detected in sulfate-reducing bacteria (Fu and Voordouw, 1998). This element is 1.2 kb in length, encodes a transposase and can actively transpose into different sites on the genome of *D. vulgaris* strain Hildenborough. Sequence analysis revealed a relation of ISD1 to the IS3 family. Members of the IS3 family have been isolated from Gram-negative and Gram-positive bacteria (Fayet et al., 1990). ISD1 may be used as a platform to generate artificial transposons for random mutagenesis in *Desulfovibrio* species.

Gene Deletion Deletion of the *hydN* gene (coding for the [NiFe]-hydrogenase) in *Desulfovibrio fructosovorans* by marker-exchange mutagenesis was the first report of a successful gene replacement in sulfate-reducing bacteria (Rousset et al., 1991). The cloned *hydN* gene was replaced by a kanamycin-resistance cassette while the conserved flanking regions were maintained to allow homologous recombination. In the applied procedure, an IncQ plasmid was used as shuttle vector and transferred to *D. fructosovorans* by electroporation. Replacement of the chromosomal *hydN* gene with the marker was verified by expression of kanamycin resistance and a 90% decrease of hydrogenase activity. Furthermore, analysis by southern hybridization confirmed the gene replacement. In subsequent studies, single and double mutants of the $NADP^+$-reducing hydrogenase were generated in *D. fructosovorans* by this method of marker exchange mutagenesis (Malki et al., 1997).

Fu and Voordouw (1997) developed a method for gene replacement based on a suicide plasmid in *Desulfovibrio vulgaris* strain Hildenborough to study the oxygen sensor DcrA. A suicide-integration plasmid (pΔDcrA2CTB) was constructed from an IncQ plasmid carrying the cloned *dcrA* gene. The vector carried a *dcrA* allele disrupted by the cat gene (conferring resistance to chloramphenicol) and contained the counterselectable marker *sacB* (coding for levansucrase; Gay et al., 1983) from *Bacillus subtilis*. Plasmid pΔDcrA2CTB was transferred from *E. coli* strain S17-1 to *D. vulgaris* by conjugation. Integration of plasmid pΔDcrA2CTB into the chromosomal *dcrA* gene by the first event of homologous recombination was selected for by the presence of chloramphenicol. Addition of sucrose to the growth medium then selected for the second homologous recombination which resulted in excision of the plasmid from the chromosome and the replacement of the *dcrA* gene. In the presence of sucrose, the gene product of *sacB* is toxic for *E. coli* and other Gram-negative bacteria (Gay et al., 1983) and has therefore widely been used as a counterselectable marker for the rare second recombination event which yields clones cured from plasmid (Ried and Collmer, 1987; Blomfield et al., 1991). The genes of the *hmc* operon (coding for the high-molecular-mass cytochrome redox protein complex, the Hmc-complex) and the *rbo* gene (like *dcrA* related to oxygen sensitivity), both of *D. vulgaris*, were also deleted employing the aforementioned method (Keon et al., 1997; Voordouw and Voordouw, 1998).

Site-Directed Mutagenesis Site-directed mutagenesis was applied to study the signal-peptide consensus box of [NiFe] hydrogenase of *Desulfovibrio vulgaris* (Hildenborough) in a fusion protein with β-lactamase from *E. coli* (Nivière et al., 1992). Exchange of an arginine residue in the consensus box for a glutamate prevented export of the fusion protein from the cytoplasm of *E. coli*.

Sulfur-Reducing Bacteria

Genome Sizes, Genomic Libraries and Cloning of Genes The genome sizes of *Desulfurella acetivorans* and *D. multipotens* were reported to be around 1.9 Mb (Pradella et al., 1998).

Genomic libraries of *W. succinogenes* were constructed using the bacteriophage (EMBL-3 (Frischauf et al., 1983; Lauterbach et al., 1987). From these, subcloning of several genes was possible. These were *frd* genes coding for fumarate reductase (Lauterbach et al., 1987); *fdh* genes coding for formate dehydrogenase (Bokranz et al., 1991); *psr* genes coding for polysulfide reductase (Krafft et al., 1992); and *sud* gene coding for the periplasmic sulfide dehydrogenase (Kreis-Kleinschmidt et al., 1995).

Physiological and Practical Prerequisites for Genetic Studies in Sulfur-Reducing Bacteria The sulfur-reducing bacterium *Wolinella succinogenes* can grow on agar plates when anoxic conditions are maintained. In addition, antibiotics can be used as selection markers, because *W. succinogenes* is sensitive to, for instance, kanamycin. Transformation is accomplished by means of electroporation and has to be performed under anoxic conditions like plating. The broad host-range plasmid pBR322 (Bolivar et al., 1977), which is commonly used as shuttle vector in Gram-negative bacteria (Maloy et al., 1996), can be used to transfer recombinant DNA from *E. coli* back to *W. succinogenes*.

Gene Deletion For gene deletion, plasmid-hosted genes from *W. succinogenes* are disrupted by antibiotic-resistance cassettes (e.g., kanamycin) leaving homologous regions to both sides of the marker. Deletion of the chromosomal target genes is then accomplished by homologous recombination. Several genes have been deleted in *W. succinogenes* by this procedure: *psr* genes coding for polysulfide reductase (Krafft et al., 1995); the *sud* gene coding for periplasmic sulfide dehydrogenase (Kotzian et al., 1996); fdh genes coding for formate dehydrogenase (Lenger et al., 1997); *frd* genes coding for fumarate reductase (Simon et al., 1998); and hyd genes coding for hydrogenases (Gross et al., 1998a; Gross et al., 1998b).

Sulfur-Reducing Archaea

At present, only initial steps in the establishment of systems for genetic manipulation of sulfur-reducing archaea have been undertaken. In contrast, a variety of genetic tools have already been developed for halophilic archaea (e.g., Cline and Doolittle, 1987). Nevertheless various genetic elements have been discovered in archaeal sulfur reducers and new, composite shuttle vectors are being developed.

Several types of viruses were discovered in *Thermoproteus* species. A plasmid, termed pDL10, was found to be present in *Desulfurolobus* species (Zillig et al., 1996). Plasmid pGT5 was isolated from Pyrococcus abyssi (Erauso et al., 1996). A mobile intron from *Desulfurococcus mobilis* could be transferred to and established in *Sulfolobus acidocaldarius* (Aagaard et al., 1995).

A new hybrid shuttle vector, designated pAG1, was constructed by combining portions of the archaeal plasmid pGT5 with the bacterial plasmid pUC19. The plasmid pAG1 was stably maintained and propagated both in bacteria and archaea (Aravalli and Garrett, 1997). A different strategy to create a new shuttle vector is to incorporate the mobile intron from *Desulfurococcus mobile* into the bacterial vector pUC18 (Aagaard et al., 1996).

CHAPTER 1.23

The Denitrifying Prokaryotes

JAMES P. SHAPLEIGH

Introduction

One of the hallmarks of bacterial physiology is the ability to use a wide variety of substrates as oxidants or terminal oxidants for respiration. Because of its high redox potential and prevalence, oxygen is generally the preferred reductant for respiratory bacteria. However, bacteria can utilize many other compounds as terminal respiratory oxidant. One of these compounds is nitrate. Nitrate respiration occurs via two dissimilar pathways that utilize the same initial substrate but produce different end products. One of these pathways, termed ammonification, is carried out by bacteria such as *Escherichia coli*, and is marked by reduction of nitrate to nitrite and then to ammonia.

The second pathway of nitrate respiration is denitrification, which is the reduction of nitrate to gaseous nitrogen oxides, principally nitrogen gas (Fig. 1). The initial step in denitrification is the reduction of nitrate to nitrite, as occurs in ammonification. In the next step, the defining reaction, nitrite is reduced to nitric oxide, a gaseous nitrogen oxide. This conversion of a fixed, non-gaseous form of nitrogen to gaseous forms has led this respiratory process to be termed "denitrification" because biologically preferred forms of nitrogen are lost. Once nitric oxide is produced, it is further reduced to nitrous oxide and then to nitrogen gas. The production of nitrogen gas connects denitrification to the nitrogen cycle via nitrogen fixation. The ammonia produced by nitrogen fixation can be converted by nitrifying bacteria to nitrite and nitrate, the substrates of denitrification. This series of reductions and oxidation reactions constitute the nitrogen cycle (Fig. 2).

Gayon and Dupetit carried out the first systematic study of nitrate conversion to gaseous forms of nitrogen in 1882 (Gayon, 1882). Noting the loss of nitrate from decomposing sewage, they called it "denitrification" and were the first to isolate denitrifying bacteria (Gayon, 1886), which they dubbed *Bacterium denitrificans* α and β. In the early stages of the study of denitrification, it was erroneously assumed that nitrate was releasing and thus supplying elemental oxygen to organisms that subsequently carried out a reaction equivalent to oxygen respiration. The observation of denitrification, although biologically significant, was disquieting to agronomists who soon realized that the addition of organic matter to soils could lead to the loss of fixed nitrogen. The agricultural importance of the process provided the impetus for much of the early work on denitrification, and by the end of the 19th century, denitrification had been reasonably well-defined.

In the 20th century, a significant interest in the agricultural consequences of denitrification has continued. However, with the realization that nitric oxide and nitrous oxide play important roles in atmospheric and biological chemistry, research emphases have shifted to the environmental consequences of denitrification and the molecular mechanisms of enzymes and gene regulation.

Defining the Denitrifiers

Prokaryotes (mostly Bacteria, but a few Archaea) constitute the vast majority of organisms capable of denitrification. A number of fungal isolates carry out reduction of nitrate to nitrous oxide, but the contribution of this reduction to cell growth is variable (Usuda, 1995). In prokaryotes and a few filamentous fungi, the reduction of nitrate to gaseous intermediates is a respiratory process. That is, reduction of nitrate is coupled to ATP synthesis via electron transport chains. With one or two exceptions, denitrifiers can also respire with oxygen as the terminal electron acceptor and, because it is usually available at higher concentrations, oxygen is typically the preferred electron acceptor. However, when oxygen becomes limiting, the capacity to utilize nitrate as a terminal oxidant allows denitrifying bacteria to continue respiration using an alternative electron acceptor.

The reduction of nitrate to nitrogen gas is a multi-step process (Fig. 1). The redox couple for each reduction step is greater that 0.35 V, making

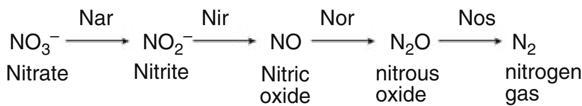

Fig. 1.

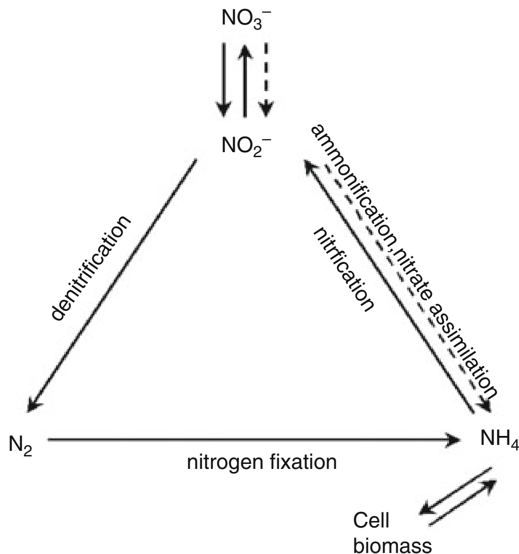

Fig. 2.

denitrification energetically comparable to oxygen reduction. Because each nitrogen oxide reduction has a positive redox couple, every step in denitrification need not be carried out to achieve a net conservation of energy. In fact, it is quite common to isolate bacteria that express only portions of the denitrification electron transport chain. Those prokaryotes that contain partial denitrification chains will be included in this chapter provided these organisms can metabolize the gaseous intermediates in denitrification, nitric oxide and nitrous oxide. So, a bacterium such as *E. coli*, which can reduce nitrate and nitrite, is not considered a denitrifier because it reduces nitrite to ammonia. Conversely, a bacterium such as *Wolinella succinogenes*, even though it also reduces nitrate to ammonia, is included in this review because it also uses nitrous oxide as sole terminal oxidant (Yoshinari, 1980).

Denitrification is a widely dispersed metabolic pathway of prokaryotes. Table 1 shows a list of prokaryotic genera, some of which are denitrifiers. A list of prokaryotic genera suggested to include dentrifying strains is shown in Table 1. This has probably led to an underestimate of the number of denitrifying strains. It is frequently concluded that, if one strain does not denitrify, neither will its close relatives. The essential criterion for inclusion in this list is the metabolism of gaseous nitrogen oxides. In most cases, this means the production of nitrous oxide or nitrogen gas from reduction of nitrate. However, all the strains in this list have not been shown to grow as denitrifiers. Several strains appear to have the capacity to reduce only nitrite or nitric oxide, making them difficult to culture under laboratory conditions.

Archaea

Only a few Archaea capable of denitrification have been isolated. With one exception, all the known archaeal species that have been isolated are also capable of aerobic respiration. Aerobic respiration is relatively frequent among some of the halophilic Archaea, which includes most of the denitrifying Archaea. The denitrification components of these halophilic bacteria have not been characterized extensively. A copper-containing nitrite reductase has been purified from *Haloferax denitrificans* and was shown to be spectroscopically similar to related eubacterial nitrite reductases; but antiserum to the copper-type nitrite reductase from the denitrifier "*Achromobacter cycloclastes*" did not react with the archaeal nitrite reductase (Inatomi, 1996). More recently, other non-halophilic Archaea have been found which are capable of denitrification. One of these is *Pyrobaculum aerophilum*, a hyperthermophile (Volkl, 1993). The genome of this organism is currently being sequenced and information from this effort will be of greatest interest since no genes whose products are required for dentrification have ever been sequenced from an Archaea or a thermophile. The other potential denitrifier from among the Archaea is the strict anaerobe *Ferroglobus placidus* (Hafenbradl, 1996). This bacterium can couple Fe^{++} oxidation to nitrate reduction. Studies on this bacterium have shown cell extracts can reduce nitrite to nitrous oxide, with nitric oxide as an intermediate (Vorholt, 1997). Even though this evidence strongly suggests this organism is a denitrifier, the capacity of whole cells to reduce nitrate to nitrite and small amounts of nitric oxide is puzzling. This result could be due to nitrite toxicity. However, further work should be done to confirm that *F. placidus* is a denitrifier inasmuch as this is one of only two reportedly strictly anaerobic denitrifiers. While denitrification is limited to a few archaeal genera, identification of more archaeal strains capable of denitrification seems likely.

Eubacteria

Denitrification ability is widespread amongst the eubacteria, and almost exclusively in those strains that are capable of aerobic growth. Also,

it is found rarely in those bacteria that carry out fermentation. Therefore, genera having strictly respiratory bacteria are likely to have denitrifying strains. Most of the characterized denitrifiers belong to the proteobacteria. However, a number of denitrifiers are in other eubacterial genera.

GRAM-POSITIVE BACTERIA Even though the majority of denitrifiers are Gram-negative, denitrifying bacteria are well represented among Gram-positive bacteria. For example, there have been a number of denitrifying *Bacillus* species described. However, because *Bacillus subtilis*

(the type strain of the most commonly studied strain of the genus) is not a denitrifier, denitrification in *Bacillus* species is often overlooked. It should be pointed out that a strain shown by rDNA analysis to be closely related to *B. subtilis*, *Bacillus azotoformans*, is a denitrifier (Mahne, 1995) and that strains designated as *B. subtilis* have been found to denitrify (Sakai, 1996; Sakai, 1996). However, these *B. subtilis* strain need to be described in more detail. Work done on characterizing denitrification enzymes in *Bacillus* has been limited (Denariaz, 1991). Other Gram-positive bacteria capable of denitrification include strains of *Propionibacterium* (Swartzlander, 1993) and *Jonesia* (originally *Listeria*) *denitrificans* (Rocourt, 1987). These strains are somewhat unusual because they seem to be denitrifying strains in groups of bacteria that are primarily non-denitrifiers. More typical is *Frankia*, in which a screen for denitrification found a number of denitrifying strains (Lensi, 1990). Recently, it has been shown that a number of actinomycetes, including *Streptomyces*, *Dermatophilus* and *Nocardia*, are capable of nitrous oxide evolution from nitrate or nitrite (Shoun, 1998). This work significantly expands the list of denitrifying Gram-positive bacteria and demonstrates that, once denitrification is observed in a group of bacteria, further characterization of its members and close relatives will uncover additional denitrifiers, even if denitrification had never been ascribed previously to any member of the group.

GRAM-NEGATIVE BACTERIA Among the Gram-negative bacteria that are not proteobacteriaare, denitrifying strains are found in the genera *Aquifex* (Huber, 1992), *Flexibacter* (Jones, 1990), and *Flavobacterium* (Coyne, 1989). *Aquifex pyrophilus* is a thermophile that constitutes one of the deepest (earliest) branches of the eubacteria. This may indicate that denitrification represents one of the first forms of respiration. Denitrifying strains of the related *Hydrogenobacter* have not been isolated as yet, but this may be due to incomplete characterization. The gliding bacterium *Flexibacter canadensis* is unique in that its nitrous oxide reductase is apparently insensitive to acetylene, unlike nitrous oxide reductases from other bacteria (Jones, 1990).

Nearly all of the bacteria defined as denitrifiers are identified because of their ability to reduce nitrate or nitrite to gaseous end products. Recently, genomic sequencing efforts indicated that *Synechocystis* sp. strain PCC 6803 is also a denitrifier, but with a truncated electron transport chain (Kaneko, 1996). Analysis of the genome sequence of PCC 6803 showed that it encodes a nitric oxide reductase and a transcriptional regulator that may regulate expression of this enzyme. This strain does not encode a nitrite or nitrous oxide reductase, making it an extreme example of an organism with a truncated denitrification electron transport chain. It will be interesting to see if genomic sequencing finds additional bacteria with truncated denitrification chains.

The majority of currently characterized denitrifiers are found in the group known as the proteobacteria (purple bacteria). The proteobacteria have been subdivided into five subdivisions, α, β, γ, δ and ε. Denitrifiers have been found in four of these. The δ subdivision, which contains a number of strict anaerobes, has not been found to contain any strains that denitrify, as yet. The α subdivision contains a number of well-characterized denitrifiers including *Paracoccus denitrificans*, various *Rhodobacter* strains, and several rhizobia. Even in the α subdivision, in which it is well established, denitrification may be overlooked if the first strains characterized do not denitrify. A good example of this problem is *Rhodobacter sphaeroides*. The original isolates of *R sphaeroides* were not robust denitrifiers, so little effort was made to determine if other strains of *R sphaeroides* were denitrifiers. However, a number of denitrifying isolates were eventually isolated (Michalski, 1988). Further work has indicated that all strains of *Rhodobacter* probably encode nitric oxide and nitrous oxide reductase, but that most have lost the ability to reduce nitrite (Kwiatkowski, 1997).

Denitrifiers of note in the α subdivision include *Hyphomicrobium*, budding bacteria often found in waste-water treatment facilities (Fesefeldt, 1998). *Hyphomicrobium* can be used to help rid water supplies of high nitrate concentrations while growing on inexpensive feedstocks such as methanol. Denitrification among the rhizobia, which are best known for their roles as nitrogen-fixing symbionts, is also noteworthy because these strains have the seemingly contradictory capacity for both nitrogen fixation and denitrification (O'Hara, 1985). This ability to both fix and "unfix" nitrogen is fairly widespread among denitrifiers: *Rhodobacter*, *Hyphomicrobium*, *Frankia*, *Azospirrilum*, *Azoarcus* and some pseudomonad strains can both fix nitrogen and reduce nitrates to nitrogen gas. Some members of the genus *Nitrobacter*, which are nitrifying α-proteobacteria, reportedly produce nitric oxide from nitrite. Even though a putative nitrite reductase has been purified from *Nitrobacter vulgaris* (Ahlers, 1990), other studies have not revealed production of nitric oxide or nitrous oxide in cultures of *Nitrobacter* species (Baumgartner, 1991; Goreau, 1980). Further studies are required to determine if these nitrifying bacteria are also denitrifiers.

Although a number of members of the β-proteobacteria denitrify, they are not as well studied, on the whole, as members of the α or γ subdivisions. However, new developments suggest this situation is likely to be only temporary. One new area of interest is the anaerobic degradation of aromatic organic compounds. In recent years, it has become evident that denitrifying bacteria can metabolize aromatic compounds under denitrifying conditions. A number of aromatic compound-degrading denitrifiers have been isolated, and many belong to the genera *Azoarcus* or *Thauera*, which are both β-proteobacteria (Fries, 1994; Springer, 1998; van Schie, 1998; Anders, 1995). Given the interest in anaerobic degradation of aromatic compounds, there is likely to be more in-depth studies on denitrification in *Azoarcus* or *Thauera*. One strain, *Azoarcus anaerobius*, is a completely anaerobic denitrifier (Gorny, 1992) and is unusual in that it cannot fix nitrogen, a trait common to all other strains of *Azoarcus*.

Another reason to expect that denitrification in members of the β subdivision will receive more attention is that both *Neisseria gonorrhoeae* and *Neisseria meningitidis* are denitrifiers. Even though it has been well documented that several other species of *Neisseria* can denitrify (in fact, one species is named *Neisseria denitrificans*), denitrification in *N. gonorrhoeae* and *N. meningitidis* was originally overlooked because of their apparent sensitivity to nitrite. However, recently it has been shown that the gene *aniA* in *N. gonorrhoeae* encodes a copper-containing nitrite reductase (Mellies, 1997). Ongoing sequence analysis of the genomes of *N. gonorrhoeae* (Roe, 1999) and *N. meningitidis* (Sanger Centre, 1999) has revealed that both organisms encode a nitrite reductase and nitric oxide reductase, but only *N. gonorrhoeae* is known to encode nitrous oxide reductase; whether *N. meningitidis* also has this gene is not determined as yet. Little is known about the regulation of these proteins or what contributions they make to the physiology of these bacteria. Nitrite reductase is apparently not required for pathogenicity (Mellies, 1997). However, because reactive nitrogen oxide is an important part of the host defense response in humans, the role of the denitrification enzymes in these pathogenic *Neisseria* will undoubtedly receive more attention.

Also, among the β subdivision denitrifiers are species of the genus *Nitrosomonas*, a genus defined by the ability to oxidize ammonia to nitrite. It has been known for some time that nitrous oxide is a product of ammonia oxidation (Goreau, 1980; Poth, 1985). Subsequent studies have confirmed these observations and a copper-containing nitrite reductase has been purified from *Nitrosomonas europaea* (Miller, 1985; Dispirito, 1985). This strongly indicates that *Nitrosomonas* species are nitrifying denitrifiers. However, the role of denitrification in *Nitrosomonas*, whether for detoxification or for energy conservation, has not been established as yet.

Denitrification in members of the γ subclass of proteobacteria has been well studied in *Pseudomonas stutzeri* and *Pseudomonas aeruginosa*. Recent characterizations of the pseudomonads has resulted in the reclassification of rRNA group II bacteria to the genus *Burkholderia*, which is in the γ subdivision (Yabuuchi, 1992). Members of the rRNA group I of the pseudomonads are tightly clustered, and *P. stutzeri* and *P. aeruginosa* are in this group.

Some very unusual nitrate respirers are found in the γ group. Both *Beggiatoa* and *Thioploca* species have the unique capacity to accumulate nitrate in internal vacuoles until they contain several thousandtimes the external concentration (McHatton, 1996; Fossing, 1995). The organisms then use this accumulated nitrate as an oxidant and sulfide in the surrounding environment as a reductant. They also make sheaths in which they move between the nitrate-rich waters and sulfide-rich sediments, allowing them to commute from one environment to another depending on their physiological requirements. A unique relative of *Thioploca* and *Beggiatoa*, *Thiomargarita*, has been described recently (Schulz, 1999). *Thiomargarita* accumulates high concentrations of nitrate in a central vacuole. This very large vacuole is the reason *Thiomargarita* is the largest known bacterium. All of these bacteria are presumed to be denitrifiers, however, there is little direct evidence for this. Some evidence suggests *Beggiatoa* species are denitrifiers (Sweerts, 1990), but more work needs to be done to show that these strains contain a nitric-oxide-producing nitrite reductase. The use of reduced sulfur compounds as electron donors is known to occur in several denitrifiers including *Aquifex* (Huber, 1992), *Paracoccus* (Friedrich, 1981), and *Thiobacillus* (Schedel, 1980).

A few denitrifiers have been found in the ε subdivision. Some exhibit truncated denitrification chains. For example, both *Wolinella succinogenes* and some *Campylobacter* species have the capacity to grow with nitrous oxide as sole terminal oxidant (Yoshinari, 1980; Payne, 1982). However, neither bacterium is able to reduce nitrite to nitrous oxide. *Thiomicrospira denitrificans*, which is closely related to the *Campylobacter* group (Muyzer, 1995), can reduce nitrite to gaseous end products (Timmer-ten Hoor, 1975). Also, *T. denitrificans* can use sulfur compounds as reductants.

Enzymology of Denitrification

As shown in Figure 1, complete denitrification is a multi-step process, requiring four separate enzymes for the reduction of nitrate and three intermediate nitrogen oxides, and ending in the evolution of nitrogen gas. The basic arrangement of the nitrogen oxide reductases is shown in Fig. 3. A basic description of the nature of these proteins and ancillary proteins is presented here. Additional information can be obtained from two recent reviews (Berks, 1995; Zumft, 1997).

Nitrate Reductase

The first step in denitrification, the two-electron reduction of nitrate to nitrite, is catalyzed by nitrate reductase. Early studies on nitrate reductase activity in cells demonstrated the existence of at least two types of nitrate reductase: a soluble assimilatory enzyme, used when nitrate is the nitrogen source, and a membrane-associated respiratory enzyme. The situation became more complicated when nitrate reductase activity was found in the periplasm of *R. sphaeroides* IL 106 (Sawada, 1980). Further work has demonstrated that this periplasmic enzyme is found in a wide variety of bacteria, including denitrifiers and *E. coli*.

Most denitrifiers contain more than one type of nitrate reductase. The enzyme typically associated with nitrate respiration is a membrane-bound three-subunit complex, whose membrane-anchoring subunit (γ or NarI) is sometimes lost during purification. A significant amount of the research on the respiratory nitrate reductase has made use of non-denitrifiers, particularly *E. coli* (Berks, 1995). The largest of the three subunits (α or NarG) contains molybdenum, bound by the cofactor molybdopterin guanine dinucleotide and a [4Fe-4S] center. The remaining subunit (β or NarH) contains several [4Fe-4S] centers and a [3Fe-4S] center. NarG and NarH are exposed on the cytoplasmic side of the inner membrane. The membrane anchoring subunit typically contains a b-type heme. The direct electron donor of the respiratory nitrate reductase is quinol. The electrons from quinol are thought to be transferred through the heme in the membrane-anchoring subunit to the [Fe-S] centers in NarH and then to the molybdenum center in NarG where nitrate reduction occurs.

The periplasmic nitrate reductase (Nap) is a heterodimer with prosthetic groups similar to those found in the membrane-bound nitrate reductase. The largest subunit (NapA) binds molybdopterin guanine dinucleotide and a [4Fe-4S] center. The smaller subunit binds heme (NapB) that is required for transfer of electrons to the active site. Electrons are transferred from the membrane-associated quinol pool to the Nap complex by a membrane-bound tetra-heme c-type cytochrome, NapC. Insertional inactivation of NapC in *R. sphaeroides* resulted in the loss of nitrate reductase activity (Reyes, 1996). NapC is related to a larger family of proteins, which apparently bind heme via a bis-His ligation (Roldan, 1998).

Recently the crystal structure of the periplasmic nitrate reductase from the non-denitrifying bacterium *Desulfovibrio desulfuricans* has been reported (Dias, 1999). This enzyme contains a single subunit containing the active site and related cofactors. This subunit has significant similarity to NapA from denitrifiers and *E. coli*. Comparisons with other known structures revealed the enzyme is structurally related to formate dehydrogenase and dimethylsulfoxide reductase, both of which contain molybdenum cofactors. Comparisons of these various struc-

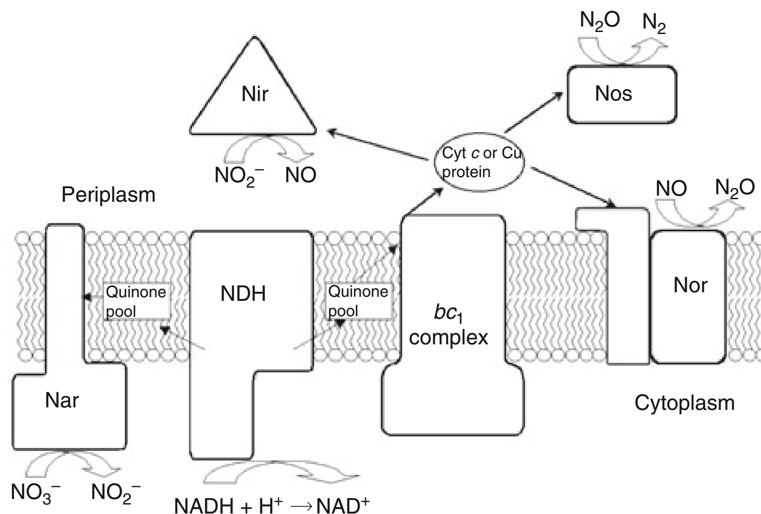

Fig. 3.

tures will be very useful in determining the structural constraints required for nitrate binding and reduction.

The periplasmic and membrane-bound enzymes can be distinguished in several ways. First, the membrane-bound enzyme is sensitive to micromolar levels of azide, whereas the periplasmic form is not (Bell, 1990). Second, the membrane-bound enzyme can reduce chlorate but the periplasmic enzyme is limited to nitrate, a result that led to the development of a useful method to select nitrate reductase mutants. Third, because the active sites of the two enzymes are on different sides of the inner membrane, the differential membrane solubilities of methyl viologen and benzyl viologen can be used to differentiate activities (Carter, 1995). Methyl viologen, which is membrane permeant, can be used as an electron source for both enzymes in whole cell assays. Benzyl viologen, which is membrane impermeant, will act as an electron source only for the periplasmic enzyme in whole cell assays. By comparing the nitrate reductase activity determined with each viologen, the relative levels of activity of each form of nitrate reductase can be estimated. Lastly, the regulation of the two enzymes is different.

While the function of the respiratory nitrate reductase in denitrification is obvious the physiological role of the periplasmic enzyme is unclear. It seems unlikely that the periplasmic enzyme is used by most denitrifiers for energy conservation inasmuch as bacteria such as *R. sphaeroides* 2.4.1 have this enzyme but can not grow anaerobically with nitrate as the sole terminal electron acceptor. Moreover, expression of the periplasmic nitrate reductase is repressed during denitrification in *P. denitrificans* and *R. eutropha* (Warnecke-Eberz, 1993; Sears, 1993). It seems likely that the major role of the periplasmic enzyme is to aid dissipation of excess reductant. This role is supported by the observation that the periplasmic nitrate reductase of *P. denitrificans* GB17 is expressed at a higher level on reduced substrates (that is, those that would likely cause a buildup of reductant) than on more oxidized substrates (Richardson, 1992). However, there are two examples of Nap being the principal nitrate reductase in a denitrifier. Inactivation of the genes encoding Nap in both *Pseudomonas* G-179 (Bedzyk, 1999) and *R. sphaeroides* resulted in a loss of nitrate reductase activity under anaerobic conditions.

The assimilatory nitrate reductase is a single-subunit enzyme. As with the other nitrate reductases the enzyme binds molybdopterin guanine dinucleotide and an [Fe-S] center. The activity of this enzyme is differentiated from the other enzymes, principally because it is only expressed when nitrate is used as a sole source of nitrogen.

Nitrite Reductase

Nitrite reduction is the defining reaction of denitrification—the step that differentiates denitrification from other forms of nitrate metabolism. Nitrite reductase catalyzes the one electron reduction of nitrite to nitric oxide. There are two types of nitrite reductases, but, unlike the different types of nitrate reductase, the nitrite reductases are not structurally related and contain different prosthetic groups. They are, however, both located in the periplasm. They also appear to be functionally redundant (Glockner, 1993). One type of nitrite reductase utilizes copper as a redox active metal (CuNir), and the other utilizes heme-bound iron (cd_1). There is no obvious phylogenetic distribution of the two enzymes. Moreover, both types of enzyme can be found within members of a single genus but have not been found in a single bacterium. In studies assessing the frequency of occurrence of either enzyme in the environment, the cd_1 type was found in a greater number of organisms (Coyne, 1989).

The CuNir has been studied extensively, and much is known about its structure and the nature of the copper centers. Enzymes from several different denitrifiers have been crystallized under different conditions and their high-resolution structures determined (Dodd, 1998; Adman, 1995; Kukimoto, 1994; Godden, 1991). These studies have revealed that the enzyme is a homotrimer with each monomer containing two copper atoms. The copper atom in type-1 centers is attached to Cys, Met and two His residues. Type-1 centers are often referred to as blue copper centers and are found in electron transfer proteins, such as azurin, or in proteins with multiple copper centers, such as laccase (Solomon, 1996). In multi-copper enzymes, including CuNir, the type-1 copper is involved in electron transfer to the active site. The other copper atom in CuNir is bound by three His residues making it a type-2 copper center. Type-2 centers are found in many multi-copper enzymes and are frequently sites of substrate binding. In CuNir, the type-2 center has been shown to be the site of nitrite binding (Adman, 1995). In the CuNir-nitrite cocrystals, the nitrite binds to the type-2 center with its oxygens and upon binding displaces a bound water (Adman, 1995). The copper centers in the cocrystal are in an oxidized state, however, which may influence how the nitrite binds. Studies of synthetic copper centers have suggested that the nitrite nitrogen binds to a reduced copper center (Halfen, 1996).

Less is known about how nitrite reduction proceeds. The redox potential of the type-1 center is higher than that of the type-2 center (Olesen, 1998). This suggests that the type-1 center acts as

a gate, by holding on to an electron until nitrite binds to the type-2 center. Nitrite binding to the type-2 center will raise its potential, permitting electron flow from the type-1 to the type-2 center. Little is known about how nitrite reduction proceeds once the type-2 center is reduced. It has been suggested that the nitrite is reduced and protonated, transiently forming a copper (II)-nitric oxide complex (Murphy, 1997). Because the nitric oxide is bound to oxidized copper, the complex is relatively unstable and nitric oxide can dissociate and diffuse away. It is critical that nitric oxide not bind to the reduced type-2 center, as such a complex would be stable and prevent enzyme function. This may explain how the type-1 center can function as a one-electron gate (Olesen, 1998).

The homodimer cd_1-type nitrite reductase contains a single c-type heme and d_1 heme molecule per monomer. The d_1 heme is a modified tetrapyrrole ring that is partly reduced and has oxo, methyl and acrylate sidegroups (Chang, 1986). The high-resolution structures of the cd_1 type enzymes from *P. denitrificans* GB17 (*Thiosphera pantotropha*) (Fulop, 1995) and *P. aeruginosa* (Nurizzo, 1997) have recently been determined. The c-heme of the oxidized form of the enzyme from GB17 enzyme is bound to two His residues. However, upon reduction, the enzyme refolds causing one of the His ligands to be lost and replaced by a Cys, a more common ligand of c-type cytochromes. This unexpected ligand shuffling does not occur in the *P. aeruginosa* enzyme because both the oxidized and reduced forms have the same His and Cys ligand (Nurizzo, 1998).

The d_1 heme in GB17 enzyme is bound by a Tyr and a His residue. The attachment of the d_1 residue is unusual in that the Tyr residue (identified as the ligand) is not conserved in other cd_1 reductases, nor does a potentially equivalent Tyr in other cd_1 reductases play a role in heme ligation (Cutruzzola, 1997). The high-resolution structure of the *P. aeruginosa* enzyme revealed that the sixth ligand of the d_1 heme is a hydroxide ion. In both the *P. aeruginosa* and GB17 enzymes, the sixth ligand is lost when substrate binds to the d_1 heme. The high-resolution structures of the reduced forms of both enzymes are very similar.

In addition to static structures, a time-resolved structural study of the catalytic cycle of the GB17 enzyme has been carried out (Williams, 1997). This work revealed the large-scale structural changes discussed above. It also indicated that the nitrite nitrogen binds to the reduced enzyme, in contrast with the oxidized CuNir. The ligand shuffling in the GB17 enzyme was postulated to change redox potentials of the heme groups to prevent formation of a Fe(II)-NO complex. The end product (Fe(III)-NO) is ensured by limiting the number of electrons available to the d_1 heme during each nitrite reductase step. Then, Fe(III)-NO can dissociate spontaneously or by the return of the Tyr ligand in the GB17 enzyme.

Both the CuNir and cd_1 enzymes also can reduce oxygen. Early studies often designated the cd_1 enzyme a cytochrome oxidase (Wharton, 1976). The product of oxygen reduction by the cd_1 enzyme is water (Lam, 1969), although it is not clear how four electrons are passed to the oxygen in this process, inasmuch as a one-electron reduction is normally carried out. The oxidase activity of these enzymes is potentially significant because, if activated oxygen species are also produced by CuNir, they can react rapidly with nitric oxide to produce reactive and toxic products such as peroxynitrite (Stamler, 1992).

Nitric Oxide Reductase

The *P. stutzeri* nitric oxide reductase has been the most intensively studied of these enzymes. It is purified as a heterodimer with subunits NorB and NorC being integral membrane proteins (Kastrau, 1994). NorC is c-type cytochrome, proposed to accept an electron from a periplasmic donor and then to pass the electron to NorB. NorB contains two b-type hemes and a non-heme iron. Spectroscopic analysis indicates one b-heme is low spin, whereas the other is high spin and capable of binding carbon monoxide. The low-spin heme is likely to be the direct acceptor of electrons from NorC. Metal analysis revealed that more iron was present than could be accounted for by heme content, indicating non-heme iron. As additional nitric oxide reductases have been purified, similar metal stoichiometry has been observed (Dermastia, 1991; Girsch, 1997). There is no evidence for nitric oxide reductase containing an [Fe-S] center.

The isolation of the genes encoding the nitric oxide reductase in *P. stutzeri* provided significant insight into the structural organization of the enzyme (Zumft, 1994). Examination of the deduced primary sequence indicated that the nitric oxide reductase is related to the heme-copper family of cytochrome oxidases (van der Oost, 1994; Saraste, 1994). Although the overall identity of nitric oxide reductases and cytochrome oxidases is low, a set of six His residues is conserved in pairwise alignments of subunit I of cytochrome oxidase and NorB of nitric oxide reductase. The conservation of these residues is significant because they have been shown to serve as metal center ligands in cytochrome oxidase. In cytochrome oxidase, these His residues bind a six-coordinate heme, five-coordinate heme, and copper—the latter two metal centers

constituting a binuclear center that is the site of oxygen binding and reduction (Iwata, 1995). By comparison, the equivalent His residues in NorB, ligate a six-coordinate heme, a five-coordinate heme and, because there is no copper in nitric oxide reductase, a non-heme iron.

Recent spectroscopic studies on the enzymes purified from *P. denitrificans* (Girsch, 1997) and *P. stutzeri* (Cheesman, 1998) support the structural similarity of nitric oxide reductase and heme-copper oxidases. The active site of nitric oxide reductase is most likely a five-coordinate heme and non-heme iron in close proximity. The two metal centers are close enough to permit interaction of the electron orbitals, as also observed in heme-copper oxidases. NMR, Raman, and FTIR analyses have demonstrated that the local molecular environment of the binuclear center in nitric oxide reductase is distinct from any type of heme-copper oxidase (Moenne-Loccoz, 1998; Mitchell, 1998). The differences in the structure are also manifested in the primary sequences. For example, in the aa_3-type cytochrome oxidases, one of the most highly conserved regions is within membrane spanning helix six, which contains the His residues that bind the five-coordinate heme. Comparison of the aa_3-type consensus sequence of the helix-six region with sequences of the similar region in nitric oxide reductases reveals significant differences in the primary sequences (Fig. 4). Of particular note is the absence of a Glu in nitric oxide reductase that may be involved in proton pumping in cytochrome oxidase and in an overall increase in polarity of the nitric oxide reductase sequence (Verkhovskaya, 1997). The sequence differences also make it possible to differentiate members of this diverse family of proteins. This is important in those bacteria, such as *N. gonorrhoeae* and *N. meningitidis*, where nitric oxide reductase has not been demonstrated, but sequence information indicates the gene encoding this enzyme is present along with other members of the heme-copper oxidase superfamily.

A variant on the *P. stutzeri* prototype structure has recently been identified in the bacterium

Fig. 4.

Ralstonia eutropha (*Alcaligenes eutrophus* H16) (Cramm, 1997). This bacterium contains two nitric oxide reductases, one designated NorZ, a product of genes on the chromosome, and the other designated NorB, a product of genes located on a plasmid. The products of these genes have significant identity (>90%) and are functionally redundant. They have significant similarity with NorB of other nitric oxide reductases such as that of *P. stutzeri*, with the exception of an N-terminal extension of about 300 residues. These extra residues of the *R. eutropha* enzymes likely add two additional membrane-spanning regions and a large hydrophilic loop. The primary sequence of the N-terminal extension does not have similarity with other known proteins. Part of its function may relate to the observation that there is no evidence for a gene encoding a NorC equivalent in *R. eutropha*. This suggests that the amino terminal extension is functionally equivalent to NorC, but no direct evidence has been provided in support of this conclusion.

A gene whose product is similar to the NorB and NorZ products has turned up in the genome of *Synechocystis* strain PCC 6803 (Kaneko, 1996). Interestingly, genes encoding nitrite and nitrous oxide reductase were not identified in this bacterium. Because PCC 6803 can not reduce nitrite, it has never been considered as capable of gaseous nitrogen oxide metabolism. This makes the presence of nitric oxide reductase unexpected. However, as discussed above, other strains have recently been characterized which have nitric oxide reductase but lack nitrite reductase, suggesting this mode of truncation of the denitrification electron transport chain may be fairly prevalent. Ongoing genome sequencing efforts in *N. meningitidis* (Sanger Centre, 1999) and *N. gonorrhoeae* (Roe, 1999) have also identified genes whose products are similar to the *R. eutropha* nitric oxide reductases. *Neisseria* and *R. eutropoha* are both in the β-subgroup of the proteobacteria (Table 1), but it is unclear if this class of enzymes will be preferentially found in one taxonomic group. Alignment of nitric oxide reductases also demonstrates that the *R. eutropoha*-type nitric oxide reductases have other unique sequence motifs not found in the *P. stutzeri* type reductases (Fig. 4).

The reduction of nitric oxide to nitrous oxide occurs at the binuclear center. Current models suggest that two nitric oxide molecules bind at the active site, although it is not clear if nitric oxide binds to both metal centers or if a dinitrosyl complex is formed (Ye, 1994; Moenne-Loccoz, 1998). Electrons enter the Nor complex through the cytochrome c in NorC and then flow to the six-coordinate heme in NorB. Electrons are then transferred to the binuclear center. The high affinity of reduced heme for nitric oxide

makes it unclear if reduction of the catalytic site involves formation of a ferrous heme-nitric oxide species. Irrespective of the exact electron transfer steps, it is clear that proximity of the two nitric oxide molecules is critical in the formation of the N-N bond.

Nitrous Oxide Reductase

The presence of nitrous oxide reductase can be identified independently of the other reductases because many organisms can grow with nitrous oxide as sole terminal oxidant. This has led to the identification of nitrous oxide reductase in several bacteria that are not complete denitrifiers (Yoshinari, 1980; Payne, 1982). The purification and characterization of nitrous oxide reductase was difficult because its activity is lost in cell extracts. Nutritional studies had identified copper as an essential nutrient for nitrous oxide reductase activity (Matsubara, 1982) and further work led to the isolation of a soluble copper protein which, under the proper conditions, had nitrous oxide reductase activity (Zumft, 1982). Additional studies have demonstrated that enzyme purified anaerobically and assayed using reduced viologens as electron donor has the highest specific activity. The latter observation is somewhat puzzling because the natural electron donors to nitrous oxide reductase are likely to have much higher redox potential.

Nitrous oxide reductases from several complete denitrifiers have been extensively characterized (Riester, 1989; SooHoo, 1991; Hulse, 1990; Snyder, 1987). These enzymes are all related and are multi-copper periplasmic proteins. The protein appears to be homodimeric in most preparations, with four coppers per subunit. Current data suggest there are two binuclear copper centers in the active enzyme. These centers undergo spectroscopic shifts depending on their redox state, and this has resulted in the characterization of different colored forms of the enzyme.

One of the copper centers has been structurally defined as a CuA site. The CuA center was described originally in the heme copper oxidases. However, the exact nature of this site was unclear until the related site in nitrous oxide reductase was characterized. Analysis of the deduced primary sequence of the nitrous oxide reductase identified a structural motif found otherwise only in the CuA-containing subunit of cytochrome oxidase (Viebrock, 1988). Additional spectroscopic studies provided further evidence of the similarities between one of the sites in nitrous oxide reductase and the CuA site of cytochrome oxidase (Farrar, 1991; Scott, 1989; Antholine, 1992). A more precise understanding of the structure of the CuA center has been obtained with the determination of the high-resolution structure of two cytochrome oxidases (Tsukihara, 1995; Ostermeier, 1997). In both cytochrome oxidase and nitrous oxide reductase, the CuA site has a role in transferring electrons from external electron donors to the active site. The other copper center in nitrous oxide reductase is, by exclusion, assumed to be the site of nitrous oxide binding and reduction. This site has been designated CuZ. Initial studies suggested both CuZ and CuA sites were bis-thiolate-bridged dinuclear copper sites (Farrar, 1991). Isolation of spectral signals arising from the CuZ center has proved difficult. Spectroscopic analysis of the CuZ signals has relied on poising the enzyme in specific oxidation states to make the CuA center Electron Paramagnetic Resonance (EPR) or optically silent. However, it has been suggested that the signals assigned to the CuZ site are actually different redox states of the CuA center (Farrar, 1998). In this latter work, it was shown that both the CuA site and the putative CuZ site were bis-thiolate-bridged dinuclear copper sites. This would require, if these were separate sites, four conserved Cys residues for formation of the two binuclear centers. Alignment of deduced nitrous oxide reductase sequences does not identify four conserved Cys residues. Instead, there are only two absolutely conserved Cys residues in nitrous oxide reductase. It is possible that the position of a Cys is shifted in one sequence relative to others accounting for the deficiency of conserved residues. However, mutation of one of the Cys residues outside the CuA domain does not lead to a loss of nitrous oxide reductase activity (Dreusch, 1996). Taken together, these data are not consistent with assuming that there are two bis-thiolate-bridged dinuclear copper sites in nitrous oxide reductase.

If conserved residues do not bridge the catalytic center, what then is its structure? Alignment of available nitrous oxide sequences does indicate there are a number of completely conserved His residues. The catalytic center might therefore be a His-ligated structure similar to the Type 3 copper centers found in enzymes such as laccase (Solomon, 1996). However, there is currently no direct evidence for the presence of such a center.

Given the uncertainty in the structure of the catalytic center, it is difficult to develop a useful model of the nitrous oxide reductase catalytic cycle. Nitrous oxide is chemically inert and also a poor ligand, making its reduction an interesting problem in transition metal-ligand chemistry (Kroneck, 1990). Other enzymes, including nitrogenase (Jensen, 1986) and carbon monoxide dehydrogenase (Lu, 1991), also have been found to have nitrous oxide reductase activity, indicat-

ing that it is possible that transition metals other than copper can reduce nitrous oxide.

Only copper-containing nitrous oxide reductases have been purified from complete denitrifiers. However, there appear to be variants of this structure present in other bacteria. The nitrous oxide reductase from *W. succinogenes* has been purified and shown to contain both copper and iron (Teraguchi, 1989; Zhang, 1991). The iron is attributed to an associated cytochrome c, though EPR suggests the presence of a CuA site. Because the primary structure of the *W. succinogenes* enzyme is unknown, the relationship of this enzyme to other nitrous oxide reductases is unknown. Another novel nitrous oxide reductase has been suggested to occur in *Flexibacter canadensis* (Jones, 1990). Most nitrous oxide reductases are inhibited by acetylene (Balderston, 1976; Yoshinari, 1976). However, the nitrous reductase from *F. canadensis* is insensitive to this compound (Jones, 1990). Preliminary characterization of this enzyme suggests it is membrane-associated, further differentiating it from other reductases (Jones, 1992). The nitrous oxide reductase from *R. sphaeroides* IL106 was also thought to be divergent because it was reported to contain Zn and Ni in addition to copper (Michalski, 1986). However, a more rigorous characterization of this enzyme suggests it is similar to typical copper-containing enzymes (Sato, 1998).

Genetics of Denitrification

Gene Organization

Analysis of the structure and organization of denitrification genes has been investigated in denitrifiers that are primarily members of the proteobacteria. The most extensive characterizations have been carried out with genomes of the pseudomonads as well as that of *P. denitrificans* strains. Although no true denitrifier has had its chromosome sequenced, there are several projects to sequence organisms that are partial or complete denitrifiers.

NITRITE AND NITRIC OXIDE REDUCTASE The most extensive examinations of denitrification gene organization have involved *P. aeruginosa* and *P. stutzeri* in which the nitrite reductase and nitric oxide reductase structural genes are about 10 kb apart (Arai, 1995; Braun, 1992). This tight linkage is found also in *P. denitrificans* (Baker, 1998). In general, such tight linkage of the nir and nor gene clusters is not observed in those denitrifiers containing a copper-type nitrite reductase. In *R. sphaeroides* strains IL106 and 2.4.3, the genes for nitrite reductase are not closely linked to the genes for nitric oxide reductase (Schwintner, 1998; Tosques, 1997). This is also the case in *N. gonorrhoeae* (Roe, 1999) and *N. meningitidis* (Sanger Centre, 1999). One exception is *Pseudomonas* G-179 (which is apparently a member of the α proteobacteria subclass) where it has been shown that the gene encoding the copper-type nitrite reductase is in a cluster with the genes for nitric oxide reductase and the periplasmic nitrate reductase (Bedzyk, 1999).

Genes encoding proteins required for assembly of a particular reductase are typically found clustered with the structural gene for that particular reductase. For example, in those bacteria encoding a cd_1-type nitrite reductase, several genes whose products are involved in the synthesis of d_1 heme will be required for the production of an active enzyme. Systematic inactivation of genes closely linked to the nitrite reductase structural gene has identified a number of genes whose products are involved in heme d_1 biosynthesis (Kawasaki, 1997; Palmedo, 1995). Although this has led to the identification of a set of genes uniquely required for heme synthesis during denitrification, the details of the biosynthesis of heme d_1 are not elucidated as yet.

The organization of the genes for assembly of the cd_1 protein is dissimilar in every denitrifier. In *P. aeruginosa*, eleven adjacent genes have been identified whose products are suggested to be involved in nitrite reductase activity (Arai, 1994). These genes are transcribed in the same direction and are postulated to be transcribed in a single transcript (Kawasaki, 1997). In *P. stutzeri*, this cluster of genes has been rearranged so that the genes are no longer adjacent and at least three different transcripts are produced (Palmedo, 1995).

The total number of proteins that is required for expression of an active copper-containing nitrite reductase would be expected to be less than with the heme-type nitrite reductase. Examination of sequence flanking the structural gene encoding the copper-type nitrite reductase in *N. gonorrhoeae* (Roe, 1999), *N. meningitidis* (Sanger Centre, 1999), *R. sphaeroides* 2.4.3 and *Pseudomonas* G-179 (Bedzyk, 1999) revealed only one other conserved gene. In *R. sphaeroides* 2.4.3, this undesignated gene is located about 200 bp downstream of the putative translation stop of nirK (the nitrite reductase structural gene). Preliminary evidence suggests it is transcribed from the nirK transcription start. The role of the product of this gene is unclear. The difference in the amount of DNA required to produce an active copper-containing nitrite reductase versus the heme-containing nitrite reductase is notable. In *R. sphaeroides* 2.4.3, about 2.5 kb are required to encode the copper-

containing nitrite reductase and the accompanying gene of unknown function. In *P. aeruginosa*, about 10 kb appear to be required to code for proteins necessary for assembly of an active nitrite reductase.

The structural genes for the heterodimeric form of nitric oxide reductase, designated norC and norB, have been sequenced from a number of denitrifiers. In every case, the transcription start precedes norC and the gene order is norCB. The complete nor operon consists of norCB and one or two additional genes. For example, in *P. denitrificans* and *R. sphaeroides* norQ and norD follow norB (Bartnikas, 1997; De Boer, 1996). In *P. aeruginosa* and *P. stutzeri*, norD follows norB (Arai, 1995; Zumft, 1994). In both these pseudomonads norQ (designated nirQ) is present, but it is immediately upstream, and divergently transcribed from the structural gene for nitrite reductase, nirS (Arai, 1994; Jungst, 1992). Inactivation of norQ or norD leads to a loss of nitric oxide reductase activity but does not appear to inhibit assembly of nitric oxide reductase (Jungst, 1992; Mitchell, 1998; De Boer, 1996). This suggests the likelihood that both NorQ and NorD are accessory proteins required for the assembly of nitric oxide reductase. One possible role would be insertion of non-heme iron.

Neither norQ nor norD has been found in those denitrifiers encoding the single subunit type of nitric oxide reductase. There are no obvious orthologs of either norQ or norD present in the chromosome of *Synechocystis* sp. strain PCC 6803 (Kaneko, 1996). Nor have norQ or norD orthologs been identified in the ongoing genome sequencing efforts in *N. gonorrhoeae* or *N. meningitidis*. The absence of these proteins in these denitrifiers is somewhat surprising given the sequence similarity of the single subunit and heterodimeric nitric oxide reductases. The sequence of the *R. eutropha* norB is preceded by an open reading frame (ORF) encoding a protein containing a high percentage of His residues (Cramm, 1997). It is possible the product of this gene might play a role in assembly of an active nitric oxide reductase.

R. eutropha is unusual in that it contains two nitric oxide reductase structural genes (Cramm, 1997). One of these, norB, is located on a megaplasmid while the other, norZ, is located on the chromosome. This is the only bacterium described in which functionally redundant terminal N-oxide oxidoreductases have been observed. It is also interesting that in *R. eutropha* norZ does not appear to be tightly linked to the nitrite reductase structural gene. *R. eutropha* contains a cd_1-type nitrite reductase. This genetic organization is different from those bacteria containing a heterodimeric nitrite oxide reductase and a cd_1-type nitrite reductase.

In *P. denitrificans*, there are two additional genes, designated norE and norF, whose products appear to be required for nitric oxide reductase activity (De Boer, 1996). These genes are located immediately downstream of the norCBQD cluster. Insertional inactivation of either norE or norF reduces nitric oxide reductase activity but does not significantly affect its expression. Orthologs of norE have been found in other denitrifiers, for example, the ORF175 protein in *P. stutzeri* (Glockner, 1996) and in *Pseudomonas* sp. G-179 (Bedzyk, 1999). However, no norE ortholog has been identified in *R. sphaeroides* or in those bacteria encoding the single subunit nitric oxide reductase. No obvious norF orthologs have been identified, but genes whose products have some similarity to norF have been described in *P. stutzeri* (ORF82) and in *Pseudomonas* sp. G-179 (Bedzyk, 1999). The role of norE and norF remain undetermined. However, because of its similarity to the subunit III of cytochrome oxidases, it has been suggested NorE is a third subunit of the nitric oxide reductase protein complex (De Boer, 1996). Experimental conformation for NorE as a part of an active nitric oxide reductase complex is lacking.

Nitrous Oxide Reductase While the nir and nor gene clusters are often linked, the location of the nos gene cluster (nos refers to genes related to nitrous oxide reductase and not to genes for nitric oxide synthase) relative to other denitrification genes is more variable. In *P. stutzeri*, the genes encoding nitrous oxide, nitrite and nitric oxide reductase are within a stretch of about 30 kb (Jungst, 1991). In *P. aeruginosa*, the nitrous oxide reductase gene cluster is not as tightly linked to the nitrite and nitric oxide reductase genes (Vollack, 1998). However, the genes for all four nitrogen oxide reductases are located within the 20- to 36-min segment of the *P. aeruginosa* chromosome. In several denitrifiers, including *R. eutropha* (Zumft, 1992), *Sinorhizobium meliloti* (Holloway, 1996) and *R. capsulatus* (Rhodobacter, 1999), nos genes are found on plasmids. By comparison, all denitrifiers characterized in detail have both nir and nor located on the chromosome. The variable location of the nos cluster may reflect nitrous oxide's lack of toxicity, and therefore the accumulation of nitrous oxide that would follow the loss of nitrous oxide reductase activity has only limited consequences.

Gene organization within the nos cluster is much more conserved than is that in the nir or nor clusters. In almost every sequence, nosR is immediately upstream of nosZ, and nosZ is typically followed by nosDFYL. Undefined genes clustered with nosZ are likely to be involved in assembly of an active nitrous oxide reductase,

perhaps in copper incorporation. Inactivation of nosF, nosD or nosY leads to production of an inactive nitrous oxide reductase (Zumft, 1990). Sequence analysis indicates that nosY encodes a membrane-bound protein, nosD a periplasmic protein, and nosF a cytoplasmic nucleotide-binding protein. It has been suggested these proteins form a complex involved in copper processing and insertion into nitrous oxide reductase (Zumft, 1997).

In *S. meliloti*, a gene that has been designated nosX follows nosL. Inactivation of nosX causes a loss of nitrous oxide reductase activity in *S. meliloti* (Chan, 1997). Possible nosX orthologs have been found in other denitrifiers including "*A. cycloclastes*" (McGuirl, 1998) and *B. japonicum* (Genbank accession number {AJ002531}). A gene encoding a product similar to the nosX product has also been identified in *P. denitrificans*, but since it is part of the nir gene cluster it has been designated nirX (Genbank accession number AJ001308). A nosX ortholog has not been identified as yet in the peudomonads. The role of nosX is unclear but current data do not suggest a role in copper processing.

Isolation of mutants of *P. stutzeri* unable to use nitrous oxide as sole terminal oxidant led to the isolation of an additional gene whose product is required for nitrous oxide reductase activity. This gene was designated nosA, and it was shown to encode an outer membrane protein that is required for copper transport into the cell (Lee, 1991; Lee, 1989). Inactivation of nosA results in expression of the nitrous oxide reductase apoprotein. Putative nosA orthologs have been found in other denitrifiers, including *P. aeruginosa* (Yoneyama, 1996), but nosA is not found in the nos cluster of *P. stutzeri*. This organization may be because the nosA product is playing a more general role in cell physiology.

Nitrate Reductase

Of the various nitrate reductases, the respiratory and periplasmic forms have been studied in the most detail in the context of denitrification. Genes encoding the respiratory nitrate reductase, designated nar, have been completely sequenced in *P. aeruginosa* (Genbank accession number {Y15252}) and partially sequenced in *P. denitrificans* (Berks, 1995) and *Pseudomonas fluorescens* (Philippot, 1997). The nar genes are not clustered with other genes required for denitrification in *P. aeruginosa* (Vollack, 1998). The relatively limited interest in the nar genes in denitrifiers is due to the extensive study of nar genes in *E. coli* and other non-denitrifiers.

Genes encoding the periplasmic nitrate reductase have been characterized in several denitrifiers including *P. denitrificans* GB17 (Berks, 1995) and *R. sphaeroides* (Reyes, 1996). The structural genes for this nitrate reductase are napA and napB: napA encodes the molybdopterin cofactor and napB encodes the cytochrome c containing subunit. These two genes are clustered with other genes that have been designated napCDE. The napC gene encodes a membrane-bound cytochrome c, which is the likely electron donor for the periplasmic nitrate reductase; napD encodes a cytoplasmic protein and napE a small membrane protein. The function of these genes' products is unknown. The nap genes of *P. aeruginosa* are present on the chromosome but are not tightly linked to nar or other denitrification-related gene clusters (Vollack, 1998). In *R. eutropha* (Siddiqui, 1993)and *R. sphaeroides* strain 2.4.1 (Schwintner, 1998), the nap genes are localized on plasmids. In *R. sphaeroides* IL106, the nap genes are apparently located on the chromosome (Schwintner, 1998). In *Pseudomonas* G-179, the nap genes are part of a large cluster which includes nir and nor genes (Bedzyk, 1999).

Additional Genes Required for Denitrification

A few other genes frequently associated with nitrogen oxide gene clusters deserve mention. One is hemN, which encodes an oxygen-independent coproporphyrinogen oxidase (Gibson, 1992). *R. sphaeroides* encodes two hemN paralogs, the second of which is designated hemZ (Zeilstra-Ryalls, 1995). The *R. sphaeroides* hemN is clustered with the genes encoding nitric oxide reductase (unpublished). Inactivation of hemN (which was originally designated hemF) inhibits the ability to grow anaerobically under any conditions tested (Gibson, 1992). Aerobic growth is not affected because there is an oxygen-dependent form of this enzyme. The role of the hemZ product is unclear. Interestingly, hemZ is adjacent to fnrL whose product is an important regulator of anaerobically expressed genes (Zeilstra-Ryalls, 1995). These two genes are clustered with the ccoN operon that encodes the cbb_3-type oxidase. The cbb_3-type oxidase is a heme-copper enzyme and is the oxidase with the highest level of similarity to nitric oxide reductase (Saraste, 1994). It is notable then that both hemZ and hemN are clustered with related terminal oxidoreductases and regulatory proteins important in maintaining anaerobic physiology. It is possible that this gene arrangement may have occurred by gene duplication providing further evidence for the evolutionary link between aerobic respiration and denitrification.

The hemN gene is clustered with denitrification genes in *Pseudomonas* sp. G-179 (Bedzyk, 1999) and is clustered with the ccoN genes in both *P. denitrificans* (van Spanning, 1997) and *P. aeruginosa* (Zumft, 1997). A hemN ortholog has not been found in the nor cluster in *P. denitrificans* or *P. aeruginosa*. The regulation of hemN in *P. aeruginosa* (discussed in more detail below) further emphasizes the importance of the activity of the hemN product during denitrification (Rompf, 1998).

Sequencing of the nor cluster in *R. sphaeroides* (Bartnikas, 1997) and nos region in *P. stutzeri* (Glockner, 1996) has revealed a gene present in both regions whose product may be important to the physiology of denitrification. This gene has been designated nnrS in *R. sphaeroides* and orf396 in *P. stutzeri* (Fig. 5). The product of the genes from both bacteria is a membrane protein probably containing twelve membrane-spanning regions. In *R. sphaeroides*, nnrS is expressed only during denitrification and is regulated by NnrR, which also regulates nirK and nor (unpublished). Inactivation of nnrS has no obvious effect on growth under any conditions (unpublished). Though nnrS orthologs have not been found in the denitrification gene clusters of other well studied denitrifiers, examination of ongoing genomic sequencing efforts reveal the presence of nnrS orthologs in every denitrifier. In *R. capsulatus*, a nnrS ortholog is present on a plasmid and is closely linked to the nos genes (Rhodobacter, 1999). There is also an nnrS ortholog located on the chromosome. Copies of genes encoding products similar to nnrS have been identified in the *N. gonorrhoeae* (Roe, 1999), *N. meningitidis* (Sanger Centre, 1999) and *P. aeruginosa* chromosome (Pseudomonas, 1999), although none of these are clustered with denitrification genes. Significantly, nnrS orthologs have not been found in non-denitrifying bacteria. The function of nnrS has not been determined, but it is obviously not essential for denitrification or it would likely have been isolated in mutant screens. However, work in *R. sphaeroides* and its distribution among the bacteria indicates nnrS is a denitrification-associated gene. It seems likely that as more work is done on the genetics of denitrification, many genes that are not essential to, but whose products are physiologically important for, denitrification will be described.

Regulation of Genes Required for Denitrification

This section will focus primarily on the regulation of those genes encoding respiratory nitrogen oxide reductases and genes required for their assembly. As denitrification depends on the presence of nitrogen oxides, it is natural to describe denitrification genes as part of a stimulon, a term that refers to operons responding together to a particular environmental stimulus (Neidhardt, 1990). In general, the regulators of denitrification can be differentiated into the nitrate, nitric oxide, and nitrous oxide stimulons. The organization of denitrification genes roughly reflects the organization of the stimulons. The nitrate and nitrous oxide stimulons are primarily made up of the nar and nos gene clusters, respectively. These two, independently regulated, gene clusters are not linked to each other and are frequently distant from other denitrification-related clusters. The nitric oxide stimulon is made up of both the nir and nor clusters. These two gene clusters are the most strongly linked of any of the denitrification gene clusters.

As denitrification is, in most cases, an anaerobic process, other stimulons and regulons required for anaerobic growth overlap the denitrification-related stimulons. This overlap can make it difficult to differentiate regulatory factors that directly modulate gene expression from those that indirectly affect gene expression. This discussion will focus on those proteins that current data suggest are directly involved in regulation of the nitrogen oxide reductases. It is important to note that a particular stimulon will likely include genes whose products are not directly required for denitrification and, consequently, not covered in this review. However, this does not minimize the usefulness of organizing denitrification genes into stimulons.

One other important consideration is the relationship of denitrification and oxygen respiration. Denitrification is primarily an alternative form of respiration inasmuch as oxygen is a preferred oxidant. However, this does not imply that all denitrifiers have the same set point at which oxygen respiration is switched to nitrogen oxide respiration. Available data suggest that the onset of expression of denitrification genes occurs over a wide range of oxygen concentrations. The best example of an aerobic denitrifier is *P. denitrificans* GB17, which was originally described as an aerobic denitrifier (Robertson, 1984). In addition, other strains have been described as aerobic denitrifiers (Bonin, 1991; Patureau, 1994; van Niel, 1992; Frette, 1997; Robertson, 1995; Ka-Jong, 1997). None of the intensively studied model denitrifiers activate gene expression, even at moderate concentrations of oxygen. Therefore, the molecular mechanisms that permit aerobic denitrification are not currently understood.

Nitrate Stimulon The presence of nitrate and a reduction in oxygen tension stimulates

Fig. 5.

expression of the nar genes. Because nitrate respiration leads to the production of the other denitrification intermediates, it can be difficult in wild type cells to demonstrate that nitrate is the effector for only a limited set of genes. Evidence for a nitrate stimulon was then demonstrated by experiments using nitrite reductase-deficient cells. These experiments showed that nitrate alone was not sufficient to activate expression of genes whose products are required for reduction of the other nitrogen oxides (Tosques, 1997; Korner, 1993). Nor does nitrite alone cause significant induction of nitrate reductase. However, there is evidence of cross talk between the nitrate and nitrous oxide stimulons in *P. stutzeri* and *P. denitrificans* (Baumann, 1996; Korner, 1989), although it is difficult to rationalize why this occurs. Experiments monitoring gene expression in relation to oxygen concentration show that the nar genes and nitrate reductase are expressed at higher oxygen levels than the nir and nor genes (Baumann, 1996). Expression of nos occurs at similar oxygen levels.

The molecular mechanisms required for nar activation have not been extensively studied in a denitrifying bacterium. A pair of two component sensor-regulators is responsible for regulating nar in *E. coli*. The function of these proteins has been extensively studied and has been reviewed in Darwin (1996). A nitrate sensor (NarL) and its response regulator (NarX) have been characterized in *P. stutzeri*. However, their deletion did not affect denitrification (Hartig, 1999). This has led to the suggestion that there is a nitrate-responsive system that functions independently of the NarXL system.

Nitric Oxide Stimulon Even before isolation of the proteins regulating the genes encoding the nitrite and nitric oxide reductases, it had been observed that the expression of nitric acid reductase in nitrite reductase mutants was negatively affected. This dependence of nitric oxide reductase expression on the activity of nitrite reductase has been demonstrated in many denitrifiers (Ye, 1992; Tosques, 1997; de Boer, 1994; Zumft, 1994). The decrease in nor gene expression in nitrite reductase mutants appears indirect, as any mutation that leads to a loss of nitrite reductase activity has a negative affect on nor expression (de Boer, 1994; Zumft, 1994). The expression of nir genes is also dependent on nitrite reductase activity (Tosques, 1997). The expression of nir is not directly dependent on nitric oxide reductase, but the accumulation of nitric oxide in nitric oxide reductase mutants probably affects nitrite reductase activity (Kwiatkowski, 1996; Zumft, 1994).

The observation that it is nitrite reductase activity not nitrite reductase per se that is required for the expression of nir and nor genes suggests that a product of nitrite reduction is required for gene expression. An obvious candidate for the likely effector is nitric oxide, a possibility consistent with the observation that addition of nitric oxide generators to nitrite reductase-deficient strains results in expression of both nir and nor genes (Kwiatkowski, 1996). Moreover, trapping of nitric oxide by hemoglobin decreases expression of nir and nor genes (Kwiatkowski, 1996). The accumulated evidence strongly indicates that it is the production of nitric oxide that stimulates expression of those genes in the nitric oxide stimulon. However, it is also possible that a derivative of nitric oxide may be the actual signal.

The role of nitric oxide as a signal molecule in humans is well known (Schmidt, 1994). The first use of nitric oxide as a signal molecule by a living organism, however, was likely by denitrifying bacteria. It is easy to rationalize why nitric oxide or some derivative serves as a signal molecule for denitrifiers. Denitrifying bacteria must keep the steady state levels of nitric oxide low to minimize potential cytotoxic reactions. As nitric oxide acts to regulate expression of the genes whose products are responsible for establishing the steady state levels of nitric oxide, the possibility nitric oxide might accumulate to cytotoxic levels is abated. Also, as it reacts rapidly with oxygen, nitric oxide will accumulate to the levels required to activate gene expression only when oxygen tension is low. This permits a single molecule to be used as an indicator of both oxygen and nitrogen oxide concentrations in the environment. The direct control of nitric oxide levels by oxygen may explain why nitrite reductase is expressed at lower oxygen concentrations than nitrate and nitrous oxide reductase.

In several denitrifiers, a gene has been isolated whose product directly regulates nir and nor expression but not nar or nos genes. The regulation of nir and nor by a single regulatory protein not involved in regulating expression of the other nitrogen oxide reductases is consistent with studies of gene expression indicating three separate stimulons. Not surprisingly, this gene has been given a different name in each bacterium. In *P. denitrificans*, it is designated nnr (van Spanning, 1995), nnrR in *R. sphaeroides* (Tosques, 1996), dnr in *P. aeruginosa* (Arai, 1995) and dnrD in *P. stutzeri* (Hartig, 1999). The family of proteins encoded by these genes will be referred to as the Nnr family in this review. Recent sequencing efforts have also identified likely orthologs in *Synechocystis* strain PCC 6803 (Kaneko, 1996), *Pseudomonas* sp. G-179 (Bedzyk, 1999) and *R. capsulatus* (Rhodobacter, 1999). All of these proteins are members of the

Fnr/CRP family of transcriptional regulators (Spiro, 1994).

Comparison of the sequences of these various proteins reveals little about how they might interact with an effector. Significantly, there are no obvious metal binding motifs in any of these proteins. Fnr and CooA, which are also members of the Fnr/CRP family, have metal centers that are targets for effector interaction. Fnr from *E. coli* binds an iron-sulfur center that apparently undergoes structural changes as the oxygen concentration in the cell changes (Popescu, 1998). CooA from *Rhodospirillum rubrum* binds a heme protein that acts as a carbon monoxide sensor (Shelver, 1997). Current data is not consistent with members of the Nnr family containing any type of metal center.

Phylogenetic analysis of the Nnr family reveals that the relatedness of the proteins does not coincide with relatedness predicted by 16S rRNA analysis. For example, *R. sphaeroides* is closely related to both *R. capsulatus* and *P. denitrificans*. The Nnr from *P. denitrificans* and the putative Nnr ortholog identified in *R. capsulatus* have significant identity but have only limited similarity to NnrR from *R. sphaeroides* (Fig. 6). This suggests species relatedness is not the major factor controlling the degree of relatedness of the members of the Nnr family.

Based on available data, a model can be presented in which nitrite produced by nitrate reductase activity is reduced by nitrite reductase, and some compound (most likely nitric oxide or a nitric oxide derivative) activates the transcriptional regulator resulting in expression of genes in the nitric oxide stimulon. Even though this model may be generally correct, differences appear in the regulation of the expression of various members of the Nnr family. In *R. sphaeroides*, NnrR appears to be constitutively expressed but may be negatively autoregulated (Tosques, 1996). There is no evidence of negative autoregulation of Nnr in *P. denitrificans* (van Spanning, 1995). Expression of Dnr in *P.* may be regulated by another member of the Fnr/Crp family, Anr, an apparent ortholog of Fnr in *E. coli* (Arai, 1995). This suggests a regulatory hierarchy where under low oxygen tension Anr activates expression of dnr, whose product can then activate expression of nir and nor genes under appropriate conditions. This type of regulatory hierarchy is not present in *P. stutzeri* (Hartig, 1999).

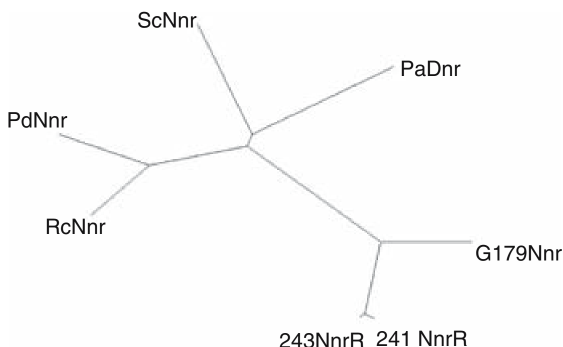

Fig. 6.

In *P. aeruginosa*, Dnr and Anr both regulate hemN, which encodes an oxygen-independent coproporphyrinogen oxidase required for heme synthesis (Rompf, 1998). The hemN gene is also coregulated by NnrR and FnrL in *R. sphaeroides* (Shapleigh, unpublished). Both FnrL and NnrR regulate the gene encoding pseudoazurin in *R. sphaeroides* (Jain and Shapleigh, unpublished). This dual regulation of selective genes by both a global regulator such as Anr/Fnr and a regulator of a limited set of genes such as Dnr/NnrR suggests that transcriptional activation by the global regulator alone is not sufficient for optimal growth under denitrification conditions. Therefore, denitrifiers have developed mechanisms to ensure sufficient levels of expression of genes whose products are in heavy demand during denitrification and other modes of anaerobic growth. Further, in *R. sphaeroides* nitrite accumulation negatively affects expression of FnrL regulated genes (Shapleigh, unpublished). This may provide another explanation as to why FnrL and NnrR are dual regulators of specific genes. It seems likely such dual regulation will be observed in other denitrifiers and will probably encompass a larger set of gene targets.

NITROUS OXIDE STIMULON Evidence for a nitrous oxide stimulon was initially provided by the observation that growth on nitrous oxide strongly stimulates nitrous oxide reductase expression, modestly stimulates expression of the nitrate reductase, and does not stimulate expression of nitrite or nitric oxide reductase (Korner, 1989). The observation that inactivation of the regulator of genes in the nitric oxide stimulon did not affect growth at the expense of nitrous oxide provided additional support for existence of a set of genes whose transcription depends solely on the presence of nitrous oxide.

The nature of the genes responsible for regulating nitrous oxide expression is not well defined. One gene suggested to play a role in regulation of nos genes is nosR. Inactivation of nosR in *P. stutzeri* inhibited expression of nosZ, the nitrous-oxide-reductase structural gene (Cuypers, 1992). NosR is a putative membrane protein containing a cytoplasmic C-terminal domain with two motifs that resemble [Fe-S] containing motifs. This unusual combination of a membrane bound, [Fe-S] protein involved

in expression of a copper-containing protein increases interest in this protein. It seems unlikely NosR is involved in copper metabolism, as inactivation of nosR results in the inhibition of nosZ transcription (Cuypers, 1992). In contrast, inactivation of nosFDY, suggested to be involved in copper metabolism, does not cause inhibition of nosZ transcription (Zumft, 1990).

Other Regulatory Proteins Searches for regulatory proteins required for expression of denitrification genes are only just beginning to identify possible regulators and to determine their physiological roles. Although the majority of the genes discussed in the preceding sections have been found in most denitrifiers, other putative regulatory proteins have been identified in only a single bacterium. One example is nirI, a gene implicated in regulation of expression of nirS, the structural gene for nitrite reductase in *P. denitrificans* (Genbank accession number AJ001308). Interestingly, the nirI product is similar to NosR, which is required for expression of nos genes. The involvement of NirI in nitrite reductase expression makes it less likely that NosR is involved in nitrous oxide reductase assembly. Instead, NosR and NirI are likely members of a family of proteins involved in regulation of nitrogen oxide metabolism in denitrifiers. Other regulatory proteins have been found clustered with denitrification genes, but their role in denitrification has not been defined. Clearly, our understanding of the regulation of denitrification genes is very limited. The list of the various proteins involved in regulation will expand, no doubt, as additional denitrifiers are characterized in greater detail.

Metabolism of Related Nitrogen Oxides

Because of its reactivity, nitric oxide will react with many compounds generating a wide range of different nitrogen oxide containing molecules. Some of these derivatives are more toxic than nitric oxide. For example, nitric oxide can react with the thiol of glutathione to generate S-nitrosoglutathione (GSNO), which has been shown to be more toxic for *Salmonella typhimurium* than nitric oxide (De Groote, 1995). Another very toxic nitric oxide derivative, peroxynitrite, is generated from the reaction of nitric oxide and superoxide (Squadrito, 1998). There has been a great deal of interest in the interaction of these types of compounds with pathogenic bacteria inasmuch as they are generated as part of the host defense mechanism during infection. These compounds could possibly be generated during denitrification as well. If so, denitrifiers have probably developed mechanisms to mitigate the potentially cytotoxic effects of such derivatives.

Despite the paucity of work on the metabolism of nitric oxide derivatives by denitrifiers, some data suggest that denitrifiers are useful models for understanding how cells mitigate nitric oxide toxicity. In experiments assessing the sensitivity of *R. sphaeroides* strains to GSNO, those strains with nitrite reductase activity were completely resistant to levels of GSNO to which *S. typhimurium* exhibited sensitivity (Wu, 1998). Comparable assays on a naturally occurring nitrite reductase-deficient strain of *R. sphaeroides* demonstrated that its sensitivity to GSNO was similar to that exhibited by *S. typhimurium*. There was no indication that the resistant strain had any special capacity to degrade GSNO suggesting the likely modification of a GSNO-sensitive target in the resistant strain. The results of this study need to be extended to other denitrifiers to determine whether general resistance to GSNO is intrinsic to denitrifiers. Also, it will be interesting to determine if denitrifying bacteria have any resistance mechanisms to other toxic nitric oxide derivatives such as peroxynitrite. Probing the molecular mechanisms denitrifiers have developed for resistance to nitric oxide derivatives is of broad scientific interest and is further justification for the study of the diverse group of bacteria linked by their shared capacity to reduce nitrate and nitrite to gaseous nitrogen oxides and nitrogen gas.

Acknowledgments. I would like to thank W. J. Payne for critically reading the manuscript. I would also like to thank him for nurturing my interest in microbiology and introducing me to denitrification. I would also like to thank my colleagues working in this field for their contributions. The work in my laboratory is funded by the U.S. Department of Energy.

CHAPTER 1.24

Dinitrogen-Fixing Prokaryotes

ESPERANZA MARTINEZ-ROMERO

Introduction

Dinitrogen fixation, the biocatalytic conversion of gaseous nitrogen (N_2) to ammonium, is an exclusive property of prokaryotes. The enzymes responsible for this reaction are nitrogenases. Proof that bacteria associated with leguminous plants can fix atmospheric N_2 (making it available to the plants for growth) was first reported in 1888 (reviewed in Quispel, 1988). Nitrogen fixation is the most important way N_2 from air enters biological systems and therefore it is a key step in the nitrogen cycle. From a practical point of view, the importance of the process rests with its ability to reduce the chemical fertilization of crops, even under conditions of environmental stress (Bordeleau and Prévost, 1994; Zahran, 1999). Indeed, agronomically important crops such as soybean, alfalfa, pea, clover and bean obtain substantial amounts of their nitrogen from bacterial N_2 fixation. One of the long-term goals of N_2 fixation research is to select or engineer major cereal crops such as rice, maize and sugarcane so they can satisfy the bulk of their nitrogen requirements, either indirectly by association with N_2-fixing bacteria, or directly by insertion of N_2-fixing genes into the plant.

Many diazotrophs (*di* = two, *azo*te = nitrogen; *trophs* = eaters: dinitrogen fixers) are found to be associated with the roots of plants where they exchange fixed nitrogen for the products of photosynthesis. Plants associated with N_2 fixers can grow in very poor soils and swamps (Koponen et al., 2003) and be used successfully for soil remediation.

Nowadays industrial fixation of atmospheric N_2 exceeds the amount estimated to be produced by biological nitrogen fixation each year (Karl et al., 2002) and increased nitrogen (N) deposition seems to be responsible for loss of biodiversity and plant species extinction (Stevens et al., 2004). Biological N_2 fixation is still the main source of nitrogen in soil, marine environments such as oligotrophic oceanic waters (where dissolved fixed-nitrogen content is extremely low; Zehr et al., 1998; Staal et al., 2003), subtropical and tropical open ocean habitats (Karl et al., 2002), and hydrothermal vent ecosystems (Mehta et al., 2003). N_2 fixation in coastal marine environments may diminish because of habitat destruction and eutrophication (Karl et al., 2002). Dinitrogen fixation may be a major nitrogen source for supporting primary and secondary production of biomass in Antarctic freshwater and soil habitats (Olson et al., 1998) and has been reported to occur in moss carpets of boreal forests (DeLuca et al., 2002) and in woody debris (Hicks et al., 2003). Dinitrogen fixation by bacteria inside insect gut helps to compensate termites for their nitrogen-poor diet (Kudo et al., 1998; Nardi et al., 2002).

N_2-fixing prokaryotes inhabit a wide range of exterior environments (including soils, seas, and the oceans) and interior environments (including insects, cow rumena, human intestines, and feces; Bergersen and Hipsley, 1970), and even printing machines and paper-making chemicals (Vaisanen et al., 1998). Nevertheless, the presence of a N_2-fixing bacterium is not evidence for the occurrence of N_2 fixation. On the basis of N balance analyses, N_2 fixation seemed to account for excess N in humans with a low N diet, and N-fixing bacteria were obtained from their guts (Bergersen and Hipsley, 1970; Oomen and Corden, 1970).

Dinitrogen fixers are encountered in Bacteria and in some groups of Archaea. The number of nitrogen-fixing phyla or lineages within the domain Bacteria increased from 5 to 6 when nitrogen-fixing bacteria were discovered within the Spirochaetes (Lilburn et al., 2001). The inventory of the phyla containing nitrogen-fixing bacteria is probably still far from complete but enlarging, as with the report of a strain of *Verrucomicrobium* that is reported to have nitrogen fixation genes (Rodrigues et al., 2004). Lists of N_2-fixing prokaryotes have been published (Young, 1992; Phillips and Martínez-Romero, 2000), and new nitrogen-fixing species are continuously being described (Chen et al., 2001; Moulin et al., 2001; Distel et al., 2002; Von der Weid et al., 2002; Bianciotto et al., 2003; Rosenblueth et al., 2004). Nevertheless knowledge of

N_2 fixers is limited, and some not yet identified N_2 fixers could be found among the novel bacterial divisions that are mostly unculturable (Rappé and Giovannoni, 2003). The distribution of N_2 fixers among the prokaryotes is patchy (Young, 1992). They constitute restricted groups within larger bacterial clusters. The existence of non-fixers that are closely related to fixers has been explained by the loss of N_2 fixation genes or by the lateral transfer of these genes among bacterial lineages (Normand and Bousquet, 1989; Vermeiren et al., 1999). Nitrogen fixation is an energy costly process, which may explain why nitrogen fixation was lost in many bacterial lineages when not needed. The possession of N_2-fixing genes does not confer a selective advantage to bacteria in nitrogen-rich environments, as is the case where fixed nitrogen is added to agricultural fields. Application of ammonium sulfate reduced the number of *Azotobacter* in the plant rhizosphere, and when compared with plants fertilized with both nitrogen and phosphorus, maize treated with phosphate alone had increased nitrogenase activity (Döbereiner, 1974).

Similarly, very few or no *Gluconacetobacter diazotrophicus* microorganisms were isolated from sugarcane plants from heavily fertilized areas (Fuentes-Ramírez et al., 1993; Muthukumarasamy et al., 1999), and, perhaps as a result of chemical nitrogen fertilization, the bacterial population had very limited genetic diversity (Caballero-Mellado and Martínez-Romero, 1994; Caballero-Mellado et al., 1995). Subsequently, sugarcane colonization by *A. diazotrophicus* was found to be inhibited in plants supplied with chemical nitrogen fertilizer (Fuentes-Ramírez et al., 1999). Another effect of adding fixed nitrogen (diminished genetic diversity of *Rhizobium* from *Phaseolus vulgaris* bean nodules) was observed when the plants were treated with the recommended level of chemical nitrogen (Caballero-Mellado and Martínez-Romero, 1999).

The complete genome sequence of the Archaeon *Methylobacterium thermoautotrophicum* was reported in 1997 revealing the presence of *nif* genes (Smith et al., 1997), but N_2 fixation could not be demonstrated in this strain (Leigh et al., 2000). The sequences of the genomes of the legume-nodulating bacteria belonging to the genera of *Mesorhizobium* (Kaneko et al., 2000), *Sinorhizobium* (Galibert et al., 2001) and *Bradyrhizobium* (Kaneko et al., 2002) revealed contrasting chromosome sizes and highly diverging genomes. A common ancestor of *Mesorhizobium* and *Sinorhizobium* was deduced to exist nearly 400 million years ago (Morton, 2002). One of the most novel areas in nitrogen fixation research is genomics, and for sure many N_2-fixing bacteria will be used for the determination of their whole genome sequence in the near future. Post-genomic studies are already on course as well.

Diazotroph Isolation and Conditions for N_2 Fixation

N_2-fixing bacteria are normally isolated in N-free media. Whether a microorganism is a N_2 fixer is not easy to determine. In the past, claims for many fixers were shown to be erroneous, mainly because fixers were recognized by their ability to grow in nitrogen-free media. However, traces of fixed nitrogen in the media sometimes accounted for the bacterial growth. At other times, oligotrophic bacteria and fungi, which can grow on nitrogen-free media, have been incorrectly reported to be N_2-fixing organisms. These microorganisms appear to meet their nitrogen requirements by scavenging atmospheric ammonia (Postgate, 1988). Photosynthetic bacteria have been known for more than 100 years, but the capacity of some of these bacteria to fix N_2 was not recognized until much later. Microorganisms may fix N_2 under special conditions that may not be readily provided in the laboratory. For example, nitrogenases are inactivated in the presence of oxygen, and different levels of oxygen seem to be optimal for different N_2-fixing organisms. Also, some bacteria (e.g., some *Clostridium*) fix N_2 only in the absence of oxygen. In other cases, fixation may require specific nutritional conditions or a differentiation process or both. A remarkable case is the differentiation process of *Rhizobium* to form N_2-fixing bacteroids (Bergersen, 1974; Glazebrook et al., 1993) inside plant root or stem nodules. *Bradyrhizobium* species can fix N_2 both in plant nodules and in vitro, when provided with succinic acid and a small amount of fixed nitrogen (Phillips, 1974). To fix N_2, bacteria belonging to the genus *Azoarcus* (obtained from Kallar grass and more recently also from rice plants) require proline, undergo differentiation, and form a structure called a "diazosome" (Karg and Reinhold-Hurek, 1996). Stimulated by plants, cyanobacteria differentiate into N_2-fixing heterocysts that protect nitrogenase from oxygen (Wolk, 1996). Light was found to induce circadian rhythms of N_2 fixation in the cyanobacterium *Synechococcus* (Chen et al., 1993). Wheat germ agglutinins were found to stimulate N_2 fixation by *Azospirillum*, and a putative receptor of this agglutinin was found in the *Azospirillum* capsule. The stimulus generated from the agglutinin-receptor interaction led to elevated transcription of both structural and regulatory nitrogen-fixation genes (Karpati et al., 1999).

Methods for Detecting Nitrogen Fixation

The methods used to measure biological N_2 fixation include the quantification of the total nitrogen difference from Kjeldahl analysis, acetylene reduction, and ^{15}N incorporation or dilution. The acetylene reduction assay has been used for over 30 years to measure nitrogenase activity and as an indicator of N_2 fixation (Hardy et al., 1968). These methods have been used both in the laboratory and the field, and improvements of the methods especially for field evaluations have been proposed, including double labeling using ^{34}S as a control reference (Awonaike et al., 1993). The ^{15}N-based techniques have been thoroughly reviewed (Bergersen, 1980; Hardarson and Danso, 1993).

Nitrogenases may reduce other substrates in addition to N_2 and this has been the basis for the acetylene reduction assay, which measures N_2 fixation activity indirectly. However, the nitrogenase described by Ribbe et al. (1997) does not have the ability to reduce acetylene. In *Paenibacillus*, N_2 fixation has been demonstrated in some cases by the increase in nitrogen measured by the microKjeldahl method but not by acetylene reduction (Achouak et al., 1999).

To circumvent the problems of estimating N_2 fixation under laboratory conditions, a strategy to detect nitrogenase genes has been successfully followed. This strategy was made possible by identification of conserved signatures (useful as primers for the synthesis of the nitrogenase reductase gene by means of polymerase chain reaction [PCR] amplification) in the structural *nif* gene sequences, namely *nifH*, found in many microorganisms (Dean and Jacobson, 1992; Ueda et al., 1995). In other cases, homologous or heterologous probes have been used in hybridization experiments to detect N_2 fixers. With some *nifH* primers containing conserved sequences, alternative nitrogenases may also be amplified but not the nitrogenase (superoxide) that is structurally unrelated to the classical nitrogenase (Ribbe et al., 1997). Thus a search for N_2-fixing organisms using a procedure based only on the classical *nifH* gene would be incomplete. Nevertheless, with nitrogenase DNA primers and PCR synthesis, novel N_2-fixing genes may be found. Eight *nifH* gene types corresponding mainly to those of diazotrophic Proteobacteria were detected in rice root from endophytic or rhizoplane-borne bacteria (Ueda et al., 1995). Remarkably, none of the sequences amplified corresponded to previously described *nifH* sequences. The nucleotide sequence of one of the types was found to resemble those of the *Azoarcus nif* genes. Some bacteria in the gut of termites also have *nifH* sequences similar to those obtained from rice roots (Ohkuma et al., 1999). *nif* genes were found in human and bovine treponemas (Lilburn et al., 2001) but not in the completely sequenced genomes of the spirochetes *Treponema pallidum* or *Borrelia burgdorferi*.

Few N_2-fixing organisms from the oceanic environment have been cultivated and it is estimated that less than 10% of marine diazotrophs are cultivable. Nevertheless, on the basis of the amplification of nitrogenase *nifH* genes, new N_2-fixing organisms have been detected in oligotrophic oceans. Nitrogenase genes characteristic of cyanobacteria and of Alpha- and Betaproteobacteria were obtained, whereas *nifH* sequences from samples associated with planktonic crustaceans were found to be clustered with the corresponding sequences from either sulfate reducers or clostridia (Zehr et al., 1998). Since knowledge of the nitrogenase gene diversity has improved (over 1500 sequences were available at the time this manuscript was being written), different sets of primers have been designed (Bürgmann et al., 2004) to better amplify *nifH* genes directly from DNA extracted from various samples including environmental samples. More diverse diazotrophic populations have been revealed with this approach than with classical microbiological techniques that require culturing of the bacteria (Zehr et al., 1998; Bürgmann et al., 2004).

A different method of N_2-fixation detection involves the growth of indicator non-N_2-fixing organisms in a co-culture with putative N_2-fixing bacteria. Such an approach has the additional advantage of identifying bacteria that not only fix N_2 but also can release fixed nitrogen into the environment and thereby have potential use in agriculture. *Gluconacetobacter diazotrophicus* (Yamada et al., 1997), a N_2-fixing isolate from sugarcane, was cultured with the yeast *Lipomyces kononenkoae* on nitrogen-free medium, and yeast growth was shown to be proportional to the amount of N_2 fixed (Cojho et al., 1993).

Distribution of Dinitrogen-Fixing Ability among Prokaryotes

Archaea and Bacteria nitrogenases are phylogenetically related (Leigh, 2000), and supposedly the last common ancestor was a N_2-fixing organism (Fani et al., 1999). Alternatively, nitrogen fixation could have evolved in methanogenic archaea and subsequently transferred into the bacterial domain (Raymond et al., 2004). Nowadays, only 6 out of 53 currently identifiable major lineages or phyla within the domain Bacteria

have nitrogen-fixing members, namely: Proteobacteria, cyanobacteria, Chlorobi (green nonsulfur), spirochetes and the Gram-positives (Firmicutes and Actinobacteria; Fig. 1).

Dinitrogen-fixing organisms have an advantage over non-fixers in N_2-deficient but not in N_2-sufficient environments where the N_2 fixers are readily outcompeted by the bulk of microorganisms. The *nif* genes may be expected to disappear from bacteria that become permanent inhabitants of environments with available fixed N_2; this may explain why some non-N_2 fixers emerged and are closely related to N_2 fixers in phylogenetic trees of bacteria. Even within species of N_2 fixers, some strains do not fix N_2 perhaps because of the loss of this unique capacity, as is evident in *Azotobacter*, *Beijerinckia* (Ruinen, 1974) and *Frankia* (Normand et al., 1996). In *Rhizobium*, *nif* genes and genes for nodule formation may be easily lost concomitantly with the symbiotic plasmid (Segovia et al., 1991). Similarly, nonsymbiotic *Mesorhizobium* strains are found in nature that lack a symbiotic island (Sullivan et al., 1996). N_2-fixing species seem to be dominant in Rhodospirillaceae (Madigan et al., 1984), and within the methanogens (in Archaea), nitrogen fixation is widespread (Leigh, 2000). While all *Klebsiella variicola* isolates were N_2-fixing bacteria (Rosenblueth et al., 2004), only 10% of its closest relatives (*K. pneumoniae* from clinical specimens) had this capacity (Martńez et al., 2004).

The N_2-fixing capability is unevenly distributed throughout prokaryotic taxa, and N_2-fixing bacteria are in restricted clusters among species of non-N_2-fixing bacteria. Only a subset of cyanobacterial species are able to fix N_2. *Gluconacetobacter diazotrophicus* and a couple of other N_2-fixing species are the only diazotrophs in a larger group comprising *Acetobacter*, *Gluconacetobacter* and *Gluconobacter* (Fuentes-Ramŕez et al., 2001). Similarly, among aerobic endospore-forming Firmicutes (Gram-positive

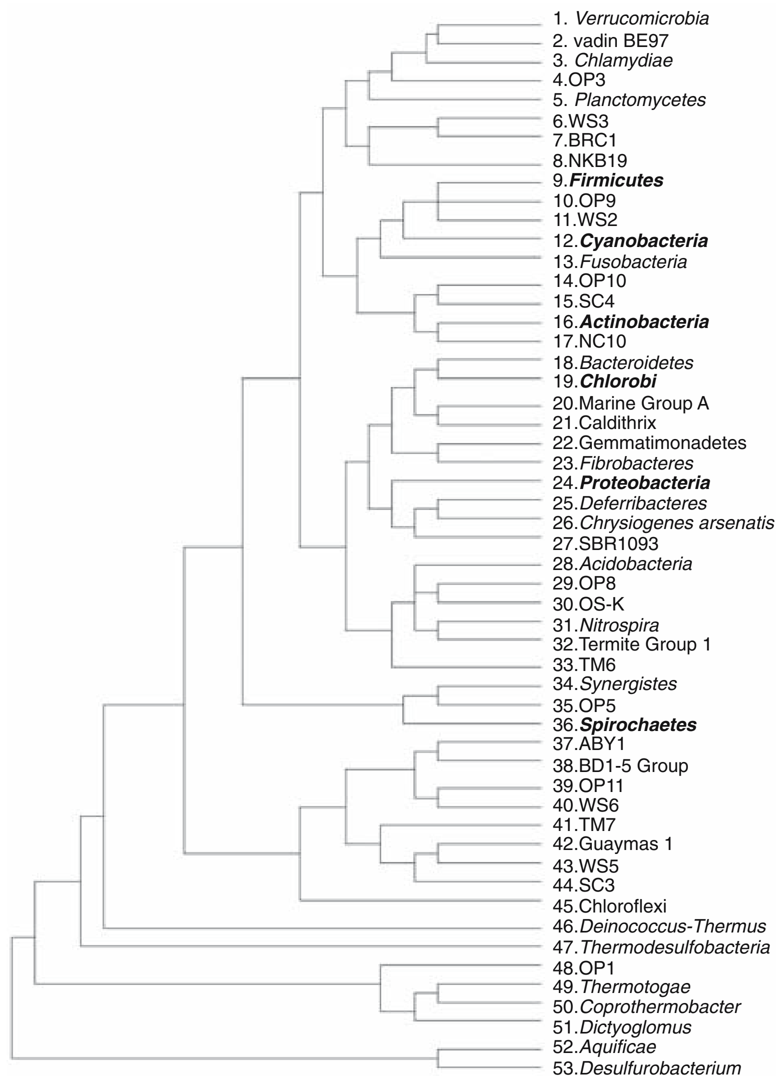

Fig. 1. Relatedness of *nifH* genes from different organisms according to DNA sequence (after Hurek et al., 1997a; Ueda et al., 1995; Young et al., 1992; Zehr et al., 1995). In parentheses, the Proteobacteria subclass.

bacteria), N_2 fixers are encountered mainly in a discrete group (defined by cluster analysis from 16S rRNA gene sequences) corresponding to *Paenibacillus* (Achouak et al., 1999). Among the actinomycetes, N_2-fixing *Frankia*, represented by a diversity of phenotypes from different habitats, are grouped by their 16S rRNA gene sequences (Normand et al., 1996). In Archaea, N_2-fixing organisms are found in the methanogen group and in the halophile group within the Euryarchaeota but not in the sulfur-dependent Crenarchaeota (Young, 1992).

Pseudomonas spp. were considered unable to fix N_2, but recently new isolates have been recognized as N_2 fixers. Some isolates, closely related to fluorescent pseudomonads, possess in addition to the FeMo nitrogenase an alternative molybdenum-independent nitrogenase (Loveless et al., 1999; Saah and Bishop, 1999). Dinitrogen-fixing *Pseudomonas stutzeri*, (previously designated *Alcaligenes faecalis*) (Vermeiren et al., 1999), is widely used as a rice inoculant in China (Qui et al., 1981). Following rice inoculation, *P. stutzeri* aggressively colonize the roots, and the *nifH* gene is expressed in these root-associated bacteria (Vermeiren et al., 1998). Other reports list different N_2-fixing *Pseudomonas* species that have been isolated from sorghum in Germany (Krotzky and Werner, 1987), from *Capparis* in Spain (Andrade et al., 1997), and from *Deschampsia caespitosa* in Finland (Haahtela et al., 1983). The sporadic occurrence of *nif* genes in *Pseudomonas* may be explained by the acquisition of these genes by lateral transfer (Vermeiren et al., 1999). *Pseudomonas stutzeri* strains are known to be naturally competent for DNA uptake (Lorenz and Wackernagel, 1990). Other *nifH* gene sequences obtained from rice-associated bacteria were in the same cluster as the *P. stutzeri nifH* gene (Ueda et al., 1995; Vermeiren et al., 1999).

The phylogenetic relationship of N_2-fixing organisms inferred from the comparative analysis of *nif* and 16S rRNA gene sequences led Hennecke et al. (1985) to propose that the *nifH* genes may have evolved in the same way as the organisms that harbor them; a similar conclusion was obtained by Young (1992) from the analysis of a larger number of diazotrophs. Ueda et al. (1995) and Zehr et al. (1995), using different reconstruction methods, reported *nifH* gene phylogenies in general agreement with the phylogenetic relationships derived from 16S rRNA gene sequences, with some exceptions. A more recent comparison of *nif*H and 16S rRNA phylogenies has been performed with a very short fragment of the *nifH* gene. An early possible duplication of *nifH* and paralogous comparisons make interpretations difficult (see Fig. 3 in Zehr et al., 2003). Four major clusters of *nifH* are recognized and functional nitrogenases are found in three of them (Zehr et al., 2003). The phylogenies of *nifH* genes are continuously revised and updated with novel sequences (including environmental ones) and more robust reconstruction methods. *nifH* genes from Gammaproteobacteria are found in different groups, as well as those from Betaproteobacteria (Bürgmann et al., 2004). Anomalies in the phylogenetic position of Betaproteobacteria have been reported as well (Hurek et al., 1997; Minerdi et al., 2001).

Ecology of Dinitrogen-Fixing Prokaryotes

The communities of dinitrogen-fixing bacteria in natural environments may be studied with approaches such as the amplification by PCR of the nitrogenase reductase gene (*nifH*) with *nifH* primers using environmental DNA, with subsequent analyses by cloning and sequencing, by terminal restriction fragment length polymorphism (T-RFLP; Ohkuma et al., 1999; Tan et al., 2003), or by denaturing gradient gel electrophoresis (DGGE; Muyzer et al., 1993). Hybridization to macro- and microarrays may reveal the presence and frequency of different N_2-fixing prokaryotes (Jenkins et al., 2004; Steward et al., 2004).

The ecology of the symbiotic N_2-fixing soil bacteria that are collectively designated rhizobia, has been comprehensively reviewed by Bottomley (1992), and ecogeographic and diversity reviews of these bacteria have been reported (Martínez-Romero and Caballero-Mellado, 1996; Sessitsch et al., 2002). Additional aspects of *Rhizobium* ecology in soil also have been reviewed (Sadowsky and Graham, 1998). *Frankia* symbiosis including some ecological aspects has been reviewed by Baker and Mullin (1992) and by Berry (1994). New molecular approaches have recently enhanced our perception of microorganisms in their natural habitats. By using PCR primers targeted to nitrogenase genes, the description and natural histories of communities of N_2-fixing microorganisms may be established more accurately than with traditional microbiological techniques. The fluctuations of marine diazotroph populations have been analyzed with these approaches. The bulk of N_2 fixation appears to shift from cyanobacterial diazotrophs in summer to bacterial diazotrophs in fall and winter (Zehr et al., 1995). The heterocystous cyanobacteria are not as efficient fixing nitrogen as the nonheterocystous cyanobacteria at the high temperatures of the tropical oceans (Staal, 2003). The diversity of marine N_2 fixers in benthic marine mats was determined from the sequences of *nifH* genes. The *nifH*

sequences obtained were most closely related to those of anaerobes, with a few related to Gammaproteobacteria including *Klebsiella* and *Azotobacter* species (Zehr et al., 1995).

The role of N_2 fixation was examined in microbial aggregates embedded in arid, nutrient-limited and permanent ice covers of a lake area in the Antarctic, and also in mats in soils adjacent to the ice border. Molecular characterization by PCR amplification of *nifH* fragments and nitrogenase activity measured by acetylene reduction showed a diverse and active diazotrophic community in all the sites of this environment. Nitrogenase activity was extremely low, compared to temperate and tropical systems. Diazotrophs may be involved in beneficial consortial relationships that may have advantages in this environment (Olson et al., 1998). Nitrogen fixation, observed in moderately decayed wood debris, was shown to be stimulated by warm temperatures (Hicks et al., 2003).

The diversity of the N_2-fixing microorganisms within the symbiotic community in the gut of various termites was studied without culturing the symbiotic microorganisms. Both small subunit (ss) rRNA (Kudo et al., 1998) and *nifH* genes (Ohkuma et al., 1999) were amplified in DNA extracted from the mixed microbial population of the termite gut. The analysis of the *nif* clones from diverse termites revealed different sequences in most of the individual termite species. Whereas the *nif* groups were similar within each termite family, they differed between termite families. Microorganisms from termites with high levels of N_2-fixation activity could be assigned to either the anaerobic *nif* group (clostridia and sulfur reducers) or to the alternative *nif* methanogen group. Highly divergent *nif* gene sequences (perhaps not even related to nitrogen fixation) were found in termites that showed low levels of acetylene reduction (Ohkuma et al., 1999). Expression of the N_2 fixation gene *nifH* was evaluated directly by amplifying *nifH* cDNA from mRNA by reverse transcription (RT)-PCR (Noda et al., 1999). Only the alternative nitrogenase (from *anf* gene) was preferentially transcribed in the gut of the termite *Neotermes koshunensis*. The levels of expression of the *anf* gene were related to the N_2 fixation activity recorded for the termites. The addition of Mo (molybdenum) to the termite diet did not repress the expression of the *anf* genes; however, Mo repression of other *anf* genes has been described (Noda et al., 1999). Estimates are that the contribution of insect-borne nitrogen-fixing bacteria in insects may be up to 30 kg of N/hectare (ha)/year (Nardi et al., 2002).

Endosymbionts from marine bivalve species, located in the shipworm gills, are cellulolytic and N_2-fixing. They provide cellulolytic enzymes to the host. They are a unique clade in the Gammaproteobacteria related to *Pseudomonas* and were designated as a new genus and species *Teredinibacter turnerae*, which fixes nitrogen in microaerobic in vitro conditions (Distel et al., 2002).

The arbuscular mycorrhizal fungus (*Gigaspora margarita*) has been shown to harbor a viable and homogeneous population of endosymbiotic bacteria that has been designated as "*Candidatus Glomeribacter gigasporarum*" (Bianciotto et al., 1996) related to Betaproteobacteria such as *Ralstonia* (Bianciotto et al., 2003). In the genomic library of total DNA from the fungal spores, clones carrying the bacterial genes *nifD* and *nifK* were identified. Both of these genes were arranged in a similar manner to the corresponding genes in archaea or bacteria and were similar to nitrogenases from different diazotrophs (Minerdi et al., 2001; Minerdi et al., 2002). mRNAs for the *nif* genes were detected, but whether these endosymbionts fix nitrogen is unknown.

Dinitrogen-fixing cyanobacteria form symbioses with diverse hosts such as fungi, bryophytes, cycads, mosses, ferns, and an angiosperm, *Gunnera* (Bergman et al., 1992). The genome of the cyanobacteria *Nostoc* (which is a symbiont of cycads, *Gunnera* and others) may be the largest among those from Prokaryotes, with nearly 10 Mb (Meeks et al., 2001).

New symbionts capable of forming nodules in the leguminous plant *Lotus corniculatus* were obtained in agricultural fields after the lateral transfer of genetic material to native nonsymbiotic soil mesorhizobia (Sullivan et al., 1995; Sullivan et al., 1996). Nonsymbiotic soil rhizobia, which outnumber symbiotic bacteria in some cases (Segovia et al., 1991; Laguerre et al., 1993), have been considered to be potential recipients of symbiotic plasmids. Molecular analyses (including the sequence of DNA fragments of 16S rRNA genes, the fingerprints of digested genomic DNA, and the hybridization patterns to cloned fragments) clearly demonstrated that a large segment of genetic material was acquired by soil *Mesorhizobium* bacteria (Sullivan et al., 1995) and that the original *Mesorhizobium loti* strain applied to the soil as an inoculant was the donor of these symbiotic genes. The mobilizable 500-kb DNA fragment has been designated a symbiosis island and it encodes genes for symbiotic N_2 fixation (*fix* genes) as well as those for the synthesis of vitamins (Sullivan et al., 2002). The symbiotic island was integrated into the phenylalanine-tRNA gene (Sullivan and Ronson, 1998). Interestingly, pathogenicity islands in other bacteria range up to 190 kb in size and most are either found adjacent to or integrated

within tRNA genes or flanked by insertion sequences (Cheetham and Katz, 1995; Kovach et al., 1996). In *M. loti*, the symbiotic genes are chromosomally located as in most *Mesorhizobium* and *Bradyrhizobium* sp. A similar symbiotic chromosomal region was identified in *M. loti* (Kaneko et al., 1999) that was later classified as *M. huakuii* (Turner et al., 2002). Only a few *Mesorhizobium* species such as *M. amorphae* possess symbiotic plasmids (Wang et al., 1999b), which are a common characteristic of *Rhizobium* and *Sinorhizobium* species (Martńez et al., 1990). The great chromosomal diversity, mainly based on 16S rRNA sequence (Wang and Martńez-Romero, 2000) and on glutamine synthetase (GSII) genes (Wernegreen and Riley, 1999) encountered in *M. loti*, may be ascribed to the natural occurrence of genetic transfer of symbiotic genes in *Mesorhizobium* (Sullivan et al., 1996).

The range of nodulating bacteria has enlarged. Nodulating *Methylobacterium* have been reported from *Crotalaria* nodules (Sy et al., 2001). Surprisingly, some Betaproteobacteria in the genera *Burkholderia* (Moulin et al., 2001) and *Ralstonia* (Chen et al., 2001) are capable of nodulating legumes. These bacteria have been classified as *Burkholderia phymatum*, *B. tuberum* (Vandamme et al., 2002), *B. caribensis* (Chen et al., 2003) and *Wautersia taiwanensis* (previously designated *Ralstonia taiwanensis*) (Chen et al., 2001; Vaneechoutte et al., 2004). Like *Rhizobium* and *Sinorhizobium* spp., these Betaproteobacteria possess symbiotic plasmids that carry nodulation genes (Chen et al., 2003). The similarity of these *nod* genes to those of the Alphaproteobacteria suggested that lateral transfer of *nod* genes occurred, most probably from Alpha- to Betaproteobacteria (Moulin et al., 2001; Chen et al., 2003). Similarly the lateral transfer of *nod* genes has been implied as a possible explanation for the nodulation capacity in *Devosia*, and a new species has been identified that carries *nodD* and *nifH* genes similar to those of *R. tropici* (Rivas et al., 2002).

Dinitrogen-Fixing Prokaryotes in Agriculture

The first industrial production of *Rhizobium* inoculants began at the end of the nineteenth century. In the absence of nitrogen fertilization, spectacular increases in plant and seed yield may be obtained by inoculation of legumes where the specific rhizobia for the legumes are absent or scarce (Singleton and Tavares, 1986). Factors affecting nodule occupancy by rhizobia inoculants were reviewed by Vlassak and Vanderleyden (1997). Inoculation of soybean is a common practice in Brazil (Hungria et al., 2000) or in the United States where production of soybean inoculants is a top priority for inoculant-producing companies (Paau, 1989), and inoculation of cash crops with nitrogen-fixing inoculants is considered a realistic alternative to the ever increasing use of fertilizers. High quality inoculants (whose characteristics were discussed by Maier and Triplett, 1996) as well as the improvement of management systems, are useful not only for agriculture but also for reforestation of devastated areas. Leguminous trees with their corresponding rhizobia have been recommended for many and diverse uses including reforestation, soil restoration, lumber production, cattle forage, and for human food. The so-called "actinorhizal plants" that associate with *Frankia* are also of great value for reforestation; actinorhizal plants belong to eight families (Baker and Mullin, 1992; Berry, 1994).

A high impact goal of nitrogen fixation research has been to extend nitrogen fixation to non-legumes and this has promoted the search for nitrogen fixing bacteria that are associated with agriculturally valuable crops. From a basic research perspective this has increased our knowledge of their diversity. The impact on agriculture and potential as a substitute for the high levels of fertilizer used in intensive agriculture is debatable, and a critical review of the actual contributions of N_2 fixation to the amount of fixed N present in cereals and other grasses finds that N_2-fixing bacteria in agriculture provide only a limited amount of fixed N. Careful long-term N balance studies would be required to accurately estimate these contributions (Giller and Merckx, 2003). Levels of fixed nitrogen (as low as 5–35 kg N/ha per year) that contribute over the long term to sustain fertility in nonagricultural areas (Stevens et al., 2004) are neglible for present modern intensive agricultural needs but may be of use in traditional, low input small farming systems. Legumes may fix over 200 kg N/ha per year and this is a significant contribution of nitrogen. Conservative values for bacterial fixation in nonlegumes are 20–30 kg N/ha per year, but higher, substantial values have been also estimated (see below). The rate of fixation of the tree *Acacia dealbata* is considered sufficient to replace the estimated loss due to timber harvesting (May and Attiwill, 2003).

Sugarcane and rice are the Gramineae most extensively studied with regard to N_2 fixation, but other crops are being studied as well (see below). Sugarcane has been grown for more than 100 years in some areas of Brazil without nitrogen fertilization or with very low nitrogen inputs, and removal of the total harvest has not led to decline in yield and soil nitrogen levels. This observation suggested that N_2 fixation may have been the source for a substantial part of the

nitrogen used by this crop (Döbereiner, 1961). Alternatively, irrigation water has been implicated as a possible source of N (Giller and Merckx, 2003).

From 25–55% (Urquiaga et al., 1989; Yoneyama et al., 1997) or perhaps as much as 60–80% (Boddey et al., 1991) of the plant N could be derived from associative dinitrogen fixation, but scepticism about the occurrence of high levels of nitrogen fixation has been expressed (Giller and Merckx, 2003). The problems of estimating sugarcane N_2 fixation, discussed by Boddey et al. (1995), include different patterns of nitrogen uptake by different sugarcane varieties (Urquiaga et al., 1989), declining ^{15}N enrichment of soil mineral nitrogen, carryovers of nitrogen from one harvest to the next, and differential effects on control plants during the three-year study (Urquiaga et al., 1992). The mean estimates of fixed N_2 for two sugarcane hybrids grown in concrete tanks ranged from 170–210 kg N_2 fixed/ha (Urquiaga et al., 1992). Correction for micronutrient soil deficiencies and high soil moisture seem to be key conditions that promote N_2 fixation in sugarcane plants (Urquiaga et al., 1992). The evidence of large differences in N_2 fixation among different sugarcane cultivars is compelling.

Dinitrogen-fixing bacteria isolated from the rhizosphere, roots, stems and leaves of sugarcane plants include *Beijerinckia*, *Azospirillum*, *Azotobacter*, *Erwinia*, *Derxia*, *Enterobacter* (reviewed in Boddey et al., 1995), *Gluconacetobacter* (Cavalcante and Döbereiner, 1988), and *Herbaspirillum* (Baldani et al., 1986). *Gluconacetobacter diazotrophicus* has the capacity to fix N_2 at low pH and in the presence of nitrate and oxygen. A *G. diazotrophicus nifD* mutant that cannot fix N_2 has been tested on plants derived from tissue cultures. Plant height was significantly increased by the wildtype strain and not by the mutant strain inoculants, suggesting a positive effect of N_2 fixation by *G. diazotrophicus* on sugarcane (Sevilla et al., 1998). Beneficial effects of *G. diazotrophicus* inoculation in experimental fields also have been reported (Sevilla et al., 1999), but global N balances were not analyzed. Selected strains of *Herbaspirillum* were reported to stimulate plant development (Baldani et al., 1999). *Gluconacetobacter diazotrophicus* (James and Olivares, 1997), *Herbaspirillum seropedicae* and *H. rubrisubalbicans* (Olivares et al., 1996) have been clearly shown to colonize sugarcane plants internally. Colonization by *G. diazotrophicus* was inhibited by nitrogen fertilization (Fuentes-Ramírez et al., 1999). Probably N_2 fixation in sugarcane is performed by a bacterial consortium.

Several studies have been carried out on nitrogen balance in lowland rice fields in Thailand (Firth et al., 1973; Walcott et al., 1977), in Japan (Koyama and App, 1979), and at the experimental fields of the International Rice Research Institute (IRRI) in the Philippines (App et al., 1984; Ventura et al., 1986). These studies report a positive balance with estimates of around 16–60 kg of nitrogen fixed per ha per crop (App et al., 1986; Ladha et al., 1993). In a nitrogen-balance study carried out on 83 wild and cultivated rice cultivars (6 separate experiments, each with 3 consecutive crops), large and significant differences between cultivars were found (App et al., 1986). But other assays showed only a small or nonsignificant contribution of fixed N_2 in rice (Watanabe et al., 1987b; Boddey et al., 1995).

Many different N_2-fixing bacteria have been isolated from rice roots. These include *Azotobacter*, *Beijerinckia* (Döbereiner, 1961), *Azospirillum* (Baldani and Döbereiner, 1980; Ladha et al., 1982), *Pseudomonas* (Qui et al., 1981; Barraquio et al., 1982; Barraquio et al., 1983; Watanabe et al., 1987a; Vermeiren et al., 1999), *Klebsiella*, *Enterobacter* (Bally et al., 1983; Ladha et al., 1983), *Sphingomonas* (described as *Flavobacterium* in Bally et al., 1983), *Agromonas* (Ohta and Hattori, 1983), *Herbaspirillum* spp. (Baldani et al., 1986; Olivares et al., 1996), sulfur-reducing bacteria (Durbin and Watanabe, 1980; reviewed in Barraquio et al. [1997] and in Rao et al. [1998]), *Azoarcus* (Engelhard et al., 1999) and methanogens (Rajagopal et al., 1988; Lobo and Zinder, 1992). The nitrogenase genes of *Azoarcus* are expressed on rice roots (Egener et al., 1998), and *Herbaspirillum seropedicae* expresses *nif* genes in several gramineous plants including rice (Roncato-Maccari et al., 2003).

Cyanobacteria have long been used to fertilize agricultural land throughout the world, most notably rice paddies in Asia. Increases in rice plant growth and increases in nitrogen content in the presence of cyanobacteria have been documented by many investigators. Plant promotion may also be related to growth-promoting substances produced by the cyanobacteria (Stewart, 1974). *Azolla* is a small freshwater fern that grows very rapidly on the surface of lakes and canals. Extensive employment of *Azolla-Anabaena* as a green manure in rice cultivation has been documented. *Anabaena*, a representative filamentous cyanobacterium, establishes symbioses with a diversity of organisms including *Azolla*. Unfortunately, various cyanobacteria also produce highly poisonous toxins and some of them are related to the high incidence of human liver cancer in certain parts of China. Highly toxic strains have been found in *Anabaena* and in other genera of cyanobacteria, and identification of such strains requires sophisticated biochemical tests (Carmichael, 1994).

Alternatively, other bacterial species are being tested to promote rice growth, such as the N_2-fixing *Burkholderia vietnamiensis* (Gillis et al., 1995). In some agriculture sites in Vietnam, this species has been isolated as the dominant N_2-fixing bacterium in the rice rhizosphere (Trâ Van et al., 1996). *Burkholderia vietnamiensis* inoculation has resulted in significant increases (up to 20%) in both shoot and root weights in pots and its use in rice inoculation seems highly promising (Trâ Van et al., 1994). However, a note of caution has been raised with a proposed moratorium on the agricultural use of *B. vietnamiensis*, which has a close genetic relationship to human pathogens implicated in lethally infecting patients with cystic fibrosis (Holmes et al., 1998). Detailed molecular analysis may allow for the distinction of pathogenic and environmental isolates (Segonds et al., 1999).

For over seven centuries, rice rotation with clover has significantly benefited rice production in Egypt. Clover is normally associated with *Rhizobium leguminosarum* bv. *trifolii* that forms N_2-fixing nodules in the root of this plant. Surprisingly, strains of this bacterium also were encountered inside the rice plant with around 10^4–10^6 rhizobia per gram (fresh weight) of root. These values are within the range of other bona fide endophytic bacteria (Yanni et al., 1997). Promotion of rice shoot and root growth was dependent on the rice cultivar, inoculant strain, and other conditions. Inoculation of rice with a selected strain gives best results in presence of low doses of nitrogen fertilizer. A number of investigators have reported growth stimulation of crops such as wheat and corn inoculated with a *R. leguminosarum* bv. *trifolii* strain, but these effects may not be related to N_2 fixation (Holflich et al., 1995).

In non-legumes (such as *Arabidopsis thaliana* [a model plant]), penetration of rhizobial strains has been found to be independent of nodulation genes that are normally required for bacterial entry into the legume root (Gough et al., 1996; Gough et al., 1997; Webster et al., 1998; O'Callaghan et al., 1999). This process probably requires cellulases and pectinases (Sabry et al., 1997). *Azorhizobium caulinodans*, in addition to forming nodules on *Sesbania rostrata*, has been found to colonize the xylem of its host (O'Callaghan et al., 1999) as well as to colonize wheat (Sabry et al., 1997). In wheat, *A. caulinodans* promotes increases in dry weight and nitrogen content as compared to uninoculated controls; acetylene reduction activity was also recorded. The interaction between azorhizobia and wheat root resembles the invasion of xylem vessels of sugarcane roots by *G. diazotrophicus* (James and Olivares, 1997) and *Herbaspirillum* spp. (Roncato-Maccari et al., 2003) and of wheat by *Pantoea agglomerans* (Ruppel et al., 1992). The xylem vessels may be the site of N_2 fixation because they provide the necessary conditions (carbohydrates and low oxygen tension), although the nutrient levels in the xylem have been considered as too low to maintain bacterial growth and N_2 fixation (Fuentes-Ramŕez et al., 1999; Welbaum et al., 1992). In acreage cultivated using *Sesbania rostrata*-rice rotation, *A. caulinodans* survives in the soils and rhizosphere of wetland rice (Ladha et al., 1992). *Azorhizobium caulinodans* can colonize the rice rhizosphere (specifically around the site of lateral root emergence), penetrate the root at the site of emergence of lateral roots, and colonize subepidermally intercellular spaces and dead host cells of the outer rice root cortex (Reddy et al., 1997).

The application of green manure has been an agronomic practice for increasing rice production, and legumes also can be used because of their symbiosis with N_2-fixing rhizobia. A large number of species are used both before and after rice culture including *Macroptilium atropurpureum*, *Sesbania* and *Aeschynomene* spp. (Ladha et al., 1992). Owing to their high N_2-fixing capacity and their worldwide distribution, flood-tolerant legumes such as *Sesbania rostrata* have been the focus of research. *Sesbania herbacea* nodulated by *R. huautlense* is also a flood-tolerant symbiosis (Wang and Martńez-Romero, 2000).

Nitrogen fixation in non-legumes is conditioned more by the plant than by the bacteria. Interestingly, aluminum-tolerant plants are more capable of maintaining bacterial nitrogen fixation than plants that are not tolerant (Christiansen-Weniger et al., 1992), maybe because they excrete dicarboxylics that are adequate to support bacterial N_2-fixation.

N_2-fixing bacteria associated to maize include: *Azospirillum*, *Herbaspirillum*, *Klebsiella* (Chelius and Triplett, 2001), *Burkholderia vietnamiensis* (Trâ Van et al., 1996), *R. etli* (Gutiérez-Zamora and Martńez-Romero, 2001), and the newly described species (*Paenibacillus brasilensis*; [Von der Weid et al., 2002] and *Klebsiella variicola* [Rosenblueth et al., 2004]). *Klebsiella variicola* was also found associated with banana plants (Martńez et al., 2003). Soil type instead of the maize cultivar determined the structure of a *Paenibacillus* community in the rhizosphere (Araujo de Silva et al., 2003).

Sweet potato (*Ipomoea batatas*) may grow in poor N-soil and associated N-fixation has been considered to contribute N to these plants. By a cultivation-independent approach, bacteria similar to *Klebsiella*, *Rhizobium* and *Sinorhizobium* were inferred to be present as sweet potato endophytes (Reiter et al., 2003).

Perspectives of Application of Nitrogen Fixation Research

The transgenic plants that will herald a revolution in agriculture are those with functional nitrogenase genes that, when expressed, will satisfy all the plant's nitrogen needs. The source of these genes will be prokaryotic. Research efforts are directed towards the ambitious goal of transforming rice plastids (Potrykus group in Zürich discussed in Rolfe et al., 1998) and plastids of the alga *Chlamydomonas reinhardtii* (Dixon et al., 1997; Dixon, 1999). Introduction of additional genes into plants to protect nitrogenase from oxygen damage will be needed. Such approaches could only be based on a profound understanding of N_2 fixation biochemistry, gene regulation and organization, as well as the structure and function of nitrogenases. Whether such a goal is feasible is difficult to predict.

The identification and selection of plant-associated microorganisms and their genetic improvement is an alternative strategy for obtaining agricultural crops that benefit from prokaryotic N_2 fixation. N_2 fixation (N_2 fixation without nodules) from associated bacteria is being considered as a suitable mode to exploit N_2 fixation in non-legumes (Triplett, 1996). Rhizosphere N_2 fixation by *Rahnella aquatilis* has been reported to occur in maize and wheat (Berge et al., 1991), and in other plants (Heulin et al., 1989). Mycorrhiza associate with most plants, and interestingly, bacteria-like organisms with nitrogenase genes have been found to be natural endosymbionts of the mycorrhiza (Minerdi et al., 2002). This association may be exploited to transfer N_2 fixation to non-legumes. The genetic improvement of mycorrhiza and bacterial symbionts may constitute a highly efficient system for the provision of fixed nitrogen to the plants.

The usefulness of N_2-fixing bacteria in bioremediation is also being recognized (Suominen et al., 2000; Prantera et al., 2002). Increased transformation of contaminating polychlorinated biphenyls was obtained with alfalfa inoculated with *Sinorhizobium meliloti* at 44 days after planting (Mehmannavaz et al., 2002). Dinitrogen fixation may decrease the need for nitrogen required by bacterial consortia used to degrade diesel fuel (Piehler et al., 1999).
